Background: Our group has previously demonstrated a surprisingly high prevalence of Vitamin C deficiency (VCD) in patients with upper gastrointestinal bleeding (UGIB). We aimed to prospectively analyse the prevalence of VCD in patients presenting with acute variceal bleeding (AVB) and its association with clinical outcomes. **Methods:** Adult patients e 18 years presenting with AVB were prospectively collected over a 34-month period (2020 – 2022) with fasting serum vitamin C levels measured on admission. Primary outcomes were: (i) the prevalence of VCD (defined as a Vitamin C level < 23 μmol/L, severe VCD < 12 μmol/L), as well as (ii) in-hospital mortality, (iii) rebleeding and (iv) a composite outcome of adverse events, encompassing in-hospital mortality, rebleeding and massive red cell transfusion stratified by VCD status. Secondary outcomes were prolonged hospital length of stay (LOS) (> 7 d) and the need for ICU admission. **Results:** In total, 74 patients with AVB were included in the study. Mean age was 54.9 ± 13.5 years and 52.7% were male. The median MELD score was 15 (IQR 12-18) and median Child-Pugh score was 8 (IQR 7-9). Oesophageal varices were found in 71 patients (95.9%) and gastric varices were found in 8 patients (10.8%). VCD was identified in 30 (40.5%) and severe VCD in 14 (18.9%) patients. The prevalence of VCD did not differ in Child-Pugh class B and C patients, compared to A (38.7% vs. 50%, p = 0.47). VCD was associated with significantly higher in-hospital mortality (30% vs. 6.8%, p < 0.01), increased rebleeding (33.3% vs. 4.5%, p < 0.01) and a non-significant trend towards a higher composite endpoint (53.3% vs. 31.8%, p = 0.07), compared to patients with normal vitamin C levels. VCD was also associated with prolonged hospital LOS (76.7% vs. 43.2%, p < 0.01) and increased ICU admissions (36.7% vs. 15.9%, p = 0.04). All multivariate logistic regression models indicated VCD was independently associated with higher in-patient mortality and rebleeding, even after adjusting for MELD (table 1). **Conclusion:** VCD is highly prevalent in patients presenting with AVB and deficiency is associated with higher in-hospital mortality and rebleeding independent of the severity of liver disease. Prospective interventional trials are required to investigate the impact of early vitamin C supplementation on clinical outcomes in AVB.

Table 1: Multivariate logistic regression with vitamin C deficiency as factor of interest

Model	Covariates	In-hospital mortality		Rebleeding	
		VCD odds ratio	95% CI	VCD odds ratio	95% CI
	Vitamin C deficiency (univariable)	5.86	1.43 – 23.96	10.5	2.1 – 52.47
1	Male, Age	6.23	1.47 – 26.39	9.91	1.74 – 56.44
2	Albumin, haemoglobin	5.94	1.43 – 24.64	10.46	1.98 – 55.08
3	AIMS65≥2, haemoglobin	5.93	1.43 – 24.63	10.2	1.95 – 53.28
4	MELD	10.9	1.58 – 75.4	11.98	2.32 – 61.86
5	MELD, Male	11.22	1.57 – 80.07	14	2.53 – 77.54
6	MELD, Male, Age	10.22	1.25 – 83.37	10.93	1.84 – 64.79

Background: The pharmaceutical industry is currently facing increasing challenges in drug discovery due to long drug development times combined with low clinical trial success rates. Over 20% of approved drugs suffer from market withdrawal for severe liver injury at therapeutic doses, becoming a significant cause of death worldwide, with an estimated 2 million patients in the United States. Three-dimensional (3D) cellular models, obtained by mixing cells with a biomaterial in a pre-specified structure, are emerging as a physiologically relevant cellular microenvironment holding a great promise for drug safety and efficacy in the early phase of drug development. **Methods:** Here, we developed human 3D livers combining hepatocytes (HepaRG), hepatic stellate cells (HSCs) (LX-2), and immune cells (THP-1), the three main cell types of the liver, in a 2:1:1 ratio. We used a well-established mixture of gelatine methacryloyl (GelMA) and carboxymethyl cellulose methacrylate (CMCMA), a biodegradable and non-biodegradable material, respectively. Lithium Phenyl(2,4,6-trimethylbenzoyl)phosphonate was used as a photo-initiator. Cells were combined with the GelMA-CMCMA mixture (1:1) and exposed to UV light for 30 seconds. The 3D livers were kept in culture for up to 30 days in serum-free medium. They were challenged with acetaminophen and LPS, two well-described hepatotoxic compounds, to recreate the pathophysiological phenotype of liver damage in vitro. Dexamethasone was used as an anti-inflammatory drug to test the ability of 3D livers to predict drug efficacy. **Results:** The 3D livers did not show any signs of distress while resembling many characteristics of the native healthy liver. We evaluated the cell viability, morphology, and gene expression of hepatocytes, HSCs, and immune cells in the 3D livers during the 30 days. The LPS and acetaminophen challenge induced extensive liver damage characterized by HSC activation and proliferation. These cells acquired the typical myofibroblast phenotype of activated HSC in vivo. Moreover, we assessed gene expression markers of hepatocyte functionality, such as albumin, OTC, and CPS1, as well as the CYP3A4 enzyme activity, which were impaired upon treatments. The inflammation level of the system was measured by the transition from the THP-1 monocytes to macrophages releasing proinflammatory cytokines into the medium. Finally, the potent beneficial effect of dexamethasone was observed, both by reducing cell damage in hepatocytes and by decreasing HSC activation and collagen production. **Conclusion:** Human 3D livers are suitable for long-term cultures and can be used to test the toxicity and efficacy of drugs, as has been demonstrated with LPS and acetaminophen, and dexamethasone. These results also validated this multicellular system as a valuable tool for measuring liver damage and inflammation, as the 3D livers successfully displayed the characteristics of chronic liver damage in vitro.

3201-A | A NOVEL PROGNOSTIC MODEL BASED ON PORTAL VEIN DIAMETER FOR PATIENTS WITH ACUTE-ON-CHRONIC LIVER FAILURE

Qiao Zhang[1], Juan Li[1], Yushan Liu[1], Yamin Wang[1], Xiaoli Zhang[2], Taotao Yan[1,3], Yingren Zhao[1,4] and Yingli He[1,5], (1)The First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, Shaanxi, China, (2)First Affiliated Hospital of Xi'an Jiaotong University, (3) Shaanxi Provincial Clinical Research Center for Infectious Diseases, Xi'an, Shaanxi, China, (4)Clinical Research Center for Infectious Disease, the First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, Shaanxi, China, (5)National Regional Infectious Diseases Center Co-Constructed By National Health Commission of PRC and People's Government of Shaanxi Province, Xi'an, Shaanxi, China

Background: The prompt and accurate prognostication of acute-on-chronic liver failure (ACLF) patients is crucial for clinical intervention and reducing mortality. Portal vein hypertension is a common and potentially fatal complication of ACLF. However, no current prediction models for ACLF have integrated portal vein parameters. Since portal vein diameter (PVD) can effectively reflect portal vein hypertension, this study aimed to investigate its value in predicting the short-term prognosis of ACLF patients and develop a novel nomogram prognostic model for ACLF patients. **Methods:** A prospective cohort of 127 ACLF patients was enrolled to develop the prognostic model for 90-day mortality, which was then validated in a prospective cohort of 105 ACLF patients. The PVD was assessed using computed tomography images within 7 days of ACLF diagnosis. Logistic regression analyses were performed to identify independent prognostic indicators and construct the nomogram prognostic model. Concordance index (C-index), receiver operating characteristics (ROC) and decision curve analysis were applied to compare the performance of nomogram, model for end-stage liver disease (MELD) score and Child-Turcotte-Pugh (CTP) score. **Results:**

1. A total of 232 ACLF patients were included, with a 90-day mortality rate of 42.24%.
2. The PVD was significantly higher in non-survivors than survivors (14.79 ± 73mm vs 13.18 ± 2.52mm, $P = 0.027$).
3. PVD ($OR = 310$, 95% CI: 1.065~1.612, $P = 0.011$), age ($OR = 1.055$, 95% CI: 1.001~1.111, $P = 0.047$), neutrophil percentage ($OR = 1.069$, 95% CI: 1.013~1.128, $P = 0.015$), sex ($OR = 0.097$, 95% CI: 0.020~0.479, $P = 0.004$) and total bilirubin ($OR = 1.009$, 95% CI: 1.003~1.015, $P = 0.002$) were identified as independent predictors for the new PVD-based nomogram prognostic model, PANST (Figure1).
4. The C-index (0.878) of PANST score was higher than MELD score and CTP score (0.687, 0.639,

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

respectively; $P < 0.001$). The ROC and decision curves demonstrated that the PANST score was superior to MELD score and CTP score.

5. Subgroup analysis: the C-indices of PANST score for hepatitis B virus-related ACLF (HBV-ACLF) and non-HBV-ACLF patients (0.842/0.950) were significantly higher than those of MELD score (0.730/0.608; all $P < 0.05$) and CTP score (0.701/0.513, all $P < 0.05$).
6. Patients with a score exceeding 152.9 had a higher risk of death ($OR = 17.607$, 95% $CI = 5.694$~446, $P < 0.001$). Subgroup analysis yielded similar results (HBV-ACLF group: OR = 10.714, 95% CI: 2.879~39.800, $P < 0.001$; non-HBV-ACLF group: $OR = 63.000$, 95% CI: 4.957~800.677, $P = 0.001$).
7. These results were confirmed in the validation cohort (Figure2).

Conclusion: The inclusion of PVD in the novel prognostic model PANST exhibited high predictive accuracy for predicting 90-day mortality in ACLF patients, which was superior to MELD and CTP score.

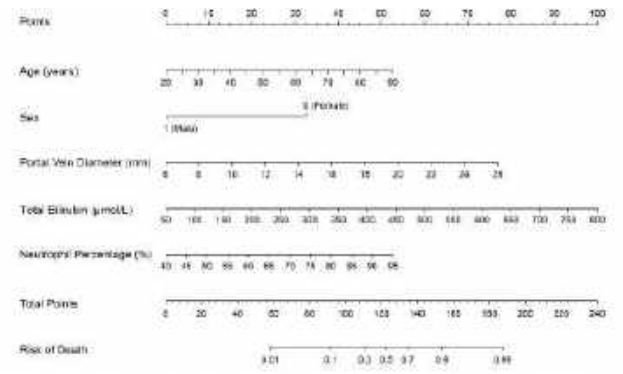

Figure 1 PANST, a novel nomogram prognostic model, including portal vein diameter, age, neutrophil percentage,sex and totalbilirubin for 90-day mortality in patients with ACLF. To apply the nomogram prognostic model, find the patient's value on each variable axis and add up the corresponding points to locate the total score on the "TotalPoints" axis. Then, draw a line down to the "Risk ofDeath" to determine the 90-day mortality probability for ACLFpatients. ACLF, acute-on-chronic liver failure.

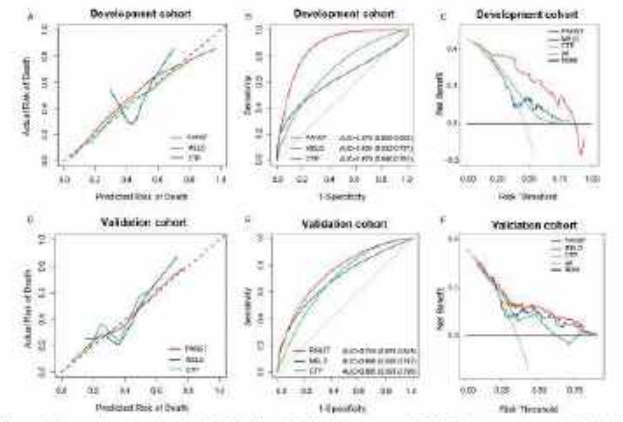

Figure 2 The calibration (A,D) , ROC (B,E) and DCA (C,F) curves of PANST prognostic model,MELD score, and CTP score for predicting90-day mortality in the development cohort and validation cohort of ACLF patients. ROC, Receiver operating characteristic; DCA, Decision Curve Analysis; PANST, the prognostic model based on PVD, age,neutrophil percentage, sex and total bilirubin; MELD, model for end-stage liver disease; CTP, Child-Turcotte-Pugh; ACLF,acute-on-chronic liver failure.

3202-A | A NUTRITION-BASED RADIOMICS-CLINICAL MACHINE LEARNING MODEL TO PREDICT THE PROGNOSIS OF PATIENTS WITH ACUTE-ON-CHRONIC LIVER FAILURE

Qian Zhang, Yunsong Peng, Xinhua Luo, Rongpin Wang and Hong Peng, Guizhou Provincial People's Hospital

Background: Acute-on-chronic liver failure (ACLF) is a syndrome characterized by acute decompensation (AD) associated with chronic liver disease and organ failure, leading to high short-term mortality. Effective identification of patients with poor prognosis and early intervention are crucial for saving patients' lives. Meanwhile, the basic nutritional status of patients is vital in the prognosis of chronic liver diseases. Hence, the study aims to apply artificial intelligence to extract nutrition-based imaging features in ACLF patients and construct a radiomics-clinical prognostic model to predict the 90-day adverse prognosis. **Methods:** 163 ACLF patients who met the APSAL diagnostic criteria and had follow-up records were recruited from our hospital. The patients were randomly assigned to the training cohort (n = 99) and the test cohort (n = 64). The regions of interest of the third lumbar spine skeletal muscle, subcutaneous fat, and visceral fat were obtained during the enhanced CT arterial phase, and the imaging features were extracted. The blood routine and blood biochemistry were collected. The least absolute shrinkage and selection operator (LASSO) regression model was applied to select imaging features and form a new feature subset. Finally, the linear discriminant classifier was used for endpoint prediction. **Results:** In the training and test cohorts, 30.3% (30/99) and 29.7% (19/64) of patients experienced disease progression (death or liver transplantation), respectively. LASSO regression screened 15 features for constructing a radiomics-clinical model, most of which were texture features of skeletal muscles. The area under the curve (AUC) of this model in the test cohort was 0.873 (95% CI 0.773-0.972), with sensitivity and specificity of 0.895 and 0.711, respectively. The Delong test was used to compare the AUC of the radiomics-clinical model with sub-models (radiomics model and clinical model) and traditional classical models (MELD and MELD-Na). The results showed that the radiomics-clinical model was superior to any of the above models ($p < 0.05$).

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Conclusion: The nutrition-based radiomics-clinical machine learning model can effectively predict the 90-day adverse prognosis of ACLF patients. This comprehensive model may provide a novel and valuable method for clinical practice to identify patients who require active intervention as early as possible, thereby improving the survival rate of ACLF patients.

f 3203-A | ALCOHOL BINGE EXACERBATES LIVER DAMAGE IN A NOVEL CHOLESTATIC MODEL OF ACUTE-ON-CHRONIC LIVER FAILURE BY PROMOTING NETs AND NECRO/PYRO-PTOTIC CELL DEATH

Marti Ortega-Ribera, Yuan Zhuang, Veronika Brezani, Radhika Joshi, Prashanth Thevkar Nagesh, Mrigya Babuta, Yanbo Wang and Gyongyi Szabo, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Background: Acute-on-chronic liver failure (ACLF) is defined by systemic inflammation, multi-organ failure, and high short-term mortality in patients with advanced chronic liver disease (CLD). Alcohol abuse is one of the most frequent precipitating factors in ACLF; nevertheless, preclinical models fully mimicking this clinical setting are scarce. The aim of this study was to develop an alcohol-induced ACLF model & further dissect its underlying molecular mechanisms. **Methods:** Liver fibrosis was induced in 10-12 weeks old male C57BL/6 or gasdermin D knockout (GSDMD KO) mice by common bile duct ligation (BDL) for 28 days (n e 4 per group). Alcohol binge (5g/Kg) was given to a subgroup of animals to induce ACLF. Sham surgery groups receiving either alcohol or water binge were used as controls and tissue collection was performed 9 hours after binge. Human tissues from patients with cholestatic CLD or ACLF were provided by the Liver Tissue and Cell Distribution Center. **Results:** Hepatocellular damage after BDL was further aggravated by alcohol binge in the ACLF group as shown by higher transaminases and bilirubin, decreased albumin and coagulation factors expression compared to BDL. Endotoxin, tumor necrosis factor α and interleukin-6 levels were significantly increased in ACLF mice as compared to BDL. Moreover, alcohol binge in BDL mice resulted in hyperammonemia, sickness behavior (open-field test), increased blood urea nitrogen and creatinine suggesting hepatic encephalopathy-like features and kidney dysfunction in ACLF. Neutrophil count and extracellular trap (NET) release (citrullinated H3 and neutrophil elastase) were increased in serum and liver of ACLF mice compared to BDL. ACLF mice livers also exhibited increased necroptosis (RIP3 expression), inflammasome activation and pyroptosis (increased cleaved-GSDMD, IL-1β, and IL-18) without changes in apoptosis (caspase 3, caspase-cleaved-CK18) compared with BDL alone. *In vitro*, both ethanol and bile acids induced NET release from normal neutrophils. Furthermore, these cell-free NETs induced RIP upregulation in HepG2 cells. NETosis, pyroptosis and RIP3 activation were validated in human livers with ACLF. GSDMD KO mice were partially protected from ACLF compared to WT indicated by reduced neutrophil infiltration (Ly6G, CXCL1 & CXCL2) and reduced cell death (decreased RIP3 and IL-1β expression) in the liver. **Conclusion**: Our novel preclinical ACLF model involving alcohol binge in BDL mice mimics ACLF pathophysiology including acute liver damage, hepatocyte dysfunction, systemic inflammation, kidney injury and brain & coagulation impairment. Mechanistically, we show that ACLF occurs in the setting of neutrophil infiltration, NETosis and hepatocellular death involving inflammasome activation and necroptosis, which are attenuated upon GSDMD deletion.

3204-A | APPLICATION OF DIFFERENT DIAGNOSTIC CRITERIA FOR ACUTE ON CHRONIC LIVER FAILURE IN PROGNOSIS ASSESSMENT ON PATIENTS WITH SEVERE ALCOHOLIC HEPATITIS

Fangyuan Meng, Yanhang Gao, Guangfei Yuan and Yue Sun, The First Hospital of Jilin University

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Severe alcoholic hepatitis (SAH) is the most serious form of alcohol-related liver diseases (ALD) with a high fatality rate. If ALD-acute on chronic liver failure (ACLF) is present, the disease progression will be accelerated. Currently, among many diagnostic criteria for ACLF, the definitions of EASL-CLIF ACLF, NACSELD ACLF and COSSH-ACLF are widely accepted. The purpose of this study was to explore the value of the above three diagnostic criteria in the prognosis assessment of patients with SAH. **Methods:** This study is a two-way cohort study. The data of 309 patients with SAH in the Department of Hepatology, the First Hospital of Jilin University from 2012 to 2022 were collected retrospectively and prospectively, including baseline data, incidence and type of organ failure, and survival data at 7, 28, 90 days after admission or diagnosis of ACLF. The effects of three diagnostic criteria for ACLF on the prognosis of patients with SAH were compared and analyzed. **Results:** Among the 309 SAH patients, 183 (59.2%), 106 (34.3%) and 16(5.2%) patients met the COSSH-ACLF, EASL-CLIF and NACSELD ACLF criteria, respectively. In predicting 7-day mortality, NACSELD criteria had higher overall accuracy (95.58% vs 67.69 % vs 42.86%, $P < 0.001$), specificity (96.49% vs 67.25% vs 41.46%, $P < 0.001$) and positive predictive value (37.50% vs 6.00% vs 4.00%, $P < 0.001$) than EASL-CLIF criteria and COSSH-ACLF criteria. But the sensitivity is low. EASL-CLIF criteria also had higher overall accuracy (66.69% vs 42.86%, $P < 0.001$) and specificity (67.25% vs 41.46%, $P < 0.001$) than COSSH-ACLF criteria.In the prediction analysis of 28-day mortality, the performance was similar to that of 7-day mortality. In the 90-day mortality prediction, the sensitivity and negative predictive value of the NACSELD criteria decreased significantly, and the overall accuracy was equal to the EASL-CLIF criteria, which was still higher than the COSSH-ACLF criteria. EASL-CLIF criteria still had higher overall accuracy and specificity than COSSH-ACLF criteria. The 7, 28,and 90 days survival rates of patients who met the EASL-CLIF criteria but did not meet the NACSELD criteria were 97.8%, 80.2%, and 59.8%, respectively. **Conclusion:** The incidence of ALD-ACLF in SAH patients was higher, and the mortality increased significantly. NACSELD ACLF standard has higher overall accuracy in predicting short-term mortality, and can identify patients with very high mortality more accurately. EASL-CLIF and COSSH-ACLF have higher sensitivity, which can identify high-risk patients who benefit from supportive treatment and liver transplantation earlier. However, the standard specificity of COSSH-ACLF is low, and the overall accuracy does not show obvious advantages. Further evaluation of ALD-ACLF in patients with SAH is helpful to optimize the prognostic management strategy in order to improve the survival rate.

3205-A | CHRONIC LIVER DISEASE AND RISK OF SHOCK IN ACUTE HEART FAILURE PATIENTS UNDERGOING ENDOSCOPIC PROCEDURES: AN ANALYSIS OF THE NATIONAL INPATIENT SAMPLE

Ikechukwu Eze, John Gharbin, Claudia Gyimah and Miriam Michael, Howard University Hospital, Washington, DC

Background: Endoscopic procedures are commonly performed for diagnostic and therapeutic purposes in Acute Heart Failure (AHF) patients with gastrointestinal disorders. The risk of shock and associated risk in AHF patients undergoing endoscopic procedure is currently under-explored. This study aimed to utilize the National Inpatient Sample to investigate the incidence and risk factors for shock in AHF patients undergoing endoscopic procedures. **Methods**: This was a retrospective cohort study using the National Inpatient Sample Database from 2017 to 2020. Adult patients aged e 18 years with a primary diagnosis of Acute Heart Failure who underwent non-elective endoscopic procedures using the International Classification of Diseases, Tenth Revision (ICD-10). For this analysis, endoscopic

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

procedures refer to esophagoduodenoscopy (EGD) and colonoscopy. The primary outcome was the incidence of shock. Multivariate logistic regression analyses were performed to adjust for potential confounders and identify associated risk factors. A 2-sided $p < 0.05$ was considered significant throughout the analyses. STATA/SE 17.0 Stata Corp LLC was used for the data analyses. **Results**: A total of 3445 hospitalizations of patients with Acute Heart Failure who underwent endoscopic procedures were identified. Colonoscopy was performed more frequently than EGD in the study population. The mean age of AHF patients who underwent an endoscopic procedure was 68.5 years ($P < 0.01$). The incidence of shock was 17.6%. Patients with AHF who underwent endoscopic procedures had significantly higher risk of shock [Odds Ratio (OR) 3.1, 95% Confidence Interval (CI) 2.4 – 3.9, $p < 0.01$]. Chronic Liver Disease (CLD) was associated with the development of shock in AHF patients undergoing endoscopic procedures (OR 2.2, 95%CI 1.93 - 2.4, $p < 0.001$). Other associated risk factors include Chronic Kidney Disease (CKD) (OR 1.23, 95%CI 1.12 - 1.35, $p < 0.001$), presence of atrial fibrillation (OR 1.6, 95%CI 1.5 - 1.7, $p < 0.001$) and other arrhythmia (OR 2.0, 95%CI 1.8 - 2.3, $p < 0.001$). There was no statistically significant difference in the odds of shock between AHF patients undergoing EGD versus colonoscopy (OR 0.6, 95% CI 0.34 - 1.32, $p > 0.05$). **Conclusion**: This study suggests that the risk of shock in AHF patients undergoing endoscopic procedure was significant in patients with chronic liver disease. Other associated risk factors were CKD, the presence of atrial fibrillation and other arrhythmias. The overall risk of shock in AHF patient who underwent endoscopic procedure was also increased. Understanding the drivers of poor clinical outcomes in shock through further research in this patient population is imperative for better clinical decision making and patient care.

3206-A | CLINICAL CHARACTERISTICS OF END-STAGE LIVER DISEASE COMPLICATED BY BACTERIAL OR FUNGAL INFECTIONS: A MULTI-CENTER RETROSPECTIVE STUDY FROM CENTRAL CHINA

Wei Liu[1,2], Qiuyu Cheng[1,2], Yunhui Liu[1,2], Zhongyuan Yang[1,2], Meng Zhang[1,2], Tingting Liu[1,2], Yuxin Niu[1,2], Xiaojing Wang[1,2], Tao Chen[1,2] and Qin Ning[1,2], (1) Institute and Department of Infectious Disease, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, (2)Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonostic Infectious Disease, Huazhong University of Science and Technology

Background: To analyze the clinical characteristics in patients with end-stage liver disease (ESLD) complicated by bacterial or fungal infections. **Methods:** A total of 1208 patients diagnosed with acute on chronic liver failure (ACLF), acute decompensation of liver cirrhosis (ADC), and chronic liver failure (CLF) were involved in this retrospective cohort study from 16 tertiary hospitals in January 2012 to December 2018 in central China. Clinical characteristics and mortality risk factors of these patients were analyzed. **Results:** Out of all 1208 ESLD patients, 565 (46.8%) were complicated by bacterial infections and 16 (1.3%) were complicated by fungal infections. Bacterial or fungal infections happened in 64.4%, 60.2% and 37.4% patients with ACLF, CLF and ADC respectively. Spontaneous peritonitis (51.1%) is the most common type of infection, followed by pneumonia (43.7%), urinary tract infection (7.9%), bacteremia (2.8%) and others (1.9%). 72 samples showed positive culture results, among which 28 (38.9%) were gram-positive organism, 28 (38.9%) were gram-negative organism and 16 (22.2%) were fungus. The most common strain was *coagulase-negative staphylococci* in gram-positive organisms and *Escherichia coli* in gram-negative organisms respectively. Patients with bacterial or fungal infections both showed significantly higher level of white blood cell (WBC) and procalcitonin (PCT), severer liver and coagulation dysfunction, and more likely to develop ascites, hepatorenal syndrome (HRS), hepatic encephalopathy (HE), upper gastrointestinal bleeding (UGB), and hepatopulmonary syndrome (HPS) than those without. Bacterial or fungal infections were mortality risk factors for patients with ESLD. CLF, ACLF and ADC with HRS were identified as independent predictors for poor outcomes in ESLD patients with bacterial or fungal infections. The mortality risk factors were HRS and increased total bilirubin (TBIL) and lactate dehydrogenase (LDH) level for ACLF, higher neutrophil (NEUT) count and HE for CLF and elevated PCT level for ADC. **Conclusion:** CLF, ACLF and ADC showed homogeneity in the occurrence and clinical characteristics of bacterial or fungal infection, which was an independent risk factor of mortality of ESLD. Key Words: end-stage liver disease, acute-on-chronic liver failure, chronic liver failure, acute decompensation of cirrhosis, infection

3207-A | DISTINCT EFFECTS OF SENESCENCE CLEARANCE ON ALCOHOL-INDUCED LIVER INJURY IN YOUNG AND AGING INK-ATTAC MICE

Tian Tian[1], Chunbao Sun[2], Sreenivasulu Basha[2], Hua Wang[1] and Liya Pi[2], (1)Anhui Medical University, (2) Tulane University School of Medicine, New Orleans, LA

Background: Senescence is a state of permanent cell cycle arrest employed by cells due to replicative or stress-related mechanisms. The INK-ATTAC is a genetic tool based on dimerization of active caspase 8 domain by the AP20187 compound for inducible elimination of senescent cells under the control of p16Ink4a promoter. This study aims to use INK-ATTAC transgenic mice and examine roles of senescence during alcohol-induced liver injury in young and aging conditions. **Methods:** Suicide gene-meditated ablation of p16Ink4a-expressing senescent cells was carried out through intraperitoneal injection of AP20187 into young (8-week-old) or aging(20-month-old) INK-ATTAC mice at or age respectively. The chronic-on-acute liver injury was induced by feeding of 5% ethanol-containing Lieber DeCarli diet for one month plus repetitive ethanol binge (5 g/kg body weight, once per week for total 4 times). AP20187 (10 mg/kg) was administered to the young or aging adult mice every 3 days before the end time points. Control mice received the same treatment except vehicle for the alcohol-induced liver injury. Hepatic inflammation, steatosis, and levels of serum markers for liver function were examined. **Results:** Higher levels of p16Ink4a and increased activities of senescence-associated beta-galactosidase were found in aging livers than those in young groups. Elimination of senescence in these old adult livers by AP20187 reduced number of neutrophils as revealed by IHC for myeloperoxidase (MPO), attenuated fat accumulation in Oil red staining, and decreased levels of alanine aminotransferase (ALT) and aspartate amino-transferase (AST) in sera compared to age-matched vehicle-treated controls, indicating that senescence clearance reduced ethanol-induced injury in aging livers. Further, elimination of $p16^{high}$ cells ameliorated immune cell infiltration. An enzyme-linked immuno-sorbent analysis showed that the higher cytokine secretion levels of IFN-γ, TNF-α and interleukin 6 (IL-6, a critical modulator of innate immunity) in the AP20187 treated group compared to age-matched vehicle-treated controls could be observed. **Conclusion:** Senescence clearance is beneficial and protects aging but not young mice from the ethanol-induced chronic-on-acute liver injury.

3208-A | EFFICACY AND SAFETY OF PLASMA EXCHANGE WITH HUMAN SERUM ALBUMIN 5% ON SHORT-TERM SURVIVAL IN PATIENTS WITH ACUTE-ON-CHRONIC LIVER FAILURE AT HIGH RISK OF HOSPITAL MORTALITY: APACHE STUDY DESIGN AND PROGRESS

Nikolaos T. Pyrsopoulos[1], Giovanni Perricone[2], Jasmohan S. Bajaj[3], Thierry Gustot[4], Thomas Reiberger[5], Mireia Torres[6], Peter Nelson[6], Javier Fernandez[7,8] and On behalf of the APACHE Study Investigators, (1)Rutgers-New Jersey Medical School, (2)Asst GOM Niguarda, (3)Virginia Commonwealth University, (4)HUB Erasme Hospital, Université Libre De Bruxelles, (5)Medical University of Vienna, (6) Grifols, (7)EF Clif, Easl-Clif Consortium and Grifols Chair, (8)Hospital Clínic, Idibaps and Ciberehd

Background: Acute-on-chronic liver failure (ACLF) is an increasingly recognized syndrome in patients with cirrhosis, characterized by acute decompensation of cirrhosis that results in severe organ injury with high rates of short-term mortality. Liver transplantation is currently the only treatment to improve survival. A pilot study suggested that plasma exchange with human serum albumin 5% (PE-A5%) as a replacement fluid is feasible and safe in patients with ACLF and may improve organ function and survival. The aim of this study is to assess PE-A5% as a treatment for patients with ACLF in a pivotal study **Methods:** A phase 3, multicenter, randomized (1:1), controlled, parallel-group, open-label study (APACHE) compares standard medical treatment (SMT) + PE-A5% (treatment arm) to SMT alone (control arm). PE-A5% is performed using Albutein 5% (Grifols). Treatment schedule consists of two initial PE-A5% sessions on consecutive days followed by every other day PE-A5% (minimum 4, maximum 9 PE-A5%). Patients receive IVIG (200 mg/kg) after every 2 PE-A5% to prevent hypogammaglobulinemia-associated infections, and FFP after each PE-A5% to prevent coagulopathy. Eligible patients are adult (18-79 years old), with ACLF-1b, ACLF-2, or ACLF-3a at admission or during hospitalization. Main exclusion criteria are patients with ACLF-1a or ACLF-3b, ACLF > 10 days prior to randomization, septic shock requiring norepinephrine (> 0.3 μg/kg/min) or a second vasopressor, active infection, and severe respiratory failure. **Results:** Target enrollment is 380 patients with ACLF at high risk of hospital mortality. As of May 2023, enrollment is occurring at 26 sites across North America and Europe, with 244 patients screened and 208 patients randomized (54.7% of sample size). The primary efficacy endpoint is the 90-day overall survival. Secondary efficacy endpoints include 90-day transplant-free survival and 28-day overall survival. Main exploratory endpoints include overall and transplant-free survival at days 28 and 90, in-patient hospital and ICU

stay, incidence of organ failures and ACLF course. Safety analyses include adverse events, vital signs, physical assessments, and laboratory tests. **Conclusion:** APACHE should provide pivotal results on the efficacy and safety of PE-A5% as a potential treatment to improve survival in ACLF (NCT03702920, EudraCT: 2016-001787-10).

Background: Acute-on-Chronic liver failure is a disease with a high mortality rate, the only cure currently available is liver transplantation.Our previous study showed that intravenous injection of mesenchymal stem cells could improve survival rate of acute-on-chronic liver failure patients, and expressed higher levels of Mertk, which could promote macrophage phagocytosis of apoptotic cells and reduced the occurrence of secondary necrosis in the efferocytosis . Mertk can be cleaved by a cell membrane protein ADAM9 and subsequently loses its biological activity. MiR-126 is an upstream molecule of ADAM9 that can inhibit its generation.In this study,we aim to load miR-126 into exosomes of mesenchymal stem cells by electroporation as engineered exosomes,then apply it to the treatment of acute-on-chronic cell model and explore the mechanism. **Methods:** MiR-126 mimics and inhibitors were transfected into M1 polarization macrophages RAW264.7 induced by LPS in vitro,Mertk and ADAM9 were detected by western blotting,inflammatory and anti-inflammatory cytokines were tested by qPCR. Apoptotic AML12 cells were added and co-cultured with the transfected macrophages,apoptosis related proteins were detected by Western Blotting,efferocytosis/phagocytosis index were observed by fluorescence microscope.Finally,miR-126 loaded into the exosomes of mesenchymal stem cells co-cultured with M1 polarization macrophages,efferocytosis index and the expression of related signaling pathway proteins were detected. **Results:** Compared with the control group, transfection of miR-126 mimics resulted in a decrease in ADAM9 expression and an increase in Mertk expression in M1 macrophages. The qPCR results showed that the inflammatory cytokines in the transfection group decreased, while the anti-inflammatory factors increased compared to the control group. After co-culturing with apoptotic AML12 cells, the expression of cleaved caspase-3 decreased in the transfection group, while the expression of Bcl-2 increased; Efferocytosis index in the transfected group is enhanced compared to the control group under fluorescence microscope. **Conclusion:** After transfection with miR-126 mimics, the expression of Mertk increased, M2 polarization related proteins increased, the efferocytosis enhanced, and cellular inflammatory response weakened.

3210-A | EUTHYROID SICK SYNDROME INDICATES INCREASED RISK FOR ACUTE-ON-CHRONIC LIVER FAILURE AND MORTALITY IN PATIENTS WITH CIRRHOSIS

Lukas Hartl[1,2], Benedikt Simbrunner[3,4,5], Mathias Jachs[2,6], Peter Wolf[7], David Josef Maria Bauer[1,2], Bernhard Scheiner[1,2], Lorenz Balcar[2,8], Georg Semmler[1,2], Michael Schwarz[2,6], Rodrig Marculescu[9], Michael Trauner[1], Mattias Mandorfer[1,5] and Thomas Reiberger[2,3,6], (1)Medical University of Vienna, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria, (2)Medical University of Vienna, Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria, (3) Christian Doppler Laboratory for Portal Hypertension and Liver Fibrosis, Medical University of Vienna, (4) Cemm Research Center for Molecular Medicine of the Austrian Academy of Sciences, (5)Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, (6) Medical University of Vienna, (7)Medical University of Vienna, Division of Endocrinology, Department of Internal Medicine III, Vienna, Austria, (8)Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, (9)Medical University of Vienna, Department of Laboratory Medicine, Vienna, Austria

Background: Euthyroid sick syndrome as evident by low free triiodothyronine (fT3) levels has been described in patients with cirrhosis. While hepatic function impacts on transport, conversion and metabolism of thyroid hormones, hepatic metabolism is affected by thyroid hormones. We aimed to analyze the pituitary-thyroid axis in advanced chronic liver disease (ACLD) and the prognostic value of low fT3. **Methods:** Patients with ACLD (liver stiffness measurement e 10kPa or hepatic venous pressure gradient [HVPG] e 6mmHg) undergoing HVPG measurement between 04/2007-09/2022 with available thyroid stimulating hormone (TSH) levels were included. Exclusion criteria were hepatocellular carcinoma (HCC), liver transplantation, infections, portal vein thrombosis, vascular liver disease or intake of thyroid hormones. Clinical stages of ACLD were defined as: likely ACLD (L-ACLD): LSM e 10kPa+HVPG < 6mmHg, S0: subclinical portal hypertension (PH; HVPG 6-9mmHg), S1: clinically significant PH (CSPH), S2: CSPH with varices, S3: prior variceal bleeding, S4: prior non-bleeding hepatic decompensation and S5: prior further decompensation. **Results:** Overall, 647 patients with ACLD (median age: 54.8 y; 65.8% male) were included: 316 were compensated (i.e. cACLD; L-ACLD: n = 31; S0: n = 35; S1: n = 85; S2: n = 165), 331 were decompensated (i.e. dACLD; S3: n = 33; S4: n = 169; S5: n = 129). While median levels of TSH ($p < 0.001$; see Figure) and

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

C-reactive protein (CRP; $p < 0.001$) increased with progressive ACLD stage, fT3 levels (available in $n = 297$; $p < 0.001$) decreased and free thyroxin (fT4) levels did not change (available in $n = 328$; $p = 0.373$). 38 patients had low fT3 levels, with a higher prevalence in dACLD (dACLD: 17.3% vs cACLD: 7.0%; $p = 0.009$). Of note, the majority of patients (97.4%) with low fT3 exhibited normal TSH. In multivariate linear regression analysis, TSH (aB: 0.49; $p < 0.001$) and fT3 (aB: -0.17; $p = 0.048$) were associated with CRP per mg/dL adjusted for age, Child-Pugh score, creatinine, sodium and HVPG. Low fT3 was linked to higher risk of acute-on-chronic liver failure (ACLF; asHR: 5.3; 95% CI: 1.8-15.8; $p = 0.002$) and liver-related death (asHR: 7.5; 95%CI: 2.7-20.4; $p < 0.001$) considering HCC, etiological cure, LT and non-liver-related death as competing events. **Conclusion:** Increasing TSH and declining fT3 levels in more advanced ACLD stages are indicative of a low T3 (i.e. euthyroid sick) syndrome. Low fT3 was associated with systemic inflammation, a key disease driving mechanism. Importantly, low fT3 in patients with ACLD is an independent risk factor for ACLF and liver-related death and might identify patients who may benefit from therapeutic interventions (e.g. thyroid hormones, thyroid hormone receptor beta agonists).

3211-A | GRANULOCYTE COLONY-STIMULATING FACTOR FOR PEOPLE IN ADVANCED CHRONIC LIVER DISEASE. A COCHRANE SYSTEMATIC REVIEW AND METANALYSIS

Agostino Colli, Fondazione Irccs Ca' Granda Ospedale Maggiore Policlinico, Milano, Daniele Prati, Fondazione Irccs Ca' Granda Ospedale Maggiore, Policlinico Milano, Mirella Fraquelli, Fondazione Irccs Ospedale Maggiore, Policlinico Milano and Giovanni Casazza, University of Milan

Background: Advanced chronic liver disease (ACLD) is considered responsible for more than one million deaths annually worldwide. No treatment is available and liver transplantation remains the only curative option. Granulocyte colony-stimulating factor (G-CSF) is currently available for mobilization of haematopoietic stem cells from the bone marrow. Multiple courses of G-CSF infusion might be associated with improved hepatic regeneration, liver function, and survival. This systematic review assesses the benefits and harms of G-CSF. **Methods:** We followed standard Cochrane procedures. We included randomized clinical trials comparing G-CSF, independent of the schedule of administration, alone or combined with stem cell infusion, or with other co-interventions versus no intervention or placebo, in adults with chronic compensated or decompensated ACLD or acute-on chronic liver failure.

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Primary outcomes were all-cause mortality, serious adverse events, and health-related quality of life Secondary outcomes were liver disease-related morbidity, nonserious adverse events, and liver function scores. We undertook meta-analyses and presented results using risk ratios (RR) for dichotomous outcomes, and I^2 values for heterogeneity. **Results:** 20 trials (1419 participants) were included. The experimental intervention was G-CSF alone, or G-CSF plus growth hormone, erythropoietin, N-acetyl cysteine, infusion of CD133- positive haemopoietic stem cells. Very low certainty evidence suggested: -a decrease in mortality with G-CSF (RR 0.53, 95% CI 0.38 to 0.72; $I^2 = 75\%$; 1419 participants; 20 trials) -no difference in serious adverse events (RR 1.03, 95% CI 0.66 to 1.61; $I^2 = 66\%$; 315 participants; 3 trials). Eight trials (518 participants) reported no serious adverse events. Two trials (165 participants) assessed the quality-of-life score and suggested an improvement of both the physical and mental component summary. **Conclusion:** G-CSF, alone or in combination, may decrease mortality in decompensated ACLD of whatever aetiology and with or without acute-on-chronic liver failure, but the certainty of evidence is very low because of high risk of bias, inconsistency, and imprecision. The results of trials conducted in Asia and Europe were discrepant; this could not be explained by differences in participants selection, intervention, and outcome measurement. Data on serious adverse events, health-related quality of life and secondary outcomes were few and inconsistently reported.

3213-A | LIVER FAILURE VERSUS ORGAN FAILURE IN ACUTE ON CHRONIC LIVER FAILURE: SEQUENCE AND CONSEQUENCE

Young Chang, Soonchunhyang University

Background: Acute-on-chronic liver failure (ACLF) is a syndrome characterized by acute decompensation of chronic liver disease or cirrhosis associated with organ failures, resulting in high short-term mortality. This study aimed to determine the sequence and consequences of organ failures, particularly hepatic and renal failure, and to identify their impact on short-term survival rates in ACLF patients. **Methods:** We extracted 340 ACLF patients from the prospective Korean Acute-on-Chronic Liver Failure cohort. Timing of organ failure, especially hepatic failure and renal failure, was assessed and overall survival was compared according to organ failure sequence. Overall survival (OS) was estimated by Kaplan-Meyer survival analysis with log-rank test and multivariate survival analysis was conducted with Cox proportional hazards model. **Results:** Compared to the group without hepatic failure, the OS was worse in the group manifested by initial hepatic failure (adjusted hazard ratio [aHR] = 3.6; $p = 0.008$), and in the group with hepatic failure during the disease period (aHR = 5.7; $p = 0.002$). There was no difference in OS between the group without renal failure and the group manifested by initial renal failure (aHR = 0.8, $p = 0.51$), but the group with renal failure during the disease period showed a poor prognosis (aHR = 1.9, $p = 0.056$). Initial renal failure only group had significantly longer OS than initial hepatic failure group (aHR = 10.8, $p = 0.02$). **Conclusion:** Organ failure that develops during hospitalization is more fatal than organ failure that manifested initially. ACLF manifested with initial renal failure has better prognosis than with initial hepatic failure. ACLF with initial renal failure show a great prognosis with 28-day survival rate of over 90%, but the prognosis is dismal if renal dysfunction develops during hospitalization.

3214-A | MARIJUANA USE IS ASSOCIATED WITH BETTER OUTCOMES IN PATIENTS WITH CIRRHOSIS

Tae Hoon Lee[1,2], Kristel K. Hunt[1,2], David E. Kaplan[3,4] and Tamar H. Taddei[5,6], (1)James J. Peters VA Medical Center(Bronx), (2)Icahn School of Medicine at Mount Sinai, (3)Division of Gastroenterology and Hepatology, Department of Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA, (4) Corporal Michael J. Crescenz VA Medical Center, Philadelphia, PA, (5)Yale University, New Haven, CT, (6)West Haven VA Medical Center

Background: Despite legalization and increasing use of marijuana in many states of the U.S., its effect on cirrhotic patients has not been well described. We performed a retrospective large database analysis using the Veterans Outcomes and Costs Associated with Liver Disease (VOCAL) cohort from VA Informatics and Computing Infrastructure. **Methods:** The VOCAL cohort includes all veterans with cirrhosis, receiving care between 2008 – 2016 at the Veterans Health Administration. All patients' urine and serum toxicology reports were utilized to define groups: If a patient had any positive result for marijuana, the patient was classified as a marijuana user (THC_User). All negative results classified the patient as a nonuser (THC_Nonuser) and someone who had never been tested, was classified as no test group (Not_Tested). Baseline characters were compared between the groups. Survival and decompensation were compared between groups using Kaplan-Meier Survival curve with Log Rank Test and Cumulative Incidence with Gray's Test after matching possible confounding variables with Mahalanobis Distance Matching. **Results:** Out of 129,981 cirrhotic

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

veterans, 63,860 were in THC_Nonuser, 29,456 were in THC_User, and 36,665 were in Not_Tested groups. Regarding etiologies of cirrhosis, alcohol (either alcohol alone or alcohol with chronic hepatitis C, HCV) was the most common cause in THC_Nonuser group (55.6%) and THC_User group (65.7%). NASH was the most common cause in Not_Tested group (38.7%). NASH was more common in THC_Nonuser (21.9%) and Not_Tested (38.7%) groups than THC_User group (7.0%). Several comorbidities were more common in THC_Nonuser than THC_User group, including diabetes (59% vs 49%), chronic heart failure (CHF, 35% vs 25%), chronic kidney disease (CKD, 50% vs 25%). The median baseline MELD score was 6 (Interquartile Range 6-14) in all three groups. Most patients were Child-Turcotte Pugh class A (60%). After matching for age, BMI, baseline MELD score, impaired fasting glucose/diabetes, CKD and CHF, THC_User had significantly better survival than THC_Nonuser in alcoholic cirrhosis patients. ($p < 0.01$, Figure 1) There was no significant survival difference between THC_User and THC_Nonuser in HCV ($p = 0.58$) and NASH ($p = 0.51$) cirrhosis patients. THC_User had significantly less cumulative incidence of decompensation than THC_Nonuser in alcoholic ($p < 0.01$), NASH ($p < 0.01$), and HCV ($p < 0.01$) cirrhosis patients. **Conclusion:** In cirrhosis patients, marijuana use is correlated with better outcomes including decompensation and survival. Further studies are needed to identify the potential mechanism of marijuana use leading to better outcomes.

Background: Acute-on-chronic liver failure (ACLF) is syndrome defined by acute decompensation of cirrhosis associated with single or multi-organ failures and high 28- and 90-day mortality between 20 and 80% or more according to the number of organ failures. The DHELIVER study is an ongoing multicenter Phase IIb RCT double-blinded POC trial that aims to demonstrate the efficacy of Human Allogeneic Liver-derived Progenitor Cells (HepaStem®) on overall survival in patients with persistent ACLF grades (G) 1 and 2. The purpose of the current analysis is to describe the characteristics of patients with ACLF who were randomized in the study. **Methods:** Patients with initial ACLF G1 or G2 (EASL-CLIF definition) were assessed at the beginning and at the end of screening, 3 to 7 days after the initial ACLF diagnosis. Only patients with confirmed persistent ACLF were randomized. **Results:** Up to 10-MAY-2023, 121 patients with ACLF (M/F 89/32), aged 52.0 ± 10 yrs (range: 25-73 yrs), were screened in 27 sites in 12 European countries. Among all screened patients, 77 had G1 (63.6%) and 44 G2 (36.4%). 46 patients were screen failures (SF), mostly because ACLF resolved (58.7%), they did not meet the enrollment criteria (21.7%) or because they died (10.9%) during screening. 75 patients (48 G1 and 27 G2) fulfilled all enrollment criteria and were randomized (M/F 59/16), with mean age 51.0 ± 10.9 yrs, slightly younger compared to SF (53.7 ± 9.4 yrs). In those randomized patients the etiology of cirrhosis was mainly alcohol alone (92.0% of G1, 100% of G2) or combined with other etiologies (6.3% of G1). Precipitating events of ACLF were mostly acute alcoholic hepatitis (AAH)/active alcoholism (up to 81.5% in G2) and bacterial infection (up to 25.5% in G1). Most G1 patients had liver failure (72.9%), primarily associated with mild or moderate hepatic encephalopathy (66.7%); while most patients with G2 had liver failure (96.3%), associated with coagulation failures (77.8%). Mean bilirubin, WBC and CRP did not differ in randomized patients with ACLF G1 and G2, MELD-Na and CLIF-ACLF scores were higher in G2 patients. Randomized patients with ACLF compared to SF had higher total bilirubin 22.0 vs 15.6 mg/dL; CRP 40.0 vs 33.4 mg/L and WBC 12.9 vs 10.0 10^9/L. MELD-Na was very similar between screen and randomized patients. **Conclusion:** Patients with persistent ACLF enrolled in DHELIVER study were characterized mainly by presence of liver failure (in G1) associated with coagulation failure (in G2). High level of bilirubin and significant systemic inflammation were recorded. Predominant etiology of cirrhosis was alcohol-related liver disease.

Background: We aimed to investigate the association between acute-on-chronic liver failure (ACLF) development and systemic inflammatory markers in acutely decompensated chronic liver disease patients. **Methods:** We enrolled 1,249 patients without ACLF at baseline in Korean ACLF cohort. Rrgan failure and ACLF were defined by European Association for the Study of the Liver-Chronic liver failure (EASL-CLIF) criteria. Primary outcome was ACLF development and new organ failure development within 1 year. **Results:** Most common etiology of chronic liver disease was alcohol (66.1%), followed by viral hepatitis (15.5%). Mean model for end-stage liver disease and CLIF-C AD score were 16.3 ± 5.4 and 49.7 ± 9.3, respectively. Patients with high C-reactive protein (CRP) (e 1.0 mg/dL), white blood cell count (WBC) (e $10.0x10^9/mm^3$), procalcitonin level (1.0 mg/dL) showed significantly higher 1-year ACLF development rate than patients with low CRP ($P < 0.001$), WBC ($P = 0.004$) and procalcitonin ($P = 0.014$), respectively. Those with systemic inflammatory response syndrome (SIRS) also had significantly higher ACLF development rate than those without SIRS ($P = 0.045$). Cox proportional hazard regression model showed that SIRS, bacterial infection, low albumin and Na levels, high bilirubin, international normalized ratio (INR), CRP, creatinine, and procalcitonin levels were significant factors in univariate

analysis, and bilirubin (Hazard ratio (HR) 2.266, $P = 0.012$), INR (HR 6.047, $P < 0.001$). CRP (HR 2.242, $P = 0.011$), and procalcitonin (HR = 2.437, $P = 0.011$) level were independent factors for ACLF development. Those with high CRP level had significantly higher renal ($P < 0.001$), coagulation ($P < 0.001$), cerebral ($P = 0.013$), circulatory ($P = 0.009$) failure development ($P = 0.001$) than those with low CRP, and those with high procalcitonin had significantly higher renal failure development rate ($P = 0.032$). The ACLF development rate of the patients with low CRP at baseline but high CRP at 7th day was significantly higher than that of the patients with high CRP at baseline but low CRP at 7th day ($P = 0.01$) and similar to that of the patients with persistently high CRP ($P = 0.629$). The change of the SIRS also showed similar results to the CRP change. **Conclusion:** Persistent or worsening systemic inflammation is a main driver for development of organ failure and ACLF. The resolution of inflammation could reduce the ACLF development. Reducing systemic inflammation can be a treatment target to prevent disease progression.

Background: With the increasing prevalence of metabolic dysfunction-associated fatty liver disease (MAFLD), there is a corresponding increase in the prevalence of MAFLD-related acute-on-chronic liver failure (MAFLD-ACLF). Factors determining the outcome in these patients have not been well studied.

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Methods: We identified MAFLD as the etiology of chronic liver disease among a prospective cohort of patients with ACLF from the Asian Pacific Association for the Study of the Liver (APASL) ACLF Research Consortium (AARC) database. MAFLD was considered the etiology after excluding other known etiologies (such as alcohol, HBV, HCV, etc.) from the cohort. We randomly divided the cohort into two well-matched groups: a derivative cohort (n = 258, comprising 70% of the patients) to identify factors determining the outcome and create a predictive model, and a validation cohort (n = 111, comprising 30% of the patients) to validate the model. The outcome was defined as death within 90 days from enrollment. Transplanted patients were excluded. Only the baseline clinical and laboratory features and severity scores were analyzed. **Results:** The derivative cohort consisted of 258 patients with a mean age of 53, of which 60% were males. Diabetes was present in 27% of the cohort, and hypertension in 29%. The dominant precipitating causes for ACLF included acute viral hepatitis in 32% and drug-induced liver injury in 29%. The MELD-Na and AARC scores at admission were 32 ± 6 and 10.4 ± 1.9, respectively. At the 90-day follow-up, only 132 (51%) patients survived. Non-viral etiology as a precipitant, diabetes, bilirubin, INR, and encephalopathy were found to be independent factors influencing mortality. By adding diabetes and etiology to the MELD-Na and AARC scores, we constructed the MAFLD-MELD-Na score (+12 points for diabetes and -12 points for viral etiology) and the MAFLD-AARC score (+5 for diabetes, -5 for viral etiology). Both of these scores performed significantly better than the general MELD-Na and AARC scores, both in the derivative cohort and the validation cohort (Figure). **Conclusion:** Nearly one in two patients with MAFLD-ACLF succumbs to death by day 90. The presence of diabetes and non-viral precipitant causes independently influence the outcome. The newly developed and validated MAFLD-MELD and MAFLD-AARC scores, calculated at baseline, reliably predict 90-day mortality in patients with MAFLD-ACLF.

3218-A | RESNET PREDICTION MODEL BASED ON SUBCAPSULAR OF LIVER 3D VASCULAR TREE SMI IMAGE OF PATIENTS WITH ACUTE-ON-CHRONIC LIVER FAILURE AND CONVOLUTIONAL NEURAL NETWORKS ESTABLISHED BY ARTIFICIAL INTELLIGENCE

Mingyue Xiao[1], Xuyang Li[2], Run Lin[2], Yuankai Wu[1], Jieyang Jin[1], Jie Ren[1], Yutian Chong[1], Ruixuan Wang[2] and Lili Wu[1], (1)The Third Affiliated Hospital of Sun Yat-Sen University, (2)Sun Yat-Sen University

Background: Acute on-chronic Liver Failure (ACLF) is the main type of liver failure in China. Early prognosis assessment is the key to treatment. Hepatic perfusion is the main determinant of liver repair and regeneration ability. Early non-invasive assessment of liver microperfusion can guide clinical treatment. Superb MicroVascular Imaging (SMI) can display low-speed blood flow with high vascular spatial resolution. However, there is no relevant standard and it is subjective. Advances in deep learning technology can supplement this deficiency. Based on the Deep Residual Network (ResNet), the 3D vascular tree SMI image under the liver capsule of ACLF patients was analyzed and the prediction model was established, aiming to reflect the prognosis of ACLF patients effectively and accurately in the early stage. **Methods:** Patients with ACLF admitted to the Department of Infectious Diseases of our center from June 2020 to October 2021 were examined by conventional ultrasound (US), contrast-enhanced ultrasound (CEUS) and SMI. Conventional US scan was used to find the best section, and the largest section of the right liver was shown in the intercostal space. Subsequently, CEUS was performed, and SMI was performed 2 minutes after CEUS to obtain 3D vascular tree images. The 3D images were manually segmented to obtain the most vascular information. We used a ResNet model with 50 layers to solve the problem of network optimization by adding a "residual module". The model adopted five-fold cross validation, and the data augmentation strategy was used to expand the data volume. The generalization performance of the model on tasks was evaluated using the receiver operating characteristic (ROC) curve and the precision-recall (PR) curve. Based on Layer-wise Relevance Propagation (LRP) method, the importance of features learned by the model from images was visualized. **Results:** A total of 54 patients with ACLF were enrolled, 10 patients died or underwent liver transplantation, and 44 patients were improved. A total of 72 data files were included in the model. After data enhancement, the proportion of data labeled 1 and 0 in each fold of the patient data was the same (25 groups), and one group contained 15 two-dimensional vascular maps. The false positive rate and true positive rate of the model were about 20% and 80%, respectively, and the area under the ROC curve was 0.831. The recall and precision of the model were close to 80%, and the average precision was 0.813. LRP can intuitively explain the positive and negative basis of the model's classification decision. **Conclusion:** The ResNet prediction model based on the SMI image of the subcapsular vascular tree can predict the prognosis of ACLF patients in the early stage non-invasively. The model has certain interpretability, which can provide effective new ideas for the diagnosis of ACLF.

3219-A | SEMA6B INDUCES KUPFFER CELL INFLAMMATION AND HEPATOCYTE APOPTOSIS IN HEPATITIS B VIRUS-RELATED ACUTE-ON-CHRONIC LIVER FAILURE

Hui Yang[1], Qun Cai[2], Jiaxian Chen[1], Xi Liang[3], Jiaojiao Xin[1], Dongyan Shi[1] and Jun Li[1], (1)The First Affiliated Hospital, Zhejiang University School of Medicine, (2) Ningbo Medical Center Lihuili Hospital, Affiliated Lihuili Hospital of Ningbo University, (3)Taizhou Central Hospital (Taizhou University Hospital)

Background: Semaphorin-6B (SEMA6B) plays vital roles in pathogenesis of hepatitis B virus-related acute-on-chronic liver failure (HBV-ACLF), but its molecular basis is unclear. This study aims to elucidate the mechanisms of SEMA6B in HBV-ACLF. **Methods:** Prospective clinical data from 290 subjects with ACLF, liver cirrhosis (LC), chronic hepatitis B (CHB) and healthy control (NC) were studied, and 43 subjects (ACLF, n = 20; LC, n = 9; CHB, n = 10; NC, n = 14) among them underwent mRNA sequencing with peripheral blood mononuclear cells (PBMCs). The transcriptome was performed to clarify mechanisms of SEMA6B in ACLF, and validated in vitro with hepatocytes and macrophage, and in vivo with SEMA6B knockout mice. **Results:** PBMCs transcriptome showed that SEMA6B expression was significantly higher in ACLF patients than in LC, CHB and NC subjects (all, $P < 0.05$). SEMA6B high-expression in ACLF patients were significantly correlated to 28-/90-day mortality rates (all, $P < 0.05$), and inflammation-related genes including ICAM1, IL-10, TNF, IL-1α, IL-1β, CCL2 and apoptosis-related genes including Bim, Caspase-8 and Caspase-9 (all, $P < 0.05$). Immunofluorescence assessment in liver tissues of ACLF patients showed a high expression of SEMA6B in Kupffer cells and hepatocytes. SEMA6B over-expression in macrophages activated immune response and cytokine secretion (IL-6, IL-1β, IL-10, CCL2; all, $P < 0.05$). SEMA6B over-expression in hepatocytes inhibited the hepatocellular proliferation through G0/G1 cell-cycle phase arrestation and triggered the hepatocyte apoptosis. SEMA6B knockout mice with liver failure were rescued though improving liver functions and attenuating inflammatory response (TNF-α, IL-6, IL-1β, IL-10; all, $P < 0.05$), and decreasing hepatocyte apoptosis. A significant downregulation of six inflammation/apoptotic related biological processes were observed in SEMA6B knockout mice with liver failure. **Conclusion:** SEMA6B, as a potential biomarker for disease severity in the development and progression of ACLF, induces Kupffer cell inflammation and hepatocyte apoptosis in ACLF, and provides a novel clinical target for treating ACLF.

f 3220-A | SERUM LACTATE AND MEAN ARTERIAL PRESSURE THRESHOLDS IN THE TREATMENT OF SEPTIC SHOCK IN PATIENTS WITH CIRRHOSIS: VALIDATION OF THE SEPSIS-3 GUIDELINES

Thomas Smith[1], Chansong Choi[2], Puru Rattan[3], Laura Piccolo Serafim[1], Alice GalloDeMoraes[3] and Douglas A. Simonetto[4], (1)Mayo Clinic School of Graduate Medical Education, (2)University of Nebraska Medical Center, (3)Mayo Clinic - Rochester, (4)Mayo Clinic Rochester, Rochester, MN

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

Background: Despite the 2016 Sepsis-3 guideline's lowering of serum lactate cutoff (2 mmol/L) to include patients with higher risk-adjusted hospital mortality, further investigation is needed in patients with known derangements in lactate metabolism and hemodynamics such as those with cirrhosis. Expert opinion also differs regarding optimal mean arterial pressure (MAP) targets during resuscitation in this population based on altered baseline hemodynamics. This study aims to investigate the association between initial serum lactate and resuscitation MAP on in-hospital mortality in patients with and without cirrhosis. **Methods**: Retrospective cohort study of patients admitted to a Mayo Health System ICU for treatment of septic shock between 2006 and 2021. Patients with identified infection source and vasopressors administered within 6 hours of ICU admission were included. Patients with cirrhosis documented on imaging and ICD codes were compared to patients without cirrhosis on ICD codes. Subgroups were created based on ICU-admission lactate levels (<2, 2-4, >4 mmol/L) and median 2-hour MAP (<60, 60-65, >60 mmHg), and in-hospital mortality and need for renal replacement therapy (RRT) was compared. The effect of median 24-hour MAP on in-hospital mortality was analyzed post-hoc. **Results**: We identified 595 patients with cirrhosis and 575 patients without cirrhosis admitted for treatment of septic shock. In those with cirrhosis, admission lactate 2-4 mmol/L was associated with increased in-hospital mortality compared with lactate <2 ($p=0.035$, OR 1.69). Admission lactate >4 mmol/L was associated with increased in-hospital mortality in both cirrhosis ($p<0.001$, OR 3.84) and non-cirrhosis groups ($p<0.001$, OR 2.23). Admission lactate >4 mmol/L was associated with increased need for RRT during hospitalization in both the cirrhosis ($p<0.001$, OR 3.46) and non-cirrhosis groups ($p<0.001$, OR 2.53). Median 2-hour MAP 60-65 mmHg was not associated with increased in-hospital mortality in either the cirrhosis ($p=0.55$) or non-cirrhosis subgroups ($p=0.29$). However, in the cirrhosis group median 24-hour MAP 60-65 mmHg was associated with increased hospital mortality compared to MAP >65 ($p<0.001$, OR 2.92). **Conclusion**: Patients with cirrhosis were found to have increased in-hospital mortality with initial ICU lactate >2 mmol/L, supporting the continued use of this as a cutoff for septic shock definition. Admission lactate >4 mmol/L was associated with increased RRT during hospitalization in both groups, and patients with cirrhosis and lactate >4 mmol/L may benefit from early renal evaluation and intervention. Although median 2-hour MAP 60-65 mmHg was not associated with increased hospital mortality in either group, median 24-hour MAP 60-65 mmHg was associated with increased hospital mortality for patients with cirrhosis and supports 65 mmHg as an optimal MAP target during resuscitation in this population.

3221-A | SURVIVAL AFTER ACUTE ON CHRONIC LIVER FAILURE: CHANGES WITH ERA AND IMPACT OF TRANSPLANTATION AND NON-TRANSPLANT INTERVENTIONS.

William Bernal, Mark John William McPhail, Francesca Maria Trovato, Eliza Montague-Johnstone, Georgina Kerry, Rajat Raja, Stacey Calvert, Pervez Khan, Sameer Patel, Tasneem Pirani, Robert Loveridge and Julia Wendon, King's College Hospital

Background: Acute on Chronic Liver Failure (ACLF) is a common complication of cirrhotic chronic liver disease (CLD) with high mortality but little is known of how survival has changed over time, and of the current relative impacts of medical interventions and liver transplantation (LT). We examined short- and longer-term survival of a large CLD patient cohort with unplanned admission to a LT centre specialist ICU over a 20-year period. **Methods:** Consecutive patients with CLD admitted 2000-2020 were studied, classified as Acute Decompensation (AD) or ACLF grades 1-3 according to EASL-CLIF criteria and by CLIF-SOFA Score. Era 1 of admission was 2000-06, Era 2 2007-12 and Era 3 2013-20. Data is reported as median (IQR) or n (%): analysis utilised Kaplan-Meier methods and logistic and Cox-regression. **Results:** 1828 patients (median age 52 (42-60) years, 61% male, 51% with alcohol-related CLD) were studied: 447 (24%) with AD, 319 (17%) with ACLF1, 407 (22%) ACLF2 and 655 (36%) ACLF3 on admission. Overall, 90-day and 1-year

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

survival rose from 29% and 23% in Era 1 to 49% and 39% in Era 3 ($p < 0.001$). Survival was lowest in ACLF3, but 1-year survival increased from 11% in Era 1 to 24% in Era 3 ($p < 0.007$). Overall, 232/1828 (12.7%) underwent LT at median 24 (8-130) days after ICU admission; the proportion increased from 41/422 (9.7%) in Era 1 to 134/719 (18.6%) in Era 3 ($p < 0.001$). In those transplanted 1-year survival was 90% compared to 26% in those who were not ($p < 0.001$): in ACLF3 93% vs. 11% ($p < 0.001$). Evaluating only patients managed without LT, on multivariate analysis adjusting for age, aetiology, indication for admission and illness severity, 1-year survival improved from from Era 1 to Era 2 (Odds Ratio 2.8 (95% CI 2.0-3.9)) and between Era 1 and Era 3 (3.2 (2.2-4.7), $P < 0.001$ for both), but not between Era 2 and 3 (1.15 (0.84-1.55) $p = 0.37$). **Conclusion:** Survival for critically ill patients with CLD has improved markedly over time, but that with medical care alone appears to have now plateaued. Survival with LT may be transformative but is utilised in only a minority of patients. However, without LT medium-term survival remains poor, particularly in those patients with ACLF3: patients surviving such an episode of ACLF should be assessed for LT. Novel medical therapies and/or improved access to LT are required to further improve survival.

3222-A | THE CHRONIC LIVER FAILURE CONSORTIUM (CLIF-C) ACLF SCORE AS A PREDICTOR OF OVERALL SURVIVAL AFTER LIVER TRANSPLANTATION IN PATIENTS WITH ACUTE-ON-CHRONIC LIVER FAILURE

Jorge Enrique Sinclair De Frías, Andrew Paul Keaveny, Trisha Singh, Ananya Vasudhar, Terri Menser, Colleen Ball, Philip Lowman, Devang K. Sanghavi, Kristopher P. Croome and Pablo Moreno-Franco, Mayo Clinic Florida, Ponte Vedra Beach, FL

Background: Acute-on-chronic liver failure (ACLF) in patients with decompensated chronic liver disease is associated with increased short-term mortality and liver transplantation (LT) is the only curative treatment. To facilitate more accurate prognostication in ACLF, the European Association for the Study of the Liver–Chronic Liver Failure (EASL-CLIF) consortium developed the CLIF-Consortium score for ACLF (CLIF-C score). This score is a validated prognostic tool for patients with ACLF. However, there are only limited data evaluating the CLIF-C in predicting survival after LT in patients with ACLF. **Methods:** We retrospectively studied all patients with cirrhosis and ACLF admitted to the intensive care unit (ICU) who underwent LT at our center between January 2010 and December 2021. Hazard ratios (HRs) and corresponding 95% confidence intervals were estimated from Cox proportional hazards regression, where patients were censored on the date of the last clinical follow-up. The concordance index (c-index) was estimated to evaluate the ability of CLIF-C to discriminate overall survival and survival free of retransplantation. Kaplan-Meier method was used to estimate cumulative survival probability post-LT according to CLIF-C categories. **Results:** Our cohort included 691 LT recipients; 61% were male (419/691), 84% white (577/691), the median age was 59 years (IQR 51-65, Range 18-75). The median time in ICU prior to LT was 2.7 days (1.2-10.5). The CLIF-C score was a median of 44.3 points (IQR 38.1-52.2) and 49.5 points (IQR 42.3-56.5) at time of admission to ICU and at LT, respectively. The median donor risk index was 1.4 (1.2-1.8). During a median clinical follow-up of 3.4 years (IQR 1.5-8.0 y), 189 patients died ($n = 155$). The probability of surviving 30 days and one-year post-LT was 97.4% (95% CI 96.2% to 98.6%) and 90.8% (95% CI 88.6% to 93.1%), respectively. Neither the CLIF-C score at time of LT or change in CLIF-C score from ICU admission to LT reliably predicted 30-day survival post-LT or 30-day survival free from transplant, with c-indices of 0.528 and 0.564, respectively (Table 1). **Conclusion:** The prognostic value of the CLIF-C score for predicting survival post-LT in our cohort of cirrhotic patients with ACLF in ICU was limited. Our data suggest an absolute CLIF-C score or change in CLIF-C should not be the sole determinant in deciding the futility of transplantation.

Table 1. 30-day transplant-free survival probabilities after liver transplant

	No. Patient	Deaths within 30 Days, n (%)	Retransplant within 30 Days, n (%)	30-day survival probability	30-day survival probability free from retransplant
CLIF-C Score at transplant				c-index=0.528	c-index=0.564
Less than 40.0	126	2 (2%)	12 (10%)	98.4% (96.3%-100%)	89.7% (84.5%-95.2%)
40.0 to 49.9	219	4 (2%)	5 (2%)	98.2% (96.4%-100%)	95.9% (93.3%-98.6%)
50.0 to 59.9	216	4 (2%)	1 (<1%)	98.1% (96.4%-100%)	97.7% (95.7%-99.7%)
60.0 to 69.9	100	4 (4%)	1 (1%)	96.0% (92.2%-99.9%)	95.0% (90.8%-99.4%)
70.0 or higher	17	1 (6%)	0	94.1% (83.6%-100%)	94.1% (83.6%-100%)
Change in CLIF-C Score from admission to transplant				c-index=0.555	c-index=0.484
Less than -2.0	132	0	3 (2%)	100% (100%-100%)	97.7% (95.2%-100%)
-2.0 to 1.9	131	1 (1%)	14 (11%)	99.2% (97.8%-100%)	89.3% (84.2%-94.8%)
2.0 to 5.9	123	4 (3%)	0	96.7% (93.7%-99.9%)	96.7% (93.7%-99.9%)
6.0 to 10.9	128	5 (4%)	1 (1%)	96.1% (92.8%-99.5%)	95.3% (91.7%-99.1%)
11.0 or higher	141	4 (3%)	1 (1%)	97.2% (94.5%-99.9%)	96.5% (93.5%-99.6%)

3223-A | THE EFFECTIVENESS OF PLASMA EXCHANGE IN IMPROVING SHORT-TERM SURVIVAL IN PATIENTS WITH ACUTE-ON-CHRONIC LIVER FAILURE

Hoang Huu Bui[1], Van Huy Vo[1], Sang The Phan[1], Phong Tien Quach[1], Duy Khanh Bui[1] and Hai Thi Thu Nguyen[2], (1)University Medical Center, Ho Chi Minh City, Vietnam, (2)Nguyen Trai Hospital, Ho Chi Minh City, Vietnam

Background: Acute-on-chronic liver failure (ACLF) is a clinical condition with a very high short-term mortality rate. Liver transplantation is the best available treatment for severe patients, increasing their chance of survival. Plasma exchange (PE) could be a viable and life-saving treatment option for ACLF patients in a country with limited liver donor resources. The purpose of this study is to determine the effect of PE on the short-term survival of ACLF patients. **Methods:** From January 2019 to July 2022, ACLF patients hospitalized to the University Medical Center in Ho Chi Minh City, Vietnam had a retrospective comparison of the treatment responses to PE and supportive medical care (SMC). Following enrollment in the Asian Pacific Association for the Study of the Liver (APASL), patients were diagnosed with ACLF. Analysis was done on the sequential liver biochemical tests, levels of consciousness, and survival rates. **Results:** 95 patients in total (72 patients in the SMC group and 23 patients in the PE group) met the inclusion criteria. The PE group had higher serum total bilirubin levels and lower white blood cell count at baseline than the SMC group; however, other variables were not significantly different. The cumulative survival rates at day 30 and day 90 in the PE group and SMC group were, respectively, 60.87% and 38.11% ($p = 0.036$), and 39.13% and 27.78% ($p = 0.303$). Overt hepatic encephalopathy, INR, lactate, ammonia, MELD, MELD-Na, AARC score, and PE were all related to the 30-day survival rate, but only PE was proven to be an independent factor for improving survival in multivariate analysis. Despite the fact that several factors were found to be associated with the survival rate at day 90, no single variable was identified as being significantly related. **Conclusion:** Regardless of the failure to improve the 90-day survival rate, the 30-day survival rate in the PE group was significantly higher than the SMC group, indicating that PE may be an effective treatment in prolonging patients' survival while waiting for a liver transplant.

3224-A | TRANSPLANT SURVIVAL BENEFIT OF ACUTE-ON-CHRONIC LIVER FAILURE WITH CIRCULATORY FAILURE IN HBV POPULATION

Jinjin Luo[1], Yu Wu[2], Changze Hong[3], Peng Li[1], Meiqian Hu[1], Jiaojiao Xin[1], Jing Jiang[1], Dongyan Shi[1], Jinjun Chen[3], Yu Chen[2] and Jun Li[1], (1)The First Affiliated Hospital, Zhejiang University School of Medicine, (2) Beijing Youan Hospital Capital Medical University, Beijing, China, (3)Nanfang Hospital, Southern Medical University

Background: Circulatory failure (CF) is a severe type of extrahepatic organ failure in acute-on-chronic liver failure (ACLF). This study aimed to identify the prognosis of hepatitis B virus-related ACLF (HBV-ACLF) patients with CF and their survival benefit from liver transplantation (LT). **Methods:** Hospitalized patients with HBV-ACLF between January 2015 and December 2022 were enrolled from the Chinese Group on the Study of Severe Hepatitis B open cohort. **Results:** Among 2247 HBV-ACLF patients, 59 patients were diagnosed with CF at admission, 2188 patients were diagnosed with non-CF (163 developed CF during hospitalization, 2025 did not develop). HBV-ACLF patients who developed CF (median time: 10 (5-19) days) had more serious disease severity and worse prognosis (90-day LT-free mortality: 97.9% vs. 37.5%, $p < 0.001$) than those without CF. Age, white blood cell counts and international normalized ratio were the independent risk factors of CF development. Among 222 patients with CF, the main types of CF were distributive and hypovolemic shock. The unmatched analysis (LT/n = 35; non-LT/n = 187) and propensity score matching analysis (LT/n = 35; non-LT/n = 28) showed the 360-day survival rate of HBV-ACLF patients with CF undergone LT was higher than those without LT (54.3% vs. 4.8%; 54.3% vs. 7.1%, both $p < 0.001$). The stratification analysis further showed CF patients with INR < 3.5 had higher survival benefit from LT than those with INR ≥ 3.5 (360-day post-LT survival: 68.0% [52.0-89.0] vs. 20.0% [5.8-69.1], $p < 0.001$; net survival benefit rate: 60.0% vs. 20.6%, $p < 0.001$). **Conclusion:**

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

HBV-ACLF patients with CF exhibited a very poor prognosis and LT could significantly improve their survival. Patients with INR < 3.5 derived a higher net survival benefit from LT.

3225-A | TRENDS IN ETIOLOGY OF ACUTE DECOMPENSATION AND ACUTE ON CHRONIC LIVER FAILURE: ANALYSIS FROM A TERTIARY CARE CENTER IN ASIA.

Dr Shalimar[1], Sagnik Biswas[1], Umang Arora[1], Shekhar Swaroop[1], Manas Vaishnav[1] and Subrat Kumar Acharya[2], (1)All India Institute of Medical Sciences, New Delhi, (2)Kiitniversity

Background: Acute on chronic liver failure (ACLF) burden is increasing and is associated with high mortality. Alcohol, hepatitis viruses, autoimmune liver disease are important causes of cirrhosis; active alcoholism, sepsis and viral etiologies are common precipitants of ACLF. Etiologies of cirrhosis and acute precipitants vary across countries. Published data suggest that outcomes in ACLF vary with etiology. **Methods:** This was a retrospective analysis from a tertiary care center in Asia. All consecutive patients admitted with acute decompensation (AD) and ACLF were included. For analysing changing trends in etiology, we divided patients into 3 groups according to the time-period of admission: 2011-2013, 2014-2017 and 2018-2021. We analysed the differences in etiologies between the three groups. **Results:** We included 1150 patients, median (IQR) 42 (34-50) years, 914 (79.5%) males; AD: ACLF 287 (25.0%): 863 (75.0%). Etiologies of cirrhosis were alcohol 637 (55.4%), viral 154 (13.4%), autoimmune 83 (7.2%), cryptogenic 182 (15.8%), non-alcoholic fatty liver disease (NAFLD) 52 (4.5%) and others 42 (3.7%). Proportions of ACLF grades 1, 2, 3 were 287 (25.0%), 167 (14.5%), 325 (28.3%) and 371 (32.3%), respectively. The median CTP score, MELD-Na were 13 (11-14), 31.5 (25.5-37.4), respectively. The number of patients with AD/ACLF who were admitted/year in the hospital over time-intervals (2011-2013, 2014-2017 and 2018-2021) showed an increasing trend: 40, 115 and, 135, respectively. Out of total number of patients, the proportions of ACLF cases were 88/135 (65.2%), 347/466 (74.5%) and 428/549 (78.0%), respectively (P = 0.008). The median CLIF-C ACLF score increased over time, 48 (41-55), 51 (44-57) and 52 (44-59), respectively. Mortality rates were 61.4%, 88.2% and 87.1%, respectively. There was an increase in the proportion of patients with alcohol-related ACLF over time (46.6%, 62.8% and 61.4%), whereas viral-related ACLF reduced over time (27.3%, 11.8% and 8.9%), respectively (P < 0.001) (Figure 1a). Similar trends were seen in patients with AD (Figure 1b). **Conclusion:** Alcohol-related ACLF is increasing over time, with more severe disease. Alcohol is now the most common cause of hospital admission for ACLF. Viral etiology-related ACLF admissions are reducing over time. These findings are alarming, and public health interventions are needed to mitigate the future burden of alcohol-related liver disease. Figure 1. Trends in etiology of cirrhosis in a) ACLF, b) AD.

3300-A | ACCURATE NON-CERULOPLASMIN COPPER AS A DIAGNOSTIC TEST FOR WILSON DISEASE IN ACUTE LIVER FAILURE

Thomas Damgaard Sandahl[1], Chris Harrington[2], Geoffrey Carpenter[2], Leisa Douglas[2], Jody A. Rule[3], William M. Lee[3], Ayse Coskun[4] and Michael L. Schilsky[5], (1)Aarhus University, (2)Supra Regional Assay Service, Trace Element Laboratory, (3)University of Texas Southwestern Medical Center, (4)Yale School of Medicine, New Haven, CT, (5)Yale University

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Diagnosing Wilson disease (WD) presenting as acute liver failure (ALF-WD) is challenging but important as there are disease specific therapies to try to stabilize the patient while awaiting emergency liver transplantation. Methods for early diagnosis in adults, the alkaline phosphatase (ALP) to total bilirubin and AST to ALT ratios at presentation are readily available and provide acceptable diagnostic accuracy (Korman et al Hepatology 2008), while low serum zinc seems informative in children (Sintusek et al J Pediatr Gastroenterol Nutr 2016). Recently, a new method, the A*ccurate Non-Ceruloplasmin Copper* (ANCC) was developed (Solovvev et al Anal Chim Acta 2020). The **Aim** of this study was to determine the diagnostic utility of ANCC in the setting of acute ALF-WD, and explore other factors that may aid diagnostic accuracy in this setting. **Methods:** Serum samples and data were collected at admission from adult patients prospectively enrolled in the U.S. ALF Study. ANCC was measured by strong anion exchange chromatography coupled to triple quadrupole inductively coupled plasma mass spectrometry. Receiver operating characteristic analysis was performed for candidate variables. Using logistic regression analysis, a simple combined score of ANCC and ALT was developed (ANCC-ALT score). **Results:** ALF study patients with WD (23), acetaminophen (11), autoimmune (10), drug induced liver injury (13), and other etiologies (15)) were included in the study. Serum copper (s-Cu) and ANCC measurements were strongly correlated ($r = 0.76$, $P < 0.001$) in patients with ALF. ANCC (> 484 μg/L) was superior in identifying ALF-WD (AUROC of 0.94, Table). High s-Cu (> 1369 μg/L) and low ALP (≤ 42 (U/L)) and ALT (≤ 81 (U/L)) provided relevant diagnostic information with AUROC´s > 0.87. Combining ANCC and ALT into one score improved diagnostic accuracy, AUROC 0.98, sensitivity 85% and specificity 100% using a cutoff of 1.92. Serum ceruloplasmin was not statistically significantly lower in WD-ALF compared to other ALF etiologies. Adding ALP:total bilirubin ratio or AST:ALT ratio or serum zinc to ANCC did not improve the diagnostic yield for ALF-WD **Conclusion:** In ALF-WD, most s-Cu is not bound to ceruloplasmin. Both s-Cu and ANCC, with use of appropriate cutoff values, are100% specific for diagnosing WD-ALF. Sensitivity for diagnosis of ALF-WD was further increased using ANCC-ALT while maintaining 100% specificity. In adults with ALF, low serum zinc was not diagnostic for ALF-WD.

Variable	WD-ALF n=23 Median (IQR)	Non-WD-ALF n=49 Median (IQR)	AUC	Cut-off value	Sensitivity	Specificity	*Correctly classified*	*LR+*	*LR−*
s-Copper μg/L	2260 (1975)	755 (344)	0.89	>= 1369 μg/L	73.90%	100.00%	91.70%	-	0.26
s-Ceruloplasmin mg/dl	17 (6.6)	18 (14)	0.6	<= 19 mg/dL	82.35%	48.00%	61.90%	1.58	0.37

(3)Liver Unit, Vall d´Hebron University Hospital, Vall d`Hebron Research Institute (VHIR), Barcelona, Spain, (4)Clinic for Pneumology, Vall d´Hebron Hospital, Barcelona, Spain, (5)Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark, (6)Department of Medicine, Gastroenterology and Hepatology Unit, Sahlgrenska University Hospital, Gothenburg, Sweden, (7)Department of Hepatogastroenterology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic, (8) Institute of Forensic and Traffic Medicine, Heidelberg University Hospital, Heidelberg, Germany, (9) Department of Internal Medicine I and Clinical Chemistry, Heidelberg University Hospital, Heidelberg, Germany, (10)University of Birmingham, Birmingham, United Kingdom, (11)University Hospital, Rwth Aachen

Background: Alpha-1 antitrypsin deficiency (AATD) arises from mutations in *SERPINA1* and predisposes to liver cirrhosis. However, the liver phenotype is variable and modifying factors are poorly understood. We studied the impact of alcohol consumption on liver-related parameters in individual's with the characteristic heterozygous/homozygous Pi*Z variant (Pi*MZ/Pi*ZZ genotype) found in the community-based United Kingdom Biobank (UKB) and the European Alpha1 liver consortium. **Methods:** Anamnestic data on alcohol consumption were evaluated in 17 145 Pi*MZ and 141 Pi*ZZ subjects as well as 425 002 non-carriers (Pi*MM) from the UKB. 561 Pi*ZZ individual's from the Alpha1 liver consortium were assessed including a measurement of carbohydrate deficient transferrin (CDT). Non-transgenic and Pi*Z mice were subjected to Lieber-DeCarli (LDC) diet. **Results:** > 80% of individual's reported no/low alcohol intake, while harmful consumption (women ≥ 40g/d, men ≥ 60g/d) was rare (~1% in most groups). In UKB participants with Pi*MM/Pi*MZ genotype, significant alcohol consumption (women 12-39 g/d, men 24-59 g/d) resulted only in a < 30% increase in transaminases above the upper limit of normal (ULN), while the effect on GGT was more pronounced (Pi*MM: 15.0% vs. 23.0%; Pi*MZ: 15.7% vs. 22.5%). In both genotypes, harmful alcohol intake led to an at least twofold increase in the proportion of Pi*MM/Pi*MZ subject with elevated transaminases, GGT serum levels, and elevated AST-to-platelet ratio (APRI). In Pi*ZZ individual's from both cohorts, moderate alcohol intake had no obvious impact on transaminase serum levels, although GGT levels were numerically more frequently elevated. In the European cohort, Pi*ZZ subjects with moderate alcohol consumption tended to have higher continuous attenuation parameters (CAP) suggestive of liver steatosis. 14% of Pi*ZZ individual's had elevated CDT serum levels (≥ 1.7%). In univariable analysis, they displayed higher GGT levels (72.5 vs. 60.0 % ULN, $p = 0.011$) and APRI scores (0.36 vs. 0.30 units, $p = 0.006$). Among Pi*ZZ individual's from the European cohort who reported no/low alcohol consumption, those with increased CDT levels more often had signs of advanced liver disease. LDC diet did not increase AAT accumulation in Pi*Z mice, while its impact on collagen mRNA was similar in both genotypes. **Conclusion:** Moderate alcohol consumption seems to be tolerated in the majority of Pi*MZ and Pi*ZZ subjects. CDT values might be helpful in those with advanced fibrosis.

3302-A | ALPHA-1 ANTITRYPSIN DEFICIENCY-ASSOCIATED LIVER DISEASE: A GLOBAL RETROSPECTIVE NATURAL HISTORY STUDY

Pavel Strnad[1], Jeffrey Teckman[2], Alice Turner[3], Jen-Chieh Chuang[4], May Hagiwara[4], Chitra Karki[4], Ed G. Marins[4], Kaili Ren[4], Anne E. Wyman[4], Angel Valladares[5], Monica P. Goldklang[6], Jeanine M. D'Armiento[6] and Virginia Clark[7], (1)University Hospital Rwth Aachen, Aachen, Germany, (2)Saint Louis University, St Louis, Missouri, US, (3)University of Birmingham, Birmingham, United Kingdom, (4)Takeda Development Center Americas, Inc., Cambridge, MA, USA, (5)Iqvia, New York, NY, USA, (6)Columbia University Irving Medical Center, New York, NY, (7) University of Florida, Gainesville, FL, USA

Background: Alpha-1 antitrypsin deficiency-associated liver disease (AATD-LD) is a rare genetic disease that is often initially asymptomatic and is underdiagnosed. The protease inhibitor (Pi) ZZ genotype confers the greatest risk of AATD-LD, and a liver transplant is the only way to resolve advanced disease. Owing to a lack of robust natural history data, our study aims to leverage real-world data using innovative methodology to examine the natural history of AATD-LD. **Methods:** This is a retrospective, longitudinal, multicenter, observational cohort study in adults with a confirmed diagnosis of AATD-LD and a documented Pi*MZ, Pi*SZ, or Pi*ZZ genotype. The study will leverage data from multiple registries and other data sources from the EU, UK, and US. An umbrella protocol approach will enable standardized definitions and methodology for data pooling and analyses, and customized protocols will enable the generation of standardized, aggregated outputs from each data source (Figure). Outcomes of interest include disease progression (advancement by $\geq$1 fibrosis stage, incidence of liver disease-related clinical events, or $\geq$3-point increase in Model for End-Stage Liver Disease score), all-cause mortality, and disease regression (decrease in $\geq$1 fibrosis stage). The study will also examine pulmonary function, diagnostic and monitoring patterns, health-related quality of life, and healthcare resource utilization. Analyses of outcomes by genotype and baseline fibrosis stage will also be conducted. All analyses will be summarized using descriptive statistics, except for time to disease progression which will be analyzed using Kaplan–Meier estimates. Meta-analysis of aggregated data will provide further insights into AATD-LD natural history. **Results:** The study began in Sept-2022, with finalization of the umbrella protocol and statistical analysis plan estimated by Sept-2023. Reporting of preliminary data from customized protocols is estimated in 2024 and the final meta-analysis in 2025. Additional registries and clinically rich data sources will be explored and added to the meta-analysis. **Conclusion:** Natural history studies of rare diseases using *de novo* registries are challenging. This study's umbrella protocol design and meta-analysis will leverage global patient registries and other data sources to generate comprehensive and robust insights into the natural history of AATD-LD and inform drug development, patient care, and disease monitoring. Writing assistance was provided by Matthew Reynolds of Oxford PharmaGenesis, Oxford, UK and funded by Takeda Development Center Americas, Inc.

f 3303-A | ALPHA-1 ANTITRYPSIN PIMZ, PISS AND PISZ PHENOTYPES ARE ASSOCIATED WITH INCREASED LIVER RELATED DEATH IN ALCOHOL-ASSOCIATED AND NAFLD CIRRHOSIS

Sunny Sandhu[1], Dustin R Bastaich[2], David E. Kaplan[3], Tamar H. Taddei[4], Bassam Dahman[2], Binu V John[5] and VOCAL group of investigators, (1)University of Miami - Jackson Memorial Hospital, Miami, FL, (2)Virginia Commonwealth University, (3)Division of Gastroenterology and Hepatology, Department of Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA, (4)Yale University, New Haven, CT, (5)University of Miami and Miami VA Health System, Miami, FL

Background: Cirrhosis related to alpha-1 antitrypsin deficiency (A1ATD) is rare, but likely under-diagnosed. Prior studies examining association of non-PiZZ phenotypes on liver disease outcomes, particularly cirrhosis, have been limited by sample size. We aimed to examine the association of non-PiZZ variants on outcomes of cirrhosis due to NAFLD and alcohol. **Methods:** This was a retrospective study of patients with cirrhosis from the Veterans Affairs Health System. Clinical and lab data on participants who underwent A1AT phenotype testing were identified, with A1AT phenotype extracted using natural language processing. A1AT was considered as a categorical variable-groups PiMM, PiMS, PiMZ, PiSS/SZ, and PiZZ. Participants with a diagnosis of NAFLD or alcohol-associated cirrhosis were included. Propensity score inverse probability of treatment weighting was performed to reduce confounding bias by creating a weighted sample that balanced the distribution of observed covariates between the various phenotypes. We excluded participants with decompensation at cirrhosis diagnosis for that outcome, but included them for outcomes of HCC and liver-related death (LRD). The associations between A1AT phenotype with decompensation, HCC, and LRD were modeled with Fine-Gray competing risks, with transplant and death as competing risks for decompensation/HCC, and transplant and non-LRD, competing risks for LRD. The multivariable models adjusted for age, race, sex, cirrhosis etiology, as well as time-varying BMI, platelet count, AUDIT-C and MELD. **Results:** Of 3189 participants with NAFLD/alcohol-associated cirrhosis who underwent A1ATD testing, the following phenotypes were identified: PiMM 2,628, PiMS 246, PiMZ 203, PiSS/SZ 61, and PiZZ 51 In participants with NAFLD cirrhosis, PiMZ phenotype was associated with an increase in LRD (subHazard Ratio [sHR] 4.77, 95% CI 3.50-6.50, $p < 0.001$), but not decompensation (sHR 1.15, 95% CI 0.99-1.33, $p = 0.06$) or HCC (sHR 0.83, 95% CI 0.59-1.15, $p = 0.25$), while PiSS/SZ phenotypes were associated with an increase in decompensation (sHR 1.57, 95% CI 1.35-1.81, $p < 0.001$), HCC (sHR 1.79, 95% CI 1.38-2.33, $p < 0.0001$), and LRD (sHR 8.14, 95% CI 6.02-11.01, $p < 0.0001$). In alcohol-associated cirrhosis, PiMZ phenotype was associated with an increase in decompensation (sHR 2.06, 95% CI 1.78-2.39, $p < 0.0001$), and LRD (sHR 1.65, 95% CI 1.22-2.24, $p = 0.001$), but not HCC (sHR 1.32, 95% CI 0.96-1.81, $p = 0.09$), while PiSS/SZ phenotypes were associated with an increase in LRD (sHR 4.81, 95% CI 3.62-6.39, $p < 0.0001$), but not decompensation (sHR 1.13, 95% CI 0.98-1.31, $p = 0.08$) or HCC (sHR not

evaluable due to low event rate). **Conclusion:** In this large study of Veterans with NAFLD and alcohol-associated cirrhosis, A1ATD PiMZ, SS and SZ phenotypes are associated with increased liver-related complications. Testing for A1ATD phenotype in patients with cirrhosis is warranted to recognize those at higher risk of complications.

f 3304-A | ALTERATIONS IN BILE ACID PHYSIOLOGY IN WILSON'S DISEASE

Clavia R. Wooton-Kee[1], Ahmed Elsayed[1], Islam Mohamed[1], Fuad Zain Aloor[1], Prasun Jalal[1], Kenneth David Reginald Setchell[2], Ayse Coskun[3], Monica Narvaez-Rivas[4], Nagireddy Putluri[1], Michael L. Schilsky[3] and David D. Moore[5], (1)Baylor College of Medicine, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Yale School of Medicine, New Haven, CT, (4)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (5)University of California, Berkeley

Background: Wilson's disease (WD) is an autosomal recessive disorder that results in hepatic copper (Cu^{++}) accumulation due to mutations in the Cu^{++}-transporting P-type ATPase (ATP7B) transporter. WD is characterized by steatosis, fibrosis, cirrhosis, and liver failure. The composition of TCA cycle, amino acid, and glycolytic metabolites are changed in WD patients and *Atp7b*$^{-/-}$ mice. Previous studies revealed dysregulation of many FXR metabolic target genes, including Bsep, the major determinant for bile flow. We tested the hypothesis that the FXR-cistrome is decreased in *Atp7b*$^{-/-}$ mice and coincides with dysregulated bile acid homeostasis. **Methods**: RNA and ChIP-Seq analysis of livers was performed in 6-month-old *Atp7b*$^{-/-}$ and wild-type mice and significantly changed genes and FXR-binding events were overlapped. Bile acids were measured

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(UPLC-MS/MS) in *Atp7b*$^{-/-}$, DKO$^{Atp7b:FXR}$, and wild-type mice, as well as healthy and WD males (WD-treatment positive) aged 26-65 (Baylor College of Medicine and Wilson's Disease Registry). **Results**: ECM-Receptor Interaction, Bile Secretion, and Tryptophan Metabolism were the most represented transcriptome pathways in *Atp7b*$^{-/-}$ vs. wild-type mice. Global hepatic FXR-binding events were reduced 22% in *Atp7b*$^{-/-}$ vs. wild-type mice ($p < 0.01$), supporting previous findings of reduced FXR activity in *Atp7b*$^{-/-}$ mice. FXR binding status revealed that positive FXR binding in upregulated genes mapped to the Focal Adhesion pathway and negative FXR binding in decreased genes mapped to the Metabolic pathway, which agrees with dysregulation of hepatic FXR activity and metabolic homeostasis. Tauro-cholic acid (T-CA), tauro-chenodeoxycholic acid (T-CDCA), and tauro-α/β-muricholic acid (T-MCA) bile acid concentrations were changed in *Atp7b*$^{-/-}$ mice: T-CA (13-fold increase, $P = 0.002$, serum; 1.6-fold, $P = 0.005$, liver); T-CDCA (10-fold, $p = 0.02$, serum); T-MCA (71-fold increase, $P = 0.006$, serum; 55% decrease, $P = 0.005$ liver). Expression of the bile acid-FXR regulated target genes Ostβ and Fgf15 was decreased in the small intestine of *Atp7b*$^{-/-}$ mice, which suggests impairment of bile flow. Changes in bile acid composition were exacerbated in *Atp7b:FXR* double knockout (DKO$^{Atp7b:FXR}$), indicating that *Atp7b*$^{-/-}$ mice retained partial FXR activity. Total bile acid measurement in serum of WD patients vs. healthy controls was not significantly changed (5-fold increase, $P = 0.2$). Comparison of bile acid profiles in WD patients with "liver", "neurological", or "mixed" disease vs. healthy controls revealed increased T-CDCA (39-fold increase, $P = 0.0002$) and glyco-CDCA (7.8-fold increase, $P < 0.0001$) in WD-liver vs. healthy controls. **Conclusion**: *Atp7b*$^{-/-}$ mice and WD patients exhibited changes in bile acid speciation, which is likely due to FXR dysfunction.These findings provide new insight into possible aberrant bile acid homeostasis in WD patients.

3305-A | ATP7B R778L MUTANT HEPATOCYTES RESIST COPPER TOXICITY BY ACTIVATING AUTOPHAGY AND INHIBITING NECROPTOSIS

Shan Tang[1], Chen Liang[1], Wei Hou[1], Zhongjie Hu[1], Xinyue Chen[1], Jing Zhao[1], Zhongping Duan[2], Li Bai[1,3] and Sujun Zheng[1], (1)Capital Mecical University Beijing Youan Hospital, (2)Beijing Youan Hospital Capital Medical University, Beijing, China, (3)Beijing Key Laboratory of Liver Failure and Artificial Liver Treatment Research, Beijing, China

Background: Wilson's disease (WD) is an inherited disease characterized by copper metabolism disorder caused by the mutations in adenosine triphosphatase copper transporting β gene (ATP7B). Currently, WD cell and animal model targeting the most common R778L mutation in Asia is lacking. In addition, the mechanisms by which hepatocytes resist copper toxicity remain to be further elucidated. In this study, we aimed to construct a novel WD cell model with R778L mutation, and dissected the molecular basics of copper resistance. **Methods:** A novel HepG2 cell line stably expressing ATP7B R778L gene (R778L cell) was constructed. The expression of necroptosis- and autophagy-related molecules was detected by PCR and Western blot (WB) in wild-type (WT) HepG2 and R778L cells with or without $CuSO_4$ treatment. In addition, we detected and compared the levels of autophagy and necroptosis in $CuSO_4$-treated R778L cells with the activation and inhibition of autophagy. Moreover, the mRNA and protein levels of autophagy and necroptosis signaling molecules were compared in R778L cells with the overexpression and knockdown of Unc-51 Like Autophagy Activating Kinase 1 (ULK1) and Autophagy Related 16 Like 1 (ATG16L1). **Results:** We constructed successfully a R778L mutation HepG2 cell line. $CuSO_4$ triggered the enhanced expression of autophagy and necroptosis signaling molecules in WT HepG2 cells and R778L cells. Remarkably, higher levels of autophagy and necroptosis were observed in R778L cells compared with those in WT cells. Autophagy activation led to weaken necroptosis mediated by RIPK3 and MLKL, conversely, autophagy inhibition brought about enhanced necroptosis. At the molecular level, ULK1- and ATG16L1-overexpression resulted in reduced necroptosis level, and vice versa. **Conclusion:** ULK1- and ATG16L1-mediated autophagy activation protects hepatocytes against RIPK3- and MLKL-mediated necroptosis in our new WD cell model treated with $CuSO_4$. Targeted

3306-A | BELCESIRAN WAS WELL-TOLERATED AND REDUCED SERUM AAT LEVELS IN HEALTHY VOLUNTEERS IN A PHASE 1 STUDY: FINAL RESULTS

Michael Soliman[1,2], Dhruv Patel[1], Anne-Sophie Sejling[1,2], Mohamed Tawfik[2], Miao Yu[1] and Folke Sjoberg[3], (1)Novo Nordisk, (2)Novo Nordisk a/S, (3)TC Clinical Trial Consultants AB, Linköping University

Background: Alpha-1 antitrypsin deficiency (A1ATD) is a rare disease that leads to alpha-1 antitrypsin protein (AAT) misfolding, which may cause liver disease. Belcesiran is a novel Dicer-substrate small interfering RNA oligonucleotide that is designed to silence the mutant SERPINA1 gene in individual's with A1ATD. Here, we report long-term, final results from a first-in-human, Phase 1 study of belcesiren. **Methods:** This was a single ascending dose study in healthy volunteers (HVs; NCT04174118) randomized 2:1 to a single subcutaneous injection of belcesiran (0.1, 1.0, 3.0, 6.0 or 12.0 mg/kg) or placebo and followed until Day 57/end-of-treatment (EOT). At EOT, if serum AAT had not returned to ≥80% of baseline, HVs entered an additional, conditional follow-up period until serum AAT returned to ≥80% baseline. Overtly healthy, non-smoking males or females aged 18–55 years with serum AAT > 100 mg/dL, forced expiratory volume in one second (FEV1)/forced vital capacity ≥0.7 and FEV1 ≥85% predicted were eligible. The primary endpoints were safety and tolerability. Change in AAT concentration was a secondary endpoint. Spirometry and diffusing capacity of the lungs for carbon monoxide (DLCO) were performed to monitor pulmonary function. **Results:** Overall, 30 HVs were enrolled. Mean age was 36.7 years, most were male (n = 27). Robust, dose-dependent reductions in serum AAT were observed with belcesiran (Figure). Mean reduction from baseline ranged from 48–78% with belcesiran 1.0–12.0 mg. An average serum AAT reduction of > 70% was sustained for at least 12 weeks in the 6.0 mg/kg and 12 mg/kg cohorts. All HVs who completed the study and the conditional follow-up returned to AAT levels ≥80% baseline. No serious adverse events (AEs) were reported. 40 treatment-emergent AEs (TEAEs) occurred in 21 HVs (37 events [Grade 1], 3 events [Grade 2], 0 [Grade ≥3]). Grade 2 events were nasopharyngitis in 1 HV in the 0.1 mg/kg cohort and gastroenteritis and staph skin infection in 1 HV in the 6 mg/kg cohort. The most common TEAEs were injection site reactions (5/20 [belcesiran], 0/10 [placebo]) and headache (4/20 [belcesiran], 2/10 [placebo]). Twelve HVs experienced TEAEs that were considered treatment-related in the belcesiran group, all were mild severity (Grade 1). No clinically significant abnormalities in lung function were reported. **Conclusion:** In this first-in-human Phase I study, belcesiran was well-tolerated with dose-dependent and reversible effects on serum AAT levels in HVs.

Figure. Mean (± SD) change from baseline in serum AAT concentrations

3307-A | BETTER UNDERSTANDING THE NATURAL HISTORY OF WILSON'S DISEASE THOUGH EXPLANT HISTOLOGY– PRELIMINARY ANALYSIS AND EXPERIENCE FROM A UK TERTIARY TRANSPLANT CENTRE

James Liu Yin, Deepak Joshi, Marianne Samyn, Varuna Aluvihare, Anil Dhawan, Rosa Miquel and Aftab Ala, King's College Hospital

Background: Wilson's disease (WD) is a life changing genetic metabolic condition that can present across many organ systems with devastating presentations e.g. acute liver failure, dysphasia and acute psychosis. Histological analysis of liver tissue is a key part of identifying WD and forms part of the diagnostic criteria of the internationally validated Leipzig scoring system. However, the significant variation and non-specific findings in histological appearance often proves a diagnostic challenge. King's College Hospital (KCH), London has the largest cohort of transplanted and non-transplanted adult and paediatric WD patients in the UK. Our aim is to perform a descriptive study of explant histology at KCH and correlate this with clinical presentation and disease progress. **Methods:** We reviewed explant histology of all patients transplanted for WD since 1990. Diagnosis of WD was made by a combination of genetics, clinical symptoms and biochemistry. We collected clinical data on these patients to confirm WD, exclude other liver conditions and to calculate the Leipzig score. All explants were independently assessed with an expert liver histopathologist to identify key histological features and correlate with clinical presentation. **Results:** We identified 65 explants from patients transplanted for WD (Figure 1). Preliminary findings showed a distinct histological pattern for acute, acute on chronic and chronic WD presentation and interestingly we found these findings did not fully correlate with their prior reported clinical presentation. Whilst commonly described features of WD such as female preponderance, steatosis, vacuolated nuclei and tissue copper staining were seen in most cases, there was significant variation on relative amount and distribution of lesions across the samples. Of particular note, was the unique combined micro-and-microvacuolar steatosis seen in discrete nodules, often in isolation. There was also a wide spectrum of distinct collapse/fibrosis seen across acute presentations, a key feature that requires further clarification. We identified marked variation in common histological findings between explants that we suspect is due to the multifactorial effects of age, treatment and other co-morbid factors potentially triggering decompensation. **Conclusion:** Histological examination of the explanted livers of patients with WD has confirmed the presence of previously described, non-specific, but characteristic microscopic lesions that we have compared with clinical presentation. Histological analysis correlated to clinical features could prove to be the key gateway to better understanding of the natural history, pathogenesis and characterisation of the unique presentations of WD requiring transplantation. Further international collaborative work is needed to achieve this goal which could expand to investigating response to treatment and disease progression at a cellular level.

f 3308-A | CHARACTERISTICS OF PATIENTS TREATED WITH GIVOSIRAN IN ELEVATE, A GLOBAL OBSERVATIONAL LONGITUDINAL REGISTRY OF PATIENTS WITH ACUTE HEPATIC PORPHYRIA

Bruce M. Wang[1], David Cassiman[2], Laurent Gouya[3], Eliane Sardh[4], Yanling Hu[5], Ana Camejo[5], Tom Brown[5] and Manisha Balwani[6], (1)University of California San Francisco Medical Center, (2)University Hospital Leuven, (3)Centre Français Des Porphyries, (4) Porphyria Centre Sweden, Centre for Inherited Metabolic Diseases, Karolinska Institutet, Karolinska University Hospital, (5)Alnylam Pharmaceuticals, (6) Icahn School of Medicine at Mount Sinai

Background: Acute hepatic porphyria (AHP) is a group of rare, chronic, multisystem disorders with acute attacks, progressive elements, and long-term complications. The ELEVATE registry (NCT04883905) is a global, prospective, observational real-world data collection study designed to investigate the natural history and management of patients with AHP and characterize the long-term safety and effectiveness of givosiran, an RNA interference therapeutic approved for the treatment of AHP in adults in the US and adults and adolescents age ≥12 years in the EU. This analysis

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

describes characteristics at enrollment of patients with AHP that have ever been treated with givosiran. **Methods:** Registry patients have a documented AHP diagnosis with biochemical and/or genetic testing, are managed as per standard of care, and no study-related procedures are recommended; medication is not provided. Data are collected at least once every 12 months via patient-reported outcome questionnaires, routine clinical encounters for AHP, or medical records. **Results:** A total of 84 patients that were ever treated with givosiran were enrolled (acute intermittent porphyria, N = 75; variegate porphyria, N = 6; hereditary coproporphyria, N = 2; type not reported, N = 1) as of March 2, 2023. Median (range) ages at AHP symptom onset, AHP diagnosis, and study consent were 29 (6–63), 30 (5–63), and 42 (14–71) years, respectively. The majority of patients are age ≥ 18 years (97.6% [82/84]), female (86.9% [73/84]), and white (77.4% [65/84]). Twenty-eight (33.3%) patients ever received medications other than givosiran for AHP; 25.0% had received hemin prophylaxis. Fourteen (16.7%) patients have history of chronic kidney disease and 10 (11.9%) had history of liver disease. The most common comorbid conditions at enrollment were anxiety (28.6% [24/84]), hypertension (27.4% [23/84]), and depression (20.2% [17/84]). The most frequently reported AHP symptoms upon ELEVATE enrollment were pain (47.6% [40/84]), nausea (31.0% [26/84]), fatigue (29.8% [25/84]), tingling, numbness, weakness or paralysis (26.2% [22/84]), and anxiety (23.8% [20/84]). **Conclusion:** These initial data from ELEVATE in patients with AHP ever treated with givosiran characterize comorbidities and symptoms in this population at enrollment. ELEVATE will enhance understanding of the natural history and management of patients with AHP, and the long-term safety and effectiveness of givosiran for AHP treatment.

3309-A | CLINICAL CHARACTERIZATION OF PATIENTS WITH WILSON'S DISEASE AT LEIPZIG UNIVERSITY MEDICAL CENTER

Magdalena Hahn[1], Johannes Wiegand[1], Madlen Matz-Soja[1], Maja Schirmer[1] and Thomas Berg[2], (1)Division of Hepatology, Department of Medicine II, Leipzig University Medical Center, Leipzig, Germany, (2) University Hospital of Leipzig

Background: Wilson's disease (WD) is rare and patients are referred to tertiary centers for treatment. We aimed to characterize the patient cohort at Leipzig University Medical Center regarding the use of the Leipzig Score for diagnosis, long-term outcome and especially the course of treatment in a real-world setting. **Methods:** All WD outpatients from Leipzig University Medical Centre, Division of Hepatology, from 2011-2020 were included. Data were anonymously and retrospectively collected from patients' records using the REDCap software. **Results:** A total of 34 patients were included, of which 20 were female. The majority (n = 13) presented with WD diagnosis, that was established earlier at different centers. In 50% data about establishment of diagnosis was lacking. In 4 cases WD was diagnosed at Leipzig

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

University Medical Center. Phenotype at establishment of Wilson's disease was mostly neurologic/psychiatric (n = 13), with (n = 5) and without concomitant liver disease (n = 2) and without investigation of liver disease (n = 6). 10 Patients presented with chronic liver disease and 5 patients with an acute liver failure. Diagnosed after family screening were 3 patients. One patient presented with Keyser-Fleischer corneal ring as single symptom. Liver biopsy was performed in 8 patients and molecular genetic analysis of ATPase7B gene mutations were evaluated in 8 patients. In none of the patients the Leipzig Score was performed as part of the initial diagnostic work-up. As initial treatment D-Penicillamin (DPA) was chosen in 25 patients, Trientine Dihydrochloride (TRI) in 5 patients, Zinc in two patients and combination of TRI and Zinc as well as DPA and Zinc in one patient respectively. No patient received Trientine Tretrahydrochloride as first medication. Half of the patients never changed medication in the course of disease (DPA n = 12, TRI n = 4, Zinc n = 1). Reasons for treatment modifications were side effects (28.2%), insufficient treatment response (25.6%), pregnancy (10.3%), insufficient adherence to treatment (5.1%) and others (36%). In the long-term follow-up, none of the patients suffered from acute or chronic liver failure, hepatocellular carcinoma, or required liver transplantation. At the end of follow-up liver cirrhosis was present in 19 patients and half of all patients had liver enzymes above upper limit of normal. A resolution of clinical symptoms was observed in less than half of all patients (n = 16). **Conclusion:** Albeit different available treatment options for WD, more than half of the patients developed liver cirrhosis and less than half of patients report resolution of clinical symptoms. Main reasons for changes in therapy are side-effects and insufficient therapy response, which highlight the importance of regular follow-up and screening for side-effects.

3310-A | COMPARISON OF NON-CERULOPLASMIN COPPER ASSESSED BY PROTEIN SPECIATION (NCC-SP) AND EXCHANGEABLE COPPER (NCC-EX) IN ADULTS WITH WILSON DISEASE ENROLLED IN A RANDOMIZED TRIAL OF CHELATION THERAPY (CHELATE; NCT 03539952).

Peter Ott[1], Thomas Damgaard Sandahl[1], Omar F Kamlin[2], Michael L. Schilsky[3] and On Behalf of the CHELATE Trial Investigators, (1)Aarhus University, (2) Orphalan, (3)Yale University

Background: Non-ceruloplasmin bound copper (NCC) is the bioavailable or "exchangeable" (Cu) fraction in blood. Current guidelines(1) recommend a treatment target of 50-150 μg/L in patients with Wilson disease (WD). The Chelate trial enrolled 53 clinically stable WD patients on maintenance D-penicillamine (DPA) (2). After a 12-week run-in period, patients were randomized to either continue DPA (N = 27) or mg-to-mg change to trientine tetrahydrochloride (TETA4;N = 26) for 24 weeks study period + 24 weeks extension. The sponsor (Orphalan, France) planned to use NCC-Ex(3) to guide treatment and as primary endpoint. That was rejected by FDA so a new method, NCC-Sp(4), was developed and batch analyzed for the primary endpoint. Aim: We aimed to examine the relationship between NCC-Sp and NCC-Ex and its development over time during chelator treatment. **Methods:** Samples were collected at 4 weekly intervals from the initial screening test until primary endpoint (week 24 post-randomization) with a final sample at the end of the extension period (week 48). Cu was determined by ICP-MS. NCC-Sp is the measured ceruloplasmin-Cu following speciation of serum proteins by anion-exchange HPLC subtracted from total serum Cu(4). NCC-Ex utilized chelation of the NCC fraction by adding ETDA to serum to effect removal of loosely bound copper to proteins by ultracentrifugation. NCC-Ex was assessed in the filtrate (3). **Results:** Of 541 paired determinations of NCC-Sp and NCC-Ex (325 on DPA, 216 on TETA4), 28% of NCC-Sp and 48% of NCC-Ex were < 50 μg/L. NCC-Sp and NCC-Ex were strongly correlated without treatment effects (Figure). As judged by linear regression, the NCC-Ex/NCC-Sp ratio depended on NCC-Sp level: NCC-Sp 25μg/L, ratio 1.2; 50 μg/L, 0.97; 75μ/L, 0.84; 100μg/L, 0.77; 200μg/L, 0.67. In patients exclusively exposed to DPA (DPA arm;N = 27), NCC-Sp and NCC-Ex differed over time (Fig. Panel C). NCC-Ex was less variable than NCC-Sp which was more dynamic despite only minor dose changes (N = 4), partly explained by the relation of NCC-Sp level vs NCC-Ex/NCC-Sp ratio. The same relation was observed in the TETA4 arm (not shown). **Conclusion:** Values below 50μg/L in 28% to 48% suggest the need for revised and methodology specific target ranges for NCC-Sp and NCC-Ex. Though NCC-Sp and NCC-Ex strongly correlated, NCC-EX/NCC-Sp ratio was not constant. The deviation between these two methodologies to measure NCC challenges the interpretation of the dynamic change in NCC during the monitoring of treatment. Better understanding of these differences may help optimize treatment monitoring.

3311-A | CORRELATION BETWEEN AGE AND PROGRESSION OF LIVER DISEASE IN PATIENTS WITH LYSOSOMAL ACID LIPASE DEFICIENCY (LAL-D): DATA FROM THE INTERNATIONAL LAL-D REGISTRY

William F. Balistreri[1], Jennifer Evans[2], Florian Abel[2] and Lorenzo D'Antiga[3], (1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Alexion, Astrazeneca Rare Disease, (3)Azienda Ospedaliera Papa Giovanni XXIII

Background: Lysosomal acid lipase deficiency (LAL-D) is a rare, hereditary, lysosomal storage disease that may present at any age and can be associated with progressive chronic liver disease, liver fibrosis, and eventually cirrhosis. We analyzed data from the International LAL-D Registry to determine biopsy-assessed liver fibrosis severity and the use of the aspartate aminotransferase (AST) to platelet ratio index (APRI) as a noninvasive indicator of fibrosis severity. **Methods:** This was a retrospective observational study of treatment-naive children and adults with confirmed LAL-D identified from the LAL-D Registry (NCT01633489) through Apr 3, 2023. Patients with rapidly progressive (infantile) LAL-D were excluded. The age x fibrosis analysis utilized the first available Ishak-staged biopsy (or pathology score if Ishak stage was unavailable) for each patient and age at time of biopsy. The APRI x fibrosis analysis utilized the first available staged biopsy for patients with a corresponding APRI, which was based on AST and platelet levels obtained on the same day, and within 12 months prior to or one month post biopsy. Pre-treatment biopsies performed as part of the clinical program for sebelipase alfa were included. **Results:** Of 239 patients with available data, 77 had ≥ 1 staged liver biopsy (male, 60%; white, 90%); age: <12 y, $n=36$; $\geq 12-<18$ y, $n=15$; ≥ 18 y, $n=26$). Patients aged <12 y tended to have a higher fibrosis stage than patients ≥ 12 y (ordinal regression using trichotomized fibrosis categories [stage 0−1, 2−4, and 5−6] odds ratio 2.71 [95% CI, 1.05−7.00]; $P=0.039$). Median age tended to be lower with increasing fibrosis stage (Figure); however, analysis of variance showed no statistically significant

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

difference in average age among trichotomized fibrosis scores ($P = 0.2732$). Among 43 patients with biopsy fibrosis stage and corresponding APRI (male, 56%; white, 88%), median (Q1, Q3) APRI did not differ by fibrosis stage: stage 0 (0.40 [0.40, 0.40]; n = 1), stage 1 (0.88 [0.45, 1.06]; n = 9), stage 2 (0.55 [0.42, 0.82]; n = 9), stage 3 (0.47 [0.44, 0.71]; n = 13), stage 4 (0.42 [0.25, 1.06]; n = 4), stage 5 (0.42 [0.30, 0.55]; n = 2), stage 6 (0.73 [0.55, 1.50]; n = 5). Only two (40%) of five patients with stage 6 fibrosis had APRI ≥ 1.5, suggesting that APRI is a poor indicator of disease severity in patients with LAL-D. **Conclusion:** Results from the LAL-D Registry indicate that the degree of liver injury in LAL-D is variable, with advanced fibrosis observed across a broad age range. More severe liver injury was noted in patients presenting at younger age, possibly due to a more severe clinical phenotype as the indication for biopsy. APRI is a poor indicator of LAL-D severity. Future efforts to identify noninvasive parameters predictive of fibrosis in patients with LAL-D would be valuable for the management of this rare disease. Investigations for the diagnosis of LAL-D should be considered at any age, regardless of the degree of liver disease progression.

3312-A | DESIGN OF THE FIRST PHASE 3 STUDY (REDWOOD) EVALUATING FAZIRSIRAN IN ADULTS WITH ALPHA-1 ANTITRYPSIN DEFICIENCY-ASSOCIATED LIVER DISEASE

Susana Gonzalez[1], Anne E. Wyman[1], Pavel Strnad[2], Virginia Clark[3], Rohit Loomba[4], Charlie Strange[5], Jeffrey Teckman[6], Michael Hoy[1], Paresh Thakker[1], Lisi Wang[1], Ed G. Marins[1] and Nirav K. Desai[1], (1)Takeda Development Center Americas, Inc., Cambridge, MA, USA, (2)University Hospital Rwth Aachen, Aachen, Germany, (3)University of Florida, Gainesville, FL, USA, (4)University of California, San Diego, San Diego, CA, (5)Medical University of South Carolina, Charleston, SC, USA, (6)Saint Louis University, St. Louis, MO, USA

Background: Alpha-1 antitrypsin deficiency-associated liver disease (AATD-LD) is a rare genetic disease characterized by accumulation of misfolded AAT in hepatocytes resulting in low levels of circulating AAT. Patients with AATD and a homozygous "Z" mutation of the *SERPINA1* gene (Pi*ZZ) have an increased risk of liver disease (LD) progression, but have no approved pharmacologic treatment options. Fazirsiran is a small RNA interference (RNAi) therapeutic designed to reduce the production of AAT thereby preventing toxic accumulation of Z-AAT in the liver. In two phase 2 studies (NCT03946449, NCT03945292) in patients with AATD-LD and a Pi*ZZ genotype (AATD-LD-Pi*ZZ), fazirsiran reduced intrahepatic Z-AAT, improved biomarkers of liver injury and fibrosis, led to fibrosis regression and was well tolerated. The phase 3 Redwood trial was designed as a registrational study to further evaluate the efficacy and safety of fazirsiran in ~160 adults with AATD-LD-Pi*ZZ. **Methods:** Redwood is an ongoing multicenter, randomized, double-blind, placebo-controlled study (NCT05677971) that will enroll adults (18–75 y) with AATD-LD-Pi*ZZ. Patients will receive subcutaneous fazirsiran 200 mg or placebo on Day 1, Week 4 and then every 12 weeks until Week 196 (Figure). Eligible patients require a diagnosis of AATD with a Pi*ZZ genotype, METAVIR fibrosis stage F2, F3 or F4 at baseline, and must be non-smokers with lung function meeting protocol requirements. Exclusion criteria include a history of decompensated cirrhosis and evidence of other chronic liver diseases. The

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

primary endpoint is a decrease from baseline of at least one METAVIR fibrosis stage in the centrally read liver biopsy at Week 106 in patients with initial F2 or F3 fibrosis. Key secondary endpoints (at Week 202) include a decrease of at least one METAVIR fibrosis stage in patients with initial F2, F3 or F4 fibrosis and disease progression as defined by a number of liver-related clinical events. Safety (including lung function) will be monitored over the duration of the study, with an interim safety assessment at Week 52 (Figure). **Results:** Patient recruitment began March 2023 and is ongoing. **Conclusion:** AATD-LD is a rare disease with no approved treatment options. Redwood is the largest, prospective, placebo-controlled, registrational study to evaluate the first RNAi therapeutic, fazirsiran, as a potential treatment for patients with AATD-LD-Pi*ZZ.

3313-A | DIFFERENCES IN SYMPTOM SEVERITY AND RADIOLOGICAL PHENOTYPE BETWEEN PATIENTS WITH ISOLATED POLYCYSTIC LIVER DISEASE VERSUS COMBINED POLYCYSTIC KIDNEY AND LIVER DISEASE

Avisnata Das, Benjamin Giles, Aqeel Jamil, Joanna Dowman, Andrew Fowell and Richard James Aspinall, Portsmouth Hospitals University NHS Trust

Background: Polycystic Liver Disease (PLD) is a rare genetic condition, which can occur in isolation or as combined Polycystic Kidney and Liver Disease (PKLD). The Polycystic Liver Disease-specific Questionnaire (PLD-Q) and PLD-Q score are useful in assessing disease, with higher scores correlating with impaired quality of life. We wished to compare variations in PLD-Q scores, age of diagnosis of liver cysts, number and size of liver cysts between isolated PLD and combined PKLD patient groups. **Methods:** Patients were identified from a prospective departmental database in a large acute hospital. We evaluated PLD-Q scores in a fully phenotyped group of 10 patients with isolated PLD and 18 patients with combined PKLD where each of these patients had > 10 liver cysts. We also evaluated age of diagnosis of PLD, Qian's grade (based on number of liver cysts) and presence of one or more dominant liver cyst(s) (> 8 cm in size) in the two groups, with 11 patients in PLD arm and 29 patients in PLKD arm. **Results:** PLD-Q scores ranged from 17 to 83 with a mean of 44 and median of 45 in the isolated PLD group. In the PKLD group, the score varied from 3 to 61 with a higher mean of 53.3 and median of 57.6. Using independent sample *t*-test, the difference in the distributed means of scores between the two groups was at the margin of statistical significance ($p = 0.068$, 95% CI). The age of PLD diagnosis had a mean of 49.5 years, median of 52 years and varied from 23 to 70 in the PLD-only group while the mean, median and range were 53.3, 57.6 and 41 (32-73) respectively in the PKLD group. No statistically significant difference existed between the two means ($p = 0.234$, 95% CI). On abdominal imaging, in the isolated PLD group, 4 out of 11 (36%) had grade 2 liver cysts (11-20 cysts), 4 (36%) had grade 3 cysts (> 20) and 3 (28%) had Grade 4 cysts (> 20 cysts with symptomatic hepatomegaly). In the PKLD group of 29 patients, the number and percentages of Grade 2, Grade 3 and Grade 4 cysts were 3 (10.3%), 18 (62.1%) and 8 (27.6%) respectively. One or more dominant cysts were present in 3 (28%) patients with isolated PLD, and 9 (31%) patients with PKLD. **Conclusion:** The proportion of patients with > 20 liver cysts and the prevalence of dominant cysts were comparable between the PLD and PKLD groups. However, the PKLD group had higher mean and median PLD-Q scores compared to the isolated PLD group and the mean age of diagnosis of liver cysts was higher for the PKLD group. Patients with PKLD have a greater symptomatic burden than those with isolated PLD and delays in presentation or diagnosis may contribute to higher PLD-Q scores. We are exploring this relationship further using a national registry dataset.

3314-A | DOES HETEROZYGOUS ALPHA-1-ANTITRYPSIN PI*MZ GENOTYPE INFLUENCE THE DEVELOPMENT OF HEPATIC EVENTS IN PATIENTS WITH LEAN NAFLD?

Sameer Prakash[1] and Arvind R. Murali[1,2], (1)University of Iowa Hospitals and Clinics, (2)Orlando Health

Background: Alpha-1antitrypsin (A1AT) Pi*MZ has been shown to increase the risk of liver related outcomes

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

in patients with obesity and nonalcoholic fatty liver disease (NAFLD). More recently, patients with lean-NAFLD were shown to have worse liver related outcomes as compared to non-lean NAFLD. We aimed to study the interaction between A1AT Pi*MZ and lean-NAFLD in the development of liver related outcomes. **Methods:** Patients with NAFLD who also had A1AT genotyping performed from 2005-2020 were identified based on the ICD-10 codes. Clinical and demographic data were collected. We performed logistic regression analysis to determine the association between A1AT genotype and lean and non-lean NAFLD for the development of hepatic events. **Results:** A total of 2023 NAFLD patients, with 1796 Pi*MM and 226 Pi*MZ were included. Mean age was 56 (7.8) and 57% were males. Lean-NAFLD was seen in 337 (17%) patients, while 1685 (83%) patients had non-lean NAFLD. Among all NAFLD patients, A1AT MZ was associated with a significant increased risk of development of hepatic events, OR 1.2 (1.01-1.3, p = 0.03). Among patients with non-lean NAFLD, A1AT Pi*MZ significantly increased risk of hepatic events, OR 1.2 (1.03-1.40, p = 0.01), with the highest Odds noted among patients with BMI > 40, OR 1.5 (1.1-2.1, p = 0.01). However among patients with lean NAFLD, A1AT Pi*MZ was not significantly associated with an increased risk of hepatic events (OR 1.1, 0.75-1.6, p = 0.59). **Conclusion:** While A1AT PI*MZ variant significantly increases the risk of liver related events in patients with non-lean NAFLD, it interestingly, did not seem to significantly increase the risk of developing hepatic events in patients with lean-NAFLD. Further larger studies are needed to confirm our findings and understand the complex interaction between A1AT Pi*MZ variant and lean-NAFLD.

Lean vs Non-Lean NASH	Odds ratio	95% Confidence Interval		P value
All patients (n=2023)	1.2	1.01	1.30	0.03
BMI < 24.5 (n=337)	1.1	0.75	1.6	0.59
BMI >24.5 (n=1659)	1.2	1.03	1.4	0.01
BMI > 35 (n=639)	1.3	1.02	1.5	0.03
BMI > 40 (n=320)	1.5	1.1	2.2	0.01

3315-A | EXPLORATION OF THE HEPATIC LIPIDOMIC PROFILE IN TWO MOUSE MODELS OF WILSON DISEASE.

Tagreed Mazi[1], Noreene M Shibata[2], Gaurav Vilas Sarode[2] and Valentina Medici[2], (1)King Saud University, (2)University of California Davis, Sacramento, CA

Background: Wilson disease (WD) is characterized by hepatic manifestations, including hepatocellular steatosis, inflammation, cirrhosis, and hepatic failure. WD is also associated with dysregulated lipid metabolism. Up to date, the underpinnings of hepatocellular inflammation and necrosis are not understood, especially in early stages of WD. It is thought that copper, by inducing the formation of reactive oxygen species (ROS), upregulates oxidative stress and the non-enzymatic oxidation of membrane-bound polyunsaturated fatty acids (PUFA), which consequently impair cellular structures and function. Products of PUFA oxidation are collectively known as oxylipins (OXL), which can also be produced via enzymatic pathways including lipoxygenases (LOXs), cyclooxygenases (COXs), cytochrome P450 monooxygenases (CYPs). These bioactive lipids modulate inflammation and are associated with hepatic inflammation. The goal of this study was to examine hepatic OXLs profile at early stages of WD in two established mouse models, the toxic milk mouse from The Jackson Laboratory (tx-j) and the *Atp7b* knockout mouse (*Atp7b*$^{-/-}$), compared to respective control mice with normal copper metabolism. **Methods:** Targeted lipidomic profiling of OXLs was performed by ultra-high-performance liquid chromatography-electrospray ionization-tandem mass spectrometry (UPLC-ESI-MS/MS) in livers from 19-20 weeks old male and female mice. **Results:** Compared to corresponding controls, both genotypes showed signs of hepatocellular inflammation on histological examination. There were altered hepatic OXL profiles, including higher levels of PUFA alcohols, diols, and ketones. The markers of oxidative stress, 9-HETE and 9-HEPE were higher in both genotypes, however, significant in tx-j mice. Some OXLs correlated positively with 9-HETE ($r > 0.4$-0.7, $p = < 0.05$, FDR-adjusted $p = < 0.2$). These findings indicate that early stages of WD are associated with upregulation of oxidative stress, non-enzymatic oxidative pathways, and LOX pathways. Prostaglandin and thromboxane levels were found higher in both mouse models, indicating upregulation of COX pathway. Both genotypes showed altered PUFA-epoxides, more marked in tx-j mice, suggesting altered CYP(s) activities. **Conclusion:** Our findings suggest that both non-enzymatic ROS-dependent and enzymatic PUFAs oxidation via COX and LOX pathways are associated with early stages of liver disease in WD. They also indicate altered CYPs activities in both animal models of WD. Our data highlight genotype-related variations, suggesting that in *Atp7b*$^{-/-}$ model there are likely compensatory protective mechanisms in response to copper toxicity and reacting to the inflammatory response.

3316-A | HEPATIC BIOPRINTED TISSUE THERAPEUTICS (BTTS) AS A CELL THERAPY FOR MONOGENIC LIVER DISEASES INCLUDING PKU AND A1AT DEFICIENCY

Zainab A Bazzi, Stephanie A Campbell, Oksana Nemirovsky, Farin Vaez Livary, Fiona Li, Haley Tong, Rishima Agarwal, Matthew R Zeglinski, Lyndsey Hayes, Jaedyn D Foley, Paola Romero, Mahinur Efe, Reza Jalili, Simon Beyer, Tamer Mohamed, Samuel Wadsworth, Spiro Getsios, Rafal P Witek and Christopher Dickman, Aspect Biosystems

Background: Alpha-1 antitrypsin (A1AT) deficiency is caused by mutations in the *SERPINA1* gene, leading to significantly lower levels of blood A1AT. The absence of A1AT can result in destruction of the lung parenchyma resulting in emphysema. Phenylketonuria (PKU) is caused by mutations in the *PAH* gene, resulting in the inability of hepatocytes to convert phenylalanine to tyrosine. Therefore, individual's with PKU have elevated levels of plasma phenylalanine, and if left untreated, results in significant neurological disability. For both A1AT deficiency and PKU, the most efficacious treatment is liver transplantation; however, this option is problematic due to invasiveness, need for long-term immune suppression, and limited supply of donor livers. Herein, using proprietary microfluidic 3D bioprinting technology, we demonstrate the ability of our hepatic Bioprinted Tissue Therapeutics (BTTs) to replace the function of aberrant liver enzymes in PKU and A1AT deficiency. **Methods:** Primary human hepatocyte (PHH) spheroids were generated in the presence and absence of mesenchymal stem cells (MSCs). Aspect Biosystems' proprietary microfluidic 3D bioprinting technology was utilized to generate BTTs using hepatocyte-containing spheroids and alginate-based biomaterials. BTTs were challenged with disease-relevant levels of phenylalanine and implanted in immune-deficient mice to assess release of A1AT. Additionally, BTTs were assessed for cytochrome P450 activity, albumin secretion, viability, and gene expression. **Results:** Gene expression analysis demonstrated that BTTs express *PAH* and *SERPINA1*, indicating their potential ability to restore PAH and A1AT activity, respectively. Additionally, when challenged with disease-relevant levels of phenylalanine, BTTs with and without MSCs were able to metabolize > 500 nmol phenylalanine/million PHHs/day. Furthermore, BTTs demonstrate secretory and additional metabolic functions, including albumin secretion (> 10 μg/million cells/day) and CYP3A4 activity over a period of 7 days. When implanted into NSG mice, BTTs containing 1 million hepatocytes, produced human A1AT with levels peaking after 8 days at 2440 ng/mL. **Conclusion:** Hepatic BTTs have been shown to possess PAH activity *in vitro* and A1AT release *in vivo*. This demonstrates that BTTs have viable therapeutic potential for the treatment of PKU and A1AT deficiency. Further studies are warranted to assess the efficacy of BTTs on PKU and A1AT deficiency in small animal models.

3317-A | HETEROZYGOSITY AND SERUM LEVELS FOR ALPHA-1 ANTITRYPSIN AS PREDICTORS OF WAITLIST MORTALITY IN LIVER TRANSPLANT CANDIDATES

Vinh Vincent Tran[1], Anjiya Shaikh[2], Christo Mathew[1], Ankur Patel[1], Kadon Caskey[1], Ronald Samuel[1], Abbas Rana[1], John A. Goss[1], N. Thao N. Galván[3], John M. Vierling[1], Avegail Flores[1], Rise Stribling[1], Gagan K. Sood[3], Fasiha Kanwal[4], Hashem B. El-Serag[1], Tzu-Hao (Howard) Lee[1] and George Cholankeril[1], (1)Baylor College of Medicine, (2)University of Connecticut, (3) Baylor College of Medicine, Houston, TX, (4)Michael E. Debakey VA Medical Center

Background: Heterozygosity for alpha-1-antitrypsin (A1AT) deficiency may increase risk for hepatic decompensation but the effect on outcomes in liver transplant (LT) candidates with advanced liver disease has yet to be examined. Our aim was to evaluate A1AT heterozygosity as a risk factor for waitlist mortality, and the potential predictive value of low serum A1AT levels in those with normal phenotype. **Methods:** We performed a retrospective cohort study in adult patients listed for LT from January 2017 to August 2018 with follow up to April 2023. As part of our transplant evaluation protocol, serum A1AT levels and phenotype testing were collected. MZ, MS, FM, and ZS phenotypes were considered heterozygotes. Sociodemographic and clinical characteristics were collected at time of waitlisting. A1AT heterozygote phenotypes and serum A1AT levels in patients with normal phenotypes were evaluated separately as predictors for waitlist dropout, defined as removal due to death or deterioration. Fine and Gray analyses were performed to assess risk of waitlist dropout, accounting for competing risks of undergoing LT, and delisting for clinical improvement. **Results:** 300 patients were waitlisted for LT, of which 15.3% (n = 46) had heterozygous A1AT phenotypes for MZ, MS, MF, or ZS, and 6.0% (n = 18) were heterozygotes for MZ phenotype. Serum A1AT cutoff < 120 captured 94.4% of MZ heterozygotes and 60.9% of all A1AT heterozygotes. In the competing risk analyses, MZ (sHR, 3.46, 95% CI, 1.68 – 7.12) was associated with a higher risk for waitlist dropout than all other patients on the waitlist, with similar findings seen for all A1AT

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

heterozygotes (sHR, 2.45 95% CI, 1.38 – 4.37). In those with normal A1AT phenotypes, a decrease in serum A1AT levels (sHR, 0.99, 95% CI, 0.98 – 0.99) was associated with an increased risk for waitlist dropout. After adjusting for etiology, hepatocellular carcinoma, age, and MELD score, serum A1AT values < 120 (sHR, 2.79, 95% CI, 1.44-5.39) and < 100 (sHR, 6.38 95% CI, 2.24 – 18.10) were associated with a nearly three-fold and six-fold increased risk for waitlist dropout, respectively. **Conclusion:** Heterozygotes for A1AT with advanced liver disease are at higher risk for morality on the waitlist. A1AT heterozygosity and low serum A1AT levels in phenotypically normal patients may have prognostic value in assessing disease progression and warrant closer surveillance for waitlist management.

Table 1. Demographics, Decompensation, and LT Waitlist History Between Heterozygotes, Normal Phenotypes with A1AT <120 and Normal Phenotypes with A1AT >150

	Heterozygote (n= 46)	Normal phenotype A1AT < 120 (n = 31, 10.4%)	Normal phenotype A1AT > 150 (n = 156)
Age, mean (SD)	56.0 (9.6) 57.3 [48.6 – 62.6]	54.8 (11.2) 56.2 [48.4 – 63.5]	55.5 (11.8) 58.8 [49.6 – 64.2]

f 3318-A | HIGH PREVALENCE OF CIRRHOSIS AMONG HEREDITARY HEMOCHROMATOSIS INDIVIDUALS IN A LARGE POPULATION-BASED COHORT

Christopher Danford[1], Richard Gilroy[2], Nephi Walton[2], Michelle Lai[3] and Xuehong Zhang[4], (1)Intermountain Health, Millcreek, UT, (2)Intermountain Health, (3) Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (4)Brigham and Women's Hospital, Harvard Medical School

Background: Homozygosity for the C282Y mutation of the *HFE* gene is one of the most common genetic disorders in those of northern European descent affecting ~0.4% of the US population.[1] Lifetime cumulative incidence of cirrhosis in hereditary hemochromatosis (HH) is unknown, but has been previously reported to be low (0-2.5%) in unselected, population-based cohorts.[2] Cirrhosis due to HH is avoidable if identified and treated early, however, population-based screening is not currently recommended given our poor understanding of which patients are at highest risk and would benefit from treatment. Our aim was to evaluate the prevalence of cirrhosis in C282Y homozygous patients identified in HerediGene, an unselected population-based cohort through Intermountain Health. **Methods:** All adults (age > 18 y) who had blood drawn at an Intermountain lab were invited to participate in HerediGene starting in 2020. Subjects enrolled underwent genotyping and are linked to the Intermountain electronic medical record. Those who had genotyping data available between inception and December 2022 and were identified to be homozygous for the *HFE* C282Y mutation were included in the study. Cirrhosis was identified by either ICD-10 code or FIB-4 calculation with subsequent confirmation on manual chart review. Comorbidities were identified by ICD-10 code. **Results:** Among the first 106,828 patients enrolled in HerediGene, 486 (0.45%) were homozygous for the *HFE* C282Y variant with a mean ferritin of 469 ng/mL. Seventeen (3.5%) had cirrhosis by ICD code by a mean age of 58. When non-invasive screening for cirrhosis (FIB-4) was applied, an additional 14 patients with potential cirrhosis were identified, twelve of which were confirmed on manual chart review (n = 29, 6%). Only 78 (16%) of patients were previously aware of their diagnosis of HH (Table 1). There was no evidence that the 12 patients without an ICD code for cirrhosis identified by FIB-4 were aware of their diagnosis. **Conclusion:** Our data support that prevalence of cirrhosis among C282Y homozygotes is higher than previously reported and at a relatively young age. Prior reports are limited by small population size and inadequate phenotyping for the identification of cirrhosis. Cirrhosis from hemochromatosis is preventable. This data from an unselected, population-based cohort highlights the need for improved understanding of risk factors associated with the development of cirrhosis in HH to better inform population-wide screening.

Table 1. Demographic, laboratory findings, and associated diagnoses among C282Y homozygotes identified in HerediGene (n = 486). Mean and standard deviation reported.

Age (years)	58.6 ± 18.4
Sex (% male)	37.5
Ferritin (ng/mL)	469.5 ± 1366.9
Platelet count (K/μL)	240 ± 69.8
Iron overload (%; ferritin > 200 ng/mL in women or > 300 ng/mL in men)	55.9 (men), 32.2 (women)
ALT (unit/L)	38.8 ± 72.7
ALT > 40 unit/L (%)	25
Known hereditary hemochromatosis (%)	16
Cirrhosis by ICD code (%)	3.5
Cirrhosis by FIB-4 (%)	6
Alcohol use disorder (%)	0.95
Atrial fibrillation (%)	9.1
Non-ischemic cardiomyopathy (%)	3.8
Type 2 Diabetes (%)	16.2
Osteoarthritis (%)	27.2
Fatigue (%)	21.5
Hypogonadism (%)	4.3

3319-A | HOST PRECONDITIONING AND TRANSIENT MITOGEN EXPRESSION VIA mRNA-LNP LEAD TO ROBUST PRIMARY HUMAN HEPATOCYTE ENGRAFTMENT AND TRANSIENT iPSC-DERIVED HEPATOCYTE SURVIVAL IN A MURINE MODEL OF AATD LIVER DISEASE

Anna R Smith[1], Fatima Rizvi[1], Elissa Everton[1], Anisah Adeagbo[1], Hua Liu[1], Ying Tam[2], Norbert Pardi[3], Drew Weissman[3] and Valerie Gouon-Evans[1], (1)Boston University School of Medicine, (2)Acuitas Therapeutics, (3) University of Pennsylvania Perelman School of Medicine

Background: Alpha-1 antitrypsin deficiency (AATD) is a genetic disease caused by a single base pair mutation of the *SERPINA1* gene and increases risk of liver and lung disease. The most common mutation causes AAT protein to misfold, leading to polymerization of AAT in hepatocytes, cell death, fibrosis, and cirrhosis. Liver transplantation is the only treatment for AATD patients that develop end stage liver disease, though donor organs are quite scarce. Alternatively, transplantation of healthy liver cells – either primary human hepatocytes (PHH) or induced pluripotent stem cell (iPSC) derived hepatocyte-like cells (HLC) – is a promising approach to restore liver function. PHH transplantation has been validated as safe in humans, yet major challenges that remain are low efficiency and lack of sustained benefit. HLC transplantation remains entirely preclinical, and factors that limit HLC engraftment in liver disease mouse models include poor survival, proliferation, and maturation of transplanted cells. We hypothesize that stimulating key regenerative pathways in transplanted hepatocytes using hepatocyte growth factor (HGF) and epidermal growth factor (EGF) and preconditioning the host liver with P21 expression to prevent host hepatocyte proliferation will improve survival, proliferation, and engraftment of PHHs and HLCs in an injured mouse liver. **Methods:** We established a safe way to transiently express HGF+EGF specifically in the liver using nonintegrative nucleoside-modified mRNA encapsulated in lipid nanoparticles (mRNA-LNP). We use AAV8-Tbg-P21 to precondition the host mouse liver with long lasting P21 expression in hepatocytes. NSG-PiZ mice serve as our injury model, recapitulating AATD liver disease. **Results:** We find that both preconditioning the host with AAV8-Tbg-P21 and the HGF+EGF mRNA-LNP treatments significantly augment transplanted PHH survival and proliferation in vivo, evidenced by histological quantification of transplanted cells and human serum albumin levels in comparison to control. Combined preconditioning with P21 and treatment with HGF+EGF leads to robust repopulation of the mouse liver with functional human cells (~30% for combined treatment vs. ~2% for control) and amelioration of AATD liver disease. Furthermore, HGF+EGF mRNA-LNP transiently improves transplanted iPSC-derived HLC survival in vivo. **Conclusion:** Thus, stimulating survival and proliferation in transplanted hepatocytes with HGF+EGF mRNA-LNP and blocking host hepatocyte proliferation with AAV8-Tbg-P21 augments PHH engraftment in the NSG-PiZ mouse, making these highly promising strategies to improve iPSC-derived HLC engraftment to treat human liver diseases.

3320-A | IDENTIFICATION OF PATIENTS WITH ALPHA-1 ANTITRYPSIN DEFICIENCY-ASSOCIATED LIVER DISEASE USING AN ARTIFICIAL INTELLIGENCE CLINICAL DECISION SUPPORT TOOL

Virginia Clark[1], Suyin Lee[2], Chitra Karki[3], Ed G. Marins[3], Kaili Ren[3], Marco Vilela[3], Thikshaya Mahendran[4], Amanda Sees[2], May Hagiwara[3] and Rohit Loomba[5], (1)University of Florida, Gainesville, FL, USA, (2)Iqvia, Plymouth Meeting, PA, USA, (3)Takeda Development Center Americas, Inc., Cambridge, MA, USA, (4)Iqvia, Bengaluru, India, (5)University of California, San Diego, San Diego, CA

Background: Diagnosis (dx) of alpha-1 antitrypsin deficiency (AATD)-associated liver disease (LD) is challenging due to the variable risk and asymptomatic nature of the disease. An artificial intelligence/machine learning informed clinical decision support tool (AI/ML-CDST) may inform the identification of patients (pts) at risk of having undiagnosed AATD-LD. Here, we report the first-stage development of the AI/ML-CDST using data from the US IQVIA Ambulatory Electronic Medical Records (AEMR) database. **Methods:** The study population comprised pts aged ≥18 years with ≥1 encounter for any medical activity in the IQVIA AEMR database from Oct 2015 to Oct 2022. The positive cohort comprised pts with a recorded AATD dx (ICD-9/10 or SNOMED) and either a liver transplant or AATD-related liver conditions. The negative cohort comprised all other pts. For each pt, cross-sectional data with 12-month lookback and outcome periods with 1-month shift were generated. A cross-section that included the first date of AATD-LD (based on liver transplant or AATD-related liver conditions) in the outcome period was considered a positive cohort cross-section. All other cross-sections were considered negative. Algorithm features were captured within the database and metrics were engineered for each variable. Data were split into training, test and hold-out sets. An XGBoost algorithm was developed using temporal cross-validation on the training/test set. Recursive feature elimination was performed to evaluate the impact of algorithm simplification on model performance. Final model performance was evaluated on the hold-out set and assessed by fold-improvement over incidence of AATD-LD observed in the IQVIA AEMR data. **Results:** Of the 43 419 885 individual's in the IQVIA AEMR database, 1653 were pts with AATD-LD. Among the 400 features included to predict increased risk of underdiagnosed AATD-LD, prior AATD dx was the most predictive, followed by aspartate aminotransferase (AST) levels > 34 U/L and body weight > 180 or < 100 lb (Table). The AI/ML-CDST achieved an area under the curve of 0.8. **Conclusion:** The most predictive features of undiagnosed AATD-LD were prior AATD dx (35%) and AST levels (7%). However, as AATD is an underdiagnosed condition, the use of the AI/ML-CDST to identify pts with AATD-LD in the general population may be limited. Future model refinement and prospective validation can examine the utility of broad scale deployment of the tool, potentially in specialty practices, to support pt identification.

Table

Top 10 features associated with an increased risk of undiagnosed AATD-LD[a]	Model feature importance,[b] %	Threshold at which a patient has an increased risk of undiagnosed AATD-LD
AATD diagnosis	35	More than one AATD diagnosis encounter
Aspartate aminotransferase (AST)	7	Most recent AST >34 U/L
Body weight	6	Body weight >180 or <100 lb
Alanine aminotransferase (ALT)	4	Most recent ALT >30 U/L
Body mass index (BMI)	3	BMI initially or most recently <18.5 or >25 kg/m^2
Race (Caucasian)	2	Patient reporting as Caucasian
Age	2	>40 years
Serum alpha-1 antitrypsin (AAT)	1	First serum AAT <100 mg/dL
Sodium	1	Mean <135 and >145 mEq/L
Proton pump inhibitors	1	Encounter in the past 100 days

[a]Captured algorithm features included demographic, knowledge-driven, data-driven and custom.
[b]Model gain normalized to proportion of total feature importance.
AATD, alpha-1 antitrypsin deficiency; AATD-LD, alpha-1 antitrypsin deficiency-associated liver disease

3321-A | INTOLERANCE TO PHLEBOTOMY IS COMMON IN OLDER HEMOCHROMATOSIS PATIENTS

Elias Kovoor[1], Yolanda Rodriguez Villalvazo[1] and Kyle E. Brown[2], (1)University of Iowa Carver College of Medicine, (2)University of Iowa Carver College of Medicine, Iowa City, IA

Background: Hereditary Hemochromatosis (HH) is a genetic disorder that can cause iron deposition and multiorgan damage. Since there is no physiologic mechanism to excrete iron, patients with HH undergo phlebotomy to mobilize excess iron stores. HH is most often diagnosed in middle-age, but occasionally is discovered later in life. We hypothesized that older adults might not tolerate the aggressive phlebotomy regimens commonly used to treat HH. **Methods:** Using hemochromatosis ICD codes to identify patients, we conducted a retrospective chart review of patients diagnosed with HH at our institution between 01/2000-9/2022. Only patients with C282Y/C282Y or C282Y/H63D genotypes and well-documented phlebotomy history were included. Baseline serologies, imaging, and biopsy findings were recorded, as were etiology of intolerance for phlebotomy such as episodes of hypotension, syncope, severe anxiety, or difficulty with venous access. **Results:** 95 patients met our inclusion criteria, 85 were diagnosed before age 65 and 10 were diagnosed at age > 65. Of the entire group, phlebotomy intolerance was reported in 27 (28.4%) patients. Among patients diagnosed at age < 65, 21/85 experienced phlebotomy intolerance; the proportion was significantly higher among those diagnosed at age > 65 years (6/10 [p = 0.0192]). Reported intolerance with phlebotomy occurred at similar rates among female and male patients and those with evidence of cirrhosis versus those without. Ferritin levels at diagnosis were also similar among patients who experienced intolerance to phlebotomy and those who did not. **Conclusion:** A surprisingly large proportion (28.4%) of patients undergoing phlebotomy for HH at our institution experience intolerance to phlebotomy. Patients diagnosed at age > 65 comprise a minority of HH patients, but this group had higher rates of intolerance to phlebotomy than those diagnosed before age 65. Clinicians should be aware of the possibility that HH patients diagnosed at older ages may have difficulties with phlebotomy and shared decision making may play a key role in management of these patients. The impact and optimal treatment of HH in this age group requires further study.

	Did not tolerate phlebotomy (n = 27)	Tolerated phlebotomy (n = 68)	P-value
Diagnosis age < 65	21	64	0.0192*
Diagnosis age > 65	6	4	
Female	12 (44.4%)	21 (30.9%)	0.2100
Signs of cirrhosis	8 (29.6%)	25 (36.8%)	0.5100
Initial ferritin	1363 +/- 386	1489 +/- 329	0.6693

Table 1: Characteristics of hemochromatosis patients based on tolerance to phlebotomy

3322-A | METHANOBACTIN RESTORES BILIARY COPPER EXCRETION IN WILSON DISEASE RATS VISUALIZED BY 64Cu PET/MRI

Emilie Munk[1], Mikkel Holm Vendelbo[1], Frederik Teicher Kirk[1], Mette Irene Theilgaard Simonsen[1], Aage Kristian Olsen Alstrup[1], Tamara Rieder[2], Tea Lund Laursen[1,3], Peter Ott[1], Hans Zischka[2,4] and Thomas Damgaard Sandahl[1], (1)Aarhus University, (2)Technical University Munich, (3)Randers Regional Hospital, (4)Helmholtz Center Munich, German Research Center for Environmental Health

Background: Methanobactins (MBs) are small peptides with a very high copper affinity currently under investigation in preclinical trials for the treatment of Wilson disease (WD). Chelation treatment with D-penicillamine

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(DPA) and trientine facilitate urinary copper excretion. We aimed to investigate how MB affects *in-vivo* copper metabolism and excretion using 64-copper [^{64}Cu] PET/MRI in WD rats, compared to either DPA- or sham-treated, or to heterozygote control rats. **Methods:** Nineteen WD and four heterozygote control rats were injected intravenously with [^{64}Cu] and scanned one hour later. WD rats were then injected intraperitoneally with one dose of MB (ARBM-101 or MB-OB3b), DPA, or sodium chloride (sham) and scanned for 90 minutes and after 24 hours, while controls were not injected but scanned accordingly. [^{64}Cu] levels were estimated as the mean standard uptake value (g/ml) in volumes of interest in liver, kidney, bladder, and gut. **Results:** One hour after [^{64}Cu] injection, WD rats had elevated liver [^{64}Cu] activity compared to controls (9.0 ± 2.4 vs. 6.2 ± 1.9) and lower [^{64}Cu] activity in the gut (0.42 ± 0.24 vs. 2.87 ± 1.47) as expected. At 10-15 minutes after MB injection, [^{64}Cu] was visible in the small intestines of WD animals with levels equal to controls (2.2 ± 1.4) and that further increased to above control levels after 90 minutes (7.2 ± 4.9). [^{64}Cu] did not appear in the gut of DPA- or sham-treated rats, but DPA routed more [^{64}Cu] in the bladder (SUV = 7.9 ± 5.1 vs. 1.8 ± 2.2 in MB-treated rats). During the 90 minute-scan, liver [^{64}Cu] levels tended to decrease in MB-treated animals but were stationary in the other animals. From baseline to 24 hours after [^{64}Cu] injection, the liver [^{64}Cu] levels in control rats decreased by approximately 50%, whereas in MB-treated WD rats, liver [^{64}Cu] levels increased by 28%, DPA-treated by 76% and sham-treated by 40%. Fecal [^{64}Cu] increased by a factor 1000 upon injection with ARBM-101. **Conclusion:** In this study, a single dose of intraperitoneal MB rapidly facilitated biliary copper excretion in WD rats from comparable to double the level of controls. Liver [^{64}Cu] levels initially decreased within 90 minutes post-MB injection, followed by a subsequent rise at 24 hours, likely because of extra-hepatic [^{64}Cu] reaching the liver. DPA treatment did not show similar effects, but instead exhibited elevated bladder [^{64}Cu] activity. This suggests that a single dose of MB improves copper removal from the liver.

Background: Wilson disease (WD) typically results in liver injury and may affect extrahepatic organs, most notably the central nervous system. Endpoints for treatment include reversing liver injury and improving liver function. Hepatic fibrosis is an important consequence of liver injury in patients with WD, and there is increasing interest in estimating the degree of fibrosis non-invasively. The ability to follow hepatic fibrosis in WD in patients on treatment is important for clinical studies and standard practice. APRI and Fib4 estimates of fibrosis have proven useful for helping estimate the degree of fibrosis in other liver disorders, and some preliminary ranges for patients with WD were proposed (Paternostro et al Liver Int 2020). The Aim of this study was to determine the ranges for APRI and Fib4 in patients with Wilson disease and determine our ability to distinguish patients with cirrhosis from those with earlier stages of fibrosis. **Methods:** Data was analyzed for patients at enrollment in the WD Registry Study (n = 163, median (IQR) treatment 6.3 y (1.1, 20.0) with min 0, max 53.8 y). At the time of enrollment, site investigator determined the patient to be without or with cirrhosis based on liver biopsy, radiologic imaging and presence or absence of clinical signs of portal hypertension. Some patients (n = 19) had liver biopsy within 12 months of study entry, while others (n = 59) had liver biopsy > 1 year prior to enrollment. APRI and Fib4 was calculated from data at the time of study enrollment. **Results:** Data for the APRI and Fib4 calculations are shown in the Table below. Differences were statistically significant between mean values for APRI and Fib4 for patients with liver biopsy > 1 year of treatment before study entry with 0-3 fibrosis versus > 3 fibrosis, $p < 0.001$, and in investigator deemed non-cirrhotic versus cirrhotic, $p < 0.001$. As expected, values for these scores were higher in patients where the investigator deemed the patient to have cirrhosis. **Conclusion:** Both APRI and Fib4 scores may be useful to help identify patients with WD and cirrhosis which is important for clinical care and potentially for prognosis. Increasing our data collection will improve the accuracy and predictive value for these non-invasive fibrosis estimates in patients with WD. Additional analysis and correlation of longitudinal results for APRI and Fib4 with patient outcomes will help validate their use in treatment trials and in our standard of care practice.

f 3324-A | NON-INVASIVE FIBROSIS TESTS PREDICT LIVER-RELATED ENDPOINTS IN A LONGITUDINAL STUDY OF ADULTS WITH SEVERE ALPHA-1 ANTITRYPSIN DEFICIENCY (PI*ZZ GENOTYPE)

Malin Fromme[1], Samira Amzou[1], Barbara Burbaum[1], Philipp Striedl[2], Mattias Mandorfer[3], Monica Pons[4], Joan Genesca[4], Marc Miravitlles[5], Katrine Holtz Thorhauge[6], Benedikt Schäfer[7], Heinz Zoller[7], Aleksander Krag[6], Elmar Aigner[2], Christian Trautwein[8] and Pavel Strnad[1], (1)Medical Clinic III, Gastroenterology, Metabolic Diseases and Intensive Care, University Hospital Rwth Aachen, Aachen, Germany, (2)First Department of Medicine, Paracelsus Medical University, Salzburg, Austria, (3)Medical University of Vienna, Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Vienna, Austria, (4)Liver Unit, Vall d´Hebron University Hospital, Vall d`Hebron Research Institute (VHIR), Barcelona, Spain, (5)Clinic for Pneumology, Vall d´Hebron Hospital, Barcelona, Spain, (6)Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark, (7)Department of Internal Medicine I, Medical University Innsbruck, Innsbruck, Austria, (8)University Hospital, Rwth Aachen

Background: Homozygous Pi*Z mutation (Pi*ZZ genotype) confers a strong predisposition to lung and liver disease. While phase 2 clinical trials suggested that treatment with small interfering RNA may improve Pi*ZZ-associated liver phenotype, very little is known about the natural disease course as well as factors predicting the development of liver-related endpoints. To change that, we evaluated risk factors and the predictive utility of non-invasive tests in the multi-center European Pi*ZZ liver cohort. **Methods:** 480 Pi*ZZ subjects without concomitant liver diseases or pathological alcohol consumption received a baseline clinical, laboratory, and elastographic assessment. 407 of them had a detailed follow-up interview at least 12 months after their baseline examination. **Results:** During a median follow-up of 3.8 years, 25 Pi*ZZ individual's deceased. The main causes of fatality were lung and liver disease, accounting for 9 and 8 deaths, respectively. 18/5 individual's received a lung/liver transplant. 17 Pi*ZZ subjects who developed a hepatic endpoint (liver transplant/death, or decompensated cirrhosis) presented with significantly higher BMI (28 vs. 24 kg/m^2, $p = 0.001$), liver stiffness measurement (14 vs. 5 kPa, $p = 6.0 \times 10^{-10}$), AST-to-platelet ratio index (APRI, 1.0 vs. 0.3 units, $p = 1.8 \times 10^{-7}$), fibrosis-4 index (3.6 vs. 1.3, $p = 3.0 \times 10^{-6}$), and liver enzymes in their baseline examination. Multivariate Cox regression analysis revealed LSM ≥ 15 kPa (aHR 40.3, 95% CI 11.0-147.8, $p = 2.4 \times 10^{-8}$) and APRI ≥ 1.0 units (aHR 37.3, 95% CI 10.3-135.5, $p = 3.9 \times 10^{-8}$) as strong predictors of liver-related endpoints. Notably, 310 individual's with LSM < 7.1 kPa at baseline did not develop any hepatic endpoint during their follow-up (Table 1). **Conclusion:** LSM and APRI accurately stratify Pi*ZZ individual's according to their risk of liver-related events. Thus, these non-invasive tests may allow risk stratification in clinical practice as well as selection for clinical trials.

LSM (kPa)	n	Follow-up years	Liver-related endpoints	Endpoints/100 FU years
<7.1	310	1174.5	0	0
7.1 – 10	52	205.6	5	2
10.1 – 14.9	26	103.4	4	4
≥15	19	66.1	8	12

Table 1: Liver stiffness measurement via vibration-controlled transient elastography stratifies Pi*ZZ individuals into risk categories. Abbreviations: LSM, liver stiffness measurement; FU, follow-up.

3325-A | REMOVAL OF COPPER BY ATP7B EXPRESSION IN PRIMARY HEPATOCYTES FROM WILSON'S DISEASE PATIENTS

Maria S Collado[1], Napoleon Butler II[1], Jeanine Fogarty[1], Andrew Pryor[1], Stephen Hoang[1], Meng Lee[2], Joseph Petty[2] and Roshan Padmashali[2], (1) Hemoshear Therapeutics Inc, (2)Takeda Pharmaceuticals

Background: Wilson's disease (WD) is a rare disorder characterized by copper accumulation in vital organs as a result of the inability of the liver to remove excess copper from the body due to mutations in the ATP7B gene. Excess free copper can induce hepatotoxicity and ultimately liver failure, often requiring liver transplantation. We developed an *in vitro* human WD liver model using patient-derived hepatocytes and demonstrated efficacy of gene therapy to restore ATP7B function and lower intracellular copper. **Methods:** Liver explants were procured with consent from WD patients undergoing transplantation during acute liver failure. Hepatocytes were isolated and cryopreserved using conventional isolation protocols. WD hepatocytes were transduced with adenovirus containing full-length hATP7B gene, or GFP as a control, at various MOIs for 8 hrs and cultured for 10 days under static or hemodynamic and flow conditions using our REVEAL-Tx™ technology. Several functional endpoints were assessed including ATP7B expression, intracellular copper, secreted ceruloplasmin, and copper-related genes. **Results:** All livers procured from WD patients were diseased and cirrhotic, yielding only limited quantities of functional hepatocytes suitable for *in vitro* studies. WD hepatocytes contained copper levels > 16-fold higher than normal hepatocytes, showed elevated gene expression of copper storage protein metallothionine and reduced gene expression of copper transporter CTR1. These biomarkers remained intact during culture. Bile canaliculi formation was similar between WD and normal hepatocytes. Expression of ATP7B at physiological levels in WD hepatocytes cultured under REVEAL-Tx™ flow conditions resulted in a 30-40% reduction in intracellular copper after only 10 days in culture. Higher levels of ATP7B expression were effective on static culture. Under flow conditions, treatment with the copper chelator tetrathiomolybdate also resulted in a small reduction of intracellular copper. However, combination of gene and chelator therapy did not potentiate removal of copper, suggesting that a significant amount of the intracellular copper in WD hepatocytes may be stably bound to metallothionine. **Conclusion:** WD hepatocytes isolated from patients stably store high levels of copper. Expression of ATP7B in our WD liver model reduced intracellular copper, suggesting that gene therapy has the potential to restore ATP7B function and reduce excess copper stored in WD patient's livers.

3326-A | TARGETING PKM2 IN NASH-HCC: CROSS TALK BETWEEN HEPATIC MACROPHAGE REGULATION AND TGF-BETA SIGNALING

Kazufumi Ohshiro[1], Krishanu Bhowmick[1], Xiaochun Yang[2], Dillon Voss[3], Adrian R Krainer[3] and Lopa Mishra[1,3], (1)The Institute for Bioelectronic Medicine, Feinstein Institutes for Medical Research, & Cold Spring Harbor Laboratory, Department of Medicine, Division of Gastroenterology and Hepatology, Northwell Health, Manhasset, New York, USA., (2)The Institute for Bioelectronic Medicine, Feinstein Institutes for Medical Research & Cold Spring Harbor Laboratory, Department of Medicine, Division of Gastroenterology and Hepatology, Northwell Health, NY, USA., (3)Cancer Center, Cold Spring Harbor Laboratory, NY, USA.

Background: Pyruvate kinase isozyme M2 (PKM2), a rate-limiting enzyme in glycolysis, mediates inflammation, ferroptosis and aerobic glycolysis (Warburg effect) in NASH-HCC. Increased macrophage PKM2 is associated with poor prognosis in HCC. We reported that liver-specific TGF-β/SMAD4 knockout mice develop hemochromatosis through hepcidin loss and increased iron absorption-a model for ferroptosis (*Cell Metab*. 2005;2:6). Recently, we found that liver-specific knockout of a TGF-β/SMAD adaptor βII-spectrin ($SPTBN1^{LSKO}$), blocks NASH and HCC, and βII-spectrin siRNA reverses NASH in human NASH 3D cultures (*Sci Transl Med.* 2021,13:624). Because TGF-β and PKM2 converge on ferroptosis, we examined whether βII-spectrin modulates PKM2 expression in NASH and HCC. **Methods:** HCC cells were treated with ASOs targeting PKM2. Western diet (WD) and DEN were given to $SPTBN1^{Flox}$ (control) and SPTBN1 LSKO mice for NASH-associated HCC. Since antisense oligonucleotides (ASOs) promote a splicing switch from the cancer-associated PKM2 to the PKM1 isoform, we explored the potential of ASO-based PKM splice switching as a targeted therapy for liver cancer. PKM2

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

expression was determined by immunohistochemical labeling using liver sections of these mice. **Results:** ASO induced PKM splice switching and inhibited the growth of cultured HCC cells, and increased pyruvate-kinase activity and altered glucose metabolism. Increased PKM2 expression was observed in NASH and HCC Kupffer cells from control SPTBN1^{Flox} mice fed WD. In contrast, PKM2 expression in the liver was markedly reduced in SPTBN1^{LSKO} mice fed WD and DEN in which NASH and HCC are blocked. Additionally, we observed that microbiome profiles and TGF-β/SMAD3–regulated fibrosis were altered, and expression of inflammatory genes was significantly reduced in the LSKO mice compared to the NASH mice. **Conclusion:** Hepatocyte βII-spectrin knockdown decreased PKM2 expression in Kupffer cells, suppressing pro-inflammatory cytokine production, and blocking NASH-associated HCC. Our study suggests cross talk between stromal regulation of glycolysis and TGF-β signaling. The study provides new insight into molecular mechanisms for two disorders that preferentially affect males, hemochromatosis and HCC.

3327-A | THE CLINICAL PRESENTATION AND CHARACTERIZATION OF WILSON DISEASE

Ashley O'Mara, Betsy Malkus, Serap Sankoh, Jack Allen and Jason Cataldo, Ultragenyx Pharmaceutical Inc.

Background: Wilson Disease (WD) is a rare disorder caused by mutations in the *ATP7B* gene (encodes transporter protein to regulate copper levels) that cause a toxic buildup of copper in the liver, brain, and other organs and can result in liver disease, neurological symptoms, and psychiatric behavioral disorders. An observational study was conducted to describe WD clinical presentation, capture the patient experience, and inform endpoint selection for future WD interventional studies. **Methods:** All participants had a confirmed diagnosis of WD and were prescribed standard of care (zinc and copper chelators). Medical history; patient-reported outcomes (PROs); clinician-reported outcomes (ClinROs); clinical performance tests of fine motor skills, strength, walking quality, speed, and endurance; and 24 hr urine and blood samples were completed at Day 0. PROs and 24 hr urine and blood samples were repeated on Days 15 and 30. Following Day 30, participants completed a qualitative interview. **Results:** This study included 16 participants (7 men, 9 women) with ages ranging from 14 to 70 years old. A copper-restricted diet was prescribed to 77% of participants; values of copper biomarkers were consistent with current therapeutic guidelines. Table 1 shows the clinical outcome assessment (COA) results. **Conclusion:** Study results demonstrate the broad spectrum of symptoms and impacts that patients with WD can experience. Given the heterogeneity of WD, selecting endpoints to adequately capture symptoms and impacts across all patients is challenging. Our findings suggest walking deficits and fatigue are experienced among patients with various clinical manifestations. Qualitative patient interviews are being conducted to further understand fatigue within the WD population and the context in which patients experience walking impairments.

Table 1 Clinical outcome assessment results

ClinRO	Minimal neurologic, hepatic, and psychiatric symptoms for all subjects.
WD and Global PROs	Symptoms ranged from none to highest severity rating. 63% reported experiencing fatigue and 77% (n=10/13) reported relevance when interviewed.
EQ-5D-5L	VAS scores ranged from 47-100 on a scale of the worst to the best health you can imagine.
BPI-SF	31% reported pain (3.15/10 at its worst).
Grip Strength	Right hand means were 76.11 % predicted and 86.76 % predicted for female and male subjects respectively.
Gait speed, Balance, 9HPT	No clinically significant deficits noted.
6MWT	All with impaired walking distance: 51-81% predicted.

3328-A | THE HIGHER RISK OF LIVER CIRRHOSIS IN PI*MZ SERPINA1 CARRIERS IS NOT CAUSED BY THE PRESENCE OF A DIFFERENT PRECIPITATING MUTATION

Sona Frankova[1], Zuzana Rabekova[2], Magdalena Nerolodova[2], Ondrej Fabian[2], Martin Kveton[2], Milan Jirsa[2] and Jan Sperl[1], (1)Department of Hepatogastroenterology, Institute for Clinical and

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

Experimental Medicine, Prague, Czech Republic, (2) Institute for Clinical and Experimental Medicine

Background: The homozygous carriage of the mutated Z allele at the rs28929474 locus in the *SERPINA1* alpha-1-antitrypsin (AAT) gene leads to pulmonary emphysema and liver cirrhosis. Recently, it has been shown that Pi*MZ heterozygotes have an increased risk of liver cirrhosis if they have liver disease of other aetiologies. The underlying mechanism of this risk has not yet been elucidated. The aim of our study was to test whether AAT also precipitates in hepatocytes in Pi*MZ heterozygotes and whether other variants in the *SERPINA1* gene localized in the trans position contribute to the higher risk of liver cirrhosis. **Methods:** The investigated cohort consisted of 1108 patients with advanced liver cirrhosis referred to liver transplantation between 1994 and 2020. The cohort consisted of 1021 Pi*MM homozygotes, 55 Pi*MZ heterozygotes, and 32 carriers of the Pi*MS genotype of the *SERPINA1* gene. Immunohistochemical examination with polyclonal anti-AAT antibody was performed in all available liver samples; in 46 of 55 Pi*MZ heterozygotes, in 10 of 18 Pi*MM homozygotes, and in 1 of 29 Pi*MS genotype carriers, i.e. in patients in whom the histological examination of the explanted liver revealed PAS-D (Periodic Acid-Schiff Diastase) positive granules in the cytoplasm of hepatocytes. Sanger sequencing of the coding regions and adjacent non-coding regions of the *SERPINA1* gene was performed in all 55 Pi*MZ heterozygotes, in 7 Pi*MM homozygotes, and in one Pi*MS genotype carrier with immunohistochemical evidence of AAT granules in hepatocytes. **Results:** Sequencing of the *SERPINA1* gene identified eight different single nucleotide substitutions in the study cohort. Of these eight variants, seven have already been described in the NCBI SNP database. One single nucleotide substitution c. 832 C > T was not reported in the database, and it can be assumed that it is a rare, previously undescribed variant. Six variants had the predicted missense effect on the amino acid sequence, i.e. the nucleotide change resulted in an amino acid substitution in the protein. In two cases, rs20546 and c. 832 C > T, the nucleotide substitution did not result in an amino acid substitution. The missense variant rs111850950 was described in the NCBI SNP database as having no clear clinical significance, while the remaining missense variants rs709932, rs20546, rs6647, and rs1303 - PiM3 are considered benign. **Conclusion:** The mechanism of liver damage in Pi*MZ heterozygotes is the same as in Pi*ZZ homozygotes and is caused by the proteinopathic effect of the precipitating variant AAT in the endoplasmic reticulum of the hepatocytes. The presence of other, previously unknown *SERPINA1* gene variants, is not the cause of AAT precipitation in hepatocytes and a higher risk of liver cirrhosis.

Disclosures: Sona Frankova – Gilead Sciences: Speaking and Teaching, No, No; Abbvie: Speaking and Teaching, No, No; AOP Orphan: Advisor, No, No; Disclosure information not available at the time of publication: Zuzana Rabekova, Magdalena Nerolodova, Ondrej Fabian, Martin Kveton, Milan Jirsa, Jan Sperl

3329-A | THE ROLE OF THE INTESTINE IN WILSON DISEASE: CHARACTERIZATION OF A NEW INTESTINE-SPECIFIC Atp7b KNOCK-OUT MOUSE MODEL.

Amanda Caceres[1], Noreene M Shibata[1], Gaurav Vilas Sarode[1], Tagreed Mazi[2], Margarida Bettencourt[1], Marie C. Heffern[1], Svetlana Lutsenko[3] and Valentina Medici[1], (1)University of California Davis, Sacramento, CA, (2) King Saud University, (3)Johns Hopkins University

Background: The clinical manifestations of Wilson disease (WD) are related to copper accumulation in the liver and brain, but little is known about the role of other organs expressing the ATP7B copper transporter on the metabolic changes characterizing WD. In organoids derived from intestinal epithelial cells from global knockout mice for the *Atp7b* gene (*Atp7b*$^{-/-}$) there is dysregulated lipid metabolism but the systemic effects of the intestinal *Atp7b* mutation and its significance in affecting the phenotype are unknown. To examine the metabolic consequences of intestine *Atp7b* inactivation in the absence of hepatic copper accumulation, we generated a new mouse strain, the *Atp7b*$^{\Delta IEC}$ mouse and characterized its phenotype over a time-course study. **Methods:** *Atp7b*$^{\Delta IEC}$ mice were generated using B6.Cg-Tg(Vil1-cre)997Gum/J mice from the Jackson Laboratory and *Atp7b*$^{Lox/Lox}$ mice. Cre-mediated removal of a 1.6-kb fragment in exon 2 results in enterocyte-specific *Atp7b* inactivation. *Atp7b*$^{\Delta IEC}$ mice were compared to wildtype mice with same genetic background (iWT). The *Atp7b* null global knockout (*Atp7b* $^{-/-}$) on a C57Bl/6 background was previously generated and compared to respective WT. Both male and female mice were studied at 9, 16, and 24 weeks of age. Liver histology, lipid metabolism parameters, including liver and plasma cholesterol and triglycerides levels, hepatic copper quantification were assessed. **Results:** At 9 and 16 weeks, *Atp7b* $^{-/-}$ mouse livers exhibit hepatocytes with irregular nuclei, mild inflammation, and no steatosis. However, at 24 weeks, *Atp7b* $^{-/-}$ mice display prominent irregularities in nuclei size, mild to moderate inflammation, and early fibrosis. Whereas at earlier ages, *Atp7b*$^{\Delta IEC}$ livers exhibit regular nuclei size, no steatosis, and no inflammation, at 24 weeks of age, they develop evidence of periportal inflammatory infiltrate and cytosolic glycogenosis. There was no difference in plasma cholesterol and triglyceride levels between the two mutant strains and their respective control mice. No changes in hepatic and enterocyte copper levels were seen in *Atp7b*$^{\Delta IEC}$ livers, whereas,

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

as expected, hepatic copper was 20-40 times higher in *Atp7b* $^{-/-}$ mice compared to WT mice. At 16 weeks of age, compared with iWT, *Atp7b*$^{\Delta IEC}$ mice showed changes highlighting increased liver triglycerides, diglycerides, and unsaturated fatty acids. In plasma, *Atp7b*$^{\Delta IEC}$ mice showed higher levels of lysoPCs and lysoPEs and reduced sphingomyelins and ceramides. **Conclusion:** Intestine-specific *Atp7b* deficit affects systemic lipid metabolism as shown by lipidomic analysis independently from hepatic copper accumulation indicating evidence that WD phenotype is affected by organ-specific *ATP7B* variants.

3330-A | WHAT TO CONSIDER WHEN RESULTS SHOW HYPERFERRITINEMIA AND NORMAL IRON SATURATION IN AN ASIAN POPULATION; IT COULD BE FERROPORTIN DISEASE: A FAMILY STUDY WITH SLC40A1 GENE MUTATION

Nairuti Shah[1], David Feldman[2] and Ira M. Jacobson[2], (1)NYU Langone Hospital - Long Island, (2)NYU Grossman School of Medicine

Background: Ferroportin, a transmembrane protein genetically encoded by *SLC40A1*, mediates iron export from intestinal cells to plasma. Ferroportin disease (FD), formerly known as hereditary hemochromatosis (HHC) type 4, is associated with dominant mutations in *SLC40A1* and is considered a rare disease. Classical FD (HHC type 4A) is due to loss of function mutations in *SLC40A1* that impair iron export. Affected patients usually have elevated ferritin but normal transferrin saturation (TSAT). We present a family of three sisters of Asian descent who share the same novel p.Met216Val mutation (c.646A > G) in *SLC40A1.* Despite sharing the same mutation, we found variable penetrance and disease severity within one family. **Methods:** Patient 1 the index patient is a 59 year-old woman initially evaluated for thrombocytopenia related to platelet clumping. She had hyperferritinemia from 318-424 and normal TSAT. Patient 2 is a 61 year-old woman with a history of nonalcoholic fatty liver disease (NAFLD) with ferritin 630 and normal TSAT. MRI of the abdomen showed diffuse hepatic steatosis with iron deposition. Patient 3 is a 64 year-old woman with a ferritin level of 529 and normal TSAT. MRI showed mild hepatic iron overload and splenic iron deposition. Her subsequent ferritin level was 652 and she had 4 phlebotomy sessions with ferritin 197. Repeat MRI showed resolution of hepatic iron overload and reduced splenic iron overload. All three patients are first degree relatives and genetic testing in all identified the p.Met216Val missense mutation in *SLC40A1* in the heterozygous state. **Results:** FD involves loss of function mutations in *SLC40A1* that impair the iron export efficiency of ferroportin leading to iron retention in reticuloendothelial cells and hyperferritinemia with normal TSAT. FD in later stages may have increased TSAT and iron accumulation in hepatocytes making it a progressive iron overload disorder. Therefore, it is important to test for the disease as it can often be confused with other common causes of hyperferritinemia with normal TSAT. **Conclusion:** FD should be considered in patients without typical features of type 1 (HFE) HHC. In Asian populations, such as this family of sisters, the HFE mutation is rarely detected, making awareness of FD in patients with features of genetic iron overload important. It is likely that disease presentation and penetrance of underlying mutations are affected by a patient's comorbidities, including age, metabolic syndrome and hepatic steatosis, making certain patients more susceptible to fibrosis in FD. Treatment if needed is with phlebotomy, which is often poorly tolerated and inefficient. Likely with more widespread testing the prevalence of the ferroportin mutation will become known. Further research is needed to better understand the mechanisms underlying this disorder and to develop effective treatments for affected individual's.

Patient	Patient 1 Index patient	Patient 2 Sister	Patient 3 Sister
Age	59	61	64
Reason for Consult	Thrombocytopenia	Hyperferritinemia	Neutropenia
Other liver disease	Hepatic Steatosis	NAFLD	None
Ferritin	318	630	529
Iron saturation	29%	20%	23%
Genetic mutation	*SLC40A1	*SLC40A1	*SLC40A1
Imaging consistent with Iron Overload	No	Yes, in liver	Yes, in liver and spleen
Phlebotomy	No	No	Yes

3400-A | A DIGITAL LIVER TWIN DEMONSTRATING THE INTERPLAY BETWEEN BIOMECHANICS AND CELL KINETICS CAN EXPLAIN FIBROTIC SCAR FORMATION

Jieling Zhao[1], Seddik Hammad[2], Mathieu De Langlard[3], Pia Erdoesi[2], Yueni Li[4], Paul Van Liedekerke[5], Andreas Buttenschoen[6], Jan G. Hengstler[7], Matthias Ebert[8], Steven Dooley[9] and Dirk Drasdo[1,3], (1)Ifado, (2)Medical Faculty Mannheim Heidelberg University, Mannheim, (3)Inria, (4)Medical Faculty Mannheim Heidelberg University, Mannheim, Germany, (5)Ghent University, (6)University of Massachusetts Amherst, (7)Department of Toxicology, Leibniz Research Centre for Working Environment and Human Factors, Technical University Dortmund, Ardeystr 67, 44139, Dortmund, Germany, (8) Medical Faculty Mannheim, Heidelberg University, (9) University Medical Center Mannheim, Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany

Background: Upon different types of liver injury, distinct patterns of fibrosis arise, such as extracellular matrix (ECM) septa connecting pericentral (CV) areas due to toxic injury. Formation of specific liver fibrosis patterns is a dynamic and multi-cellular process, which is difficult to uniquely explain by experiments both, in vivo and in vitro, and therefore not sufficiently understood. **Methods:** A well-designed digital liver twin is warranted to explore the possible mechanisms of fibrotic scar formation and progression as it permits a unique mapping from a set of hypothesized mechanisms to its consequences. The digital twin (DT) resolves liver microarchitecture including sinusoids, hepatocytes, hepatic stellate cells (HSCs), macrophages (Mph) and the ECM network, and integrates biomechanics and cell kinetics to study the mechanistic interplay of chronic injury-mediated formation of septal fibrotic walls based on iterative sets of experiments informing the model. Quantitative measures of fibrosis pattern-characterizing parameters were obtained through analysis of 2D and 3D images from mouse experiments to inform the DT. **Results:** The DT investigates the orchestration of cell types during septal fibrosis development and the mechanical interaction of cell populations with the ECM network. Using this DT, a potential scenario distinguishing regeneration of a characteristic cell death pattern after acute hepatotoxic insult and repeated hepatotoxic exposure leading to formation of septal fibrotic walls is proposed based on the spatial pattern of CYP2E1 (key metabolic enzyme) expressing cells. The attraction of activated HSC and Mph is controlled by damage-associated molecular patterns (DAMPs), which are governed by the spatial-temporal localization of CYP2E1 expressing hepatocytes. In addition, the remaining (healthy) cells proliferate to replace the dead hepatocytes, thereby mechanically compressing the fibrotic collagen network into "wall"-like shapes. DT predictions are quantitatively comparable with experimental findings using CYP2E1-disturbed mice upon CCl4 injections. To predict further players in septal fibrosis formation, DT-simulations upon perturbations (e.g. inhibition of hepatocyte proliferation, migration of HSC and phagocytic activity of Mph) are performed and permit DT validation. **Conclusion:** With the above, the DT predicts that septal

fibrosis is driven by the spatial-temporal distribution of CYP2E1 expressing cells (source of DAMPs) and shaped by hepatocyte proliferation. The DT can be extended to investigate the switch from advanced fibrosis or cirrhosis to cancer setting.

3401-A | ABHD17B REGULATES HEPATIC STELLATE CELL ACTIVITY TO PROMOTE LIVER FIBROSIS

Wenyang Li[1,2], Robert Sparks[3], Cheng Sun[3], Lorena Pantano[4], Rory Kirchner[4], Jennifer Y. Chen[5], Victor Barerra Burgos[4], Shannan Ho Sui[4], Gary Aspnes[6], Michael Schuler[6], Jennifer Smith[7], Carine Boustany[6], Jörg Rippmann[6], Daniela Santos[6], Julia Doerner[6] and Alan C. Mullen[3,8], (1)Peking University, (2) Massachusetts General Hospital, (3)UMass Chan Medical School, (4)Harvard T.H. Chan School of Public Health, (5)University of California, San Francisco, (6) Boehringer Ingelheim Pharmaceuticals, (7)Iccb-Longwood Screening Facility, Harvard Medical School, (8)Broad Institute

Background: Chronic liver injury leads to hepatic stellate cell (HSC) activation and transdifferentiation into HSC myofibroblasts, which produce the extracellular matrix (ECM) responsible for fibrosis. While inhibiting the fibrotic activity of HSC myofibroblast has the potential to reduce progression and promote resolution of fibrosis, there are currently no therapies directed at interfering with the activity of these cells. **Methods:** We performed a high-throughput screen using small interfering RNAs (siRNAs) in primary human HSC myofibroblasts to identify gene products necessary to maintain the fibrotic phenotype. The primary screen analyzed siRNAs targeting > 7,500 mRNAs and > 2,000 long noncoding RNAs (lncRNAs), quantifying lipid accumulation as a phenotypic readout for HSC inactivation. The primary screen was performed with four siRNA duplexes for each target RNA. A deconvolution screen was then applied to assess the activity of each individual siRNA duplex for hits in the primary screen, and final candidates were evaluated to determine how siRNAs impacted expression of *COL1A1* and *ACTA2*. This analysis identified ABHD17B (Abhydrolase domain containing 17B, depalmitoylase) as a potential regular of HSC activity. ABDH17B was depleted in multiple primary human HSC lines, and the fibrotic activity of HSCs was evaluated by mRNA and protein expression. *Abhd17b-/-* mice were then challenged with carbon tetrachloride (CCl_4) as a model of chronic liver injury. Structural analysis of ABHD17B with molecular dynamics simulations following *de novo* folding with AlphaFold was performed to identify key amino acids in the hydrolase pocket of ABHD17B, and mass spectrometry was carried out to identify protein partners. **Results:** Depletion of ABHD17B in multiple primary human HSC lines resulted in reduced expression of *COL1A1* and *ACTA2*, and RNA-seq demonstrated a broader impact on ECM genes. Through mutation analysis, the active serine residue for hydrolase activity was defined, and mutation of this residue appeared to affect expression of *COL1A1*. Mice deficient in *Abhd17b* developed less liver fibrosis when exposed to CCl_4, and mass spectrometry analysis suggested that ABHD17B may promote fibrosis by allowing HSCs to respond to profibrotic cues from their environment. **Conclusion:** ABDH17B promotes expression of collagen and ECM proteins in HSC myofibroblasts to promote liver fibrosis. Targeting ABHD17B may have potential as an antifibrotic therapy.

3402-A | ASK1/p38 AXIS INHIBITION BLOCKS THE RELEASE OF MITOCHONDRIAL "DANGER SIGNALS" FROM HEPATOCYTES AND SUPPRESSES PROGRESSION TO CIRRHOSIS AND LIVER CANCER

Zhenwei Peng[1,2], Guangyan Wei[1,2], Pinzhu Huang[1], Ping An[1], Shuangshuang Zhao[1], Yi Lin[1], Li Tan[1], Kahini Vaid[1], Disha Skelton-Badlani[1], Imad A. Nasser[1], Grant Budas[3], David Lopez[3], Li Li[3], Robert P. Myers[3], John McHutchison[3], Ming Kuang[4] and Yury V. Popov[5], (1) Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (2)The First Affiliated Hospital, Sun Yat-Sen University, (3)Gilead Sciences, Inc., (4)The First Affiliated Hospital of Sun Yat-Sen University, (5)Harvard Medical School, Boston, MA

Background: Apoptosis Signal-regulating Kinase 1 (ASK1) is activated by various pathological stimuli and induce cell apoptosis via downstream p38 activation. We studied the effect of pharmacological ASK1 inhibition on cirrhosis and its sequalae using comprehensive preclinical in vivo and in vitro systems. **Methods:** Short- (4-6 weeks) and long-term (24-44 weeks) ASK1 inhibition using small molecule GS-444217 was tested in thioacetamide-induced and BALB/c.*Mdr2-/-* murine models of cirrhosis and hepatocellular carcinoma (HCC), and in vitro using primary hepatocyte cell death assays. **Results:** Short-term GS-444217 therapy in both models strongly reduced phosphorylated p38, hepatocyte death, and fibrosis by up to 50%. In vitro and in vivo, profibrogenic release of mitochondrial DAMP mtDNA from dying hepatocytes was blocked by ASK1 or p38 inhibition. Long-term (24 weeks) therapy in BALbc.Mdr2-/- model resulted in moderate 25% reduction in bridging fibrosis, but not in net collagen deposition. Despite this, development of cirrhosis was effectively prevented, with strongly reduced $p21^{+}$ hepatocyte staining (by 72%), serum ammonia levels (by 46%) and portal pressure (average 6.07 vs 8.53 mmHg in controls). Extended ASK1 inhibition for 44 weeks in aged BALB/c.*Mdr2-/-* mice resulted in markedly reduced tumor number and size by ~50% compared to control group. **Conclusion:** ASK1 inhibition suppresses profibrogenic release of mtDNA from dying hepatocytes in p38-dependent manner and protects from liver fibrosis. Long-term ASK1 targeting resulted in diminished net antifibrotic effect, but the progression to liver cirrhosis and cancer in BALBc/*Mdr2*$^{-/-}$ mice was effectively inhibited. These data support the clinical evaluation of ASK1 inhibitors in fibrotic liver diseases.

3403-A | C-C MOTIF CHEMOKINE RECEPTOR 2 INHIBITION REDUCES LIVER FIBROSIS BY RESTORING THE IMMUNE CELL LANDSCAPE

Jinhang Gao, Department of Gastroenterology, Chengdu, China and Yangkun Guo, West China Hospital, Sichuan University

Background: The accumulation of extracellular matrix (ECM) proteins in the liver leads to liver fibrosis and end-stage liver cirrhosis. C-C motif chemokine receptor 2 (CCR2) is an attractive target for treating liver fibrosis. However, limited investigations have been conducted to explore the mechanism by which CCR2 inhibition reduces ECM accumulation and liver fibrosis, which is the focus of this study. **Methods:** Liver injury and liver fibrosis were induced by carbon tetrachloride(CCl_4) in wild-type mice and *Ccr2* knockout (*Ccr2*$^{-/-}$) mice. Mice in the control group (olive oil group) were i.p. injected with olive oil for 6 weeks. For the murine preventive model, wild-type mice were i.p. administered 4 dosages of CVC (15 mg/kg body weight, Selleck #S8512) and 2 dosages of CCl_4 per week for 6 consecutive weeks. For the murine treatment model, mice were i.p. injected with CCl_4 for 3 weeks to induce liver fibrosis, and then 4 dosages of CVC and 2 dosages of CCl_4 per week were administered for another 3 weeks. For the acute liver injury experiment in *Ccr2*$^{-/-}$ mice, 2 doses of CCl_4 were i.p. injected. All mice were sacrificed 48 hours by an overdose of pentobarbital sodium after the final injection, and livers were taken for subsequent experiments. **Results:** CCR2 was upregulated in murine and human fibrotic livers. Pharmacological CCR2 inhibition with cenicriviroc (CVC) reduced ECM accumulation and liver fibrosis in prevention and treatment administration. In

single-cell RNA sequencing (scRNA-seq), CVC was demonstrated to alleviate liver fibrosis by restoring the macrophage and neutrophil landscape. CVC administration and CCR2 deletion can also inhibit the hepatic accumulation of inflammatory FSCN1$^+$ macrophages and HERC6$^+$ neutrophils. Pathway analysis indicated that the STAT1, NFκB, and ERK signaling pathways might be involved in the antifibrotic effects of CVC. Consistently, *Ccr2* knockout decreased phosphorylated STAT1, NFkB, and ERK in the liver. *In vitro*, CVC could transcriptionally suppress crucial profibrotic genes (*Xaf1*, *Slfn4*, *Slfn8, Ifi213*, and *Il1b*) in macrophages by inactivating the STAT1/NFkB/ERK signaling pathways. **Conclusion:** In conclusion, this study depicts a novel mechanism by which CVC alleviates ECM accumulation in liver fibrosis by restoring the immune cell landscape. CVC can inhibit profibrotic gene transcription *via* inactivating the CCR2-STAT1/NFkB/ERK signaling pathways.

3404-A | CONNECTIVE TISSUE GROWTH FACTOR IN LIVER SINUSOIDAL ENDOTHELIAL CELLS DRIVES LIVER FIBROGENESIS AND PORTAL HYPERTENSION IN CONGESTIVE HEPATOPATHY

Seiya Kato[1], Hayato Hikita[1], Akira Doi[2], Kazuhiro Murai[1], Yuki Tahata[2], Akira Nishio[3], Kunimaro Furuta[1], Takahiro Kodama[2], Tomohide Tatsumi[2] and Tetsuo Takehara[2], (1)Osaka University, Graduate School of Medicine, (2)Osaka University Graduate School of Medicine, (3)Osaka University Graduate School of Medicine, Bethesda, MD

Background: The detail mechanism of pathogenesis in congestive hepatopathy, such as right-sided heart failure, post-Fontan surgery and Budd-Chiari syndrome, remains unclear. We aimed to elucidate it focusing on the mechano-stress response in liver sinusoidal endothelial cells (LSECs). **Methods:** Partial IVC ligation (pIVCL) was performed to induce hepatic congestion in mice. Single-cell RNA sequencing (scRNA-seq) was performed using livers from the mice with pIVCL and sham operation. As in vitro experiments, primary murine LSECs or TMNK-1 cells, human liver endothelial cell line was subjected to mechano-stress including periodic mechanical stretch and hydrostatic pressure stimulation. **Results:** In the pIVCL group, portal venous pressure was significantly elevated 2 weeks after surgery compared with the sham group, and liver fibrosis was observed mainly in Zone3, which developed over time. Liver tumors were observed in half of the mice at 48 weeks after pIVCL. The scRNA-seq results showed that the expression of YAP/TAZ target genes, which play a central role in mechano-stress responses, was upregulated in LSECs in the pIVCL group, and that connective tissue growth factor (CTGF) was the most greatly upregulated gene in the whole LSEC population and more upregulated in zone 3 LSECs than in zone 1 LSECs. LSECs isolated from pIVCL-treated mice showed increased expression of YAP/TAZ target genes including CTGF, and the YAP/p-YAP ratio was increased at the protein level. In vitro experiments showed that the expression of YAP/TAZ target genes was upregulated in murine LSECs and TMNK-1 cells by mechanical stretch or hydrostatic pressure stimulation. The mechano-stress-induced CTGF upregulation in TMNK-1 cells was suppressed by siRNA-induced silencing of YAP/TAZ or YAP inhibitors. We generated tamoxifen-inducible endothelial cell-specific CTGF knockout mice (Cdh5-CreERT2+ CTGF$^{fl/fl}$), followed by pIVCL. CTGF KO in endothelial cells decreased the amount of intrahepatic hydroxyproline, Sirius red staining positive area in liver tissue sections and portal venous pressure in pIVCL-treated mice. **Conclusion:** In congestive hepatopathy, mechano-stress in the liver sinusoids activates YAP/TAZ and enhances CTGF expression in LSECs, which may contribute to the development of liver fibrosis and portal hypertension.

3405-A | DELETION OF IGFBP7 INHIBITS THE PRO-FIBROGENIC EFFECTS OF M1 MACROPHAGES THROUGH YAP TARGET GENES

James C. Reed, Dana Lau-Corona, Min Xu, Charlotte Warner, Volney Spalding, Shadi Salloum and Raymond T. Chung, Massachusetts General Hospital and Harvard Medical School

Background: Insulin-like growth factor binding protein 7 (IGFBP7) has been implicated in the development of steatosis and fibrosis in NAFLD and NASH through partially known mechanisms. IGFBP7 is highly expressed in hepatic stellate cells (HSCs), macrophages, and other immune cells. It has been demonstrated that silencing IGFBP7 in liver macrophages reduces hepatic steatosis. Under pathological conditions, liver macrophages can polarize into distinct phenotypes (M1 and M2), which play crucial roles in promoting inflammation and liver fibrosis. In this study,

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

we sought to investigate the contribution of macrophage-derived IGFBP7 to the activation of pro-fibrogenic programs and pathways that mediate this activation. **Methods:** U937-derived macrophages were transfected with small interfering RNA (siRNA) targeting IGFBP7. Furthermore, macrophages were polarized into M1 (IFN-γ and LPS) or M2 (IL-4/IL-13) phenotypes, with and without IGFBP7 silencing. Hepatic stellate cells (HSCs) were then exposed to conditioned media obtained from M0, M1, or M2 macrophages, both with and without TGF-β. Changes in gene expression associated with fibrosis and YAP-target genes were evaluated using quantitative real-time polymerase chain reaction (qRT-PCR). **Results:** Silencing of IGFBP7 in U937-derived M0 macrophages resulted in increased expression of genes associated with regenerative macrophages (e.g., MMP12, MMP13, IGF-1), while decreasing the expression of genes associated with inflammatory macrophages (e.g., TNF-α). Culturing HSCs in conditioned medium from M1 macrophages upregulated the expression of fibrosis-related genes (CTGF, TIMP1) and YAP-regulated genes (ANKRD1, CYR61). However, silencing IGFBP7 in M1 macrophages inhibited the ability of the corresponding conditioned medium to induce the upregulation of these genes in HSCs. Importantly, this inhibitory effect was not reversed by the addition of TGF-β to the culture medium. **Conclusion:** Our study provides evidence that IGFBP7 plays a central role in mediating the pro-fibrogenic properties of M1 macrophages on HSCs through the activation of YAP target genes. Further study is required to elucidate the precise molecular mechanisms by which IGFBP7 exerts its fibrogenic effects, but these findings highlight IGFBP7 as a possible therapeutic target for blockade of liver fibrosis.

3406-A | DEVELOPMENT OF ORALLY ADMINISTRABLE NUCLEIC ACID WITH LIVER FIBROSIS-IMPROVING EFFECT

Yoshiki Murakami[1,2], Masakatsu Takanashi[3], Tomohiro Umezu[1] and Masahiko Kuroda[1], (1)Tokyo Medical University, (2)Asahi University, (3)Azabu University

Background: There are currently no drugs primarily targeted for liver fibrosis. The current treatment of liver fibrosis is to prevent the progressing fibrosis by controlling the underlying disease, or to wait for the extracellular matrix accumulated as a result of inflammation to be absorbed naturally. Liver transplantation is the only treatment for severe liver cirrhosis. Previously, we have shown that treatment of miR-29a has an effect of promoting improvement of liver fibrosis in mouse chronic liver disease model. To investigate effective nucleic acid therapy with smaller doses, a modified nucleic acid was prepared based on the seed sequence of miR-29a. **Methods:** Modified nucleic acid constructed DNA-RNA hybrid with Fluoro and LNA substituents in 2' position. Liver fibrosis murine models (carbon tetrachloride) was used as chronic liver injury. Nucleic acid was dissolved in saline and orally administered, and a group administered with only saline was used as a comparison control. All cases were followed up for 7 weeks. (1) Carbon tetrachloride (CCL4) was administered for 5 weeks, followed by modified nucleic acid administration for 2 weeks (W). (2) CCL4 was administered for 7W, and nucleic acid was used in combination for the last 2W. Hepatic fibrosis and inflammation were evaluated by histological analysis. **Results:** We at first examined the localization of modified nucleic acids when administered orally. Mice labeled with Alexa647 on modified nucleic acid and fasted for 18 hours were orally administered with saline and sacrificed 2, 4, 24 hours later. When the labeled nucleic acid was observed on IVIS imaging system, the nucleic acid reached the small intestine after 2 hours and was not detected in the intestinal tract after 24 hours. The distribution of nucleic acids was

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

observed in the liver and urinary system. After CCL4 stimulation, modified nucleic acid by oral administration for 2W, liver fibrosis-improving effect was observed as compared with the saline administered group. In addition, when stimulation with CCL4 was continued for 7W, and oral administration of modified nucleic acids for the last 2W, showed inhibitory effect on the progression of fibrosis compared to the saline administered group. **Conclusion:** we newly developed nuclease resistant nucleic acid. It was showed that this nucleic acid exhibits an anti-fibrotic effect orally without the use of liposome preparations, and is expected to be useful as a new method for treating fibrosis.

3407-A | DIFFERENT ROLE OF GLUTAMINOLYSIS IN LUNG AND LIVER FIBROSIS

Ayse Okesli Armlovich, Olga Gulyaeva, Saritha Kusam, Yeonju Lee, Wallace Liu, Wesley Minto, Kelly Staiger, Devan Naduthambi, Tina Mistry, Minji Seung, Kelli Boyd, Bhanu Singh, Bruno Marchand, Lauri Diehl, Grant Budas, Anna Zagorska and Jamie Bates, Gilead Sciences, Inc.

Background: Activated fibroblasts are responsible for the deposition of extracellular matrix driving liver and lung fibrosis[1]. Glutaminolysis driven by GLS1 is required for metabolic reprogramming of hepatic stellate cells (HSCs) and lung fibroblasts (LFs) in vitro[2,3]. GLS1 protein expression increases in the scar region in human F4 NASH, whereas hepatocyte-restricted GLS2 decreases3. GLS1i reduced fibrosis markers in an acute liver fibrosis model (single injection of CCl4)[4] and a bleomycin model (BleoM) of idiopathic pulmonary fibrosis (IPF)[5]. **Methods:** GLS1/GLS2 expression was validated using immunohistochemistry, immunofluorescence. HSC/LFs were treated with TGFβ +/- GLS1i (48h), analyzed for pro-collagen and αSMA with ELISA and imaging. GLS1i IPN-60090 was tested at 100, 30, 10, and 3 mg/kg BID in a rat choline deficient high fat diet (CDHFD) model (6 wks diet plus 6 wks dosing) and mouse BleoM (dosing day 7-21). **Results:** In F4 NASH, GLS1 is in fibroblasts, immune cells, and vascular endothelial cells. In IPF, GLS1 is in fibroblasts, epithelial cells, and immune cells. GLS1$^+$PDGFRα$^+$ area increased ~4x in both IPF and NASH in comparison to healthy samples. GLS2 expression was undetected in IPF. Similar expression patterns were observed in the animal models. In LFs, GLS1i blocked TGFβ-induced cellular pro-collagen and α-SMA with a EC_{50} of 70 ± 7 and 53 ± 8 nM, respectively. Glutamate (Glu) was reduced (EC50 of 76 ± 35 nM), with concurrent increase in glutamine (Gln). Similar effects were observed in HSCs. In CDHFD model, GLS1i exacerbated fibrosis by increasing PSR$^+$ area 1.3x and α-SMA+ area 1.6x in 30 mg/kg group. Liver toxicity was observed in 100 mg/kg group after 2 wks. In BleoM, GLS1i reduced Ashcroft score significantly from 4 to 2.5, and PSR$^+$ area from 2.2% to 0.5%. Liver Gln and Glu levels both increased 3.5x and 1.4x in the CDHFD model, whereas lung Gln levels increased 1.7x without significant change in Glu levels in BleoM. **Conclusion:** In liver and lung fibrosis GLS1 expression is elevated, however, GLS1$^+$ cell types and GLS2 expression differ in these organs. GLS1i resulted in opposite outcomes in liver vs lung fibrosis models. This could be due to differences in (1) mode of action in different cell types (2) adaptation mechanisms or (3) off-target effects of GLS1i. Additional studies are required to further understand the divergent roles of glutaminolysis in lung and liver fibrosis.

3408-A | DISRUPTING DNA OF NEUTROPHIL EXTRACELLULAR TRAPS ATTENUATES ACTIVATION OF HEPATIC STELLATE CELLS AND AMELIORATES LIVER FIBROSIS IN A MODEL OF ALCOHOL PLUS NASH DIET INDUCED STEATOHEPATITIS.

Mrigya Babuta, Caroline Morel, Marcelle Ribeiro, Christopher Copeland, Prashanth Thevkar Nagesh, Yanbo Wang, Yuan Zhuang, Marti Ortega-Ribera, Jeeval Metha, Imad A. Nasser and Gyongyi Szabo, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Background: Heavy alcohol use in obesity and non-alcoholic steatohepatitis (NASH) is associated with increased liver damage, fibrosis, and liver-related death. Mechanisms by which alcohol increases progression of NASH are unclear. Here, we aim to identify cellular and molecular mechanisms through which repeated alcohol binges exacerbate liver injury in a high fat-cholesterol-sugar diet (NASH diet) induced model of NASH. **Methods:** 8-10 weeks old male

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

C57BL/6 mice received either chow or NASH diet for 3 months with or without weekly alcohol binges. Liver tissue was analyzed for fibrosis and inflammation markers by immunohistochemistry, qPCR and western blotting. Neutrophil infiltration and neutrophil extracellular traps (NETs) were examined via Flow Cytometry, ELISA and immunofluorescence. **Results:** Alcohol binges in a diet-induced model of NASH lead to increased liver injury (transaminases level), profound fibrosis [protein level alpha-smooth muscle actin (α-SMA) and vimentin], neutrophil infiltration ($Ly6G^+$) and NETs formation (neutrophil elastase and citrullinated histone) compared to lean and NASH alone mice. We discovered that alcohol binge induced NETs *in vitro* an *in vivo* in the liver that was higher in NASH diet fed mice. The alcohol-induced cell-free NETs induced a robust pro-fibrotic phenotype in HSCs *in vitro* indicated by increased α-SMA and collagen 1 expression. Additionally, cell-free NETs promoted a pro-inflammatory phenotype in monocytes as evidenced by increased production of interleukin 1β, monocyte chemoattractant protein 1 and tumor necrosis factor-α. Abrogation of the fibrillar structure of NETs by DNase treatment prevented activated phenotype in both HSCs and monocytes. Furthermore, *in vitro*, reconstitution of NETs by culturing HSCs with recombinant citrullinated histone and DNA lead to activation of HSCs. Interestingly, alcohol-induced production of NETs and sensing of NETs by HSCs and monocytes was NLRP3 inflammasome dependent. *In vivo* inhibition of NLRP3 either by administration of MCC950 (NLRP3-inhibitor), or genetic deletion of NLRP3, significantly attenuated liver damage, neutrophil infiltration, NETs formation and fibrosis in steatohepatitis model. A similar protective phenotype was observed when NETs were disrupted by DNase treatment *in vivo*. **Conclusion:** We show that alcohol binges plus NASH induce steatohepatitis, neutrophil infiltration, NETs and fibrosis. Cell-free NETs directly induce pro-fibrotic stellate cells and pro-inflammatory monocyte phenotypes. Inhibition of NLRP3 or NET disruption by DNase treatment can prevent stellate cell and monocyte activation both *in vitro* and *in vivo* and attenuating liver injury. Thus, inhibition of NETs and/or NLRP3 may represent a therapeutic target to combat the pro-fibrotic effects of alcohol in NASH.

3409-A | DKK3-EXPRESSING FIBROBLASTS PROMOTE HCC/ICC TUMOR PROGRESSION

Neda Yahoo[1], Florian Müller[1], Paula Cantallops Vilà[2], Mirian Fernández Vaquero[3], Silvia Affo[2] and Mathias Heikenwälder[3,4,5], (1)German Cancer Research Center, Dkfz, (2)Idibaps, (3)Division of Chronic Inflammation and Cancer, German Cancer Research Center, Heidelberg, Germany, (4)The M3 Research Institute, (5) Heidelberg University

Background: Hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (iCC) are the two most common primary liver cancers occurring in the chronic inflamed liver. The liver tumor microenvironment (TME) consists of different cell populations including cancer cells, infiltrating immune cells, endothelial cells and cancer associated fibroblasts (CAFs). CAFs are a very heterogenous cell-population within the TME, and they have a substantial influence on the development and progression of cancer through a wide variety of mechanisms including, secretion of cytokines and growth factors. We have identified a glycoprotein DKK3 specifically expressed in the liver tumor area by CAFs and we aim to investigate the potential of genetic or therapeutic suppression of DKK3 in controlling the liver cancer progression. **Methods:** Non-alcoholic steatohepatitis (NASH)-HCC model: C57BL/6 and DKK3 knockout ($DKK3^{-/-}$) mice were fed with choline-deficient high fat diet for 12 months to induce NASH and NASH-HCC. iCC model: To develop an iCC model, six-eight-week old mice were injected through hydrodynamic tail vein injection with different combinations of tumor oncogene plasmids and were characterized 6-8 weeks post injection. CAF isolation: CAFs were isolated by in situ liver perfusion/in vitro digestion and gradient centrifugation. Cells were further purified and sorted by negative selection strategy (EpCAM-CD45-CD31-) and submitted to the 10x genomics for library preparation and scRNA sequencing. Sphere formation: DKK3 knockout LX2 cells or control LX2 cells co-cultured with either hepatoma cell line, Hep3b, or cholangiocarcinoma cell line, Hucct-1, in ultra-low attachment plate to form spheres. **Results:** Co-localization of DKK3 and αSMA in fibrotic TME shows that activated fibroblasts are responsible for DKK3 expression in HCC and iCC. scRNA seq analysis not only confirmed our histological observations but also

revealed that the two most common fibroblast subsets including inflammatory CAFs and myofibroblastic CAFs are high expressors of DKK3. Notably, these findings are corroborated in human primary liver cancers. The comparison between tumor growth in wild type and knockout mice in NASH-HCC model shows the significant reduction in tumor size in DKK3$^{-/-}$ livers compare to wild type counterparts. This is corroborated with reduced proliferation of cancer cells in the absence of DKK3+ fibroblasts. Notably, CD44v6 + cancer cells are barely seen in knockout tumors while the corresponding control wild type HCC are enriched with CD44v6+ cancer cells. In iCC model the number of large lesions was significantly higher in wild type mice when compared to DKK3$^{-/-}$ mice. In addition, deletion of DKK3 results in higher infiltration of immune cells into the tumor. **Conclusion:** DKK3 is expressed by activated fibroblasts within tumors and DKK3+ fibroblasts have a tumor promoting activity in both primary liver cancer types, HCC and iCC.

3410-A | DRUG-INDUCED PERTURBATIONS OF NON-PARENCHYMAL STELLATE CELLS IN HUMAN LIVER ORGANOIDS USING CELL PAINTING AND SINGLE-CELL RNA SEQUENCING

Sophia Meyer[1], Charles Zhang[1], Robert J. Fontana[2] and Jonathan Sexton[3], (1)University of Michigan, (2) University of Michigan Medical Center, Ann Arbor, MI, (3)University of Michigan Medical Center

Background: In efforts to develop more physiologic in vitro models of human drug-induced liver injury (DILI), directed differentiation of stem cells towards human liver cells and multicellular human liver organoids (HLOs) have been developed. Here, we employ a multicellular HLO microfluidic chip platform as a model of DILI that is composed of ~60% hepatocytes, ~20-30% hepatic stellate cells (HSCs), and < 1% tissue-resident macrophages. There are limited in vitro HSC models that are capable of exhibiting physiologically relevant quiescent and activated states. We hypothesize that the HSC population of our HLO model is capable of drug-specific fibrotic intercellular signaling. **Methods:** Induced pluripotent stem cell line 72.3 was differentiated into definitive endoderm and then to HLOs over 28 days. HLOs were dispersed into single cells and cultured either on 384-well plates or microfluidic chips (HLO-chips). After 7 days of culture, cells were harvested for CYP450 expression quantification by qRT-PCR or CYP450 activity with 1- and 2-hour drug incubation by LC-MS. Mature HLO-chips at day 7 were cultured with either acetaminophen or fialuridine for an additional 7 days and stained for high-content imaging or harvested for single-cell RNA sequencing using NovaSeq 600. **Results:** Our HLO model is primarily composed of functional hepatocytes as evidenced by biomarkers, CYP450 expression, and CYP450 activity. The hepatic stellate cell population accounts for ~20-30% of the HLO population identified by reelin and desmin expression and 3-5% of HSCs express α-SMA. Under acetaminophen and fialuridine treatment, the hepatocyte population demonstrated evidence of intrinsic hepatotoxicity with elevated ALT and AST and decreased albumin expression. scRNA-seq analysis of the HSC population showed three distinct transcriptional profiles including an activated HSC state that was characterized by higher expression of inflammatory and cell proliferation markers. In addition, we observed a greater than 30% increase in the activated HSC population upon treatment with acetaminophen and fialuridine. Morphological profiling of distinct HSC phenotypes with high-content imaging will be presented. **Conclusion:** Along with parenchymal function displayed by hepatocytes, HSCs from our HLO model display mechanotransduction competency that can be specifically perturbed by hepatotoxic drug treatment. The HSC population is activated under drug treatment and cell signaling is specifically perturbed. Further development of the HLO-derived HSC may provide a superior bioassay system for modeling hepatic stellate cell dynamics.

B)

HSC Phenotype (scRNA-seq Markers)	Day 7 Control (DMSO)	1μM Fialuridine x 7 Days	100μM Acetaminophen x 7 Days
Quiescent (NTM, MAPT, NGFR, GFAP)	80%	40%	20%
Activated (ACTA2, COL1A1, LOX)	2%	35%	38%
Inactivated (PPARA, DBP, NGFR, GFAP)	18%	25%	18%

Fig 1. 3411-A | FIBROBLAST-SPECIFIC ADIPOCYTE ENHANCER BINDING PROTEIN 1 IS A POTENTIAL PATHOLOGICAL TRIGGER AND PROGNOSTIC MARKER FOR LIVER FIBROSIS INDEPENDENT OF ETIOLOGY

Wen Zhang[1,2], Yujia Li[3], Wei Chen[4,5], Ning Zhang[1,2], Yameng Sun[1,2], Shuyan Chen[1,2], Tao Huang[4,5] and Hong You[1,2], (1)Liver Research Center, Beijing Friendship Hospital, Capital Medical University, (2) Beijing Key Laboratory of Translational Medicine in Liver Cirrhosis, National Clinical Research Center of Digestive Diseases, Beijing, China, (3)Emory National Primate Research Center, Emory University, (4)Beijing Clinical Research Institute, Beijing, China, (5) Experimental and Translational Research Center, Beijing Friendship Hospital, Capital Medical University

Background: The glycosylated adipocyte enhancer binding protein 1 (AEBP1) is an extracellular protein involved in adipogenesis, epithelial-mesenchymal transition, epithelial cell hyperplasia and collagen fibrillogenesis. The main study objective was to analyze the potential of AEBP1 as a pathological target or prognostic marker for liver fibrosis regardless of etiology. **Methods:** Dysregulation pattern, clinical relevance and biological significance of *AEBP1* gene in liver fibrosis were analyzed using publicly available transcriptomic profiles, different liver fibrosis mouse models, biological databases, and *AEBP1* gene silence followed by RNA sequencing in human hepatic stellate cells (HSCs). **Results:** *AEBP1* was upregulated and positively correlated with liver fibrogenesis independent of any etiology, which was further verified in liver fibrosis mouse models induced by different pathogenic factors. Higher expression of liver *AEBP1* gene had potential to predict poor prognosis in liver fibrosis. Systematical bioinformatics analyses revealed *AEBP1* expression was HSCs-specific and associated with ECM remodeling and its downstream mechanical-chemical signaling transition. *AEBP1* knockdown by specific siRNAs in HSCs inhibited ECM-receptor interaction and immune-related pathways as well as HSCs proliferation.
Conclusion: Our current study confirmed high expression of *AEBP1* was specifically associated with liver fibrosis and predicted its poor prognosis and the role of AEBP1 in HSCs, providing a new insight for understanding AEBP1 in liver fibrosis.

3412-A | FIBULIN-1 DEFICIENCY ALLEVIATES LIVER FIBROSIS THROUGH INHIBITING HEPATIC STELLATE CELLS ACTIVATION VIA p38 MAPK PATHWAY

Jingyu Zhang, Wenshan Zhao and Wen Xie, Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, China

Fibulin-1 deficiency alleviates liver fibrosis through inhibiting hepatic stellate cells activation via p38 MAPK pathway Jingyu Zhang[1#], Wenshan Zhao[1#],Wen Xie[1*] [1]Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, China; **Background:** The stablization of elastin has been linked with reversibility of fibrosis. Fibulin-1 could participate in elastin assembly which promoted its stability. However, the role of Fibulin-1 in liver fibrosis has not been characterized. **Methods:** We examined the expression and localization of Fibulin-1 in CCl_4-induced liver fibrosis mouse models and cirrhosis patients. We constructed Fibulin-1-siRNA and overexpression plasmid to investigate the influence of Fibulin-1 on HSCs. Furthermore, we inhibited the expression of Fibulin-1 *in vivo* to observe the effect on elastin deposition and liver fibrosis reversal. Moreover, the regulation of elastin in different conditions on HSCs were detected. Finally, we used transcriptomic analysis to screen out the possible mechanism of Fibulin-1 in fibrosis and further confirmation was preformed *in vitro*. **Results:** Firstly, we

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

found that Fibulin-1 level was increased in liver fibrosis models and plasma of cirrhosis patients, in parallel with significant accumulation of Fibulin-1 in cirrhosis stage. Fuctional analyses showed that Fibulin-1 silencing in HSCs could inhibit the HSCs activation, while the opposite effects were detected in Fibulin-1 overexpression. Moreover, Fibulin-1 depletion in CCl_4-induced liver fibrosis models could markedly ameliorated fibrosis progression, accompanied with decreased expression of profibrogenic genes and insoluble elastin contents. Furthermore, Fibulin-1D increased during liver fibrogenesis, rather than Fibulin1C, which might play a major role in elastin assembly. The stiffness of elastin combined with Fibulin-1D recombinant protein was dramatically increased than that of elastin alone. Based on these coated-plate models, LX-2 cells co-cultured with elastin and Fibulin-1D showed a higher expression levels of α-SMA, elastin and collagen I than those in elastin. Mechanistically, integrated RNA-sequencing and bioinformatic analysis indicated that Fibulin-1 mediated p38 MAPK pathway activation and inhibitor of p38 was used for further confirmation *in vitro*. **Conclusion:** Fibulin-1 deficiency alleviated liver fibrosis through reducing insoluble elastin, HSCs activation and p38 MAPK pathway might participate in the function of Fibulin-1.

3413-A | GADD45 α- REGULATES HEPATIC STELLATE CELL ACTIVATION

Jessica Maiers[1], Reese A Baxter[1], Wenjun Zhang[2], Ethan D Goins[1], Alexander Jackson[1], Zachary Hanquier[1] and Burcin Ekser[1], (1)Indiana University School of Medicine, (2)Division of Transplant Surgery, Department of Surgery, University School of Medicine

Background: Chronic liver disease is a global health concern resulting from sustained liver injury. Liver damage activates hepatic stellate cells (HSCs) which deposit extracellular matrix proteins to drive fibrosis. Activated HSCs exhibit endoplasmic reticulum (ER) stress which induces the Unfolded Protein Response (UPR). UPR signaling in activated HSCs promotes fibrogenesis, but the profibrotic mechanisms downstream of the UPR are unclear. Our prior work showed that HSC activation and survival is dependent on UPR signaling downstream of Activating Transcription Factor 6α (ATF6α). Published scRNAseq analysis of HSCs isolated from CCl_4-treated mice revealed increased expression of Growth arrest and DNA-damage-inducible protein (GADD45A) compared to HSCs from controls. GADD45A is a UPR responsive protein which binds and modifies kinases and is implicated in cell survival. These data led us to study whether ATF6α facilitates HSC activation and fibrogenesis through GADD45A. **Methods:** RNAseq data from cirrhotic or non-cirrhotic livers was analyzed for *GADD45a* expression (GSE14323). Primary human HSCs (hHSCs) were treated with TGFβ ± ATF6α inhibitor Ceapin-A7 for 24h and analyzed by Western blot and qPCR. HSCs were isolated from non-fibrotic patients, immortalized, treated with TGFβ for 24h, and analyzed by mass spectrometry. LX-2 cells (immortalized HSCs) were transfected with siRNA targeting GADD45A or a scrambled oligo, and treated with vehicle or TGFβ. HSC activation was analyzed by qPCR, Western blot, or microscopy. *Gadd45a* $^{fl/fl}$ and *Gadd45a*$^{HSC\ \Delta/\Delta}$ mice received biweekly injections of CCl_4 or vehicle for 6 weeks before livers were harvested. Fibrosis markers were analyzed by hydroxyproline assay, Sirius Red staining, Western blot, and qPCR. **Results:** GADD45a expression increased in patients with cirrhosis and in hHSCs treated with TGFβ. TGFβ induction of GADD45a was blocked by ATF6α inhibition ($p < 0.05$). Proteomics analysis of HSCs isolated from patients revealed significant changes in several GADD45A binding partners (MAPK14, AURKA, CLEC3B, DNM2) following TGFβ treatment, and altered signaling downstream of GADD45A binding partners IRGM and p53. siRNA-mediated knockdown of GADD45A mitigated HSC activation and fibrogenesis, limiting both procollagen I induction by TGFβ and collagen I deposition ($p < 0.001$). In contrast to our *in vitro* findings, conditional deletion of *Gadd45α* from HSCs did not limit CCl_4-induced liver injury and increased *Col1a1* expression. **Conclusion:** We show that GADD45A is important for HSC activation and fibrogenesis downstream of ATF6α *in vitro*, but this role did not translate *in vivo*. This could be due to the diverse roles of GADD45A binding partners in HSCs or discrepancies between mouse and human HSCs. Future work will focus on understanding how GADD45A regulates HSC activation through its downstream targets, and how these mechanisms are differentially regulated between humans and mice.

3414-A | GALECTIN-9+ MACROPHAGES ATTENUATE LIVER FIBROSIS BY SUPPRESSING ACTIVATED HEPATIC STELLATE CELLS THROUGH TIM-3

Chaerin Woo, Tom Ryu, Min Jeong Kim, Song Hwa Hong and Won-Il Jeong, Kaist

Background: Liver fibrosis is characterized by the excessive accumulation of extracellular matrix, and

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

currently, there is no standard treatment available. Recent studies have reported a correlation between serum galectin-9 levels and the extent of liver fibrosis in patients. However, the involvement of galectin-9 and its receptor, T-cell immunoglobulin mucin domain-containing-3 (Tim-3), in liver fibrosis remains unclear. Therefore, we investigated the specific cell types for the expression of galectin-9 and Tim-3, and their roles in the liver fibrogenesis. **Methods:** Liver fibrosis was induced in C57BL/6 wild-type (WT), Tim-3 knockout (Tim-3KO), and hepatic stellate cell (HSC)-specific Tim-3 conditional knockout (Tim-$3^{\Delta HSCs}$) mice. Serum and liver samples were collected for the biochemical and histopathological assessments including Sirius red staining and immunofluorescent staining, and the analyses of qRT-PCR and bulk-RNA sequencing. The liver mononuclear cells (MNCs) were subjected to flow cytometry analysis. Primary HSCs were isolated and cultured for subsequent *in vitro* experiments. **Results:** At sacrifice, serum levels of galectin-9 significantly increased in fibrotic WT mice compared to the control WT mice. In addition, qRT-PCR and FACS analyses revealed the increased expression of galectin-9 in $CD11b^{+}Ly6G^{+}$ neutrophils and $CD11b^{+}F4/80^{+}$ macrophages. Immunofluorescent staining showed that most galectin-9-expressing cells were macrophages and localized in fibrotic septa. However, Tim-3KO mice showed more increased liver fibrosis with Sirius red staining and elevated mRNA expression of *Acta2* and *Col1a1* than those of WT mice. Interestingly, bulk-RNA sequencing analysis demonstrated an upregulation of Tim-3 mRNA in activated WT HSCs compared to quiescent WT HSCs, which was also confirmed by qRT-PCR analysis. Moreover, treatments of recombinant galectin-9 decreased *Acta2* and *Col1a1* mRNA levels in activated WT HSCs but not in Tim-3-deficient HSCs. Furthermore, liver fibrosis was more severe in Tim-$3^{\Delta HSCs}$ mice than WT mice, with increased collagen accumulation and higher mRNA levels of *Acta2* and *Col1a1* in liver tissues. **Conclusion:** Our findings suggest that the galectin-9/Tim-3 axis contributes to the attenuation of liver fibrosis by suppressing HSC activation. Therefore, the interplay between galectin-9^{+} macrophages and Tim-3^{+} HSCs could be a potential therapeutic intervention for liver fibrosis.

f 3415-A | GLYCOLYSIS-DEPENDENT EXTRACELLULAR VESICLES FROM HEPATIC STELLATE CELLS PROMOTE IN VIVO LIVER FIBROSIS.

Shalil Khanal[1], Ivan Vuckovic[1], Song Zhang[1], Vijay Shah[2] and Enis Kostallari[3], (1)Mayo Clinic, (2)Mayo Clinic Rochester, Rochester, MN, (3)Mayo Clinic, Rochester, Rochester, MN

Background: Platelet-derived growth factor (PDGF)-activated hepatic stellate cells (HSCs) release fibrogenic extracellular vesicles (EVs), important in cell-to-cell communication. Moreover, activated HSCs display increased glycolysis. While we have previously demonstrated that glycolysis is involved in EV release and liver fibrosis, the aim of this study is to decipher the mechanism of how HSC-specific glycolysis promotes biogenesis of fibrogenic EVs and how transplanting these EVs *in vivo* amplifies liver fibrosis. **Methods:** Primary human HSCs were examined by Glucose-Glo^{TM} assay, nuclear magnetic resonance (NMR) immunofluorescence (IF), electron microscopy (EM), qPCR and western blot (WB). *In vivo,* EVs were transplanted intraperitoneally, and liver fibrosis was induced by carbon tetrachloride (CCl_4) administration. **Results:** *In vitro*, PDGF increased glucose consumption (Glucose-Glo^{TM}, $n = 3$, $p < 0.05$) and lactate production (NMR, $n = 3$, $p < 0.05$) as compared to vehicle, suggesting that PDGF increases glycolysis in HSCs. Since PDGF also enhances HSC-derived EV biogenesis and subsequent release, we examined the effect of glycolysis on EV biogenesis. HSCs were treated with glucose or 2-deoxyglucose (2DG), where 2DG is a modified glucose that cannot be metabolized. Compared to glucose, 2DG significantly decreased multivesicular body (MVB)-associated CD63 staining by 2-fold (IF, $n = 5$, $p < 0.05$) and intraluminal vesicle number per MVB by 1.5-fold (EM, $n = 3$, $p < 0.05$), suggesting that glycolysis promotes EV biogenesis. Functionally, EVs from glucose-treated donor HSCs enhanced mRNA and protein levels of collagen 1 alpha 1 (Col1a1) and alpha smooth muscle actin (αSMA) in recipient HSCs by 1.5-2-fold compared to no-glucose condition. This was abrogated by EVs from 2DG-treated donor HSCs ($n = 4$, $p < 0.05$). To investigate the fibrogenic role of glycolysis-dependent EVs *in vivo*, we performed a mouse-to-mouse EV transplant. We utilized glycolysis-deficient donor mice where hexokinase 2 (HK2) is deleted specifically in PDGFRβ^{+} HSCs, namely $HK2^{\Delta HSC}$ mice, and their $HK2^{fl/fl}$ controls. Compared to control, EVs from CCl_4-treated $HK2^{fl/fl}$ donor mice significantly increased Sirius red staining, Col1a1 and aSMA mRNA levels by 2.5, 3 and 2-fold, respectively. However, fibrosis was reduced when recipient mice were administered with EVs isolated from CCl_4-treated $HK2^{\Delta HSC}$ mice (9-10 mice/group, $p < 0.05$). **Conclusion:** Our results suggest that HSC-specific glycolysis promotes EV biogenesis to amplify fibrosis *in vitro* and *in vivo*.

3416-A | HEPATIC STELLATE CELL-DERIVED THROMBOSPONDIN-2 AS A NOVEL THERAPEUTIC TARGET FOR LIVER FIBROSIS

Ning Zhang[1], Xiaoning Wu[2], Wen Zhang[1], Xuzhen Yan[3], Anjian Xu[1], Qi Han[4], Aiting Yang[3], Hong You[1] and Wei Chen[1], (1)Liver Research Center, Beijing Friendship Hospital, Capital Medical University, (2)Liver Research Center, Beijing Friendship Hospital, Capital Medical University, National Clinical Research Center of Digestive Diseases, Beijing, China, (3)Beijing Clinical Research Institute, Beijing, China, (4)Beijing Key Laboratory of Translational Medicine in Liver Cirrhosis, National Clinical Research Center of Digestive Diseases, Beijing, China

Background: Thrombospondin-2 (THBS2) dysregulation is closely associated with liver fibrosis regardless of etiology, and emerging to be a potential circulating biomarker. However, whether and how THBS2 acts a prominent role in the pathogenesis of liver fibrosis has not been elucidated yet. **Methods:** The *in vivo* effects of silencing *Thbs2* in hepatic stellate cells (HSCs) were examined using an adeno-associated virus vector (serotype 6, AAV6) containing short hairpin RNAs (shRNAs) targeting *Thbs2*, under the regulatory control of cytomegalovirus (CMV), U6 or smooth muscle α-actin (αSMA) promoter, in carbon tetrachloride (CCl_4) induced liver fibrosis mouse models. Crosstalk between THBS2 and toll-like receptor 4 (TLR4) as well as the cascaded signaling was systematically investigated in mouse models, primary HSCs, and human HSC cell lines. **Results:** THBS2 was predominantly expressed in activated HSCs and dynamically increased with liver fibrosis progression and decreased in regression. Selective interference of HSC *Thbs2* evidently retarded fibrosis progression and intrahepatic inflammatory infiltration (~55% inhibition) in mouse models challenged by CCl_4 intoxication. Mechanically, extracellular THBS2, as a dimer, specifically recognized and directly bound to TLR4 receptor, activating HSCs via stimulating downstream profibrotic focal adhesion kinase (FAK)/transforming growth factor beta (TGF-β) pathways. Disruption of THBS2-TLR4-FAK/TGF-β signaling axis notably alleviated HSC activation and liver fibrosis aggravation. **Conclusion:** THBS2 plays a crucial role in HSC activation and liver fibrosis progression through TLR4-FAK/TGF-β signaling in an autocrine manner. Therapies targeting HSC *Thbs2* via AAV6 vector-capsulated shRNA may represent a novel promising strategy to prevent or treat liver fibrosis.

3417-A | HYDRONIDONE AMELIORATES LIVER FIBROSIS BY INHIBITING ACTIVATION OF HEPATIC STELLATE CELLS VIA Smad7-MEDIATED DEGRADATION OF TGFβRI

Xianjun Xu[1], Yuecheng Guo[1], Xin Luo[1], Zhenyang Shen[1], Zhongshang Sun[2], Bo Shen[1], Cui Zhou[1], Junjun Wang[1], Jingyi Lu[1], Qingqing Zhang[1], Yanping Ye[3], Ying Luo[3], Ying Qu[1], Xiaobo Cai[1], Hui Dong[1] and Lungen Lu[1], (1)Shanghai General Hospital, Shanghai Jiao Tong University School of Medicine, (2)Huaian First People's Hospital, Nanjing Medical University, (3)Continent Pharmaceuticals Co., Ltd.

Background: Liver fibrosis is a wound-healing reaction that eventually leads to cirrhosis. Hydronidone (HDD) is a new pyridine derivative with the potential to treat liver fibrosis. In this study, we explored the antifibrotic effects of HDD and its potential mode of action. **Methods:** Histology, western blot, immunofluorescence staining, and RT-qPCR were used to detect the antifibrotic effect of HDD on 3, 5-diethoxycarbonyl-1, 4-dihydropyridine (DDC) and carbon tetrachloride (CCl_4) mouse hepatic fibrosis models. The effects of HDD on the activation of hepatic stellate cells were detected by western blot, immunofluorescence staining and RT-qPCR. Transcriptome sequencing analysis of HDD in hepatic stellate cells. Intervention of Smad7 in hepatic stellate cells with lentivirus and plasmid. The effect of HDD on transforming growth factor β receptor I (TGFβRI) was detected by western blot and immunoprecipitation. Construction of adeno-associated virus targeting Smad7 in hepatic stellate cells. **Results:** In DDC and CCl_4 mouse hepatic fibrosis models, HDD alleviated liver damage, collagen accumulation, decreased the expression of fibrosis-related genes, and inhibited the activation of hepatic stellate cells. HDD decreased the expression of fibrosis gene in hepatic stellate cells. HDD significantly up-regulated Smad7 expression and inhibited TGFβ-Smad signaling pathway in hepatic stellate cells. HDD promoted Caveolin-1 (Cav-1) mediated TGFβRI degradation via Smad7. Specific knockdown of Smad7 in vivo blocked the antifibrosis effect of HDD. **Conclusion:** HDD ameliorates liver fibrosis by inhibiting hepatic stellate cells activation via Smad7-mediated TGFβRI degradation. HDD is a potential drug candidate for the treatment of liver fibrosis.

3418-A | INHIBITION OF ENDOGENOUS HYDROGEN SULFIDE PRODUCTION REDUCES ACTIVATION OF HEPATIC STELLATE CELLS VIA THE INDUCTION OF CELLULAR SENESCENCE

Sandra A. Serna Salas[1], Turtushikh Damba[2], Mengfan Zhang[3], Zongmei Wu[1], Harry Van Goor[4], Javier Ventura-Juarez[5], Martin Humberto Munoz-Ortega[5], Manon Buist-Homan[6] and Han Moshage[1], (1)University Medical Center Groningen, (2)Mongolian National University of Medical Sciences, (3)Hospital of Zhengzhou University, (4)Umcg, (5)Universidad Autonoma De Aguascalientes, (6)University Medical Center of Groningen

Background: In fibrogenesis, quiescent hepatic stellate cells (HSCs) transdifferentiate into activated myofibroblast-like cells and produce large amounts of extracellular matrix. Cellular senescence is characterized by irreversible cell-cycle arrest, arrested cell proliferation and the acquisition of the senescence associated secretory phenotype (SASP) and reversal of HSCs activation. We hypothesized that inhibition of endogenous H_2S production induces cellular senescence and reduces activation of HSCs. **Methods:** Rat HSCs were isolated and cultured-activated and treated with H_2S slow releasing donor GYY4137 and/or DL-propargyl-glycine (DL-PAG), an inhibitor of the H_2S producing enzyme CTH, as well as the PI3K inhibitor LY294002. Senescence was determined by measuring the cell-cycle arrest markers Cdkn1a, p53, the SASP marker Il-6 and the activity of the senescence marker β-galactosidase. **Results:** CTH expression was significantly increased in fully activated HSCs compared to quiescent HSCs. Inhibition of CTH reduced proliferation and expression of fibrotic markers Col1a1 and Acta2 in HSCs and increased the cell-cycle arrest markers Cdkn1a, p53 and the SASP marker Il-6 as well as the number of β-galactosidase positive senescent HSCs was increased. H_2S donor GYY4137 partially restored the proliferation of senescent HSCs and attenuated the DL-PAG-induced senescent phenotype. Inhibition of PI3K partially reversed the senescence phenotype of HSCs induced by DL- PAG. **Conclusion:** Inhibition of endogenous H_2S production reduces HSCs activation via induction of cellular senescence in a PI3K-Akt dependent manner. Our results suggest that cell specific inhibition of endogenous H_2S production could be novel target for anti-fibrotic therapy via induction of cell senescence.

3419-A | LONG-TERM ACCUMULATIONS OF POLYSTYRENE NANOPLASTICS SPECIFICALLY ACTIVATE HEPATIC STELLATE CELLS

Jae-Hyuk Yim, Su-Min Baek, Tae-Un Kim, Woo Jun Kim and Jin-Kyu Park, Kyungpook National University

Background: As plastics use increased, nanoplastics ingestion frequently increased by food or water due to environmental pollution. There have been several studies

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

showing that the ingestion of nanoplastics can cause damages to the marine lives by accumulation of nanoplastics in livers, kidneys, and brains. However, there is a lack of studies on how the accumulation of nanoplastics can cause organ damages in mammals over a long period of time. Therefore, we assessed the effects of long-term accumulation of nanoplastics on mammal liver and evaluated the risk of liver fibrogenesis. **Methods:** Liver fibrosis was induced by CCl_4 and polystyrene nanoplastics (PS-NPs) were injected 5 times a week for 12 weeks. Gross examination and histopathological analysis, serum biochemistry, immunofluorescence (IF) and immunohistochemistry (IHC) were performed to assess liver injury and fibrosis. Western blot and qRT-PCR were performed to reveal the related genes. **Results:** For 12 weeks, a scattered accumulation of PS-NP was observed in mice livers. Interestingly, some of PS-NPs were accumulated in α-SMA positive cells. When examining the α-SMA positive expression level in liver administered with PS-NP compared to liver without PS-NP, a higher number of extravascular α-SMA positive spindle cells were observed in PS-NP administered group. Furthermore, in western blot, it was found that the expression of α-SMA protein in the liver tissue was significantly increased in the PS-NP administrated group compared with the non PS-NP group. To analyze the effect of PS-NP on activation of hepatic stellate cells (HSCs), mice were treated with CCl_4 and PS-NP to induce liver fibrosis for 3 weeks. As a result of CCl_4 and PS-NP administration, it was confirmed that the number of α-SMA positive cells significantly increased, and α-SMA protein expression levels also increased by PS-NP administrations. **Conclusion:** This study has shown that long-term administration of PS-NPs were generally accumulated in the HSCs, thereby causing activation of these cells. HSCs, a key cell for inducing liver fibrogenesis, showed a higher α-SMA expression levels in the PS-NP treated groups compared with those non PS-NP treated groups in the CCl_4 group, which suggests continuous consumption of PS-NP promotes liver fibrosis by PS-NP induced HSC activations.

3420-A | MAGP1 DEFICIENCY AUGMENTS EXTRACELLULAR MATRIX STABILITY AND RETARDS LIVER FIBROSIS REGRESSION VIA UPREGULATING MATRIX LOXL1

Wen Zhang[1,2], Wei Chen[3,4], Ning Zhang[1,2], Yameng Sun[1,2], Shuyan Chen[1,2], Xuzhen Yan[3,4], Qi Han[1,2], Aiting Yang[3,4] and Hong You[1,2], (1)Liver Research Center, Beijing Friendship Hospital, Capital Medical University, (2)Beijing Key Laboratory of Translational Medicine in Liver Cirrhosis, National Clinical Research Center of Digestive Diseases, Beijing, China, (3)Beijing Clinical Research Institute, Beijing, China, (4) Experimental and Translational Research Center, Beijing Friendship Hospital, Capital Medical University

Background: Microfibril-associated glycoprotein 1 (MAGP1) is a glycoprotein in the extracellular matrix (ECM) involved in the formation of microfibrillar skeletal structures. Up to present, the relationship between MAGP1 and liver fibrosis has not been reported yet. Herein, we aim to investigate the expression pattern, potential role, and possible mechanisms of MAGP1 involved in liver fibrosis. **Methods:** The expression pattern of MAGP1 in liver fibrosis was examined using publicly available transcriptomic gene expression profiles, tissue array of cirrhotic patients and carbon tetrachloride (CCl_4)-induced liver fibrosis mouse models. The roles of MAGP1 in liver fibrosis progression and regression were investigated using *Mfap2*(MAGP1 gene) knockout mice (*Mfap2*$^{-/-}$) undergoing CCl_4 injection or cessation. Mechanisms of MAGP1 deficiency involved in ECM stability and liver fibrosis regression were further explored using tissue decellularization, mass spectrometry proteomics, bulk RNA sequencing, and *in vitro* studies with human hepatic stellate cells (HSCs). **Results:** MAGP1 was predominantly expressed in activated HSCs and dynamically increased with liver fibrosis progression and decreased in regression. *Mfap2* knockout had no significant effect on liver fibrosis progression but increased ECM inflammatory infiltration and activated hepatic focal adhesion signal. However, interestingly, *Mfap2* ablation delayed the reversal of liver fibrosis after CCl_4 cessation. Liver decellularization followed by mass spectrometry proteomics revealed a significant increase in ECM insoluble collagen I and lysyl oxidase-like 1 protein (LOXL1) in *Mfap2*$^{-/-}$ mice compared to their littermates, which represented a possible cause resulting in the inhibition of liver fibrosis regression after

Mfap2 ablation. Further *in vitro* experiments in human HSCs confirmed overexpression of MAGP1 could inhibit LOXL1 expression, highlighting a compensatory crosstalk with each other. **Conclusion:** MAGP1 deficiency significantly promoted ECM stability and delayed liver fibrosis regression, compensatively by increasing matrix LOXL1 level. Our study might gain novel knowledge underlying liver fibrosis regression.

3421-A | MECHANISM OF LIVER FIBROSIS CAUSED BY AUTOPHAGY-DEFICIENCY

Arissa Mercer, Bilon Khambu and Xiao-Ming Yin, Tulane University School of Medicine, New Orleans, LA

Background: Autophagy-deficiency in hepatocytes presents liver pathologies such as liver injury, inflammation, and fibrosis similar to common liver diseases affected by autophagy impairment. It is unknown how fibrosis develops in livers that are autophagy deficient. This study aims to examine the kinetics and mechanism of liver fibrosis development in autophagy-deficient livers. **Methods:** A conditional and inducible model of liver specific Atg7 knockout was characterized for liver fibrosis. Atg7 deletion was induced by tamoxifen injection on days 1 and 2. Trichrome C staining and Desmin or aSMA immunofluorescence staining or immunohistochemistry were used to assess the presence of fibrosis and the upregulation of fibrosis-related cells. Quantitative polymerase reaction and immunoblotting were used to examine fibrotic genes and proteins. **Results:** We found that Trichrome C staining for collagen was increased on the 20th day following Atg7 knockout. We also saw that markers for hepatic stellate cells and portal fibroblasts were increased in a pattern aligning with their involvement in the initiation and continuation of hepatic fibrosis. **Conclusion:** Autophagy-deficient livers activate portal fibroblasts (PF) and hepatic stellate cells (HSC) following an injury to the liver. The activation of PFs and HSCs can lead to the development of liver fibrosis in autophagy-deficient livers. The underlying signaling mechanism of PF and HSC activation and fibrosis development in the autophagy-deficient liver is currently being investigated. This study will be clinically relevant in understanding molecular events that are important in the early stages of liver diseases.

3422-A | MEDIUM-CHAIN FATTY ACIDS SUPPRESS COLLAGEN PRODUCTION AND ALTER THE PHENOTYPE OF HEPATIC STELLATE CELLS

Masashi Sakaki, Joo-Ri Kim-Kaneyama, Masahito Noguchi, Aya Miyauchi, Takahiro Fuji, Yumi Otoyama, Yoko Nakajima, Ikuya Sugiura, Jun Arai, Yuki Ichikawa, Shojiro Uozumi, Yuu Shimozuma, Manabu Uchikoshi and Hitoshi Yoshida, Showa University

Background: Medium-chain fatty acids (MCFAs) contain C6–C10 fatty acids that are absorbed from the upper gastrointestinal tract, transported to the liver via the portal vein, and rapidly become an energy source for hepatocytes. MCFA supplementation improves the metabolic pathology of adult-onset type II citrullinemia which pathogenesis is impairment of glycolysis, lipogenesis, and energy metabolism in hepatocytes by providing hepatocyte energy supply. Hence, the metabolic functions of the liver may be directly influenced by dietary intake of MCFAs. However, the detailed mechanism remains unclear. MCFAs may affect the pathogenesis of NASH, and in vitro, MCFAs may suppress collagen production in hepatic stellate cells (HSC) and alter the phenotype of HSC. **Methods:** NASH-HCC model mice (STZ-HFD) were divided into 4 groups at 10 weeks on (1) control fat diet, (2) medium-chain fatty triglyceride (MCT) diet (C8:C10 = 60%:40%), (3) long-chain triglyceride (LCT) diet, and (4) high carbo diet, and liver tissue steatosis, inflammation and fibrosis were evaluated at 15 weeks. The effects to the hepatic stellate cells of MCFA (C6, C8, C10) on hepatic stellate cells were evaluated in vitro using LX-2 and human hepatocytes (hHSC). **Results:** In the mouse model, MCT diet significantly inhibited steatosis, ballooning, and fibrosis compared to the control group ($p < 0.05$), and C10 stimulation significantly inhibited LX-2 and hHSC collagen production in vitro ($p = 0.039$, $p = 0.0062$). Furthermore, C10 stimulation significantly decreased PDGFRβ($p < 0.0001$) and PAI-1($p < 0.0001$) expression and induced FOXO1 phosphorylation in hHSC. Inactivation of FOXO1 with FOXO1 inhibitor significantly suppressed collagen production in a concentration-dependent manner and attenuated the expression of PAI-1. **Conclusion:** MCFAs have beneficial effects on NASH pathology. C10 may suppress collagen production and alter the phenotype of HSC through FOXO1.

f 3423-A | MMP2+MMP14+TIMP2+ HEPATIC STELLATE CELLS IN LIVER TUMOR VS. LIVER FIBROSIS

Gurmehr Brar[1], Hye Yeon Choi[1], Issei Tsuchiya[1], Natalie Osterlund[1], Janice Seol[1], Linda S. Sher[2] and Hidekatzu Tsukamoto[1], (1)University of Southern California, (2)University of Southern California, Los Angeles, CA

Background: Hepatic stellate cells (HSC) co-expressing MMP2, MMP14, and TIMP2 (triple$^+$), activate MMP2 to mediate both matrix remodeling in liver fibrogenesis and tumor promotion via generation of a COL1 fragment and its binding to DDR1. However, how triple$^+$ HSC differ in liver fibrosis vs. tumor is largely unknown. **Aim:** We aimed to compare transcriptomic profiles of triple$^+$ HSC in liver tumor vs. fibrosis and identify potential tumor promoter genes uniquely expressed by HCC-associated triple$^+$ HSC in mice and patients. **Methods:** Liver IB analysis was performed for pro- vs. activated-MMP2 and intact vs. cleaved COL1 on *Col1a1-GFP* mice with F1-F2 liver fibrosis by alcohol-associated hepatitis (AH), bile-duct ligation (BDL), or CCl4 injections (CCl4) and with HCC by DEN injection and Western alcohol diet (DEN). Col1a1-GFP$^+$ HSC with vitamin A$^+$ (VitA$^+$) or VitA$^-$ were isolated by FACS and subjected to scRNA-seq. Aggregated sequencing data were filtered by *Mmp2*, *Mmp14*, and *Timp2* expression to compare transcriptomes of *Lrat*$^+$ triple$^+$ vs. *Lrat*$^+$ triple$^-$ cells. Patient HCC scRNA-seq data at scAtlasLC of NCI were re-analyzed and 10x Visium spatial transcriptomic analysis performed on patient HCC. **Results:** Active MMP2 and cleaved COL1 were similarly increased in the liver of all 4 models. The percentages of VitA$^+$ *Lrat*$^+$ triple$^+$ and VitA$^-$ *Lrat*$^+$ triple$^+$ cells in total *Lrat*$^+$ HSC were: 33% and 25% in AH, 36% and 52% in BDL, 74% and 64% in CCl4, 17% and 32% in DEN. Despite the lower %, the DEN triple$^+$ cells exhibited distinct transcriptomic profiles vs. the fibrosis models. Twenty-eight and 27 upregulated DEGs were identified in VitA$^+$ triple$^+$ and VitA$^-$ triple$^+$ cells in DEN vs. the fibrosis models. Upregulated DEGs shared by DEN VitA$^+$ and VitA$^-$ *Lrat*$^+$triple$^+$ cells included those implicated in angiogenesis (*Angptl6*), cell growth (*Efemp1*), chemotherapy resistance (*Inmt*), M2 macrophage polarization and EMT (*Bmp4*), and lipid transfer (*Pltp*). VitA$^+$triple$^+$ unique DEGs included *Ecm1* implicated in angiogenesis and *Plvap,* a VEGF-regulated gene in tumor-associated vascular fenestration. VitA$^-$ triple$^+$ unique DEGs included *Ccl19* involved in caner growth, *Sertad1*, a CDK4 stimulator and immunosuppressive *Gsn*. Human HCC spatial transcriptomic analysis revealed the close proximity of *ACTA2*$^+$triple$^+$ spots with *AFP*$^+$ or *HNF4A*$^+$*YAP1*$^+$ spots in HCC nodules and upregulation of the murine DEN triple$^+$ DEGs in *ACTA2*$^+$ triple$^+$ vs. *ACTA2*$^+$ triple$^-$ spots. Re-analysis of patient HCC scRNA-seq data confirmed *MMP2*$^+$ CAF are largely *MMP14*$^+$*TIMP2*$^+$ and their higher expression of the murine triple$^+$ DEGs such as *EFEMP1*, *INMT*, *BMP4*, and *PLTP*. **Conclusion:** HCC-associated triple$^+$ HSC express a unique set of genes with potential tumor promoting activities vs. triple$^+$ cells in liver fibrosis. The triple$^+$ aHSC in patient HCC with these genes upregulated and localized close to HCC cells, suggest their tumor promoting roles in addition to and independent of the COL1-DDR1 mechanism.

3424-A | NEUTROPHIL GRANULOCYTES ARE INVOLVED IN THE DEVITALIZATION OF SCHISTOSOMA MANSONI EGGS

Ricarda Nadja Sölter, Verena Von Bülow, Dorothee Dreizler, Grit Stampa, Thomas Quack, Christoph Gero Grevelding, Max Möscheid, Annette Tschuschner, Heike Müller, Martin Roderfeld and Elke Roeb, Justus-Liebig-University, Giessen

Background: *Schistosoma mansoni* is a widespread parasitic disease with over 250 million people affected worldwide and is characterized by a complex lifecycle starting with the egg excretion with the feces. The larval stage of the cercariae can penetrate human skin. The schistosome couples migrate into the mesenterial veins, where they start the egg production. However, 50% of the eggs are flooded with the blood stream into different organs, like the liver, where they induce a chronic inflammation, leading to liver fibrosis and in combination with for example hepatitis B or C to hepatocellular carcinoma. The immune response is a crucial part of the granuloma formation and the resulting liver fibrosis. It is important to understand this process, to find treatments for *S. mansoni* infections and to stop the development of fibrosis and the carcinogenesis. **Methods:** In an animal experiment 4 groups of C57BL/6 mice were investigated. At the age of 8 weeks, they were infected with 100 cercariae of *Schistosoma mansoni*. 2 groups were also treated with Diethylnitrosamin at the age of 2 weeks to induce hepatocellular carcinoma. In total, 1 group was treated with DEN and infected with *S. mansoni.* Serving as controls, 1 group was treated with DEN and one group was infected with *S. mansoni.* The last group served as a super control. We did a histological grading of the liver tissue focusing on the inflammation and immunohistochemistry stainings of myeloperoxidase and CD-11b. Furthermore, a cocultivation of *S. mansoni* eggs and myeloperoxidase

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

was performed. **Results:** *S. mansoni* infection leads to hepatic inflammation. During the histological grading, about 20% of the eggs seemed to be devitalized. Around and partly in these eggs are myeloperoxidase and CD-11b positive cells. Furthermore, the nuclear shapes are histologically identical to neutrophile granulocytes. The cocultivation of myeloperoxidase and *S. mansoni* eggs resulted in a higher percentage of calcein positive, vital eggs in the heat-inactivated myeloperoxidase group compared with the active myeloperoxidase, meaning the myeloperoxidase devitalize *S. mansoni* eggs *in vitro.* **Conclusion:** In total, neutrophil granulocytes seem to be involved in the destruction of *S. mansoni* eggs in the liver of infected mice. Myeloperoxidase can devitalize the *S. mansoni* eggs *in vivo* and *in vitro.* It might be one of the key substances in the inflammatory responses of the immune system to fight the chronic liver fibrosis, induced by misguided and stuck *S. mansoni* eggs in the liver.

3425-A | OVEREXPRESSION OF AP5M1 IN LIVER ENHANCES CCI4-INDUCED LIVER FIBROSIS BY ACTIVATING TGF-B AND IL11

Ju-Yeon Cho, Tae-Hyoung Kim, Seung-Hyun Myung, Ji-Hye Han and Junghee Park, Chosun University

Background: In the initiation of liver fibrosis, transforming growth factor (TGF)-β plays an important role in the activation of hepatic stellate cells. Dysregulation of TGFβ1 and downstream IL-11 is associated with fibrotic diseases and a recent study reported that IL11 played a crucial role in the development of non-alcoholic steatohepatitis in mouse models. AP5M1, also called MUDENG, is known to participate in cell death and has been reported to be involved in Golgi trafficking. In a previous study by the authors, MUDENG transgenic mice demonstrated rapid development of fibrosis compared to C57BL/6N mice. In this study, we further identified the physiological effects of AP5M1 in mouse liver with overexpression and suppression of IL11. **Methods:** Eight 8-weeks-old male human AP5M1 transgenic (hAP5M1-Tg) mice and eight C57BL/6N male mice were injected with carbon tetrachloride (CCl_4) at a concentration of 2 μl per 1 g of mouse body weight intraperitoneally twice weekly (1:7 dilution with Olive oil). Lenti-mIL11 and Lenti-mIL11 mutein viruses were injected intraperitoneally into 6-week-old mice and intranasally into the mice after a week. (Fig1a-d) Livers were harvested at baseline for control and biweekly after intraperitoneal injection of CCl_4. The difference in the percent collagen area of the MUDENG transgenic mice and C57BL/6N mice was evaluated. Opensource software ImageJ (distributed by NIH) was used to calculate the collagen proportionate area of the liver after undergoing picoSirius red staining. **Results:** The collagen proportionate area (CPA) in C57BL/6N mice infected with Lenti:mIL11 or Lenti:mIL 11 mutein showed no difference in the absence of liver injury caused by CCl_4. However, CCl_4 injected Lenti:mIL11 mutein infected C57BL/6N mice demonstrated significantly reduced collagen accumulation in the liver tissue compared to Lenti:mIL11 infected C57BL/6N mice. (Fig 1e-f) In hAP5M1 transgenic mice, the infection of Lenti:mIL11 or Lenti:mIL 11 mutein showed no significant difference in the CPA. (Fig1g, 1i) The expression levels of collagen, α-SMA, and TGF-β were higher in the liver of hAP5M1-Tg mice challenged with CCl_4 than in the liver of C57BL/6 mice. (Fig1h) **Conclusion:** Overexpression of hAP5M1 enhances liver fibrosis caused by intraperitoneal injection of CCl_4. Compared to previous reported studies demonstrating that IL11 is a key factor of TGF-β-mediated liver fibrosis, C57BL/6N mice injected with Lenti:mIL11 mutein showed significantly reduced collagen accumulation in the liver. The application of IL11 mutein may be considered as a potential treatment method for alleviating liver fibrosis.

3426-A | ROLE OF CEACAM1 IN NASH-ASSOCIATED HEPATIC FIBROSIS

Raziyeh Abdolahipour[1], Harrison T Muturi[1] and Sonia Najjar[2], (1)Ohio University, (2)University of Toledo

Background: Non-alcoholic Fatty Liver disease (NAFLD/NASH) has reached an epidemic rise

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

amounting to a global prevalence of about 25% - 60% in obese individual's and in patients with type 2 diabetes. NASH, a chronic state of liver inflammation and injury, implicates activation of hepatic stellate cells and their transformation into myofibroblasts. This leads to excessive production of extracellular matrix (ECM) and collagen deposition, which destroys the architecture of the liver and causes liver fibrosis and dysfunction. Insulin-resistant obese subjects with NAFLD show low hepatic levels of CEACAM1, a plasma membrane glycoprotein that mediates insulin clearance and repression of fatty acid synthase activity in hepatocytes upon its phosphorylation by the insulin receptor tyrosine kinase. Consistently, CEACAM1 null mice (*Cc1−/−*) display spontaneous hyperinsulinemia and steatohepatitis with hepatic fibrosis when fed a regular diet. Feeding wild-type mice with a high-fat diet reduces CEACAM1 transcription via a mechanism depending on the activation of PPARα by free fatty acids (FFA). We herein tested whether GAN diet similarly reduces hepatic CEACAM1 expression by a PPARα-dependent mechanism and whether this leads to hepatic fibrosis. **Methods:** Knockin mice (Δ*Ppre*) bearing a mutation on the well-conserved PPRE on Ceacam1 promoter were generated and fed a GAN diet (2% cholesterol, 22% fructose, and 20% fatty acids) for 24 weeks to examine whether they are protected against GAN-induced hepatic fibrosis. Metabolic characterization, Western blot analysis and Sirius red staining were conducted to evaluate their NASH phenotype. **Results:** Mutating PPRE/RXRa on Ceacam1 promoter protected CEACAM1 against high-fat diet (45%). Interestingly, GAN diet caused insulin resistance, inflammation, and chicken-wire bridging fibrosis in wild-type but not in Δ*Ppre* knockin mice. In parallel, GAN diet caused a reduction in hepatic CEACAM1 protein levels in wild type but not in Δ*ppre* mice. **Conclusion:** Together, the data assign a key role for CEACAM1 repression in the pathogenesis of hepatic fibrosis.

3427-A | SECRETOME OF SENESCENT HEPATIC STELLATE CELLS FAVORS MALIGNANT TRANSFORMATION FROM NONALCOHOLIC STEATOHEPATITIS-FIBROTIC PROGRESSION TO HEPATOCELLULAR CARCINOMA

Yuan Zhou[1], Li Zhang[1], Yue Ma[1], Li Xie[1], Yongyu Yang[1], Cheng Jin[1], Hui Chen[1], Jia Ding[2] and Jian Wu[1,3,4], (1)Dept. of Medical Microbiology, Fudan University School of Basic Medical Sciences, Shanghai 200032, China, (2)Shanghai Jing'an District Central Hospital, (3)Fudan University, Department of Gastroenterology and Hepatology, Zhongshan Hospital, Shanghai, China, (4)Shanghai Institute of Liver Diseases, Fudan University Shanghai Medical College, Shanghai 200032, China

Background: Hepatic fibrosis is a premalignant lesion, and how injured hepatocytes transform into malignancy in a fibrotic microenvironment is poorly understood. Senescence is one of major fates of activated hepatic stellate cells (HSCs). Paucity of literature is available regarding the influence of senescent HSCs on behaviors of steatotic hepatocytes. **Methods:** A mouse model of nonalcoholic steatohepatitis (NASH)-fibrosis-hepatocellular carcinoma (HCC) was established to recapitulate the progression from NASH to HCC by feeding high fat/calorie diet plus high fructose and glucose in drinking water (HFCD-HF/G) for 14 months. Senescent HSCs were identified in the mouse model and human NASH-HCC specimens. *In vitro* models of senescent HSCs were established from two perspectives including drug-induced DNA damage and cellular senescence due to natural replicative failure. Secretome of senescent HSCs was analyzed by label-free mass-spectrum (NanoRPLC-MS/MS) and verified quantitatively. **Results:** Senescent HSCs were increased along with the progression from nonalcoholic fatty liver (NAFL) (3.82%), NASH to NASH-fibrosis (12.57%), and reached a peak at the stage of advanced fibrosis (40.41%) and then decreased when hepatocellular dysplasia (22.86%) or HCC (14.58%) was developed. Critical components, such as platelet-derived growth factor, tumor necrosis factor, Y-box-binding protein 1 and vimentin affecting proliferation, epithelial-mesenchymal transition (EMT) or migration were identified from secretome of senescent HSCs. Two major secretary ligands for Hedgehog and Wnt signaling pathways, sonic Hedgehog (SHh) and Wnt-10b, were further verified by ELISA. Immunofluorescent staining and quantitative RT-PCR assays demonstrated that secretome of senescent HSCs might activate morphogenic Hedgehog or oncogenic Wnt signaling pathways to accelerate malignant transformation from steatotic or dysplastic hepatocytes. Primary hepatocytes stimulated with conditioned medium from or co-cultured with senescent HSCs exhibited an enhanced proliferating or EMT profile including increased expression levels of pluripotent genes, such as c-Myc, Oct-4, KLF-4, Nanog and Sox-2, and EMT-related genes, such as N-cadherin and vimentin. **Conclusion:** Senescent HSCs secreted a characterized profile of proteins favoring malignant transformation of steatotic or dysplastic hepatocytes through activating morphogenic Hedgehog or oncogenic Wnt signaling pathways in the progression of from NASH to malignancy. This initial discovery facilitates to develop preventive

3428-A | SIRT7 PROTECTS LIVER FIBROSIS BY SUPPRESSING STELLATE CELL ACTIVATION VIA THE TGF-Β/SMAD2/3 PATHWAY

Cong Ding, Bohao Liu, Tingzi Yu, Wang Zhiqiang, Wenbin Tang and Zhuan Li, Hunan Normal University

Background: SIRT7 belongs to class III HDACs deacetylases, which regulates histone and non-histone protein acetylation and play critical role in various biological processes. Aberrant expression of SIRT7 is associated with tumorigenesis and tumor progression of liver cancer. However, the involvement of SIRT7 in hepatic fibrosis has not been fully elucidated. **Methods:** SIRT7 expression levels in human liver were examined by WB and IHC. Myeloid cell-specific knockout mice (LysM-Cre SIRT7$^{-/-}$) were generated by crossing SIRT7$^{flox/flox}$ mice with LysM-Cre mice. LysM-Cre SIRT7 and control mice (Srit7$^{flox/flox}$) were intraperitoneally injected CCl4 to induce liver fibrosis. The liver fibrosis was assessed by measuring fibrosis markers and associated genes. Primary hepatic stellate cells isolated to examine the effect of SIRT7 on HSC activation. The interaction of SIRT7 and SMAD2/3 were analyzed in vitro using overexpression, inhibitor, and immunoprecipitation assays. **Results:** SIRT7 expression were gradual decreased as it from hepatitis, fibrosis to cirrhosis patients, with minimal SIRT7 expression observed in cirrhosis but a significant increase in liver cancer samples. IHC indicated that SIRT7 primary expressed in nonparenchymal cell in hepatitis and fibrotic liver but predominantly expressed in hepatocyte in liver cancer. LysM-Cre SIRT7$^{-/-}$ resulted in significantly elevated alanine aminotransferase (ALT) levels, liver fibrosis and inflammation compared with wild-type mice after CCl4 administration. In response to TGF-β, SIRT7$^{-/-}$ primary hepatic stellate cells showed significant elevated α-SMA expression, mRNA related to HSC activation, and protein expression of α-SMA, smad2/3, and p-smad2. Inhibition of smad2/3 phosphorylation using a selective TGFβR (ALK5) inhibitor reversed SIRT7-mediated stellate cell hyperactivity. Mechanistically, we revealed that SIRT7 interacts with and deacetylates smad2/3 in LX2 cells. Overexpression of SIRT7 inhibited the TGF-β/smad2/3 signaling pathway. Most importantly, we observed that ALK5 abolished stellate cell activation and liver fibrosis in LysM-Cre SIRT7 mice after CCl4. **Conclusion:** Our findings demonstrate that SIRT7 directly modulates hepatic stellate cell activation by regulating the acetylation of SMAD2/3, thereby influencing the progression of liver fibrosis.

f 3429-A | SOX7 ATTENUATES HEPATIC STELLATE CELL ACTIVATION AND LIVER FIBROSIS VIA REPRESSING Β-CATENIN AND TGFβ/SMAD SIGNALING PATHWAYS

Yuwei Liu and Junqi Niu, The First Hospital of Jilin University

Background: Liver fibrosis (LF) occurs after chronic liver injuries. Hepatic stellate cells (HSCs) activation is the essential pathological process of LF. The transcription factor SRY-related high mobility group box 7(SOX7) has been studied in angiogenesis and tumorigenesis, such as hepatocarcinogenesis. However, the role of SOX7 in hepatic stellate cell activation and liver fibrogenesis has not yet been investigated. In the current study, we explored the effect of SOX7 on liver fibrogenesis and the underlying molecular mechanism. **Methods:** We first screened the potential core transcription factors through differential expression analysis of HSCs microarray data and weighted gene co-expression network analysis (WGCNA) of liver tissue microarray data among GEO datasets and chose SOX7 for further investigation. Histological and transcriptome analyses on human cirrhotic livers were performed. Carbon tetrachloride (CCL4) treatment and bile duct ligation surgery were employed to induce liver fibrosis in mice. To establish in vitro activated cell model, LX-2 cells were stimulated with recombinant human transforming growth factor β1 (TGFβ1). The mRNA and protein levels of SOX7 and fibrogenic genes were compared in liver tissue with and without fibrosis and in quiescent and activated HSCs. Then, HSCs activation, proliferation, apoptosis, and modulated pathways were detected in SOX7 knockdown and overexpressed LX-2 cells. **Results:** SOX7 was decreased markedly in human and mouse fibrotic livers, particularly at the fibrotic foci. SOX7 was also downregulated in primary activated HSCs and TGFβ1 stimulated LX-2 cells. SOX7 knockdown promoted activation and proliferation of LX-2 cells while inhibiting their apoptosis. On the other hand, overexpression of SOX7 suppressed the activation and proliferation of HSCs. Mechanistically, SOX7 attenuates HSCs activation and LF by decreasing the expression of β-catenin and phosphorylation of SMAD2 and SMAD3 induced by TGFβ1. **Conclusion**:

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

SOX7 attenuates HSCs activation and LF via repressing β-catenin and TGFβ/Smad signaling pathways. Targeting SOX7, therefore, could be a potential novel therapeutic strategy to ameliorate LF.

3430-A | STELLATE CELL WNTS REGULATE ENDOTHELIAL CELL-HEPATOCYTE ZONATION TO BALANCE HEPATIC METABOLISM-PROLIFERATION HOMEOSTASIS

Anya Singh-Varma[1], Shikai Hu[1], Leon Min[1], Brandon M. Lehrich[2], Minakshi Poddar[2], Ian Sipula[1], Fiona M Bello[1], Amber M Vandevender[1], Sucha Singh[2], Aaron W. Bell[3], Michael Jurczak[1], Silvia Liu[2] and Satdarshan (Paul) Monga[2], (1)University of Pittsburgh School of Medicine, (2)University of Pittsburgh, (3)University of Pittsburgh, Sewickley, PA

Background: The liver, a main regulator of homeostasis, is histologically organized into metabolic zones defined by distinct gene expression along the portal-central axis for functional division of labor. Current understanding of the maintenance of zonation defines endothelial cells (ECs) in pericentral zones as the source of Wnt2 and Wnt9b, which regulate hepatocyte ß-catenin activity and gene expression in this zone. Here, we investigate if there is any role of Wnts from hepatic stellate cells (HSCs) by characterizing mice incapable of secreting Wnts from these cells. **Methods:** Male and female HSC-specific Wntless (Wls) knockout (KO) mice were generated by interbreeding Wls-floxed mice and lecithin retinol acyl-transferase-driven Cre transgenic mice. Single nuclei RNA sequencing (snRNA), single cell spatial transcriptomics (scST), and immunohistochemistry (IHC) were performed to identify changes in gene expression and zonation between KO and littermate controls. Metabolism was assessed by bile acid composition and Oroboros and proliferation assessed after partial hepatectomy (PH) and acetaminophen (APAP) challenge. **Results:** No difference in baseline liver functions were evident in HSC-Wls KO versus controls. KO mice were overall smaller and had a greater lean-to-fat mass body composition than controls ($p < 0.05$). scST, validated with IHC, revealed expanded expression of normally pericentral genes like *Cyp2e1*, *Cyp7a1*, and *Cyp1a2* to mid- and periportal zones. Additionally, midzonal and periportal markers showed retracted expression to the periportal zone. Ingenuity Pathway Analysis on snRNA sequencing identified significant upregulation of xenobiotic, cholesterol, and bile acid metabolic pathways in hepatocytes. Bile acid analysis confirmed increased bile acid synthesis in KOs. Oroboros O2k Respirometry on mitochondria from KO livers demonstrated increased fatty acid metabolism and efficiency. Intriguingly, the observed zonation changes were not due to altered HSC zonation but rather pericentralization of sinusoidal ECs throughout the hepatic lobule as seen by altered Fabp4, c-Kit, and Wnt2 expression. Analysis of liver regeneration following insult by APAP toxicity or PH revealed impaired hepatocyte regeneration measured by Ccnd1 and Ki67 positive hepatocytes. **Conclusion:** HSC-Wnts regulate zonation of ECs and hepatocytes, to serve as the master regulator of metabolism and proliferation balance in the liver.

Engineering Research Center of Biodiagnositics and Biotherapy, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China., (2)Shaanxi Provincial Clinical Research Center for Liver and Spleen Diseases, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China., (3)Shaanxi International Cooperation Base for Inflammation and Immunity, Xi'an, China

Background: Chronic liver disease is a serious threat to human health. Hepatic fibrosis is a key stage in the progression of chronic liver disease. Immune cells of liver participate in the process of liver fibrosis to varying degrees. The spleen can influence the progression of liver fibrosis by regulating liver immune cells, but the mechanism is still unknown. GABA is a major inhibitory neurotransmitter regulating interneuronal communication, which has also been fully proved to determine the fate of immune cells recently. GABA is synthesized and secreted by B cells outside the brain. B cells are important immune cells in the spleen and liver. Whether B cell-derived GABA plays a role in spleen regulating liver immunity and affecting the progression of liver fibrosis is worth study. **Methods:** In this study, flow analysis has demonstrated that B lymphocytes, especially $CD86^+$ B cells in liver of CCl_4-induced liver fibrosis mice was significantly increased compared with control group. And splenectomy reduced the proportion of B lymphocytes and $CD86^+$ B cells in liver of CCl_4-induced liver fibrosis mice. LC-MS analysis revealed that the content of GABA in liver and serum was significantly increased in the CCl_4-induced liver fibrosis mice compared with control group. However, the content of GABA in liver and serum was reduced in the liver fibrosis mice with splenectomy. Histopathological staining revealed that the degree of liver fibrosis in mice with splenectomy was alleviated. While, this situation was reversed by B cell reinfusion. It is also revealed that feeding GABA aggravated the degree of liver fibrosis in the CCl_4-induced liver fibrosis mice. Cell experiments showed that GABA could regulate the secretion of CCL2 and TGF-β by macrophage Raw264.7, which made JS1 highly express α-SMA and promote fibrosis. **Results:** Therefore, GABA content was increased with increased B lymphocytes in fibrosis mice. Increased GABA resulted in more secretion of CCL2 and TGF-β by macrophage, which made hepatic stellate cells expressed higher α-SMA and promoted fibrosis. However, splenectomy can reduce B lymphocytes and GABA content. **Conclusion:** Thus, the spleen may affect the progress of liver fibrosis by influencing the production of GABA by B cells to regulate liver immunity. Key words: liver fibrosis, spleen, B cells, GABA, immune regulation

3432-A | TGFβ2 UPREGULATION ON REACTIVE CHOLANGIOCYTES LIMITS THE THERAPEUTIC EFFICACY OF TGFβ TRAP RAP-1332 IN MOUSE MODELS OF CHRONIC BILIARY INJURY AND FIBROSIS

Pinzhu Huang[1], Monica Shipman[1], Disha Skelton-Badlani[1], Richard Chen[2,3], Shekar Suragani[3], Patrick Andre[3], Wen Gao[1], Heansika Matta[1] and Yury V. Popov[4], (1)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (2)Merck & Co., Inc, (3)Acceleron Pharma Inc, (4)Harvard Medical School, Boston, MA

Background: RAP-1332 (murine ortholog of ACE-1334), is a new recombinant Fc fusion protein that functions as a ligand trap for TGFβ1 and TGFβ3 isoforms, but spares TGFβ2. Herein we report therapeutic effect of RAP-1332 in direct comparison with non-isoform selective TGFβ signaling inhibitor of ALK5, in mouse models of primary sclerosing cholangitis (PSC)-like biliary injury and fibrosis. **Methods:** RAP-1332 (1, 3 and 10 mg/kg twice a week) or ALK5 inhibitor (SB-525334, 30 mg/kg/day) was tested in clinically relevant mouse model of PSC-like mouse models of pre-established biliary fibrosis (BALBc.Mdr2-/-, n = 6-12/group) starting at 4 weeks (early therapy) or 6 weeks (delayed therapy) of age for the following 4-6 weeks, respectively. Portal venous pressure (PVP), serum liver function tests and histologic analyses were assessed at study endpoint. 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) feeding model of sclerosing cholangitis was used as a second, mechanistically different validation model. **Results:** Non-selective TGFβ suppression using Alk5 inhibitor led to readily detectable improvement of all liver injury and fibrosis parameters in both Mdr2-/- and DDC models. In contrast, both early and delayed administration of RAP-1332 into Mdr2-/- mice did not ameliorate PVP, splenomegaly, liver function, and liver fibrosis at low and medium doses, and led to paradoxical worsening of disease at high dose. In delayed therapy arm, ALT and AST were increased by 53.50% and 44.14%, respectively at high 10 mg/kg dose RAP-1332. Exacerbated ductular reaction and worsened periductular fibrosis was observed in mice receiving high dose of TGFβ1/3 trap, with 2-fold increase of collagen (histologically via morphometry) and 69.59% increase of hepatic hydroxyproline content compared to placebo. Likewise, TGFβ1/3 trapping by 10 mg/kg RAP-1332 in DDC model led to similar exacerbation of biliary injury and fibrosis, (40.23% increased hepatic hydroxyproline content).

Realtime PCR and *in situ* hybridization showed remarkable upregulation of TGFβ2 expression on actively proliferating reactive cholangiocytes. This was accompanied by adjacent expansion of α-SMA+ hepatic stellate cell and exacerbated inflammation (CD45+ and CD68+ cells). **Conclusion:** Our results suggest that selective blocking TGFβ1 and TGFβ3 in chronic biliary fibrosing disease is inefficient due to compensatory upregulation of TGFβ2 on reactive cholangiocytes. This non-dispensable pathological role of TGFβ2 should be accounted for in future design of TGFβ traps and therapeutic TGFβ targeting.

3433-A | THERAPEUTIC INHIBITION OF MIR-155 ATTENUATES LIVER FIBROSIS VIA THE TGFβ/SMADS/ STAT3 AXIS

Shashi Bala[1], Yuan Zhuang[1], Prashanth Thevkar Nagesh[1], Adam Zivny[1], Yanbo Wang[1], Jun Xie[2], Guangping Gao[2] and Gyongyi Szabo[1], (1)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (2)UMass Chan Medical School

Background: Most chronic liver diseases progress to liver fibrosis, which if left untreated, can lead to cirrhosis and end-stage liver disease. miRNA-targeted therapeutics has become attractive approaches to treat diseases. miR-155 is a multifactorial miRNA that is uniquely expressed in both non-parenchymal and parenchymal cells in the liver. In this study, we investigated the therapeutic potential of miR-155 inhibition in a well-established mouse model of liver fibrosis, bile-duct ligation (BDL) and evaluated the role of miR-155 in chronic liver fibrosis using miR-155 deficient mice. **Methods:** WT and miR-155 knockout (KO) mice were subjected to carbon tetrachloride (CCl_4) for 9 weeks or BDL for 2 weeks. For therapeutic inhibition of miR-155, rAAV8-scrambled or rAAV8-anti-miR-155 tough decoy was administered in BDL-induced liver fibrosis mouse model. *In vitro*, miR-155 gain- and loss-of-function studies were performed in human LX2 cells and isolated mouse primary hepatic stellate cells (HSCs) were used for gene expression and biochemical studies. **Results:** Liver miR-155 expression was elevated in patients with cirrhosis and in the mouse models of liver fibrosis (BDL or CCl_4) compared to normal controls. Liver fibrosis was significantly reduced in miR-155 KO mice after CCl4 administration or BDL. The administration of a rAAV8-anti-miR-155 tough decoy inhibitor *in vivo* significantly reduced liver damage and fibrosis in BDL. We found that BDL-induced protein levels of αSMA, vimentin, TGFβ, total SMAD 2/3, p-SMAD 2/3 and p-STAT3 were attenuated in anti-miR-155 treated mice compared to control mice revealing mechanistic insights into regulation of fibrotic pathways by miR-155. Consistent with the fibrosis promoting role of miR-155, hepatic stellate cells from miR-155 KO mice showed attenuation in the expression of activation, fibrosis and mesenchymal markers. *In vitro*, miR-155 gain- and loss-of-function as well as rescue studies using STAT3 inhibitor revealed that miR-155 regulates activation of stellate cells in part via STAT3 signaling. **Conclusion**: Our findings highlight miR-155 as an important regulator of liver fibrosis via its ability to modulate hepatic steallate cell activation via multiple molecular targets of the fibrogenesis pathway. Therapeutic inhibition of miR-155 might be an effective approach to ameliorate liver fibrosis.

f 3434-A | TREATMENT STRATEGY FOR LIVER FIBROSIS BASED ON Tcf21-INDUCED DEACTIVATION OF FIBROGENIC HEPATIC STELLATE CELLS

Takayo Yanagawa[1,2], Noriaki Hirayama[1], Jumpei Yasuda[1], Harumi Ogawa[1], Sachie Nakao[1], Mayumi Watanabe[1], Kota Tsuruya[3], Yoshitaka Arase[3], Tatehiro Kagawa[3] and Yutaka Inagaki[1], (1)Center for Matrix Biology and Medicine, Graduate School of Medicine, Tokai University, (2)Department of Physiology, Tokai University School of Medicine, (3)Division of Gastroenterology and Hepatology, Department of Internal Medicine, Tokai University School of Medicine

Background: Despite many attempts to suppress activation of hepatic stellate cells (HSCs) or inhibit excessive collagen production in activated HSCs, their application to anti-fibrotic treatment has not been

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

established yet. We recently identified Tcf21 as a deactivation factor of fibrogenic HSCs. Adeno-associated virus-mediated *Tcf21* transfer into cultured HSCs and mice with experimental liver fibrosis not only suppressed fibrogenic gene expression but also restored the quiescent HSC marker expression both *in vitro* and *in vivo*. This change in gene expression profile of HSCs was accompanied by regression of steatohepatitis and fibrosis as well as improved hepatic architecture and function. In the present study, we explored the mode of action of Tcf21 and identified several small molecules that mimic the anti-fibrotic effect of Tcf21. **Methods:** *In silico* homology modeling and docking simulations were used to predict the minimal functional region of Tcf21 and for screening of small molecules that act as Tcf21 agonists. Anti-fibrotic effects of the candidate molecules were examined using primary human HSCs *in vitro* and experimental murine liver fibrosis models *in vivo*. **Results:** *In silico* homology modeling uncovered the ternary structure of the complex composed of Tcf21, its counterpart Tcf3, and target DNA. It also predicted a contiguous 28 amino acid sequence of Tcf21 that is essential for its binding to both Tcf3 and DNA. Transfection experiments revealed that the suppressive effect of this Tcf21 peptide on type I collagen gene transcription was comparable to that of full length Tcf21 in the presence of Tcf3. *In silico* screening of *ca* 7.7 million compounds identified 63 candidates that mimic the ternary structure of the functional Tcf21 peptide. Some of them suppressed expression of *ACTA2*, a representative target gene of Tcf21/Tcf3, in primary human HSCs in dose- and time-dependent manners. Administration of these small molecules to mice with experimental liver fibrosis inhibited *Acta2* and type I collagen gene expression, resulting in suppression of liver fibrosis without any overt adverse effects. **Conclusion:** A combination of *in silico* drug discovery methodology and *in vitro*/*in vivo* verification determined the minimal functional region of Tcf21 that mediates its anti-fibrotic effect and identified several hit compounds that mimic the anti-fibrotic action of Tcf21. These findings eventually lead to development of novel therapy for intractable liver fibrosis.

3435-A | USE OF DEEP LEARNING AND ARTIFICIAL INTELLIGENCE ALGORITHMS TO ANALYZE MACROPHAGES IN THE HEPATIC MICROENVIRONMENT

Omar A Saldarriaga[1], Esteban Arroyave[1], Daniel Millian[2], Timothy Wanninger[3], Daniel Bao[1], Sundus Bhatti[1], Michael Kueht[1], Moghe Akshata[1], Santhoshi Krishnan[4], Arvind Rao[5], Michael Zeitlin, Denis Papp and Heather Lynne Stevenson-Lerner[1], (1)University of Texas Medical Branch, (2)University of Texas Southwestern Medical Center, (3)University of Texas - Houston, (4)Rice, (5)University of Michigan

Background: We use several cutting-edge platforms that preserve the tissue architecture to study macrophages *in situ* within the hepatic microenvironment. **Methods:** Using imaging analysis software platforms with artificial intelligence capabilities, we custom design algorithms that allow us to not only quantify the numbers of macrophages within the liver and their spatial location but also their interaction with other phenotypes. We then compare the transcriptomic signatures of liver biopsies from patients using GeoMx digital spatial profiling and nCounter technology, enabling the identification of key biological pathways and biomarkers that portend poor outcomes. Using these platforms and algorithms, we study a variety of liver diseases including autoimmune hepatitis, non-alcoholic steatohepatitis, and infectious diseases such as viral hepatitis C and ebolavirus. We hypothesized that the heterogeneity of macrophages and associated gene expression profiles in different types of liver disease could explain the variability in the progression of injury and may provide potential targets for therapy. **Results:** Digital spatial profiling and multiplexed stained liver biopsies were scanned with imaging platforms. The heterogeneity of these various macrophage populations in the different types of liver disease was evaluated using deep learning/artificial intelligence applications to generate phenotype profiles, heat map matrices, t-distributed stochastic neighbor embedding plots (t-SNE) (Visiopharm®, MATLAB 2020a), and uniform manifold approximation and projection for dimension reduction (UMAP) comparisons. Variations in individual patients in each disease type were assessed using AVM software (Aqumin®) and showed that several patients within each disease group had variable expressions of specific genes that correlated with clinical outcome and severity of the liver injury. **Conclusion:** In summary, the use of custom-designed algorithms in several different types of liver disease revealed similar proinflammatory mediators within the hepatic microenvironment that included the enrichment of specific phenotypes, like those that were Mac387 positive. These findings suggest that intrahepatic macrophages, including proinflammatory phenotypes, are common critical contributors to immunopathogenesis in a variety of liver diseases.

3436-A | ZNF469 AS A NOVEL PRO-FIBROTIC FACTOR IN LIVER FIBROSIS

Chaiyaboot Ariyachet, Faculty of Medicine, Chulalongkorn University

Background: Activation of quiescent hepatic stellate cells (HSCs) into proliferative myofibroblasts drives liver fibrosis; nevertheless, transcriptional network that promotes such the process remains elusive. From RNA sequencing data of human HSCs and liver tissues, we identified a putative zinc-finger transcription factor, ZNF469, upregulated upon HSC activation and in human cirrhotic livers. Thus, we hypothesized ZNF469 as a potential pro-fibrotic factor and aimed to elucidate its function in HSC activation. **Methods:** We modulated expression levels of ZNF469 in primary human HSCs and examined activation phenotypes including proliferation, migration, and collagen production. We then examined if TGF-b pathway regulated ZNF469 expression. We further cloned a full-length open reading frame (ORF) of ZNF469 with an epitope tag to study protein localization and perform chromatin immunoprecipitation (ChIP). Finally, we performed the RNA sequencing experiment of ZNF469-knockdown cells to assess its impact on

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

gene expression in HSCs. **Results:** Knockdown expression of ZNF469 in primary human HSCs impaired proliferation, migration, and collagen production. In addition, ZNF469 suppression reduced deposition of collagen in HSC spheroids. Conversely, overexpression of ZNF469 in HSCs yielded the opposite results. TGF-beta can promote expression of ZNF469 in a Smad3-dependent manner. A cluster of Smad3 binding sites was found at the ZNF469 promoter, and the binding of Smad3 was enhanced upon TGF-beta stimulation. We successfully cloned a full-length ORF of ZNF469 (~12 kb) with an epitope tag and identified a nuclear localization of the protein. ChIP assays revealed the presence of ZNF469 at the promoter of fibrotic genes, supporting its function as a transcription factor. RNA sequencing data of ZNF469-knockdown HSCs revealed downregulation of several genes involved in biosynthesis of extracellular cellular matrix. **Conclusion:** ZNF469 is a profibrotic transcription factor that promotes activation phenotypes in myofibroblasts. We are testing its antifibrotic potential *in vivo* by development of adeno-associated virus (AAV) to suppress expression of ZNF469 in fibrotic livers. Together, this study will advance our understanding in transcriptional regulation of activated HSCs and suggest ZNF469 as a novel target for antifibrotic therapy.

f 3437-A | BUILDING DISEASE: LIVER EXTRACELLULAR MATRIX-BASED BIOREACTORS TO ENGINEER COMPLEX LIVER CELL NICHES

Alejandro Mayorca Guiliani, Nordic Bioscience a/S

Background: The extracellular matrix (ECM) spanning the liver determines the architecture of its interconnected vascularity and the regularity of its parenchyma. ECM is an interwoven network that includes more than 300 proteins and glycans, organized to provide biomechanical support and biochemical orientation to all liver cells. Native liver ECM topography is enormously complex and cannot be replicated with current manufacturing technology, however, the centrality of the ECM in disease progression and collective cell behavior calls for disease models that factor this complexity in. Here, we present a liver bioreactor where cells are challenged to organize a 3D cell niche while being regulated by a microenvironment that retains the biological cues provided by the ECM. **Methods:** The hepatic bioreactor was designed to fit in a microscope stage and provide sterility, humidity, temperature, perfusion and waste removal. An optical window allows monitoring while set in a 2-photon microscope. To source native ECM, we performed post-mortem microsurgery in mice to catheterize the portal vein, resect a hepatic lobe and connect it to the bioreactor. Surgery was followed by decellularization, perfusion and cell repopulation. As proof-of-concept, we repopulated the liver matrix with cancer cells, fibroblasts, and macrophages to rebuild the liver metastatic niche. We then repopulated with human cells from colorectal liver metastasis aiming to recreate a human metastatic niche. To validate the bioreactor, we immunostained the liver matrix and evaluated ECM remodeling and global kinase signaling compared to *in vivo* and *in vitro* signaling. **Results:** The hepatic bioreactor successfully hosts ECM repopulation, under microscopic monitoring, longer than 21 days. It captured cell colonization in 3D and high-resolution, detecting cell division, migration, apoptosis, and cancer cell extravasation. We also imaged ECM remodeling driven by cancer cells and fibroblasts, thus simulating fibrosis and cell niche formation. Kinome phosphorylating activity in the bioreactor approximates to that found *in vivo*, thus suggesting that ECM imposes *in vivo*-like patterns of cell signaling. **Conclusion:** The ECM hepatic bioreactor is a novel, flexible disease model that opens the possibility to build engineered liver cell niches and experimental setups that would be impossible *in vitro* or *in vivo*. Cells in this system recapitulate *in vivo* signaling and remodel native ECM, suggesting its potential as drug development model.

3438-A | DUAL αVβ6/αVβ1 INTEGRIN INHIBITOR BEXOTEGRAST ATTENUATES PROFIBROGENIC GENE EXPRESSION ACROSS MULTIPLE PATHOLOGIC CELL TYPES IN HUMAN LIVER EXPLANT TISSUE WITH BILIARY FIBROSIS

Johanna Schaub, Steve Ho, Chris S Her, Richard Ahn, Vikram Rao, Mahru An, Scott Turner and Martin Decaris, Pliant Therapeutics

Background: Bexotegrast (PLN-74809), a dual inhibitor of TGF-β-activating integrins $\alpha_V\beta_6$ and $\alpha_V\beta_1$, is currently in clinical development for the treatment of primary sclerosing cholangitis (PSC). To examine the effects of

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

bexotegrast on the pathogenesis of PSC, we combined 10x single nuclei RNA sequencing (snRNA-Seq) with the precision-cut liver slice (PCLivS) platform to characterize the response of unique cell populations in fibrotic PSC and primary biliary cholangitis (PBC) PCLivS to bexotegrast treatment. **Methods:** Liver explants were collected from patients with PSC (n = 3) and PBC (n = 1) at the time of transplant. PCLivS were generated and cultured for 2 days in the presence of bexotegrast or vehicle (DMSO). A TGF-β receptor I kinase inhibitor (ALK5i; R-268712) was evaluated as a positive control for TGF-β signalling inhibition. Nuclei were isolated from two pooled slices per treatment and processed for single nuclear barcoding using 10x Chromium Next GEM 3' HT kits. Resulting libraries were sequenced, processed using CellRanger, and analyzed using Seurat. Custom annotation of cell types was performed using gene markers from published data sets. Differential gene expression was determined using a non-parametric Wilcoxon rank sum test. Analysis focused on genes with log2 fold-change > 0.5 and an FDR < 0.05. **Results:** snRNA-Seq analysis of PCLivS showed clear effects from bexotegrast treatment on distinct subpopulations of mesenchymal cells, endothelial cells, and cholangiocytes previously shown to be relevant in the pathogenesis of fibrotic liver disease. Bexotegrast significantly reduced type I collagen (*COL1A1)* expression in *PDGFRA*-high myofibroblasts composed of activated portal fibroblasts (*GREM1*$^{+}$) and activated hepatic stellate cells (*NGFR*$^{+}$) when compared to vehicle. Top gene ontologies (GO) for the genes downregulated by bexotegrast in myofibroblasts include "collagen fibril organization" (GO:0030199) and "extracellular matrix organization" (GO:0030198). In addition, bexotegrast significantly reduced the expression of profibrogenic ligands such as *PDGFB* in scar-associated endothelial cells (*CD34*$^{+}$*PLVAP*$^{+}$) and significantly reduced the expression of *ITGB6* and *EPHB2* in cholangiocytes. Reduction of profibrogenic gene expression from bexotegrast treatment across these cell types was similar in degree to that from ALK5i. **Conclusion:** Bexotegrast treatment resulted in clear reductions in profibrogenic gene expression across multiple pathologic cell populations in PCLivS prepared from human liver explants with biliary fibrosis. The similar degree of antifibrotic effect from bexotegrast compared to ALK5i in these experiments demonstrates the importance of the $\alpha_V\beta_6/\alpha_V\beta_1$ integrin-TGF-β activation pathway in fibrotic biliary disease. These data support ongoing clinical studies evaluating the anti-fibrotic effects of bexotegrast in PSC.

3439-A | GENDER DIFFERENCES IN REPAIR MECHANISMS OF CHRONIC CHOLANGIOPATHIES WITH PROGRESSIVE FIBROSIS

Massimiliano Cadamuro[1], Labjona Haxhiaj[2], Chiara Montanaro[2], Erica Villa[3], Annarosa Floreani[2], Nora Cazzagon[2], Giovannella Baggio[2], Mario Strazzabosco[4], Paolo Simioni[2,5] and Luca Fabris[2,4,5], (1)Univeristy of Padua, (2)University of Padova, (3)Clinica Universitaria Policlinico Modena, (4)Yale University, New Haven, CT, (5)Padua University-Hospital

Background: In chronic liver disease pathophysiology, gender dimorphism is much less characterized compared with degenerative disorders affecting other organs. Repair mechanisms are instrumental to direct fibrogenesis and progression of chronic inflammatory conditions. Therefore, we investigated the gender-specific differences in tissue repair culminating in liver fibrogenesis and sustained by activation of hepatic progenitor cells (HPC) and ductular ductular reaction (DR) in two models of diseases of the biliary epithelium (cholangiopathies) featuring progressive fibrosis. We considered the Pkhd1$^{del4/del4}$ and the Mdr2$^{-/-}$ mouse models, orthologous of the human congenital hepatic fibrosis/Caroli's disease (CHF/CD) and primary sclerosing cholangitis (PSC), respectively, and in sections of human PSC and CHF/CD. **Methods:** Serial sections of liver tissue specimens of PSC (n = 9 M/n = 5 F) and CHF/CD (n = 3 M/n = 1 F), along with Pkhd1$^{del4/del4}$ (n = 11 M/n = 23 F), and Mdr2$^{-/-}$ mice (n = 5 M/n = 3 F), were stained with Sirius Red (histological staining) and with immunohistochemistry for myofibroblasts (α-SMA), macrophages (CD68, human samples only), and RDC/DR (K19). Extent of DR, fibrosis, inflammation and number of HPC were evaluated with computer-assisted morphometry. **Results:** In both mouse models and human diseases, fibrosis resulted higher in M compared with F, without significant differences in myofibroblast accumulation and HPC activation. In both Mdr2$^{-/-}$ mice and PSC patients, extension of DR was more prominent in M than F, whereas in Pkhd1$^{del4/del4}$ mice, dysgenetic biliary lesions were greater in F than in M. In addition, in PSC samples, the number of CD68+ macrophages was higher in M as respect to F. Similar trends were also found in human CHF/CD samples. **Conclusion:** This study shows gender-specific differences in tissue repair mechanisms of the biliary epithelium in both mouse models and human samples of PSC and CHF/CD. In particular, we found more severe fibrogenesis associated with more intense inflammatory infiltrate dominated by macrophages in males compared to females, thereby providing mechanistic evidence of the more severe clinical course of chronic liver diseases affecting men as reported in viral and metabolic etiologies.

3440-A | GULLIVER-2: A SUBGROUP ANALYSIS COMPARING TRANSAMINASE AND MODEL FOR END-STAGE LIVER DISEASE RESPONSES IN GB1211- VS PLACEBO-TREATED PATIENTS WITHOUT PHENOTYPIC NON-ALCOHOLIC STEATOHEPATITIS

Bertil Erik Lindmark[1], Dimitar Tonev[1], De Phung[1], Vassilios Aslanis[1], Becky Smith[1], Robert Slack[2], Fredrik Zetterberg[1], Brian Jacoby[1], Mike Gray[1], Zahari Krastev[3] and Jordan Genov[4], (1)Galecto Biotech, (2)Galecto Biotech AB, (3)Comac Medical Ltd, (4)University Multiprofile Hospital for Active Treatment (UMHAT) "Tsaritsa Yoanna - Isul"

Background: Galectin-3 (Gal-3) is a beta-galactoside binding lectin which regulates liver inflammation and fibrosis; high levels of Gal-3 correlate with severe liver disease. GB1211, a novel oral Gal-3 inhibitor, has shown potential in preclinical studies for reducing fibrosis and offering hepatocellular protection, as indicated by a reduction in transaminase leakage. Part 2 of the GULLIVER-2 trial (NCT05009680) is a Phase 2, double-blind, placebo-controlled study of patients (pts) with Child-Pugh B liver cirrhosis. Prior analyses demonstrated that GB1211 reduced transaminases and gamma-glutamyl transferase in the overall population. Among pts who completed 12 weeks of therapy, those treated with GB1211 had a decrease in model for end-stage liver disease (MELD) score of −1.4 vs an increase of +0.5 in pts who received placebo (Lindmark et al. AASLD 2022). Here, we compare the effect of GB1211 vs placebo in a subset of the GULLIVER-2 Part 2 study population, where pts with phenotypic non-alcoholic steatohepatitis (NASH) were excluded, to assess whether etiology affects pt response. **Methods:** Pts were randomized 1:1 to GB1211 100 mg twice daily or matched placebo for 12 weeks. Pts with phenotypic NASH were identified based on medical history, body mass index, and controlled attenuation parameter (CAP) values. The following parameters were assessed using percentage change from baseline: clinical biochemistry, MELD score, steatosis (assessed by CAP), and biomarkers (Gal-3 and cytokeratin-18 [M65]). **Results:** Thirty pts were randomized to GB1211 (n = 15) or placebo (n = 15). Five pts met the selection criteria for phenotypic NASH and were excluded from this analysis: 4 in the GB1211 group and 1 in the placebo group. Improvements were observed with GB1211 vs placebo for all parameters (Table); this was comparable with the total population. Of note, the MELD score decreased in pts treated with GB1211 but increased in pts treated with placebo (mean percentage change from baseline: −8.07 and +8.77, respectively; difference [95% confidence interval]: −16.83 [−37.79, 4.12]). **Conclusion:** The effects of GB1211 in pts without phenotypic NASH were consistent with those seen in the overall population of pts with Child-Pugh B liver cirrhosis (Lindmark et al. AASLD 2022). The safety and efficacy of GB1211 will be further explored in future studies in a defined population with NASH, as well as in pts with alcohol-related liver disease.

Table: Summary statistics of the percentage change from baseline to Day 84 for assessed parameters in a pt population excluding pts with phenotypic NASH

Variable	Parameter	GB1211 (n = 11)	Placebo (n = 14)
ALT	n	10	12
	Mean	−40.66	13.60

3441-A | HUMAN AMNION EPITHELIAL CELL TRANSPLANTATION IS SAFE AND WELL TOLERATED IN PATIENTS WITH COMPENSATED CIRRHOSIS – A FIRST IN HUMAN TRIAL

William Sievert[1], Rebecca Lim[2], Sherryne Leanne Warner[3], Alexander D. Hodge[4], Gregory Moore[1], Jeanne Correia[1], Siow Chan[2], Mihiri Goonetilleke[2] and Stuart Lyon[1], (1)Monash Health, (2)Hudson Institute of Medical Research, (3)Monash Medical Centre, (4) Eastern Health

Background: We conducted a Phase 1 clinical trial to assess the safety and tolerability of human amnion epithelial cells (hAEC) in patients with compensated cirrhosis. hAEC are placental stem cells with anti-inflammatory and anti-fibrotic properties. **Methods:** We examined administering increasing hAEC doses and two doses over time in 9 patients in 3 cohorts (median age 57 years; 8 with NAFLD and 1 with prior HCV infection). Patients in cohort 1 (n = 3) received 0.5 x 10^6/kg hAEC in one IV infusion. Patients in cohort 2 (n = 3) received 1 x 10^6/kg hAEC in one IV infusion. Patients in cohort 3 received 1x10^6/kg hAEC at day 0 and at day 28. Follow-up to post-infusion day 56 is reported here. **Results:** No serious adverse events occurred. Six patients experienced no study related adverse events while 3 patients reported headaches that were possibly infusion related; all were mild (Grade 1). We observed a transient decrease in serum platelet levels in all patients which returned to near or above baseline screening values by day 5 post infusion. We observed significantly lower FIB-4 values at day 58 (Figure, $p = 0.007$). While not statistically significant, median serum AST values and liver stiffness measurements at day 56 were lower than at baseline. Hepatic venous pressure gradient (HVPG) was elevated at baseline in all patients except one patient whose baseline HVPG was 5 mm Hg. This patient was clinically cirrhotic with portal hypertension based on ultrasound findings, LSM 75 kPa and low serum platelets. At 2 months post infusion, this patient showed an increase in HVPG from 5 to 13 mm Hg likely reflecting the true portal pressure gradient. In 4 patients, there was a decline in HVPG at 2 months. Four patients showed either no change or a small increase in HVPG. **Conclusion:** Intravenous infusion of allogeneic hAEC in patients with compensated cirrhosis at the doses used in this study was safe and well tolerated. There was no difference between patients who received a single dose compared with those who received two doses. Promising signals of decreased hepatic inflammation, liver stiffness and portal hypertension support larger studies to understand which patients may benefit from this therapy.

3442-A | IMPACT OF CONCOMITANT CARDIOVASCULAR MEDICATIONS ON OVERALL SURVIVAL IN PATIENTS WITH LIVER CIRRHOSIS

Moying Li[1], Timo Itzel[1], Nathally Espinosa-Montagut[2], Thomas Falconer[3], Jimmy Daza[1], Jimyung Park[4], Jae Youn Cheong[4], Rae Woong Park[4], Isabella Wiest[1], Matthias Ebert[1], George Hripcsak[3] and Andreas Teufel[1], (1)Medical Faculty Mannheim, Heidelberg University, (2)School of Medicine, Universidad De Los Andes, (3)Columbia University Irving Medical Center, New York, NY, (4)Ajou University Graduate School of Medicine

Background: Liver cirrhosis is the end-stage liver disease associated with poor prognosis. Cardiovascular comorbidity could significantly impact morbidity and mortality of cirrhotic patients. However, little knowledge exists for specific impact of diverse concomitant cardiovascular drugs in cirrhotic patients. Here, we conducted a large, retrospective study to investigate the survival impact of cardiovascular co-medications in patients with liver cirrhosis. **Methods**: A study-specific R package was processed on the local databases of partner institutions within the Observational Health Data Sciences and Informatics (OHDSI) consortium, namely Columbia University, New York City (NYC), U.S.A. and Ajou University School of Medicine (AUSOM), South Korea. For survival analysis, first diagnosis of cirrhosis was limited between 2000 and 2020. Final analysis of the anonymous survival data was performed at the Medical Faculty Mannheim. **Results**: We investigated a total of 32,366 patients with liver cirrhosis. Our data showed that administration of antiarrhythmics amiodarone or digoxin presented as a negative prognostic indicator ($p = 0.000$ in both cohorts). Improved survival was associated with angiotensin-converting enzyme inhibitor ramipril ($p = 0.005$ in NYC cohort, $p = 0.075$ in AUSOM cohort) and angiotensin II receptor blocker losartan ($p = 0.000$ in NYC cohort, $p = 0.005$ in AUSOM cohort). Non-selective beta blocker carvedilol was associated with a survival advantage in the NYC ($p = 0.000$) cohort but not in the AUSOM cohort ($p = 0.142$). Patients who took platelet inhibitor clopidogrel had a prolonged overall survival compared to those without ($p = 0.000$ in NYC cohort, $p = 0.003$ in AUSOM cohort). **Conclusion**: Liver cirrhosis is a complex chronic disease requiring multidisciplinary management. Concomitant cardiovascular medications used in cirrhotic patients are associated with distinct survival difference. Thus, a judicious choice of the proper cardiovascular co-medication in patients with cirrhosis is crucial.

3443-A | IMPACT OF SAMPLING SIZE ON VARIABILITY OF FIBROSIS ASSESSMENT IN LIVER NEEDLE BIOPSIES USING SECOND HARMONIC GENERATION/TWO PHOTON EXCITATION MICROSCOPY AND ARTIFICIAL INTELLIGENCE ANALYSIS BASED FIBROSIS STAGING

Kutbuddin Akbary[1], Elaine Lay Khim Chng[2], Ya-Yun Ren[1], Dean Tai[2], Jonathan Andrew Fallowfield[3], Timothy James Kendall[4], Nikolai V. Naoumov[5], David E Kleiner[6] and Arun Sanyal[7], (1)Histoindex Pte Ltd, (2) Histoindex Pte Ltd, Singapore, (3)University of Edinburgh, (4)The University of Edinburgh, (5)Novarits Pharma AG, London, United Kingdom, (6)Laboratory of Pathology, National Cancer Institute, Bethesda, MD, (7) Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Small liver biopsy increases the impact of sampling variability. Prior studies have defined minimum biopsy size for reliable assessment of fibrosis and informed guidelines for clinical trials in non-alcoholic steatohepatitis (NASH). Although digital pathology is increasingly employed in these trials, influence of sampling sizes on fibrosis assessment with this technology is poorly defined. We aimed to investigate the effect of sample size on quantification of fibrosis, qFibrosis (qF), and validate its impact on digital pathology readouts. **Methods:** 100 samples (taken from liver resections and explants), 20 each of pathologist-assigned NASH CRN - F0/F1/F2/F3/F4, were evaluated. Each sample was subjected to one virtual needle biopsy, fixed width 0.7mm, length between 5 and 20mm. qF stages were determined using Single Harmonic Generation/Two Photon Excitation (SHG/TPE) microscopy and artificial intelligence (AI)-based analysis. qF stage was compared with pathologist-assigned fibrosis stage and agreement was evaluated by calculating inter-observer Kappa values. Additionally, percentage cases where qF stage was higher or lower than pathologist's stage was calculated. **Results:** Analysis of Kappa values, both unweighted and weighted, showed greater concordance between qF and pathologist assessments as length of tissue samples increased. The Kappa values leveled off at 11mm upwards with asymptote around 15 mm, aligning with the current recommendations for pathologists (Table 1). Highest weighted Kappa value observed was 0.78, consistent with previously published inter-observer Kappa values. Percentage of cases where qF indicated higher fibrosis stages

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

compared to pathologist assessments were greater when tissue length was shorter. Additional study of effects of other variables, including width and sample fragmentation, on accuracy of qF will also be presented at the meeting. **Conclusion:** In this systematic study, our findings demonstrate that qF tends to underestimate the extent of fibrosis in small biopsy sizes and a minimum tissue length of 15mm is required for qF to achieve reproducible agreement with pathologist's staging. This highlights the importance of considering minimum length of liver biopsy when utilizing qF as a clinical diagnostic tool.

Table 1: Concordance rates and percentage agreement rates for qF stage versus pathologist stage for different lengths of virtual biopsy

Tissue length	qF vs pathologist Unweighted Kappa	qF vs pathologist Linear weighted Kappa	%Cases (qF stage<pathologist stage)	%Case (qF stage>pathologist stage)
5 mm	0.43	0.63	27%	19%
6 mm	0.38	0.62	28%	22%
7 mm	0.39	0.63	27%	22%
8 mm	0.46	0.67	23%	20%
9 mm	0.53	0.70	19%	19%
10 mm	0.46	0.68	26%	17%
11 mm	0.51	0.71	21%	18%
12 mm	0.55	0.74	20%	16%
13 mm	0.59	0.77	17%	16%
14 mm	0.60	0.76	16%	16%

Background: Hepatocyte nuclear factor 4 alpha (HNF4α) is a nuclear receptor and master regulator of liver development and function. HNF4α expression is dysregulated in fibrotic liver disease and upregulation of this key transcription factor has been shown to improve hepatocyte function. The HNF4α gene is driven by two promoters, with isoforms derived from the P1 promoter demonstrating enhanced transcriptional activity associated with therapeutic benefit. The OMEGA platform develops programmable mRNA medicines called Omega Epigenomic Controllers (OECs) that precisely tune gene expression by site-specifically modulating epigenetic state and can be delivered using tissue-specific lipid nanoparticles (LNPs). Using OECs to induce selective upregulation of the P1 isoform of HNF4α in a liver-specific manner represents a novel therapeutic strategy for the treatment of fibrotic liver disease. **Methods:** The multigenic Insulated Genomic Domain and component sequences driving epigenetic control of the human *HNF4A* gene were interrogated and OECs were designed to modulate its expression. AML (K562) and hepatic stellate (LX-2) cell lines and primary human hepatocytes were transfected with LNP-encapsulated OECs (LNP-OEC) and qPCR or IHC was performed to assess HNF4α expression. For the *in vitro* fibrosis assay, LX-2 cells were treated with TGFβ1 and transfected with LNP-encapsulated OECs, and changes in expression of pro-fibrotic markers were measured by qPCR. To measure *in vivo* induction of HNF4α, a single dose of LNP-encapsulated OEC was administered intravenously to humanized $Fah^{-/-}$/$Rag2^{-/-}$/$Il2rg^{-/-}$ (FRG) mice and qPCR was performed to measure HNF4α expression. **Results:** Treatment with single OECs or combinations of OECs in K562 and LX-2 cells resulted in robust upregulation of total HNF4α mRNA levels and corresponding increases in HNF4α protein levels were observed. Treatment of primary human hepatocytes with OECs resulted in a strong induction of HNF4α P1 promoter isoforms compared with minimal effect on P2 promoter isoforms. Col1a1 and αSMA expression was significantly reduced (~50%) in LX-2 cells following treatment with a combination of OECs. A single, optimized OEC was developed that led to durable induction of HNF4α mRNA levels (up to 10 d, as intended/programmed) in both K562 cells and primary human hepatocytes. Administration of a single dose of the optimized OEC to the FRG mouse resulted in a significant induction of HNF4α mRNA compared with untreated mice. **Conclusion:** We demonstrate the ability to increase the expression of HNF4α with OEC treatment both *in vitro* and *in vivo*. In addition, this modulation preferentially induces the upregulation HNF4α P1 promoter isoforms resulting in inhibition of fibrotic responses *in vitro*. Future studies will test the efficacy of this upregulation in liver disease models and further explore the therapeutic potential of epigenomic targeting of HNF4α in fibrotic liver disease.

3445-A | INHIBITION OF HISTONE DEACETYLASE (HDAC) DECREASES LIVER FIBROSIS IN MICE

Devadoss J. Samuvel[1], John J. Lemasters[1], C. James Chou[1,2] and Zhi Zhong[1], (1)Medical University of South Carolina, (2)Neuroene Therapeutics

Background: Liver fibrosis/cirrhosis is one of the most common causes of death in adults world-wide for which effective therapy is unavailable. Some HDAC isoforms stimulate fibrosis. In this study, we explored the therapeutic effects of novel, potent HDAC1,2,3 inhibitors (HDACi) on liver fibrosis. **Methods**: To determine the effects of HDACi in vitro, human immortalized hepatic stellate cells (hTERT cells) were cultured for 24h and then incubated with LP342 (0.1 and 0.3 μM), a lead of the new HDACi, or vehicle for 48h. To determine the effects of HDACi *in vivo*, mice were treated with CCl_4 twice weekly for 6wk to induce liver fibrosis. LP340 (0.05mg/kg, ig), another lead HDACi, was given during the last 2 weeks of CCl_4 treatment. **Results**: Cultured hTERT cells underwent activation as indicated by expression of α-smooth muscle actin (αSMA) and collagen-1α1. LP342 inhibited hTERT cell activation dose-dependently. SnoN binds to Smad4, thus acting as a negative regulator of profibrotic TGFβ/Smad signaling. miR23a promotes TGFβ signaling by decreasing SnoN. LP342 markedly decreased miR23a and TGFβ downstream signaling molecule phospho-Smad2/3 in cultured hTERT cells. After 6wk of CCl_4 treatment in vivo, ALT increased, and cell swelling, steatosis, cell death, and leukocyte infiltration occurred in livers. Moreover, TNFα and myeloperoxidase markedly increased, indicating inflammation. LP340 decreased liver injury and inflammation. After CCl_4 treatment, αSMA increased ~80% and collagen-1α1 expression increased ~6-fold, indicating HSC activation and fibrogenesis. Moreover, fibrosis, indicated by increased trichrome staining in liver sections, occurred primarily in the pericentral regions with bridging fibrosis also occurring. LP340 blunted the increases of αSMA, collagen-1α1 and trichrome staining. After CCl_4 treatment, formation of potent profibrotic cytokine TGFβ and phospho-Smad2/3 markedly increased, which LP340 blunted. Moreover, miR23a increased ~7-fold and SnoN decreased ~50% after CCl_4, both blunted by LP340. By contrast, LP340 had no effect on MMP9 expression. LP340 markedly increased acetylated histone-3 but did not increase acetylated tubulin, indicating inhibition of

3446-A | INHIBITION OF INTEGRIN αVβ1 ATTENUATES PROFIBROGENIC GENE EXPRESSION BY MYOFIBROBLASTS IN FIBROTIC HUMAN LIVER EXPLANTS

Steve Ho, Mahru An, Richard Ahn, Vikram Rao, Scott Turner, Martin Decaris and Johanna Schaub, Pliant Therapeutics

Background: Integrin $\alpha_V\beta_1$ is a (myo)fibroblast-specific integrin that activates transforming growth factor (TGF)-β, promoting fibrogenesis. Inhibition of $\alpha_V\beta_1$ is antifibrotic in mouse models of liver fibrosis; however, data in human tissue are limited. Precision-cut liver slices (PCLivS) bridge the gap between cell-based models and *in vivo* models of liver fibrosis, providing a translational assay platform for investigating fibrogenesis in small sections of intact fibrotic human tissue cultured *ex vivo*. Here we use human PCLivS and single nuclei RNA-Seq (snRNA-Seq) to evaluate the effects of an $\alpha_V\beta_1$-selective inhibitor on individual cell populations present in fibrotic human liver tissue. **Methods:** Human liver tissue with or without evidence of fibrosis (fibrotic and normal, respectively) was obtained from rejected organ donors. PCLivS were generated from fibrotic liver tissue and cultured for 2 days in the presence of an $\alpha_V\beta_1$-selective inhibitor, a TGF-β receptor I kinase inhibitor (ALK5i; R-268712) or vehicle (DMSO). Intact nuclei were isolated from slices using a combination of detergent-based lysis, mechanical disruption, and filtration. Transcriptomic analysis of PCLivS single nuclei was performed using 10x Chromium Next GEM 3' technology. Custom annotation of cell types was performed using gene markers established from recently published data sets. Integrin $\alpha_V\beta_1$ protein levels in donor tissues were quantified by custom Meso Scale Discovery electrochemiluminescence assay. **Results:** Fibrotic livers had elevated $\alpha_V\beta_1$ protein concentrations relative to normal livers. Sequencing of single nuclei isolated from cultured PCLivS identified multiple unique cell populations, with hepatocytes, cholangiocytes, myofibroblasts, and endothelial cells comprising the most abundant annotated clusters. Differential gene expression analysis on the myofibroblast cluster showed $\alpha_V\beta_1$ inhibition significantly reduced *COL1A1* expression (FDR < 0.05) as well as several other genes related to collagen-containing extracellular matrix (GO:0062023), such as *BGN*, *GREM1*, and *CTHRC1*. Overlap in the specific genes downregulated by $\alpha_V\beta_1$ inhibition and ALK5i was observed, with a similar degree of effect from $\alpha_V\beta_1$ inhibition and TGF-β receptor signalling inhibition with ALK5i. **Conclusion:** Treatment of fibrotic human PCLivS with an $\alpha_V\beta_1$ inhibitor resulted in clear reductions in profibrogenic gene expression by myofibroblasts. The overlap with the effect of ALK5i demonstrates the importance of the $\alpha_V\beta_1$ integrin-TGF-β activation pathway in fibrotic liver disease. These data support $\alpha_V\beta_1$ integrin inhibition as a promising approach for targeted inhibition of TGF-β signalling in fibrotic liver disease.

3447-A | MACROPHAGES EXPRESSING CX3CR1 ORCHESTRATE THE REGRESSION OF MURINE LIVER FIBROSIS

Dabing Ping[1], Lu Xing[1], Kai Huang[2], Xin Sun[2], Xudong Hu[3] and Chenghai Liu[2,4], (1)Institute of Liver Diseases, Shuguang Hospital, Affiliated to Shanghai University of TCM, (2)Shanghai Key Laboratory of Traditional Chinese Clinical Medicine, (3)Department of Biology, School of Basic Medical Sciences, Shanghai University of Traditional Chinese Medicine, (4)Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine

Background: The critical role played by macrophages in chronic liver damage has been established, with the identification of distinct subpopulations that either promote fibrosis or counteract it. This research aims to uncover the specific phenotype of macrophages that exhibit anti-fibrotic effects and to shed light on the mechanisms underlying this phenomenon. **Methods:** Wild type (WT) and $CX3CR1^{-/-}$ mice were administered carbon tetrachloride (CCL_4) via injection for a duration of 6 weeks to induce liver fibrosis. After the final injection of CCl_4, the mice were allowed to recover for 3 days or a week. In the macrophages infusion experiment, Bone marrow-derived macrophages (BMDMs) from WT, $CX3CR1^{-/-}$ or $CCR2^{-/-}$ mice were polarized into M_0 or M_1 macrophages, respectively.

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

These BMDMs were administered to mice at start of the third weeks through the tail vein. The progression of fibrosis and associated molecular changes were subsequently assessed. **Results:** During the process of liver fibrosis regression in mouse models induced by CCL4, there was an increase in the number of macrophages expressing CX3CR1. However, the recovery from liver fibrosis and the inhibition of activated hepatic stellate cells (HSCs) were prevented in CX3CR1-deficient conditions. Results from cytotherapy experiments showed that BMDMs obtained from both WT and CCR2$^{-/-}$ mice, whether M_0 or M_1, were effective in reducing liver fibrosis. However, BMDMs from CX3CR1$^{-/-}$ mice did not show significant effectiveness in combating liver fibrosis. The mechanism is likely due to the production of matrix metalloproteinases (MMPs) and TNF-related apoptosis-inducing ligand (TRAIL), which promote collagen degradation and induce HSCs apoptosis, respectively. **Conclusion:** An increased number of CX3CR1-expressing macrophages contributed to the accelerated resolution of fibrosis, providing a potential therapeutic strategy for addressing this pathological condition. Key Words: Liver fibrosis; CX3CR1; Macrophage; Degradation; Hepatic stellate cells Figure 1. Macrophages that expressed CX3CR1 played a role in hastening the resolution of fibrosis.

3448-A | PROLONGED-RELEASE PIRFENIDONE IN PATIENTS WITH COMPENSATED CIRRHOSIS. FINAL RESULTS OF THE MULTICENTER STUDY ODISEA, CONTROLLED AGAINST PLACEBO, PLUS STANDARDIZED CARE

Linda Elsa Munoz-Espinosa[1], Aldo Torre[2], Laura Cisneros[3], Iaarah Montalvo-Gordon[4], Rene Male[5], Scherezada Mejía[6], Juan Ramón Aguilar-Ramírez[4], Javier Lizardi-Cervera[4], María Eugenia Icaza-Chávez[7], Frida Gasca[4], Larissa Hernandez-Hernandez[4], Paula Cordero-Perez[1], Luis Alberto Chi Cervera[7], Lilian Torres Made[8], Fatima Rodríguez-Alvarez[9], Graciela Tapia[10] and Jorge Luis Poo[4], (1)University Hospital "José Eleuterio Gonzalez", Uanl, (2)Instituto Nacional De Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico, (3)Investigaciones Medicas Cisneros, Monterrey, NL, Mexico, (4)Grupo Mexicano Para El Estudio De Las Enfermedades Hepáticas, (5)Instituto De Salud Digestiva, (6)Hospital Juarez De Mexico, (7) Hospital Star Médica, (8)Instituto De La Salud Digestiva, (9)Instituto Nacional De Ciencias Médicas y Nutrición Salvador Zubirán, (10)Facultad De Medicina Veterinaria y Zootecnia. U.N.a.M.

Background: Advanced liver fibrosis (ALF) is a predictor of adverse prognosis in chronic liver disease. In addition to etiological treatment, a new approach to stop or reverse residual fibrosis is desirable. Our aim was to assess efficacy and safety of a prolonged-release pirfenidone formulation (PR-PFD) compared to placebo, plus standardized care, in patients with compensated liver cirrhosis. **Methods:** 180 patients with ALF (F4 by elastography) of various causes, were randomly assigned to 3 groups: placebo (G1), PR-PFD: 1200 mg/d (G2) or 1800 mg/d (G3), plus standardized care, during 24 months. All participants underwent standard lab tests, quality of life assessment, elastography, fibrotest, liver US and endoscopy at baseline, and 12 and 24 months. **Results:** 165 patients were eligible for the efficacy and 180 for the safety analysis. At baseline, demographics, etiology, stage of cirrhosis, Child-Pugh or MELD scores , quality of life or fatigue scales , and liver stiffness (kPa) and Fibrotest (units) scores (mean ± 1SE) were similar between groups (multivariate mixed model). The estimated fibrosis scores presented a significant reduction, mainly in G2 (Table). Decompensations were detected in 19 patients: variceal bleeding (5), encephalopathy (4), hepatocarcinoma (4) with similar distribution between groups. Ascites (12) was more frequent in the placebo group ($p = 0.003$). G2 patients presented significant

improvements between baseline and 24 months in: ALT (43.5 ± 3.8 vs 31.3 ± 4.8 UI/L, p = 0.003), albumin (4.2 ± 0.06 vs 4.5 ± 0.07 g/dL, p < 0.001); total bilirubin (0.90 ± 0.08 vs 0.65 ± 0.10 mg/dL, p < 0.001); platelets (121.7 ± 7.8 vs 144.3 ± 9.7 x10³/µL, p < 0.001), MELD (9.73 ± 0.32 vs 9.03 ± 0.40, p = 0.022) and quality of life (83.7 ± 1.5 vs 90.9 ± 1.9 %, p = 0.002). Adverse events were mainly mild from the GI tract (n = 48, 46, and 35) and skin (n = 15, 22, and 12), in G1, G2, and G3, respectively. **Conclusion:** Prolonged-release pirfenidone at a dose of 1200 mg significantly decreased indirect fibrosis markers at 24 months and induced improvement in LFTs, MELD, and quality of life in compensated cirrhosis, and without safety concerns. Ethics Committee number HI14-004

3449-A | REPEATABILITY OF LIVER STIFFNESS MEASUREMENT BY VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY AND CONTROLLED ATTENUATION PARAMETER IN PATIENTS WITH CIRRHOSIS

Daniel Q Huang[1], Nabil Noureddin[2], Jaclyn Bergstrom[3], Maral Amangurbanova[3], Egbert Madamba[3], Christie Hernandez[3], Claude B. Sirlin[3] and Rohit Loomba[4], (1) National University Health System (NUHS), (2)University of California San Diego, (3)University of California, San Diego, (4)University of California, San Diego, San Diego, CA

Background: The regulatory qualification of non-invasive tests (NITs) for liver fibrosis severity assessment is a major unmet need for drug development and clinical care in cirrhosis. Ultrasound-based methods such as vibration-controlled transient elastography (VCTE) evaluate liver stiffness measurement (LSM) and controlled attenuation parameter as a marker for fibrosis severity and steatosis, respectively. Repeated use of VCTE has the potential to assess disease response and progression. However, this potential application has been limited by a paucity of repeatability data in the patient population at risk. The aim of this prospective study from the San Diego Cirrhosis Registry was to address this knowledge gap and contribute to the evidentiary basis needed for the qualification of ultrasound-based methods in various contexts of use in clinical trials and practice. **Methods:** A prospective cohort of adults with suspected or established cirrhosis underwent two FibroScan examinations (Fibroscan Expert 630, Echosens, France) on the same day performed by the same experienced operator. LSM by VCTE and CAP measurements were reported and analyzed in units of kPa and dB/m, respectively. The primary endpoint was the same-day/same-operator repeatability coefficient (RC), which represents the value under which the difference between repeated measurements should fall with a 95% probability. Secondary outcomes include the intra-class correlation coefficient (ICC) which represents the proportion of total variation explained by between-patient differences rather than measurement variation, and the within-case coefficient of variation (wCV), which represents the ratio of within-patient variation to overall measurement values. **Results:** Same day repeat scans were available in 36 participants. The mean age was 60 years, 56% were women, mean BMI was 30.5 kg/m^2). The percentage of cases due to nonalcoholic steatohepatitis, alcohol, and hepatitis C virus, were 42%, 25%, and 14%, , respectively. RC was 12.0 kPa for LSM by VCTE and 77.4 B/m for CAP, meaning that any change greater than those values has a 95% probability to reflect true change rather than measurement error. ICC was excellent for LSM (.94) and fair for CAP (.77), while wCV indicate that the within-patient variation is close to the overall measurement values for LSM and CAP (Table 1). **Conclusion:** LSM and CAP measurement by FibroScan 630 model, demonstrated good repeatability within patients with cirrhosis. These repeatability estimates are likely to inform ultrasound-based NIT qualification by defining the values that are expected to reflect a true change in the context of clinical trials or clinical care.

Table 1: Repeatability, intra-class correlation, and within-case coefficients for LSM by VCTE and CAP

	Mean (SD)	Repeatability Coefficient (RC)	Intra-class Correlation ICC (95% CI)	Within-case Coefficient of Variation (wCV)
Repeatability of LSM by VCTE (kPa)	23.5 (16.3)	12.0	.94 (.88 - .97)	18.1%
Repeatability of CAP (dB/m)	257.4 (54.6)	77.4	.77 (.60 - .87)	11.1%

3450-A | SIGNIFICANTLY HIGHER INCIDENCE OF CIRRHOSIS AND THE RELATED CLINICAL PRESENTATION IN ELDERLY PATIENT

Ke-Qin Hu and Hien Lau, UC Irvine

Background: The prevalence of chronic liver diseases (CLDs) in elderly patients ($\geq$60 y old by WHO) is increasing. This study was aimed to assess the clinical presentation, incidence of cirrhosis and associated factors in elderly patients (pts). **Methods:** A single-center retrospective study of 454 consecutive pts with CLDs, regular follow-ups and liver biopsy at the UCIMC Liver Clinic. Clinical, histological, imaging and laboratory data were collected for statistical analysis. **Results:** The mean age $\pm$ SD was 56 $\pm$ 14 years old; 230 pts were male (49.9%). Chronic hepatitis C (CHC) and B (CHB) and non-alcoholic fatty liver disease (NAFLD) were the main causes of CLDs, i.e. 89 (20.0%), 83 (18.6%) and 122 (27.4%), respectively. Compared to 205 pts $<$ 60 years old, 249 elderly pts (54.8%) carried significant higher incidences of cirrhosis (58.0% vs 42.0%, $p < 0.01$), decompensation (58.4% vs 41.6%, $p = 0.01$), diabetes mellitus (DM) (41.4% vs 31.0%, $p = 0.02$), hyperlipidemia (HLD) (57.1% vs 46.4%, $p = 0.02$), diuretics use (60.2% vs 39.8%, $p < 0.01$), biopsy-proven fibrosis stage 3-4 (55.8% vs 44.2%, $p < 0.01$), stage 3-4 fibrosis on sheer-wave elastography (SWE) (56.8% vs 43.2%, $p < 0.01$), FIB-4 score $>$ 1.45 (64.0% vs 40.0%, $p < 0.01$). In multivariate analysis, female gender (95% CI: .39-.90; $p = 0.01$) and cirrhosis (95% CI: .22-.57; $p < 0.01$) were significantly associated with pts $\geq$60 years old, independently to decompensation, DM or HLD. Compared to 91 elderly pts with biopsy-proven stage 0-2 fibrosis, 86 elderly pts with stage 3-4 fibrosis were significantly associated with CHC as the primary CLD (61.7% vs 38.3%, $p = 0.04$), 3 different CLDs (56.8% vs 43.2%, $p < 0.01$), DM (62.5% vs 37.5%, $p < 0.01$), splenomegaly on ultrasound (62.5% vs 37.5%, $p < 0.01$), albumin $<$ 3.5 g/dL (66.7% vs 33.3%, $p < 0.01$), and INR $\geq$1.2 (78.6% vs 21.4%, $p < 0.01$). Multivariate analysis showed that having $\geq$3 different CLDs (95% CI: 1.0-6.8; $p = 0.04$), DM (95% CI: 1.3-7.2; $p < 0.01$), INR $\geq$1.2 (95% CI: 1.7-21.1; $p < 0.01$), and platelet $\leq 120 \times 10^9$/L (95% CI: 1.3-8.3; $p = 0.01$) were independently associated with biopsy-proven stage 3-4 fibrosis in elderly patients. SWE showing stage 3-4 fibrosis (69.6% vs 30.4%, $p < 0.01$), APRI score $>$ 1 (63.0% vs 37.0%, $p < 0.01$), and FIB-4 score $>$ 2.67 (57.0% vs 43.0%, $p < 0.01$) were significantly associated with biopsy-proven stage 3-4 fibrosis in these patients. **Conclusion:** Elderly pts with CLDs have higher incidences of cirrhosis and decompensation. Female gender and cirrhosis were independently associated with being elderly with CLDs. Elderly pts with biopsy-proven stage 3-4 fibrosis were more likely to have $\geq$3 different CLDs, DM, thrombocytopenia, and elevated INR. SWE, APRI and FIB-4 scores were all well-associated with histological hepatic fibrosis in elderly pts.

f 3451-A | TARGETING THE HEDGEHOG PATHWAY TRANSCRIPTION EFFECTOR Gli2 IS A NOVEL THERAPEUTIC STRATEGY FOR SEVERE SCHISTOSOMIASIS MANSONI FIBROSIS AND PORTAL HYPERTENSION

Thiago De Almeida Pereira, Stanford University School of Medicine, San Francisco, CA, Paula Vidigal, School of Medicine, Federal University of Minas Gerais, Anna Mae Diehl, Duke University, Thomas Wynn, Pfizer and Philip Beachy, Stanford University School of Medicine

Background: Schistosomiasis is a major cause of liver fibrosis and portal hypertension in the Global South. IL13 and Hedgehog (Hh) signaling pathways have both been implicated in the pathogenesis of fibrosis and could be potential therapeutic targets. Our aims were to determine if there is cross-talk between IL13 and Hh pathways and if Hh pathway inhibitors could be used as anti-fibrotic therapy in schistosomiasis mansoni. **Methods:** Hh/IL13 signaling were investigated by qRT-PCR, immunohistochemistry and ELISA in uninfected healthy transplant donors ($n = 22$), infected hepatointestinal schistosomiasis patients (liver granulomas, low fibrosis, $n = 17$), infected hepatosplenic patients (advanced fibrosis and portal hypertension $n = 72$); in *Schistosoma mansoni* infected mice (wild-type, IL13Rα1-/- and TKO (IL-10-/- IL12p40-/-IL13Rα2-/-) treated with anti-IL13 antibody, Hh pathway inhibitors (Smoothened antagonists Vismodegib or XL139 vs Gli2 antagonists Arsenic Trioxide (ATO) or HPI vs Vehicle), in mice overexpressing IL13 (plasmid) and in human liver cells stimulated with recombinant IL13 (rIL13) and treated with STAT6 siRNA, Vismodegib or HPI). This study was approved by the human and animal ethics committees of Federal University of Minas Gerais, Duke University, NIH, and Stanford University. **Results:** Hh signaling is upregulated in human

schistosomiasis and correlates with IL13, fibrosis stage, and severity of portal hypertension. Overexpression of IL13 (plasmid, infected TKO mice, rIL13) induced Hh ligand production/pathway activation; lack of IL13 signaling (IL13Rα1-/- infected mice, anti-IL13 antibody, STAT6 siRNA) implicated in reduced Hh pathway, indicating that Hh signaling is dependent on IL13. STAT6 Chromatin Immunoprecipitation assay further demonstrated that STAT6 directly binds to the promoter region and regulates the transcription of Hh ligands (Ihh, Dhh) and transcription factors (Gli1, Gli2, Gli3). Smoothened antagonists Vismodegib or XL139 effectively blocked inflammation and fibrosis during acute schistosomiasis but failed to inhibit Hh signaling, inflammation, and fibrogenesis when treatment was initiated in the chronic phase due to Smoothened-independent IL13-mediated Gli2 activation. Gli2 inhibition with ATO or HPI in the chronic phase impaired Hh signaling, inflammation, and fibrogenesis. **Conclusion:** Activation of the Hh pathway in schistosomiasis is highly dependent on IL13-mediated signaling. Targeting Hh pathway with Gli2 antagonists may be a novel therapeutic strategy to treat schistosomiasis fibrosis and portal hypertension.

3452-A | THE RELATIONSHIP BETWEEN LIVER FIBROSIS AND HEMOSIDEROSIS IN PATIENTS WITH UNTREATED HEPATITIS C

Shahana Prakash[1], Amelia Fierro-Fine[2], Anthony Snow[1], Sarag Boukhar[3] and Kyle E. Brown[4], (1) University of Iowa Hospitals and Clinics, (2)St. Cloud Hospital, (3)Robert Wood Johnson Medical School, (4) University of Iowa Carver College of Medicine, Iowa City, IA

Background: Evidence of dysregulated iron metabolism is seen in several common forms of chronic liver disease, including hepatitis C infection (HCV). Variable proportions of HCV patients have abnormal serum iron tests, with secondary hepatic iron deposition occurring primarily in subjects with significant fibrosis. To evaluate the relationship between iron deposition and fibrosis, it is essential to establish the temporal sequence of hemosiderosis vis-a-vis fibrosis progression. To address this question, we examined changes in iron deposition (grade and localization) and fibrosis over time in HCV patients who underwent serial liver biopsies in the pre-direct acting antiviral (DAA) era. **Methods:** HCV patients who underwent > 1 liver biopsy at our institution between 1996 and 2015 and who had HCV viremia at the time of all biopsies were selected for study. The first and last liver biopsies for each subject were selected for review. Two pathologists independently scored hepatocyte iron deposition using the method of Scheuer; Kupffer cell (KC) iron was graded as none, mild, moderate, or severe. Liver fibrosis was staged according to the Batts-Ludwig scoring system. Spearman correlation coefficients between fibrosis and iron scores were computed using SPSS 28. **Results:** We identified 107 HCV with > 1 liver biopsies performed between 1996 and 2015. Of the entire cohort, 39/107 (36%) of patients demonstrated progression of liver fibrosis (Group A), while fibrosis remained stable or appeared to improve in 68/107 patients (64%) (Group B). The time interval between liver biopsies did not differ between the groups (Group A: 5.5 years; Group B: 5.8 years; $p = 0.7$). Fibrosis stage on the first biopsy showed a weak but significant correlation with the KC iron score on the same biopsy ($\rho = 0.20$; $p = 0.04$). The fibrosis stage on the second biopsy correlated with the initial KC iron score ($\rho = 0.27$; $p = 0.005$) as well as the second KC iron score ($\rho = 0.29$; $p = 0.003$). There was also a significant positive correlation between change in fibrosis stage

and both the second KC iron score ($\rho = 0.23$; $p = 0.02$) and the change in Scheuer score ($\rho = 0.22$; $p = 0.02$). **Conclusion:** Serial biopsies done in the pre-DAA era provide a unique resource to address basic questions about changes that accompany increases in fibrosis over time. Our data show that KC iron is more closely associated with fibrosis progression than hepatocyte iron, but the relationship between iron deposition in either cell type and fibrosis progression is weak.

f 3453-A | A CCR2-TARGETED PET PROBE FOR LIVER FIBROSIS DETECTION AND STAGING IN PRECLINICAL MODELS

Tuo Shao, Wenyu Lin and Raymond T. Chung, Massachusetts General Hospital and Harvard Medical School

Background: Hepatic stellate cell (HSC) and Kupffer cell activation are accompanied by increased expression of chemokines and chemokine receptors, including CC-chemokine receptor 2 (CCR2). Molecular imaging targeting the CCR2 could provide a non-invasive means of evaluating the expression and function of the CCR2 on activated HSCs (aHSCs) and macrophages in the injured liver, and thus provide important prognostic information in chronic liver disease. ^{68}Ga-DOTA-ECL1i is a radiotracer specific for CCR2. In this study, we sought to compare differences in uptake of the ^{68}Ga-DOTA-ECL1i between normal and injured liver to evaluate its utility for assessment of fibrogenesis. **Methods:** We used PET/CT to assess changes in CCR2 binding of intravenously-administered ^{68}Ga-DOTA-ECL1i in the livers of mice with bile duct ligation (BDL)- and carbon-tetrachloride (CCl_4)-induced liver fibrosis compared with controls. We performed Sirius red staining to assess liver fibrosis, immunofluorescence to identify the location of CCR2 expressed in fibrotic liver, and measured protein and messenger RNA expression of CCR2, F4/80 and alpha smooth muscle actin (α-SMA) in control and fibrotic livers. Autoradiography was performed to evaluate tracer uptake in liver sections both in animal models. **Results:** Fibrotic mouse livers displayed enhanced ^{68}Ga-DOTA-ECL1i uptake and retention. The radiotracer was demonstrated to bind specifically to CCR2 mainly expressed on aHSCs and Kupffer cells. The hepatic radiotracer uptake at 30 min post-injection was higher in fibrotic livers compared to control livers. Autoradiography and histopathology confirmed the PET imaging results. Further, the mRNA and protein level of CCR2 and its signaling complex were higher in CCl_4 and BDL models compared to controls. Autoradiography confirmed the PET imaging finding of high radioactivity binding in fibrotic liver in both animal models. **Conclusion:** Imaging hepatic CCR2 with PET and ^{68}Ga-DOTA-ECL1i offers a potential noninvasive method for monitoring the progression of liver fibrosis.

3454-A | BIOMARKERS OF FIBROSIS AND PORTAL HYPERTENSION OF FONTAN-ASSOCIATED LIVER DISEASE IN CHILDREN AND ADULTS

Chaowapong Jarasvaraparn, Jessica Thoe, Andrew Rodenbarger, Howard C. Masuoka, Mark Payne, Larry Wayne Markham and Jean P Molleston, Indiana University

Background: Fontan-associated liver disease (FALD) refers to structural and functional changes of the liver caused by hemodynamic changes from Fontan circulation. Currently, liver biopsy is the standard to assess liver fibrosis. We investigated correlation of biomarkers with severity of fibrosis on liver biopsy and portal hypertension in children and adults with FALD. **Methods**: A retrospective study of Fontan patients > 10 years old who underwent liver biopsy was reviewed. Liver biopsy reports were used by the congestive hepatic fibrosis staging including 0 (no), 1 (central zone fibrosis), 2 (central and portal fibrosis), 3 (bridging fibrosis), and 4 (cirrhosis). Advanced liver disease (ALD) was defined as bridging fibrosis and/or cirrhosis. AST-to platelet ratio index (APRI) and Fibrosis-4 (FIB-4) were used as non-invasive fibrosis scores. Liver stiffness (LS) from FibroScan

and features of portal hypertension which were calculated using the VAST (one point each for Varices, Ascites, Splenomegaly, Thrombocytopenia) were obtained; VAST score $\geq$ 2 signifies portal hypertension. Fontan pressure, wedge and free hepatic venous pressure (HVP) were obtained at the same time with liver biopsy. Hepatic venous pressure gradient (HVPG) was calculated as wedge HVP minus free HVP. **Results**: Among 66 patients (47 adults and 19 children), ALD was observed in 26/47 (55.3%) of adults and 13/19 (68.4%) of children. ALD was significantly associated with lower platelet count, higher APRI, and higher FIB-4. Liver fibrosis score correlated with APRI (0.34, $p = 0.02$) and FIB-4 (0.47, $p = 0.001$) in adults, not children. FIB-4 was the only diagnostic marker for prediction of ALD in FALD (FIB-4 > 0.57, sensitivity 71.8%, specificity 48.2%, AUC 0.67 $\pm$ 0.07, $p = 0.02$). Liver fibrosis score from biopsy in adults and children with ALD were similar. LS correlated with Fontan pressure (0.62, $p = 0.003$), wedge HVP (0.61, $p = 0.003$), and free HVP (0.63, $p = 0.002$), not liver fibrosis score from biopsy. Patients with significant portal hypertension had lower albumin (3.77 vs. 4.47, $p = 0.01$), higher Fontan pressure (17.11 vs 12.9, $p = 0.001$), higher HVPG (1.28 vs. 0.94, $p = 0.03$) and higher fibrosis score from biopsy (3.19 vs. 2.48, $p = 0.002$) than without significant portal hypertension. **Conclusion**: APRI and FIB-4 had modest discrimination to identify adults with ALD, not children, indicating that these values may be followed as a marker of FALD progression. LS reflects Fontan pressure but not biopsy fibrosis score. Portal hypertension in FALD is possibly caused by elevated venous pressure and liver fibrosis. Further prospective studies are essential to develop non-invasive biomarkers for screening FALD.

Table Characteristics, laboratory tests, and non-invasive fibrosis scores between non-advanced fibrosis and advanced fibrosis/cirrhosis from liver biopsy in Fontan patients

	Fontan with non-advanced fibrosis (N=27)	Fontan with advanced fibrosis/cirrhosis (N=39)	P-value
Age at liver biopsy (years, mean ± SD)	25.56 ± 10.2	23.36 ± 8.7	0.36
Age at Fontan procedure (years, mean ± SD)	4.84 ± 5.98	4.32 ± 2.96	0.67
Time since Fontan until liver biopsy (years, mean ± SD)	22.05 ± 7.21	19.06 ± 6.99	0.1
Protein losing enteropathy (%)	2 (7.4)	5 (12.82)	0.69
Gender (%)

3455-A | DETERMINING THE OPTIMAL TRANSIENT ELASTOGRAPHY CUTOFFS IN CHRONIC HEPATITIS B PATIENTS WITH CONCURRENT HEPATIC STEATOSIS

Fajuan Rui[1], Xiaoming Xu[1], Wenjing Ni[1], Liang Xu[2], Jeff Liang[3], Yee Hui Yeo[3] and Jie Li[4], (1)Nanjing Drum Tower Hospital Clinical College of Nanjing University of Chinese Medicine, Nanjing, Jiangsu, China, (2)Clinical School of the Second People's Hospital, Tianjin Medical University, Tianjin, China, (3)Cedars-Sinai Medical Center, Los Angeles, CA, (4)Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, Jiangsu, China

Background: Transient elastography (TE) is a non-invasive method for diagnosing liver fibrosis through liver stiffness measurement. The current cutoff values of TE are designed to assess liver fibrosis in patients with a singular liver disease, such as chronic hepatitis B (CHB) or non-alcoholic fatty liver disease (NAFLD). However, the cutoff value of TE in CHB patients with concurrent hepatic steatosis (HS) remains unverified. Using biopsy as the gold standard, this study aims to establish the optimal cutoff for TE for this cohort. **Methods:** This study consecutively enrolled CHB patients with concurrent HS who underwent liver biopsy and Fibroscan at the Tianjin Second People's Hospital between January 2016 and September 2021. The area under the receiver operating characteristic curve (AUROC), sensitivity (SE), specificity (SP), positive predictive value (PPV), and negative predictive value (NPV) of contemporary TE cutoff for patients with CHB or NAFLD (9.7kPa) was calculated. The optimal TE cutoff for patients with concurrent CHB and NAFLD was estimated using the Youden index. The Delong test was used to compare the differences between AUROCs of the contemporary and optimal cutoffs. Subgroup analysis by body mass index (BMI) was conducted. **Results:** We included 613 CHB patients with concurrent HS, with a median age of 36 years (IQR: 30-46). Seventy-four patients had advanced fibrosis. The recommended TE cutoff for patients with CHB or NAFLD was 9.7 kPa, and the corresponding AUROC was 0.681, with SE at 55.41%, SP at 80.71%, PPV at 28.30%, and NPV at 92.90% (Table). At the optimal cutoff value (8.8 kPa), the corresponding AUROC was 0.733, significantly higher than 0.681 ($P = 0.015$). The SE, SP, PPV, and NPV of the optimal cutoff values (8.8

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

kPa) were 70.27%, 76.25%, 28.9%, and 94.9%, respectively. The SE, PPV, and NPV of the optimal cutoff value (8.8 kPa) were higher than those of the existing cutoff value (9.7 kPa). Subgroup analysis showed that for patients with a BMI < 25 kg/m^2, the optimal cutoff (8.8 kPa) AUROC was 0.708, significantly surpassing the corresponding value of the contemporary cutoff (AUROC = 0.566) ($P = 0.003$). In patients with BMI ≥ 25 kg/m^2, the optimal cutoff AUROC was 0.742, exceeding that of the contemporary cutoff (AUROC = 0.737), although without significant difference ($P = 0.747$). **Conclusion:** The optimal TE cutoff for assessing advanced fibrosis in CHB patients with concurrent HS was 8.8 kPa, lower than 9.7 kPa in CHB patients. In CHB patients with concurrent HS, a more stringent TE value is needed to enable more precise advanced fibrosis evaluation. The findings warrant further validation.

Table. Comparison of the diagnostic efficacy of the optimal cutoff of 8.8 kPa and the existing cutoff of 9.7 kPa for advanced fibrosis.

Advanced fibrosis	cutoff	SE	SP	PPV	NPV	AUC	P
Overall	>9.7	55.41	80.71	28.30	92.90	0.681	0.015
Overall	>8.8	70.27	76.25	28.90	94.90	0.733	
BMI < 25kg/m2	>9.7	24.00	89.23	22.20	90.20	0.566	0.003
BMI < 25 kg/m^2	>8.8	56.00	85.64	33.30	93.80	0.708	
BMI ≥ 25kg/m2	>9.7	71.43	75.87	29.70	94.90	0.737	0.747
BMI ≥ 25kg/m2	>8.8	77.55	70.93	27.50	95.70	0.742

3456-A | DOES SENESCENT CHANGE IN SPLEEN AFFECT SPLENOMEGALY IN ELDERLY PATIENTS WITH LIVER CIRRHOSIS?

Yunjeong Lee and Jin-Wook Kim, Seoul National University Bundang Hospital

Background: Splenomegaly has been considered a classic hallmark of portal hypertension and frequently used as a diagnostic criterion for liver cirrhosis. Meanwhile, it is also known that the size of spleen shrinks gradually over the later decades of life because of ageing-related changes to spleen architecture. However, the change in spleen volume has not been thoroughly evaluated in elderly patients with advanced hepatic fibrosis. This study aimed to elucidate the pattern and diagnostic significance of splenomegaly in elderly patients with hepatic fibrosis by measuring spleen volume and liver-to-spleen volume ratio (LSVR) from computed tomography (CT) images. **Methods:** In this observational cohort study, all patients were identified who received both liver biopsy and liver CT studies in our institute between July 2004 and December 2022 and classified into two groups: control and geriatric group (≥ 75 y). Propensity score matching was used to balance the two groups. Whole spleen and liver volumes were measured on abdominal CT scan images using Inobitec DICOM Viewer. Comparison between the two groups was done using a two-sample t-test with equal variances in Stata/SE 14.0. ROC analysis was used to assess the diagnostic performance of each parameter. **Results:** Both groups included all histologic grades of fibrosis (F0 8.1%, F1 23.7%, F2 23.7%, F3 12.6%, F4 31.9% in geriatric group and F0 9.3%, F1 22.0%, F2 20.1%, F3 6.9%, F4 41.7% in control group). In control group, patients with advanced fibrosis (METAVIR F3 and F4) had significantly larger spleen volume (277 cm^3) compared to F0-F2(163 cm^3) ($p < 0.001$). However, in geriatric group, patients with F3-F4 showed no statistically significant difference in spleen volumes compared to those with stage F0-F2 (174 vs 129 cm^3, respectively; $p = 0.051$). Whereas, the area under the ROC curve of spleen showed that the same cut-off volume for F3-F4 was similar between control and geriatric group (0.691 vs 0.692; cut-off, 158 vs 128 cm^3 for sensitivity of 70%, respectively; $p = 0.991$). Also, the ROC curve analysis generated a similar result when comparing spleen volumes in patients with liver cirrhosis (F4) and the others (F0-F3) between control and geriatric group (0.677 vs 0.706 (Fig.); cut-off, 159 vs 128 cm^3, respectively; $p = 0.696$). For LSVR, the area under the ROC curve showed no significant differences when comparing the volumes not only for F0-F2 vs. F3-F4(0.282 vs 0.301; cut-off, 4.165 vs. 5.317 for sensitivity of 70%, respectively; $p = 0.802$) but also for F0-F3 vs. F4 (0.308 vs 0.284; cut-off, 4.303 vs. 5.317; $p = 0.74$) as well. **Conclusion:** In elderly patients, splenomegaly may not seem as evident with advanced hepatic fibrosis as younger patients, however, the cutoff values from ROC curve analysis was not different from those in younger population. Spleen volume may still be used for the prediction of advanced fibrosis since our ROC analysis showed similar AUC values between control and geriatric groups.

3457-A | HEPATITIS B, HEPATITIS C AND ALCOHOL-RELATED DECOMPENSATED CIRRHOSIS: FACTORS AFFECTING RECOMPENSATION

Umang Arora[1], Vishwa Vadodaria[1], Sanil Garg[1], Ritik Mahaveer Goyal[2], Ishan Gupta[1], Gurasis Boparai[1], Shubham Mehta[1], Rosemary Jha[1], Isha Singh[1], Hari Narayan A[1], Sabreena Sheikh[1], Manas Vaishnav[1], Raju Sharma[1] and Dr Shalimar[1], (1)All India Institute of Medical Sciences, New Delhi, (2)Rutgers New Jersey Medical School

Background: Recompensation of cirrhosis describes a subset of patients with decompensated cirrhosis who achieve sustained clinical improvement following etiology-specific treatments, as defined by the Baveno VII consensus. Effective etiology-specific treatments include antivirals for hepatitis B virus (HBV) and hepatitis C virus (HCV), and abstinence from alcohol. The present study assessed factors associated with cirrhosis and adverse prognosis, such as sarcopenia and osteopenia, among patients who developed recompensation from decompensated cirrhosis. **Methods:** A case-control study was performed- cases included patients who achieved recompensation, and controls were patients who remained decompensated. Patients with cirrhosis due to HBV, HCV or alcohol who received etiology-specific treatment after decompensation were included. Patients with hepatocellular carcinoma diagnosed within 6 months of presentation, and those with two etiological factors such as coinfections or significant alcohol use in a patient with chronic viral hepatitis, were excluded. Anthropometric, biochemical, liver stiffness measurements (LSM) were recorded. Computed tomography (CT) parameters included sarcopenia {L3 vertebral skeletal muscle index below 38 cm^2/m^3 (women) or 42 cm^2/m^2(men)}, and osteoporosis (L1 vertebra attenuation $\leq$ 149 Hounsefield Units). Comparison between the two groups was performed using chi2 for categorical variables and Mann Whitney U test for continuous variables that were expressed as median (interquartile range). **Results:** A total of 109 patients with decompensated cirrhosis were analysed (n = 40: recompensated, n = 69: remained decompensated). The etiology of cirrhosis was HBV (n = 35), HCV (n = 35) and alcohol (n = 39). Median duration of follow-up was 2.8 (1.1 - 6.1) years. A larger proportion of patients with recompensated cirrhosis had viral etiology compared to alcohol-related cirrhosis (77% vs 23%, p = 0.03). There were no differences in body mass index (BMI), prevalence of diabetes and baseline liver function parameters between the 2 groups. (Table 1) However, those with recompensation had a significantly lower median age at index presentation and baseline MELD score. The MELD-sarcopenia score was borderline significant (p = 0.051). LSM showed a significantly greater decline in patients with recompensation (-21.7 vs 3.4 kPa, p = 0.013). Baseline Child-Pugh score, LSM, or prevalence of sarcopenia or osteopenia were not associated with the occurrence of recompensation (P > 0.05). There was no difference between the two groups in the time of initiation of treatment after decompensation (92 d vs 112 d, p = 0.93). **Conclusion:** Sarcopenia, osteoporosis, or time to treatment initiation were not associated with the occurrence of recompensation in this case-control study. Lower MELD score at baseline and greater decline in liver stiffness measurements on follow-up correlated with recompensation.

Table 1.Comparison of clinical, treatment, and CT parameters between patients who achieve recompensation (n=40) on follow up vs those who remain decompensated.

	Decompensated (n=69)	Recompensated (n=40)	Total (n=109)	p value

3458-A | METABOLIC BIOMARKER CONSTELLATIONS ALLOW SIMULTANEOUS AND INTEGRATED LIVER AND KIDNEY FUNCTION MONITORING IN CHRONIC LIVER DISEASE

Frank Stämmler[1], Laurence Derain-Dubourg[2], Sandrine Lemoine[2], Jeffrey Meeusen[3], Surendra Dasari[3], John Lieske[3], Andrew Robertson[1] and Eric Schiffer[1], (1) Numares AG, (2)Hospices Civils De Lyon, (3)Mayo Clinic

Background: Renal impairment often occurs in liver disease. Altered hemodynamics and creatinine metabolism in liver disease causes overestimation of glomerular filtration rate (GFR) using creatinine-based GFR estimating equations (eGFR). Accurate liver function testing often requires ascites and hepatic encephalopathy grading, which are subjective and difficult to obtain. Using nuclear magnetic resonance (NMR), our group has clinically and analytically validated an eGFR based on valine, myoinositol, and creatinine - in combination with cystatin-C, age, and sex (*AXINON*® GFR_{NMR}). A test determining different aspects of liver function such as Child-Pugh class has also been developed on the same NMR platform. We present the performance of these renal and liver function tests in chronic liver disease. **Methods:** For eGFR estimation, we compared equations in a multicenter retrospective study of 203 chronic liver disease patients with a measured GFR (mGFR) (iothalamate or inulin clearance). Serum was analyzed to estimate GFR based on GFR_{NMR}, CKD-EPI_{2021}Cr (eGFR based on creatinine alone) and CKD-EPI_{2021}Cr-Cys (creatinine and cystatin C). For liver function estimation, a logistic regression model was built on 709 and evaluated on 300 cirrhotic patients undergoing hepatocellular carcinoma surveillance. **Results:** Compared to mGFR, GFR_{NMR} had a mean bias of -1.64 mL/min/1.73m^2 [-3.43 - 0.16], statistically smaller than both CKD-EPI_{2021}Cr of 7.5 [4.9 - 9.8], and CDK-EPI_{2021}Cr-Cys of -2.9 [-4.8 - -1.3]. P_{30} was similar in GFR_{NMR} and CKD-EPI_{2021}Cr-Cys (83% [79 - 89] and 86% [81 - 90]) but lower for CKD-EPI_{2021}Cr (74% [68 – 80]). P_{15} was highest for GFR_{NMR} at 59% [53 - 65] compared to 47% [40 - 53] for CKD-EPI_{2021}Cr and 54% [47 - 61] for CKD-EPI_{2021}Cr-Cys. Concordant classification by mGFR CKD stage was highest for GFR_{NMR} at 59%, 54% for CKD-EPI_{2021}Cr-Cys, and 51% for CKD-EPI_{2021}Cr-Cys respectively. Liver function score evaluation yielded an AUC of 0.89 (CI: 0.86-0.93) for differentiation of Child-Pugh A from B/C. Furthermore, a strong correlation of 0.76 (CI: 0.71 - 0.81; Pearson) between the overall model score with the Child-Pugh score was observed. **Conclusion:** These findings confirm that the addition of NMR-analyzed myoinositol and valine improved the correlation of GFR_{NMR} with mGFR concerning bias and precision in liver disease, and accurately differentiates liver function scoring. NMR offers a novel method to simultaneously determine both renal and hepatic function in chronic liver disease patients.

3459-A | NOVEL SERUM FIBROSIS MARKERS TO PREDICT RAPID LIVER FIBROSIS PROGRESSION POST LIVER TRANSPLANT

Rambabu Surabattula[1], Sudharani Myneni[1], Tim Zimmermann[2] and Detlef Schuppan[1,3], (1)University Medical Center Mainz, (2)Klinikum-Worms, (3)Harvard Medical School

Background: Liver transplantation (LTX) is the only curative treatment option for end stage liver disease. However, up to 30% of patients develop recurrent cirrhosis (RC) post LTX within 5 years. In view of emerging antifibrotic therapies, there is an urgent need of non-invasive serum biomarkers to predict RC after LTX. We established and validated novel liver fibrosis serum markers in LTX patients with no, moderate and severe fibrosis progression followed-up for up to > 5 years post-transplant. **Methods:** ELISA assays measuring the matricellular fibrosis marker thrombospondin-2 (TSP2) and the metabolism/fibrosis-related marker insulin-like growth factor binding protein-7 (IGFBP7) were established using combinations of recombinantly expressed protein, commercial and proprietary monoclonal/polyclonal antibodies. CD163 and GDF15 were measured via commercially available sandwich ELISAs. Sensitivity and specificity for serum or plasma showed intra- and inter assay variations below 10% and 15%, resp. 45 LTX patients were divided into super-rapid (< 1 y), rapid progressors (3-5 y) after LTX and non-progressors. Serum markers were determined at 3,6 and 12 months post-LTX in a subset of 19 rapid-progressors to cirrhosis within 1 year. **Results:** Levels of TSP2 & CD163 were significantly increased in RC < 1 year (mean 253 & 1409 ng/ml, resp.) at 3,6 & 12 months after LTX compared to non-progressors (mean 86.9 & 705 ng/ml, resp) at 1, 2 & 3 years. IGFBP7 and GDF15, were not significantly different. RC < 1 vs non-progressors at 1 year after LTX were clearly differentiated with: TSP2: 261 vs 94, CD163: 1136 vs 716 ng/ml, and IGFBP7: 376 vs 549. 3 years after LTX, all markers were significantly elevated in rapid progressors vs non-progressors (TSP2: 224 vs 90; IGFBP7: 537 vs 362; CD163: 1176 vs 639 ng/ml; GDF15: 2433 vs 1146 pg/ml). The AUROC values to distinguish progressors from non-progressors were 0.90, 0.846 and 0.85 for the combination

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

of TSP2 & IGFBP7, TSP2 & CD163 and TSP2, IGFBP7 & CD163, resp. The combination of all 4 markers also differentiated rapid progressors vs RC < 1 with an AUROC of 0.76. All serum markers were significantly elevated in patients who finally died vs surviving patients. **Conclusion:** The matricellular fibrosis marker TSP2 reflects fibrogenesis and predict rapid fibrosis progression in patients post LTX. Other markers contributed to prediction at later stages post LTX. The novel markers may support early antifibrotic interventions post LTX.

3460-A | OPTIMAL DUAL CUT-OFFS OF LIVER STIFFNESS FOR COMPENSATED ADVANCED CHRONIC LIVER DISEASE IN ON-TREATMENT PATIENTS WITH CHRONIC HEPATITIS B

Xiaoning Wu[1], Yameng Sun[2], Jialing Zhou[1], Yongpeng Chen[3], Chenghai Liu[4], Huichun Xing[5], Wei Jiang[6], Hong Zhao[7], Bingqiong Wang[2], Shuyan Chen[1], Tongtong Meng[8], Xiaojuan Ou[2], Hong You[9] and Jidong Jia[2], (1)Beijing Friendship Hospital, Capital Medical University, Beijing, China, (2)Liver Research Center, Beijing Friendship Hospital, Capital Medical University, National Clinical Research Center of Digestive Diseases, Beijing, China, (3)Nanfang Hospital of Southern Medical University, (4)Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, (5)Beijing Ditan Hospital, Capital Medical University, Beijing, China, (6)Shanghai Institute of Liver Diseases, Fudan University Shanghai Medical College, Shanghai 200032, China, (7)Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, China, (8)Clinical Epidemiology and EBM Unit, Beijing Friendship Hospital, Capital Medical University, Beijing Clinical Research Institute, Beijing, China, (9) Liver Research Center, Beijing Friendship Hospital, Capital Medical University

Background: The risk of disease progression is significantly reduced but not eliminated in patients with chronic hepatitis B (CHB) who has initiated antiviral treatment. Identifying the compensated advanced chronic liver disease (cACLD) is important for on-treatment monitoring. However, dual cut-offs for cACLD in on-treatment patients with CHB are unclear. **Methods:** Adult CHB patients from three clinical studies (NCT01938781, NCT01938820, NCT01943617) who had liver biopsy and LSM simultaneously at least 6 months after initiation of antiviral treatment were enrolled. Compensated advanced chronic liver disease was defined as ≥F3 according to the METAVIR scoring system. LSM were performed with FibroScan (Echosens, Paris, France) or Fibrotouch (Wuxi Hisky Medical Technology Co., Ltd., Wuxi, China). The performance of LSM to identify cACLD in on-treatment CHB patients was analyzed by using area under receiver operating characteristic curve (AUROC). **Results:** A total of 816 patients were enrolled and randomly divided into training set and validation set at a ratio of 2:1. In the training set, about 74.3% (404/544) of them were male with a median age was 42.0 (34.3, 49.7) and the mean duration from initiation of antiviral treatment to liver biopsy was 1.5 (1.0, 3.1) years. Most patients were treated with Entecavir (85.3%) and achieved HBVDNA undetectable as well as ALT normalization at the liver biopsy. There were 205 (37.7%) patients staged ≥F3 with METAVIR scoring system. The Baveno **e** cut-offs of < 10 and > 15 kPa showed 56% sensitivity and 98% specificity to exclude and diagnose cACLD, respectively. Examining the ROC curve, a more optimal dual cut-off at < 7 and > 11 kPa, with 90% sensitivity and 90% specificity for excluding and diagnosing cACLD (AUC = 0.83, 95%CI:0.79-0.86, P < 0.001) were derived. The new threshold is much lower than the previous Baveno **e** LSM cut-off which was adopted for different etiologies of chronic liver diseases. With this new threshold, misclassified patients decreased 5.3% (10.5% to 5.2%) for excluding cACLD. Results in the validation set were similar with the training set. **Conclusion:** The optimal dual cut-off of liver stiffness measurement to exclude and diagnose compensated advanced liver disease were < 7 kPa and > 11 kPa in on-treatment patients with chronic hepatitis B.

Stepanova[5], (1)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (2)Center for Liver Disease, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, VA, (3)Inova Medicine, Inova Health System, Falls Church, VA, (4)Division of Endocrinology, Inova Health System, Falls Church, VA, (5)Center for Outcomes Research in Liver Diseases, Washington, DC

Background: Genetic risk factors have been linked to histologic stage of fibrosis in NAFLD. These associations with non-invasive biomarkers such as ELF have not been established. **Methods:** Clinical data, serum and whole blood were collected from consented patients with NAFLD. In addition to standard laboratory test (liver enzymes, platelet count, to calculate FIB-4), ELF score was measured (ADVIA Centaur, Siemens Healthineers). Genomic DNA was extracted from the whole blood [QIAamp DNA Blood Mini Kit (Qiagen)] and used for determination of minor allele frequency for genomic loci rs641738 (MBOAT7), rs58542926 (TM6SF2), rs738409 (PNPLA3), rs62305723 (HSD1713B) using CFX96 (Bio-Rad). Individual alleles were evaluated for the association with elevated (≥ 9.8) and high (≥ 11.3) ELF, elevated (≥ 2.67) and high (≥ 3.25) FIB-4 as well as advanced histologic fibrosis (Metavir stage 3 or 4) in NAFLD. **Results:** There were 1072 NAFLD patients: 57 ± 14 years, 57% male, BMI 34.4 ± 9.2, 33% type 2 diabetes. Of these patients, 83% had low ELF score (< 9.8) and 2.2% had high ELF (≥ 11.3). Furthermore, 8.5% had elevated and 4.9% had high FIB-4 scores. Of the 4 studied SNPs, only *PNPLA3*-rs738409 (51% CC, 42% CG, 7% GG) was significantly ($p < 0.05$) associated with higher ELF scores: elevated ELF 12% in CC vs. 19% in CG/GG, high ELF 0.6% in CC vs. 3.6% in CG/GG (both $p < 0.01$). The same allele was also associated with elevated (6.0% in CC vs. 9.9% in CG/GG) and high (3.1% vs. 6.3%, respectively) FIB-4 scores (both $p < 0.05$), as well with having advanced histologic fibrosis among patients who had a liver biopsy (13% in CC vs. 30% in CG/GG, $p = 0.0011$). However, among patients who had liver stiffness measurement (LSM) by transient elastography, there was no association of LSM with the allele ($p > 0.05$). In multivariate analysis adjusted for age, sex, BMI and type 2 diabetes, having *PNPLA3*-rs738409 CG/GG genotype was independently associated with higher risks of elevated and high ELF and FIB-4 scores as well as advanced histologic fibrosis: odds ratio (OR) = 1.78 (1.22-2.59) for elevated ELF, OR = 5.78 (1.66-20.10) for high ELF (both $p < 0.01$); OR = 2.04 (1.19-3.50) for elevated FIB-4, OR = 2.23 (1.12-4.46) for high FIB-4 (both $p < 0.025$); OR = 2.48 (1.21-5.09) ($p = 0.013$) for advanced histologic fibrosis. **Conclusion:** In patients with NAFLD, the polymorphism rs738409 in the *PNPLA3* gene was associated with having advanced histologic fibrosis and its surrogates such as ELF score.

3462-A | POINT OF CARE REAL WORLD HOLOGIC MACH40 AND FIBROSCAN COMPARED TO FIB4 FIBROSIS RISK GUIDELINE BASED

Allan Weston, SSM Health St Anthony and Jennifer Rickman, Digestive Health Center of the Four States, LLC

Background: NAFLD is widespread and frequently asymptomatic and diagnosed only after complications related to cirrhosis become manifest. Multiple risk factors have been identified including BMI > 30, DM, and HTN. Detection of fatty liver and fibrosis severity using simple blood studies to determine FIB4 score has been advanced in AASLD and AACE guidelines. If the FIB4 score is indeterminate or high risk, then liver stiffness measurement (LSM) by Elastography is recommended. The LSM measurement then re-stratifies the risk as low, indeterminate or high. Guidelines state that Transient Vibration Elastography (TVE) is preferred over 2D Shearwave Elastography (SWE). Several different SWE US platforms are available for clinical use which has generated conflicting data on SWE accuracy; however, Hologic (previously SuperSonic) utilizes propriety software that generates ultrafast, reliable, reproducible LSM. The newest generation MACH40 Hologic system has additional features that provide not only LSM but also liver viscosity and liver speed. **Methods:** Consecutive patients seen over a 5 month period who were either being seen for f/u of NASH or known Cirrhosis (of any cause) or as new referrals for either abnormal liver function tests, concern for NASH or abnormal imaging of the liver underwent point of care sequential FIBROSCAN imaging to obtain a fibrosis score and CAP value followed by transabdominal US imaging using MACH 40 platform to obtain 2D SWE score, liver viscosity value, liver speed followed by Hepatic Renal Ratio (HRR) value. Data was collected regarding demographics, BMI, alcohol consumption, smoking history, medical illnesses, and laboratory data used to determine FIB4 score and NAFLD Fibrosis score. STATA was used to examine what features are

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

predictive of success of obtaining a LSM score by MACH40 vs TVE. LSM scores obtained by TVE and 2D SWE were also compared to FIB4 fibrosis risk stratification and liver viscosity. **Results:** 85 pts underwent MACH40 scanning and 82 concurrent TVE: LSM were obtained in 97.6% for SWE and only 81.7% for TVE. Both cases of unreliable/unattainable SWE. TVE was also unsuccessful: both pts morbidly obese, wheelchair bound and had ascites. Features predictive of inability to obtain TVE included skin to liver distance > 3.5 cm ($p < 0.00001$) and presence of ascites ($p < 0.00001$) but not BMI. FIB4 using lab data +/- 60 days was available for 55 pts. High risk FIB4 score was confirmed as high risk LSM score by TVE 54.5% compared to 68.1% for SWE. Low risk FIB4 score was confirmed as low risk LSM score by TVE 53.8% compared to 76.9% for SWE. Liver Viscosity scores were significantly higher for high risk LSM group compared with low risk LSM group. **Conclusion:** MACH40 US is able to generate LSM in significantly more patients and has higher congruence with FiB4 risk stratifcation than TVE. Liver viscosity scores above 3.2 Pa.s obtained with MACH40 are significantly more likey to reflect high risk LSM group.

3463-A | PSEUDOCIRRHOSIS: UNVEILING AN UNCONVENTIONAL HEPATIC MASQUERADE

Kikelomo Olaosebikan[1], Ahmed Shehadah[2], Elizabeth Soladoye[1] and Raissa Nana Sede Mbakop Forlemu[1], (1)Piedmont Athens Regional, Athens, GA, (2) Rochester General Hospital

Background: Pseudocirrhosis is a rare hepatic complication typically associated with chemotherapy use. It manifests as morphological changes in the liver that closely resemble cirrhosis, despite lacking the typical histopathological changes. While primarily seen in metastatic breast cancer, it has also been reported in other malignancies. We present a unique case of pseudocirrhosis leading to the diagnosis of primary lung malignancy. **Methods:** A 76 y.o. Female with a significant smoking history presented to the hospital with worsening abdominal pain, fatigue, and unintentional weight loss over three months. Initial evaluations at multiple hospitals suggested cirrhosis based on hepatomegaly and a cirrhotic picture on an abdominal CT scan, despite no risk factors or clinical evidence. She was cachectic, non-jaundiced, normal bowel sounds, no distention, moderate epigastric tenderness, and no fluid thrill. Laboratory investigations revealed elevated lipase, liver enzymes, and normal total bilirubin, and platelets. MRI abdomen showed numerous liver nodules suggestive of metastatic disease, likely indicative of pseudocirrhosis. Subsequent CT chest revealed a right middle lung mass with mediastinal adenopathy, consistent with primary lung malignancy. However, the patient declined further testing. **Results:** This case highlights the importance of avoiding premature closure in the evaluation of suspected cirrhosis or abnormal liver enzymes. The initial misdiagnosis delayed the recognition of primary lung malignancy. Pseudocirrhosis was not initially considered due to its rare occurrence in non-chemotherapy patients. However, the imaging findings were attributed to the lung malignancy, which was overlooked in earlier studies. Thus, considering pseudocirrhosis as a potential cause of cirrhosis-like imaging findings is crucial, even in the absence of chemotherapy. Pseudocirrhosis associated with primary lung malignancy is uncommon. Existing literature reports only a few cases, mostly involving liver metastasis and imaging findings resembling cirrhosis. The pathophysiology of pseudocirrhosis varies and can overlap. In chemotherapy-naive patients, pseudocirrhosis has been associated with factors such as tumor size, progression, and desmoplastic reactions. Diagnosing pseudocirrhosis can be challenging, as it is rarely observed on pre-chemotherapy imaging. Capsular retraction, delayed contrast uptake, and morphological liver changes are characteristic features of pseudocirrhosis, mimicking untreated liver metastases or cirrhosis. **Conclusion:** Pseudocirrhosis should be considered in patients with cirrhosis-like imaging findings, even in the absence of chemotherapy history. This case report underscores the importance of including pseudocirrhosis in the differential diagnosis of liver diseases, emphasizing the significance of early detection and treatment for optimal patient outcomes.

3464-A | REPEATABILITY OF LIVER STIFFNESS MEASUREMENT BY MAGNETIC RESONANCE ELASTOGRAPHY AND REPEATABILITY OF STEATOSIS MEASUREMENT BY MRI PROTON DENSITY FAT FRACTION IN PATIENTS WITH CIRRHOSIS

Daniel Q Huang[1], Nabil Noureddin[1], Jaclyn Bergstrom[1], Maral Amangurbanova[1], Egbert Madamba[1], Christie Hernandez[1], Claude B. Sirlin[1] and Rohit Loomba[2], (1) University of California, San Diego, (2)University of California, San Diego, San Diego, CA

Background: The regulatory qualification of non-invasive tests (NITs) for liver fibrosis severity assessment is a

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

major unmet need for drug development and clinical care in cirrhosis. Non-invasive imaging tests such as magnetic resonance elastography evaluate liver stiffness measurement (LSM) for fibrosis severity, and magnetic resonance imaging proton density fat fraction-(MRI-PDFF) evaluates steatosis. Repeated use of non-invasive imaging tests has the potential to assess disease response and progression. However, this potential application has been limited by a paucity of repeatability data in the patient population at risk. The aim of this prospective study from the San Diego Cirrhosis Registry was to address this knowledge gap and contribute to the evidentiary basis needed for the qualification of MRI-based methods in various contexts of use in clinical trials and practice. **Methods:** A prospective cohort of adults with suspected or established cirrhosis underwent two MRI exams (including MRI-PDFF and MRE) on the same day. The primary endpoint was the same-day/same-operator repeatability coefficient (RC), which represents the value under which the difference between repeated measurements should fall with a 95% probability. The intra-class correlation coefficient (ICC) which represents the proportion of total variation explained by between-patient differences rather than measurement variation, and the within-case coefficient of variation (wCV), which represents the ratio of within-patient variation to overall measurement value, were also evaluated. **Results:** Same day repeat MRIs were available in 25 participants. The mean age was 61 years, 70% were women, mean body mass index (BMI) was 29.8 kg/m^2. RC was 1.32 kPa, and 0.89 for LSM by MRE, and steatosis by MRI-PDFF, respectively, meaning that any change greater than those values has a 95% probability to reflect true change rather than measurement error. ICC was excellent for LSM by MRE (.95) and steatosis by MRI-PDFF (.99), while wCV indicated that the within-patient variation was close to the overall measurement values for MRE and MRI-PDFF (Table 1). **Conclusion:** LSM and steatosis measurements by MRE, and MRI-PDFF, demonstrated good repeatability within patients with cirrhosis. These repeatability estimates are likely to inform MRI-based NIT qualification by defining the values that are expected to reflect a true change in the context of clinical trials or clinical care.

Table 1: Repeatability, intra-class correlation, and within-case coefficients for the repeatability of LSM by MRE and steatosis by MRI-PDFF

	Mean (SD)	Repeatability Coefficient (RC)	Intra-class Correlation ICC (95% CI)	Within-case Coefficient of Variation (wCV)
Repeatability of LSM by MRE (kPA)	6.04 (2.28)	1.32	.95 (.88 - .98)	8.26%
Repeatability of steatosis by MRI-PDFF	5.44 (4.51)	0.89	.99 (.98 - .99)	5.87%

3465-A | SERUM MAC-2 BINDING PROTEIN GLYCOSYLATION ISOMER (M2BPGi) SHOWS DIFFERENT VALUES IN DIFFERENT LIVER DISEASES BY THE NEWLY DEVELOPED QUANTITATIVE M2BPGi METHOD, STRONGLY SUGGESTING THE EXISTENCE OF SUBTYPES OF M2BPGi

Haruki Uojima[1], Masashi Mizokam[1], Kazumi Yamasaki[2], Masaya Sugiyama[1], Ken Shirabe[3], Kiyoaki Ito[4], Yasuhiro Asahina[5], Takumi Kawaguchi[6], Hidenori Toyoda[7], Masayuki Kurosaki[8], Akinobu Taketomi[9], Takeji Umemura[10], Kentaro Matsuura[11], Hiroko Iijima[12], Sohji Nishina[13], Hiroshi Yatsuhashi[2], Masayoshi Kage[14] and Hisashi HIdaka[15], (1)National Center for Global Health and Medicine, (2)Nagasaki Medical Center, (3) Gunma University, (4)Aichi Medical University, (5)Tokyo Medical and Dental University, (6)Kurume University School of Medicine, (7)Ogaki Municipal Hospital, (8) Musashino Red Cross Hospital, Tokyo, Japan, (9) Hokkaido University Graduate School of Medicine, (10) Shinshu University of Medicine, (11)Nagoya City University Graduate School of Medical Sciences Nagoya, (12)Hyogo Medical University, Nishinomiya, Japan, (13)Kawasaki Medical School, (14)Kurume University, (15)Kitasato University School of Medicine

Background: Currently, research on glycoproteins as a "third life chain" is progressing rapidly. We developed a semiquantitative method to measure WFA-positive Mac-2-binding protein glycan isomer (M2BPGi) as a serum marker for liver fibrosis. M2BPGi is currently used clinically as an alternative to liver biopsy. In this study, we developed a more accurate quantification method for M2BPGi and investigated the quantification method for M2BPGi in various liver diseases. **Methods:** This multicenter study was conducted at thirteen locations in Japan. The inclusion criteria were chronic liver disease (CLD) diagnosed by the combination of the specific laboratory tests and liver biopsy. The clinical data, serum samples, and pathological slides of the enrolled patients were collected to the research center. We evaluated the confidence ratio of the M2BPGi-Qt levels by the new methods of quantitative system and the M2BPGi levels by the current methods of semi-quantitative system to validate the clinical utility of the new method. We also evaluate the influence of fibrosis to the M2BPG-Qt levels in the different etiologies of CLD by the quantitative measurement. If a correlation between fibrosis and M2BPGi in a particular etiology was absence, we analyze

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

other clinical factors which influence of M2BPGI besides liver fibrosis. **Results:** A total of 1108 patients were recruited to the measurement of M2BPGi. The numbers of patients with hepatitis C virus (HCV), hepatitis B virus (HBV), non-alcoholic fatty liver disease (NAFLD), autoimmune hepatitis (AIH), primary biliary cholangitis(PBC) and Alcoholic liver disease (ALD) were 507, 163, 158, 152, 111,17, respectively. The correlation coefficient between M2BPGi-Qt and M2BPGi was very strong in all range. ($R = 0.987$, $p < 0.001$). M2BPGi-Qt levels increased with the progression of liver fibrosis in patients with HCV, HBV, NAFLD, and PBC. ALD was not evaluated due to insufficient cases. No significant difference was observed between fibrosis stage and M2BPGi-Qt levels in patients with AIH. (Figure 1). Of the analyzed clinical factors, the degree of liver inflammation was positively correlated with M2BPGi levels in patients with AIH. **Conclusion:** The quantitative M2BPGi measurement system revealed that the diffidence of M2BPGi levels according to the etiology of liver disease depends on both the progression of liver fibrosis and the degree of liver inflammation. The result strongly suggesting the existence of subtypes of M2BPGi.

3466-A | THE CROSS-LINKED TYPE III COLLAGEN BIOMARKER, CTX-III, REFLECTS FIBROSIS RESOLUTION AND IS RELATED TO INTERVENTION AND SURVIVAL IN CHRONIC LIVER DISEASE

Alejandro Mayorca Guiliani[1], Ida Lønsmann Sorribes[2], Peder Frederiksen[1], Emilie Skovgaard[1,3], Martin Pehrsson[1], Judith Ertle[4], Corinna Schoelch[5], Robert Schierwagen[6], Michael Praktiknjo[7], Morten Karsdal[8], Diana J. Leeming[2], Flemming Bendtsen[9], Julie Steen Pedersen[10] and Jonel Trebicka[6], (1)Nordic Bioscience a/S, (2)Nordic Bioscience A/S, (3)University of Copenhagen, (4)Boehringer Ingelheim International Gmbh, (5)Boehringer Ingelheim Pharma Gmbh, (6) University Hospital Münster, (7)University of Bonn, (8) Nordic Bioscience a/S, Denmark, (9)Hvidovre Hospital, (10)Copenhagen University Hospital of Koege

Background: The liver extracellular matrix (ECM) is a scaffold of proteins and glycans supporting all liver cells. Progressing fibrosis results in increased ECM deposition. Thus, fibrosis regression, upon insult removal or therapy, should tilt the balance towards ECM degradation. As therapies against fibrosis advance, biomarkers to prognosticate and monitor fibrosis regression become a necessity. Here, we aimed to investigate whether a MMP degraded and cross-linked fragment of type III collagen, called CTX-III, could: 1) mark decreasing disease activity and regression after intervention and 2) predict survival in chronic liver disease. **Methods:** We homogenized human liver segments (healthy $n = 1$; diagnosed with steatohepatitis $n = 2$; steatohepatitis and bridging fibrosis $n = 2$; steatohepatitis, ballooning and bridging fibrosis $n = 1$) and measured CTX-III using ELISA. Blood samples were collected from patients undergoing bariatric surgery ($n = 65$ with blood samples taken at 3-, 6-, and 12-months follow-up) and transjugular intrahepatic porto-systemic shunt (TIPS) ($n = 86$). Biomarkers CTX-III and PRO-C3 were measured in an

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

automated high precision platform. **Results:** We confirmed *in vitro* that CTX-III is present in the human liver tissue, with higher levels in diseased tissue. Then, we assessed the monitoring properties of CTX-III in a non-alcoholic fatty liver disease cohort (NAS Score 0 points = 0 patients; 1 = 6; 2 = 19; 3 = 16; 4 = 10; 5 = 13; 6 = 1; 7 = 0, 8 = 0) and liver fibrosis (F0 = 1; F1 = 55; F2 = 8; F3 and F4 = 0) undergoing bariatric surgery. We found a 23% (IQR 4-63%) median CTX-III increase after surgery ($p \leq 0.001$), while PRO-C3 showed a non-significant increase ($p = 0.161$). CTX-III increase coincided with decreases in body mass index and liver enzymes (ALT $p = 0.006$; GGT $p = < 0.001$). We then measured CTX-III and PRO-C3 in a cohort with decompensated cirrhosis receiving TIPS. A CTX-III:PRO-C3 ratio below the median was associated with shorter transplant-free survival (Hazard ratio 1.69, 95% CI 1.02-2.86; $p = 0.04$). **Conclusion***: In vitro*, increased CTX-III suggests diseased ECMs are richer in crosslinked collagen. When measured in patients undergoing bariatric surgery, CTX-III levels suggest increased ECM degradation, and thus CTX-III potential as a monitoring biomarker associated with liver structure remodeling. Additionally, assessing both ECM formation (PRO-C3) and degradation (CTX-III) might aid in prognosis stratification of patients with decompensated cirrhosis.

3467-A | THE ENHANCED LIVER FIBROSIS TEST IS ASSOCIATED WITH DEVELOPMENT OF CIRRHOSIS AND HEPATOCELLULAR CARCINOMA IN INDIVIDUALS WITH TYPE 2 DIABETES MELLITUS

Paul M Trembling[1], Sheila M Grecian[2], Mark W J Strachan[2], William M. Rosenberg[1] and Jonathan A Fallowfield[3], (1)University College London, (2)Western General Hospital, Edinburgh, (3)University of Edinburgh

Background: The Enhanced Liver Fibrosis (ELF) test accurately stratifies liver fibrosis severity, monitors changes in fibrosis and predicts liver-related events in patients with a range of chronic liver diseases. Type 2 diabetes mellitus (T2DM) is a major metabolic risk factor for liver fibrosis and progression to cirrhosis and hepatocellular carcinoma (HCC), yet non-invasive tools for predicting such outcomes are not well established in this population. The Edinburgh Type 2 Diabetes Study is a prospective population-based cohort study investigating the role of potential risk factors in the development of complications of T2DM. A total of 1066 men and women with T2DM, aged 60-75 years at baseline, were recruited between 2006 and 2007. We aimed to estimate association between ELF and development of cirrhosis and / or HCC (events) in this population. **Methods:** In a nested sub-study of 254 participants, ELF scores were measured one and four years after recruitment. Participants were followed up for incident events. Cox proportional hazards analysis was performed estimating association of year-1 ELF at thresholds of 9.8 and 10.51 (established thresholds for advanced fibrosis) with events, adjusted for age and baseline biochemical parameters (high serum ALT & AST, low platelet count). Immortal time bias was evaluated using time-dependent Cox analysis, using time of sample where ELF first reached threshold. **Results:** Over a median follow-up period of 10 years, 14 (4%) participants experienced pre-specified events. Mean ELF scores in 'no event' and 'event' groups were 8.86 (SD 0.85) and 10.13 (SD 1.45) respectively. Significant associations between ELF score and events were seen at both thresholds (table). Hazard ratios (not shown) were similar using ELF as a time-dependent variable, indicating immortal time is not a confounder. The AUROC for ELF for predicting events was 0.8 (95% CI 0.6-1.0). Higher initial ELF score was associated with an increased risk of events, such that a one-unit higher ELF score was associated with 27% greater risk of cirrhosis and / or HCC. Mean change in ELF score per year was higher in the events group (0.13 v 0.09 / year, $P = 0.94$). **Conclusion:** There is significant association between ELF score and progression to cirrhosis / HCC in this cohort of older individual's with T2DM. These data indicate that the ELF test may be a useful clinical prognostic tool in this setting, enabling risk stratification and better targeting of care.

ELF threshold	Unadjusted / Adjusted model	Cox	
		Hazard Ratio (95% CI)	*P* value (at 5% level)
9.8	Unadjusted	24.47 (7.61-78.67)	<0.001
	Adjusted	29.20 (7.26-117.42)	<0.001
10.51	Unadjusted	26.22 (8.65-79.47)	<0.001
	Adjusted	18.36 (5.08-66.38)	<0.001

3468-A | THE VALIDATION STUDY OF LIVER STIFFNESS MEASUREMENT BY ULTRASOUND-BASED ELASTOGRAPHY IN THE PRESENCE OF CO-EXISTING INFLAMMATION

Ryosuke Kasuga, Nobuhito Taniki, Po-sung Chu, Rei Morikawa, Takaya Tabuchi, Fumie Noguchi, Yukie Nakadai, Mayuko Kondo, Takanori Kanai and Nobuhiro Nakamoto, Keio University School of Medicine

Background: Elastography is used for noninvasive measurement of liver stiffness. It is previously reported that measured value of elastography varies under the influence of inflammation. However, the details regarding the impact of inflammation on liver stiffness has not been well established. In the current study, we aimed to develop strategy for the best use of elastography to evaluate patients at risk for liver fibrosis in the presence of co-existing inflammation. **Methods:** We retrospectively recruited 274 patients who underwent liver tissue biopsies performed since January 2018 in our institution. This study is approved by local institutional IRB (no. 20170202). Histological fibrosis and inflammation were evaluated according to the METAVIR fibrosis and activity score and we defined active inflammation as METAVIR A2 and 3 grade. We assessed the diagnostic performance of elastography including Vibration-Controlled Transient Elastography: VCTE (Fibroscan; Echosens) and Shear Wave Elastography: SWE (Logiq-E9; GE) using ROC analysis focusing on accuracy to discriminate each fibrosis stage at the presence of inflammation. And we also compared elastography with other non-invasive predictors that define fibrosis; serum biomakers (4COL7S, M2BPGi, ATX), scoring systems (FIB-4 index, APRI). **Results:** The underlying liver diseases were viral hepatitis in 80 cases (29%) and non-viral hepatitis in 194 cases(71%). METAVIR fibrosis stage was F0 in 81 cases(30%), F1 in 47 cases(17%), F2 in 42 cases(15%), F3 in 33 cases(12%), F4 in 71 cases(26%). The AUROC of FIB-4 index for each fibrosis stage $F=0$ vs $F\geq1$, $F\leq1$ vs $F\geq2$, $F\leq2$ vs $F\geq3$, $F\leq3$ vs F4 were 0.72, 0.76, 0.76, 0.76, and FIB-4 index provided the highest diagnostic accuracy among serum bio-markers and scoring systems. The AUROCs of VCTE and SWE were 0.88, 0.90, 0.91, 0.93 and 0.85, 0.88, 0.87, 0.86. In cases with active inflammation, AUROC of FIB4 index significantly decreased by 0.63, 0.68, 0.69, 0.68 while VCTE (0.88, 0.87, 0.87, 0.91) and SWE (0.82, 0.82, 0.82, 0.91) were still effective. On the other hand, the measurement values of VCTE and SWE tended to increase at the presence of inflammation especially in mild fibrosis stage. VCTE values of A0,1 vs A2,3 were 6.3 vs 8.0 kPa ($P=0.0005$) and SWE values were 1.41 vs 1.54 m/s ($P=0.012$) in F0 stage, 7.6 vs 11.5 ($P=0.064$), 1.51 vs 1.68 ($P=0.177$) in F1, 12 .2 vs 15.9 ($P=0.062$), 1.72 vs 1.86 ($P=0.098$) in F2, 16.0 vs 15.8 ($P=0.810$), 1.88 vs 1.93 ($P=0.678$) in F3, 33.4 vs 27.7 ($P=0.728$), 2.02 vs 2.19 ($P=0.149$) in F4. **Conclusion:** Our findings revealed that ultrasound-based elastography can distinguish fibrosis stage with accuracy even in the presence of active inflammation. Since overestimation of liver stiffness induced by inflammation occurs only in mild fibrosis stage, the risk of overestimation can be avoided by raising cut-off value in such specific cases.

3469-A | VISUALIZED TRANSIENT ELASTOGRAPHY TO ASSESS FIBROSIS AND STEATOSIS IN PATIENTS WITH CHRONIC LIVER DISEASE

Andres M. Corona[1], Uche C. Ezeh[1], Maria Lourdes Olson[1], Katheryn Dae[1], Edisson J. Aguilera Herrera[1], Jiovanna N. Fernandez[1], Franchesca Escobar[1], Jasmina Kovacevic[2], Leopoldo R. Arosemena[1], Emmanuel Thomas[1], Diane Sabogal[1] and Eugene R. Schiff[1], (1)University of Miami Miller School of Medicine, Schiff Center for Liver Diseases, (2)University of Florida College of Medicine

Background: Assessment of liver fibrosis and steatosis in patients with chronic liver disease (CLD) is important for risk-stratification and management decisions. Various non-invasive techniques including transient elastography and laboratory-based scoring systems are used in practice for fibrosis staging in CLD. The purpose of this study was to compare fibrosis and steatosis measurements between the FibroScan® 630 (vibration-controlled transient elastography, VCTE) and the recently developed Hepatus Series Diagnostic ultrasound system® (visualized transient elastography, ViTE). **Methods:** We performed a prospective study of 48 patients with CLD at the Schiff Center for Liver Diseases between August 2022 to March 2023. We reported descriptive continuous variables as mean ± standard deviation (SD). The shapiro-wilk test was conducted to determine the normality of the data. We used a paired t-test to compare the means of the VCTE kPa vs. ViTE kPa and a wilcoxon signed-rank test to compare the means of the VCTE CAP vs. ViTE LiSA. We used Pearson correlation (r) to assess whether there was an association between BMI, height and weight and the aforementioned clinical values. IBM SPSS v28 was used to conduct statistical analysis and

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

$p < 0.05$ was considered statistically significant. **Results:** Among the 48 patients, the mean age (years) was 52.7 (13.88), the mean BMI was 30.675 (0.97), weight (lbs.) was 198.77 (7.00), and height (cm) was 170.70 (1.56) (Table 1). The mean VCTE kPa was 8.33 (4.92) and ViTE kPa 8.38 (4.13). There was no statistically significant difference between their mean values ($p = 0.868$). The mean VCTE CAP was 284.44 (7.55) and ViTE LiSA was 276.58 (7.71). There was no statistically significant difference in the VCTE CAP compared to ViTE LiSA ($p = 0.133$). There was a statistically significant, moderate positive correlation between VCTE kPA ($r = 0.326$, $p = 0.024$), ViTE kPA ($r = 0.326$, $p = 0.024$) and VCTE CAP ($r = 0.370$, $p = 0.010$) and weight. There was no statistically significant correlation between height and VCTE kPa, VCTE CAP, ViTE kPa, and ViTE LiSA ($p > .05$). Additionally, there was a statistically significant, moderate positive correlation between VCTE kPA ($r = 0.402$, $p = 0.005$), ViTE kPA ($r = 0.527$, $p = < 0.001$), ViTE LiSA ($r = 0.315$, $p = 0.029$), VCTE CAP ($r = 0.429$, $p = 0.002$) and BMI. **Conclusion:** Our data indicates similar liver fibrosis and steatosis measurements between VCTE and ViTE. ViTE's real-time visual guidance may offer a quicker and more reliable method for non-invasive liver fibrosis staging. Further studies evaluating the accuracy of ViTE compared to VCTE across BMI classes with a larger cohort are warranted.

Table 1. Pearson Correlation of Liver Measurements for VCTE and ViTE with Height, Weight, and BMI (n=48).

	VCTE kPa	VCTE CAP	ViTE kPa	ViTE LiSA
Height (cm)	0.004 (0.979)	0.058 (0.695)	0.07 (0.638)	-0.065 (0.663)
Weight (lbs.)	**0.326 (0.024)**	**0.326 (0.024)**	**0.37 (0.010)**	0.165 (0.263)

3470-A | CELLULAR SENESCENCE PRIMES LIVER FIBROSIS REGRESSION THROUGH NOTCH-EZH2

Ping Song and Lin Wang, Fourth Military Medical University

Background: Liver fibrosis is reversible once the injury is removed. Cellular senescence which plays a pivotal role in wound healing potentially drives liver fibrosis regression. However, the involved mechanism has not been fully elucidated. **Methods:** Senescent cells were detected by SA-β-gal staining and removed by dasatinib and quercetin. Macrophages were depleted by Clodronate. EZH2 signaling was blocked by EPZ6438. Disruption of Notch in macrophages was achieved by Lyz2- Cre RBP-$J^{f/f}$ transgenic mice. Notch signaling was blocked by Ly3039478 or exosome-mediated RBP-J decoy oligodeoxynucleotides. **Results:** At the initiation of liver fibrosis regression, accumulated senescent cells were detected by SA-β-gal staining. Marker genes of senescence were upregulated meanwhile. Flowcytometry combined with single-cell RNA sequencing analyses revealed that most of senescent cells were liver non-parenchymal cells, especially Kupffer cells and liver endothelial cells. Removing senescent cells by dasatinib and quercetin, alleviated hepatic cellular senescence, impeded fibrosis regression and disrupted liver sinusoids. Besides, clearance of senescent cells not only decreased senescent macrophages but also shrank the proportion of anti-inflammatory M2 macrophages through apoptotic pathway. Subsequently, macrophages were depleted by Clodronate, which diminished hepatic senescent cells and impaired fibrosis regression. Mechanistically, the change of the epigenetic regulator EZH2 accompanied with the emergence of hepatic senescent cells while liver fibrosis regressed. Blocking EZH2 signaling by EPZ6438 reduced hepatic senescent cells and macrophages, decelerating liver fibrosis regression. Moreover, the promoter region of EZH2 was transcriptionally suppressed by Notch-Hes1 signaling. Disruption of Notch in macrophages using Lyz2-Cre RBP-$J^{f/f}$ transgenic mice, enhanced hepatic cellular senescence and facilitated fibrosis regression by upregulating EZH2 and blocking EZH2 abrogated the above effects caused by Notch deficiency. Ultimately, adopting Notch inhibitor Ly3039478 or exosome-mediated RBP-J decoy oligodeoxynucleotides accelerated liver fibrosis regression by augmenting hepatic cellular senescence. **Conclusion:** Blockage of Notch promoted the accumulation of EZH2-regulated senescent cells to initiate liver fibrosis regression, providing a promising treatment of liver fibrosis.

3471-A | MARCO-POSITIVE MACROPHAGES DEMONSTRATE ANTI-INFLAMMATORY PHENOTYPE COMPARED TO MARCO-NEGATIVE MACROPHAGES DURING LIVER INJURY.

Sofia Jerez[1], Shawna Cooper[1], Usman Yaqoob[2], Abid Anwar[3], Enis Kostallari[3], Nidhi Jalan-Sakrikar[2], Man Xie[1], Bushra Arif[1], Sheng Cao[2] and Vijay Shah[2], (1) Mayo Clinic, (2)Mayo Clinic Rochester, Rochester, MN, (3)Mayo Clinic, Rochester, MN

Background: The **Ma**crophage **R**eceptor with **Co**llagen Structure protein (MARCO) is a scavenger receptor predominantly expressed on healthy tissue-resident macrophages (Macs), including Kupffer cells in the liver. It is known that Macs can exhibit anti- or pro-inflammatory properties, thereby regulating inflammation. At the same time, chronic inflammation is a key factor in hepatic fibrosis. However, the role of MARCO and its expression in liver Macs during liver diseases remains unknown. This study aims to identify MARCO-dependent differences between subsets of liver Macs and analyze the role of MARCO-expressing Macs during liver fibrosis. **Methods:** Single-cell RNA-sequencing (scRNAseq) and spatial transcriptomics (ST) (10x genomics), as well as Immunohistochemistry (IHC) and immunofluorescence (IF) staining was performed on livers from olive oil and carbon tetrachloride (CCl_4)-treated mice. Liver non-parenchymal cells (NPCs) were isolated from vehicle- or lipopolysaccharide (LPS)-injected mice and analyzed by flow cytometry. For *in vitro* studies, RAW264.7 Macs cell line, which is deficient in MARCO, was used for overexpression studies using transient plasmid-expression of MARCO and inflammatory stimulus with LPS. nCounter inflammation assay (NanoString), was used to analyze changes in gene expression. Validation was done by qPCR. **Results:** scRNAseq data shows two Macs subsets, distinguishable by their MARCO expression. $MARCO^+$ population was found to be increased in CCL_4-treated mice (Log2FC 3.6, $p = 3.55e\text{-}17$, 56% in CCl_4 vs. 16% in Olive oil). IHC and ST data show that $MARCO^+$ Macs were located in non-fibrotic areas, and $MARCO^-$ Macs were populated in zones with fibrosis. Also, flow cytometry of primary isolated NPCs shows an increase in the $MARCO^+$ population in response to LPS-induced liver injury (57.6% in LPS vs. 21.8% in vehicle). *In vitro* studies with MARCO-expressing Raw264.7 cells show downregulation of Tnf gene expression on $MARCO^+$ Macs compared to $MARCO^-$ population (log2FC -0.5, $p = 0.02$). nCounter assay, also show reduced expression of inflammatory cytokines, including Il12b, Il6, Ccl5, Cxcl2, and lower expression of Nfkb1 gene, which encodes a main regulator of inflammatory cytokines expression (n = 2). Finally, $MARCO^+$ cells demonstrated cytoskeletal remodeling and reduced migration capacity. These results suggest they may have an immune regulatory role in the immune niche of the liver, playing a possible anti-fibrotic role by reducing inflammation. **Conclusion:** $MARCO^+$ cells exhibit anti-inflammatory genes expression suggesting immunomodulatory effects in response to injury. This Macs subset, through their modulation of immune responses, migration, and involvement in actin filament remodeling, may play a role in mitigating liver inflammation, and consequently, in the development of fibrosis. Ongoing studies will help elucidate the underlying mechanisms and therapeutic potential of $MARCO^+$ macrophages.

3500-C | A HUMAN LIVER-ON-A-CHIP MODEL FOR STUDYING THE ROLE OF LSECS IN ALCOHOL-RELATED LIVER DISEASE

Lien Reolizo, Cedars-Sinai Medical Center, Los Angeles, CA, Michitaka Matsuda, The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Takeshi Saito, Medicine, Division of Gastrointestinal and Liver Diseases, Keck School of Medicine, University of Southern California, Los Angeles, CA and Ekihiro Seki, Cedars-Sinai Medical Center, Torrance, CA

Background: Alcohol-related liver disease (ALD) is associated with excessive alcohol intake and abuse. Hepatic steatosis followed by steatohepatitis characterized by liver injury and inflammation occurs during the initial stage of ALD. Subsequently, the ALD spectrum progresses from reversible fatty liver to acute alcoholic hepatitis, chronic fibrosis and cirrhosis which are irreversible.

A 3D in vitro hepatic micro-physiological system, Liver-on-a-Chip, is designed to recapitulate in vivo functional conditions of the liver microenvironment using human-originated cells. In this project, we aim to investigate the role of liver sinusoidal endothelial cells (LSEC), the first defense hepatic barrier against insults from blood, in ALD and whether a human ALD Liver-on-a-Chip can be used to model alcohol-induced fatty liver and injury. **Methods:** To recreate the hepatocyte-sinusoidal interface, hepatocytes were cultured in the upper channel on top of the ECM-coated membrane whereas LSECs

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

were cultured on the lower channel to allow cell-cell interaction. To model human ALD, the biomimetic Liver-on-a-Chip was subjected to EtOH exposure. **Results:** We have established an ALD Liver-on-a-Chip model that can better mimic alcohol-induced injury compared to conventional 2D plate system. Our Liver-on-a-Chip demonstrated high cellular activity, active expression of biochemical indicators (albumin, urea) and improved expression of alcohol metabolizing enzymes (ADH1, CYP2E1, ALDH2). Treatment of the Liver-on-a-Chip with EtOH augmented EtOH-induced hepatocyte damage compared with 2D system. Moreover, we discovered that LSECs are protective in alcohol-related liver injury by contributing to the clearance of acetaldehyde via Aldehyde Dehydrogenase 2 (ALDH2) expression on a Liver-on-a-Chip. We also showed that ALDH2 silencing in LSEC causes acetaldehyde overload and enhanced hepatocyte damage under EtOH exposure. **Conclusion:** Our study demonstrates that ALDH2-mediated aldehyde metabolism in LSECs is a novel underlying mechanism for ALD. This has prompted us to propose the future therapy for ALD by targeting LSECs.

3501-C | A MULTI-DISCIPLINARY ALCOHOL-ASSOCIATED LIVER DISEASE CLINIC: THE ONE YEAR EXPERIENCE AT A TERTIARY CARE CENTER

Chanelle K Benjamin[1], Jessica Ann Musto[1], Nora Hill[1], Randall Brown[1] and Margarita N. German[2], (1) University of Wisconsin, (2)University of Wisconsin, Madison

Background: Alcohol-associated liver disease (ALD) is increasing in prevalence and currently the leading indication for liver transplantation in the US. Multi-disciplinary treatment for ALD and alcohol use disorder (AUD) is the recommended standard of care but infrequently implemented. Herein we describe the early experience of a multi-disciplinary ALD/AUD clinic after one year of operation at a single tertiary care center. **Methods:** The mult-disciplinary ALD/AUD clinic opened in November 2021. At the initial visit, each patient was evaluated by a hepatologist, addiction medicine specialist or counselor and social worker. Eligible patients had varying severities of ALD with less than 6 months of alcohol abstinence and a willingness to speak with an addiction medicine provider. Psychosocial questionnaires, hepatic function labs and non-invasive measures of hepatic fibrosis were collected. **Results:** 80 new patients were seen during the clinic's first year of operation. Average age was 48 years-old (range 24-75), and 40 (50%) were males. 59 patients (74%) had severe AUD, 14 (18%) moderate and 7 (9%) mild. 68% had co-morbid psychological conditions (95% reported an anxiety disorder) and 53% co-morbid substance use disorders. 44% of patients reported having some degree of consequence related to their alcohol or drug use, as reported on their Drug Abuse Screening Test. At the initial visit, only 21% reported prior pharmaceutical treatment for AUD and 66% reported non-pharmaceutical treatment. After their first visit, 54 patients (68%) initiated relapse prevention medication (a majority utilizing gabapentin) and 64 (80%) committed to addiction counseling. Following their first visit, 64 patients (80%) had at least one follow up appointment. At first follow-up visit, 64 patients (56%) had initiated addiction counseling and 53 (66%) started relapse prevention medication. 46 (72%) patients had stopped alcohol use completely while 42 (47%) reported episodic cravings. Between their initial visit and first follow-up, 23 patients (36%) had at least one hospitalization or ED visit; 48% for relapse to alcohol use, 30% for complications of ALD, and 22% for problems unrelated to ALD or AUD. Of the initial cohort of patients, 70% remain active in the ALD/AUD clinic, 7% expired, and 18% were lost to follow up. **Conclusion:** A mult-disciplinary approach to treatment of ALD is the recommended standard of care. We demonstrate the feasibility of establishing a mult-disciplinary clinic to provide the most comprehensive care for patients with ALD while incorporating use of pharmacotherapy for AUD.

Kamath[10], Shiv Kumar Sarin[11] and Yong-Fang Kuo[12], (1)University of South Dakota, (2)Icahn School of Medicine at Mount Sinai, (3)University of Pennsylvania, (4)Stanford University School of Medicine, (5)UPMC, (6)Ilbs, (7)U Penn, (8)Post Graduate Institute of Medical Education and Research, Chandigarh, India, (9)Barcelona Clinic, Barcelona, Spain, (10)Mayo Clinic, Rochester, MN, (11)Institute of Liver and Biliary Sciences, (12) University of Texas Medical Branch

Background: Alcohol-associated hepatitis (AH) is a unique clinical syndrome, with new onset or worsening of jaundice, with 90-day mortality of up to 90% in most severe forms. NIAAA has proposed clinical criteria for AH diagnosis (AST > 50 and < 400 IU/L, serum bilirubin [SB] > 3 mg/dL, presentation within 60 d from last alcohol use) for management and for enrollment in clinical trials. However, these criteria are not evidence-based. We performed this multicenter study with the aim of validating NIAAA clinical criteria for diagnosis in patients with alcohol-associated liver disease (ALD). **Methods:** Two cohorts of ALD patients, first one from two centers on patients receiving liver biopsy for clinical management and the second from four centers on liver transplant recipients. Gold standard for AH diagnosis was defined on liver histology, with presence of hepatocyte ballooning, neutrophilic lobular inflammation, and Mallory hyaline (definite AH). Patients with AST > 400, non-ALD etiology, bile duct obstruction, and liver cancer were excluded. **Results:** Among 416 patients (250 biopsied [2014-18] and 166 explants [2002-22]), 267 met clinical AH criteria. Of 219 with histology (biopsy or explant) obtained within 30 d from presentation (median age 42 yrs., 79% males, 45% whites, 3% ACLF, 29% steroids, median days to last drink 52 d, median MELD score 36), 63 (29%) had definite AH. The cohort was randomly split (1:1) to training (n = 110) and validation (n = 109) datasets. The accuracy and c-statistics to predict definite AH was 0.573 using NIAAA criteria and 0.724 based on: *-0.424 + 0.0040*AST + (- 0.0674)*AST/ALT + (-0.0114)*days from last drink + (-0.0064)*SB*. The new algorithm in the validation model a) had a c-statistics of 0.651 with accurate classification of definite AH in 80% (Brier score 0.204), b) performed better than NIAAA criteria at a cut-off score of 0.291, and c) showed good calibration between expected and observed probability, correlation coefficient 0.839 (Figure). **Conclusion:** A novel validated model based on AST, AST/ALT ratio, serum bilirubin is more accurate compared to the current clinical criteria, for clinical diagnosis of AH and for recruitment of patients into clinical trials. Larger prospective studies are needed to validate these findings.

3503-C | A PHASE 2a, RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED STUDY EVALUATING THE SAFETY, TOLERABILITY, EFFICACY, AND PHARMACOKINETICS OF INT-787 IN SUBJECTS WITH SEVERE ALCOHOL-ASSOCIATED HEPATITIS: STUDY DESIGN, OBJECTIVES, AND NOVEL ASSESSMENTS

Thomas Capozza, Steven Lauder, Sam Madison and Jennifer Callahan, Intercept Pharmaceuticals, Inc., Morristown, NJ

Background: Severe alcohol-associated hepatitis (sAH) is the most acute and serious form of alcohol-associated liver disease. It is identified clinically by the presence of jaundice, hepatitis, and systemic inflammatory response, which results in significant morbidity and mortality. Currently, therapeutic options for sAH are limited, with corticosteroids improving only short-term survival. INT-787 is a potent farnesoid X receptor (FXR) agonist and a potential treatment option for sAH. Preclinical studies of FXR agonists have demonstrated improvements in hepatic steatosis, inflammation, fibrosis, and intestinal mucosal integrity, as well as reductions in plasma endotoxin and bile acids, in various liver-related disorders. The goal of our study is to evaluate the safety, tolerability, early efficacy, and pharmacokinetics (PK) of INT-787 in patients with sAH. **Methods:** In this phase 2a, randomized, double-blind, placebo-controlled, multicenter, dose-escalation proof-of-concept study, oral INT-787 will be administered to patients with a diagnosis of sAH, with a Model for End-Stage Liver Disease-Sodium (MELD-Na) score of 18-25. Five dose cohorts are planned, starting at 5 mg (Figure 1). Each cohort includes 10 randomized subjects (4:1) receiving INT-787 or placebo for 28 days. If there are no significant safety or tolerability concerns, dose escalation for the next cohort will not exceed a 3-fold increase. The maximum cohort dose will not exceed 120 mg. Corticosteroids will not be used during the study. Subjects will undergo a 7-day screening period, followed by a 28-day treatment period, with a 56-day follow-up. The primary endpoint is the assessment of sAH disease progression by Lille score. Secondary endpoints include changes in MELD-Na score, occurrence of infectious complications, clinical outcomes (short- and intermediate-term mortality or liver transplant), and PK. Safety and tolerability will be determined by adverse events, laboratory assessments, electrocardiograms, vital signs, and physical examinations; hepatic and renal safety of INT-787 in sAH will be assessed by expert adjudication committees blinded to treatment. Other novel assessments include serum markers of bacterial translocation (LBP, 16S rDNA), stool microbiome analysis, and alpha-1-antitrypsin. **Results:** 50 patients are being targeted at 25 investigation sites globally. Study completion is targeted for May 2024. **Conclusion:** INT-787 is a promising FXR agonist with preclinical data supporting its exploration in the treatment of sAH.

3504-C | ACUTE ETHANOL INDUCTION AND SUBCELLULAR LOCALIZATION OF HEPATIC CYP2E1

Taia Mendenhall, Kelly R. Misare, Hyland Gonzalez, Patrick Mulholland and Jessica H. Hartman, Medical University of South Carolina

Background: Alcohol is known to increase hepatic levels of the cytochrome P450 2E1 (CYP2E1), particularly in the endoplasmic reticulum (or microsomal fraction) and to some extent in the mitochondria of hepatocytes. CYP2E1 is well known to metabolize ethanol to acetaldehyde in a parallel pathway to alcohol dehydrogenase. Interestingly, the half-life of CYP2E1 is much longer in the mitochondria (>24h) compared to the endoplasmic reticulum (~8h). Therefore, we hypothesized that after acute ethanol induction of CYP2E1, the endoplasmic reticulum form would rapidly clear while the mitochondrial form would persist. **Methods:** To test the temporal expression of CYP2E1 following acute alcohol ingestion, young female C57BL/6J mice were given voluntary access to ethanol (or water) for two hours and allowed to drink. Mice we sacrificed immediately following drinking (0h) and 24 and 48 hours later. Protein levels and subcellular localization were determined using multiplexed immunofluorescent staining with antibodies against CYP2E1 and markers of the mitochondria (COX4) and endoplasmic reticulum (Calreticulin). **Results:** The relative expression of CYP2E1 in the liver of mice treated with acute levels of ethanol was >2-fold higher ($p<0.001$) than the control group in the 0h group, and correlated with the amount of alcohol consumed ($p<0.05$). The increase was partly driven by a subtle increase in the radius of expression from the central vein. In contrast, there was no statistical significance in CYP2E1 levels at 24 or 48h post-drinking mice when compared to the control, indicating that the overall induction of CYP2E1 was transient, which agrees with previous studies. For subcellular localization, super-resolution Airyscan confocal microscopy was performed to maximize resolution of the mitochondria and ER. Deconvolution with Huygen's software and calculation of co-localization between CYP2E1 and organellar markers are ongoing. **Conclusion:** We find that acute voluntary drinking in mice triggers increased pericentral CYP2E1 that correlates with amount of ethanol consumed and clears within 24h. Ultimately the results of this study will provide insight into the subcellular distribution of CYP2E1 at baseline, immediately following drinking, and in the following days.

3505-C | AGE DEPENDENT RISK FACTORS FOR THE DEVELOPMENT OF ALCOHOL-RELATED LIVER DISEASE: A POPULATION-BASED COHORT STUDY

Rachael Mahle[1], Prasanna K Challa[2], Augustin Vannier[3], Wei Zhang[1], Russell P. Goodman[2], Esperance Schaefer[2] and Jay Luther[4], (1)MGH, (2) Massachusetts General Hospital, (3)University of Chicago, (4)Massachusetts General Hospital, Anodover, MA

Background: Mortality associated with alcohol-related liver disease (ALD) is rising, particularly in younger patients. However, the factors influencing this concerning epidemiological trend remain unclear. In this study, we aimed to assess age dependent risk factors for the development of ALD in patients with alcohol use disorder (AUD). **Methods:** 9,207 patients with AUD and without a history of ALD were identified within the Mass General Brigham health system via ICD-9,10 coding. These patients were stratified into five age groups (<40, 40-50, 50-60, 60-70, >70 y) and were followed for incident ALD, the primary outcome of the study. Multivariate regression models were used to examine the association of risk factors with ALD diagnosis, stratified by age. **Results:** Over a median follow up of 11.8 years, 69/2278 (3%), 109/1263 (9%), 189/1976 (9%), 224/1969 (11%), and 117/1721 (7%) of AUD patients aged <40, 40-50, 50-60, 60-70, and >70 years, respectively, developed ALD. The distribution of female patients was highest in younger age groups (49% in <40 vs 33% in >70 y). A diagnosis of severe AUD conferred an age-dependent increased risk for ALD, with highest impact in those <40 (<40: HR 15.4, 95%CI 7.18-33.07, $p<0.005$; 40-50: HR 8.13, 95%CI 4.62-14.32, $p<0.005$; 50-60: HR 5.88, 95%CI 3.85-8.98, $p<0.005$; 60-70: HR 4.22, 95%CI 3.03-5.87, $p<0.005$; >70: HR 4.01, 95%CI 2.71-5.93, $p<0.005$). Hepatitis B also increased the risk of ALD incident in patients <40 years (HR 3.65, CI 1.11-12.05, $p=0.034$) but was not significantly associated in other age groups. Moderate to high intensity exercise had a protective effect in older patients (60-70 years: HR 0.41, CI 0.19-0.91, $p=0.028$; >70 years: HR 0.12, CI 0.02-0.97, $p=0.046$), but not in patients <40 years. Psychotherapy prior to ALD diagnosis was associated with a greater degree of protection against ALD in patients <40 years (HR 0.36, 95%CI 0.21-0.61, $p<0.005$) compared to older patients. AUD pharmacotherapy prior to ALD diagnosis was statistically more protective in all age categories except for patients <40 (HR 0.69, 95%CI 0.41-1.17, $p=0.166$). **Conclusion:** Despite the overall lower incidence of ALD among younger patients, diagnoses of severe AUD and comorbid hepatitis B

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

were strongly associated with incident ALD. Further, AUD psychotherapy has a superior protective effect on ALD incidence in the youngest age group (< 40 y), whereas exercise and pharmacotherapy associated with less protection.

3506-C | ALARMING TRENDS IN ALCOHOLIC LIVER DISEASE MORTALITY RATES AMONG ALL RACES IN THE US OVER TWO DECADES

Mohamed Boshnaf[1], Abdul Gader Gheriani[2], Sabri Elmansouri[3], Seif Bugazia[4] and Omer Najem[1], (1) Baptist Health-University of Arkansas Medical Science, (2)Mountain View Hospital, (3)Insight Hospital & Medical Center Chicago, (4)Henry Ford Macomb Hospital

Background: The prevalence of alcoholic liver disease (ALD) has been increasing in the United States, with alcohol-related liver cirrhosis emerging as the second leading cause of liver-related deaths. This abstract aims to provide an inclusive overview of ALD across all races in the United States. **Methods:** In this study, we utilized the Wide-ranging Online Data for Epidemiologic Research (WONDER) database provided by the U.S. Centers for Disease Control and Prevention to identify patients who had died due to alcoholic liver disease, as determined by an ICD-code version (C70.x) registered as the underlying cause of death. We then examined and compared trends in alcoholic liver disease-related mortality rates across all races (including White, Black, Asian or Pacific Islander, and American Indian or Alaska Native) in the United States between 1999 and 2020. Age-adjusted mortality rates were calculated per 1000,000 persons (PMP), standardized to the US census data from 1999, and stratified by race. **Results:** During the period from1999 to 2020, the study identified a total of 371,751 deaths related to alcoholic liver disease across all races, resulting in an overall age-adjusted mortality rate of 50.7 (PMP). Out of these deaths, 322,879 were in White individual's, 30,942 in Black individual's, 13,301 in Asian or Pacific Islander individual's, and 4,629 in American Indian or Alaska Native individual's. The overall age-adjusted mortality were 172.9 PMP, 53.5 PMP, 36.1 PMP, and 12.8 in the American Indian or Alaska Native, White, Black, Asian or Pacific Islander populations respectively. Furthermore, over the 21-year period, the study observed an 8% decrease in age-adjusted mortality rates among Black individual's, from 50.5 PMP in 1999 to 46.5 PMP in 2020. However, the rates increased significantly among other racial groups, with a 99% increase in White individual's (from 42.8 PMP in 1999 to 85.2 PMP in 2020), a 98% increase in Asian or Pacific Islander individual's (from 10.3 PMP in 1999 to 20.4 PMP in 2020), and a 66% increase in American Indian or Alaska Native individual's (from 162.9 PMP in 1999 to 270.3 PMP in 2020). **Conclusion:** In conclusion, the findings of this study suggest that alcoholic liver disease-related mortality rates varied significantly among different racial groups in the United States between 1999 and 2020. Specifically, the highest mortality rates were observed in American Indian or Alaska Native individual's, while the lowest rates were observed in Asian or Pacific Islander individual's. Additionally, the mortality rate was found to be twice as high in White individual's compared to Black individual's. Notably, the study also observed a decrease in alcoholic liver disease-related mortality rates among Black individual's over the 21-year period, whereas rates increased among all other racial groups.
Disclosures: The following people have nothing to disclose: Mohamed Boshnaf, Abdul Gader Gheriani, Sabri Elmansouri, Seif Bugazia, Omer Najem

3507-C | ALBUMIN PROTECTS AGAINST ETHANOL-INDUCED LIVER INJURY

Bryan Mackowiak, Taylor Lehner, Yaojie Fu, Janos Paloczi, Yuhong Lin, Pal Pacher and Bin Gao, National Institute on Alcohol Abuse and Alcoholism (NIAAA)

Background: Rising alcohol consumption during the pandemic has led to concurrent increases in alcohol-associated liver disease (ALD). There is an urgent need to identify novel mechanisms of early ALD progression that are potential therapeutic targets, as late-stage ALD has poor prognosis and limited treatment options. Albumin, a liver-derived circulating protein, plays key roles in oncotic pressure, molecular transport, and immune response. Circulating albumin is decreased, and albumin supplementation is used therapeutically in late-stage ALD, but whether circulating albumin levels change earlier in ALD or albumin plays a role in ALD progression is unknown. **Methods:** To determine how albumin levels change and correlate with other clinical parameters after heavy ethanol consumption, we analyzed clinical data from Li et al. (2017) comparing healthy controls, heavy drinkers, and heavy drinkers that have been abstinent > 10d. Albumin knockout mice (ALB KO) were used as a model to investigate how albumin affects ethanol-induced liver injury and changes in vascular function. ALB heterozygous (ALB

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Het) were found to have similar liver and serum protein levels of albumin to WT mice and were used as a control group. Blood pressure (BP) was measured 3h after vehicle or 5g/kg ethanol gavage using PV catheterization. **Results:** Plasma albumin levels were lowest in heavy drinkers and increased in abstinent heavy drinkers but remained lower than healthy controls. Albumin levels were also negatively correlated with AUDIT scores in both heavy drinking groups. To determine whether these decreases in albumin may contribute to progression of ALD, we subjected ALB KO and ALB Het mice to the 10d + binge model of ethanol consumption (NIAAA model) and found that ALB KO mice exhibited worse liver injury than ALB Het mice. Pathway analysis of liver tissue RNA-seq identified perturbations in bile acid metabolism, inflammation, and vascular function. We further analyzed our clinical dataset and found that plasma albumin is correlated with lymphocyte and platelet counts in heavy drinkers, and positively correlated with BP heavy drinkers, indicating that systemic functions of albumin in the circulatory and immune systems may also affect liver injury. The BP of ALB KO mice was lower at baseline and further decreased after ethanol gavage compared to controls, confirming the BP-albumin correlation. **Conclusion:** Heavy drinking alone is sufficient to decrease plasma albumin, indicating that albumin decreases are an early event in ALD progression. Studies in our mouse model show that albumin protects against ethanol-induced liver injury through tissue-specific and systemic mechanisms, likely including cardiovascular and immune system alterations that are under investigation. Our findings point to a previously unrecognized role for albumin in ALD progression, and further studies are needed to determine the potential of albumin as a treatment in early ALD.

3508-C | ALCOHOL CONSUMPTION DECREASES PLASMA PERFLUOROOCTANOIC SULFONATE (PFOS) LEVELS

Tyler C. Gripshover[1], Frederick Ekuban[1], Kushal Biswas[2], Banrida Wahlang[1], Kimberly Head[1], Dhimiter Bello[2] and Matthew Cave[1], (1)University of Louisville, Louisville, KY, (2)University of Massachusetts Lowell

Background: Perfluoroalkyl Substances (PFAS) are a large family of surfactant-like toxicants that are considered persistent organic pollutants. PFAS exposures have been associated with several adverse health effects including dyslipidemia. While mechanistic PFAS studies are still emerging, one consistent observation is activation of the peroxisome proliferator activating receptor alpha (PPARα). Furthermore, research suggests that PFAS require active transport during distribution, one class of transporters being organic anion transporting polypeptides (OATPs). We recently characterized a model for how polychlorinated biphenyl 126 enhanced alcohol-associated liver disease (ALD). However, there are no known reports on how PFAS may enhance ALD or perhaps how alcohol consumption influences PFAS kinetics. We hypothesize that perfluorooctane sulfonic acid (PFOS) will promote hepatic steatosis and dyslipidemia and ethanol will disrupt PFOS tissue partitioning. **Methods:** Male C57BL/6J mice were fed *ad libitum* Lieber-DeCarli diet with 5% EtOH or control diet for 15 days. Beginning on day 6, mice were exposed to 1 mg/kg/day PFOS or vehicle (2% Tween-80) *via* oral gavage. At euthanasia, blood and tissue samples were collected for downstream analyses. **Results:** Steatosis and hepatomegaly were observed in mice fed the EtOH diet and exposed to PFOS; however, a significant interaction effect was not evident. PFOS was capable of activating PPARα, as shown by target gene induction (*Cyp4a10*). Interestingly, both PFOS and EtOH activated CAR *via* its target gene induction (*Cyp2b10*). We did observe significantly enhanced expression of *Cd36* and *Fabp1*, which are involved in lipid scavenging and transport, due to PFOS in EtOH-fed mice. Furthermore, hepatic gene expression of PFOS transporters, *Slco1a1* and *Slco1b2*, were decreased 90% and 40%, respectively, by EtOH. Mean plasma PFOS levels were significantly decreased by ~40%, by EtOH feeding, implying that alcohol consumption may impact PFOS partitioning or excretion. **Conclusion:** Overall, this study demonstrated that PFOS was unable to promote ALD, unlike our previous model. However, the importance in this study lies that plasma PFOS was significantly decreased with chronic EtOH feeding. This may be a special consideration for future PFOS research as EtOH consumption may impact tissue partitioning. Future studies will measure PFOS partitioning in other organs of interest, such as the liver and kidney, to further understand lifestyle factor influences on PFOS distribution.

f 3509-C | ALCOHOL INDUCED EPIGENETIC CHANGES PREVENT FIBROSIS RESOLUTION AFTER ALCOHOL CESSATION IN MICE.

Michael Schonfeld, Steven A. Weinman and Irina Tikhanovich, University of Kansas Medical Center

Background: Alcohol-associated liver disease (ALD) is a major cause of alcohol related mortality. Recently we identified hepatic H3K4 demethylases KDM5B and KDM5C as important epigenetic regulators of alcohol response in the liver. In this study we aimed to study the role of KDM5-demethylases in ALD resolution. **Methods:** Mice were fed a combination of Western diet with alcohol in the drinking water for 20 weeks (WDA model), for resolution experiments mice were biopsied at the end of the feeding and placed on chow diet for 2-8 weeks. To assess the role of demethylases, male and female *Kdm5b* floxed and *Kdm5c* floxed mice were treated with AAV-Control, AAV-CMV.Cre or AAV-TBG.Cre vectors at the time of alcohol withdrawal. Gene expression and epigenetic changes were assessed using RNA-seq and scATAC-seq. Cell-cell communication was studied using *in vitro* hepatocyte – non-parenchymal cell co-culture experiments. **Results:** We found that alcohol induced pathological changes in cell-cell communication in the liver that are in part mediated by KDM5B and KDM5C-dependent epigenetic changes in hepatocytes. These changes correlated with defects in fibrosis resolution after alcohol cessation in ALD mice. scATAC-seq analysis showed that during ALD resolution epigenetic cell states largely reverted to control conditions. In addition, we found unique epigenetic cell states distinct from both control and alcohol states and identified associated transcriptional regulators, epigenetic regulators including H3K4 demethylases, and nuclear receptors including LXRα. Using cell type specific knockout mice, we found that loss of KDM5B/KDM5C demethylases promoted fibrosis resolution after alcohol cessation. This mechanism involved changes in hepatocyte-macrophage crosstalk and LXRα activation, which we identified to be critical for pro-resolving macrophage phenotype and the fibrosis resolution process. LXR inhibition prevented fibrosis resolution in KDM5B/KDM5C deficient mice. **Conclusion:** In summary, KDM5B and KDM5C demethylases are regulators of cell-cell crosstalk involved in fibrosis resolution.

3510-C | ALCOHOL MODULATES HEPATIC AMYLOID BETA AND LIPID METABOLISM IN APP/PS1 MOUSE MODEL OF ALZHEIMER'S DISEASE

Veronika Brezani, Radhika Joshi, Marti Ortega-Ribera, Mrigya Babuta, Yanbo Wang and Gyongyi Szabo, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Background: Chronic alcohol abuse impairs liver function and increases the risk of dementia. In Alzheimer's disease (AD), the leading cause of dementia, the liver is thought to play an important role in maintaining lipid metabolism and clearance of the neurotoxic amyloid-β (Aβ) peptide from the circulation. However, the contribution of alcohol-induced hepatic changes on peripheral AD features remains unexplored. Thus, we aim to evaluate hepatic lipid metabolism and Aβ clearance in the preclinical dual insult model of AD and alcohol abuse. **Methods**: Twelve to fifteen-month-old wild type (WT) or APP/PS1 mice received either water or ethanol binges (3.5 g/kg, i.g.) every other day for 28 days. Lipid and alcohol metabolism, amyloid precursor protein (APP) processing and Aβ clearance were assessed in the liver by qPCR. **Results**: We found that alcohol binges significantly increased serum alanine transaminase (ALT) levels only in the APP/PS1 mice compared to water treatment, suggesting increased alcohol-induced liver damage in AD mice. Moreover, enzymes (alcohol dehydrogenase 1, aldehyde dehydrogenase 2, and cytochrome P450 2E1) and regulators (farnesoid X receptor) involved in alcohol metabolism were markedly increased in APP/PS1 mice treated with alcohol compared to WT controls, indicating dysregulated alcohol metabolism. Next, we investigated the regulation of lipid metabolism, and we observed increased expression of molecules involved in fatty

acid uptake (fatty acid transport protein 1, cluster of differentiation 36), oxidation (peroxisome proliferator-activated receptor alpha), de novo lipogenesis (fatty acid synthase), and hepatic lipid export (apolipoprotein B, phosphatidylethanolamine N-methyltransferase) in alcohol-treated APP/PS1 mice compared to APP/PS1 alone or alcohol-treated WT mice. Apolipoprotein E, a major risk factor for AD and a key regulator of lipoprotein metabolism was also upregulated in alcohol-treated APP/PS1 mice further supporting evidence of lipid dysregulation. Lastly, we observed that alcohol binges increased APP expression as well as the components of the molecular machinery involved in APP processing (beta-secretase 1, a disintegrin and metalloprotease 10) and Aβ clearance (low-density lipoprotein receptor-related protein 1, insulin-degrading enzyme) compared to that of water-treated APP/PS1 mice indicating increased turnover of Aβ. **Conclusion**: We show for the first time that AD mice are more susceptible to alcohol-induced liver damage compared to WT. Our results suggest that chronic alcohol exposure modulates the production and metabolism of hepatic lipids and Aβ which could be linked to altered alcohol metabolism in a mouse model of AD.

3511-C | ALCOHOL RELAPSE AFTER LIVER TRANSPLANT FOR ALCOHOL ASSOCIATED LIVER DISEASES

Georgios Voidonikolas, Jill Frese, Ju Dong Yang, Todd Brennan, Kambiz Kosari, Justin Steggerda, Tsuyoshi Todo, Steven Wisel, Alexander Kuo, Walid S. Ayoub, Hirsh Trivedi, Allen Chen, Benjamin Ferrel, Amy Christianson, Nicholas Nissen and Irene Kim, Cedars-Sinai Medical Center, Los Angeles, CA

Background: Alcohol-associated liver disease is the leading indication for liver transplant surgery in the United States. There is a lack of consensus on selecting an appropriate candidate for liver transplantation among patients with alcohol-associated liver diseases. We aim to report the frequency of alcohol relapse after liver transplantation and risk factors for post-transplant alcohol use. **Methods:** All patients who received liver transplantation for alcohol-associated liver diseases (with/without alcoholic hepatitis) between 03/2015-09/2021 were identified from the institutional liver transplant database. Demographical, clinical, and psychosocial features of recipients were extracted from the database. Baseline characteristics were summarized as mean or median for continuous variables and as n (%) for categorical data. We obtained p-values using Kruskal-Wallis rank sum test for continuous variables and Pearson's Chi-squared test for categorical variables. **Results:** A total of 214 patients were included. The majority of patients (80%) were male and half of the recipients were Hispanic. Twenty-three patients (10.8%) were transplanted for severe alcoholic hepatitis. A total of 49 patients (24.6%) had an alcohol relapse after liver transplantation. Patients with relapse were younger than those without relapse (48 vs. 52-year-old, $P = 0.01$). There was a trend toward higher risk of relapse in Non-Hispanic White than Hispanic, and other ethnicity (31.4% vs. 19.8% vs. 20%, $P = 0.18$). The proportion of relapse was similar between patients with/without alcoholic hepatitis (28.6% vs.24.4, $P = 0.68$) and median length of sobriety prior to liver transplant was similar in recipients with vs. without relapse (6 vs. 6 mo, $P = 0.62$). Additionally, proportion of relapse was similar regardless of previous rehab attempt, DUI or EOTH-related legal consequences, history of substance abuse, and comorbid psychiatric illness. There was a trend toward a lower risk of relapse among those with good social support than those with fair or limited social support (23.4% vs., 34.6%, $P = 0.23$). Proportion of relapse was higher among those with noncompliance to post-transplant clinic visit vs. compliant patients (52.5% vs. 22.3%, $P < 0.01$). Mean SALT scores were 2.6, 2.3, for patients with, and without relapse, respectively ($P = 0.54$). Mean SIPAT scores were 19.2, 16.1, for patients with, and without relapse, respectively ($P = 0.09$). **Conclusion:** A quarter of patients who underwent liver transplantation have alcohol relapse. Relapse occurs more frequently in younger patients and those who were not compliant with clinic follow up. Alcoholic hepatitis and median length sobriety prior to liver transplant were not associated with post-transplant alcohol relapse.

3512-C | ALCOHOL RELAPSE AFTER LIVER TRANSPLANTATION: RISK FACTORS, OUTCOMES, AND A COMPARISON OF RISK STRATIFICATION MODELS

Karen Young[1], Yuval Patel[2], Benson Hoffman[1], Sarah Peskoe[1], Shein-Chung Chow[1], Karli Erhart[1], Jennifer Jackson[1] and Stephanie Garbarino[1], (1)Duke University, (2)Baylor College of Medicine

Background: Alcohol-related liver disease (ALD) is a leading cause of liver transplantation (LT) in the United States (1-3). Considering transplantation for ALD requires weighing the risk of alcohol relapse, which can lead to allograft failure (4). Multiple studies have examined factors and created scoring systems to predict relapse after LT, such as the SALT and HALT scores (5, 6). We aimed to assess risk factors and compare the effectiveness of SALT and HALT scores at predicting relapse after LT at our large transplant center. **Methods:** This was a retrospective chart review of 69 adults who underwent LT for ALD at Duke University Hospital from 1/1/2018 to 1/1/2021. Primary outcome variables included relapse detected post-LT, severity of relapse, and evidence of graft dysfunction. Data analysis included generalized linear models to assess associations between relapse risk factors and outcome measures, as well as concordance statistics when applying the SALT and HALT scores. **Results:** 67 patients with a median follow up time of 43 months after LT were included. Eighteen (27%) experienced any relapse of alcohol after LT. Out of those who relapsed, 15 (83%) had heavy alcohol use (i.e., > 2 drinks/day for men and > 1 drink/day for women) and three of those patients (17%) experienced graft dysfunction (i.e., biopsy grade 3 or greater of fibrosis, signs of portal hypertension, or jaundice). Factors associated with a significant risk of relapse included younger age, prior relapse, significant psychiatric co-morbidities, alcohol use after cirrhosis diagnosis, shorter duration of abstinence prior to LT listing, and prior participation in an alcohol treatment program (Table 1). When applying the SALT and HALT scores to this data using area under the curve (AUC) modeling, these scores indicated good discrimination (AUC = 0.69 and 0.66, respectively). **Conclusion:** Several clinical risk factors for alcohol relapse after LT were identified in our cohort, as with previously published data. In our cohort, heavy alcohol use prior to transplant and legal issues did not predict relapse, which is a common component of prediction scores. Less than 5% of patients transplanted for ALD at our center had graft dysfunction due to relapse after LT, suggesting overall good graft outcomes even in those that unfortunately relapsed. The HALT and SALT scores interestingly had underwhelming predictive value in our cohort, suggesting the need for further optimization of prediction scores. References: please see link

3513-C | ALCOHOL RELAPSE SCORES AND INDIVIDUAL SOCIAL DETERMINANTS OF HEALTH PREDICT ALCOHOL RELAPSE AFTER LIVER TRANSPLANT

Yara Sarkis[1], Elizabeth Williams[1], Maria Guarnizo Ortiz[1], Saad Saadat[1], Allie Carter[2], Lauren D. Nephew[2] and John Holden[1], (1)Indiana University School of Medicine, (2)Indiana University

Background: Alcohol-associated liver disease (ALD) is a leading indication for liver transplant (LT) in the United States. Alcohol relapse is common and is associated with decreased post-LT survival. Risk scores have been used to predict relapse, however the impact of individual and area-level social determinants of health (SDOH) has not been fully explored. We hypothesize that SDOH are associated with post-LT alcohol relapse and survival. **Methods:** Adult patients with ALD who were transplanted at Indiana University Hospital from 9/2007 to 12/2021 with at least 6 months of follow-up were identified. Demographics, clinical characteristics, and alcohol use history were collected via chart review. Three relapse scores were calculated: High-Risk Alcoholism Relapse scale (HRAR), Alcohol Relapse Risk Assessment (ARRA) score, and Sustained Alcohol use post-LT (SALT) score. Six individual-level SDOH (marital status, living situation, education level, employment status, social security disability status and insurance type) and three area measures of deprivation (social deprivation index, area deprivation index, and % income below the federal poverty level) were collected. Multivariable logistic and Cox regression analyses were performed to identify factors associated with relapse and post-LT survival. **Results:** 405 patients underwent LT; mean age was 54.4 ± 8.4 years old, 22.2% were female and 4.7% were Black race. Mean MELD at time of LT was 19.4 ± 7; 25.4% had hepatocellular carcinoma (HCC) and 36.5% had psychiatric comorbidities. In regard to SDOH, 48.2% were married, 88.6% lived with another person, 20.7% did not complete high school, 23.7% were insured by Medicaid, and 24.1% lived in the most deprived quartile by area deprivation index. 53 patients relapsed to alcohol and 83 patients died during follow-up. On multivariable analysis, being unmarried, Medicaid insurance, and ARRA group (III/IV) were associated with higher odds of alcohol relapse (figure 1A). Medicare, HCC status, psychiatric comorbidities and HRAR score > (4+) were associated with increased risk of death (figure 1B). There was no significant association between area-level SDOH and alcohol relapse or post-LT survival. **Conclusion:** Alcohol risk scores and individual-level SDOH were associated with alcohol relapse and survival. Interventions to support this population should consider both, requiring a multidisciplinary approach.

3514-C | Alcohol use disorder treatment during COVID-19 among Veterans with cirrhosis

Brittany Bromfield[1], Sebastian Niezen[1], Vera Yakovchenko[2], Patrick Spoutz[3], Timothy R. Morgan[4], Jasmohan S. Bajaj[5], Rachel Bachrach[2,6], Ponni Perumalswami[7,8] and Shari S. Rogal[2,6], (1)University of Pittsburgh Medical Center, (2)VA Pittsburgh Healthcare System, (3)Veterans Integrated Service Network 20, (4) VA Long Beach Healthcare System, (5)Virginia Commonwealth University and Central Virginia Veterans Healthcare System, (6)University of Pittsburgh, (7)VA Ann Arbor Healthcare System, (8) University of Michigan

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: The COVID-19 pandemic has accelerated an already increasing prevalence of alcohol use disorder (AUD) and caused disruptions in already low rates of AUD adoption, particularly for women. Despite the growing number of women with alcohol-related liver diseases (ALD), there is limited research regarding AUD treatment patterns for women with liver disease. This study aimed to identify AUD treatment patterns among Veterans with cirrhosis, overall and specifically for women. **Methods:** Electronic health record data, including Veterans with two outpatient or one inpatient ICD-10 codes for cirrhosis and AUD between October 2019 and September 2022, was extracted from VA's Corporate Data Warehouse. AUD treatments (behavioral and pharmacotherapies) were identified using pharmacy data and validated combinations of ICD-10, Current Procedural Terminology (CPT), and stop codes. Multivariable logistic regression models, controlling for relevant demographics, liver-related conditions, and comorbidities, were used to identify factors associated with any AUD treatment and each type (behavioral and pharmacological), overall and stratified by gender. **Results:** Among 40,796 Veterans with cirrhosis and AUD, 3% were women, 40% had prior hepatic decompensation, and the mean MELD-Na score was 11 ± 6. Compared with men, women with AUD and cirrhosis were younger, with higher rates of homelessness, mental health and substance use disorders and lower comorbidity scores. Over a 180-day follow-up period, 3,371 individual's (8%) received any AUD treatment, 2,393 (6%) received pharmacotherapy alone, and 215 (0.5%) received both behavioral and pharmacotherapy. Women were less likely than men to receive any form of AUD treatment (adjusted odds ratio [AOR]: 0.8; 95% confidence interval [CI] 0.7 – 0.9; $p = 0.003$). Receipt of AUD treatment in the overall cohort was otherwise significantly associated with younger age (AOR 0.9; 95% CI 0.9 – 1.0, $p < 0.001$), homelessness (AOR 1.7; 95% CI 1.5 – 1.9, $p < 0.001$), co-occurring anxiety (AOR 1.7; 95% CI 1.5 – 1.9; $p < 0.001$), PTSD (AOR 1.6; 95% CI 1.4 – 1.8; $p < 0.001$), lower MELD-Na score (AOR 0.9; 95% CI 0.9 – 1.0; $p < 0.001$), and lower comorbidity score (AOR 0.9; 95% CI 0.9 – 1.0; $p < 0.001$). Odds of receiving pharmacotherapy were decreased for people who were non-Hispanic and Black (AOR 0.9; 95% CI 0.8 – 1.0; $p = 0.02$), but otherwise the models by type of AUD treatment were similar to the overall model. Factors associated with treatment were similar in models stratified by gender, except that pharmacotherapy was not significantly associated with race for women. **Conclusion:** During the COVID-19 pandemic, AUD pharmacotherapy accounted for a higher percentage of AUD treatment in VA patients with AUD and cirrhosis than previously described. The models defined key targets for intervention, including that women with AUD and cirrhosis were less likely than men to receive AUD treatment.

Table 1. Characteristics of Veterans with Alcohol-Use Disorder (AUD) and Cirrhosis by Gender, and AUD treatment status

Background: About half of the people with cirrhosis go on to develop cirrhotic cardiomyopathy and cardiovascular death is the leading cause of mortality in patients with alcohol use disorder. A strong association has been shown between serum bilirubin levels and arrhythmia. Bile acids have been thought to cause QT prolongation. Cardiac arrhythmia, importantly QT prolongation is responsible for the sudden cardiac death rather than ischemic heart disease. Paroxysmal tachycardia can occur in patients with alcoholic liver disease even in the absence of left ventricular dysfunction. **Methods:** This is a retrospective analysis of the National Inpatient Survey (NIS) database of the year 2020. We identified adults aged 18 and above with the discharge diagnosis of Alcoholic Liver Disease with and without cardiac arrhythmias using the International Classification of Disease-10 (ICD-10). Then, we analyzed them separately in terms of prevalence by age, sex and race along with inpatient mortality, inpatient morbidity and mean length of stay (LOS). **Results:** A total of 82620 patients were diagnosed with alcoholic liver disease (ALD) out of which 7365 were found to have different types of arrhythmias. Atrial fibrillation (64.02%) was the most common followed by ventricular tachycardia/ fibrillation (28.38%) with long QT being present in 7.6%. The mean age of people with ALD was 52.94 $\pm$0.11 whereas that of people with ALD and cardiac arrhythmia was 60.93 $\pm$ 2.81 years ($p < 0.001$). Hypertension was present in 32.64% of patient with ALD without arrhythmia and 28.78% of patients with arrhythmia (p-value 0.004) whereas coronary artery disease was present only in 5.46 % of patients with ALD without arrhythmia and 19.08% of patients with arrhythmia (p-value 0.000). Similarly, 3.49% of ALD patients without arrhythmia had heart failure while 16.9 % of patients with arrhythmia had heart failure (p-value 0.0000). Hyperlipidemia was present in 13.42% of patient with ALD without arrhythmia and 25.87% of patients with arrhythmia (p-value 0.000) The mortality rate of patients with ALD and arrhythmia was 9.64% whereas 4.67% mortality was recorded in patients without arrhythmia. ($P = 0.0000$). Patients with ALD and arrhythmia had mean length 5.81 $\pm$ 0.7 days of stay in the hospital whereas those without arrhythmia had 8 $\pm$ 0.27 days. **Conclusion:** Patients with ALD tend to develop various types of arrhythmia like atrial fibrillation, ventricular tachycardia/ fibrillation and long QT syndrome. The cardiovascular morbidity in patients with ALD along with arrhythmia was higher compared to those without arrhythmia. Additionally, the mean length of hospital stay and mortality were also higher in the group with ALD and arrhythmia.

3516-C | ALCOHOLIC LIVER DISEASE IN PEOPLE WITH HIV IN LOW- AND MIDDLE-INCOME COUNTRIES: PREVALENCE AND FACTORS ASSOCIATED WITH SEVERITY OF HEPATIC FIBROSIS

Niharika R. Samala[1], Suzanne Goodrich[2], Marie Kerbie Plaisy[3], Antoine Jaquet[3], Gilles Wandeler[4], Cleophas Chimbetete[5], Dhanushi Rupasinghe[6], Sonali Salvir[7], Mark H. Kuniholm[8], Kathy Lancaster[9], Hugo Perazzo[10], Rodrigo Moreira[11], Stephanie Duda[12], Naga P. Chalasani[13] and Agrrey Sameere[14], (1)Indiana University, Indianapolis, IN, (2)Indiana University, (3) University of Bordeaux, (4)University Hospital Bern, (5) Newlands Clinic, (6)The Kirby Institute, University of New South Wales (UNSW), (7)6Byramjee Jeejeebhoy Government Medical College, (8)University at Albany, State University of New York, (9)Ohio State University, (10)APHP UPMC Liver Center, (11)9Evandro Chagas National Institute of Infectious Disease-Oswaldo Cruz Foundation, (12)Vanderbilt University, (13)Indiana University Medical Center, Indianapolis, IN, (14) Makerere University

Background: In people with HIV (PWHIV) in the US, active alcohol use is associated with alcohol-associated liver disease (ALD). Worldwide 5% of global disease burden is attributable to alcohol consumption. Among PWHIV 30% have alcohol use disorder. ALD has not been explored in PWHIV in low- and middle-income countries. We aimed to determine the prevalence of ALD and associated fibrosis severity in PWHIV. **Methods:** PWHIV $\geq$ 40 years and $\geq$ 6 months on antiretroviral therapy were prospectively enrolled in the Sentinel Research Network (SRN) of the IeDEA (International epidemiology Databases to Evaluate AIDS) consortium (Asia-Pacific, Central Africa, East Africa, Southern Africa, West Africa, Caribbean, Central and South America networks) were analyzed. All participants who completed AUDIT questionnaire to determine alcohol use and had reliable Vibration Controlled Transient Elastography using FibroScan® ($\geq$ 10 valid reads & $\leq$ 30% IQR) to determine hepatic steatosis and fibrosis were included. ALD was defined as a Controlled Attenuation Parameter $\geq$ 285dB/m and an AUDIT-score $\geq$ 7 in females and $\geq$ 8 in males. Clinically significant fibrosis (CSF) was defined as Liver Stiffness Measurement (LSM) $\geq$ 8.6kPa. Metabolic syndrome was defined based on ATP-III definition. Analysis was performed using SAS. **Results:** There were 2333 PWHIV in the IeDEA-SRN cohort, 57% females, with median age of 51 (46, 56) years, median BMI of 25 (22, 28) kg/m^2; 8% had diabetes, 23% had hypertension, 55% had dyslipidemia and 28% had metabolic syndrome. Hazardous alcohol use was seen in

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

12% (275). ALD was seen in 1.2% (29) of the entire cohort and in 11% of those with hazardous alcohol use. Liver disease other than ALD was seen in 372 (16%) of the cohort. Among those with ALD, 17% (5/29) had CSF. PWHIV with ALD had higher median BMI (29 vs. 24 kg/m2, $p < 0.0001$), were more likely to be male (79% vs. 41%, $p < 0.0001$), have type 2 diabetes (17% vs. 6%, $p = 0.03$), and metabolic syndrome (55% vs 29%, $p = 0.008$) compared to those without liver disease. Furthermore, PWHIV with ALD had significantly higher LSM (median (IQR) 5.2 (4.4, 5.9) vs. 4.6 (3.8, 5.5), $p = 0.009$), and CSF (5 (17%) vs. 60 (3%), $p = 0.002$) compared to those without liver disease. **Conclusion:** In low to middle income countries, ALD is present in 1.2% of PWHIV and in 11% of PWHIV with hazardous alcohol use. A sizable proportion of PWHIV with ALD have evidence for clinically significant fibrosis. Metabolic syndrome may predispose PWHIV to ALD

Background: The burden of cirrhosis, especially due to alcohol and metabolic factors is increasing, more so during the pandemic period. However, the impact of these various etiologies of cirrhosis across different regions of the world remains unclear. **Methods:** The multi-national CLEARED consortium prospectively enrolled in-patients with cirrhosis without COVID-19 and followed them for 30-days post-discharge. Etiology related to alcohol, NASH, HCV, HBV, Autoimmune and others were studied with respect to presentation, decompensation, complications, course in hospital and survival at 30-days post discharge across all 6 continents. **Results:** Total of 4238 patients from 107 centers in 27 countries were included. The predominant etiology was alcohol (1689,39.5%) followed by NASH/ Cryptogenic (913,21.5%), HBV (751, 17.7%), auto-immune (396,9.3%) and HCV (299,5.4%). Ethanol was commoner in men (78.6%), NASH was gender balanced (55%) and AILD (24%) mainly in females. Patients with alcohol-related cirrhosis (ARC) had more advanced cirrhosis [prior HE (45.6%), refractory ascites

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

(40.9%), hospitalization (40.6%)] than other etiologies ($p < 0.001$), but had lower listing for LT. Alcohol related Cirrhosis patients were admitted with higher MELD-Na 23 (IQR 17-29) vs 21 (IQR15-27). Infection at admission, SBP, GI Bleed, HE, AKI and anasarca were more likely seen in ARC than other etiology significantly (Figure). The hospital stay of Alcohol related Cirrhosis patients was accompanied by more complications due to higher nosocomial infection, in-hospital AKI, ICU transfer and in-patient mortality. There were 104(2.5%) in-hospital transplants, of which fewer were done among ARC patients than others [NASH (12.5% vs 31.7%) and they were sicker with a higher baseline MELD Na of 23 (IQR 17-29) and at discharge 21 (IQR 15-27) than others ($p < 0.001$). During follow-up, the 30 days readmission and mortality was higher with ethanol. Transplant (ethanol-39.2%, NASH-27.6%, Viral 11.6%, AILD 11.6%, $P < 0.001$) rate was better of the total 81(5.5%) within 30days of discharge ($p < 0.001$). In multivariate analysis, the inpatient mortality was higher in ARC vs HCV, OR 1.07(0.65-1.76), NASH, OR 1.41 (1.06-1.89), and AILD, OR 1.79(1.23-2.59), $p < 0.003$). On the other hand, HBV related cirrhosis had a lower in-hospital mortality (5.6% vs 11.1 average, $p < 0.01$) and were at lower risk of in-hospital death compared to ARC patients [OR 0.55(0.37-0.83, $p < 0.003$]. **Conclusion:** In a prospective global cohort of inpatients with cirrhosis, alcohol related cirrhosis remains the most common etiology across the world. The alcohol related cirrhosis associated with more severe disease, higher in-hospital complications, mortality and lower in-hospital likelihood of getting a liver transplant. Alcohol-related liver diseases deserve special focus, monitoring during and after discharge and early liver transplant, across the world.

(2)Hospital General De México "Eduardo Liceaga", Saint Luke School of Medicine, Mexico City, Mexico, (3) Hospital General De Mexico "Eduardo Liceaga"

Background: Alcohol-related liver disease is becoming more common worldwide. Recently, women's alcohol consumption has increased significantly, raising the risk of developing alcohol-associated hepatitis, cirrhosis, and hepatocellular carcinoma. Greater susceptibility to alcohol-related liver damage seems to confer higher mortality and decompensation risk in women. Our study aimed to assess mortality rate and alcohol consumption patterns in female patients with alcohol-related cirrhosis. **Methods:** We conducted a single-center retrospective cohort study of patients hospitalized for chronic alcohol consumption at the General Hospital of Mexico "Dr. Eduardo Liceaga" between 2018 and 2021. The electronic patients' medical records were used to estimate the survival rate after the first hospitalization with the Kaplan-Meier curve for women and men. **Results:** One hundred ninety-two electronic patients' medical records were included (50% women). The mortality rate during the first hospital hospitalization was 32.8% (61.9% for women and 38.9% for men). The mean age for survival after chronic alcohol consumption was significantly lower for women [33.8 $\pm$1.6 (95%CI, 30.5-37.1)] compared with men [37.0 $\pm$1.2 (95%CI, 35.4-38.6)] ($p = 0.002$). The median for the onset of chronic alcohol consumption was statistically significantly older in women than in men (18 vs. 16.5 years old, respectively; $p < 0.001$). The median for alcohol consumption was statistically significantly lower in women than in men (160 vs. 290 g, respectively; $p < 0.0001$), and also the time of chronic alcohol consumption (24.5 vs. 30 y; respectively; $p < 0.001$) **Conclusion:** Mortality due to alcohol-related liver damage is higher in women than in men; it is associated with a lower amount of g/day alcohol consumption, a shorter period of continued chronic consumption, and a lower age at the onset of drinking. Mortality in women in the coming years could increase since there is evidence of a prevalence increase in alcohol consumption within this group.

Background: Gut dysbiosis and permeability are suggested treatment targets for alcohol-related liver disease (ArLD). ReFerm®, a post-biotic drink made from an oat composition fermented with *Lactobacillus plantarum 299v*, improves the gut barrier in patients with irritable bowel syndrome. We investigated the effect of ReFerm® on formation of liver fibrosis by hepatic stellate cell activity, composition of gut microbiome, and circulatory bile and amino acids in patients with compensated advanced chronic liver disease (cACLD) related to alcohol. **Methods:** We randomized 56 patients with cACLD 1:1 to receive ReFerm® or Fresubin®, a medical protein-rich supplement, for 24 weeks, with liver biopsies, plasma, and stool collected at baseline and end-of-treatment. We assessed hepatic stellate cell activity by immunohistochemistry of liver biopsies for quantification of α-smooth muscle actin (α-SMA) using automated digital imaging analysis. Primary outcome was $\geq$10% reduction in α-SMA. Compliance was assessed every two

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

weeks. Microbiome composition was analyzed by shotgun metagenomics, and concentrations of plasma amino- and bile acids were obtained by liquid chromatography-mass spectrometry (LC-QQQ, Agilent). To facilitate comparison across outcome measures, the treatment effect was standardized as Cohens d. **Results:** Median age was 63 years (57-67), most patients were male (83%) mainly with cirrhosis (F2/F3/F4 = 4/15/33). Baseline alcohol intake was 36 grams/day, comparable between groups during the study. Thirteen in the ReFerm® group and 18 in the Fresubin® group achieved high compliance (> 85%). In the Referm® group, 8/20 (40%) of patients improved ≥ 10% in α-SMA compared to 4/20 (20%) in the Fresubin® group (OR = 2.3; 95%CI 0.6-9.5; p = 0.246). In patients with high compliance, ReFerm® significantly improved α-SMA compared to Fresubin® (OR = 5.6; 95%CI 1.2-27.1; p = 0.032). Increasing compliance of ReFerm® correlated with improvements in α-SMA (Rho = -0.6623, P = 0.0011). Referm® decreased the abundance of *Flavonifractor platii* and *Veillonella dispar* (p = 0.0118, p = 0.0129), two species that have been associated with liver fibrosis formation. We found a clear tendency of plasma bile acids decreasing in the ReFerm® group compared to the Fresubin® group, a possible sign of better liver performance. The reversed tendency was found within plasma amino acids, as ReFerm® increased amino acids overall compared to the Fresubin® group, hereof four significantly (Taurine (p = 0.037), Homocitrulline (p = 0.028), L-Isoleucine (p = 0.046), and L-Leucine(p = 0.039)). There is increasing evidence that these amino acids benefit the liver, especially in the advanced stage of fibrosis. **Conclusion:** Treatment of advanced ArLD with the post-biotic drink ReFerm® reduces liver fibrosis formation by decreasing α-SMA. ReFerm® may act via a reduction in gut microbes driving fibrogenesis and improvements in circulating bile and amino acids.

3520-C | ANSWERS RISING FROM THE (N)ASHES - THE USE OF PHOSPHATIDYLETHANOL TESTING AMONG PATIENTS WITH NAFLD/NASH

Zachary Fricker[1,2] and Annabel McLaughlin[1], (1)Beth Isreal Deaconess Medical Center, West Newton, MA, (2)Harvard Medical School

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Non-Alcoholic fatty liver disease (NAFLD) and Non-Alcoholic Steatohepatitis (NASH) may overlap with or be exacerbated by alcohol-use. This creates diagnostic uncertainty and may result in inappropriate counseling for patients. Clinical history alone may be inadequate to identify patients with inappropriate alcohol use. The role for, current use, and yield of biochemical testing for durable alcohol metabolites, e.g., phosphatidylethanol (PETH) remains uncertain. **Methods:** We retrospectively reviewed all outpatients seen at our center since January 1, 2020 with a diagnosis of NAFLD/NASH and without prior diagnosis of any alcohol-related condition (via ICD-10 codes). We identified comorbidities informing likelihood of NAFLD (DM, HTN, HL, and obesity, as well as BMI). We collected laboratory data (AST, ALT, PLT, and MCV) as well as liver stiffness (by VCTE) when available. We identified all PETH measurements and categorized as positive or negative at a threshold of $>=20$ ng/mL, chosen to reflect a minimum level of alcohol use likely associated with greater risk of hepatic fibrosis. Logistic regression was used to identify parameters associated with a positive PETH result. **Results:** We identified 19,587 eligible patients. Of these, 736 (3.8%) had PETH results. Of those tested, 247/736 (34%) had positive PETH results. We found that PETH testing was performed and yielded positive results more often in men. Positive PETH results were also associated with metabolic comorbidities and more abnormal laboratory values (see table). Multivariable logistic regression revealed independent associations between positive PETH result and male sex (OR 1.8, 95%CI 1.04-3.2), AST (OR 1.03 per IU/L, 95% CI 1.01-1.04), and MCV (OR 1.04 per fL, 95%CI 1.01-1.09). As a predictor of positive PETH results, a simple model with these parameters yielded an AUROC = 0.73. **Conclusion:** This study reflects current practice at our academic medical center and demonstrates the relatively high rate of inappropriate alcohol use among patients with NAFLD suggesting a potential for misdiagnosis and an area for risk reduction even in the absence of otherwise harmful alcohol use. We identified several factors associated with the presence of a positive test result which are readily apparent and could help inform real-time clinical decisions. Further study may improve predictive capacity and could determine a cost-effective threshold for testing. These retrospective results should be interpreted with caution until confirmed prospectively.

3521-C | ASPIRIN AND NSAIDS ARE ASSOCIATED WITH REDUCED MORTALITY AND CANCER RISK IN PATIENTS WITH CHRONIC LIVER DISEASES

Knut Stokkeland[1,2], Karin Söderberg Löfdal[2], Pär Villner[2] and Johan Frank[1,2], (1)Region Stockholm, (2) Karolinska Institutet

Background: Anti-inflammatory drugs such as aspirin and NSAIDs may be beneficial in chronic liver diseases. We aimed to explore the possible effect of exposure of anti-inflammatory drugs in patients with chronic liver disease. **Methods:** A population-based cohort of patients with chronic liver disease between 2005 and 2020 (n = 21 439) was studied. All patients had been hospitalized in Region Stockholm. Data from the Patient Register, the Prescribed Drug Register, the Death Certificate Register, the Cancer Register, two

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

laboratories and the Stockholm Center for Health Data primary care database were used. We analyzed death, adverse liver events (bleeding esophageal varices, hospitalization for liver disease, liver cancer and liver transplantation), liver cancers and all cancers in relation to drug exposure. **Results:** Mean age at diagnosis ranged from 48.9 years for viral hepatitis and 65.9 years for primary biliary cholangitis. Total follow-up time was 147 045 patient-years during which 10 279 patients (47.9%) died. There were 4 206 patients exposed to ASA and 6 756 exposed to NSAIDs. The was a reduced risk of mortality for all patients exposed to NSAIDs aHR 0.68, 95% CI 0.64-0.72, and a reduction in risk for ASA HR 0.86, 95%CI 0.82-0.91 after adjusting for comorbidities (Charlson comorbidity index) and severity of the liver disease (MELD-score). Similar mortality risks reductions were seen for immunomodulators and antivirals. There was a reduced risk for all cancers when patients were exposed to ASA HR 0.68 95%CI 0.63-0.73 and NSAIDs aHR 0.80, 95%CI 0.75-0.86. There was a reduced risk for liver cancer in patients exposed to ASA aHR 0.48, 95%CI 0.41-0.57 and to NSAIDs aHR 0.71, 95%CI 0.62-0.82. Patients with alcohol-associated liver disease exposed to ASA had a reduced mortality risk, aHR 0.82, 95%CI 0.76-0.89 and exposed to NSAIDs the mortality risk was also reduced aHR 0.74, 95%CI 0.69-0.80. For the risk of liver cancer there was a reduced risk when exposed to ASA aHR 0.40, 95%CI 0.31-0.51 and NSAIDs aHR 0.79, 95%CI 0.65-0.97. **Conclusion:** Exposure to aspirin or NSAIDs in patients with chronic liver diseases was associated with decreased mortality risk and reduced cancer risks including risk for liver cancer.

3522-C | ASSOCIATION OF HEPATOLOGY CONSULT AND RECURRENCE OF ALCOHOL USE IN ALCOHOL USE DISORDER IN INPATIENT TREATMENT POPULATION

Hanna Blaney[1], Mian Khalid[1], Bilal Asif[1], Alex Yang[1], Anusha Vittal[1], David Goldman[1], David George[1], Yvonne Horneffer[1], Nancy Diazgranadanos[1] and Theo Heller[2], (1)National Institute of Health, (2)Translational Hepatology Section, Liver Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health

Background: Alcohol-associated liver-disease (ALD) is a common and severe complication of excessive alcohol use. Alcohol cessation is the only intervention that both prevents and halts progressions of ALD. Studies have suggested the patients with more advanced liver disease on biopsy have lower rates of rapid recurrence of alcohol use. However, little is known on whether extensive evaluation of the liver with a hepatologist affects outcomes of AUD in treatment seeking patients without known advanced liver disease. The aim of this study was to assess the relationship between recurrence of alcohol use and consultation with a hepatologist in treatment seeking patients with AUD. **Methods:** Patients with AUD were enrolled in a 4-week multidisciplinary inpatient treatment program at the NIH. Laboratory values were collected at admission, weeks 1 and 3. Beginning 2018, most of these patients were seen by Hepatology with Fibroscan performed at weeks 1, 2, and 4. Patients enrolled in this program prior to 2018 and patients who did not see Hepatology (due to unavailability of hepatology consultation) served as controls. After discharge, all patients were invited to submit AUDIT questionnaires at week 26. AUDIT-C was used as a surrogate for recurrence of alcohol use. Analyses comparing AUDIT responses between groups were performed. **Results:** 242 patients were admitted during the study period, with 143 patients seen by hepatology. Of the hepatology group, 87 (60.8%) patients completed AUDIT at week 26 v 46 (46%) of the controls ($p = 0.74$). There were no significant differences in baseline characteristics between groups including laboratory results, admission AUDIT ($p = 0.79$), and baseline drinking patterns. There was no difference in rates of prescribing AUD therapy, with 51 patients (59%) in the hepatology group and 21 patients (48%) in the control group receiving medication on discharge ($p = 0.24$). At week 26, 39 (45%) patients the hepatology group v 31 (70%) in controls ($p = 0.006$) answered affirmatively to Question 1 having any alcohol (> 0 to "how often do you have a drink containing alcohol?"), with mean scores of 1.46 and 2.09, respectively ($p = 0.053$). Patients seen by hepatology had decreased rates of hazardous alcohol use as defined by AUDIT-C (> 3 for females or greater than 4 for males) compared to controls, with 36 (41%) v 29 (66%) ($p = 0.008$) patients, respectively, reporting hazardous use. **Conclusion:** Patients who saw hepatology during inpatient treatment of AUD had significantly lower rates of recurrence of alcohol use at 26 weeks than patients who did not have hepatology evaluation. Patients seen by hepatology also had lower rates of hazardous drinking as defined by AUDIT-C. These finding suggest that hepatology evaluation during inpatient treatment of AUD may influence behavior and ultimately lead to decreased rates of early recurrence of alcohol use.

3523-C | ASSOCIATION OF PROGNOSIS AND RESPONSIVENESS TO STEROID WITH GUT MICROBIOME IN SEVERE ALCOHOLIC HEPATITIS

Jae Hyun Yoon[1], Sung Bum Cho[2], Ga Ram You[2] and Sung Kyu Choi[1], (1)Chonnam National University Hospital, (2)Hwasun Chonnam National University Hospital

Background: Severe alcoholic hepatitis has been well known to have grave prognosis. Despite many attempts, therapeutic agents or interventions has failed to improve survival outcome and only systemic steroid showed modest survival benefit in limited studies. However, with the pandemic of COVID-19, the amount of alcohol consumption demonstrated increasing tendency and alcohol related health problem has been raised as social problem for long time. The association between gut microbiome and alcoholic liver disease such as hepatitis, or cirrhosis has been previously proposed. However, the role of gut microbiome in prediction of prognosis and response to systemic steroid has not been studied. Hence, we investigated the relationship between gut microbiome and patients course in severe alcoholic hepatitis. **Methods:** From March of 2021 to January of 2023, total 36 patients were enrolled and finally 20 patients were eligible for microbiome analysis. Severe alcoholic patients were defined as patients who took alcohol more than 100g/d in previous one month and Maddrey's Discriminant Function Score $\geq$ 32. Patients with combined etiology of acute hepatitis such as viral hepatitis, and drug induced liver injury were all excluded. 16S rRNA amplicon sequencing was used to analyze the gut microbiota in enrolled patients from stool. The primary endpoint was 6-month survival and the definition of response to systemic steroid was Lille model score $>$ 0.45 after 1 week of systemic steroid. **Results:** Among 20 patients, 75.0% patients were male and the mean age was 47.43. The mean MELD score was 22 and Maddrey's discriminant factor was 53.48. We analyzed the averaged taxonomic compositions of the microbiome taxonomic profiling (MTP) set and *Fusobacteriaceae and Bacteroidales* was more prominent in patients who survived and also *Fusobacterium nercogenes* was abundant in patients who survived while *Rothia mucilaginosa* was more abundant in patients who did not survive. Furthermore, we analysized the taxonomic composition of the MTP sets between who underwent systemic steroid treatment. Patients who responded to systemic steroid had more abundant family of *Fusobacteriaceae* and *Bacteroidales*, especially *Fusobacterium necrogenes* and *Bacteroides caccae* while patients who did not respond do systemic steroid had abundant family of *Micrococcales*, especially *Rothia mucilaginosa.* **Conclusion:** The composition of gut microbiome may aid in prediction of prognosis and responsiveness to systemic steroid treatment.

3524-C | BACTERIODES THETAIOTAOMICRON PROTECT AGAINST ALCOHOL-ASSOCIATED LIVER DISEASE THROUGH INTESTINAL ILC3 IN MICE

Mukesh Kumar Sriwastva, Chao Lei, Zhishan Xu, Zhongbin Deng, Irina A. Kirpich and Craig J. McClain, University of Louisville, Louisville, KY

Background: The gut microbiota is a major player in alcoholic liver disease (ALD) progression via the gut-liver axis. *Bacteroides* thetaiotaomicron (*Bt*) is a major component of the intestinal microbiota and contribute to the interactions between the microbiota and the gastrointestinal tract. *Bt* produce multiple capsular polysaccharides (CPS), cell surface components that play roles in modulating host immunity. Group 3 innate lymphoid cells (ILC3s) are innate immune effectors that contribute to intestinal epithelial cells (IEC) homeostasis and produce IL-22, a cytokine can ameliorate alcohol-induced liver injury. Our goal is to test the hypothesis that boat and its-related CPS prevent the ALD development by regulating the crosstalk between IEC and gut immune cells, particularly via IL-22-producing ILC3. **Methods:** WT C57B/6J male mice were subjected to chronic EtOH feeding model. The mice were given *Bt* with and without CPS by oral gavage daily. Liver injury was assessed by plasma ALT and AST. Hepatic fat accumulation was examined by Oil Red O staining and liver triglyceride measurement. Liver inflammation was evaluated by the expression of pro-inflammatory cytokines, and neutrophil infiltration. Expression of genes involved in mucosal barrier and mucin production was evaluated in the IEC. Immune response to Bt treatment was evaluated in the lamina propria immune cells. **Results:** *Bt*-treatment attenuated hepatic steatosis, reduced the levels of ALT and AST and the infiltration of neutrophils. *Bt*-treated mice displayed reduced systemic inflammation, enhanced mucin production and increased IL-22-producing ILC3. Mechanistically, Bt treatment resulted in increased AhR transcription and activity in IEC, which was mediated by CPS. We further demonstrated that *Bt* treatment promote IEC AhR-dependent IL-23 secretion. IEC-derived IL-23 promotes the secretion of IL-22 by ILC3s, which attenuate the ALD via gut-liver axis. **Conclusion:** *Bt* supplementation can maintain intestinal immune homeostasis and ameliorate experimental ALD. *Bt*-related CPS induce IEC AhR activation. AhR/IL-23 axis

3525-C | BINGE ALCOHOL INTAKE IN OBESITY INCREASES SERUM AND HEPATIC ETHYL ARACHIDONATE AND EXACERBATES LIVER INJURY

Kumiko Shirai[1], Hayato Hikita[2], Sadatsugu Sakane[3], Kazuhiro Murai[1], Akira Nishio[4], Kunimaro Furuta[1], Takahiro Kodama[5], Tomohide Tatsumi[5] and Tetsuo Takehara[5], (1)Osaka University, Graduate School of Medicine, (2)Osaka University, Graduate School of Medicine, Osaka, Japan, (3)Osaka National Hospital, San Diego, CA, (4)Osaka University Graduate School of Medicine, Bethesda, MD, (5)Osaka University Graduate School of Medicine

Background: Obesity and alcohol consumption work synergistically to exacerbate liver injury. However, the underlying mechanisms are still unclear. We investigated alcohol-induced changes in lipid metabolism and their influence on liver pathogenesis during alcohol consumption in obesity. **Methods:** 6-week-old C57BL/6J male mice were fed a high-fat diet (HFD) or normal diet (ND) for 8 weeks. On the last day of HFD/ND feeding, mice were given a single dose of ethanol (5 g/kg body weight) or isocaloric maltodextrin by oral gavage. We analyzed a total of four groups: HFD-ethanol, HFD-maltodextrin, ND-ethanol, and ND- maltodextrin. AML12 cells, a cell line of murine hepatocytes, were treated with ethyl arachidonate. **Results:** Nine hours after oral gavage, the HFD-ethanol group showed increased serum ALT level, increased number of TUNEL-positive cells in liver tissue, and increased serum caspase 3/7 activity compared to the other three groups, indicating increased hepatocyte apoptosis. The protein expression levels of PERK in the liver of HDF-ethanol group were increased compared to the other three groups. Metabolomic analysis of liver tissue at three hours after oral gavage showed that the HFD-ethanol group showed a different lipid distribution than both the HFD-maltodextrin and ND-ethanol groups. Ethyl arachidonate was significantly elevated in liver tissue in the HFD-ethanol group compared to the HFD-maltodextrin and ND-ethanol groups, respectively. Serum metabolomic analysis revealed that ethyl arachidonate was significantly elevated in the HFD-ethanol group compared to the HFD-maltodextrin and ND-ethanol groups, respectively. The expression of FAEE carboxylesterase in liver tissue was not significantly different between the HFD-ethanol group and HFD-maltodextrin or ND-ethanol group, suggesting that ethanol intake in obesity increases the synthesis of ethyl arachidonate in serum and its influx into the liver. Ethyl arachidonate treatment decreased viable cell number in AML12 cells in a concentration-dependent manner. Ethyl arachidonate-treated AML12 showed increased expression levels of ER stress-related and oxidative stress-related proteins. **Conclusion:** Ethanol intake in obesity increases ethyl arachidonate in serum and liver tissue, contributing to exacerbation of liver injury.

3526-C | BURDEN OF INVASIVE FUNGAL DISEASE IN PATIENTS WITH SEVERE ALCOHOLIC HEPATITIS IN FRANCE: A 2012-2021 NATIONAL RETROSPECTIVE STUDY

Charlotte Mouliade[1,2], Lucia Parlati[1,2], Samir Bouam[3], Eric Nguyen Khac[4], Marion Corouge[1,2], Philippe Sogni[1,2], Stanislas Pol[1,2], Alexandre Alanio[5,6] and Vincent Mallet[1,2], (1)AP-HP.Centre Université Paris Centre, Groupe Hospitalier Cochin Port Royal, Dmu Cancérologie Et Spécialités Médico-Chirurgicales, Service d'Hépatologie, Paris, France, (2)Université Paris Cité, F-75006, Paris, France, (3)AP-HP.Centre Université De Paris, Groupe Hospitalier Cochin Port Royal, Dmu Prim, Service d'Information Médicale, Paris, France, (4)CHU Amiens-Picardie, Hôpital Sud, Service Hépato-Gastroentérologie, Amiens, France, (5) Institut Pasteur, Université Paris Cité, Centre National De Référence Mycoses Invasives Et Antifongiques, Groupe De Recherche Mycologie Translationnelle, Département De Mycologie, F-75015 Paris, France, (6) Laboratoire De Parasitologie-Mycologie, AP-HP, Hôpital Saint-Louis, F-75010 Paris, France

Background: There is a lack of knowledge on the burden of invasive fungal disease in patients with severe alcoholic hepatitis. **Methods:** Among the 1,438,049 patients diagnosed with alcohol use disorders in French hospitals between 2012 and 2021, we selected individual's with hepatic failure, portal hypertension bleeding, transjugular liver biopsy, or extrahepatic organ failure within 4 weeks following the diagnosis of alcoholic hepatitis. Our primary objective was to investigate the incidence of invasive fungal disease abd to assess the associated risk factors. We examined the 6-month mortality rate as an outcome measure. The main exposure was invasive fungal disease, while bacterial pneumonia served as the control exposure. To assess the strength of the associations, we employed multivariate logistic

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

regression models and Cox proportional hazards models stratified by age categories, severe comorbidities, and deprivation. **Results:** The sample comprised 30,361 patients. Median (interquartile range) age was 55.0 (47.0-62.0) years and 73% were men. Invasive fungal disease [invasive candidosis (n = 269, 0.9%); aspergillosis (n = 105, 0.3%); pneumocystosis (n = 47, 0.2%); cryptococcosis (n = 3, 0.01%)] and bacterial pneumonia were diagnosed in 411 (1.4%) and 8,787 (10.8%) of patients, respectively. Approximately one-fifth (19.7%) of patients were documented with sepsis, and one-fourth progressed to extrahepatic organ failure. The 6-month mortality rate was ~1/4 (26.5%). Multivariate associations comprised younger ages [aOR 0.73 per decade, 95% CI (0.66-0.81) $P < 0.001$]; sepsis [aOR 3.32, (2.63-4.21) $P < 0.001$]; bacterial pneumonia [aOR 3.09 (2.48-3.85) $P < 0.001$]; extrahepatic organ failure [aOR 2.19 (1.72-2.80) $P < 0.001$]; severe comorbidities [aOR 1.14 (1.00-1.30) $P < 0.001$]; and 6-month mortality [aOR 2.98 (2.40-3.71) $P < 0.001$]. The probabilities of 6-month survival (95% CI) were 72.2 (71.7-72.7) and 40.5 (35.9-45.9) percent without and with invasive fungal disease, respectively ($P < 0.001$), and 73.3 (72.8-73.9) and 63.2 (61.7-64.6) percent without and with bacterial pneumonia, respectively ($P < 0.001$). Invasive fungal disease was associated with an independent, increased, instant, risk of 6-month death of ~80% [aHR 1.81 95% CI (1.58-2.08), $P < 0.001$]. Bacterial pneumonia was not associated with mortality. **Conclusion:** Invasive fungal disease, and not bacterial pneumonia, increased the risk of 6-month mortality in patients with severe alcoholic hepatitis in France 2012-2021.

3527-C | CCR4+CXCR5+ PERIPHERAL MYELOID CELLS MAY SERVE AS A CELLULAR BIOMARKER OF ELEVATED INFECTION RISK IN PATIENTS WITH ALCOHOL-ASSOCIATED HEPATITIS

Brett McGettigan[1], Tejasav Sehrawat[2], Shawna Cooper[1], Sheng Cao[3], Vijay Shah[3], Harmeet Malhi[4] and AlcHepNet Clinical Investigators, (1)Mayo Clinic, (2)Mayo Clinic, New Haven, CT, United States, (3)Mayo Clinic Rochester, Rochester, MN, (4)Mayo Clinic, Rochester, Rochester, MN

Background: Individual's with alcohol-associated hepatitis (AH) are at increased risk of developing bacterial infections, which is frequently a cause of mortality. This risk is independent of corticosteroid therapy suggesting that there is inherent immune dysfunction in AH which predisposes to infection. Furthermore, the immune mechanisms driving this risk are not well understood. In this study, we hypothesized that AH causes immune dysfunction within peripheral blood mononuclear cells (PBMC) and that there are cellular biomarkers of infection risk that may aid in risk stratification of AH patients being considered for corticosteroid therapy. **Methods:** We analyzed PBMC from patients enrolled in the AlcHepNet observational study using CyTOF and CITE-seq—a single-cell RNA-seq platform that provides cell-surface protein data. Retrospectively, patients with AH were compared to those that subsequently developed a clinically significant infection within 30 days of collection (AH-inf). These were also compared to healthy controls (HC) and heavy drinkers without AH (HD). The CyTOF analysis included 40 patients, and the CITE-seq analysis included 12 patients (3 per group). Clustering and marker analysis was performed with Cytobank (CITRUS; CyTOF) and Seurat (CITE-seq). **Results:** HC PBMC were predominantly lymphocytes ($78 \pm 2\%$; mean $\pm$ SEM), but there was a progressive loss of total lymphocytes among HD ($49 \pm 9\%$), AH ($52 \pm 9\%$), and AH-inf ($32 \pm 5\%$) patients respectively ($p < 0.01$). This trend was due to a loss of NK cells, cytotoxic T cells, and naïve T cells. Analysis of the myeloid compartment revealed an inverse trend. That is, the average number of myeloid cells per patient in the AH-inf group ($8.0 \times 10^4 \pm 0.9$) was significantly higher than HC ($4.6 \times 10^4 \pm 0.8$, $p = 0.02$) and AH ($5 \times 10^4 \pm 1$, $p = 0.06$) groups. This was due to expansion of a myeloid cluster that was lower in HLA-DR expression ($p < 0.01$) and enriched for CCR4 and CXCR5 (AH-inf $46 \pm 6\%$, AH $24 \pm 6\%$, HC 1.9 ± 0.9, $p < 0.01$). CITE-seq analysis of the AH-inf myeloid cells suggested that it they had an immune-regulatory phenotype compared to controls. **Conclusion:** AH patients at-risk for infection have a PBMC compartment that is dominated by HLA-$DR^{low}CCR4^{+}CXCR5^{+}$ monocytes. Prior published

studies in mice and humans suggest that these molecules are markers of an immune-regulatory phenotype. This population may serve as a novel biomarker of infection risk in patients with AH. Further prospective and functional studies are necessary to confirm this possibility.

Background: Alcohol-associated hepatitis (AH) corresponds to a severe entity with high short-term mortality; however, few studies have been published in patients with moderate or "no-severe" AH. Aim: To characterize patients with moderate AH in a global study, identify characteristics, define prognostic factors and survival at 30, 90, and 180 days.

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Methods: We conducted a retrospective cohort study, which included patients with moderate AH between 2009-2019. Moderate AH was defined as MELD $\leq$ 20 at presentation. We analyze the baseline and clinical characteristics. We performed a multiple logistic regression to assess potential factors associated with mortality in moderate AH.

Results: Five hundred sixty-four patients with moderate AH were included (24 centers, 12 countries). Median age 48 $\pm$ 11.6 years, were 29.2% female, and 46.2.5% Caucasian. 51.7% of the cohort had cirrhosis, and 18.9% underwent liver transplantation. The MELD score on admission was 17 [6-20]. In the entire cohort, 37.7% used corticosteroids during the hospitalization and only 0.61% developed an acute kidney injury. Survival rates at 30, 90, and 180 days were 90.8%, 85.4%, and 81.1%, respectively. The most frequent causes of death were multiple organ failure (30.4%) and infections (11.5%). In the multivariate-adjusted model, we observed that variables independently associated with mortality were infections (OR 6.5, 95%CI: 2.1–24.4; $p < 0.001$) and age (OR 0.9, 95%CI: 0.88–0.99; $p < 0.001$). The mortality at 30, 90 and 180 days was not associated with sex, MELD-Na at admission, history of cirrhosis, or the use of corticosteroids.

Conclusion: Patients with moderate AH have a clinical course with lower mortality compared to severe cases, however, it is up to 20% at 6 months. Infections are associated with higher mortality and are the most important cause of death in these patients.

3529-C | CHARACTERIZING GHRELIN'S ROLE IN DYSREGULATING GLP-1 MEDIATED ORGAN CROSSTALK AND PROMOTING THE DEVELOPMENT OF ALCOHOL-ASSOCIATED FATTY LIVER DISEASE

Sundararajan Mahalingam[1,2], Ramesh Bellamkonda[1,2], Carol A. Casey[1,2], Kusum K. Kharbanda[1,3] and Karuna Rasineni[1,2], (1)University of Nebraska Medical Center, (2)Research Service, Veterans Affairs Nebraska-Western Iowa Health Care System, Omaha, NE, (3) Veterans Affairs Nebraska-Western Iowa Health Care System

Background: Increasing evidence implicates dysregulated organ-organ crosstalk (gut-pancreas-adipose-liver) in the pathogenesis of alcohol-associated fatty liver disease (AFLD). Considering that the organ crosstalk is majorly regulated by peptide hormones,

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

we previously reported that the chronic alcohol-induced increase in circulating ghrelin levels and the consequent reduction in insulin and adiponectin secretion from the pancreas and adipose tissue, respectively, ultimately leads to fat accumulation in the liver. In further elucidating the detrimental role of ghrelin signaling in AFLD pathogenesis, we recently reported that chronic ethanol administration increases the levels of serum glucagon-like peptide-1 (GLP-1, an incretin that increase insulin secretion/insulin sensitivity and hepatic lipid oxidation) in wildtype (WT) rats but not in ghrelin receptor knockout (GHSR KO) rats. However, while the increased serum GLP-1 in WT ethanol-fed rats did not improve insulin sensitivity or hepatic oxidation, GHSR KO ethanol-fed rats showed higher insulin sensitivity and hepatic fatty acid oxidation despite normal GLP-1 levels. This indicated that ghrelin/GHSR likely interferes with GLP-1 receptor (GLP-1R) mediated signaling. This study was conducted to understand the effect of ghrelin/GHSR signaling on GLP-1 function. **Methods:** To achieve our objective, hepatocytes freshly isolated from chow-fed rats were cultured overnight in the presence of 500 μM oleic acid to induce fat accumulation and then incubated for another 4h in serum-free media with or without ghrelin (10 nM) and/or GLP-1 analog, exendin-4 (20 nM). To identify the receptor interactions, hepatocytes transfected with fluorescently labeled GHSR (RFP) and GLP-1R (GFP) plasmids, were treated with ghrelin for 4h followed by examination by Confocal microscopy. In addition, receptor-receptor interactions were examined by immunoprecipitating GLP-1R (by GFP) in the cellular lysates of these cells and subjecting them to further analyses. **Results:** Treatment of oleic-acid-loaded hepatocytes with the GLP-1 analog, extendin-4, reduced triglyceride content; this effect was blocked by ghrelin treatment. Confocal microscopic examination revealed increased co-localization of GHSR and GLP-1R in ghrelin treated transfected hepatocytes. This increased receptor interactions were also confirmed with Western Blot analysis of the GLP-1R immunoprecipitated sample which showed significantly increased intensity of GHSR protein. Proteomic analysis revealed that ghrelin induced loss of signal transduction molecules downstream of GLP-1R. **Conclusion:** These results indicate a fundamental role of the alcohol increased ghrelin in impairing GLP-1-mediated signal transduction in hepatocytes (and likely other organs such as pancreas and adipose) to promote the development of AFLD.

3530-C | CHRONIC ETHANOL FEEDING PREDISPOSES MICE TO CHOLESTATIC LIVER INJURY IN ASSOCIATION WITH INFILTRATED NEUTROPHILS

Shengmin Yan, Ailar Arasteh, Michelle Ma, Zhen Lin and Xiao-Ming Yin, Tulane University School of Medicine, New Orleans, LA

Background: Alcohol-associated hepatitis (AH) is a severe, potentially life-threatening form of alcohol-associated liver disease (ALD) with limited therapeutic options. Existing evidence shows that the presence of biliary dysfunction and cholestasis are common in AH patients and can worsen AH prognosis, but the impact of cholestasis on ALD progression is largely unknown. **Methods:** To examine whether ethanol (EtOH) feeding can promote the susceptibility of mice to cholestasis, we included a subtoxic dose of α-naphthylisothiocyanate (ANIT), a well-studied intrahepatic cholestasis inducer, in an alcohol feeding model, as a second hit. C57BL6 mice were fed with an EtOH diet for 10 days or 4 weeks, followed by ANIT administration 48 hours before sample collection. Bulk RNAseq was performed to determine hepatic transcriptomic changes. Differentially expressed genes (DEGs) were identified by EBSeq analysis. Anti-LY6G antibody was given to deplete neutrophils in mice. DNase I was given to promote the degradation of neutrophil extracellular traps (NETs) in mice. **Results:** We found that ANIT caused limited liver injury in mice fed EtOH for 10 days. In the 4-week group, serum levels of ALT, AST, total bile acids (TBA), and hepatic levels of TBA were significantly increased in mice following EtOH feeding with ANIT, indicating that ANIT synergistically enhanced EtOH-induced liver injury. RNAseq data indicated that either EtOH or ANIT caused transcriptomic changes in the liver compared with pair-fed mice. Intriguingly, in addition to DEGs found in EtOH-fed mice and pair-fed mice with ANIT, we identified 299 genes uniquely altered in EtOH-fed mice with ANIT. Functional analysis of DEGs suggested an enrichment of genes related to inflammatory response. Histologically, the livers of 4-week EtOH-fed mice with ANIT displayed cholangitis, necrosis, and neutrophil infiltration around the periportal area as shown by H&E and LY6G staining. Hepatic Cit-H3 levels, a marker of NETs, were increased in EtOH-fed mice with ANIT as shown by immunostaining and immunoblotting. Either anti-LY6G antibody or DNase I treatment can improve the liver damage in EtOH-fed mice with ANIT. **Conclusion:** Taken together, our results indicate that chronic EtOH feeding predisposes mice to cholestasis and that a subtoxic dose of ANIT pushes EtOH-induced liver damage towards a more severe phenotype with strong inflammation. The evidence suggests a treatment scheme in mice that may be useful for studying connections between cholestasis and AH.

3531-C | COLLABORATIVE CARE FOR ALCOHOL-ASSOCIATED LIVER DISEASE: INTEGRATION OF A BEHAVIORAL HEALTH PROVIDER INTO A HEPATOLOGY CLINIC

Ponni Perumalswami[1,2], Mayank Jayaram[2], Brittany L Cornwell[2], Arpan Arun Patel[3], Suthat Liangpunsakul[4], Benjamin R. Szymanski[2], Bridget Mahoney[2], Heather McCurdy[2], Amanda Marshall[2], David Oslin[5], John F McCarthy[6] and Ira R. Katz[7], (1)University of Michigan, (2)VA Ann Arbor Healthcare System, (3)University of California, Los Angeles, (4)Division of Gastroenterology and Hepatology, Department of Medicine, Indiana University School of Medicine, Indianapolis, IN, (5)VA Philadelphia Medical Center, (6)VA Ann Arbor, (7) Veterans Health Administration

Background: The hepatology visit is an important engagement opportunity for alcohol-related care in patients with alcohol-associated liver disease (ALD). The Veterans Health Administration (VHA) has initiated a pilot program to integrate a behavioral health provider (BHP) into liver clinics at designated facilities. Quality improvement analyses will assess its impact on alcohol use disorder (AUD) treatment. **Methods:** Hepatologists at 3 VHA facilities developed a clinical workflow to refer all patients with ALD and hazardous alcohol use to a BHP co-located in a hepatology clinic. Patient data were obtained from chart review and the VHA Corporate Data Warehouse. Completing more than a single encounter with the BHP was considered engaged with the BHP. We used Kruskal-Wallis and Fisher's Exact tests to assess 1) baseline differences between referred patients by engagement with the BHP and 2) associations between engagement with the BHP and receipt of evidence-based AUD treatments (pharmacotherapy, psychotherapy) after referral. Analyses examined all ALD patients referred to a BHP at one hepatology clinic from 12//1/2022 through 4/1/2023. **Results:** 22 patients were referred to the BHP; 11 successfully engaged, 3 could not be reached and 8 declined to participate. Common patient-reported reasons for declining BHP visits were believing they could quit on their own (36.4%) and having quit alcohol use by the time the BHP attempted to engage with them (27.3%). Among all referred patients, the mean age was 62.5 ± 0.5 years, 90.9% were male, 72.7% White, 18.2% Black, and 45.5% not married. Additionally, in all referred patients 22.7% had unstable housing and 95.5% had a prior mental health diagnosis (Table 1). Out of all patients referred, 18.2% had concomitant non-alcohol fatty liver disease, 4.5% had hepatitis C virus infection, and 54.5% had a diagnosis of cirrhosis. There were no significant differences by engagement with the BHP. During the pilot period, patients who were engaged with the BHP had more AUD psychotherapy visits (4.7 vs. 0.3, $p < 0.01$) and trended toward higher AUD pharmacotherapy prescriptions (45.5% vs. 18.2%, $p = 0.36$) after referral. **Conclusion:** Early findings from the pilot program suggest that having a BHP co-located in a hepatology clinic resulted in a higher number of AUD psychotherapy visits for engaged ALD patients. Integrating BHPs in hepatology clinic may improve AUD treatment uptake.

3532-C | DEMOGRAPHICS AND UNDERLYING LIVER DISEASE AS PREDICTORS IN ALCOHOLIC HEPATITIS

Kevin Yang, Naren Srinath Nallapeta, Nariman Hossein-Javaheri, Alexander Mark Carlson, Brian Quigley and Thomas Mahl, University at Buffalo

Background: Alcoholic hepatitis confers high short-term mortality and affects diverse groups of patients regardless of age, sex, race, and co-morbidities. We aimed to examine underlying demographics and liver disease including cirrhosis, hepatitis C and B (HCV, HBV), and quantity of alcohol consumed as predictors of outcomes in this population. **Methods:** This retrospective study included all patients admitted for alcoholic hepatitis at a large urban hospital from 2020 to 2022. A subgroup for severe alcoholic hepatitis (SAH) defined as Maddrey's discriminant function > 32 was also analyzed. Outcomes recorded during hospitalization included hepatic encephalopathy (HE), gastrointestinal bleeding (GIB), ascites, acute kidney injury (AKI), hepatorenal syndrome (HRS), bacterial infections, readmissions, length of stay (LOS), and mortality at 28 and 90 days. We conducted a series of logistic regression analyses using a backward step procedure to identify significant predictors of various outcomes. **Results:** 425 patients were included in the main analysis. Average age was 47.97 (SD 11.95), 68% male and 32% female, 70.8% white, 14.8% black, and 14.4% others such as Hispanics and Asians. On admission, 56.7% had a documented history of cirrhosis, 13.6% had a history of HCV, and 2.4% had a history of HBV. Patients in this study consumed 210.25 grams (SD 165.97) of alcohol or approximately 15 standard drinks per day on average. The subgroup receiving corticosteroid therapy for SAH included 126 patients. In the analyses examining mortality as the outcome, history of cirrhosis was the only significant predictor (28-day: OR = 10.88, 95% CI = 3.81/.05, 90-day: OR = 7.98, 95% CI = 3.53/18.04). History of cirrhosis was also a significant predictor of HE, GIB, AKI, HRS, and infection. Increased age was a predictor for AKI, ascites, and longer LOS. Female sex was significantly associated with higher rates of bacterial infection. Black race was significantly associated with lower rates of HE, GIB, and infection. Quantity of alcohol consumed per day was associated with higher rates of readmission. History of HCV and HBV did not achieve statistical significance with regards to any outcomes, including in the corticosteroid therapy group. **Conclusion:** In this retrospective study, history of cirrhosis was clearly the most influential predictor of mortality and outcomes in alcoholic hepatitis. History of HCV was irrelevant, although there was no differentiation between active and treated HCV. Furthermore, older age, female sex, and non-black race were all associated with higher rates of certain complications.

	Encephalopathy	GI Bleeding	Acute Kidney Injury	Hepatorenal Syndrome	Ascites

f 3533-C | DETERMINANTS OF RISKS ASSOCIATED WITH ALCOHOL-ASSOCIATED HEPATITIS: A COMPREHENSIVE ANALYSIS OF THE ALL OF US COHORT

Chenxi Xiong[1], Xiang Liu[1], Wanzhu Tu[1], Suthat Liangpunsakul[2,3] and Jing Su[1], (1)Department of Biostatistics and Health Data, Indiana University School of Medicine, Indianapolis, in, (2) Division of Gastroenterology and Hepatology, Department of Medicine, Indiana University School of Medicine, Indianapolis, IN, (3)Roudebush Veterans Administration Medical Center, Indianapolis, in

Background: Alcohol-associated hepatitis (AH) is a severe adverse health outcome associated with

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

alcohol use disorder (AUD). Social determinants of health (SDoH), such as healthcare resources and incomes, affect health outcomes and risks. However, their roles in the association with the risk for AH are elusive. The NIH-sponsored All of Us (AoU) program was initiated to collect a wide range of data to drive discoveries that may identify risks and improve overall health. The data provide comprehensive real-world information of US population, including under-represented minorities. We aimed to determine the SDoH and the risk for AH by performing comprehensive analyses of the AoU data. **Methods**: The study cohort was selected from the AoU population using the latest data (as of 04/18/2023 with 413,376 participants). We included participants who have baseline survey data and longitudinal electronic medical record (EMR) information. Baseline demographics, co-morbidities, health insurance status, AUDIT-C score (positive score, defined as $>=5$ for men and $>=4$ for women, was considered as AUD), and the use of AUD-related medications (disulfiram, naltrexone, or acamprosate) were queried. Subjects with history of AH (using ICD9: 571.1; ICD10: K70.1, K70.10, and K70.11) prior to the enrollment into AoU were excluded in the study cohort. The primary outcome was the diagnosis of AH during the follow up. Participants were followed until the diagnosis of AH or the study closure date of July 1, 2022. A Cox proportional hazard model is used to evaluate SDoH and other factors associated with the development of AH. **Results**: A total of 208,496 with EMR and survey data comprised the study cohort (median age 58 y, 62% women, 43% from minority groups with 18% Hispanics). At enrollment, 22.5% had positive AUDIT-C score, 28% on AUD-related medications, and 93% with health insurance (36% employer-based, 21% Medicare, 17% Medicaid, and 19% from other providers). During the median follow-up of 1,095 days, 213 participants were diagnosed with AH. Using the Cox proportional hazard model, the following factors were associated with the development of AH during follow up: On Medicaid (aHR:3.6, 95%CI: 2.4-5.5, compared to employer-based) or no health insurance (aHR:2.4, 95%CI:1.5 – 3.7, compared to employer-based), positive AUDIT-C score at baseline (aHR:11.63, 95%CI:8.5-16), and age (aHR:1.69, 95%CI:0.97-2.94 for 45-65 years old compared to the 18-35 age group). **Conclusion**: Our results from the real-world AoU data suggested the health insurance status, (notably those with Medicaid or without insurance) and positive AUDIT-C score were independent risk factors associated with the development of AH. AUDIT-C administration and early intervention for those with positive score should be implemented to prevent AH development.

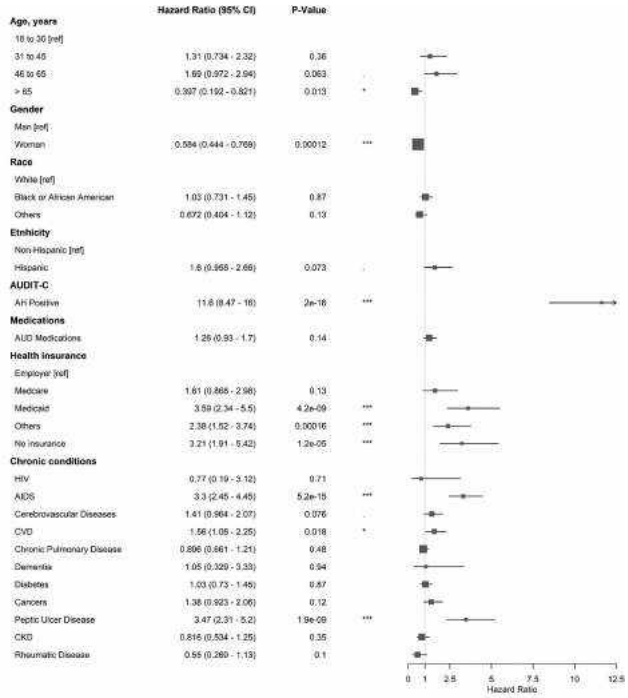

Fig 1: Adjusted hazard ratios with 95% CI and P-values for factors associated with the development of AH

3534-C | DEVELOPING AND VALIDATING NOVEL CODING ALGORITHMS TO IMPROVE CASE IDENTIFICATION ACCURACY FOR ALCOHOL- AND NON-ALCOHOL-RELATED CIRRHOSIS IN ADMINISTRATIVE DATABASES.

Liam Andrew Swain[1], Jenny Godley[1], Juan G. Abraldes[2], Mayur Brahmania[3] and Abdel-Aziz Shaheen[3], (1)University of Calgary, (2)University of Alberta, AB, Canada, (3)Cumming School of Medicine, University of Calgary, Calgary, AB, Canada

Background: Alcohol- (AC) and non-alcohol-related cirrhosis (NAC) epidemiology studies are limited by the accuracy of available administrative case definitions. In this study, we examined and compared the performance of previously used and newly developed case definitions in identifying AC and NAC hospitalizations in Calgary, Canada. **Methods:** We randomly selected 700 hospitalizations from the Discharge Abstract Database using International Classification of Diseases 10th revision (ICD-10) codes for AC, NAC, alcohol use disorder (AUD), and decompensated cirrhosis-related conditions (DC) from 2008-22. For AC case

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

identification, we evaluated the standard approach using the AC code alone, as well as 2 novel AC case definitions that selected admissions with, (i) an AUD and DC code together, or (ii) using either the AC code alone, or both an AUD and DC code together. For NAC case identification, we evaluated the standard approach using a NAC code alone, and 2 novel case definitions that selected admissions with, (i) a NAC code alone, excluding AC, alcohol-related hepatitis (AH), and AUD codes (NAC1), or (ii) both a NAC and DC code together, excluding AC, AH, and AUD codes (NAC2). Using electronic medical record (EMR) review as the reference standard, we calculated case definition positive predictive value (PPV), sensitivity, and area under the receiver operating characteristic curve (AUROC). We used AUROC tests of equality to identify statistical differences between case definitions. **Results:** Of the 700 hospitalizations, 671 had available EMRs (median age 60; 62% male), and 252 had AC, 195 NAC, 54 AH, and 263 AUD. Table 1 shows case definition accuracy estimates and ICD-10 codes used. The novel AC case definition selecting admissions with either the AC code alone or DC and AUD codes together had a PPV of 93% and was more sensitive (76% vs 44-63%) and accurate (AUROC 0.86 vs 0.71-0.81, $p < 0.001$) than the other novel and standard AC case definitions. The novel NAC1 case definition had similar PPV (84% vs 84%) but better sensitivity (57% vs 52%) and AUROC (0.76 vs 0.74, $p = 0.006$) compared to novel NAC2 case definition. The novel NAC1 case definition had better PPV (84% vs 79%) but similar sensitivity (57% vs 57%) and AUROC (0.76 vs 0.76, $p = 0.14$) compared to the standard approach using a NAC code alone (not excluding AC/AH/AUD codes). **Conclusion:** Newly developed administrative case definitions show enhanced accuracy for identifying AC and NAC hospitalizations. Future studies evaluating our proposed algorithms in different databases are warranted.

Table 1. Accuracy of previously used (known) and newly developed (novel) AC and NAC administrative case definitions for hospitalization identification.

Case definitions:	Sensitivity (95% CI)	PPV (95% CI)	AUROC (95% CI)
AC case definitions			
• Known: AC ICD-10 code alone	63.1% (56.8-69.1)	95.2% (90.8-97.9)	0.81 (0.78-0.84)
• Novel: AUD and DC ICD-10 codes together	44.4% (38.2-50.8)	91.1% (84.6-95.5)	0.71 (0.68-0.74)
• Novel: AC ICD-10 code alone or ICD-10 codes for DC and AUD together	76.2% (70.4-81.3)	92.8% (88.3-95.9)	0.86 (0.84-0.89)
NAC case definitions:			
• Known: NAC ICD-10 code alone	57.4% (50.2-64.5)	78.9% (71.2-85.3)	0.76 (0.72-0.79)
• Novel NAC1: NAC ICD-10 code alone (no AC/AH/AUD codes)	56.9% (49.7-64.0)	83.5% (76.0-89.3)	0.76 (0.73-0.80)
• Novel NAC2: NAC and DC ICD-10 codes together (no AC/AH/AUD codes)	52.3% (45.1-59.5)	83.6% (75.8-89.7)	0.74 (0.70-0.78)

3535-C | DEVELOPMENT OF ADVANCED LIVER DISEASE IN PATIENTS WITH RADIOLOGICALLY PROVEN ALCOHOL ASSOCIATED FATTY LIVER DISEASE

Jibril F. Kedir[1], Rachael Mahle[2], Adedayo Okanlawon[1], Russell P. Goodman[1], Esperance Schaefer[1], Jay Luther[3] and Wei Zhang[4], (1)Massachusetts General Hospital, (2)MGH, (3)Massachusetts General Hospital, Anodover, MA, (4)Massachusetts General Hospital, Brookline, MA

Background: Alcohol associated liver disease (ALD) is linked with significant mortality and is the number one indication for liver transplantation. Detecting ALD at an early stage is challenging, and most cases are diagnosed late. We aim to study whether radiological liver imaging can aid in early detection and improve patient outcomes in ALD. **Methods:** In this single-center retrospective study, we used ICD, 9th and 10th revision, to establish a cohort of 12,527 patients with alcohol use disorder (AUD) from the Massachusetts General Brigham (MGB) system between January 1979 and December 2022. We utilized ICD coding, liver imaging studies, and a keyword-based text mining algorithm to extract critical clinical features and classify liver images into three subgroups: normal, steatosis, or cirrhosis. We then applied cox regression models to estimate hazard ratios (HR) with time to ALD as the dependent variable and examined the influence of various comorbidity measures on this outcome. **Results:** In our cohort,

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

66.2% of patients were men, 79.4% of patients were white, the median age was 60 years, and median follow-up was 6.6 years. Among these patients 8,873 (70.8%) had normal findings, 2,334 (18.6%) showed features of steatosis, and 1,220 (9.7%) had radiologic cirrhosis on their first image. In our cox regression model, fatty liver on first liver imaging was associated with increased rate of ALD (HR, 3.63; 95% CI, 3.1-4.1; $P < 0.001$). Among patients with AUD, male gender, hypertension, chronic kidney disease (CKD) and diabetes were also associated with increased rate of ALD, while hyperlipemia was associated with 46% decreased risk (HR, 0.54; 95% CI, 0.5-0.6; $P < 0.001$). **Conclusion:** The findings of this study suggest image evidence of fatty liver disease in AUD patients can serve as early detection for progression of advanced liver disease. Appropriate integration of radiological data and early intervention in this population are likely to optimize patient outcomes.

	ALD events (n = 943)	sHR (95% CI)	P-value

3536-C | DIAMMONIUM GLYCYRRHIZINATE PROTECTS AGAINST ETHANOL INDUCED LIVER INJURY VIA INHIBITING DDX5/STAT1 PATHWAY

Xiaomei Wang, Hongqin Xu and Xiuzhu Gao, The First Hospital of Jilin University

Background: Alcoholic liver disease (ALD) is a serious worldwide health problem. Diammonium glycyrrhizinate (DG) is a medicinal form of glycyrrhizic acid (GA) extracted from licorice roots with anti-inflammatory properties. Some of its beneficial effects in vivo are reported to involve viral hepatitis. Here, we evaluated the potential and the possible mechanism of DG protecting against ethanol-induced liver injury in vitro and in vivo. **Methods:** We investigated the effects of DG on liver lipid metabolism, oxidative stress, and inflammation, induced by chronic plus binge alcohol feeding in mice in vivo by using biochemical assays, qPCR, and histology analyses. Analyses of RNAseq expression were conducted to explore potential targets exploited by DG to protect against ALD. In vitro, mouse cell line, AML12 cells were treated with DG (50μM) prior to ethanol (400 mM) for 24 h. Cell viability was analyzed by CCK8, and protein expressions were assessed by Western blot. **Results:** Chronic treatment with DG alleviated the chronic and binge alcohol-induced liver injury and inflammation, as well as the lipid deposition in hepatocytes. It also beneficially influenced hepatic metabolic and oxidative stress dysregulation. Mice liver tissue RNAseq expression indicated that DEAD-box protein 5 (DDX5) may be a potential target exploited by DG to protect against ALD. The expression of DDX5 was significantly reduced in the ethanol-treated group, following the downregulation of signal transducer and activator of transcription 1 (STAT1), and DG increased the expression of DDX5 and STAT1. These protective effects of DG against alcohol-induced liver injury were attenuated in DDX5 deficient cell line, indicating the beneficial effects of DG in ethanol-induced liver injury by up-regulating the DDX5/STAT1 pathway. **Conclusion:** DG prevented ethanol-induced hepatic injury associated with oxidative stress, inflammation, and steatosis via up-regulating the DDX5/STAT1 pathway.

3537-C | DIFFERENCES IN THE CLINICAL PRESENTATION OF ACUTE ALCOHOLIC HEPATITIS BETWEEN CAUCASIANS AND AFRICAN AMERICANS

Yiwei Hang[1], Marcus Allen Healey[1], Geetha Ramalingam[1], Ekaterina Smirnova[2], Amon Asgharpour[3], Vaishali Patel[4], Hannah Lee[4], Velimir A. Luketic[2], Scott C. Matherly[4], Mohammad S. Siddiqui[4], Joel P. Wedd[4], Arun Sanyal[5] and Richard K. Sterling[4], (1)VCU Health, (2)Virginia Commonwealth University, Richmond, VA, (3)Virginia Commonwealth University, (4)Virginia Commonwealth University Health System, (5)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Acute alcoholic hepatitis (AAH) incurs high morbidity and mortality. While differences in survival between African Americans (AA) and Caucasians have been reported, the use of steroids and disease severity upon admission are unknown. To address this gap, we aim to investigate the difference in clinical presentation and outcomes between AAs and Caucasians hospitalized for AAH to better understand the existing health disparities in AAH and help inform guidelines related to disease management. **Methods:**

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

In this retrospective analysis, patients admitted for AAH from 2012-2019 were identified and recorded in RED-Cap. Those with repeated admissions were excluded. Chart review was performed to collect data on demographics, disease characteristics, and clinical course. The diagnosis of AAH was verified using the National Institute on Alcohol Abuse and Alcoholism criteria. The primary outcomes were disease severity based on Model for End-Stage Liver Disease (MELD) and discriminant function (DF) at time of admission, the use of steroids, and 30-day (30-d) survival between Caucasians and AAs. **Results:** In total, 550 Caucasian and 245 AA patients were included in the analysis (Table 1). AAs were 5.2 years older on average. Liver markers such as aspartate aminotransferase (AST), alanine aminotransferase (ALT), albumin and international normalized ratio (INR) did not differ, but total bilirubin (TB) was lower in the AA group. Co-morbid conditions were similar except for the higher prevalence of hepatic C virus (HCV) in AA patients. While the MELD score did not vary between the two cohorts, the DF was significantly higher in Caucasian patients. Similarly, Caucasians were more likely to receive steroids than AA patients. The 30-d survival and days of hospitalization did not differ significantly between the two groups. In the multivariable model, increased weight ($p = 0.03$), higher MELD ($p < 0.001$), steroid use ($p = 0.029$), and presence of HCV antibody ($p = 0.04$) were significant predictors of 30-day survival while race was not ($p = 0.7$). **Conclusion:** AAH remains an important cause of liver-related mortality in the United States. In our urban cohort, AA patients were older, presented with less severe AAH by DF with similar MELD, and were less likely to receive steroids. However, there was no difference in survival and length of stay. This highlights the disparity in AAH by race and a need for specific treatment guidelines to manage future patient care in this population.

3538-C | DIFFERENTIAL ORIGINS AND FUNCTIONS OF CD163+ AND CD163- KUPFFER CELLS IN A MOUSE MODEL OF ALCOHOL-ASSOCIATED LIVER DISEASE

Sheetalnath Rooge[1,2], Isabel Aranzazu Pulido Ruiz[2], Kyo Sasaki[3], Kyle Yuquimpo[4], Heer Mehta[4], Ann Wozniak[2], Irina Tikhanovich[2], Sumedha Gunewardena[4] and Steven A. Weinman[5], (1)University of Kansas Medical Center, Kansas City, KS, (2)University of Kansas Medical Center, (3)Kawasaki Medical School, (4)University Kansas Medical Center, (5)University of Kansas Medical Center, Mission Hills, KS

Background: The liver macrophage pool consists of both embryonic-derived Kupffer Cells (eKCs) and infiltrating monocyte/macrophages (IMs). During disease states, these populations are dynamic with some eKCs replaced by monocyte-derived mKCs. We previously showed that replacement of CD163+ eKCs with newly formed CD163- mKCs leads to liver failure suggesting that eKCs are required for maintenance of liver function. The **Aim** of this study was to identify the origin, stability and function of KC subsets in ALD. **Methods:** C57BL/6J mice were fed a high fat (WD) diet with ad-libitum 10%-20% alcohol in the drinking water for 16 to 52 weeks (WDA model). Cx3Cr1-ER-Cre x Rosa26-mT/mG lineage tracer mice were used to evaluate the origin of KC subsets. scRNAseq was performed on total liver CD45+ cells isolated from the WDA mice model. Co-culture experiments were performed to evaluate the hepatoprotective properties of KCs. **Results:** Abundance of CD163+ KCs declined from 90% to 75% to 5% of total KCs at 0, 16 and 52 weeks of WDA diet, respectively. Tamoxifen injection of Cx3Cr1-ER-mT/mG tracer mice resulted in labeling of IMs and CD163- KCs at 1 week, but CD163+ cells remained unlabeled. At 4 weeks after injection, there was still no appearance of label in the CD163+ KCs demonstrating that they did not arise from CD163- KCs. scRNAseq with RNA velocity analysis showed that KC and IM cell identity was stable in chow-fed mice. In both WD and WDA mice, cell identity was in flux and IMs were direct precursors of CD163- KCs. In the absence of alcohol (WD only), CD163- KCs further transitioned to form CD163+ KCs, but in the presence of alcohol this transition was slowed suggesting a block of new KC maturation. Co-culture of isolated hepatocytes with CD163+ KCs preserved hepatocyte albumin production while CD163- KCs lacked this hepatoprotective effect. Gene set enrichment analysis showed that CD163+ KCs most resembled macrophages associated with hepatoprotection and fibrosis resolution while CD163- KCs most resembled lipid-associated macrophages (LAMs). **Conclusion:** CD163 expression identifies a KC subset that is largely embryonic in origin, is antifibrotic, and is critical for support of liver function during alcohol exposure. With increasing time of alcohol exposure, these KCs are progressively replaced by monocyte-derived CD163- KCs that are less hepatoprotective. We propose that loss of protective KCs may contribute to alcohol induced ACLF, as occurs in alcoholic hepatitis.

3539-C | Drp1 REGULATES GSDMD MEDIATED MITOCHONDRIAL DYSFUNCTION AND HEPATOCYTE PYROPTOSIS IN AH

Yan-Di Xie[1], Zilong Wang[2], Guangjun Song[1], Hui Ma[1] and Bo Feng[1], (1)Peking University People's Hospital, (2)Peking University People's Hospital, Peking University Hepatology Institute, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Diseases, Beijing International Cooperation Base for Science and Technology on NAFLD Diagnosis

Background: Mechanisms and consequences of Gasdermin D (GSDMD) activation in alcoholic hepatitis (AH) are unclear. In the present work, we investigated whether dynamin-related protein 1 (Drp1) regulates GSDMD mediated mitochondrial dysfunction and hepatocyte pyroptosis in AH. **Methods:** Liver damage in AH mice were assessed by HE staining, serum levels of

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

AST, ALT, TC and TG. The levels of IL-1b, IL-18, inflammasome associated proteins and hepatocyte death were allowed for determination of pyroptosis. Mitochondrial dysfunction was tested via mitochondrial DNA (mtDNA) level, ROS generation, mitochondrial membrane potential, ATP content, mitochondrial function related protein levels and morphological changes of mitochondria. **Results:** AH induced GSDMD activation with increased protein expression of GSDMD-N, NLRP3 and Caspase-11 in liver tissues. Downregulation of GSDMD alleviated alcohol induced hepatocyte pyroptosis. Alcohol also causes mitochondrial dysfunction of hepatocytes in AH, which was ameliorated by GSDMD inhibition. Moreover, improvement of mitochondrial function suppressed alcohol induced hepatocytes pyroptosis. Further, GSDMD or Drp1 knockdown improved AH induced liver injury accompanied with decreased hepatocyte pyroptosis. **Conclusion:** Drp1 regulates GSDMD mediated mitochondrial dysfunction and hepatocyte pyroptosis during AH induced inflammation and liver injury. These findings may pave the way to develop new therapeutic treatment for AH.

3540-C | DYSREGULATED CYCLIC NUCLEOTIDE METABOLISM IN ALCOHOL ASSOCIATED STEATOHEPATITIS: IMPLICATIONS FOR NOVEL TARGETED THERAPIES

Diego Montoya-Durango[1], Mary Nancy Walter[1], Walter Rodriguez-Alvarez[1], Yali Wang[1], Claudio Maldonado[1], Shirish Barve[1], Craig J. McClain[1,2] and Leila Gobejishvili[1], (1)University of Louisville, Louisville, KY, (2)Robley Rex VAMC

Background: Cyclic nucleotides are second messengers, which play significant roles in numerous biological processes including cell proliferation, differentiation, and inflammatory response. Previous work has shown that cAMP and cGMP signaling regulates various pathways in liver cells, including Kupffer cells, hepatocytes and hepatic sinusoids. Importantly, it has been shown that cAMP levels and enzymes involved in cAMP signaling are affected by alcohol. Although the role of cyclic nucleotide signaling is strongly implicated in several pathological pathways in liver diseases, the studies detailing the changes in cyclic nucleotide metabolism in ALD are lacking. **Methods:** Male C57B/6 mice were used in an intragastric model of alcohol-associated steatohepatitis (ASH) for 8 weeks. Liver transcriptome analysis was performed to examine the effect of alcohol on regulators of cyclic AMP and GMP levels and signaling. cAMP and cGMP levels were measured in mouse as well as in human healthy donor and alcohol associated hepatitis (AH) patient livers. Plasma ALT, AST, histologic grading as well as protein and real time qPCR analyses were performed to evaluate steatosis, liver inflammation and injury. **Results:** Our results show significant changes in several phosphodiesterases (PDE), with specificity to degrade cAMP (Pde4a, Pde4d, Pde8a) or cGMP (Pde5a and Pde9a), as well as dual specificity PDEs (Pde1a, Pde3b, Pde10a) in ASH mouse livers. Adenylyl cyclases (AC) 7 and 9, which are responsible for cAMP generation, were also affected by alcohol. Importantly, adenosine receptor 1, which has been implicated in the pathogenesis of liver diseases, was significantly increased by alcohol. Adrenoceptors 1 and 3 (Adrb), which couple with stimulatory G protein to regulate cAMP and cGMP signaling, were significantly decreased. Additionally, beta arrestin 2, which interacts with cAMP specific PDE4D to desensitize G protein coupled receptor to generate cAMP, was significantly increased by alcohol. Notably, we observed that cAMP levels are much higher than cGMP in the livers of humans and mice; however, alcohol affected them differently. Specifically, cGMP levels were higher in AH patients and ASH mice livers compared to controls. As expected, these changes in liver cyclic nucleotide signaling were associated with increased inflammation, steatosis, apoptosis and fibrogenesis. **Conclusion:** These data strongly implicate dysregulated cAMP and cGMP signaling in pathogenesis of ASH. Ongoing studies to identify changes of these regulators in a cell-specific manner could lead to the development of novel targeted therapies for ASH.

3541-C | EARLY LIVER TRANSPLANT FOR SEVERE ALCOHOL-ASSOCIATED HEPATITIS: HOW DOES REFERRING PROVIDER UNDERSTANDING OF MANDATED SOBRIETY IMPACT REFERRAL FOR EVALUATION?

Elizabeth Stonesifer and Eugene Lengerich, Penn State

Background: Severe alcohol-associated hepatitis (SAH) has high morbidity and mortality. Historically, six months of sobriety was required prior to liver transplantation (LT), however most SAH patients do not meet this criterion. Clinical practice guidelines now suggest LT may be offered to highly select individual's with SAH with shorter time-periods of sobriety. The impact of this change in practice on real-life referral patterns for LT remains unknown. For these reasons, we aimed to assess referring providers' knowledge, attitudes, and practices regarding LT evaluation referral of patients with SAH and less than six months of sobriety. **Methods:** We conducted a survey of community gastroenterology and primary care providers who routinely refer patients to our tertiary care academic LT center. Surveys were sent to 10,604 providers with 31 complete responses. Respondents were diverse (see Figure 1). Transplant Hepatologists at academic LT centers served as the control group. **Results:** Relative to referring providers, Transplant Hepatologists agreed 68.5% more with statements indicating knowledge of current guidelines regarding appropriate referral for LT evaluation for SAH ($p < 0.001$). They agreed 32.3% less with statements stating SAH patients should not be evaluated for LT and that SAH patients are less worthy of LT evaluation than patients with other forms of liver disease ($p < 0.001$). They agreed 70.4% with referring a patient with SAH for liver transplant evaluation ($p < 0.001$). Mean survey responses are presented in Figure 1. **Conclusion:** Community gastroenterologist and primary care providers have low understanding of current clinical practice guidelines for appropriate referral of patients with SAH for LT evaluation. There is a clear, unmet need to provide outreach and education about clinical practice guidelines for SAH, including when it is appropriate for a patient to be referred for early LT evaluation. While future study is needed to validate these findings with a larger, more geographically diverse sample, this work nonetheless remains an important as we look to improve access to life-saving LT for those most in need.

3542-C | EFFECT OF OMEGA 5 FATTY ACID AS AN ADYUVANT TREATMENT TO PREDNISONE IN PATIENTS WITH SEVERE ALCOHOLIC HEPATITIS

Jacqueline Cordova Gallardo[1], Abigail Hernández-Barragan[2], Diana Munguía-Ramos[1], Froylan David Martinez-Sanchez[1], Marisela Hernández-Santillan[2], Moises Martínez-Castillo[2], Erika Karina Tenorio-Aguirre[1], Paola Vazquez-Cardenas[1], Daniel Santana-Vargas[2], Antonio Lopez-Gomez[1] and Gabriela Gutierrez-Reyes[2], (1)Hospital General Manuel Gea González, (2)Universidad Nacional Autónoma De México (UNAM)

Background: In Mexico, alcoholic liver disease is the fourth cause of mortality. Patients with severe alcoholic hepatitis have a high mortality at 28 days and 6 months, patients receiving standard therapy with predniso(lo)ne that are non responders (Lille > 0.45) have a survival of 53.3 ± 5.1 % to 28 days. At present, there is not a completely effective treatment for non responders patients, with a high mortality, so it is necessary to look for other therapeutic strategies. The omega-5 fatty acid (punicic acid) has been considered a powerful antioxidant, it is an agonist of PPAR gamma, has been shown to reduce lipid peroxidation, and restore levels of antioxidant enzymes such as superoxide dismutase (SOD), catalase and glutathione peroxidase. It has also been shown to inhibit the expression of proinflammatory cytokines (such as IL6, IL8, IL23, IL12 and TNFalpha) through PPAR and modulation delta. The aim of this study is to evaluate the effect of Omega 5 fatty acid on survival at 28 days at 6 months. **Methods:** A Randomized Double-blind clinical trial, which included 20 patients for standard treatment (Group A: Prednisone 40 mg a day + Placebo (manufactured by the same laboratory with the same presentation and physical appearance) and 20 patients for combined treatment (Group B: Prednisone 40 mg per day + nanoemulsifiyied pomegranate seed oil rich in Omega 5 fatty acid (2 capsules of 0.64g each / day). Both groups receive 28 days of treatment. **Results:** Both

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

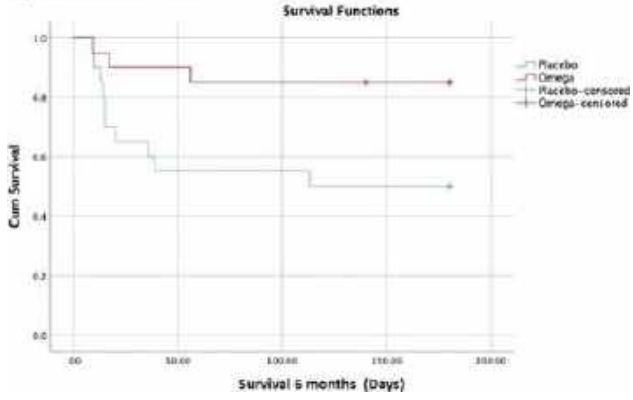
groups had similar characteristics with no difference among severity of the disease, neither alcohol consumption. Mean age was 44.2 ± 10.15 years old, the patients included were mainly men 85% (group A) and 90% (group B). The mean Mdf score was 69.51 ± 22.04 (group A) and 62.62 ± 25.14 (group B). Body mass index 27.3 ± 4.68 (group A) and 27.24 ± 4.91 (group B), alcohol consumption in grams per day were 447.58 ± 304.33 (group A) and 423.2 ± 232.78 (group B). Years of alcohol consumption were 16.49 ± 12.41(group A) and 15.08 ± 13.33 (group B). Both groups exert similar steroids response with no difference in Lille score, mean Lille score group A 0.46 ± 0.33 and group B 0.36 ± 0.28; with 10 responders in group A and 12 responders in group B. (p 0.385) For the survival rate, group B had a reduced mortality at 28-days and 6 months in Kapplan-Meier plot (p = 0.046). After adjusting by confounding factors, there was no difference in survival at day 28 between both groups (HR = 0.147, IC 95% (0.018-1.221). However, at 6-months group B had a better survival than group A (p = 0.025) with an HR = 0.243 (0.67-0.887). (Figure 1) **Conclusion:** The addition of omega 5 to prednisone treatment in patients with severe alcoholic hepatitis had a beneficial effect, increasing survival at 6 months despite the lack of reponse to prednisone.

Figure 1. Survival at 6 months



Disclosures: The following people have nothing to disclose: Jacqueline Cordova Gallardo, Abigail Hernández-Barragan, Diana Munguía-Ramos, Froylan David Martinez-Sanchez, Marisela Hernández-Santillan, Moises Martínez-Castillo, Erika Karina Tenorio-Aguirre, Paola Vazquez-Cardenas, Daniel Santana-Vargas, Antonio Lopez-Gomez, Gabriela Gutierrez-Reyes

3543-C | EMERGENCY SERVICES UTILIZATION BY PATIENTS WITH ALCOHOL-ASSOCIATED HEPATITIS: AN ANALYSIS OF NATIONAL TRENDS

Shreya Sengupta[1], Akhil Anand[1], Rocio Lopez[2], Jeremy Weleff[3], Philip Wang[1], Annette Bellar[1], Amy Attaway[1], Nicole M. Welch[1] and Srinivasan Dasarathy[4],

(1)Cleveland Clinic, (2)University of Colorado, (3)Yale University, (4)Cleveland Clinic, Cleveland, OH, United States

Background: Alcohol-associated hepatitis (AH) is the most severe form of alcohol-associated liver disease (ALD) and accounts for 0.83% of all hospital admissions in the United States. Published data on national trends in AH have focused on inpatient characteristics and outcomes, even though 80% of patients are admitted through the ED. Utilization trends and characteristics of patients presenting to the ED with AH are not known. To better understand the burden of ALD in the US, we evaluated the rates, characteristics, and outcomes of ED visits for AH in adults using data from the Nationwide Emergency Department Sample (NEDS). **Methods:** ED visits for adults aged 18 years or older were analyzed using discharge data from NEDS between January 1, 2016, and December 31, 2019. If the principal diagnosis during the ED visit was AH, this visit was classified as primary AH. Secondary AH was defined if AH was co-listed with a principal diagnosis. Numbers of patients evaluated, severity of disease, complications of liver disease, and discharge disposition were analyzed. Crude and adjusted rates were analyzed, and temporal trends were evaluated using logistic regression with orthogonal polynomial contrasts for each year. **Results:** From 2016-2019, there were 466,014,370 ED visits, of which 448,984 (0.096%) were for AH. The majority of ED visits for AH (80.6%) were for secondary AH; 85.9% (311,008/362,100) had a primary diagnosis closely linked to AH, indicating that AH was the main reason for ED utilization. The mean age was 47 years, and 66% of patients were male. ED visits for AH were most common in people aged 45-64 years (50.9%) followed by those aged 25-44 years (40.8%). Younger patients were more likely to have primary AH, while older patients were more likely to have secondary AH. The most common complications of liver disease were cirrhosis (62.5%), ascites (24.5%), and acute kidney injury or AKI (17.4%), all of which increased during the study period. Although the total number of ED visits did not change over the study period, the overall crude rate of AH increased from 85 to 106 per 100,000 ED visits. **Conclusion:** We show that the incidence of ED visits for AH increased annually prior to the COVID-19 pandemic. Patients with AH who presented to the ED were younger and had more severe illness with the majority presenting with co-existing cirrhosis or complications of portal hypertension. Given the progressive increase in ED visits for AH, optimizing health care utilization will require screening for alcohol use disorder in primary care settings to allow for early diagnosis before severe illness necessitates emergent care.

3544-C | EVALUATING INTENTION-TO-TREAT SURVIVAL FOR LIVER TRANSPLANTATION IN ALCOHOL-ASSOCIATED HEPATITIS COMPARED TO STATUS 1A FROM ACUTE LIVER FAILURE

Ankur Patel[1], Christo Mathew[1], Tzu-Hao (Howard) Lee[1], Ruben Hernaez[2], Peter Lymberopoulos[3], Anshul Bhatnagar[1], Anjiya Shaikh[4], Vinh Vincent Tran[1], Donghee Kim[5], Aijaz Ahmed[6], John A. Goss[1], Abbas Rana[1], Fasiha Kanwal[1], Gene Y. Im[7] and George Cholankeril[1], (1)Baylor College of Medicine, (2)Baylor College of Medicine, Houston, TX, (3)SUNY Downstate Medical Center, (4)University of Connecticut, (5) Stanford University Medical Center, (6)Stanford University School of Medicine, (7)Icahn School of Medicine at Mount Sinai

Background: Although post-transplant survival remains superior for patients with severe acute alcohol-associated hepatitis (AAH), other metrics to measure success with liver transplant (LT) including intention-to-treat (ITT) survival from listing and post-LT length of stay (LOS) utilization are lacking. For AAH patients, there are no data comparing these metrics with other causes of acute liver failure (ALF). Therefore, our aim was to evaluate ITT survival and LOS in patients with AAH patients compared to ALF patients with Status 1A listing. **Methods:** Using the UNOS registry, we retrospectively analyzed clinical outcomes among adult patients who were listed for LT with AAH and Status 1A in the United States between January 1, 2011 and June 29, 2021. AAH patients were propensity matched to Status 1A patients with respect to age, sex, race/ethnicity, MELD score at listing, and date of listing. We used Kaplan Meir survival methods to perform ITT analysis from listing in AAH patients and Status 1A patients. Subgroup analyses were performed comparing patients with AAH to patients with ALF from acetaminophen overdose (APAP) and acute hepatitis B virus (HBV). Cox Hazard regression analyses was used to determine risk factors associated with increased post-LT LOS. **Results:** A total of 3,844 patients were listed for LT with either AAH (n = 886, 23%) or as Status 1A (n = 2958, 77%). Overall, ITT survival at 3 years from LT was similar in AAH patients and status 1A patients (3-year survival: 94.4% vs 91.4%, P = 0.29). With propensity-matched analysis, AAH patients had higher survival benefit with listing for LT compared to Status 1A patients, (3-year survival: 80.3% vs 68.8%, P < 0.001). Upon stratification, patients with AAH that received LT had higher 3-year survival rates from listing than Status 1A patients with HBV or APAP that received LT (3-year survival: AAH, 80.2% vs HBV, 63.7% vs APAP, 67.9%, P < 0.001). On multivariable analysis, AAH LT recipients (n = 670) had significantly higher post-LT LOS (HR 2.48, 95% CI: 1.90-3.25) than patients transplanted with Status 1A. Black race, higher MELD at listing, and hemodialysis were also associated with increased LOS. **Conclusion:** AAH patients have higher survival benefit with waitlisting for LT compared to other Status 1A patients, but require higher utilization of resources in the post-LT recovery period. These data can help guide future metrics for post-LT success in this population.

3545-C | EVALUATION OF PORTAL HYPERTENSION IN PATIENTS WITH ACUTE ALCOHOL-ASSOCIATED HEPATITIS

Sara Hatoum and Don C. Rockey, Medical University of South Carolina

Background: Alcohol-associated hepatitis (AAH) is an acute form of liver injury resulting from excessive alcohol use. Most patients with AAH have significant fibrosis, or underlying cirrhosis of the liver and many may have associated portal hypertension - even when cirrhosis is not present. The gold standard technique for measuring portal hypertension is the hepatic venous pressure gradient (HVPG). Here, we aimed to assess the prevalence of portal hypertension in patients with AAH and examine the correlation between HVPG level and histological stage. **Methods:** In this cohort analysis, we examined consecutive patients with definite AAH who were admitted to an academic medical center between 2012 and 2022 and underwent HVPG measurement. Patients were considered to have definite AAH if they met clinical and histological criteria including neutrophilic lobular inflammation, degenerative changes in hepatocytes, steatosis, and pericellular fibrosis (based on NIAAA Alcoholic Hepatitis Consortia criteria). They were classified into 3 groups based on trichrome staging of their biopsies: noncirrhotic (F1-F3), cirrhotic (F4), and unable to stage (i.e., described as "chicken-wire fibrosis"). One-way ANOVA was used to compare mean HVPG among the three groups. **Results:** The cohort included 154 patients with histologically proven acute AAH (age 44, range 22-73; 47% female). Ascites and documented esophageal varices were present in 147 and 54 patients, respectively. The average HVPG overall was 17.0 ± 5.1 mmHg. 141 (92%) patients had clinically significant portal hypertension (HVPG $\geq$ 10 mmHg) and 90 (58%) patients had histological evidence of cirrhosis (Figure). Cirrhotic patients had significantly higher HVPG levels than noncirrhotic patients (18.4 ± 6.5 vs.14.2 ± 7.8 mmHg, $p = 0.02$) (Figure). The HVPG in patients with chicken-wire fibrosis was less than those with cirrhosis (15.3 ± 4.9 vs.18.4 ± 6.5 mmHg), this difference was statistically significant ($p = 0.03$). There was no significant difference in HVPG among patients with F1 to F3 fibrosis and those with chicken-wire fibrosis ($p = 0.8$) (Figure). **Conclusion:** Clinically significant portal hypertension is pervasive in patients with AAH, regardless of the degree of fibrosis and patients with cirrhosis had the highest level of portal hypertension. We speculate that the cause of portal hypertension in patients with only F1-F3 fibrosis was related to steatosis and hepatocyte swelling. Finally, we conclude that there is a positive correlation between histological stage and HVPG level in patients with AAH.

3546-C | EXOCYTOSIS OF HEPATIC GLUTAMATE VESICLES DRIVES ALCOHOL-ASSOCIATED LIVER INJURY BY STIMULATING KUPFFER CELLS

Keungmo Yang, Tom Ryu, Song Hwa Hong, Min Jeong Kim, Chaerin Woo, Katherine Po Sin Chung, Sung Eun Choi, Tolulope Esther Falana, Kyurae Kim, Kippeum Lee and Won-Il Jeong, Kaist

Background: Although alcohol-associated fatty liver (AFL) can progress to the more severe alcohol-associated steatohepatitis (ASH), the underlying mechanism of this transition remains unclear. We previously reported elevated hepatic glutamate levels and its metabotropic glutamate receptor 5 (mGluR5) in both animal models and patients with alcohol-associated liver disease (ALD). Consequently, we hypothesized that glutamate/mGluR5-related signaling pathways might play a significant role in ethanol-induced liver inflammation. **Methods:** C57BL/6J and Kupffer cell-specific *Grm5* knockout ($GRM5^{\Delta KC}$) mice were administered the binge-on-chronic (NIAAA) model to mimic ASH in humans. To identify the glutamate vesicles and spatial proximity between hepatocytes (HEPs) and Kupffer cells (KCs), electron microscopy (EM) and hydrogel-mediated tissue expansion were used. Also, *in vivo* calcium (Ca^{2+}) imaging, bulk RNA-sequencing and flow cytometry analysis were also performed. **Results:** Chronic alcohol consumption increased glutamate production (*Aldh4a1*), uptake (*Slc17a8*), and storage (*Slc1a2*)-related genes, resulting in elevated glutamate content in the liver. Furthermore, tissue expansion techniques revealed the accumulation of glutamate vesicles specifically in the perivenous HEPs. RNA-sequencing analysis showed a significant increase in SNARE complex-related genes involved in the exocytosis of glutamate vesicles. Electron microscopy also indicated close contact between ballooned HEPs and KCs. Under these conditions, *in vivo* Ca^{2+} imaging showed that binge drinking triggered glutamate release through Ca^{2+}-mediated exocytosis. The released glutamate then stimulated mGluR5 in neighboring KCs, leading to increased reactive oxygen species (ROS) production and subsequent HEP injury along with recruitment of neutrophils. We further demonstrated that genetic and pharmacological inhibition of mGluR5 in KCs suppressed glutamate-mediated ROS generation and mitigated liver injury in the NIAAA model. Lastly, similar findings were observed in liver biopsies from ASH patients, and mGluR5-mediated ROS production was observed in human primary KCs. **Conclusion:** Taken together, these findings indicate that chronic alcohol consumption induces the formation of glutamate vesicles in perivenous HEPs. Subsequent exocytosis of these vesicles stimulates mGluR5 in KCs and promotes alcohol-associated liver injury by ROS generation.

Background: Switching of macrophage activation phenotype affects pathogenesis of alcoholic liver diseases, metabolic reprogramming can provide the corresponding energy basis for macrophage phenotypes, but the molecular mechanism of immune metabolism regulating the activation of proinflammatory macrophages remains unclear. Herein we show that Fibrinogen-like protein 2 (Fgl2) promotes macrophage activation by regulating aerobic glycolysis in alcoholic hepatitis. **Methods:** Fgl2 expression was examined in alcoholic hepatitis patients and healthy controls. Liver from wild-type (WT) and Fgl2-knockout (KO) mice fed ethanol liquid diet or control diet were analyzed for liver injury and macrophage activation. Fgl2 overexpression THP-1 cell line was used to find interacting partner through immunoprecipitation plus mass spectrometry. Naive bone marrow derived macrophages stimulated with LPS and ethanol were performed for cell experiment. **Results:** Fgl2 expression was significantly elevated in macrophages from alcoholic liver tissues of both humans and mice. Fgl2 depletion ameliorated ethanol diet-induced hepatic steatosis and oxidative injury, as demonstrated by attenuated infiltration of monocytes/macrophages and decreased expression of proinflammatory factors. Fgl2 exhibited enhanced proinflammatory M1 polarization and glycolysis pathway activation in vivo and in vitro. Fgl2 interacted with the M2 isoform of pyruvate kinase in macrophages and facilitated its nuclear translocation, thus promoting glycolysis in M1 macrophage and secretion of proinflammatory cytokines. Furthermore, Fgl2 overexpression in THP-1 cells enhances PKM2-dependent glycolysis and inflammation, which could be reversed by activation of enzymatic PKM2 using DASA58. **Conclusion:** Taken together, Fgl2 promotes the progression of ALD by inducing macrophage polarization and inflammation based on the intracellular PKM2-mediated metabolic reprogramming of macrophages. More importantly, this study revealed the regulation of Fgl2 on glycolysis dependent immune response, providing important insights into the Warburg like metabolic changes of macrophages. Our research provides a new mechanism to link the metabolism and inflammation of macrophages with the progression of alcoholic liver injury.

3548-C | GENDER DIFFERENCES IN CHARACTERISTICS AND OUTCOMES OF PATIENTS WITH ALCOHOL-ASSOCIATED HEPATITIS

Anahita Rabiee, Praveena Narayanan, Bashar A Kadhim, Pramod K. Mistry and Tamar H. Taddei, Yale University, New Haven, CT

Background: The role of gender in susceptibility, presentation, and severity of alcohol associated liver disease has been previously investigated, however the data are not as clear in alcohol associated hepatitis (AH). Our goal was to assess the characteristics, severity, and outcomes among patients admitted with AH to our health system between 2013 to 2022. **Methods:** All patients with AH admitted to a single tertiary health system between 2013 and 2022 were retrospectively reviewed. Patients had to have an AH ICD code *and* meet clinical criteria (total bilirubin $>=3$, AST/ALT >1.5, AST and ALT <400). Data from the first admission meeting these criteria were collected for each patient. Biopsy reports were reviewed when available within 14 days of the index admission by a senior gastroenterology/hepatology fellow. Continuous variables with non-normal distributions were compared using Mann-Whitney U test, and categorical variables were compared using Chi square test. **Results:** A total of 2,572 patients had an ICD code for AH, however only 1,042 (40.5%) met clinical AH criteria, among whom 387 (37%) were female. AH events increased in both genders over the time studied (Figure 1). No significant difference between genders was observed in

age at presentation (median: 50) or MELD-Na (median: 24). Severe AH, defined as MELD-Na above 20 on admission, was present in 65% of women and 63% of men (p = 0.64). History of bariatric surgery was present in 5% of women vs 0.5% of men (p = < 0.001). The 30-day and 90-day mortality did not differ between groups (30-day M: 12% vs F: 15%; 90-day mortality: M: 19% vs F:21%). The above results did not change when performing a sensitivity analysis restricting the comparison to patients with severe AH. A total of 200 patients received a liver biopsy within 14 days of index admission; women were more likely to receive a liver biopsy (24% vs 16%, p = 0.003). Characteristics of AH were present on 89% of biopsy reports. The prevalence of advanced fibrosis was 98% in women and 90% in men (p = 0.09); the prevalence of cirrhosis was 69% vs 67% in women and men, respectively (p = 0.9). Other characteristics such as degree of steatosis, steatohepatitis, Mallory-Denk bodies, and ballooning degeneration were similar between groups. **Conclusion:** In our retrospective single health system study, we observed an increase in AH among both men and women over time. There was no statistically significant difference in age, MELD-Na, and short-term mortality among groups. Women were more likely to receive a liver biopsy. Among patients who had a liver biopsy confirming the diagnosis of AH, advanced fibrosis and cirrhosis were present in 94% and 68% of patients, respectively.

3549-C | GENETIC POLYMORPHISMS IN CHIT1 GENE AND LEVELS OF PLASMA CHITOTRIOSIDASE AND YKL-40 IN ALCOHOL-ASSOCIATED HEPATITIS

Praveena Narayanan[1], Jiapeng Ruan[1], Shiny Nair[1], Johannes Aerts[2] and Pramod K. Mistry[1], (1)Yale University, New Haven, CT, (2)Leiden University

Background: There is a higher risk of fungal infections in alcohol-associated hepatitis (AH) and emerging evidence implicate mycobiome changes in its pathogenesis. The human Chitinase 1 (*CHIT1*) gene encodes chitotriosidase, a chitin-hydrolyzing enzyme that exhibits potent antifungal activity. *CHIT1* and its non-enzymatic relative, Chitinase 3-like 1 (YKL-40), participate in the innate immune response in the setting of lipid metabolism dysregulation and have been studied in chronic inflammatory liver disease. However, their role in acute liver disease, particularly in AH, has not been explored. *CHIT1* is a highly polymorphic gene with up to 6% prevalence of homozygous null allele (*dup24*) in some populations; however, there is significant ethnic variability. We sought to study the prevalence and the effect of the most frequent *CHIT1* gene variants, *dup24* and *p.G102S,* in AH. Concurrently, we evaluated plasma chitotriosidase activities and YKL-40 levels as potential biomarkers for AH. **Methods:** Fifty patients admitted with AH and 11 healthy controls were studied. Genomic DNA was extracted from peripheral blood of AH patients, and *CHIT1* genotyping was performed as part of a more extensive whole exome sequencing (WES) analysis. Plasma chitotriosidase enzymatic activity and YKL-40 levels were evaluated. Additionally, we measured plasma chitotriosidase in patients with Gaucher disease (GD), as a disease control for another lipid storage disorder. Correlation analyses were run using two tailed student t-test. **Results:** Of 50 AH patients, 70% were male and 82% were Non-Hispanic White (remainder 9/50 included 7 Hispanic, one Black, and one Asian-Indian). Mean age was 46 years and mean MELD-Na 29 (range 17 to 40); there was a 30% (15/50) 90-day mortality. *CHIT1* genotyping showed that 36/50 (72%) patients harbored either *dup24* or the *p.G102S* variant (PolyPhen score 0.998). Of the 7 Hispanic patients with AH, 100% carried either variant (5/7 71% *dup24, 2/7 p.G102S*). Chitotriosidase and YKL-40 levels were significantly elevated in AH compared to healthy controls. There was a positive correlation between chitotriosidase and YKL-40 levels (r = 0.404, p = 0.0036) in AH. When the AH cohort was compared to GD cohort, chitotriosidase was less elevated, but YKL-40 was elevated by 13-fold. Within the AH cohort, there was no significant correlation between chitotriosidase and YKL-40 and MELD-Na, WBC, presence of infection, 30-day, or 90-day mortality. **Conclusion:** The majority of AH patients (72%) harbored at least one severe *CHIT1* variant. AH patients had significantly elevated plasma chitotriosidase and YKL-40 compared to healthy controls. In contrast to GD, in AH, chitotriosidase was markedly lower and YKL-40 significantly elevated. Larger sample size of AH patients alongside comparator cohorts (e.g. with NASH) will allow for validation of our findings upon which these biomarkers may leverage to promising therapeutic targets.

3550-C | GENETIC VARIATION NEAR MLXIPL, BRD3OS, AND CYP1A1 CONTRIBUTE TO RISK OF ALCOHOLIC HEPATITIS

Antonino Oliveri[1], Kelly Cushing[2], Yanhua Chen[1] and Elizabeth K. Speliotes[3], (1)University of Michigan, (2) University of Michigan Medical Center, (3)University of Michigan Medical School

Background: Alcoholic-related liver diseases (ALD) are associated with substantial morbidity and mortality. Identifying genetic predictors of disease can improve risk stratification efforts and provide insight into novel therapeutic targets. The aims of this study were to 1) determine if alcohol consumption risk loci associate with effects on ALD, and 2) identify subset-specific effects in alcoholic hepatitis (AH) and alcoholic cirrhosis (AC). **Methods:** A genome wide association study of alcohol consumption in the UK Biobank cohort was performed. Variants associating with alcohol consumption at p < 5e-08 were tested for association with ALD, AH, and AC in the UK Biobank using established ICD-10 codes (ALD: K70.1 and/or K70.3, AH: K70.1, AC: K70.3). Significant variants were defined as those reaching a p-value ≤ 0.05. Implicated variants and genes were evaluated for eQTL and gene expression effects in liver in the GTEx Portal. **Results:** A total of 23 variants significantly associated with alcohol consumption with the strongest effects observed for rs1229984-C (*ADH1B*, p = 3.7e-154), rs28712821-A (*KLB*, p = 2.4E-34), and rs1260326-C (GCKR, p = 6.5E-30). Of the 23 alcohol intake variants, 2 associated with ALD (*ADH1B*-rs1229984-C [p = 0.000419], *MLXIPL*-rs7805504-C [p = 0.0453]), 4 associated with AH (*MLXIPL*-rs7805504-C [p = 0.0104]; *ADH1B*-rs1229984-C [p = 0.017]; *BRD3OS*-rs109536-C [p = 0.0223]; *CYP1A1*-rs2470893-T [p = 0.0255]), and 1 associated with AC (*ADH1B*-rs1229984-C [p = 0.00-208]). Several implicated genes were found to be expressed in the liver (*ADH1B, MLXIPL, CYP1A1*) and several genes were found to serve as variant-specific eQTLs in the liver (*LINC00094, ULK3, MPI*). **Conclusion:** Genetic contribution to risk of ALD, AH, and AC is overlapping (*ADH1B*). However, AH has several unique contributors to disease risk including genetic variation near *MLXIPL, BRD3OS,* and *CYP1A1.* This suggests there are common and unique ways to curb alcoholic liver disease. Further studies will help us to understand the functional effects of these genes on the risk of AH.

3551-C | Glp1-AGONIST REDUCES ALCOHOL INTAKE AND LIVER INFLAMMATION IN A MOUSE MODEL OF ALCOHOL-INDUCED ACUTE HEPATITIS

Frhaan Zahrawi, Suyavaran Arumugam, Bubu A Banini and Wajahat Z. Mehal, Yale University, New Haven, CT

Background: Background and Aims: Therapeutic strategies for alcohol use disorder (AUD) and alcohol associated hepatitis (AH) are limited. Glucagon like peptide 1 agonists (GLP-1A) are a recently developed class of incretin mimetics that increase satiety and decrease appetite, and are approved for treating obesity and diabetes mellitus. To date, data suggest that GLP-1As reduce AUD and protect against various acute and chronic liver injury. In this study, we tested the effectiveness of the GLP-1A semaglutide on alcohol consumption and alcohol-induced hepatic effects in an AH mouse model. **Methods:** Adult C57-BL6J/N male mice 12-14 weeks old were maintained under ambient room temperature on a 12 h/12 h light/dark cycle. After

acclimatized to Lieber-Decarli '82 liquid control diet for 5 days ad libitum, mice were separated into 4 groups: Group 1 (n = 4) - control liquid diet; Group 2 (n = 8) - Lieber Decarli diet; Group 3 (n = 8) - Lieber Decarli diet with daily subcutaneous injection of semaglutide; and Group 4 (n = 4) - control diet with semaglutide treatment. Group 3 and 4 mice were injected with escalating doses of semaglutide as follows: 1 nmol/kg on days 1-2; 3 nmol/kg on days 3-4; 10 nmol/kg on days 5-6; 30 nmol/kg target dose on day 7 after which they were continued on target dose until day 15. On day 16, mice were gavaged (5g/kg of body weight alcohol for groups 2 and 3 and 9g/kg of body weight maltose dextrin for groups 1 and 4) and were euthanized after 9 hr. Body weight and food consumption were tracked daily. Upon sacrifice, liver tissue samples were harvested for further analyses. **Results:** The mice from Group 2 (on Lieber Decarli diet) lost weight initially compared to Group 1 mice on control diet, but regained weight starting on day 10. In contrast, mice in Group 3 treated with semaglutide while on Lieber Decarli diet lost body weight throughout drug treatment. Body weight of Group 3 mice at day 14 was significantly reduced compared to Group 2 ($P < 0.0001$). Group 3 mice also showed significantly reduced alcohol diet intake compared to Group 2 ($P < 0.0001$). The overall food intake was significantly lower in Group 3 mice compared to Group 2, as evident from area under curve (AOC) analysis (AOC 5.358 for Group 3 vs 7.094 for Group 2). These findings also correlated with changes in liver weight among the different groups. Group 2 liver showed sinusoidal hepatocytes with microvesicular steatosis with pyknotic nuclei, while group 3 liver histology showed significant suppression of these changes. Group 3 also showed a reduction in sinusoidal congestion and inflammatory cell infiltration. **Conclusion:** The GLP-1A semaglutide significantly inhibits alcohol diet consumption and reduces body and liver weight in a murine model of AH. Further molecular studies are needed to ascertain the beneficial effects of semaglutide on alcohol consumption and hepatic effects.

3552-C | HEPATIC RECOVERY IN PATIENTS WITH ALCOHOL ASSOCIATED LIVER DISEASE EVALUATED FOR EARLY LIVER TRANSPLANTATION

Allison J. Kwong[1], Weiyu Wu[2], Erick Sandoval[3], Kaleb Tesfai[3], Gurpreet Judge[4] and Veeral Ajmera[3], (1) Stanford University, (2)Stanford University, Redwood City, CA, United States, (3)University of California, San Diego, (4)Stanford University, Tracy, CA

Background: Alcohol-associated liver disease (ALD) has become the leading cause of liver transplant (LT) in the United States, with increased prevalence of ALD and wider acceptance of early LT for the most acute cases including severe alcohol-associated hepatitis (AH). We evaluated outcomes and predictors of hepatic recovery among patients with ALD and less than 6 months of abstinence from alcohol who were considered for early LT. **Methods:** This retrospective cohort included adult patients with ALD and less than 6 months from last alcohol use who were evaluated for early LT between 2017 to 2021 at two transplant centers with a high median MELD at transplant. Outcomes included death, transplant, Model for End-Stage Liver Disease (MELD) score, Child-Pugh class, and alcohol use. Multivariable Cox regression analysis was used to evaluate predictors of death and transplant-free survival. Hepatic recovery was defined as Child-Pugh class A after 6, 12, and 24 months in patients who did not receive transplant. **Results:** During the study period, 198 patients were evaluated for early LT, 94 (47%) of whom were listed and 69 (35%) transplanted. The median age was 48 years (IQR 40- 55), 36% were men, and 62% were white. The median MELD was 31 (IQR 24-38); the median time from last drink was 62 days (IQR 28-114); and 67% met NIAAA criteria for AH. The overall transplant-free survival was 35.7% at 1 year and 31.4% at 2 years. Male sex and higher BMI, bilirubin, INR, creatinine, AST, ALT, and WBC were associated with increased mortality risk. In the multivariable Cox regression analysis, significant predictors of death without transplant included INR (HR 2.22, 95% CI 1.72-2.88) and creatinine (HR 1.24, 95% CI 1.09-1.40), whereas bilirubin was not predictive (HR 1.01, 95% CI 0.97-1.04) (Table). Among the 69 patients who survived without transplant, 17% achieved Child-Pugh class A at 6 months, 43% at 12 months, and 46% at 24 months. A marked decrease in MELD was observed over 2 years of follow-up, with the greatest reduction in the first 6 months (Figure). During the follow-up period, 19 (28%) patients had a detected relapse, i.e. return to alcohol use. **Conclusion:** In patients with decompensated ALD evaluated for but not receiving early LT, higher than expected rates of hepatic recovery were observed in long-term follow-up. INR and creatinine may be more relevant predictors of transplant-free survival than bilirubin in this population. Improved prognostication is needed to better represent the risk of mortality without LT in patients with ALD and limited sobriety and to identify those who may and may not require LT.

3553-C | HEPATIC REDUCTIVE STRESS INFLUENCES ALCOHOL CONSUMPTION

Nirajan Shrestha[1], Byungchang Jin[1] and Russell P. Goodman[2], (1)Massachusetts General Hospital and Harvard Medical School, Boston, MA, (2) Massachusetts General Hospital

Background: Alcohol use disorder (AUD) is a medical condition characterized by an impaired ability to stop or control alcohol use. Heavy alcohol can lead to alcohol-associated liver disease (ALD) and cirrhosis. Genome-wide association studies (GWASs) have shown that alcohol use is highly polygenic, with about half of the risk of AUD being genetic. One genetic locus associated with alcohol use is the glucokinase regulator (*GCKR*), where a common genetic variant is associated with decreased alcohol consumption. Recent work in our lab has shown that this variant increases hepatic NADH/NAD$^+$ levels (reductive stress), activating the carbohydrate-responsive element-binding protein (ChREBP), which in turn increases fibroblast growth factor 21 (FGF21) levels. As it is well established that FGF21 regulates alcohol consumption, we hypothesized that reductive stress might influence alcohol consumption. **Methods:** We utilized a novel transgenic mouse model, mitochondrial-targeted *Lactobacillus brevis* NADH oxidase (MitoLbNOX; Alb$^{Cre/+}$), which lowers reductive stress in the liver. We performed a two-bottle choice experiment to study alcohol consumption in the mice model. Briefly, mice are singly housed in a standard cage, and the regular water bottle is replaced with two ball-bearing sipper tubes. Mice are exposed to water in both tubes for two days and to increasing concentrations of ethanol (3%, 6%, and 10%; 4 d for each concentration) in one tube and water in another. The water and ethanol consumption are recorded daily. On the final day of the procedure, mice are euthanized under 4% of isoflurane. All animal experiments are approved by MGH Institutional Animal Care and Use Committee. **Results:** In this study, we observed that MitoLbNOX; Alb$^{Cre/+}$ transgenic mice, which have lower hepatic reductive stress, have a higher intake of ethanol in both male and female mice compared to control mice. In addition to alcohol intake, alcohol preference is also higher in MitoLbNOX; Alb$^{Cre/+}$ transgenic mice. Interestingly, female mice have higher alcohol preferences than male mice. **Conclusion:** In conclusion, the mice with lower hepatic reductive stress have higher alcohol preference, supporting that the effect of *GCKR* on alcohol consumption is via reductive stress. The effect of hepatic NADH/NAD$^+$ may be associated with ChREBP, as ChREBP senses reductive stress and regulates FGF21. Hence, further research is required to explore whether changes in alcohol intake due to hepatic reductive stress are mediated through ChREBP.

3554-C | HEPATIC TET1 ALLEVIATES ALCOHOLIC FIBROSIS AND HEPATITIS VIA DOWNREGULATING IL-6

Muhammad Azhar Nisar[1], Hongze Chen[1], Nicholas Jabara[1], Eve Elkins[1], Sonali Notani[1], Bilon Khambu[1], Peng-Sheng Ting[2], Tung-Sung Tseng[3], Hui-Yi Lin[3], Shaolei Lu[4], Xuewei Bai[5] and Chiung-kuei Huang[1], (1) Tulane University School of Medicine, New Orleans, LA, (2)Johns Hopkins University, (3)Louisiana State University Health Sciences Center, (4)Alpert Medical School of Brown University, (5)The First Affiliated Hospital of Harbin Medical University

Background: Alcohol associated liver disease (ALD) is significantly correlated with cirrhosis and hepatic-associated death, with untreated fibrotic liver, regardless of the underlying cause, potentially advancing to cirrhosis in human patients. DNA methylation has been explored in the context of ALD progression. DNA demethylation is involved in 5-hydroxymethylcytosine (5hmC) formation catalyzed by the Ten-eleven translocation methylcytosine dioxygenase (TET) family proteins. Hepatic cell death has been linked to downregulated TET1 and 5hmC in ALD. The current study aimed to investigate the involvement of TET1 in the progression of ALD. **Methods:** Whole body and liver specific TET1 knockout (KO) mice were fed with a 5% alcohol liquid diet to induce ALD. Biochemical and

histological assays were adopted to characterize ALD progression. Molecular approaches were utilized for determining underlying mechanisms in the TET1-mediated ALD. **Results:** We found that TET1 deficiency facilitated the development of alcoholic liver fibrosis and inflammation. These were accompanied by an upregulation in the expression of α smooth muscle actin and collagen, markers indicative of increased fibrosis, and by an increase of macrophages and Interleukin (IL) 1β, markers of inflammation. Mechanistically, there was an elevation of IL-6 levels in the liver-specific TET1 KO mouse model. The IL-6 mediated mitogen-activated protein kinase signaling cascade is also decreased in these mice. IL-6 is epigenetically activated by TET1 KO, indicating that alcohol-mediated TET1 downregulation affects the inflammatory responses and fibrosis possibly through IL-6, thereby exacerbating ALD progression. **Conclusion:** In conclusion, our findings demonstrate the protective role of TET1 in ALD and the involvement of TET1-mediated DNA demethylation in controlling inflammatory responses and fibrosis. Activation of TET1 may serve as a potential therapeutic strategy in alleviating ALD.

3555-C | HEPATIC YES-ASSOCIATED PROTEIN (YAP) DELETION AMELIORATES ALCOHOLIC LIVER DISEASE BY REGULATING HEPATIC LIPID ACCUMULATION AND INFLAMMATION

Tuo Shao, Andre Jeyarajan, Min Xu, Shadi Salloum, Wenyu Lin and Raymond T. Chung, Massachusetts General Hospital and Harvard Medical School

Background: Alcohol-associated liver disease (ALD) is a major public health threat worldwide. There are few agents with clinical activity against alcohol associated liver injury, in large part because the pathogenesis of ALD is not well understood. Several studies have demonstrated that cell injury, inflammation and regeneration are key factors in alcohol-induced liver injury. Hippo/Yes-associated protein (YAP) is a promising therapeutic target central to liver regeneration and inflammation. Since hepatocyte injury is a major driver in the pathogenesis of ALD, whether alcohol induces liver inflammation and attenuates liver regeneration by dysregulating the YAP signaling pathway in hepatocytes is unknown. **Methods:** We generated mice with hepatocyte-specific deletion of YAP ($YAP^{flox/flox}$ mice were injected with adeno-associated virus, AAV8-TBG-Cre), and animals were gradually habituated to a Lieber-DeCarli liquid diet with 5% ethanol over a period of 1 week, then maintained on the 5% diet or isocaloric maltose dextrin for 8 weeks or treated with the YAP inhibitor verteporfin every other day for 4 weeks. Serum ALT and AST, endotoxin level, and lipid panel were assessed; Liver: YAP/p-YAP protein/gene, H&E staining, Oil-Red-O staining, F4/80, neutrophil, proinflammatory cytokines and liver triglyceride (TG) content were measured. HepG2 cells were treated with alcohol for three days or Dimethyloxallyl Glycine (DMOG, HIF-PH inhibitor) for 24 hours or verteporfin for 6-12 hours. YAP and HIF1a expression were analyzed. **Results:** Alcohol feeding significantly increased serum levels of ALT, AST and LPS in WT mice. These elevations were ameliorated in $YAP^{-/-}$ mice. Hepatic triglyceride accumulation increased in the presence of alcohol was improved in $YAP^{-/-}$ mice. Similarly, verteporfin treatment reversed liver steatosis in WT mice. Hepatocyte YAP deletion also resulted in a marked decrease in hepatic macrophage, neutrophil and inflammatory cytokine and chemokine expression (TNF-a ~3 fold, IL-6 ~2 fold and MCP-1 ~1.5 fold). In HepG2 cells, alcohol exposure and DMOG treatment increased nuclear YAP and HIF1a co-expression. However, verteporfin treatment significantly reduced both YAP nuclear translocation and HIF1a expression after alcohol exposure in HepG2 cells. **Conclusion:** Our results demonstrate that hepatocyte YAP activation is a critical driver of alcohol induced liver disease and that inhibition of YAP may represent a novel approach for the treatment of ALD.

3556-C | HEPATOCYTES AND NEUTROPHILS INCREASE OXIDATIVE STRESS AND CONTRIBUTE TO ALCOHOL-MEDIATED LIVER INJURY AND INFLAMMATION IN MYELOID TLR4 DEFICIENT MICE

Abhishek Mandal, Anuradha Ratna, Jeevitha Thanikasalam, Evelyn Kurt-Jones and Pranoti Mandrekar, University of Massachusetts Chan Medical School

Background: Alcohol associated liver disease (AALD) is characterized by a spectrum of liver pathophysiology including steatosis, inflammation, and fibrosis. Studies report whole body TLR4 deficiency is protective in AALD. However, the precise role of liver cell specific TLR4 in AALD is not clearly understood. Here, we investigate the role of myeloid-specific and hepatocyte-specific TLR4 deletion in alcohol mediated liver injury and inflammation. **Methods:** Hepatocyte-specific (HEP-TLR4KO) and myeloid-specific TLR4 deficient (M-TLR4KO) mice were generated and subjected to chronic-plus multiple binge alcohol diet. Markers of liver injury, oxidative stress, inflammatory cytokines, immune cell markers were measured. In vivo neutrophil neutralization using anti-Ly6G antibody was assessed. To assess cellular mechanisms, cytokine profiles in macrophages and hepatocytes of M-TLR4KO mice were investigated. **Results:** Our results show high serum ALT and liver triglycerides in alcohol-fed M-TLR4KO mice, indicating sustained liver injury and steatosis. Markers of oxidative stress Cyp2e1, NADPH oxidase 4 (NOX4) and ER stress marker, GRP78 are increased in alcohol fed M-TLR4KO mice. Alcohol-induced expression of TNF-α, IL-6, IL-1β was significantly reduced in M-TLR4KO livers whereas CCL2/MCP-1 ($P < 0.05$) and MIP-1α ($p < 0.0001$) was significantly induced in M-TLR4KO mice. Neutrophil marker Ly6G ($p < 0.0001$), CXCR2 ($p < 0.005$), Elane ($p < 0.05$) and MPO+ cells were induced in M-TLR4KO alcohol livers, indicating neutrophil infiltration. However, expression of immune cell markers F4/80, CD11c were reduced in M-TLR4KO alcohol livers. Finally, in vivo neutrophil neutralization reduced serum ALT, liver triglyceride, pro-inflammatory cytokines, TNFα, IL-6, IL-1β, CCL2 and oxidative stress markers, NOX4 and GRP78. To unravel cellular source of chemokines in M-TLR4KO mice, we isolated macrophages and primary hepatocytes. BMDMs from M-TLR4KO mice show decrease in LPS induced, but not PAM3CSK4 or Poly I:C mediated cytokines TNFα, IL-6, CCL-2 and IL-1β. Instead, LPS stimulation increased TNFα and rTNFα up-regulated CCL2 and IL-6 in chronic alcohol exposed primary hepatocytes from M-TLR4KO mice. Our results suggest that chronic alcohol induced CCL2 in hepatocytes contributes to neutrophil infiltration and injury in M-TLR4KO mice. **Conclusion:** Chronic alcohol associated liver injury and inflammation is independent of myeloid TLR4 and is driven by hepatocyte induced chemokines and neutrophil infiltration.

3557-C | HEPATOCYTE-SPECIFIC DEFICIENCY OF DDIT4 ATTENUATES ALCOHOL-MEDIATED HEPATIC DAMAGE

Taek Kyong Kim[1], Yoonsu Ha[1,2] and Seung-Jin Kim[2], (1)Kangwon National University, (2)Global/Gangwon Innovative Biologics-Regional Leading Research Center (GIB-RLRC)

Background: Alcohol-related liver disease is a widespread disease with a variety of pathophysiological spectrums including steatosis, alcoholic steatohepatitis (ASH), alcoholic liver fibrosis, and hepatocellular carcinoma (HCC). DDIT4 (DNA-damage-inducible transcript 4, also known as REDD1) is a highly conserved cellular stress-responsive protein induced by stress signals such as hypoxia, DNA damage, reactive oxygen species (ROS), and ER stress. DDIT4 has been reported to exhibit various regulatory functions against different mammalian cells through inhibition of the mammalian target of Rapamycin (mTOR) pathway. However, the role of DDIT4 during alcohol-induced hepatic injury remains largely undefined. In this study, we aimed to investigate the function of hepatocyte DDIT4 in the development of ASH. In this study, we aimed to investigate the function of hepatocyte DDIT4 in the development of ASH. **Methods:** To explore the function of hepatocyte DDIT4 in the progression of alcoholic steatohepatitis (ASH), mice with hepatocyte-specific deletion of DDIT4 (DDIT4-LKO) were generated. Then, mice were fed 3-months High-fat diet plus multiple binge ethanol

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

to mimic ASH. **Results:** Genetic deletion of DDIT4 in hepatocytes decreased ASH-induced hepatic damages. In particular, loss of DDIT4 in hepatocytes significantly ameliorates ASH-induced liver injury, as evidence by low levels of serum ALT and AST compared with the control group. Furthermore, RNA sequencing analyses reveal that the RAC-PAK-MAPK signaling pathways were significantly decreased in the liver of ASH-induced DDIT4-LKO mice to compare with ASH-induced WT mice. In consistent with RNA sequencing results, immunoblotting showed that the MAPK, fibrotic and apoptotic signaling pathways were significantly decreased in the liver of ASH-induced DDIT4-LKO mice compared with ASH-induced WT mice. **Conclusion:** Taken together, our results demonstrate that downregulation of DDIT4 is crucial for reducing ASH-induced hepatic damage via the attenuation of RAC-PAK-MAPK signaling axis and support the hypothesis that DDIT4 could be a therapeutic target for the control of alcohol-mediated hepatic damage.

3558-C | HEPATOLOGY REFERRAL DECREASES THE INCIDENCE OF READMISSION IN PATIENTS WITH ALCOHOLIC HEPATITIS

Nariman Hossein-Javaheri[1], Alexander Mark Carlson[2], Kevin Yang[1], Naren Srinath Nallapeta[1] and Thomas Mahl[1], (1)University at Buffalo, (2)University at Buffalo, Orchard Park, NY

Background: Alcohol abuse and liver disease are associated with high rates of hospital readmission, but factors linking alcoholic hepatitis (AH) to readmission are not well understood. Specifically, we aimed to determine the incidence of 90-day readmission in patients with AH who were referred to clinical hepatology upon discharge. **Methods:** 250 patients with a diagnosis cirrhosis or hepatic steatosis admitted for AH were identified and divided into two groups based on referral and readmission. Furthermore, length of stay (LOS), admission MELD scores, symptoms of decompensation including ascites, encephalopathy and gastrointestinal bleeding (GIB), and 90-day mortality rates, were compared between the two groups. Significance was assessed based on two-tailed t-test and $p < 0.05$ was deemed significant. **Results:** Readmission rate in persons who were referred to hepatology was 41% vs 52.6% in those who were not referred ($p = 0.03$). Those who were referred had a complicated hospitalization with a greater LOS (11 vs 7.6 d; $p = 0.02$), higher MELD scores (15 vs 9; $p < 0.001$), greater incidence of GIB (21% vs 10%; $p < 0.05$) and ascites (36.2% vs 10.8%; $p < 0.001$) but not encephalopathy (23.2% vs 23.9%; $p = 0.9$). Although patients who were referred to hepatology had decreased 90- day mortality (5.8% vs 10.2%), the difference between the two groups was not significant ($p = 0.1$). **Conclusion:** Referral to hepatology significantly reduces the rate of 90-day readmission in patients with AH. Patients with a complicated hospitalization including greater LOS, higher MELD scores on admission, and adverse complications of liver disease (specifically GIB and ascites) were more likely to be referred to a liver clinic. Considering the severity of liver disease, a greater incidence of re-hospitalization is expected in those with advanced and complicated AH. However, it appears that referral to a hepatologist upon discharge can significantly reduce rates of readmission but does not significantly reduce 90-day mortality rates. Given the high probability of hospitalization in AH, it is important to understand factors that contribute to readmission. These factors are potentially helpful for the development of consensus based guidelines, treatment strategies, and patient safety to reduced frequent hospitalization in persons with alcoholic hepatitis.

3559-C | HEPATOTOXIC EFFECTS OF ALCOHOL AND HIV: SPREADING OF LIVER INFLAMMATION BY APOPTOTIC BODIES

Siva S Koganti[1,2], Moses New-Aaron[1,2], Haritha Chava[1,2], Kusum K. Kharbanda[1,2] and Natalia Osna[1,2], (1)University of Nebraska Medical Center, (2)Veterans Affairs Nebraska-Western Iowa Health Care System

Background: About 48% of HIV-infected individual's are alcohol abusers, which tremendously potentiates HIV-induced hepatotoxicity leading to progressive liver damage and cirrhosis. The mechanisms behind these events are unclear. We recently reported that exposure to HIV and acetaldehyde induces apoptosis in hepatocytes leading to apoptotic bodies (ABs) formation. As revealed from AB's proteomic studies, the enriched datasets target various pro-inflammatory cytokines and inflammasomes, leading to extensive hepatocyte death. Since only a limited number of hepatocytes sense HIV initially, the overall goal of this study was to investigate the key mechanisms

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

underlying progressive hepatotoxicity spread in the liver. We hypothesize that this may happen via engulfment of ABs derived from HIV- and acetaldehyde-generating system (AGS)-exposed hepatocytes ($AB_{AGS+HIV}$) by neighboring hepatocytes via Asialoglycoprotein receptor (ASGP-R). **Methods:** Huh7.5-CYP2E1 (RLW) cells were pretreated for 24 h with AGS, then exposed overnight to HIV-1_{ADA} and put back on AGS for 96h. Thereafter, ABs were isolated from cell suspension and quantified by Nano-Tracking Analysis (NTA). The ABs were processed for proteomics studies. The obtained datasets carried out functional annotation as well as pathway analysis using Qiagen's Ingenuity pathway analysis (IPA). In addition, $AB_{AGS+HIV}$ were incubated with untreated RLW cells (4:1 to 3:1 ratio) to test proinflammatory genes by RT-PCR and proteins by Western blot. **Results:** Proteomic analysis of $AB_{AGS+HIV}$ along with IPA showed the enrichment of proteins associated with HIV particles, apoptosis, fibrosis, and oxidative stress. Overall, functional annotation explains the potential mechanisms of progressive damage signals pointing toward sustained liver fibrosis and HCC. When exposed to $AB_{AGS+HIV}$, RLW cells have shown a significant dose-dependent increase in cellular expression of TNFα and no change in IL-6 and IL1β. Fluorescently measured proteasome activity was suppressed in RLW $_{HIV+AGS}$ by oxidative stress. As known, TNFα supports cell survival in case downstream signaling is not blocked, and TNFα-induced activation of the NFκβ pathway requires IKβ dissociation. IKβ is a proteasome substrate, which degradation is impaired in hepatocytes exposed to HIV and AGS, thereby limiting activation of this pathway by $AB_{AGS+HIV}$ internalization. **Conclusion:** $AB_{AGS+HIV}$-triggered induction of TNFα combined with the suppression of IKβ proteasomal degradation is responsible for the hepatotoxicity spread and the progression of HIV-ethanol metabolism-induced liver injury.

3560-C | HOSPITALIZATION AND MORTALITY IN COMMERCIALLY INSURED PATIENTS WITH ALCOHOL-ASSOCIATED HEPATITIS

Suthat Liangpunsakul[1,2], Wanzhu Tu[3], Chi Mai Nguyen[3], Ryan Healey[3], Yang Li[3], Svetlana Radaeva[4], Samer Gawrieh[5], Ramon Bataller[6] and Jing Su[3], (1)Division of Gastroenterology and Hepatology, Department of Medicine, Indiana University School of Medicine, Indianapolis, IN, (2) Roudebush Veterans Administration Medical Center, Indianapolis, in, (3)Department of Biostatistics and Health Data, Indiana University School of Medicine, Indianapolis, in, (4)National Institutes of Health, Bethesda, MD, (5)Division of Gastroenterology and Hepatology, Department of Medicine, Indiana University School of Medicine, Indianapolis, in, (6) Barcelona Clinic, Barcelona, Spain

Background: Estimates of mortality in patients with alcohol-associated hepatitis (AH) vary significantly by disease severity, patient population, and study methods. Individual's covered by commercial insurance plans account for much of the clinical population in the United States. Yet, AH-related hospitalization and mortality of commercially insured patients have not been well described. Objectives: To describe the clinical characteristics, hospitalization, and mortality in commercially insured patients with AH diagnoses and clinical factors associated with mortality. **Methods:** We analyzed the administrative health claims data from Optum's Clinformatics® Data Mart (CDM) database, which contained the diagnosis, clinical care records, and mortality in members of large commercial and Medicare Advantage health plans. We identified individual's with AH diagnoses between 2007 and 2021 and examined the 90- and 180-day mortality rates in hospitalized and non-hospitalized patients. **Results:** We identified 49,995 unique patients from 71,260,839 insured individual's. We analyzed data from 32,001 patients that had at least one year of continuous insurance coverage prior to AH diagnoses. Of these, 20,912 were hospitalized within seven days of diagnosis. Mortality rates were markedly higher in hospitalized patients. Ninety and 180-day mortality rates were 12.0% (95% CI [11.6%, 12.5%]) and 16.0% (95% CI [15.4%, 16.5%]) respectively for the hospitalized patients and 3.1% (95% CI [2.8%, 3.4%]) and 5.1% (95% CI [4.6%, 5.5%]) for the non-hospitalized patients. Among the clinical factors associated with mortality, prior diagnosis of liver disease was strongly associated with an increased risk of death. In hospitalized patients, a history of moderate-to-severe liver disease was associated with a more than doubled risk of 180-day mortality (Adjusted HR = 2.31, 95% CI: [2.10, 2.54], Figure 1). **Conclusion:** AH carries significant short and intermediate-term mortality. In commercially insured patients, the risk of death is more than doubled in patients with pre-existing liver disease. The findings of the current study highlight the chronic disease context of this acute condition and the need for combination therapies to more effectively alleviate the damages caused by acute inflammation and long-term alcohol use disorder.

3561-C | HOSPITALIZATIONS IN PATIENTS WITH ALCOHOL USE DISORDER AND ASSOCIATIONS WITH OUTCOMES BEFORE AND AFTER COVID-19

Sophie Hansen[1,2], Christopher Danford[2], Jorge Sanchez-Garcia[2] and Richard Gilroy[2], (1)University of Utah, (2)Intermountain Health

Background: Existing evidence supports an increase in alcohol consumption during the COVID-19 pandemic and suggests greater hospitalizations for, and a younger age in those presenting with decompensated disease. These publications appear more commonly associated with transplant programs and diverse demographic sources. This study examines the impact of COVID-19 upon the frequency, acuity of hospitalizations, and outcomes across an entire health system of 23 hospitals. **Methods:** We conducted an electronic medical record search for all patients admitted to any of 23 hospitals in an integrated medical system from January 1, 2018 to May 1, 2022. We included all patients with a primary admitting diagnosis for alcohol-associated diagnoses (F10.10, F10.20, Z78.9, K70.30, F10.939, K70.10, F10.90, K70.9, K70.0, F10.931) and then separated to examine those with a bilirubin < 2 mg/dL, > 2 mg/dL, and > 10 mg/dL and separated for elevated AST and ALT ratios consistent with the characteristics for alcoholic hepatitis. We then divided the patients into equal pre- (1/1/2018-2/28/2020) and post-COVID (3/1/2020-5/1/2022) eras and with sufficient time to allow at least 1 year follow-up. We compared the total volume of patients admitted with alcohol-related diagnoses, and clinical characteristics between the two eras, readmission and mortality data using unpaired t-test and chi-square test as appropriate for means and proportions respectively. We also evaluated variables for predictive of risk of death using logistic regression. **Results:** In summary:

- There was no difference in the total number of admission with an alcohol-associated liver disorder or alcoholic hepatitis between the two eras.
- There was no increase in mortality in patients with high MELD scores admitted during the COVID-19 era as compared to the pre-COVID-19 era.

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

- Patient age predicted mortality in patients with high MELD scores.
- The presence of a hepatology evaluation had no impact upon mortality.
- Less than 2% of patients with or without a high MELD scores had a social work evaluation.
- There was no change in the percentage of social work encounters between the pre-COVID-19 and the COVID-19 era.

Conclusion: In contrast to previous studies, an increase in the total admissions for alcohol associated diagnosis did not occur and mortality for those with overt decompensation did not change. Although the number of cases did not change, the proportion admitted for alcohol did increase creating a perception of more alcohol use associated admissions to the system. Unfortunately, patients admitted with alcohol use were rarely connected to social work care.

3562-C | IDENTIFYING GENDER AND RACIAL DISPARITIES IN ALCOHOL USE DISORDER: A COST ANALYSIS

Chun-Wei Pan, John H. Stroger Jr. Hospital of Cook County, Neethi Dasu, Jefferson Health NJ, Chun-Han Lo, University of Nevada and Yaser Khalid, Wright Center for Gme/Geisinger Health System

Background: Alcohol-related liver disease (ALD) is a global health and economic burden, especially in the US. Between 2015-2019, there was a rising prevalence of conditions like steatosis, hepatitis, and liver cirrhosis. ALD accounted for 50% of liver disease deaths in people aged 15 and above in 2016. High-cost hospital admissions for ALD complications add to the financial burden. Effective prevention and treatment strategies are needed to address this escalating issue. Our study aims to elucidate the healthcare burden of ALD through an examination of specific demographic factors. **Methods:** This retrospective analysis utilizes the National Inpatient Sample to select cases of ALD, encompassing alcoholic hepatitis, alcoholic cirrhosis, alcoholic fatty liver disease, and other alcohol-related liver diseases. These cases were identified using their respective International Classification of Diseases (ICD-10) codes. To assess the economic burden, all total and mean costs were calculated using the inflation-adjusted cost-to-charge ratio. **Results:**

- From our analysis, costs from 2015-2019 were presented in millions of dollars (6,376.50m, 6,678.00m, 7,020.00m, 7,333.80m, 7,890.00m). When stratified into age groups, 18-44 (1,122.70m, 1,250.80m, 1,300.00m, 1,438.20m, 1,620.00m), 45-64 (4,076.60m, 4,208.20m, 4,336.80m, 4,386.00m, 4,640.00m), 65-84 (1,155.40m, 1,187.20m, 1,341.60m, 1,489.20m, 1,600.00m), > 85 (29.98m, 32.65m, 38.06m, 37.13m, 35.30m). By sex: male (4,588.90m, 4,695.80m, 4,992.00m, 5,191.80m, 5,500.00m), female (1,787.60m, 1,982.20m, 2,028.00m, 2,172.60m, 2,390.00m). By race: White (4,000.30m, 4,208.20m, 4,461.60m, 4,702.20m, 5,070.00m), black (636.56m, 668.86m, 660.40m, 701.76m, 730.00m), Hispanics (989.72m, 1,046.22m, 1,164.80m, 1,234.20m, 1,340.00m), Asian (85.02m, 93.92m, 109.20m, 109.14m, 118.00m), Others (323.73m, 362.52m, 395.20m, 404.94m, 457.00m).
- On a mean total cost basis: Amongst Males, cost increased from $16,194 (95% CI:15,742-16,646) in 2015 to $16,911 (95% CI: 16,471-17,351) in 2019. In females- cost increased from $15,530 (95% CI: 14,980-16,079) to $16,537 (95%CI: 16,020-17,055)
- Regarding race- Asians had the highest mean cost in 2016- $19,117 (95% CI: 17,011-21,222), which increased to 20,679 (95 % CI: 18,678-22,681) in 2019. On an inflation-adjusted basis, the 65-84 age group had the highest mean cost. In 2016 noted to be $17,111 (95% CI: 16,593-17,628) and increased to $17,576 (95% CI: 17,134-18,019) in 2019

Conclusion: Our analysis of the 2015-2019 National Cohort revealed rising costs of ALD; total costs increased from $6,376.50m to $7,890.00m after adjusting for inflation. Costs varied by age, sex, and race. The 45-64 age group and males accounted for higher costs, while the mean cost was highest among Asians and the 65-84 age group. This rising economic

3563-C | IMPACT OF ATRIAL FIBRILLATION ON IN-HOSPITAL OUTCOMES IN ALCOHOL-ASSOCIATED HEPATITIS PATIENTS: A NATIONWIDE ANALYSIS

Harshavardhan Sanekommu[1], Sobaan Taj[1], Jayasree Ravilla[2], Brett Miller[1], Alejandro CruzPonce[1], Qaiser Shahzad[1], Aidan Farrell[3], Muhammad Umair Akmal[4], RIda Mah Noor[5], Reza Akhtar[1], Mohammad Hossain[1] and Arif Asif[1], (1)Hackensack Meridian Jersey Shore University Medical Center, (2)Monmouth Medical Center, (3)Hackensack Meridian University School of Medicine, (4)Kazakh National Medical University, (5) International University of Kyrgyzstan-International School of Medicine

Background: Alcohol consumption is a significant risk factor for atrial fibrillation (AF). AF in cirrhotic patients is linked to adverse outcomes. However, the outcomes of AF in the context of acute alcohol-associated hepatitis (AH) have yet to be investigated. **Methods:** This retrospective cohort study utilized data from the National Inpatient Sample database, covering the period from 2016 to 2019. The study population consisted of hospitalized adults diagnosed with AH, identified using International Classification of Diseases, 10th revision, and Clinical Modification codes. Patients were divided into two groups, according to their history of AF. Subgroup analysis with and without cirrhosis was conducted amongst the group with AF. Statistical analysis involved propensity score matching, weighted means and percentages, t-tests, chi-square tests, multivariate logistic and linear regression using SAS 9.4 software. **Results:** The AH group with AF had a weighted sample size of 479,845, while the AH group without AF had a weighted sample size of 27,665. After matching for baseline characteristics, each group retained a weighted sample size of 27,080. Patients with AH and AF had a higher in-hospital mortality rate (6.6%) compared to those without AF (5.2%) (adjusted odds ratio:1.29, 95% CI: 1.10-1.52, $p = 0.021$). Patients with AF had higher odds of experiencing a clinical stroke (OR = 1.89, 95% CI: 1.19-3.00, $p = 0.073$) and developing acute kidney injury (AKI) (OR = 1.28, 95% CI: 1.17-1.40, $p < 0.0001$). Longer hospital stays (mean difference = 0.93 d, 95% CI: 0.37-1.49, $p = 0.0011$) and higher total hospital charges (mean difference = $11,845, 95% CI: $4,673-$19,017, $p < 0.0001$) were observed for patients with AF. No significant differences were found in the odds of blood transfusion and transient ischemic attack. Among patients with AH and AF, 33.5% had cirrhosis (n = 9,075). Cirrhosis was associated with higher risk of death (OR: 2.52, $p < 0.0001$) and blood transfusion (OR: 2.89, $p < 0.0001$), lower odds of stroke (OR: 0.36, $p = 0.0076$), higher odds of kidney injury (OR: 1.64, $p < 0.0001$), longer stay (mean difference: 1.40 d, $p < 0.0001$), and higher charges (mean difference: $21,528, $p < 0.0001$). **Conclusion:** Patients with AH and AF have elevated risks of in-hospital mortality, stroke, AKI, prolonged hospitalization and increased healthcare costs. The presence of underlying cirrhosis exacerbates these adverse outcomes. Appropriate management of AH and AF, especially in cirrhotic population, is essential for optimizing outcomes.

3564-C | IMPACT OF BARIATRIC SURGERY ON SEVERITY AND OUTCOMES IN ACUTE ALCOHOLIC HEPATITIS

Marcus Allen Healey[1], Geetha Ramalingam[1], Yiwei Hang[1], Ekaterina Smirnova[2], Amon Asgharpour[3], Vaishali Patel[4], Hannah Lee[4], Velimir A. Luketic[2], Scott C. Matherly[4], Mohammad S. Siddiqui[4], Joel P. Wedd[4], Arun Sanyal[5] and Richard K. Sterling[4], (1)VCU Health, (2)Virginia Commonwealth University, Richmond, VA, (3)Virginia Commonwealth University, (4)Virginia Commonwealth University Health System, (5)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Bariatric surgery (BS) is increasingly used to treat morbid obesity and is associated with higher incidence of alcohol use disorder (AUD) and acute alcoholic hepatitis (AAH). However, whether BS causes more severe presentations of AAH is less well-defined. Our aim is to compare the severity of AAH among hospitalized patients to contemporaneous matched controls from the same time period. **Methods:** Retrospective chart review of 35 hospitalized patients with AAH and prior BS and age, gender, and BMI matched (2:1) controls from 2012-2019 was performed. All values were obtained on date of index admission, except for Model for End-Stage Liver Disease (MELD) recorded both at admission and upon discharge. Demographics were obtained including age, race, sex, ethnicity, weight, and body mass index (BMI). Laboratory markers were obtained and included aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin (TB), international normalized ratio (INR), prothrombin time (PT), albumin and creatinine (Cr). Steroid administration and thirty-day (30-d) survival were compared. To define severity of AAH, both Maddrey's Discriminant Function (MDF) and MELD were calculated. **Results:** Of the BS cohort, 25/35 had Roux-en-Y performed. The demographic and clinical characteristics of BS patients and 76 controls are found in Table 1. Among laboratory parameters, those with history of BS had higher TB, PT, INR, and Cr. However, only the TB ($p = 0.017$) and albumin ($p = 0.0001$) were significantly different. Patients with BS were found to have more severe AAH when using MDF to define severity ($p = 0.026$) at all ranges of control PT values (12, 13.5, 14.8). However, when using MELD on admission and discharge, the severity of AAH between those with and without BS was not statistically significant ($p = 0.380$ and $p = 0.923$, respectively). While steroid administration was higher in the BS group ($p = 0.03$), adjusted 30-d survival was not different between those with and without BS ($p = 0.075$). **Conclusion:** Our study shows that compared to matched controls, the severity of AAH in those with prior BS is increased when using MDF, but not when using MELD. While those with BS were more likely to receive steroids for AAH due to higher MDF (due to higher TB), they had similar MELD and 30-d survival. Thus, future research into the role of these tests in AAH is needed to define the primary score to elucidate severity and pathogenesis in this unique population.

3565-C | IMPACT OF CHRONIC ETHANOL CONSUMPTION AND SARS-COV-2 ON THE GUT-LIVER AXIS IN MICE: A PILOT DOSE-RESPONSE STUDY

Smita Ghare[1], Dennis Warner[1], Josiah Hardesty[1], Jeffrey Warner[1], Paula Chilton[1], Jiyeon Lee[1], Jingwen Zhang[1], Lihua Zhang[1], Min Wan[1], Jon Gabbard[1], Charles Anderson[1], Lalit Batra[1], Chithra Sreenivasan[1], Jennifer Kraenzle[1], Matthew McCulley[1], Stephanie McCoy[1], Dibson Dibe Gondim[1], Shirish Barve[1], Wenke Feng[1], Jian Zheng[1], Kenneth Palmer[1], Craig J. McClain[1,2] and Irina A. Kirpich[1], (1)University of Louisville, Louisville, KY, (2)Robley Rex VAMC

Background: During the COVID-19 pandemic, there was a marked increase in alcohol consumption. COVID-19 superimposed on underlying liver disease notably worsens the outcome of many forms of liver injury. The goal of this study was to examine the impact/potential mechanistic interactions of ethanol (EtOH) and COVID-19 on the gut-liver axis in an experimental alcohol-associated liver disease. **Methods:** After 5 weeks of EtOH feeding, C57BL/6 male mice received SARS-CoV-2 (SARS2-N501Y$_{MA30}$) intranasally at 3x10^2, 10^3, 3x10^3, and 3x10^4 plaque-forming units (PFU). Mice were then weighed/monitored daily for morbidity/mortality for 12 days while continuing EtOH consumption. Liver injury, intestinal barrier integrity, and systemic inflammation were evaluated. The study was conducted within a Biosafety Level 3 facility. **Results:** A similar gradual weight loss was observed in all inoculated mice (slightly less in the 3x10^2 group) up to post infection day 4 (Fig. 1A). Greater mortality was observed in mice receiving the highest viral dose at days 3 and 4 post infection (20% and 26%, respectively. Fig. 1B). There was variable mortality in mice inoculated with 3x10^3 and 10^3 PFU (22% and 5% at day 4, respectively). Most mice in these groups were euthanized at day 5 due to 25% loss of weight. There was no mortality in mice receiving the lowest dose, and these mice were euthanized at day 11-12 post infection. Analysis of liver health revealed no significant changes in hepatic steatosis and a limited increase in plasma ALT levels at all viral doses *vs.* EtOH alone. However, there was an increase in TUNEL$^+$ and CAE$^+$ cells (markers of hepatocyte death and neutrophil infiltration) in livers in all but the lowest dose. Further, the highest viral dose elevated hepatic mRNA levels of several pro-inflammatory cytokines and markers of ER stress (e.g., *Il-6*, *Tnf-α* and *Atf3,* respectively). In addition, compared to EtOH alone, EtOH+SARS2-N501Y$_{MA30}$ decreased plasma IL-22 and IL-10 with the lowest levels in mice with the highest viral challenge. Lastly, in EtOH fed mice, the highest viral dose lowered expression of intestinal tight junction proteins, *Zo1*, *Cldn-5* and *Ocln*, and the antimicrobial protein *Cramp1*. **Conclusion:** We developed a unique animal model of SARS-CoV-2 and chronic EtOH consumption. This pilot study suggests that early mortality observed after high dose SARS-CoV-2 challenge could be due in part to hepatic and intestinal damage/dysfunction following chronic EtOH feeding.

f 3566-C | IMPACT OF THE COVID-19 PANDEMIC ON TEMPORAL TRENDS IN ALCOHOL-RELATED AND NON-ALCOHOL-RELATED CIRRHOSIS HOSPITALIZATIONS: A CANADIAN POPULATION-BASED STUDY.

Liam Andrew Swain[1], Jenny Godley[1], Juan G. Abraldes[2], Mayur Brahmania[3] and Abdel-Aziz Shaheen[3], (1)University of Calgary, (2)University of Alberta, AB, Canada, (3)Cumming School of Medicine, University of Calgary, Calgary, AB, Canada

Background: Few studies have examined the impact of the COVID-19 pandemic on hospitalization rates for alcohol - (AC) and non-alcohol-related cirrhosis (NAC) separately in relation to age and sex. We aimed to examine sex and age stratified temporal changes in AC and NAC hospitalizations before the pandemic (2008-19) and during the pandemic (2020-21) in Alberta, Canada. **Methods:** We used validated international classification of diseases 10th revision (ICD-10) administrative case definitions to select all adult (≥20 y) AC and NAC hospitalizations from the Discharge Abstract Database (DAD) from April 2008 to March 2021. AC was defined as admissions coded with either the AC ICD-10 code alone, or both an alcohol use disorder (AUD) and decompensated cirrhosis-related condition code together. NAC was defined as admissions with either a NAC or a decompensated cirrhosis-related condition ICD-10 code, excluding all AC, alcohol-related hepatitis (AH), and AUD codes. Age and sex standardized hospitalization rates/100,000 population were calculated using the 2016 Canada Census population estimates for Canada and Alberta. Temporal trends in yearly AC and NAC hospitalization rates were assessed using Joinpoint analysis and annual percent change (APC) stratified according to sex (male/female) and age groups (20-34, 35-49, 50-64, 65+ years). **Results:** We identified 28,884 AC (66% male; median age 55 y) and 40,026 NAC hospitalizations (54% male; median age 64 y) during our study period. Annual AC sex-stratified hospitalizations rates (Fig. 1A) decreased for men from 2015-19 (APC -4%; 95% confidence interval [CI], -7 to -2), and plateaued during the pandemic (2019-21), whereas rates in women were not affected by the pandemic, remaining stable from 2010-21. Age-stratification (Fig. 1B) showed a significant decrease in AC hospitalization rates for the 50-64 age group from 2015-21 (APC -2%; CI, -7 to -0.5]) that was not altered by the pandemic. However, in the 20-34 age group, AC hospitalization rates increased during the pandemic (2019-21; APC 28%; CI, 12-42). AC hospitalization rates remained stable for the 35-49 and ≥65 age groups after 2010 and 2014 respectively, and were not affected by the pandemic. Sex-stratified NAC hospitalization rates (Fig. 1C) were not affected by the pandemic and remained stable in women from 2011-21 but increased in men from 2010-21 (APC 2%; CI 1-3). Age-stratification showed NAC hospitalization rates (Fig. 1D) were not impacted by the pandemic but increased in those ≥65 years from 2010-21 (APC 3%; CI, 1-4), and remained stable for all other age groups from 2011-21. **Conclusion:** AC hospitalization rates among younger patients and men increased during the pandemic. NAC hospitalization rates have steadily increased particularly in men and older patients with no impact of the pandemic on their trajectories.

3567-C | IMPAIRED CHAPERONE-MEDIATED AUTOPHAGY CONTRIBUTES TO HEPATIC LIPID DROPLET ACCUMULATION IN ALCOHOL-FED RODENTS

Paul Thomes[1], Rujani Mahmud[1], Terrence M. Donohue[1], Mark A. McNiven[2] and Carol A. Casey[1], (1) University of Nebraska Medical Center, (2)Mayo Clinic

Background: Alcohol-induced fatty liver disease is characterized by the accumulation of lipid droplets (LDs) in liver cells, impairing their normal function. Autophagy, a cellular recycling process, plays a crucial role in eliminating LDs from cells, with lysosomes serving as the final destination. In this study, we investigated the impact of chronic ethanol (EtOH) feeding on chaperone-mediated autophagy (CMA) and its association with hepatic LD accumulation. **Methods:** Mice and rats were subjected to either chronic binge EtOH or chronic EtOH feeding, while EtOH-metabolizing VA-13 cells were used for *in vitro* experiments **Results:** Hepatocytes from EtOH-fed rats displayed significantly larger LDs compared to controls. Immunostaining revealed the close association of LDs with LAMP2A, a marker of CMA-positive lysosomes, and HSC-70, an essential chaperone for CMA cargo targeting. Immunoblotting analysis showed a 1.5-fold decrease in hepatic LAMP2A levels in chronic binge EtOH-fed mice, concomitant with a 2.5-fold increase in hepatic triglycerides and a 7-fold elevation in serum ALT levels. Importantly, purified lysosomes from chronic EtOH-fed mice exhibited a 20% reduction in the ability to degrade exogenously added CMA substrate ribonuclease *in vitro*. Notably, treating EtOH-metabolizing VA-13 cells with the CMA activating agent AR7 resulted in a 1.6-fold induction of cathepsin B activity and a 2-fold increase in lysosomal acid lipase activity compared to untreated cells, accompanied by a reduction in LD staining. **Conclusion:** Collectively, our findings demonstrate that CMA-positive lysosomes and associated chaperones play a crucial role in targeting LDs for degradation. However, chronic EtOH feeding compromises the lysosomes' capacity to perform CMA, leading to the intracellular accumulation of LDs and consequent fatty liver development. Notably, selectively activating CMA with pharmacological agents such as AR7 shows promise in alleviating EtOH-induced fatty liver.

Background: Acute kidney injury (AKI) is associated with poor survival in severe alcohol-associated hepatitis (sAH) patients. Clinical characteristics of AKI have not been well-characterized in sAH treated with IL-1β antagonist anakinra+zinc (AZ) in comparison to prednisone (pred). Therefore, we aimed to compare the incidence, staging, and phenotype of AKI between AZ and pred-treated patients. **Methods:** 147 patients in a multicenter clinical trial for sAH comparing AZ and pred were analyzed. AKI and its stages were defined by Kidney Disease Improving Global Outcomes consensus definitions. AKI phenotypes (pre-renal, acute tubular necrosis, hepatorenal syndrome) were determined by two blinded adjudicators and a tiebreaker in case of disagreements. Baseline characteristics between patients who did/did not develop AKI in the two treatment arms were compared. Urinary kidney injury markers [KIM1, IL18, NGAL, and LFABP) were also compared between treatment arms at days 0, 7, 14, and 28. **Results:** No patients had AKI at baseline and 33% (n = 49) developed AKI. AZ-treated patients had significantly higher rates of AKI development compared to pred-treated patients, 45% (n = 33) vs. 22% (n = 16), p = 0.004. Baseline characteristics in patients who did/did not develop AKI in each treatment arm are shown in the Table. Patients who did/did not develop AKI in each treatment arm had similar baseline MELD (p = 0.168) and Maddrey Discriminant scores (p = 0.523), and had similar baseline creatinine (p = 0.431). Compared to pred-treated patients, AZ-treated patients had more severe AKI stages at diagnosis [stage 2/3 n = 21 (64%) vs. n = 5 (31%), p = 0.033] and at peak [stage 2/3 n = 29 (88%) vs. n = 9 (56%), p = 0.025]. The frequency of AKI phenotypes was similar between the two treatment arms (p = 0.515), with acute tubular necrosis being the most common phenotype (42% AZ vs. 38% pred) followed by pre-renal (15% AZ vs. 31% pred). AZ-treated patients who developed AKI had significantly higher Day 7 urinary NGAL levels compared to patients without AKI in both treatment arms (p = 0.015) but was similar to pred-treated patients with AKI (p = 0.071). There were no significant differences between each treatment arm for NGAL on Days 0, 14, and 28. Similarly, there were no significant differences between treatment arms for KIM1, IL18, and LFABP on days 0, 7, 14, and 28. **Conclusion:** AKI was a common complication in sAH patients treated with pred or AZ but occurred more frequently and was more severe in AZ-treated patients. Further studies are needed to understand the mechanisms driving AKI development in sAH, as further insight may help with future treatment/prevention of AKI in sAH.

Table: Comparisons of Baseline Patient Characteristics Stratified by AKI development in Each Treatment Arm.

Baseline Patient Characteristics	Prednisone (n=73)		Anakinra/Zinc (n=74)		P-value
	AKI N=16	No-AKI N=57	AKI N=33	No-AKI N=41	
Age	46.6 ± 12.3	44.4 ± 10.0	44.4 ± 9.3	44.6 ± 9.4	0.884

3569-C | INTERACTION OF CHRONIC AND HEAVY DRINKING, NUTRITION, AND PROGRESSION OF LIVER INJURY ENHANCES THE MORTALITY RISK IN ALCOHOL-ASSOCIATED HEPATITIS

Aishwarya Thakurdesai, Amor J. Royer, Qian Xu, Thwisha Joshi, Luis S. Marsano, Maiying Kong and Vatsalya Vatsalya, University of Louisville, Louisville, KY

Background: Among the patients with alcohol use disorder (AUD), 20-30% eventually develop alcohol-associated liver disease (ALD). Alcohol-associated hepatitis (AH) is an acute inflammatory form of ALD with rapid progression of liver pathology resulting in high mortality. "Age-Bilirubin-INR-Creatinine" (ABIC) is a static mortality algorithm used to predict survival in AH. The role of chronic and heavy drinking and nutrition in the progression of liver injury and mortality is understudied. We evaluated the role of chronic and heavy drinking and clinical presentation in the risk of mortality in AH. **Methods:** 61 male and female adult patients were grouped by MELD (Model for End-Stage Liver Disease), as non-severe (nSAH as Gr.1, MELD < 20, $n = 26$), and severe (SAH as Gr.2, MELD ≥ 20, $n = 35$). Within each group, patients were sub-divided by ABIC grading into low (Unit < 6.71, $n = 10$ [Gr.1], $n = 6$ [Gr.2]), intermediate ($6.71 \geq$ unit $<$ 9, $n = 16$[Gr.1], $n = 20$[Gr.2]), and high (Unit > 9, $n = 9$ [Gr.2]) risk of 90-day mortality. Demographic, Nutritional status (CONUT [Controlling Nutritional Status] score), chronic (LTDH, Lifetime Drinking History [years]) and one-year drinking (AUDIT, Alcohol Use Disorders Identification Test), laboratory values (CMP [Complete Metabolic Panel], CBC [Complete Blood Count], etc.), and clinical presentation (MELD, Maddrey DF, CTP, Lille, AST:ALT [Aspartate transaminase: Alanine transaminase] ratio) were assessed. **Results:** Eight females and 18 males were in Gr.1, while Gr.2 had 13 females and 22 males. AH patients with increasingly worse prognosis (low survivability) corresponded to increasing age in both groups (Table 1). ABIC score showed positive correlation with LTDH ($r = 0.538$, $p = 0.004$); this effect was exhibited primarily in SAH ($r = 0.554$, $p = 0.011$).

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Low-risk SAH patients exhibited the highest clinically significant indicator of liver injury progression (AST: ALT) and lowest LTDH. In SAH, AST:ALT was significantly associated at high effect ($R^2 = 0.539$, $p = 0.031$) with LTDH, AUDIT and CONUT in a multivariable regression model. In SAH with intermediate risk of mortality, AST:ALT was influenced by CONUT and LTDH at a high significant effect ($R^2 = 0.657$, $p = 0.017$). **Conclusion:** SAH exhibits rapid liver injury progression when mortality risk is still low. The interplay of chronic and recent heavy drinking, and nutrition has a pivotal role in liver injury severity in SAH. Engaging checkpoint assessments for chronic and heavy drinking and nutritional status can help strategize preemptive medical management in SAH patients at high mortality risk.

Table 1. Demographics, Drinking patterns and Nutritional parameters, Laboratory and Clinical markers, Liver Disease Severity and Survival/Prognostic indices in Alcohol-associated Hepatitis.

Measures	Group 1 (Non-severe AH, MELD < 20)			Group 2 (Severe AH, MELD >/= 20)				Between group p-value
	Low risk (ABIC<6.71) (n=10; 16.40%)	Moderate risk (ABIC 6.71 to <9) (n=16; 26.23%)	Total (n=26; 42.62%)	Low risk (ABIC<6.71) (n=6; 9.84%)	Moderate risk (ABIC 6.71 to <9) (n=20; 32.79%)	High risk (ABIC>/=9) (n=9; 14.75%)	Total (n=35; 57.38%)

3570-C | LIVER SPECIFIC GLOMERULAR FILTRATION RATE EQUATIONS PROVIDE MODEST IMPROVEMENT IN 28-DAY OUTCOME PREDICTION IN ALCOHOL-ASSOCIATED HEPATITIS

Lankai Cathy Xu[1], Shivani Shah[1], Alex Miller[1], Shahid M. Malik[2] and Vikrant Rachakonda[1], (1)University of California Davis, Sacramento, CA, (2)University of Pittsburgh, Pittsburgh, PA

Background: MELD is commonly used to determine disease severity and mortality risk in alcohol-associated hepatitis (AH). AH patients often demonstrate elevated serum bilirubin, and hyperbilirubinemia can interfere with serum creatinine (sCr) assays. In addition, sCr is related to muscle mass and may misclassify glomerular filtration rate (GFR) due to gender differences in body composition. Aims: 1) to compare the performance of generalized and liver-specific GFR models in patients with AH, and 2) assess GFR-based liver disease models for outcome prediction in AH. **Methods:** this was a retrospective study of patients hospitalized with probable or definite AH from January 2016 to March 2020 at the University of Pittsburgh Medical Center ($N = 205$) and University of California Davis ($N = 181$). Clinical, demographic and laboratory data were obtained at admission. GFR was assessed using general models including Chronic Kidney Disease Epidemiology (CKD-EPI), modification of diet in renal disease-4 (MDRD-4), and European Kidney Function Consortium (EKFC) equations as well as liver-specific models including Royal Free Hospital (RFH) and GFR assessment in liver disease (GRAIL) equations. AUROC analysis was used to compare performance of GFR-based liver function models (GRAIL-MELD, GEMA) and MELD for predicting 28-day survival. **Results:** 174 (55.6%) women and 212 (44.4%) men were included. In patients with bilirubin < 20 mg/dl, GFR estimated by GRAIL was consistently greater than GFR estimated by other models, while estimated GFR were similar between models for bilirubin ≥ 20 mg/dl. In patients with sCr < 1.5 mg/dl, sCr [0.86 (IQR 0.70 – 1.01 mg/dl vs 0.70 (0.54-0.90) mg/dl, $p = 0.001$] and GFR by GRAIL [112.3 (IQR 98.5 – 129.5 ml/min/1.73m^2) vs 106.6 (91.6-123.5 ml/min/1.73m^2, $p = 0.0359$] were higher in men, while all other models demonstrated no significant gender differences in GFR. In patients with sCr ≥ 1.5 mg/dl, there were no significant gender differences in GFR or sCr. MELD was increased in men compared to women [24 (19-31) vs. 22 (19-27), $p = 0.011$], but there were no significant gender differences in MELD-GRAIL [22 (17-28) vs 20 (17-26), $p = 0.1166$] or GEMA [22 (17-28) – 19 (16-26), $p = 0.0673$]. In the whole patient population, MELD-GRAIL demonstrated slightly higher accuracy compared to MELD and GEMA for 28-day survival [0.813 (95% CI 0.759 – 0.867) vs 0.781 (0.721 – 0.842) vs 0.786 (0.724-0.847),

p = 0.042] with sensitivity of 0.81 and specificity 0.72 at an optimal cutoff of 24. In women, there were no significant differences in model accuracy. In men, MELD-GRAIL demonstrated a trend toward greater accuracy compared to MELD and GEMA [0.826 (95% CI 0.758 – 0.895) vs 0.792 (0.717 – 0.867) vs.0.792 (0.713 – 0.871), p = 0.071]. **Conclusion:** GFR models vary widely with serum bilirubin levels. MELD-GRAIL and GEMA models exhibit reduced gender variation, and MELD-GRAIL exhibits slightly increased accuracy for 28-day mortality in AH.

3571-C | LIVER TRANSPLANT ACTIVITY FOR ALCOHOL-ASSOCIATED HEPATITIS AFTER OPTN DIAGNOSIS UPDATES

Nakia L. Chung, Stanford Health, Scott W. Biggins, University of Washington, Seattle, WA and Allison J. Kwong, Stanford University School of Medicine

Background: Diagnosis codes for alcohol-associated liver disease (ALD) and specifically alcohol-associated hepatitis (AH) in the OPTN registry have been inconsistent, with only an estimated 35% of patients being correctly designated as AH. In response, the OPTN proposed to update the alcohol-related diagnoses to allow for more accurate and complete data collection regarding ALD transplant activity in the United States. This policy was implemented on August 30, 2022. We analyze temporal trends in diagnosis reporting for ALD, including AH, comparing the 6 months before and after this policy change. **Methods:** We reviewed new adult registrations and transplants in the OPTN registry from 3/1/2022 to 2/28/2023. On 8/30/2022, the diagnosis code for "Acute alcoholic hepatitis" [AH] (4217) was replaced by "Acute alcohol-associated hepatitis with or without cirrhosis" [AHWWOC] (4218) . In parallel, the diagnosis code for "Alcoholic cirrhosis" [AC] (4215) was replaced by "Alcohol associated cirrhosis without acute alcohol associated hepatitis" (4219). We evaluated national trends in listings and transplants with a primary diagnosis of ALD based on these diagnosis codes. **Results:** There were 12,825 new registrations, of which 460 (3.6%) were for AH and 4430 (34.5%) were for AC. Before the diagnosis update, 5.1% of listings for ALD were classified as AH (4217), compared to 13.5% as AHWWOC (4218) after the update (Figure A). Patients listed under the new diagnosis code for AH had a lower MELD score at listing (37 v 32, p < 0.01), were older (46 v 41 y, p < 0.01), and were less likely to be white (71.0% v. 77.7%, p = 0.047) compared to the previous diagnosis code for AH. Using the new diagnosis codes, patients with AH had higher MELD (32 v 24, p < 0.01), were younger (46 v 54, p < 0.01), and were more likely to be privately insured (60.8% v 54.4%, p = 0.004) compared to those with AC. There were 9,176 transplants, 366 (4.0%) for AH and 2948 (32.1%) for AC — 4.6% of transplants for ALD were classified as AH (4217), compared to 14.9% as AHWWOC (4218) (Figure B). Using the new diagnosis codes, AH transplants used younger donors (36 v 40 y, p = 0.02) and were less likely to use DCD donors (4.2% v 10.5%, p = 0.001) compared to AC transplants. **Conclusion:** We observed a 3-fold increase in reported AH cases after update to the OPTN diagnosis codes for ALD, with greater representation of older and non-white populations. AH patients appear distinct from the general ALD population in terms of candidate selection as well as the donors they receive. Wider education regarding the appropriate use of diagnosis codes and standardized disease definitions will contribute to a more complete and accurate national registry database and enhance future analyses.

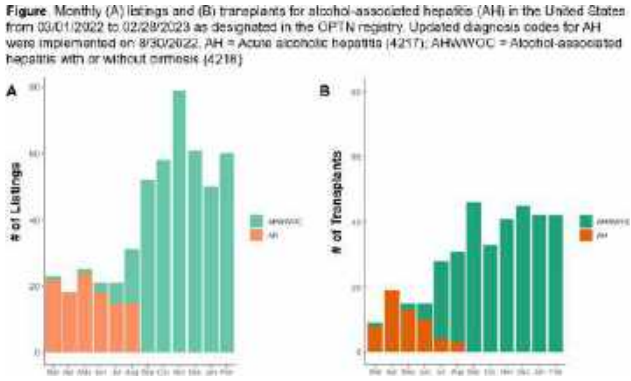

Figure. Monthly (A) listings and (B) transplants for alcohol-associated hepatitis (AH) in the United States from 03/01/2022 to 02/28/2023 as designated in the OPTN registry. Updated diagnosis codes for AH were implemented on 8/30/2022. AH = Acute alcoholic hepatitis (4217); AHWWOC = Alcohol-associated hepatitis with or without cirrhosis (4218)

3572-C | LIVER VOLUME PREDICTS MORTALITY IN ALCOHOL ASSOCIATED LIVER DISEASE

Richie Manikat, Weiyu Wu, Paul Yien Kwo, Nishita Kothary, Akshay Chaudhari and Allison J. Kwong, Stanford University School of Medicine

Background: Alcohol-associated liver disease (ALD) presents as a spectrum, ranging from fatty liver to decompensation with jaundice and advanced cirrhosis. Steatosis, hepatocellular injury, and inflammation may be reflected on cross-sectional imaging as diffuse enlargement of the liver, and progression of ALD, and over time may result in parenchymal atrophy with fibrosis and cirrhosis. The evidence linking radiological parameters such as liver volume with outcomes in ALD is limited. We hypothesized that increased liver volume in patients

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

presenting with decompensated ALD could reflect hepatic reserve and predict survival. **Methods:** We identified patients hospitalized at our center between 2018 and 2022 who had decompensated ALD and alcohol use within the past 6 months and included those who had CT imaging performed during the index admission. Liver volumes were obtained using manual segmentation. A linear regression was used to assess the relationship between liver volume and anthropometric variables, as well as time since last alcohol use. We used multivariable Cox regression analysis to evaluate the association between liver volume and 1-year transplant-free survival, adjusted for the MELD-Na score. **Results:** There were 136 patients with a median age of 44 years (IQR 38-52), median BMI of 29.2 (IQR 24.9-33.6), and median MELD-Na of 32 (IQR 25-38). Forty-nine patients (36%) were transplanted, 46 patients (34%) died, and 41 patients (30%) were alive at the end of follow-up. The median liver volume was 2216 cm^3 (IQR 1481-3124). Increased weight was associated with increased liver volume, whereas sex, height, and time since last alcohol use were not. A standardized metric of liver-body weight ratio was used to predict outcome, with increased liver-body weight ratio being predictive of transplant-free survival in a bivariate model adjusted for MELD-Na (HR 0.96, 95% CI 0.94-0.98). A liver-body weight ratio < 2% was associated with an increased risk of death, with a 1-year transplant-free survival of 26.3% at 1 year p = 0.016 (Figure). **Conclusion:** Opportunistic CT measurements of imaging done for other clinical purposes may provide valuable prognostic information. In this high-MELD population with ALD, greater liver volume was predictive of transplant-free survival independent of MELD-Na. Volumetric measurements of the liver may be used to risk stratify patients with decompensated ALD and identify those with the potential for hepatic recovery without liver transplantation. Automated segmentation of liver imaging may enable more widespread use of liver volume as a clinical predictor in ALD.

Figure. Kaplan-Meier survival curve for 1-year mortality, stratified by liver-body weight (LBW) ratio, with censoring for liver transplantation.

f 3573-C | LONG NONCODING RNA H19 MEDIATES ALCOHOL-ASSOCIATED LIVER DISEASE THROUGH ITS BINDING TO PTBP1 RESULTING IN AN ALTERNATIVE SPLICING OF BHMT AND DYSREGULATION OF METHIONINE METABOLISM

Zhihong Yang[1], Jing Ma[1], Nazmul Huda[1], Yanchao Jiang[1], Hui Gao[1] and Suthat Liangpunsakul[2,3], (1) Division of Gastroenterology and Hepatology, Department of Medicine, Indiana University School of Medicine, Indianapolis, in, (2)Division of Gastroenterology and Hepatology, Department of Medicine, Indiana University School of Medicine, Indianapolis, IN, (3)Roudebush Veterans Administration Medical Center, Indianapolis, in

Background: Alcohol-associated liver disease (ALD) is a prevalent liver disorder with no effective treatment. LncRNA H19 (H19), a paternal imprinted lncRNA with its expression only in maternal allele, has been implicated in various diseases. However, its role in ALD pathogenesis remains elusive. We conducted a translational study to explore the mechanism of H19 in ALD pathogenesis. **Methods**: H19 levels were examined in liver tissues from healthy controls (HC, n = 21), alcoholic hepatitis (AH,n = 5), and alcoholic cirrhosis (AC,n = 32) patients. For mechanistic studies, H19 maternal specific knock out ($H19^{Mat+/-}$) and overly expressed hepatic H19 ($H19^{Hep-OE}$, using AAV8, with a liver specific TBG promoter) mice were used for the gain or loss of function studies. Mice were subjected to chronic plus binge ethanol feeding model. **Results**: Hepatic H19 level was significantly increased in patients with AH and AC compared to HC. In chronic plus binge alcohol feeding model, hepatic H19 level was highly increased in ethanol-fed mice. Overexpression of hepatic *H19* worsened alcohol-induced steatosis and promoted liver injury with significant increase in serum transaminase. Alcohol-induced steatosis and liver injury were ameliorated in ethanol-fed $H19^{Mat+/-}$ mice. To dissect the mechanism, we performed the metabolomic analysis and found a significant reduction of hepatic methionine in $H19^{Hep-OE}$ mice. We examined each enzyme involving in methionine metabolism and found a marked reduction in betaine-homocysteine methyltransferase (BHMT) expression, a key enzyme in converting betaine and homocysteine to methionine. LncRNAs regulate coding genes by its interaction with specific protein. Using an RNA pull-down with biotin-

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

labeled H19, we found an interaction between H19 and PTBP1, an RNA-binding protein regulating alternative splicing. Intriguingly, the interaction of H19-PTBP1 led to an increase in the splice variant, Bhmt202, which lacks protein coding ability and a decrease in BHMT protein coding isoform, Bhmt201, causing a reduction in BHMT protein and methionine level (See Fig. 1). The restoration of hepatic BHMT using AAV-BHMT ameliorated alcohol-induced liver injury in *H19^{Hep-OE}* mice. **Conclusion**: H19-PTBP1 mediates alternative splicing of BHMT, leading to an increase in the splice variant with limited protein coding ability, a reduction in hepatic methionine, and alcohol-induced liver injury. H19-PTBP1-BHMT axis is a potential therapeutic target for ALD.

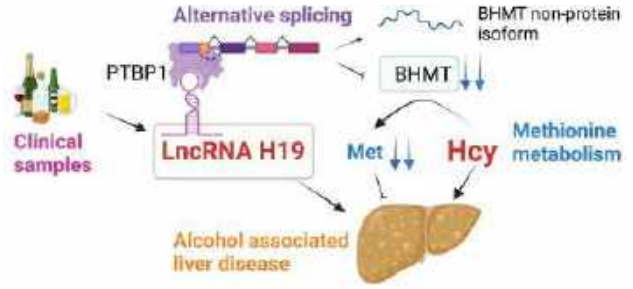

Figure 1: A schematic diagram represents the molecular mechanism of the long non-coding RNA (lncRNA) H19 in regulating alcohol-associated liver disease (ALD). Alcohol intake triggers an upregulation of H19 expression. H19 interacts with PTBP1, resulting in the disruption of alternative splicing of BHMT, a key enzyme in methionine metabolism. This disruption leads to an increase in the non-protein isoform of BHMT and an inhibition of the BHMT protein isoform, leading to a decline in methionine (Met) levels and alcohol-induced liver injury. H19-PTBP1-BHMT axis is a potential therapeutic target for ALD.

3574-C | METABOLIC PERTURBATION IN ALCOHOLIC FATTY LIVER PRIMES HEPATOCYTE INJURY THROUGH DISCORDANT TRANSMISSION OF TRANSCRIPTOME ALTERATIONS TO PROTEOME

Go Sugahara[1,2], Meng Li[3], Hayato Muranaka[4], Yuji Ishida[1,2], Jae-Jin Lee[5], Hyungjin Eoh[5], Chise Tateno[6], Z. Gordon Gordon Jiang[7] and Takeshi Saito[5], (1) Medicine, Division of Gastrointestinal and Liver Diseases, Keck School of Medicine, University of Southern California, (2)R&D, Phoenixbio Co., Ltd., (3) USC Libraries Bioinformatics Service, University of Southern California, (4)Medicine, Cedars-Sinai Medical Center, (5)Molecular Microbiology and Immunology, Keck School of Medicine, University of Southern California, (6)Phoenixbio Co., Ltd., (7)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Background: Alcohol fatty liver (AFL) and nonalcoholic fatty liver (NAFL), the initial stages of alcoholic and nonalcoholic fatty liver disease, respectively, serve as the prerequisites for disease progression to their advanced stages. ALF and NAFL are histologically identical, share genetic risk factors, and are distinguished solely by clinical context. Thus, it remains undefined whether they represent distinctive or shared pathophysiology, the elucidation of which entails a physiological, human-relevant study model. **Methods:** Human hepatocytes (HH), either primary or humanized liver chimeric mice (HLCM)- derived, were cultured for 7 days in medium containing DMSO and other hepatocyte-specific supplements to facilitate recovery from cellular stress triggered by the procurement process and to maintain the cell fate of matured hepatocyte. The HH were then treated for 7 days with either ethanol or free fatty acid-sugar cocktail to establish in vitro models of AFL and NAFL, during which time DMSO was replaced with DMSO2 due to its potent inhibitory effect on multitude of hepatic functions. HH of AFL and NAFL were applied for mRNA-seq, ribosome profiling, and quantitative proteomics to decipher the dynamics between the transcriptome, translatome, and proteome. The results obtained with in vitro studies were validated through in vivo experiments with HLCM. **Results:** In vitro cultured HH metabolized alcohol at a rate equivalent to those in the human liver. Moreover, HH treated with alcohol, or a free fatty acid-sugar cocktail developed a comparable level of macrovesicular steatosis. Despite the identical cellular morphology, the mRNA-seq analysis revealed substantial differences in the number and type of differentially expressed genes, with a small proportion of genes exhibiting overlap. Furthermore, polysome profiling studies demonstrated a significant dissociation of ribosomes from mRNAs in AFL-HH but not with NAFL, indicating that the metabolic stress in AFL induces global translatome suppression. Subsequent studies showed that the translatome inhibition is largely due to a defect in translation elongation rather than translation initiation. We also found that translatome inefficiency contributes to the development of cell toxicity. **Conclusion:** Our work revealed a marked inhibition of translatome and consequential discordance between transcriptome and proteome in HH of AFL, revealing a previously unrecognized mechanism of cell toxicity in alcoholic liver disease.

f 3575-C | N3 PUFA SUPPLEMENTATION ATTENUATES ENDOTOXEMIA AND LIVER INJURY IN EARLY STAGE OF ALCOHOL-ASSOCIATED LIVER DISEASE

Alison Floyd[1], Jeffrey Warner[1], Josiah Hardesty[1], Dennis Warner[1], Joe Hibbeln[2], Craig J. McClain[1] and Irina A. Kirpich[1], (1)University of Louisville, Louisville, KY, (2)Nih/NIAAA

Background: Early-stage alcohol-associated liver disease (ES-ALD) is often defined as an elevated ALT level in the setting of heavy drinking. We and others have reported that ~35-60% of heavy drinking patients with alcohol use disorder (AUD) in alcohol treatment programs have elevated liver enzymes and ES-ALD. ALD pathogenesis is influenced by multiple factors including dietary fatty acids. Preclinical studies in mice showed that n3 PUFA supplementation or endogenous increase in n3 PUFAs attenuated experimental ALD. The goal of the current study was to examine the effects of n3 PUFA supplementation on liver injury and intestinal permeability in a human population of heavy drinking individual's. **Methods:** Individual's with AUD were admitted to an NIH inpatient treatment program for 21 days. At discharge, subjects were randomized to either 2 g/day of n3 PUFAs (EPA+DHA, n = 46) or placebo (n = 48) for 12 weeks. The cerebrospinal fluid (CSF) fatty acid profile, plasma markers of liver injury (ALT, AST, and GGT) and endotoxemia were evaluated at randomization (baseline = hospital discharge) and at the conclusion of the study. Significant differences were determined by paired Student's *t* test ($p < 0.05$). **Results:** The targeted lipidomic analysis revealed that 12-week n3 PUFA supplementation resulted in significant increase in CSF n3 PUFAs EPA and DHA, which was not a case in a placebo group (Fig. 1A-B), suggesting the adherence of the study participants to the treatment protocol. Compared to placebo, n3 PUFA supplementation was associated with a substantial reduction in ALT, GGT but not AST levels among the whole patient cohort (Fig.1-C-D). In those patients (37%) who had ES-ALD at the time of randomization (based on ALT > 40 U/L), n3 PUFA supplementation was associated with a significant reduction in all three enzymes, ALT, AST and GGT. As an indirect marker of intestinal permeability, endotoxin levels were unchanged in the n3 PUFA supplemented group over the course of the study, but there was a significant increase in the placebo arm. There was a greater return to drinking in the placebo arm, which could have influenced both liver injury and endotoxemia. **Conclusion:** Our data suggested that n3 PUFA supplementation in heavy drinking individual's had beneficial effects on liver injury and endotoxemia. Further investigations are needed on the mechanistic role of n3 PUFAs in the pathogenesis of ALD, and possibly AUD.

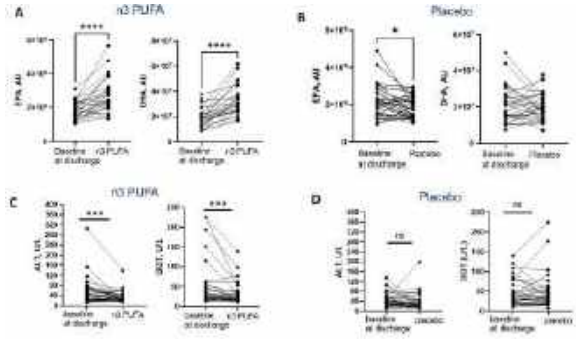

Fig. 1.: Targeted lipidomic analysis and evaluation of liver injury in heavy drinking individuals randomized to n3 PUFA supplementation or placebo arm. Cerebrospinal fluid n3 PUFAs, EPA and DHA (A-B), and plasma ALT and GGT levels (C-D) in patients at baseline (at discharge from alcohol treatment program) and after 12-week n3 PUFA supplementation. n=46 (n3 PUFA group [2 g/day EPA+DHA], and n=48 (placebo group. Paired Student's t test *p<0.05, **p<0.01, ***p<0.001, ****p<0.0001.

acute-on-chronic liver failure (ACLF), NLR has emerged as promising predictor of survival (2,3). Albeit NLR maintains its predictive value across the spectrum of ACLD etiologies, more granular data on NLR values by etiology is scarce. Aim: In this registry study, we aimed to investigate predictive value of NLR in AD/ACLF and to see if NLR values differ according to etiology of ACLF. **Methods:** Since 2014, the cirrhosis registry RH7 (NCT04767945) has been enrolling consecutive consenting adults admitted to tertiary liver unit with ACLD. For the purpouse of this study, we have identified (per protocol) patients with AD/ACLF based on EF-CLIF criteria. The cohort was then divided into three etiological groups: viral, alcoholic, and "other." We compared NLR on admission (NLR-0) and on day 7 of hospital stay (NLR-7) within each etiological group and, evaluated association of NLRs with mortality at days 28, 90, and at one year. We adopted NLR > 3 and NLR > 6 as the upper limit of normal range and upper limit of grey zone, respectively. **Results:** From 1109 patients in RH7 as of May, 2020, 283 have been identified with AD: 73.1% with alcohol-associated liver disease (ALD), 7.8% with viral hepatitis, and 19.1% with other etiologies. The average age was 51.3 years, 41% were females. NLR-0 and NLR-7 values were determined for 283 and 186 patients, respectively. Elevated NLR-0 and NLR-7 values were observed in 77.4% and 74.2% of patients, respectively. NLR-0 values were significantly higher in patients with alcoholic etiology (80.2%) compared to viral (50%) and "other" etiologies (77.8%) ($p < 0.01$). Both NLR-0 and NLR-7 values were significantly lower in survivors compared to non-survivors in all three etiological groups ($p < 0.01$); in multivariate regression analysis adjusted for usual predictors of survival in AD/ACLF, NLR was independent predictor of mortality ($p < 0.001$). There were no significant differences between NLR-0 and NLR-7 values. **Conclusion:** Three of four patients admitted with AD/ACLF have elevated baseline NLR which lends support to the immuno-pathogenesis of this syndrome. Elevated NLR-0 and NLR-7 values were associated with increased mortality, regardless of the etiology of AD/ACLF; in closer view however, NLR differed according to etiology and was highest in ALD. Dynamics of NLR over the first week of AD/ACLF has been negligible and delta NRL contributed no additional prognostic value. NLR can be considered an independent prognostic marker of AD/ACLF, providing insight in the immuno-pathophysiology of AD/ACLF and teasing us to be levered as a therapeutic target.

3577-C | NEW ROLE OF CALPAIN ACTIVITY IN EXPERIMENTAL ALCOHOL-RELATED LIVER DISEASE

Jiang Li[1], Olivia B. Bannister[1], Charis-Marie Vanderpuye[1], Gina Wang[1], Juliane I Beier[1,2], Panagiotis V Benos[3], Michael Merchant[4] and Gavin E. Arteel[1,2], (1)University of Pittsburgh, (2)Pittsburgh Liver Research Center, (3)University of Florida, (4)University of Louisville, Louisville, KY

Background: Although the progression of alcohol-related liver disease (ALD) is well documented, there is still need for new approaches to prevent and treat this disease in at-risk individual's. We showed previously that the pattern of degraded proteins in plasma samples from experimental and human ALD differs dramatically from healthy livers; informatic analysis suggested robust elevated activation of the cysteine proteases Calpains 1 and/or 2 (Capn1/2) in both human and experimental ALD. Although Calpain 1/2 have been identified as key players of inflammation and remodeling in other organs, they have not been investigated in ALD. The purpose of the current study was to investigate the impact of targeted disruption of hepatic Calpain 1/2 activity in a preclinical mouse model of ALD. **Methods:** Mice were injected with recombinant adeno-associated virus type 8 vectors (rAAV8; 1×10^{11} PFU/mouse, i.p.) encoding shRNA against Capn4 (*Capns1*; a shared regulatory subunit of Capn1/2), or control scrambled rAAV8 vectors. Mice were subsequently given ethanol diet or control (PF) for 10 days with additional gavage 'binge' of alcohol on day 11, according to the NIAAA model. Tissue and RNA were extracted for further analysis. Major endpoints were assessed by histology, biochemical analyses and/or gene expression. **Results:** rAAV8-mediated knockdown of Capn4 mediated a robust and stable suppression of hepatic *Capns1* expression, coupled with a nearly complete abrogation of detectable Capn1/2 enzyme activity. As expected, ethanol feeding caused robust inflammatory liver injury, characterized by steatosis, inflammation and cell death. Capn4 knockdown significantly attenuated lipid accumulation caused by alcohol as evidenced by histologic and biochemical assessment of lipids (e.g., FFA and TG). Despite these protective effects against alcohol-induced steatosis, Capn4 knockdown did not attenuate the increases in plasma transaminases caused by alcohol. Interestingly, Capn4 knockdown led to a more robust accumulation of neutrophils (PMN) after alcohol exposure, as well as hepatic expression of *Ly6g* mRNA. **Conclusion:** Taken

together, these results identify previously unidentified roles of Calpain activity in alcohol-related liver disease. Specifically, these results indicate that Calpain activity plays a key role in lipid accumulation caused by alcohol. However, rAAV8 knockdown of Capn4 enhanced neutrophil accumulation after alcohol and thereby did not protect against overall indices of liver injury. Since calpain activity has previously been shown to contribute to neutrophil apoptosis, a more targeted delivery of Capn1/2 inhibitors may therefore confer protective effects in ALD.

3578-C | NOGO-B (RETICULON 4B) DELETION PROMOTES ANTI-INFLAMMATORY MACROPHAGE POLARIZATION AND PROTECTS AGAINST ALCOHOL-INDUCED LIVER INJURY

Yilin Yang[1], Nao Kawaguchi[2], Jain Jeong[2], Yu Jun[3], Matthew McConnell[1], Teruo Utsumi[4] and Yasuko Iwakiri[2], (1)Yale University, New Haven, CT, (2)Yale School of Medicine, New Haven, CT, (3)Temple University, (4)VA Connecticut Health Care

Background: Nogo-B (a.k.a., Reticulon 4B) is an endoplasmic reticulum (ER) resident protein and maintains ER tubular structure. Macrophage Nogo-B correlates with the severity of liver injury in patients with alcohol-associated liver disease (ALD). We hypothesized that macrophage Nogo-B deletion would ameliorate ALD by reducing macrophage-mediated inflammation. **Methods:** Macrophage-specific Nogo-B knockout (NGB Mϕ KO) mice and littermate wild-type (WT) control (Nogo-B$^{f/f}$) mice were fed chow or high-fat diet (HFD, 60% kcal% fat) for 3 months, followed by single maltose or ethanol gavage (5 g/kg body weight). Primary bone marrow-derived macrophages (BMDM) and Kupffer cells were isolated from Nogo-B KO and their age-matched littermate WT mice. **Results:** NGB Mϕ KO mice ($n = 10$) showed a 40% lower ALT level ($p < 0.01$), 30% decreased neutrophil infiltration ($p < 0.01$), and decreased expression of pro-inflammatory cytokines, including TNF-α (75% decrease, $p < 0.05$), IL-1β (85% decrease, $p < 0.01$) and IL-6 (80% decrease, $p < 0.01$), compared to WT mice ($n = 9$) in response to HFD with alcohol. Mechanistically, we hypothesized that altered ER structure due to Nogo-B KO promotes macrophages to be pro-inflammatory type. Structural analysis of macrophage ER using fluorescent microscopy and transmission electron microscopy (TEM) indicated that Nogo-B KO increased sheet ER structure with decreased tubular ER (1.12-fold, $p < 0.05$). When we knockdown REEP5 (another ER tubular protein), similar to NGB KO, sheet ER was increased with diminished tubular ER (1.2-fold, $p < 0.01$) in BMDM. Further, REEP5 suppression inhibited pro-inflammatory polarization by decreasing IL-6 (44%, $p < 0.001$), IL-1β (15%, $p < 0.05$) and TNF-α (45%, $p < 0.001$) in BMDM, similar to NGB KO, suggesting structural alteration of ER (increased sheet to tubular ER ratio) leads to anti-inflammatory macrophage polarization. TEM analysis also showed NGB KO reduced tubular ER-mitochondria contacts (45% decrease, $p < 0.001$) and restored mitochondrial size (1.7-fold, $p < 0.001$) in LPS-treated BMDM. Further, Seahorse analysis indicated that decreased ER-mitochondria contact protected mitochondrial function (respiration rate) (1.9-fold increase, $p < 0.01$) compared to WT macrophages, suggesting a mechanistic link between ER-mitochondrial contact, metabolic alteration, and macrophage polarization. **Conclusion:** Our data supports a mechanistic role for Nogo-B as a molecular switch that functions via modulation of ER structure and metabolic function to promote an anti-inflammatory macrophage phenotype and protect against ALD. Nogo-B may therefore serve as a novel therapeutic target for the treatment of ALD.

Stage Liver Disease (MELD) score was computed with DESeq2, adjusting for age and sex. Gene set enrichment analysis (GSEA) was computed with fgsea; cell type specific markers were annotated using the Liver Cell Atlas. Results were validated with cytochrome P450 2E1 (CYP2E1)- and alcohol dehydrogenase 1 (ADH1)-overexpressing VL-17A human hepatocyte cells treated with 100mM ethanol for 48h. A false discovery rate < 0.05 was considered significant. **Results:** We identified 1,613 genes associated with MELD. Hepatocyte markers were downregulated, while fibroblast markers were upregulated with worsening AH (Figure 1A). Acute inflammation was significantly enriched. Posttranscriptional regulation of gene expression was also enriched; splicing factors linked to liver dysfunction such as APOBEC1 complementation factor (A1CF) and muscle blind-like protein 3 (MBNL3) were downregulated with increasing MELD. Non-coding RNAs (ncRNAs) comprised 9% of DE genes; 49% were long non-coding RNAs (lncRNAs), 45% small nucleolar RNAs (snoRNAs) and 3% small nuclear RNAs (snRNAs). 94% of ncRNAs were upregulated with worsening AH and comprised 18% of all upregulated genes (Figure 1B). VL-17A cells treated with ethanol also showed downregulation of hepatocyte markers and splicing factors (e.g. albumin and MBNL3, respectively), as well as dysregulation of ncRNAs, including snoRNA upregulation. **Conclusion:** Loss of hepatocyte function in AH is characterised by dysregulation of ncRNAs and splicing factors with worsening disease severity. Our results indicate that epigenome and epitranscriptome modulation may be a promising therapeutic target in AH.

3580-C | NOVEL CIRCULATING EXOSOMAL MIRNAS AND mRNA NETWORK OFFERS PATHOPHYSIOLOGIC INSIGHTS AND POTENTIAL FOR NEW BIOMARKER DISCOVERY AND THERAPEUTIC TARGETS IN PATIENTS WITH SEVERE ALCOHOL ASSOCIATED HEPATITIS (SAH)

Jing Zeng[1,2], Srinivas Koduru[3], Derrick Zhao[1], Yun-Ling Tai[1], Xuan Wang[1], Emily Gurley[1], Faridoddin Mirshahi[4], Arun Sanyal[4], Huiping Zhou[1] and Puneet Puri[4,5], (1) Department of Microbiology and Immunology, Medical College of Virginia and Mcguire Veterans Affairs Medical Center, Virginia Commonwealth University, Richmond, VA, (2)Department of Gastroenterology, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai 200092, China, (3)Gene Arrays, Omelette Inc, Seaford, NY, USA, (4)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA, (5)Division of Gastroenterology, Hepatology, and Nutrition, Richmond VA Medical Center, Richmond, VA

Background: Severe alcohol associated hepatitis (SAH) is associated with liver and multi-organ failure, resulting in a high demand for liver transplants and increased mortality. The pathogenesis of SAH involves various molecular mechanisms, including the dysregulation of microRNAs (miRs). Our hypothesis is that patients with SAH exhibit dysregulated circulating exosomal miRNAs (CE-miRs). To test this hypothesis, we examined the expression profiles and functions of hepatic miRNAs (H-miRs) and CE-miRs in SAH patients compared to healthy controls (HC). **Methods:** We extracted serum exosomes and isolated total RNA from exosomes and liver tissue. CE-miRs was analyzed using PartekFlow, while NanoString nCounter was employed for hepatic miRNAs (H-miRs). Potential target genes were identified using TargetScan and mirnet v2.0. Protein-protein interaction (PPI) networks were constructed using STRING database, and Cytoscape software was used to visualize hub genes. GSE28619 dataset data analysis were performed using ROSALIND® platform along with CE-miRs and H-miRs. **Results:** Our study included 25 patients, comprising 16 SAH patients (CE-miR n = 13, H-miR n = 3) and 9 HC (CE-miR n = 6, H-miR n = 3). In depth miR-seq data analysis revealed 78 differentially expressed CE-miRs (DE-CE-miRs). Among them, 50 were upregulated, while 28 were downregulated in SAH patients compared to HC. SAH liver tissue data exhibited 173 differentially expressed H-miRs (DE-H-miRs) compared to HC. Interestingly, among the upregulated DE-H-miRs, 11 CE-miRs were also upregulated in SAH patients. GO and KEGG analyses were performed to predict target genes for these 11 overlapping DE-miRs, and a PPI network analysis identified the top 50 hub genes. Using the GSE28619 dataset, we

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

found that 12 out of the 50 identified hub genes were significantly downregulated in SAH patients compared to HC. These downregulated genes represent potential targets of the 9 upregulated CE-miRs (Figure 1). Moreover, these DE-miRs are associated with multiple signaling pathways related to cancer, including apoptosis, stress response and angiogenesis. **Conclusion:** The overlapping DE-miRs found in the liver and circulating exosomes are associated with severe alcohol-associated hepatitis (SAH). These findings indicate their potential as diagnostic and prognostic markers, as well as therapeutic targets for SAH. The upregulation of hsa-miR-152-3p may have cancer-protective effects and warrants further evaluation. **Keywords:** alcoholic hepatitis, miRNA, gene, exosome, expression profile, microarray analysis

Eswaran[14], Oren Fix[15], Haripriya Maddur[16], Norah Terrault[1] and Brian P. Lee[1], (1)University of Southern California, (2)University of Wisconsin School of Medicine and Public Health, Madison, WI, (3)University of Wisconsin, (4)Department of Hepatology and Liver Transplantation, the University of Maryland, School of Medicine, Baltimore, MD, USA., (5)University of Maryland, (6)Icahn School of Medicine at Mount Sinai, (7)University of Pennsylvania, (8) National Institute of Health, (9)Georgetown University Hospital, (10)Houston Methodist Hospital, Houston, TX, (11)Ochsner Medical Center, (12)University of Alabama at Birmingham, Birmingham, AL, (13)University of Alabama at Birmingham, (14)Rush University Medical Center, (15)University of North Carolina at Chapel Hill, (16)Largo Medical Center, Lutz, FL

Background: While early (i.e. without mandated period of abstinence) liver transplant) for alcohol-associated hepatitis (AH) is the fastest growing indication for LT in the US and Europe, return to drinking occurs in up to 40% of LT recipients. Although harmful alcohol use post-LT is associated with poor outcomes, the effect of establishing sustained abstinence after relapse (i.e. re-abstinence) is understudied. **Methods:** In this multi-center (12 US LT centers) cohort, we included consecutive LT recipients for clinically-diagnosed severe AH between 2006-2021. Harmful alcohol use was defined by NIAAA criteria of "binge" ($\geq$5 [men] or $>$4 [women] drinks in $<$24 hours) or "frequent" ($\geq$4 d in one week) by clinical interview or phosphatidylethanol (Peth) $>$ 20ng/mL. Re-abstinence was $>$12 consecutive months without harmful alcohol use following any post-LT harmful alcohol use. Multivariable Cox regression estimated survival, adjusted for age, sex, and MELD-Na score at LT with post-LT all-cause mortality as the outcome, with analysis beginning at 1-year post-LT to minimize survivorship bias. Logistic regression was used in an exploratory multivariable analysis to identify factors associated with continued harmful alcohol use. **Results:** Among 357 LT recipients (57% male, mean age 42, mean MELD-Na at LT 38) with median post-LT follow-up of 2.2 years (IQR 1.1 – 3.6), 67 (19%) had any post-LT harmful alcohol use, of which 30 (45%) had re-abstinence. In multivariable analysis, any post-LT harmful alcohol use was associated with death (aHR 2.2, p = 0.04). However, 3- and 5-year post-LT survival (adjusted for age, sex, MELD-Na) was similar among LT recipients without harmful alcohol use vs. re-abstinence (95% and 92% vs. 93% and 89%, p = 0.84), while significantly lower among LT recipients with continued harmful alcohol use without re-abstinence (81% and 70%, p = 0.003) (Figure). Among LT recipients with continued harmful alcohol use (N = 37) vs. re-abstinence (N = 30), median time to first post-LT alcohol use was similar (340 vs. 252 d, p = 0.68), but median estimated exposure to post-LT harmful alcohol use was higher (12 mo vs 7 mo, p = 0.02). In multivariable analysis, male sex was the only risk factor for continued harmful alcohol use (vs. re-abstinence) (aOR 3.1, p = 0.046). **Conclusion:** In a cohort of LT for AH recipients, re-abstinence (vs. continued harmful alcohol use) restored 3- and 5-year survival to rates similar to LT recipients without any episode of post-LT harmful alcohol use. We identified novel differences and risk factors for continued post-LT harmful alcohol use vs. re-abstinence. These findings should inform strategies that provide early recognition of return to harmful use and enable treatments to restore abstinence that ultimately improve survival among LT recipients for AH.

3582-C | Nrf2 ACTIVATOR OMAVELOXOLONE PROTECTS MICE FROM ALCOHOL INDUCED LIVER INJURY

Claire Montgomery, Gino Cortopassi and Joy Jiang, UC Davis

Background: Alcohol-induced oxidative stress is a hallmark and major pathogenic factor of alcohol-associated liver disease (ALD). The nuclear factor erythroid 2–related factor 2 (Nrf2), a master antioxidant gene, has been shown to mediate protective signaling in response to oxidative stress in multiple types of liver injuries including ALD. Omaveloxolone is a potent Nrf2 activator and approved by FDA for human use. Aiming at finding cures, we tested omaveloxolone in a mouse model of ALD. **Methods:** Female C57B6 mice were subjected to Lieber DeCarli alcohol diet for l0 days + last day binge (NIAAA model) and dosed with either vehicle (peanut butter) or omaveloxolone (24 mg/kg daily orally) for 10 days. At the endpoint, serum ALT and AST levels were evaluated. Liver tissues were processed for histology, and RT- qPCR to assess Nrf2 downstream targets and inflammatory markers. IHC staining for 4-HNE was used to evaluate lipid peroxidation. Western blot was conducted to detect NFκB p65 phosphorylation. STING signaling has been reported to mediate NFκB activation and proinflammatory signaling, hence, STING expression in liver was analyzed by IHC staining and its downstream effector TBK1 by western blot. **Results:** Omaveloxolone significantly reduced ALT and AST levels in alcohol fed mice. The Nrf2 downstream target Nqo1 was dramatically induced. Meanwhile, Lipid peroxidation as shown by 4-HNE staining was suppressed by omaveloxolone. The inflammatory markers TNFα, MCP1, IL-1β and Cxcl1 significantly decreased in the treated mice. The treated mice showed improved liver histology as well. Omaveloxolone reduced NFκB p65 phosphorylation and STING signaling in alcohol fed mice. **Conclusion:** Nrf2 activator omaveloxone is beneficial in a mouse model of ALD by reducing oxidative stress and proinflammatory signaling. As an FDA approved drug, omaveloxolone could be a potential candidate for ALD clinic trial.

3583-C | OUTCOMES FROM A SPECIALIST PRE-LIVER TRANSPLANT HIGH INTENSITY ALCOHOL CIRRHOSIS CLINIC

Rebecca O. Kane, Muhammad Azhar Hussain, Neil Rajoriya and Andrew Holt, Queen Elizabeth Hospital

Background: Alcohol-related Liver Disease (ArLD) remains the commonest indication for liver transplantation (LT) in the United Kingdom (UK) but many patients are deemed unsuitable at the time of LT assessment. In 2015 a specialist alcohol cirrhosis high intensity clinic was set up to maximise patient's candidacy for LT. Interim analysis had shown this clinic to be an effective vehicle to optimise previously unsuitable patient groups (entering a palliative pathway), allowing perhaps fairer and equitable access to LT. The aim of this study was review longer term outcomes from this clinic. **Methods:** The multidisciplinary team (MDT) clinic comprised 2 physicians, 2 alcohol nurse specialists and a dietician. All cases were discussed in a mini-MDT meeting after clinic. Patients were seen as new referrals in advance of assessing for LT or following a negative outcome in the listing meeting, requiring further input from the clinic before representation, if appropriate. Electronic data was analysed retrospectively from all patients attending clinic (May 2016- November 2021). **Results:** 508 patients were seen in the MDT clinic (355 male, 153 female), with mean age 53 years (SD+/- 8.82) and median UKELD 54 (SD+/- 5.3). 291 (57%) were presented at the LT listing meeting. 197 (68%) were accepted for listing, with 111 (56%) undergoing LT on follow up. 1 year survival post-LT was 96%, comparable to NHSBT UK figure of 95%. Among those not transplanted (n = 397), 127 (32%) recompensated whilst 73 (18.4%) had relapsed to alcohol during follow up under the clinic. 157 patients (31%) were referred to the clinic after being initially turned down by the LT listing meeting, considered too high risk (medically, psychologically, nutritionally, or any combination). Of these patients, 105 (66.9%) were represented after clinic intervention and subsequently listed, with 61 (58.1%) undergoing LT. Of the remaining 44, 9 (8.6%) remained on the waiting list while 35 (33.3%) were removed (15 death/too unwell, 4 alcohol relapse, 16 recompensated). 9/111 (7%) patients had post-LT relapse (as defined by self-admission, blood alcohol level in clinic and trends of LFTs/MCV suggestive of alcohol use). Median follow

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

up post-LT was 47.5 months (range 2-75). **Conclusion:** A specialist high intensity ArLD MDT pre-LT clinic is an effective clinical environment for treating high risk patients and managing their risk factors. Specialist addiction and nutrition-focused MDT management enables patients who were initially deemed unsuitable for LT to be listed and shows low short term relapse in this patient cohort.

3584-C | OUTCOMES OF LIVER TRANSPLANTATION IN PATIENTS WITH ACUTE ALCOHOLIC HEPATITIS BASED ON WAITLIST DURATION

Omar Alshuwaykh, California Pacific Medical Center, George Cholankeril, Baylor College of Medicine, Donghee Kim, Stanford University Medical Center and Aijaz Ahmed, Stanford University School of Medicine

Background: Acute alcoholic hepatitis is associated with significant short-term mortality and liver transplantation can be a lifesaving option for these patients. We aim to study outcomes of patients with AAH listed for liver transplantation based on their waitlist duration **Methods:** We performed retrospective analysis using the UNOS database of all patients ³ 18 years with primary and secondary diagnosis of AAH from 5/2002 to 12/2020. We categorized patients into those with AAH only and AAH and secondary diagnoses. We calculated MELD score at LT surgery **Results:** We extracted 1028 patients; 727/1028 (71%) were transplanted. 756/1028 (74%) had AAH only and 272/1028 (26%) had AAH in addition to a secondary liver disease diagnosis. We categorized patients into 3 groups based on waitlist durations of £7 days, 8-180 days, and > 180 days. Patients with waitlist duration > 7 days had significantly higher 1-year post transplant survival rates (66%) compared to (45%) for patients with wait list of 7 or less days ($P < 0.0001$). Patients with waitlist duration > 30 days had significantly higher 1-year post transplant survival rates (74%) compared to (50%) for patients with wait list of 30 or less days ($P < 0.0001$). Patients with waitlist duration > 60 days had significantly higher 1-year post transplant survival rates (76%) compared to (51%) for patients with wait list of 60 or less days ($P < 0.0001$). Patients with waitlist duration > 90 days had significantly higher 1-year post transplant survival rates (72%) compared to (58%) for patients with wait list of 90 or less days (P 0.003). Age > 65 years predicted mortality in patients with waitlist duration of < 1 week (HR 11.8, 95% CI 3.4-41.3, $P < 0.001$), whereas male gender (HR 0.4, 95% CI 0.2-0.8, P 0.01) and age 50-65 years (HR 0.4, P 0.2-0.9, P 0.04) both had better survival probability in patients with waitlist duration of 8-180 days **Conclusion:** The encouraging data on the favorable outcomes of early LT for patient is promising. We found that the longer waitlist duration, the better outcomes regarding 1-year survival rates. Patients who were waitlisted for more than 7 days had significantly better survival outcomes compared to those waitlisted for 7 or less days. similarly, patients who were waitlisted for more than 30 days, more than 60 days, and more than 90 days had significantly better survival outcomes compared to those waitlisted for 30 or less days, 60 or less days, and 90 or less days respectively.

Table 1. Comparing baseline characteristics of patients with AAH based on their waitlist duration

Variable N (%), Median (IQR)	≤ 7 days N (408)	8-180 days N (284)	>180 days N (35)	P values*
Age (years)	40 (34-50)	45 (38-53)	55 (48-59)	<0.001, <0.001

3585-C | PHARMACOLOGICAL THERAPIES FOR ALCOHOL USE DISORDERS REDUCE HEPATIC DECOMPENSATION IN ALCOHOL-RELATED LIVER DISEASE: A GRADE EVALUATION THROUGH A SYSTEMATIC REVIEW AND META-ANALYSIS

Manya Prasad and Mohit Kumar Varshney, Institute of Liver and Biliary Sciences, New Delhi

Background: The role of behavioural therapies for Alcohol Use Disorder (AUD) in alcohol-related liver

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

disease (ALD) patients has been reported but that of pharmacological therapies is yet to be established. A systematic summary of the evidence on the use of pharmacological therapies for AUD in ALD is needed in order to guide formulation of guidelines and recommendations. Therefore, we conducted a systematic review and meta-analysis to study the use of these pharmacological interventions in ALD for patient important outcomes such as abstinence and liver-related patient important outcomes. **Methods:** We searched Medline, Embase, Cochrane database and TRIP database. Title/abstract screening, full text screening and data abstraction were carried out in duplicate. Risk of bias was assessed using the modified version of New Castle Ottawa scale. Pooled effect sizes and 95% confidence intervals were calculated using random effects model meta-analysis. We used adjusted estimates, wherever available, to pool data. The certainty in evidence was rated as high, moderate, low or very low using the GRADE tool. We used detailed GRADE guidance to assess overall risk of bias, imprecision, inconsistency, indirectness and publication bias, and summarized results in an evidence profile. **Results:** Our search yielded 546 titles and abstracts - all were identified from the electronic database search. Altogether, eleven studies (one RCT and 10 cohort studies) were included in the systematic review, and seven studies in the meta-analyses. The mean age of the participants ranged from 16 to 58 years. Meta-analysis of three cohort studies (94,887 participants) showed significantly lesser odds of hepatic decompensation over 6-12 months with use of AUD pharmacotherapy with high statistical heterogeneity (OR 0.61; 95% CI 0.41-0.89; $I^2 = 92\%$). Meta-analysis of one RCT and three cohort studies (303 participants) for the outcome abstinence revealed a pooled proportion of 60.5% (95% CI, 30.6- 90.4; $I^2 = 97.8\%$). The overall rating for certainty in estimates was very low for the outcome hepatic decompensation. The evidence was from observational studies rated down for inconsistency. **Conclusion:** The present systematic review and meta-analysis suggests pharmacological therapies in ALD may reduce incidence of hepatic decompensation and may help in achieving high level of abstinence. Meta-analysis of three retrospective cohort studies revealed a statistically significant and precise reduction in risk of hepatic decompensation in ALD over 6 to 12 months. The body of evidence arises from mostly cohort studies, and overall very few studies have adequately addressed the effect of AUD therapies on long term patient important outcomes. The findings warrant disengagement from a 'liver-centric' management of ALD to one that incorporates a multidisciplinary approach.

3586-C | PHOSPHATIDYLETHANOL (PETH) LEVELS ARE ASSOCIATED WITH MORTALITY BUT NOT SEVERITY IN ALCOHOL-ASSOCIATED HEPATITIS

Praveena Narayanan[1], Anahita Rabiee[1], Tamar H. Taddei[1,2] and Pramod K. Mistry[1], (1)Yale University, New Haven, CT, (2)West Haven VA Medical Center

Background: Phosphatidylethanol (PEth) is a validated biomarker to detect alcohol use within 21-28 days. While PEth has been studied in the setting of liver transplant evaluation and in chronic liver disease, it has not been studied in alcohol-associated hepatitis (AH). **Methods:** Using a single-center database of patients admitted from 2020 to 2023 with AH, 114 patients were identified with PEth 16:0/18:1 testing within 14 days of hospitalization. We assessed correlations between PEth and demographic factors, established markers of severity with AH, and outcomes from AH, such as mortality at 30 and 90 days. Of those 114 patients, 47 had additional information available regarding their alcohol use history. Categorical variables were compared using chi-squared test; continuous variables were compared using Mann-Whitney U test. Correlations were compared with Spearman's rank correlation coefficient. **Results:** Of 114 patients with AH and PEth testing, 82 (72%) had a positive value (>20ng/mL) compared to 32 (28%) with a negative value (<20ng/mL). Between these two groups, there were no significant differences in age (PEth- median 50.22, PEth+ median 46.28), gender (PEth- 75% Male, PEth+ 61% Male), ethnicity (PEth- 97% White, PEth+ 92% White), or MELD-Na (PEth- mean 27.62, PEth+ mean 28.26) (Figure 1). A negative PEth test was significantly correlated with higher mortality at 30 days ($p = 0.036$) and there remained a trend towards higher mortality at 90 days

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

($p = 0.09$). There was also a significant difference in AST:ALT ($p < 0.001$). Self-reports of alcohol consumption and last drink date correlated with PEth testing ($n = 44$, $r = 0.68$). **Conclusion:** Significant and sustained alcohol use underlies the development of AH, however PEth is not predictive of measures of AH severity. In our population, PEth correlated with AST:ALT ratio and self-reported alcohol consumption; interestingly, a negative PEth on admission was also associated with higher 30-day mortality. The mechanisms underlying the heterogeneity of PEth test results in the setting of AH should be further investigated to refine our understanding and guide our use of this biomarker in clinical practice.

3587-C | PHYSOXIC HIF1a-REDD1 SIGNALING PERTURBATIONS IN SKELETAL MUSCLE DISRUPT PROTEIN HOMEOSTASIS IN ALCOHOL-ASSOCIATED LIVER DISEASE

Nicole M. Welch[1], Saurabh Mishra[1], Annette Bellar[1], Vandana Agrawal[1] and Srinivasan Dasarathy[2], (1) Cleveland Clinic, (2)Cleveland Clinic Foundation

Background: Loss of skeletal muscle mass and function is frequent and greater in alcohol-associated liver disease(ALD) than in other etiologies of cirrhosis. Alcohol(ethanol,EtOH) impairs hepatocyte ureagenesis with resultant increase in circulating ammonia. In our integrated multiomics analyses studies, we previously identified that hypoxia-inducible factor(Hif)1α signaling was enriched in models of skeletal muscle hyperammonemia. We have also previously shown that skeletal muscle is sensitized by ethanol to the adverse effects of ammonia, but the mechanisms are poorly understood. We therefore sought to determine whether ethanol stabilizes Hif1a under physoxia (physiological partial oxygen pressure) and whether impaired skeletal muscle proteostasis in mouse and human inducible pluripotent stem cell (hiPSC) myotubes and skeletal muscle from humans and mice with ALD(mALD) is mediated by Hif1α. **Methods:** Differentiated C2C12 and hiPSC myotubes were not treated(UnT) or treated with 100mM EtOH for 6 and 24h. Wild-type(WT) mALD were fed an acute on chronic ethanol diet with 6% EtOH. Littermate controls were pair-fed. Assay for transposase accessible chromatin(ATACseq) was performed in C2C12 myotubes. Bulk RNA sequencing (with tissue deconvolution) and untargeted proteomics were performed in EtOH-treated C2C12 and hiPSC-derived myotubes and skeletal muscle from mALD and human patients with cirrhosis. A differentially expressed molecule (DEM) was defined as meeting a pre-defined adjusted or non-adjusted p-value cutoff designed to identify 50-2000 molecules of interest that changed with EtOH compared to UnT. Dual luciferase reporter assay was performed after double transfection of Renilla luciferase and Hif1a luciferase reporter (promoter joined to 3 consecutive hypoxia responsive elements). 3-dimensional electron microscopy (3D EM) was performed in gastrocnemius muscle from pair-fed mice and mALD. **Results:** Integration of DEMs from untargeted data from EtOH-treated models revealed increased expression of HIF1α targets including Vimentin(VIM), Fibronectin 1(FN1), Cbp/P300 Interacting Transactivator With Glu/Asp Rich Carboxy-Terminal Domain 2(CITED2), and DNA Damage Inducible Transcript 4(DDIT4/REDD1). These were experimentally validated in C2C12 myotubes treated with either EtOH or AmAc for 6h. Both treatments increased HIF1α luciferase reporter activity. Protein expression of DDIT4 in myotubes and skeletal muscle was increased with EtOH. 3D EM in mouse skeletal muscle showed changes in mitochondrial network organization with EtOH exposure. **Conclusion:** EtOH-sensitization of skeletal muscle to hyperammonemia stabilizes HIF1α under physoxic conditions and increases DDIT4 expression. DDIT4 is an mTOR inhibitor and has been shown to increase oxidative dysfunction in mitochondria. Targeting HIF1α-DDIT4 signaling may be a potential therapeutic target in ALD to increase skeletal muscle mass.

3588-C | POLYCHLORINATED BIPHENYL 126 ALTERS THE HEPATIC TRANSCRIPTOME TO ENHANCE ALCOHOL-ASSOCIATED LIVER DISEASE

Tyler C. Gripshover[1], Banrida Wahlang[1], Kimberly Head[1], Eric C. Rouchka[1], Jamie Young[2], Jianzhu Luo[1], Irina A. Kirpich[1] and Matthew Cave[1], (1)University of Louisville, Louisville, KY, (2)University of Louisville, Goshen, KY

Background: Alcohol-associated liver disease (ALD) development may be impacted by other lifestyle factors such as tobacco smoking. Previously, environmental pollutants, namely persistent organic pollutants (POPs), have demonstrated to exacerbate dyslipidemia in high-fat diet models. We recently characterized a model for how environmental toxicant, polychlorinated biphenyl (PCB) 126, can disrupt lipid metabolism and exacerbate steatosis in an alcohol feeding model. Because excessive alcohol consumption is a major cause of preventable death and humans are inevitably exposed to POPs, it is important to understand how exposures may modify lifestyle related diseases. The current study's objective is to characterize the hepatic transcriptome in mice exposed to PCB126 followed by ethanol feeding. We hypothesize that PCB126 exposure prior to alcohol feeding will result in unique differentially expressed genes (DEGs) and enriched pathways will implicate altered metabolism and signaling disruption. **Methods:** Male C57BL/6J mice were exposed to 0.2mg/kg PCB126 or corn oil vehicle by oral gavage. Mice were then fed 5% Lieber DeCarli EtOH (EF) or pair fed (PF) diet for ten days followed by 31.5% EtOH binge. Hepatic mRNA was isolated and prepared for RNA sequencing. DEG analysis was performed with DESeq2 for pairwise comparisons for $p \leq 0.05$ and $q \leq 0.05$. **Results:** Hepatic transcriptomic analyses indicated PCB126(PF v EF) had 4832 (2214↑; 2618↓) DEGs while PF(Veh. v PCB126) had 503 (339↑; 164↓) DEGs. Importantly, our EF(Veh. v PCB126) had 907 (536↑;371↓) DEGs. Among the top 20 DEGs in our EF (Veh. v PCB126) comparison, genes included were involved in xenobiotic metabolism, cytoskeleton, and lipid metabolism. Four genes (*Abcb10*, *Slc46a3*, *Tuba8*, and *Ugt1a6b*) were validated by qPCR. In the top 6 of 20 enriched Gene Ontology (GO) processes, 4 processes involved *peptidyl-tyrosine modifications*. This indicates that signaling, *via* altered phosphorylation, may have been disrupted. Other GO processes involved leukocyte regulation, migration, or proliferation, suggesting underlying immune alterations were prevalent. **Conclusion:** These preliminary analyses suggest that PCB126 exposure modifies the hepatic transcriptome to, in part, disrupt cell signaling processes. This study signifies environmental pollutant exposure's ability to enhance ALD. Based on our enriched GO process data, tyrosine modifications may indicate mechanisms related to how PCB126 disrupts signaling in EF mice to enhance ALD.

3589-C | POLYCOMB REPRESSIVE COMPLEX 2 BINDS AND STABILIZES NANOG TO SUPPRESS DIFFERENTIATION-RELATED GENES TO PROMOTE SELF-RENEWAL OF TICs OF HCCs INDUCED BY CRISPR/Cas9-MEDIATED DRIVER MUTATIONS IN HUMANIZED FRG MICE

Da-Wei Yeh, Cheng Liu, Juan Carlos Hernandez, Stanley M. Tahara, Hidekazu Tsukamoto and Keigo Machida, University of Southern California

Background: The synergistic effect of alcohol and HCV mediated through TLR4 signaling transactivates NANOG, a pluripotency transcription factor important for the stemness of tumor-initiating stem-like cells (TICs). NANOG together with the PRC2 complex suppresses expression of oxidative phosphorylation (OXPHOS) genes to generate TICs. **Methods:** CRISPR KO library screening of ARID1A KO-non-transformed immortalized hepatocytes were tested in humanized FRG hepatocellular carcinoma (HCC) mouse model for tumor size regression phenotypes in response to sorafenib treatment. We generated HCC mice in which liver parenchymal, non-parenchymal and hematopoietic cells are humanized. CRISPR/Cas9 application (*ARID1A* KO and constitutively-active *CTNNB1* knock-in) generates mutations common in HCC patients synergistically generates HCC by alcohol Western diet. This HCC model was used for gene-environment interactions. **Results:** CRISPR KO library screening of ARID1A KO-non-transformed immortalized hepatocytes identified EZH2, EED and SUZ12 as synthetic lethal targets for tumor size regression in response to sorafenib treatment. The phosphodegron sequence PEST domain of NANOG binds EED to stabilize NANOG protein by blocking E3 ligase recruitment and proteasome-dependent degradation, while the tryptophan-rich domain of NANOG binds EZH2 and SUZ12. Human ARID1A gene loss led to the resistance of FAO inhibition therapies due to reduction of mitochondrial ROS levels. Humanized HCC mouse models with mutations and metabolic liver diseases (MLD) provide experimental platforms. CRISPR-Cas9-mediated *ARID1A* knockout and/or constitutively active *CTNNB1* driver mutations promoted tumor development in humanized FRG HCC mouse models. Selective inhibitors targeting of NANOG-PRC2 complex interface efficiently reduced HCC incidence and tumor sizes in several different mouse models and human HCC specimens. FRG mice carrying a double mutation of *ARID1A knockout* and c.a.*CTNNB1* knock-in insertion, but not c.a.*CTNNB1* knock-in insertion alone, showed almost a two-fold higher incidence of tumor formation but exhibited higher sensitivity to the drug treatment. *ARID1A* knockout and constitutively active *CTNNB1* protein levels by immunoblot analyses. The *ARID1A*-knockout humanized livers displayed higher levels of stemness protein levels (including NANOG and OCT4). Use of an interface inhibitor antagonizing PRC2-NANOG binding and/or FAO inhibitor blocked tumor growth. **Conclusion:** The PRC2-NANOG interaction becomes a new drug target for normalizing differentiation by inducing differentiation-related genes, destabilization NANOG protein, and suppressing NANOG activity. This project was supported by NIH grants R01 AA025204-01A1, R21 AA025470-01A1, 1R01AA018857-01, pilot project funding (5P30DK048522-13), P50AA011999 (Animal Core, Morphology Core, and Pilot Project Program) and R24AA012885.

3590-C | POST-TRANSLATIONAL MODIFICATIONS DRIVE THE EFFECTS OF HMGB1 IN ALCOHOLIC LIVER DISEASE

Xiaodong Ge, Romain Desert, Hui Han, Sukanta Das, Zhuolun Song, Sai Santosh Babu Komakula, Ines Barahona, Daniel Lantvit and Natalia Nieto, University of Illinois at Chicago

Background: high-mobility group box-1 (HMGB1) is a non-histone chromatin-associated protein involved in the pathogenesis of chronic liver disease. We identified that HMGB1 is increased and undergoes post-translational modifications (PTMs) in response to alcohol consumption. Thus, we hypothesized that specific PTMs could drive the pathogenic effects of HMGB1 in alcoholic liver disease (ALD). **Methods:** mice with cell-specific ablation of *Hmgb1* or the *Receptor for advanced glycation end-products* (*Rage*) were generated. Mice were injected with an HMGB1 neutralizing antibody or with the HMGB1 isoforms. The Lieber-DeCarli model of ALD was used. **Results:** *Hmgb1* ablation in hepatocytes ($Hmgb1^{\Delta Hep}$) or myeloid cells ($Hmgb1^{\Delta Mye}$) partially protected while ablation in both ($Hmgb1^{\Delta Hep\Delta Mye}$) prevented ALD. Neutralization of HMGB1 prevented while injection of [H] HMGB1 promoted ALD, which was worsened by injection of [O] HMGB1. Ablation of [O] HMGB1 protected whereas ablation of [Ac] HMGB1 exacerbated ALD due to inflammatory cell infiltration, which was blocked by ablation of both. Ethanol-fed $Rage^{\Delta Mye}$ mice were significantly protected, indicating a crucial role of RAGE in myeloid cells for ALD. [O] HMGB1 signaled through RAGE in myeloid cells and was critical for driving

steatosis, inflammation, IL1β production, and alcohol-induced liver injury whereas [Ac] HMGB1 was protective by blocking the noxious effects of [O] HMGB1. **Conclusion:** [O] HMGB1 signals through RAGE in myeloid cells to drive the pathogenesis of ALD while [Ac] HMGB1 offsets the effects of [O] HMGB1.

3591-C | POST-TRANSPLANT ALCOHOL-USE IS MORE COMMON IN RECIPIENTS WITH SHORT-INTERVAL ABSTINENCE

Jessica Ann Musto[1], Geralyn Palmer[1], Mary Nemer[1], Trevor Schell[1], Gabrielle Waclawik[1], Quarshie Glover[1], Michael R. Lucey[2], Fauzia Osman[1] and John P. Rice[1], (1)University of Wisconsin, (2)University of Wisconsin School of Medicine and Public Health, Madison, WI

Background: Early liver transplant for alcohol-associated liver disease (ALD), defined as liver transplant (LT) without a pre-transplant sobriety length mandate, has increased worldwide. Return to drinking is infrequent in short term follow-up but longer-term data is lacking. **Methods:** Single-center retrospective study of adult recipients of primary LT between 2010-2020, with follow-up through July 1, 2022, categorized by indication for LT. Baseline characteristics were compared using chi-square or Fisher's exact and Kruskal-Wallis or ANOVA. Logistic regression was used to identify variables associated with post-LT alcohol use. **Results:** Of 708 patients who underwent LT, 110 (15.5%) had ALD and abstinence < 6 months prior to LT (early liver transplant, ELT), 234 (33.1%) had ALD and alcohol abstinence > 6 months prior to LT (standard liver transplant, SLT). Median follow-up was 4.6 years (IQR 2.6, 7.3). ELT recipients were younger (median age 46.3 vs 57.5 $p = 0.001$) with shorter median abstinence prior to LT (61.5 vs 552 d, $p < 0.001$). There was no difference in crude and adjusted post-LT survival. Any alcohol use (40.9 vs 21.8%, $p < 0.001$) and potentially harmful alcohol use (31.2 vs 16.0%, $p = 0.002$) were more common in ELT recipients. Recurrent decompensated ALD, either by cirrhosis or AH, trended toward more common in ELT recipients (9.1% vs 4.4%, $p = 0.09$). By logistic regression, greater than 6 months pre-LT abstinence was associated with a decreased risk of harmful alcohol use (OR 0.40, $p < 0.001$), but not in a multivariable model (OR 0.76, $p = 0.38$). Multiple previous inpatient AUD treatments (OR 3.25, 95%CI 1.12-9.47, $p = 0.03$) was the only factor associated with post-LT alcohol use in the multivariable model. **Conclusion:** Patients with ALD and less than 6-months abstinence have a higher incidence of post-LT alcohol use. Pre-LT abstinence length was associated with post-LT harmful alcohol use on univariate logistic regression, but not in a multi-variable model.

3592-C | POST-TRANSPLANT SURVIVAL AND ALCOHOL RELAPSE RATES IN LIVER TRANSPLANT RECIPIENTS BEFORE AND AFTER REMOVAL OF A MANDATORY SIX-MONTH ALCOHOL ABSTINENCE PERIOD

Carolyn C. Chang[1], C. Kristian Enestvedt[1], Ali Olyaei[1], Tiana Enos-Dano[1], Susan L. Orloff[2], Erin Maynard[3], Willscott E. Naugler[4], David L. Scott[1], David C. Woodland[1], Alexandra Bolognese[1] and Christopher R. Connelly[1], (1)Oregon Health and Science University, (2) Oregon Health And Science University, (3)Oregon Health & Science University, (4)Oregon Health & Science University, Portland, OR

Background: Alcohol-associated liver disease (ALD) portends a high mortality in patients with high Model for End-Stage Liver Disease (MELD) scores. Six-month mandatory abstinence prior to liver transplant was historically common practice, and many of these patients did not survive to transplant. Paradigms are now shifting. In 2018, our institution adopted a new policy to omit the six-month sobriety period. Our aim was to assess differences in alcohol relapse and survival before and after the policy change. **Methods:** This was a single center, retrospective cohort study of liver transplant recipients with ALD from January 1, 2010 to April 1, 2023. Patients less than 18 years and those with unclear diagnoses were excluded. Transplants were divided into Era 1 (2010-2017) and Era 2 (2018-2023). Patient characteristics, survival, and relapse were compared in patients with and without ALD in the overall cohort, and between eras. Relapse was defined by positive phosphatidylethanol test or chart documentation of relapse. Survival probability was calculated by Kaplan-Meier estimate and compared using the log-rank test. **Results:** 705 patients underwent liver transplantation, 375 in Era 1 and 330 in Era 2. 32% (n = 223) of liver transplants were performed for patients with ALD, but transplant for ALD was more frequent in Era 2 (42% v. 22%, $p < 0.001$).

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Overall, recipients with ALD were more likely to be male (81% v. 62%, $p < 0.05$) and younger (51 v. 56 years, $p < 0.001$), but were otherwise similar to non-ALD recipients in terms of MELD, race, and hepatitis C status. Ten-year post-transplant survival was similar between the ALD and non-ALD group (Figure 1A). The overall relapse rate in patients with ALD was 20%, and was significantly higher in Era 2 (23% v. 14%, $p < 0.001$). Characteristics of those with and without relapse were similar. Post-transplant survival was similar between those who experienced relapse and those who did not (Figure 1B). Five-year post-transplant survival was similar between Eras 1 and 2 in patients with ALD (Figure 1C). **Conclusion:** Our study shows an increased rate of transplant for ALD after removal of the mandatory six-month sobriety period. Survival was similar between those with and without ALD. Survival was also similar in those with ALD who did and did not experience relapse. Notably, relapse rates were higher after removal of the six-month sobriety period, but survival was similar before and after removal of this barrier to transplant. These findings suggest that the 6-month abstinence period has no impact on overall patient survival. In fact, it likely prevents otherwise suitable candidates from receiving a life-saving liver transplant.

Figure 1A. Post-transplant survival for patients with diagnosis of ALD versus other etiology (p= 0.219, log-rank)

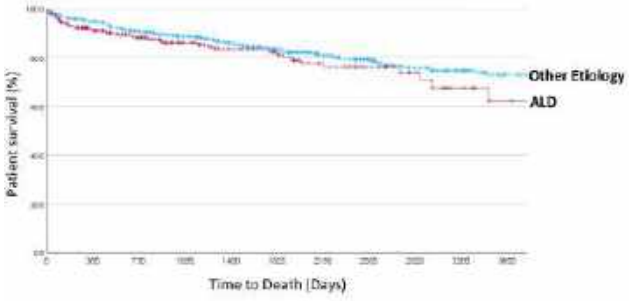

Figure 1B. Post-transplant survival for patients with diagnosis of ALD with or without relapse (p= 0.631, log-rank)

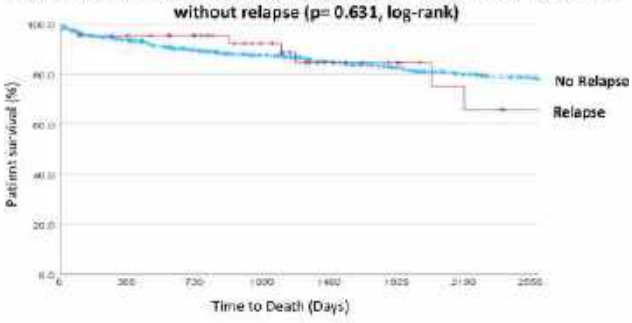

Figure 1C. Post-transplant survival for patients with diagnosis ALD at different Eras (p= 0.135, log-rank)

3593-C | PRE-AND POST-TRANSPLANT OUTCOMES IN PATIENTS UNDERGOING EXPEDITED AND STANDARD TRANSPLANT FOR ACUTE AND CHRONIC ALCOHOL-RELATED LIVER DISEASE

Olivia Karcis[1], Suzanne S. Chan[2], Michael P. Curry[1], John Messinger[3], Alison Mann[1], Isabelle Iversen[1] and Juan Ramos-Ayes[1], (1)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (2)Beth Israel Deaconess Medical Center, West Newton, MA, (3)Harvard Medical School

Background: Severe alcohol related hepatitis has limited treatment options and a high short term mortality risk with the majority of deaths occurring within months of initial presentation. Liver transplantation has been increasingly used in recent years for this indication requiring expedited assessment in patients with limited sobriety. Expedited evaluation requires rapid medical and psychosocial assessment of the patient and does not allow for the opportunity to demonstrate sobriety. **Methods:** We performed a retrospective study of demographic, psychosocial, and pre- and post-transplant outcomes of patients undergoing expedited workup (n = 65) to those who have undergone standard evaluation (n = 206) at Beth Israel Deaconess Medical Center. Expedited workup was defined by minimal (< 2 weeks) or no outpatient time between transplant evaluation and listing. **Results:** Listed patients were predominantly male (75.8% and 73.8% for expedited and standard listing groups, respectively). Expedited listings were significantly more likely to be younger patients (45.9 vs 54.1 y old, p = 3.29x10^-7). Virtually all patients undergoing standard transplant listing carried a UNOS diagnosis of alcoholic cirrhosis (99%) whereas the expedited group had a higher proportion of acute alcoholic hepatitis (35.4%). Patients who underwent expedited listing had significantly higher peak MELD scores (35.3 vs 28.1, p = 8.61x10^-8), at referral (30.4 vs 20.0, p = 2.07x10^-7), and at listing (31.6 vs 19.4, p = 2.40x10^-19). Those with expedited listings were transplanted at a higher rate (72.3% vs 33.0%) and over a shorter interval from listing to transplant (49.4 vs 402.3 d). Post-transplant relapse rates were higher in the expedited listing group at 1 year (8.5% vs 4.4%) and 3 years (12.8% vs 5.9%). Mortality rates 1 year (4.3% vs 2.9%) and 3 years (6.4% vs 5.9%)

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

post-transplant were similar for the expedited and standard groups, respectively. **Conclusion:** Patients who underwent expedited listing were more likely to have acute alcoholic hepatitis, which is probably reflective of our center-specific policy allowing for expedited transplantation if the patient did not have prior medical contacts related to alcohol use. Patients who underwent expedited listing had significantly higher illness acuity through the transplant process. The expedited patients also had higher rates of relapse likely due to the limited assessment of sobriety during evaluation. Despite this, mortality rates were similar between groups.

3594-C | PROGNOSTIC VALUE OF PRE-DAY 7 LILLE SCORES IN SEVERE ALCOHOLIC HEPATITIS

Kevin Yang, Naren Srinath Nallapeta, Brian Quigley, Alexander Mark Carlson, Nariman Hossein-Javaheri and Thomas Mahl, University at Buffalo

Background: The severe form of alcoholic hepatitis (SAH) confers exceptionally high mortality. These patients are typically started on corticosteroid therapy barring contraindications, and efficacy is assessed at day 7 with the Lille score. We aimed to evaluate prognostic value of pre-day 7 Lille Model scores (LM 2-7) versus other established prognosticators. **Methods:** This retrospective study included all consecutive patients admitted to a tertiary care center with SAH as defined by Maddrey's discriminant function (MDF) > 32. Response to steroid therapy was assessed at day 2 to day 7 of treatment using the Lille score with cutoff value of 0.45. We compared these scores to the Model for End-Stage Liver Disease (MELD), age, bilirubin, international normalized ratio, creatinine (ABIC), and Glasgow Alcoholic Hepatitis Score (GAHS) utilizing receiver operating characteristics (ROC) curves. **Results:** Out of 425 patients admitted with alcoholic hepatitis, 150 patients fit the criteria for SAH. 126 of these patients received corticosteroid therapy. In the steroid arm, average age was 49.17 (SD = 10.95). This sample was 69.8% male, 78.6% white and 7.1% black. The average length of stay (LOS) was 14.44 days (SD = 9.56). 19.8% of the group receiving corticosteroid therapy died at 28 days and 27% at 90 days, compared to the total group of 425 patients with a 28-day mortality of 11.8% and 90-day mortality of 15.3%. The area under ROC curve (AUROC) for LM2 to LM7 for 28-day mortality was 0.777, 0.771, 0.778, 0.791, 0.809, and 0.796 in consecutive order. The AUROC was 0.784 for ABIC, 0.855 for GAHS, 0.719 for MDF, and 0.748 for MELD. The LM2 to LM7 AUROC for 90-day mortality was 0.741, 0.743, 0.756, 0.770, 0.787, 0.779, consecutively. Additionally, the AUROC was 0.713 for ABIC, 0.820 for GAHS, 0.735 for MDF, and 0.744 for MELD. **Conclusion:** In this retrospective study, all LM scores from day 2 to day 7 of treatment showed comparable efficacy in predicting mortality at 28 and 90 days. All prognostic scores showed good predictive power, with MDF having the smallest AUROC at 28 days and ABIC at 90 days. The GAHS had the largest AUROC for both mortality endpoints.

3595-C | PROTECTIVE ROLE OF 17β-ESTRADIOL IN ALCOHOL-ASSOCIATED LIVER DISEASE IS MEDIATED BY SUPPRESSION OF INTEGRIN SIGNALING IN MACROPHAGES

Kruti Nataraj, Michael Schonfeld and Irina Tikhanovich, University of Kansas Medical Center

Background: Alcohol associated liver disease (ALD) is a complex disease regulated by a combination of genetic and environmental factors. Sex is an important variable, and it is known that sex hormone signaling regulate both disease and homeostasis states in the liver. Previously we showed that PRMT6 arginine methyltransferase deficiency controls liver fibrosis development in alcohol fed mice by regulating integrin methylation. However, the increase in fibrosis induced by loss of *Prmt6* was 3-fold lower in females. We hypothesized that PRMT6-intergin signaling is altered in female mice. **Methods:** 6-8 weeks old wild type or *Prmt6* knockout female mice were subjected to gonadectomy, ovaries were removed through an incision just below the rib cage, the muscle layer sutured, and the incision closed with wound clips. In sham-operated mice, incisions were made and closed as above. Mice were then fed a combination of Western diet with alcohol in the drinking water for 18 weeks (WDA model), control mice were given Western diet with plain water. To investigate the role of estrogen, peritoneal macrophages were treated *in vitro* with 10nM, 100 nM or 1μM 17β-estradiol solution. Integrin expression was assessed via qPCR and immunohistochemistry. Fibrosis was assessed using whole liver mRNA of *Col1a1* and Sirius Red staining. **Results:** We found that 17β-estradiol treatment induced *Prmt6* expression and reduced integrin (α4, αx, β1 and β2) expression in a dose dependent manner. In agreement with these data, gonadectomized females showed elevated integrin expression and decreased PRMT6 levels. In addition, 17β-estradiol treatment reduced pro-inflammatory (*Tnf, Il6, Ccl5*) and pro-fibrotic (*Tgfb1*) signaling in macrophages. Later effect was dependent on 17β-estradiol-mediated regulation of integrin expression, since in macrophages lacking integrin α4 or αx, 17β-estradiol treatment failed to reduce pro-inflammatory and pro-fibrotic signaling. Consistent with this, gonadectomized females fed alcohol showed elevated inflammation and fibrosis development (3-fold increase in Sirius Red staining and *Col1a1* expression). Moreover, the increase in fibrosis induced by loss of *Prmt6* was greater in gonadectomized females compared to sham controls suggesting that estrogen contributes to sex differences in knockout mice. **Conclusion:** Our data suggest that estrogen signaling protects mice from alcohol associated liver disease in part through suppression of integrin signaling and induction of *Prmt6* expression.

f 3596-C | PROTEOMIC PROFILING OF PLASMA AND EXTRACELLULAR VESICLES IN ALCOHOL-ASSOCIATED HEPATITIS PATIENTS: INSIGHTS INTO DISEASE MECHANISMS AND BIOMARKERS

Mrigya Babuta[1], Yanbo Wang[1], Towia Libermann[1], Bruce Barton[2], Srinivasan Dasarathy[3], Craig J. McClain[4], Mack C. Mitchell[5], Laura E. Nagy[3], Svetlana Radaeva[6] and Gyongyi Szabo[1], (1)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (2)University of Massachusetts Memorial Health Care, (3)Cleveland Clinic Foundation, (4)University of Louisville, Louisville, KY, (5)University of Texas Southwestern Medical Center, (6)National Institutes of Health, Bethesda, MD

Background: Extracellular vesicle (EVs) cargo consists of RNA and protein molecules from the cells of origin reflecting the pathophysiological state specific to a disease and thereby, are emerging as potential biomarkers. There is a significant increase in the EV number in plasma of alcohol-associated hepatitis (AH) patients compared to controls. Therefore, in this study we aim to delineate the protein composition of EV cargo and identify the potential biomarkers that distinguish moderate AH (mAH) from severe AH (sAH). **Methods:** The plasma and EV proteome from mAH (MELD > 20) and sAH (MELD < 20) patients enrolled in the DASH consortium (n = 15/each group) were analyzed on the SomaScan platform, measuring 1,305 proteins. Statistical analysis identified the proteins significantly associated with mAH or sAH. **Results:** Proteomic analysis identified 209 and 498 proteins in the cargo of EVs of mAH and sAH patients, respectively that were significantly differentially expressed (adj. $p < 0.01$) as compared to healthy controls. Similarly, proteomic analysis identified 366 and 521 proteins in the plasma of human mAH and sAH patients, respectively. Further analysis indicated that 73 proteins were increased by more than two-fold changes in mAH patients and 93 proteins in

sAH EV samples compared to control subjects. The proteins detected in the EV cargoes of both mAH and sAH patients involved cellular signaling, metabolic processes and immune system process regulation. Biological functional analysis using Ingenuity Pathway Analysis (IPA) predicted activation of liver inflammation, fibrosis, and liver damage from differentially expressed genes unique to sAH-EVs. The highly upregulated proteins in mAH-EVs compared to control EVs included Latent-transforming growth factor beta-binding protein 4, several Cathepsins, Integrin alpha-beta complex. The significantly upregulated proteins in sAH-EVs compared to control EVs were Heat shock proteins, Tumor necrosis factor receptor superfamily members, and Serine/threonine-protein kinases. There were also a significant number of proteins that were decreased by at least 50% in moderate and severe AH patients as compared to control subjects (27 and 132 proteins respectively). Interestingly, certain signature proteins that were downregulated in the EVs of mAH patients were upregulated in the EVs of sAH patients. **Conclusion:** SomaScan data demonstrate that EV cargo of moderate and severe AH has a unique proteome profile compared to their respective plasma samples. Our data also suggest that EV cargo is selectively enriched in different stages of alcohol-associated hepatitis and, therefore, could be exploited as unique biomarkers while also revealing differences about the underlying biology in moderate and severe AH.

3597-C | PROVIDER ATTITUDES AND PRACTICE PATTERNS IN SCREENING AND MANAGEMENT OF ALCOHOL USE FOLLOWING LIVER TRANSPLANTATION

Nghiem B. Ha[1], Maria J. Duarte[1], Lisa X. Deng[1], Rena Mei[1], Yejoo Jeon[1], Connie W. Wang[1], Triveni DeFries[2], Bilal Hameed[1] and Courtney B. Sherman[1], (1)University of California, San Francisco, (2)San Francisco General Hospital

Background: Alcohol-associated liver disease (ALD) is the leading indication for liver transplant (LT) though return to alcohol use occurs up to 22% by year 1 and is associated with poor post-LT outcomes. While alcohol screening along with abstinence-promoting behavioral and pharmacotherapy is the foundation in managing alcohol use disorder (AUD), it is underutilized in hepatology. We aim to examine provider attitudes and practice patterns in screening and management of alcohol use in post-LT patients. **Methods**: We conducted a survey of liver transplant providers including (1) gastroenterology, hepatology, and transplant fellows, (2) hepatology and transplant faculty and (3) advanced practice providers (APP) at a single academic transplant center. The survey included 13 questions based on Likert scale to assess provider practice/screening patterns, views and understanding/knowledge of screening and management of AUD. **Results**: Response rate: 57% fellows (16 of 28), 70% faculty (16 of 23), and 71% APP (10 of 14) with an even distribution in years since training: current (38%), <10 years (31%) and >10 years (31%). Although most (96%) felt that screening was important, screening frequency varied among providers with 90% APP screening at most/every visit compared to faculty and fellows (56% vs 50%, $p=0.04$); 31% of faculty reported never/rarely screening. Comfort in screening varied among providers with more APP being very comfortable compared to faculty and fellows (90% vs 69% vs 56%, $p=0.048$). Most (90%) used the unvalidated single question (How often do you have a drink containing alcohol?) compared to validated AUDIT-C (5%, $p=0.04$). 50% felt uncomfortable using DSM-V to diagnose AUD, particularly fellows (63%). Preferred interventions were community support meetings(76%), referral to social work (55%) or addiction medicine (43%), and use of pharmacotherapy (26%), with the latter being highest among faculty compared to fellows/APP (44% vs 25% vs 0%, $p=0.047$). Most preferred that primary care (40%) or addiction medicine (23%) initiate interventions rather than GI/hepatology providers (36%) due to low rates of comfort in AUD counseling (6% vs 13% vs 10%), familiarity with pharmacotherapy (13% vs 6% vs 10%) and discomfort in prescribing pharmacotherapy (38% vs 69% vs 90%, $p=0.05$) among faculty, fellows, and APP, respectively; though most (79%) were interested in learning best practices for treating ALD patients with AUD (Figure). **Conclusion**: Screening for alcohol use in post-LT patients is low with one-third of faculty reporting never/rare screening. Notably, three-fourth of providers did not provide behavioral/pharmacotherapy interventions for AUD due to low rates of comfort in counseling and prescribing pharmacotherapy. This data highlights the need for further efforts in training and empowering gastroenterologyl/hepatology providers to deliver

evidenced-based interventions for AUD among post-LT patients.

3598-C | RACIAL AND ETHNIC DISPARITIES IN ALCOHOL-ASSOCIATED LIVER DISEASE PREVALENCE AND OUTCOMES IN THE UNITED STATES: A SYSTEMATIC REVIEW AND META-ANALYSIS

Ahmad Anouti[1], Karim Seif El Dahan[1], Nicole E. Rich[1], Jeremy Louissaint[1], William M. Lee[1], Mack C. Mitchell[1], Amit G. Singal[1] and Thomas G. Cotter[2], (1)University of Texas Southwestern Medical Center, (2)University of Texas Southwestern Medical Center, Dallas, TX

Background: Alcohol-associated Liver Disease (ALD), which encompasses alcohol-associated hepatitis (AH), and alcohol-associated cirrhosis (AC) is on the rise in the United States (US). Racial and ethnic disparities are evident within ALD disease; however, the precise nature of these disparities is poorly defined. Therefore, we conducted a systematic review to assess racial and ethnic differences in ALD prevalence, incidence, and mortality in the US. **Methods:** We conducted a search of the PubMed/MEDLINE and EMBASE databases and national conference abstracts to identify studies published from inception through May 8, 2022, that reported ALD, AH, and AC prevalence, incidence, and mortality within the US, stratified by race and ethnicity. We calculated pooled prevalence and incidence by race and ethnicity, including odds ratios (ORs) for ALD, AH, and AC mortality using DerSimonian and Laird method for random effect models. **Results:** We identified 23 studies (18 included in quantitative meta-analysis), comprising 31,764,783 patients, that characterized disparities in ALD prevalence, incidence, or prognosis. Among the general population, ALD prevalence was highest in Hispanics (4.47%; 95%CI: 2.07-9.38), intermediate in Whites (3.13%; 95%CI: 1.53-6.31), and lowest in Blacks (2.12%; 95%CI: 1.29-3.45). Compared to Whites the pooled RR of ALD prevalence were 1.64 (95%CI: 1.12-2.39) and 0.59 (95%CI: 0.34-1.02) for Hispanics and Blacks, respectively. There was no significant difference in risk of AC among Blacks compared to Whites (RR 0.93, 95%CI: 0.77-1.12). Compared with Whites, the pooled risk of AC mortality did not differ for Hispanics (RR 1.02; 95%CI:0.76-1.38) but was significantly lower for Blacks (RR 0.82; 95%CI: 0.74-0.92) and Asians (RR 0.45; 95%CI: 0.45-0.46). Compared with Whites, there were not significant differences in all-cause mortality among Hispanics (OR 1.54, 95%CI: 0.97-2.45), Blacks (OR 1.13, 95%CI: 0.43-2.42), and Native Americans (OR 2.41, 95%CI: 0.42-13.73). Most data were cross-sectional and assessed to be of poor or fair quality. **Conclusion:** Disparities were observed in ALD, including

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

significantly higher prevalence among Hispanics and lower among Blacks, although differences in mortality among those with ALD appear smaller. Current data remains poorly defined regarding disparities in ALD prevalence and outcomes, highlighting a need for improved epidemiological studies in this area.

3599-C | RECIDIVISM IN LIVER TRANSPLANT RECIPIENTS WITH ALCOHOLIC LIVER DISEASE IN COVID-19 ERA

Jiten P. Kothadia[1,2], Anwesh Dash[3], Jarrett Rong[3], Tzu-Yu Liu[1,2], Hemnishil Marella[1], Ryan Helmick[1,2], Corey Eymard[1,2], Jason M. Vanatta[1,2] and Satheesh P. Nair[1,2], (1)University of Tennessee Health Science Center, Memphis, TN, USA, (2)Methodist University Hospital, Memphis, TN, USA, (3)The University of Tennessee Health Science Center,Memphis, TN, USA

Background: Liver transplant for alcoholic liver disease (ALD) requires careful evaluation of the patients at risk for recidivism. The COVID-19 pandemic has considerably influenced alcohol use, with an increase in alcohol-related emergencies, alcohol use, and an overall negative impact on patients with alcohol use disorders. We sought to evaluate the impact of COVID-19 on recidivism in LT recipients with ALD. **Methods:** One Hundred forty patients, who underwent liver transplantation (LT) for ALD in our institution were included in the study. Patient were divided into two groups: pre-COVID-19 Era (January 2016- February 2020) and the COVID-19 Era (March 2020-November 2021). Demographics, medical history, alcohol relapse and transplant outcomes were compared between the two groups. **Results:** Among the 140 patients, 82 patients received LT in the pre-COVID-19 Era and 58 patients in the COVID-19 Era. (Table 1). In the pre-COVID-19 Era group, a greater number of patients had abstinence of 6 months or more before liver transplantation (76% vs 58, p = 0.03 %). There were no differences between the groups in overall recidivism rate and recidivism rate within 1-year of LT. Similarly, there were no difference in the length of stay, graft loss, re-admission rate, acute rejection, biliary complications, or vascular complications between the two groups. A lower rate of infection was noted in the COVID-19 Era vs. Pre-COVID Era (10.34 % vs. 25.60 % p = 0.02) (Table 2). **Conclusion:** There was no increased risk of in the alcohol recidivism rate among the patients who underwent liver transplantation during the COVID-19 Era.

3600-C | RESPONSE TO CORTICOSTEROID THERAPY, RECOMPENSATION, AND LONG-TERM SURVIVAL IN PATIENTS WITH SEVERE ALCOHOL-ASSOCIATED HEPATITIS ARE DEPENDENT ON KARNOFSKYS PERFORMANCE STATUS

Anand V. Kulkarni, Sameer Shaik, Shantan Venishetty, Manasa Alla, Sowmya T R, Mithun Sharma, Nageshwar D Reddy and Padaki Nagaraja Rao, Aig Hospitals, Hyderabad, India

Background: Severity scores, including discriminant function score and MELD score, can predict short-term mortality in patients with severe alcohol-associated hepatitis (SAH). There are no studies evaluating the effect of the Karnofsky performance status (KPS) scores of individual's with SAH on long-term outcomes, which we aimed to assess in the prospective cohort study. **Methods:** Patients with SAH who received medical management and had complete follow-up data were included. Patients who underwent early liver transplantation were excluded. The objective was to compare the baseline characteristics and outcomes, including corticosteroid response, recompensation, and survival of patients with poor KPS (Gr.A: score < 50) vs. good KPS (Gr. B: score > 50) and lastly, to

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

assess the dynamicity of KPS and the predictors of mortality. **Results:** 133 patients with a median follow-up of 10 months (0.5-48 mo) were included. The mean KPS score at baseline was 53.38 ± 11.73. Sixty-four patients (48%) had a score of < 50 (Gr. A), and 69 patients (52%) had a score > 50 (Gr.B). Severity scores at baseline were higher in Gr. A then Gr. B (MELD: 29.56 ± 4.68 vs. 26.76 ± 5.13; P = 0.001 and mDF: 98.87 ± 60 vs. 74.34 ± 38.57 in Gr. B; P = 0.006). A higher proportion of patients in Gr. A had ascites (90.6% vs. 63.8%; P < 0.001), acute kidney injury (34.4% vs. 7.2%; P < 0.001), and hepatic encephalopathy (31.3% vs. 3%; P < 0.001) at baseline. A similar proportion of patients received beta-blockers (14.1% vs. 21.7%; P = 0.25), antibiotics (norfloxacin and/or rifaximin: 62.5% vs. 55.1%; P = 0.76), and corticosteroid therapy (61% vs. 69.6%; P = 0.36). However, 60% of patients in Gr. B responded to corticosteroid therapy (Lille's < 0.45) compared to only 39.1% in Gr. A (P = 0.01). Similarly, only 50% of Gr. A compared 76.8% of patients in Gr. B recompensated (P = 0.002). On Kaplan-Meier analysis, the mean time to recompensation was 9.6 months (95%CI, 7.11-12) in Gr. A compared to 6.33 months (95%CI, 4.42-8.25) in Gr. B (P = 0.01) (Fig. A). Furthermore, the survival was significantly higher in Gr. B (72.5%) than Gr. A (53.1%; P = 0.03). On Kaplan-Meier survival analysis, the mean survival was 15.5 months (95%CI,12.72-18.28) in Gr. A compared to 33 months (95%CI, 27.48-38.54) in Gr. B (P < 0.001) (Fig. B). KPS score remained significantly lower in Gr. A than in Gr.B till the last follow-up (Fig. C). Similarly, KPS scores remained lower in those who died (Fig. D) and those who had recidivism (Fig. E). On multivariate Cox regression analysis, poor KPS (HR,1.94 [1.04-3.62]; P = 0.02), ascites (HR, 3.07 [1.12-8.33];P = 0.02), HE (HR, 4.65 [2.44-8.86];P < 0.001), and recompensation (HR, 0.17 [0.9-0.33];P < 0.001) predicted long-term mortality. **Conclusion:** Response to corticosteroid therapy, recompensation, and long-term survival in patients with severe alcohol-associated hepatitis are dependent on Karnofsky's performance status.

3601-C | RIFAXIMIN-α HAS LIMITED EFFECT ON LIVER AND BRAIN PHENOTYPE IN MURINE MODELS OF EARLY STAGE ALCOHOL-ASSOCIATED AND NON-ALCOHOLIC FATTY LIVER DISEASE

Maximilian Joseph Brol[1], Sabine Klein[1], Robert Schierwagen[1], Mads Israelsen[2], Wenyi Gu[1], Maja Thiele[3], Frank Erhard Uschner[1], Nikolaj Torp[4], Jonel Trebicka[1], Aleksander Krag[5] and Manimozhiyan Arumugam[6], (1)University Hospital Münster, (2)Liver Research Centre, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark, (3)Department of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark, Odense C, Denmark, (4)Odense University Hospital, (5)University of Southern Denmark, Odense, Denmark, (6)University of Copenhagen

Background: Alcohol-associated and non-alcoholic fatty liver disease (NAFLD) are rapidly increasing entities and currently the most abundant liver diseases worldwide. Knowledge on pathophysiology is indispensable for the development of therapeutic strategies. Rifaximin-α is a non-absorbable antibiotic and in clinical use in late-stage liver disease for the treatment of hepatic encephalopathy. Many studies were performed in order to evaluate the beneficial effects of Rifaximin-α on alcohol-associated and non-alcoholic fatty liver disease. Here, we aim to investigate the effects of Rifaximin-α on the liver phenotype in different murine models of early stages of fatty liver diseases. **Methods:** 7-week old, C57Bl/6 mice were treated for 7 weeks with either a Methionine-Choline deficient diet (MCD) or Western diet (WD) or standard chow (n = 20 per group). Mice were firstly randomized 1:1 on whether to receive Ethanol in the drinking water (stepwise increase up to 16 vol.-%) and whether to receive Rifaximin-α with a dose of 30 μg per mouse per day or not. After sacrifice, livers were phenotyped with regard to fibrosis (hydroxyproline content, Sirius red stain), inflammation (qPCR of Il1b, Tnfa, Ccl2 and F4/80-immunohistochemistry) and steatosis (hepatic triglyceride content, Oil red stain). Brains were analysed by qPCR for inflammatory markers. **Results:** As expected, MCD treatment led to decreased body weight as well as liver steatosis and fibrosis. WD treatment led to an increase in body weight, with very mild steatosis without fibrosis. The addition of ethanol increased fibrosis in MCD-treated animals, but decreased fibrosis in WD-fed mice. Rifaximin-α did not have any significant effect on liver fibrosis,

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

steatosis or inflammation in these models. Tnfa and Il1b-levels in brains were slightly elevated in mice receiving MCD +/- ethanol compared to controls. Rifaximin-α treatment did not alter cytokine levels in brains. **Conclusion:** Ethanol displayed different effects in murine models of NALFD and NASH. Rifaximin-α treatment does not change the liver phenotype of MCD- and WD-induced early NAFLD and alcohol-associated fatty liver disease in mice . The expression of cytokines in the brain remains unchanged in early-stage liver disease and was not further affected by Rifaximin-α treatment.

3602-C | RIFAXIMIN-A REDUCES CIRCULATING CERAMIDES AND INCREASES PHOSPHATIDYLCHOLINES IN PATIENTS WITH ALD: A LIPIDOME ANALYSIS OF THE GALA-RIF TRIAL

Mads Israelsen[1], Tommi Raimo Leo Suvitaival[2], Nikolaj Torp[3], Stine Johansen[3], Maximilian Joseph Brol[4], Camilla D Hansen[5], Andressa de Zawadzki[6], Sönke Detlefsen[3], Peter Andersen[7], Johanne Kragh Hansen[7], Katrine Prier Lindvig[7], Katrine Holtz Thorhauge[8], Morten Karsdal[9], Manimozhiyan Arumugam[10], Peer Bork[11], Jonel Trebicka[12], Maja Thiele[13], Torben Hansen[10], Cristina Legido-Quigley[14], Aleksander Krag[15] and the GALAXY and MicrobLiver Consortia, (1) Odense University Hospital, (2)Steno Diabetes Center Copenhagen, (3)Department of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, (4)University Hospital Münster, (5)Centre for Liver Research, Department of Gastroenterology and Hepatology, Odense University Hospital, (6)Nordic Bioscience a/S, (7)Liver Research Centre, Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark, (8)Department of Gastroenterology and Hepatology, Odense University Hospital, Odense, Denmark, (9)Nordic Bioscience a/S, Denmark, (10)University of Copenhagen, (11)European Molecular Biology Laboratory, Embl, Heidelberg, (12) European Foundation for the Study of Chronic Liver Failure and Grifols Chair, Barcelona, Spain, (13) Department of Clinical Research, Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark, Odense C, Denmark, (14)Steno Copenhagen, (15)University of Southern Denmark, Odense, Denmark

Background: Therapeutic targets to halt alcohol-related liver disease (ALD) are highly needed. The GALA-RIF trial showed that rifaximin-α reduced progression of liver fibrosis in patients with ALD, but the mechanism of action remains unknown. The lipid metabolism plays an important role in ALD, and animal models have shown that a pharmacologic reduction of hepatic ceramides can reduce alcohol-induced liver injury. We performed plasma lipidomics from patients of the GALA-RIF trial to assess the effect of rifaximin-α on the lipid profile. **Methods:** We used plasma EDTA from the GALA-RIF trial assessing oral rifaximin-α or placebo for 18 months in a double-blind placebo-controlled 1:1 RCT in patients with biopsy-proven ALD and no previous hepatic decompensation. Plasma was sampled at baseline, after 1 month and after 18 months. Samples were analyzed using an untargeted UHPLC-QTOF/MS lipidomics platform. We performed liver biopsies at baseline and after 18 months and assessed liver fibrosis stage according to the Kleiner fibrosis

score. Histological treatment response was classified as “progression”, “stable” or “regression”. Here, we report the results based on the per-protocol population (n = 108) for the completeness of the lipidomic data. **Results:** All 108 patients were Caucasian, 91 (84%) were men and the mean age was 59 (SD 9) years. Distribution of fibrosis stages at baseline was F0/F1/F2/F3/F4 = 5/31/48/18/6. Significantly fewer patients progressed in fibrosis in the rifaximin-α group (n = 13, 24%) compared to placebo (n = 23, 43%). We identified 231 lipid species from 16 lipid classes. After 1 month treatment, rifaximin-α significantly decreased the levels of 4 ceramides (Cers) and 2 phosphatidylcholines (PCs) and increased the levels of 2 phospholipids and 1 sphingomyelin (SM) compared to placebo. At 18 months, rifaximin-α had increased the levels of 7 PCs and 2 SMs while Cers were still decreased but not significant. In the rifaximin-α group, we could stratify patients who progressed in liver fibrosis by a distinctly different lipidome at baseline with significantly elevated levels of lysophosphatidylcholines, sphingomyelins and phosphatidylcholines. **Conclusion:** The beneficial effects of rifaximin-α in patients with ALD may be mediated by the modulation of the lipid metabolism, including reducing the levels of circulating hepatotoxic ceramides. Further, rifaximin-α increases the levels of fibrosis-protective phosphatidylcholines.

3603-C | ROLE OF HEPATOCYTE MITOGEN-ACTIVATED PROTEIN KINASE PHOSPHATASE 1 (MKP1) IN SEXUAL DIMORPHISM AND SUSCEPTIBILITY TO ALCOHOL INDUCED LIVER INJURY

Mary Nancy Walter, Diego Montoya-Durango, Yali Wang, Walter Rodriguez-Alvarez, Sreelatha Reddy, Jingwen Zhang, Craig J. McClain, Shirish Barve and Leila Gobejishvili, University of Louisville, Louisville, KY

Background: It is well established that females are more susceptible to the toxic effects of alcohol. This sexual dimorphism has been attributed to a range of factors, including baseline differences in immune background and inflammatory response, although the exact mechanisms are still poorly understood. Clinical and animal studies have noted that alcohol reduces the expression of mitogen-activated protein kinase phosphatase 1 (MKP1), a negative regulator of stress MAPK pathways JNK and p38 MAPK, in the liver. However, the role of hepatocyte-specific MKP1 in the pathogenesis of ALD remains uncharacterized. This study aimed to evaluate the role of hepatocyte-specific MKP1 in the susceptibility and sexual dimorphism in alcohol-induced liver injury. **Methods:** Male and female hepatocyte-specific *Mkp1*$^{-/-}$ knockout (LSKO) and wild type (*Mkp1*$^{+/+}$ "floxed") mice were subjected to the NIAAA chronic plus binge model. Primary mouse hepatocytes were treated with 50 mM ethanol for 24 or 48 hours. Plasma alanine transaminase (ALT) and aspartate aminotransferase (AST) levels were

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

measured to determine liver injury. Hepatic ER stress and inflammation were evaluated by real-time qPCR and multiplex assays. Statistical analysis was carried out using two- and three-way ANOVA. **Results:** Ethanol treatment resulted in a time-dependent decrease in *Mkp1* mRNA expression in primary hepatocytes in both males and females; however, this effect was significantly more pronounced in hepatocytes from females. Twenty-four hours of ethanol exposure increased mRNA expression of ER stress markers in female *Mkp1* knockout hepatocytes. *In vivo*, *Mkp1* deletion led to increased liver injury in both sexes. Notably, liver injury was significantly higher in wild-type alcohol-fed (AF) female mice when compared to males. Alcohol-mediated ER stress was also higher in LSKO female and male mice, although LSKO females seemed more susceptible to alcohol-induced ER stress than males. Examination of liver inflammatory markers showed that alcohol-fed female LSKO mice had elevated levels of hepatic IL-17, IL-15, MIP-1α (Ccl3), and IL-9 protein levels compared to their pair-fed and wild-type counterparts. **Conclusion:** Hepatocyte MKP1 plays a significant role in alcohol induced liver injury in both male and female mice. However, the disproportionate effect of alcohol on MKP1 expression in female hepatocytes makes them more susceptible to increased alcohol-induced liver injury, ER stress, and hepatic inflammation.

3604-C | SARCOPENIA DEFINED WITH L3-SMI IS INDEPENDENT PREDICTOR OF SURVIVAL IN MALE PATIENTS WITH ARLD IN MAINLAND CHINA

Song Yang and Yu Zhang, Beijing Ditan Hospital, Capital Medical University, Beijing, China

Background: The burden of alcohol-related liver disease (ARLD) is increasing in China. Patients with ARLD are more likely to have comorbid sarcopenia, which may impair the survival of patients with ARLD. The relationship between sarcopenia and prognosis in Chinese patients with ARLD remains unclear. This study aimed to evaluate the relationship between the prognoses of patients with ARLD and sarcopenia, identified using the skeletal muscle index at the third lumbar vertebra level (L3-SMI). **Methods:** Hospitalized patients with ARLD were enrolled retrospectively between 2015 and 2018 and followed up for 24 months to evaluate their survival profiles. Cox proportional hazards regression models were used to estimate patient survival factors. A receiver operating characteristic curve was created to identify the cut-off point of the L3-SMI for predicting the prognoses of Chinese patients with ARLD. **Results:** The study enrolled 168 male patients with ARLD who were followed-up for 24 months or until a study endpoint was met. The overall L3-SMI in patients with ARLD was 42.61 ± 9.15 cm^2/m^2; 42.86% (72 /168) of patients with ARLD were comorbid with sarcopenia. The overall survival in patients with ARLD was 77.38% at 24 months. The survival rate of patients with sarcopenia was lower than that of patients without sarcopenia (66.67% vs. 85.42%, $P = 0.004$). Multiple Cox regression analysis showed sarcopenia, abstinence, and baseline creatinine were independent prognostic factors of 24-month survival with hazard ratios (95% confidence intervals) of 2.022 (1.025–3.991), 0.275 (0.122–0.617), and 1.018 (1.008–1.027), respectively. The cut-off value of the L3-SMI for predicting 24 months of survival was 40.0 cm^2/m^2 for male patients with ARLD. **Conclusion:** Sarcopenia is an independent mortality risk factor in male patients with ARLD in mainland China. Early diagnosis and intervention of sarcopenia are important for optimizing the management of patients with ARLD. Further studies with larger sample sizes are needed to verify the results.

Bioinformatics, Department of Family Medicine and Public Health, University of California San Diego, (3)VA San Diego Healthcare System, (4)University of California San Diego

Background: Alcohol-associated hepatitis (AH) is an acute on chronic liver disease that develops in patients with a history of heavy alcohol use. Gut dysbiosis is known to be important for the pathogenesis of this disease. Our and other studies have shown that microbiota-derived tryptophan metabolites are decreased in fecal samples from patients with AH. These metabolites are also known to be ligands for the aryl hydrocarbon receptor (AhR), a transcription factor involved in immunity. The **aim** of this study is to evaluate AhR ligand activity in the serum of patients with AH and to clarify its clinical significance. **Methods:** We measured serum AhR activity of 281 patients with AH, 79 patients with alcohol use disorder (AUD), and 76 healthy controls (HC) at the time of admission to the hospital from two multicenter observational studies, InTeam and AlcHepNet. To evaluate AhR activity, we used an AhR reporter assay; HepG2-Lucia™ AhR cells (InvivoGen) were incubated with each serum sample for 24 hours and luminescence was measured. The activity value for each sample was calculated as a percentage (fold change) of the mean of all healthy samples. **Results:** The median age of AH, AUD, and HC was 45.3 years, 50.0, and 30.9, respectively. Among the AH group, 169 cases (60.4%) were male patients. The median value of the Maddrey discriminant function was 54.5 (IQR 33.2-80.7), and MELD scores was 25 (21-31). The 30, 60, 90, and 180-day mortality rates were 13.1%, 20.9%, 23.1%, and 29.9%, respectively. Patients with AH had significantly higher AhR activity levels compared with AUD and HC (median and IQR: AH 1.56 (1.07-2.28), AUD 0.97 (0.82-1.13), HC 0.96 (0.79-1.16), *p*-value HC vs. AH = < 0.001, *p*-value HC vs. AH = < 0.001, Figure 1a). The AUROC of AhR activity in diagnosing AH was 0.791 (cutoff value = 1.37, sensitivity 59.1%, specificity 94.8%, PPV 95.4%, NPV 56.1%). Within the AH patient cohort, AhR activity was positively correlated with total bilirubin ($r = 0.518$, $p < 0.001$) and MELD score ($r = 0.361$, $p < 0.001$), negatively correlated with albumin ($r = -0.204$, $p < 0.001$). The cumulative 30, 60, 90, and 180-day survival rates for the AhR activity ≥ 2.60 group were all significantly lower than those for the AhR activity < 2.60 group (30day: 76.4 vs 89.6% $p < 0.01$, 60day: 59.9 vs 83.8% $p < 0.001$, 90day: 56.2 vs 81.8% $p < 0.001$, 180day: 56.2 vs 71.0% $p < 0.01$, Log-rank test, Figure 1b). The same optimal cutoff value was used to further stratify severe AH cases with MELD 20 or higher (90-day survival rates: 57.2% (AhR activity ≥ 2.6) vs 77.6% (AhR activity < 2.6) $p < 0.01$, Log-rank test). **Conclusion:** Unlike in the gut, serum AhR activity was significantly higher in patients with AH compared with healthy subjects and patients with AUD, and is associated with increased mortality in AH patients. Serum AhR activity has the potential to serve as a prognostic marker and possibly as therapeutic target.

3606-C | SEX DIFFERENCES IN LIVER TRANSPLANT OUTCOMES IN PATIENTS WITH ALCOHOL ASSOCIATED LIVER DISEASE (ALD) REFERRED FOR EARLY LIVER TRANSPLANT EVALUATION

Katherine M. Cooper and Deepika Devuni, UMass Chan Medical School

Background: Women experience increased hepatotoxicity from alcohol. Despite this, women with chronic alcohol liver disease (ALD) undergo liver transplant (LT) less than men. To date, no studies have compared outcomes in men versus women with early sobriety. We aimed to compare the impact of sex on LT access and outcomes in patients with early alcohol sobriety. **Methods:** We retrospectively analyzed patients with ALD and early sobriety (≤ 6 mo) who underwent early LT evaluation (eLTE) at our institution over 4 years (2018-2021). Patients were categorized by sobriety period: 0-3 mos vs. 3-6 mos. Pre-LT outcomes were LT

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

candidacy (accepted vs. declined) and use renal replacement therapy (RRT) at time of eLTE. Overall outcomes were LT rate and pre-LT death rate. Variables were compared between sex; sex in this abstract refers to sex assigned at birth (male vs. female), and hereto will be referenced as men and women. Subgroup analyses were completed by sobriety period. Data was compared using Fisher's exact & t-tests. Cox regression was used to determine the effect of patient sex on risk of death up to 2 years; patients were censored at liver transplant date or last known well if lost to follow up. **Results:** 162 patients were analyzed; 67 women (41.4%) and 95 men (58.6%). More women required RRT at the time of eLTE referral than men (17.9% vs. 7.4%, $p = 0.04$); this difference was rooted in the 0-3 mos group. MELD did not differ by sex for the total cohort (27 women vs. 29 men), but women had a higher MELD in the 3-6 mos cohort (24 vs. 18). Serum creatinine (sCr) did not differ between men and women overall (1.96 vs. 1.91. $p = 0.86$). Women had higher white blood cell count (WBC) in the 0-3 mos group (17 vs. 13, $p = 0.03$), but not in the 3-6 mod group (not shown). Days to listing did not differ by sex [14 d in men vs. 15 d in women]. Women with early ETOH sobriety were transplanted less than men (32.8% vs. 47.4%, $p = 0.06$). In both the 0-3- and 3-6-month groups, LT rate was 15% less in women. When analyzing by eLTE location, the difference in LT rate was more significant in those with outpatient eLTE (12% women vs. 35% men, $p = 0.04$). Of those who received LT, women had fewer days on the wait list(18 d vs. 39 d). Cox regression controlling for age, sCr, sodium, bilirubin and INR demonstrated a trend between female sex and death through a 2-year period ($p = 0.09$). **Conclusion:** Our results suggest sex disparities in LT persist in patients with early alcohol sobriety. Despite similar or higher MELD and more severe renal dysfunction as evidenced by increased dialysis, women with early sobriety were transplanted less often than men. Given the increasing number of patients with ALD and the transition to offering earlier LT, more research should be dedicated to mitigating disparities in women who are at elevated risk of severe liver damage from alcohol.

3607-C | SUCCESSFUL INTEGRATION OF ALCOHOL USE DISORDER TREATMENT INTO A PRIMARY CARE-BASED LIVER CLINIC

Lana Aleuy, Siri Chirumamilla, Shelly-Ann Fluker, Lesley S. Miller and Jennifer E. Lom, Emory University School of Medicine

Background: Alcohol-related liver disease is deadly, and prevalence is increasing in the US. Access to treatment for alcohol-use disorder (AUD) is limited. To address this gap, we launched a novel service line for AUD in our primary care-based liver clinic in 2022. **Methods:** The AUD clinic is embedded in the Grady Liver Clinic (GLC) at Grady Health System, a safety-net health system in Atlanta, GA. The GLC, originally established to treat hepatitis C, is a multidisciplinary clinic, staffed by general internists. Patients are eligible for AUD clinic if they have an AUDIT-C score of 4 or more and are motivated to change their alcohol use. AUD clinic services include structured assessments, motivational interviewing, medication assisted treatment and referral to peer and behavioral health support. We retrospectively collected data on patient demographics and treatment outcomes for patients seen from 1/2022-2/2023. **Results:** Of 89 patients referred 54 unique patients attended at least one visit. Of these, 52% were referred from primary care, 37% from inpatient, 6% from the emergency department, and 6% from gastroenterology. The median age was 56, 72% were male and 87% were black. Patients had public (39%) and private (33%) insurance, and 28% were uninsured. The severity of AUD was categorized into mild (31%), moderate (31%) and severe (37%) using DSM criteria; 28% had liver cirrhosis. 71% of patients had an AUD medication prescribed, of which 68% reported taking the medication. Naltrexone was prescribed most (56%) followed by acamprosate (11%) and gabapentin (4%). In the naltrexone group, 80% had a 2nd refill and 70% had reduced alcohol cravings and decreased alcohol use. All patients within the acamprosate and gabapentin groups had a 2nd refill and reported reduced alcohol cravings and decreased alcohol use. Importantly, hospitalizations for alcohol-related complications decreased. The baseline hospitalization rates for the entire cohort in the 6 months before their first visit was 48%. The hospitalization rate during the study period was 13%. **Conclusion:** Our primary care-based AUD clinic leveraged existing infrastructure to effectively treat

motivated patients for AUD. The majority of patients took prescribed medications which led to a significant decrease in alcohol related hospitalizations, supporting that this model could expand access to needed AUD care in similar settings.

3608-C | SYSTEMIC INFLAMMATION AND LOCAL SIGNALING UPREGULATE PLATELET GALECTIN-3 BINDING PROTEIN WHICH MAY INCREASE PORTAL HYPERTENSIVE EFFECTS OF HEPATIC STELLATE CELLS IN ALCOHOL-ASSOCIATED CIRRHOSIS

Matthew McConnell[1], Rolando Garcia-Milian[2], Yilin Yang[1], Jain Jeong[1], Teruo Utsumi[3], John Hwa[1] and Yasuko Iwakiri[2], (1)Yale University, New Haven, CT, (2) Yale School of Medicine, New Haven, CT, (3)VA Connecticut Health Care

Background: Platelets have been shown to adopt a proinflammatory phenotype in alcohol-associated liver disease, but the detailed mechanisms underlying this phenotype and their role in disease progression remain understudied. **Methods:** Hospitalized patients with alcohol-associated cirrhosis (AC) with portal hypertension ($n = 17$) were compared with healthy controls without known liver disease ($n = 7$). Pure platelets were isolated for RNAseq. Human hepatic stellate cell line (HSC, LX-2 Cells) and a human megakaryocytic cell line (MEG-01 cells) were used for *in vitro* experiments. **Results:** Platelet RNA from AC with portal hypertension vs healthy controls revealed 2021 genes with |fold-change| > 1.5 and $p_{adj} < 0.05$. LGALS3BP (padj $1.21e^{-20}$, 9.23 fold-increase) was one of the most altered genes. This gene encodes galectin-3 binding protein (Gal3BP) which binds its receptor galectin 3 on target cells. A Liver Single Cell Atlas (liveratlas-vilarinholab.med.yale.edu) revealed high expression of galectin-3 in HSCs (7-fold increase relative to other cell clusters, $p_{adj} = 4.11 \times 10^{-154}$, and expressed by 48.8% of HSCs). LX-2 cells treated with recombinant Gal3BP showed significant upregulation of endothelin-converting enzyme 1 expression (1.3 fold-change vs control, $p = 0.02$), which mediates increased active vasoconstrictor endothelin-1 production by HSCs and exacerbates portal hypertension. Ingenuity Pathway Analysis identified TGF-beta and TNF-alpha as potential regulators. Plasma from patients with AC vs healthy controls revealed significant upregulation of TNF-alpha (21.67 pg/mL vs 12.18 pg/mL, $p = 0.02$). Recombinant TNF-alpha upregulated Gal3BP (1.3 fold-change, $p < 0.0001$) in MEG-01 cells. Patient plasma revealed decreased TGF-beta (13.3 vs 57.6 ng/mL, $p = 0.008$), but the platelet RNAseq data revealed increased TGF-beta in platelets themselves in AC vs healthy controls (1.57 fold-change, FDR = 0.0006), suggesting potential autocrine signaling. Recombinant TGF-beta significantly upregulated Gal3BP in MEG-01 cells (2.59 fold-change, $p < 0.0001$), and when cultured with lipopolysaccharide (LPS) and ethanol which are key stimuli in alcohol-associated cirrhosis with portal hypertension, MEG-01 cells upregulated both TGF-beta and LGALS3BP in response to LPS and ethanol combined but not either alone. TNF-alpha did not significantly alter TGF-beta in MEG-01 cells. **Conclusion:** Platelets in AC with portal hypertension contain increased Gal3BP, which exacerbates the portal hypertensive effects of HSCs. Gal3BP is regulated in megakaryocytes by potential synergy between systemic inflammation (TNF-alpha) and autocrine signaling in response to alcohol and LPS via TGF-beta. The bone marrow-liver axis may be a novel therapeutic target in portal hypertension and liver fibrosis.

3609-C | SZN-043, A HEPATOCYTE-TARGETED R-SPONDIN MIMETIC, STIMULATES HEPATOCYTE PROLIFERATION AND IN A HUMANIZED LIVER FRG MOUSE MODEL

Trevor Fisher[1], Mehaben Patel[1], Stella Tran[1], Wen-Chen Yeh[2], Geertrui F Vanhove[2], Jay Tibbitts[3] and Helene Baribault[1], (1)Surrozen, Inc., (2)Surrozen, Inc, (3)Surrozen Inc

Background: Wnt signaling plays a central role in hepatocyte expansion during development and tissue repair. R-spondins (RSPOs) are known enhancers of Wnt signaling, via stabilization of Frizzled and LRP co-receptors. SZN-043 is a bispecific fusion protein and hepatocyte-specific R-spondin mimetic, currently in Phase 1 clinical trial for alcoholic hepatitis. SZN-043 induces hepatocyte-targeted Wnt signaling and hepatocyte proliferation in normal mice. To support the translation of this efficacy to humans, we tested the effects of SZN-043 on human hepatocyte proliferation, using the Fah/Rag2/Il2rg (FRG) humanized liver mouse model. **Methods:** 25 week old FRG triple mutant male

mice repopulated with human hepatocytes were obtained from Yecuris (Tualatin, OR). After 3 days acclimation, baseline serum samples were collected on Day 0. Mice were then dosed intraperitoneally with either control antibody, 10 mpk) or SZN-043 (3 or 10 mpk). Liver samples were collected upon termination on Days 1, 2, 3, 5, and 7 for RNA and immunofluorescence analysis. **Results:** SZN-043 induced a dose-dependent increase in the human gene expression of the Wnt/β-catenin targets CYP1A2, CYP2E1, and LECT2 and the proliferation marker, MKI67. Immunofluorescence using double Ki-67 and human ASGR1 staining confirmed that SZN-043 induced a wave of human hepatocyte proliferation, peaking on Days 2 and 3, and reverting to baseline by Day 5. **Conclusion:** These results show that SZN-043 can drive human hepatocyte-proliferation in humanized liver mice. This effect suggests that SZN-043 may have meaningful clinical benefit in human disease states where hepatocyte proliferation is impaired, such as in severe alcoholic hepatitis.

f 3610-C | TELOMERE LENGTH IS SIGNIFICANTLY REDUCED IN ALCOHOL-ASSOCIATED HEPATITIS COMPARED TO ALCOHOL-ASSOCIATED CIRRHOSIS AND HEAVY DRINKERS WITHOUT LIVER DISEASE

Daniel Penrice[1], Nidhi Jalan-Sakrikar[2], Puru Rattan[3], Kamalpreet S. Hara[2], Beatriz Sordi Chara[2], Tejasav Sehrawat[1], Ryan Lennon[1], Blake Kassmeyer[1], Brooke Druliner[1], Kimberly Kossick[1], Anthony Lagnado[1], Lisa Boardman[1], Jean-Pierre Kocher[4], Patrick S. Kamath[1], Vijay Shah[2] and Douglas A. Simonetto[2], (1)Mayo Clinic, (2)Mayo Clinic Rochester, Rochester, MN, (3)Mayo Clinic - Rochester, (4)Division of Biomedical Informatics, Mayo Clinic College of Medicine and Science, Rochester, MN

Background: Telomeres are DNA-protein structures located at the end of chromosomes which prevent DNA degradation and unwanted repair. Telomeres naturally shorten with ageing; however, ineffective maintenance of telomere length has been implicated in many diseases involving organs with high regenerative capacity. Alcohol-associated hepatitis (AAH) is an acute severe form of liver disease which develops in up to 30% of heavy alcohol users and is associated with high mortality. Impaired liver regeneration is one of the hallmarks of AAH and whether telomere shortening may play a role remains unknown. **Methods:** Peripheral blood mononuclear cells (PBMCs) were isolated from blood samples from 88 subjects with AAH, 64 heavy drinkers without liver disease (HD), and 59 healthy controls (HC). All subjects were enrolled in the AlcHepNet Consortium Study. Telomere length was measured in DNA isolated from PBMCs using Monochrome Multiplex Quantitative PCR (MMQPCR) and reported as telomere/single-copy gene (T/S) ratio. Liver FFPE sections were obtained from 9 subjects with AAH, 9 subjects with alcohol-associated cirrhosis (Alc Cirr), and 8 HC. Samples underwent fluorescence *in situ* hybridization with telomere probe (FISH). FISH intensity was calculated as measure of telomere length (~100 hepatocytes/subject) in a blinded fashion. P-values for group comparisons were calculated with one-way ANOVA. **Results:** Median PBMC T/S ratio was 1.29 (Q1: 1.16, Q3: 1.48) in the HC group, 1.23 (1.03, 1.41) in the HD group, and 1.13 (1.00, 1.26) in the AAH group ($P < 0.001$) (Figure 1A). The HC group was younger (mean age 35) and had a lower proportion of males (32%), however HD and AAH groups were similar (64% vs 55% males, and 48 vs 46 median age. The HD group also consumed more alcohol than the AAH group, 140 g/day vs 112 g/day ($P < 0.001$) respectively. No relationship was observed between T/S ratio and lifetime alcohol use ($r = 0.02$, $p = 0.85$). Additionally, no relationship was noted between T/S ratio and MELD score ($r = 0.02$, $p = 0.87$). Median telomere intensity score (TSI) in liver tissue samples was 718 (635.7, 898.2) in the healthy control group, 561 (489.4, 598.5) in the Alc Cirr group, and 491 (428.0, 583.2) in the AAH group ($P = 0.008$) (Figure 1B). The significantly decreased telomere length in the AAH group was seen despite subjects being younger than the cirrhosis group (median age 34.1 in AAH, 46.5 in Alc Cirr, and 49.8 in HC). **Conclusion:** Significantly reduced telomere length was observed in PBMCs and hepatocytes of patients with AAH. These findings suggest global accelerated telomere attrition in AAH rather than an organ-specific phenomenon which may carry diagnostic, prognostic, and therapeutic implications.

3611-C | THE CHARACTERISTICS OF ALCOHOL USE DISORDER IN PATIENTS AFTER BARIATRIC SURGERY

Robert Gaffey[1], Joel Rosiene[1], Melissa Fazzari[2], Kristina R. Chacko[1] and Clara Tow[1], (1)Montefiore Medical Center, (2)Albert Einstein College of Medicine

Background: Prior studies have shown that bariatric surgery predisposes patients to alcohol use disorder (AUD) and alcohol-associated liver disease (ALD). Multiple studies have demonstrated this link, but there are currently no studies examining time of incident AUD or patient characteristics associated with AUD diagnosis, specifically demographic, diagnostic and laboratory data of these patients. Aims: To determine the time to AUD diagnosis after bariatric surgery and the characteristics and degree of liver dysfunction at time of diagnosis. **Methods:** Using ICD-10 codes, we retrospectively reviewed all patients who underwent bariatric surgery (BS) versus elective cholecystectomy (CCY) at a single urban center between 2015-2020. We excluded those with previously diagnosed AUD, chronic liver disease and those under 21 years of age at time of surgery. We collected sociodemographic information and clinical parameters, including body mass index (BMI), platelets, and liver tests. FIB-4 was calculated when possible. Data were collected prior to surgery, at the time of surgery and at one-year intervals for a maximum of five years. Associations with time to AUD diagnosis were assessed via Cox proportional hazards modeling. **Results:** There were 9335 patients in the cohort: 5696 underwent BS and 3639 underwent CCY. The cohort was diverse with 19% black, 52% Hispanic, and 11% without reported race or ethnicity. There were more women than men (82.2% vs 17.8%). BMI and weight were higher in the bariatric surgery group, as were rates of hypertension, hyperlipidemia, and diabetes. Baseline labs were similar. The average time to AUD diagnosis was 932 days in the BS group and 651 days in the CCY group. There were 169 incident events of AUD in the cohort, 58 post-CCY and 111 post-BS. Univariate analysis showed that female sex, Hispanic ethnicity, and self-identified black race were associated with shorter time to incident AUD for the whole cohort. There was no association between baseline laboratory parameters and time to AUD. Baseline FIB-4 was low and similar between groups. FIB-4 at time of AUD diagnosis was intermediate in the CCY group (mean of 1.9) and low in the BS group (mean of 1.3) ($p = 0.07$). In multivariate analysis, BS was not associated with AUD when compared to the CCY group, but female sex was in both the whole cohort and the BS group. In the bariatric cohort, race, ethnicity, age at surgery, baseline metabolic risk factors, and BMI were not associated with earlier incidence of AUD. **Conclusion:** Our study uniquely examines the characteristics of bariatric surgery patients with incident AUD in a diverse population. Our study does not show an association between BS and AUD when compared to CCY. AUD diagnosis occurs significantly later in BS patients than CCY patients and at higher rates in female patients. Our study did not find laboratory evidence of liver disease at the time of AUD diagnosis.

Table 1: Baseline demographics and laboratory values

	Gastric bypass (N=5696)	Cholecystectomy (N=3639)
Female Sex	4769 (83.7%)	2905 (79.8%)
Diabetes Mellitus	469 (8.2%)	216 (5.9%)
HLD	1590 (27.9%)	620 (17.0%)
HTN	1610 (28.3%)	431 (11.8%)
Race and ethnicity		
Hispanic	3039 (53.4%)	1814 (49.8%)
Non-Hispanic Black	1175 (20.6%)	601 (16.5%)
Non-Hispanic White	151 (2.7%)	321 (8.8%)
Other	671 (11.8%)	507 (13.9%)
Mean BMI at procedure (standard deviation)	44.8 (7.98)	30.9 (6.42)
Laboratory value means at time of surgery (standard deviation)		
Albumin	4.22 (0.325)	4.26 (0.395)
Alkaline Phosphatase	84.9 (24.8)	93.5 (46.1)
Alanine transaminase (ALT)	28.6 (39.2)	44.5 (96.7)
Aspartate transaminase (AST)	24.4 (58.5)	36.0 (124)
Total bilirubin	0.427 (0.293)	0.533 (0.566)
FIB-4	0.777 (0.522)	1.11 (2.09)
Platelets	278 (66.3)	269 (72.4)

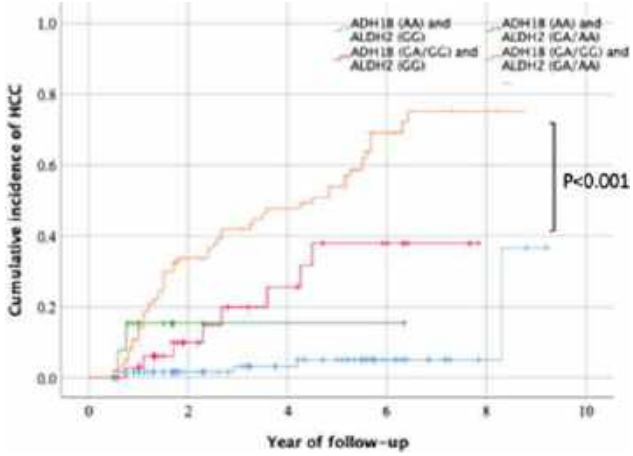
Gung University, (5)Cathay General Hospital, Taipei, Taiwan, (6)E-Da Cancer Hospital, I-Shou University, (7) Kaohsiung American School, (8)Kaohsiung Medical University, Kaohsiung, Taiwan, (9)Hepatobiliary Section, Department of Internal Medicine, and Hepatitis Center, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, (10)National Sun Yat-Sen University

Background: Hepatocellular carcinoma (HCC) is the fifth most commonly occurring cancer and the second most common cause of cancer-related death worldwide. Heavy alcohol intake and hepatitis B virus (HBV) infection has been shown to increase the development of HCC. Our previous study showed that heavy alcohol intake with ALDH2 polymorphismpromoted the HCC in HBV-related cirrhosis. However, the role of heavy alcohol intake, ADH1B and ALDH2 rs671 polymorphism and HBV infection in HCC development remains unclear and needs to be explored. This study aims to investigate the correlation of heavy alcohol intake ADH1B and ALDH2 rs671 polymorphism, and HBV infection with HCC development in cirrhotic patients. **Methods:** This retrospective cohort study enrolled 698 cirrhotic patients with heavy alcoholism or/and HBV infection in E-Da Hospital, I-Shou University, and Kaohsiung Chang Gung Memorial Hospital, and General Cathay Hospital, Taiwan from January 2013 to December 2021. Data analyses were finalized on December 2022. The ADH1B and ALDH2 rs671 polymorphism was analysis. Heavy alcohol intake was defined as consuming more than 80 g of ethanol per day for at least 5 years. The primary endpoint was newly developed HCC. **Results:** This study included 290 patients with concomitant heavy alcoholism and HBV infection, 245 patients with HBV infection, and 207 patients with heavy alcoholism. Of 698 cirrhotic patients, 598 (85.4%) were men and the median (range) age was 47 (21-75) years. The 8-year cumulative incidences of HCC were significantly higher in cirrhotic patients with concomitant HBV infection and alcoholism than in those with HBV infection alone or alcoholism alone. The ADH1B genotype (GA/GG) significantly increased the risk of HCC [hazard ratio (HR) = 7.6; 95% CI, 4.1-13.8] compared with the ADH1B genotype (AA) in cirrhotic patients with concomitant HBV infection and alcoholism.Moreover, the ALDH2 rs671 genotype (GA/AA) significantly increased the risk of HCC (HR = 10.1; 95% CI, 4.6-22.2) compared with the ALDH2 rs671 genotype (GG) in cirrhotic patients with concomitant HBV infection and alcoholism. We combined the ADH1B and ALDH2 rs671 polymorphism to analyze the HCC development. The ADH1B genotype (GA/GG) and ALDH2 rs671 genotype (GA/AA) significantly increased the risk of HCC (HR = 16.3; 95% CI, 6.5-40.6) compared with the ADH1B genotype (AA) and ALDH2 rs671 genotype (GG) in cirrhotic patients with concomitant HBV infection and alcoholism.The cumulative incidences of HCC were significantly higher in patients with the ADH1B genotype (GA/GG) and ALDH2 rs671 genotype (GA/AA) than in those with the ADH1B genotype (AA) and ALDH2 rs671 genotype (GG) in cirrhotic patients with concomitant HBV infection and alcoholism. **Conclusion:** Heavy alcohol commutation with ADH1Band ALDH2 rs671 polymorphism significantly increased the risk of HCC development in HBV-related cirrhotic patients.



Disclosures: The following people have nothing to disclose: Chih Wen Lin, Wen-Lung Wang, Ming-Chao Tsai, Sien-Sing Yang, Chih-Che Lin, Yao-Chun Hsu, Jaw-Town Lin, Yaw-Sen Chen, Hui-Ting Hu, Steven Yu Lin, Ming-Lung Yu

3613-C | THE IMPACT OF OBESITY ON SEVERITY OF ACUTE ALCOHOLIC HEPATITIS

Marcus Allen Healey[1], Geetha Ramalingam[1], Yiwei Hang[1], Ekaterina Smirnova[2], Amon Asgharpour[3], Vaishali Patel[4], Hannah Lee[4], Velimir A. Luketic[2], Scott C. Matherly[4], Mohammad S. Siddiqui[4], Joel P. Wedd[4], Arun Sanyal[5] and Richard K. Sterling[4], (1)VCU Health, (2)Virginia Commonwealth University, Richmond, VA, (3)Virginia Commonwealth University, (4)Virginia Commonwealth University Health System, (5)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Obesity and alcohol use disorder (AUD) are leading causes of liver-related injury in the United States. Moreover, their effects appear synergistic in promoting steatohepatitis. However, the impact of body mass index (BMI), a surrogate marker for obesity, on severity of acute alcoholic hepatitis (AAH) is not well defined. Our aim is to compare the severity of AAH among hospitalized obese patients with BMI $\geq$ 30 kg/m2 to those with BMI $<$ 30 kg/m2 from the same time

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

period. **Methods:** Retrospective chart review of 199 patients hospitalized with AAH with BMI ≥ 30 kg/m2 from 2012-2019 was performed. For a control group, 419 patients hospitalized with AAH with BMI < 30 kg/m2 from the same time period were used. Age, race, ethnicity and gender were obtained for demographic characteristics. Laboratory parameters were obtained to include Aspartate Aminotransferase (AST), Alanine Aminotransferase (ALT), total bilirubin (TB), international normalized ratio (INR), prothrombin time (PT), creatinine (Cr), and albumin. To define severity of AAH, both Model for End-Stage Liver Disease (MELD) and Maddrey's discriminant function (MDF) were computed. For control PT in the MDF calculation, 13.5 seconds was used. Steroid administration and thirty-day survival were compared, and odds ratio was computed for both variables. **Results:** Demographic and clinical characteristics of patients with BMI ≥30 kg/m2 and their controls are found in Table 1. Those with BMI ≥30 kg/m2 were found to have higher TB ($p = 0.002$), INR ($p < 0.001$), and creatinine ($p = 0.05$) which were statistically significant. Albumin was found to be significantly higher in those with BMI < 30 kg/m2 ($p = 0.001$). Patients with BMI ≥30 kg/m2 were found to have insignificantly lower AST and ALT ($p > .05$). MELD on admission ($p < 0.001$), MELD at discharge ($p = 0.026$) and MDF on admission ($p < 0.001$) appeared to be higher in those with BMI ≥30 kg/m2. While steroid administration was higher in the BMI ≥30 kg/m2 cohort, 30-d survival was not different between both groups. **Conclusion:** In our study, we found that when compared to those with BMI < 30 kg/m2, those with BMI ≥30 kg/m2 had more severe AAH (higher MELD and MDF). While steroid use was also higher in those with BMI ≥30 kg/m2, survival between these two groups was similar. Therefore, better methods to improve survival in AAH in this unique population are needed given the rising prevalence of both obesity and alcohol use disorder.

3614-C | THE INFLUENCE OF PARENTAL ALCOHOL MISUSE AND LIVER DISEASE ON THE DEVELOPMENT OF ALCOHOL-ASSOCIATED HEPATITIS

Wanzhu Tu[1], Lauren D. Nephew[2], Craig J. McClain[3], Samer Gawrieh[4], Srinivasan Dasarathy[5], Vatsalya Vatsalya[3], Douglas A. Simonetto[6], Qing Tang[7], Bruce Barton[8], Gyongyi Szabo[9], Patrick S. Kamath[10], Arun Sanyal[11], Laura E. Nagy[5], Mack C. Mitchell[12], Svetlana Radaeva[13], Vijay Shah[6], Naga P. Chalasani[14], Ramon Bataller[15] and the AlcHepNet Investigators, (1) Department of Biostatistics and Health Data, Indiana University School of Medicine, Indianapolis, in, (2) University of Pennsylvania, Indianapolis, IN, (3) University of Louisville, Louisville, KY, (4)Indiana University School of Medicine, Indianapolis, IN, (5) Cleveland Clinic Foundation, (6)Mayo Clinic Rochester, Rochester, MN, (7)Indiana University, (8)University of Massachusetts Memorial Health Care, (9)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (10)Mayo Clinic, Rochester, MN, (11) Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA, (12) University of Texas Southwestern Medical Center, (13) NIAAA, (14)Indiana University Medical Center, Indianapolis, IN, (15)Barcelona Clinic, Barcelona, Spain

Background: While the genetic influences of alcohol use disorder (AUD) are well-documented, and probands with NAFLD cirrhosis are known to increase the risk of fibrosis in first-degree relatives, whether parental AUD and liver disease influence the risk of alcohol-associated hepatitis (AH) remains unclear. **Methods:** We examined the effects of parental AUD and liver disease-related death on the risk of AH development in offspring by combining the data from two observational cohorts. Both studies recruited AH cases and heavy drinking controls (HDC). Parental AUD and death due to liver disease were documented in the study entry; their associations with AH in the offspring were assessed with logistic regression models. **Results:** Data from 1,280 participants (864 subjects with AH and 416 HDC; 60% male for AH and 61.4% male for HDC) were analyzed. The mean ages of AH and HDC were comparable (45.4 for AH and 46.9 for HDC). Compared to HDC, AH cases were more likely to be white (84.4% vs. 77.4%), less likely to attend trade school/college/graduate programs (56.7% vs. 68.6%) and had higher BMI (29.7 vs. 28.5 kg/m^2). The cases on average drank less (189.3 vs. 304.7 total drinks, and 18.1 vs. 23.6 drinking days in the 30 days before study entry). 56% of AH cases and 61% of HDC had a parent with AUD; 7.8% of AH and 5.6% of HDC had a parent that had died of liver disease. Multivariate logistic regression showed that having a parent die of liver disease was associated with a significantly increased risk of AH after adjusting participants' characteristics and drinking behavior (adjusted OR = 2.2, 95% CI: [1.20, 4.14]). Table 1 shows correlates of AH. **Conclusion:** There may be a hereditary component to the development of AH, as indicated by liver disease-related death in a parent. The risk, however, appears to be independent of the influences of parental AUD and participants' own drinking behavior.

Table 1. Estimated effects of potential correlates for AH development

Effect	Estimated Odds ratios	95% Wald Confidence Limits	
Age at enrollment	0.985	0.973	0.997

3615-C | THE LANDSCAPE OF INPATIENT ADMISSIONS FOR ALCOHOLIC HEPATITIS IN THE ERA OF EARLY LIVER TRANSPLANTATION

Shahana Prakash, University of Iowa Hospitals and Clinics and Tomohiro Tanaka, University of Iowa Hospitals and Clinics, Iowa City, IA

Background: Liver transplant (LT) is a recent option available in the United States (US) to treat those with severe, refractory alcoholic hepatitis (AH). We examined changes in clinical characteristics of patients admitted with AH and determined how hospital cost, length of stay (LOS), and mortality have changed as practice changes involving LT have shifted. **Methods:** Using the National Inpatient Sample, we performed a cross-sectional analysis of patients admitted with AH during the years 2016-2020 in the US. Differences in

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

clinical characteristics over time were assessed. To compare outcomes between 2016-2017 (when LT was less common) and 2018-2020 (when LT was more common), we conducted linear and logistic regression. Propensity-score matching was used to compare outcomes between patients with and without LT. **Results:** In 2018-2020 (n = 22,072 hospitalizations), compared to 2016-2017 (n = 16,946 hospitalizations), patients admitted with AH tended to have a higher frequency of infection ($p = 0.006$), hepatorenal syndrome (< 0.001), and ascites (< 0.001). Hospital costs and length of stay (LOS) were highest in transplant hospitals (n = 96 in 2016-2017, n = 274 in 2018-2020), even when LT-related admissions were excluded in years 2018-2020 [LOS: $p < 0.001$; cost: $p = 0.06$ compared to non-transplant (NT) teaching hospitals, $p < 0.001$ compared to NT non-teaching hospitals]. Use of palliative care consult remained low (< 5%), regardless of hospital type. Costs rose over time in both NT teaching (n = 11,090 in 2016-2017 and n = 15,781 in 2018-2020) and non-teaching hospitals (n = 5,760 in 2016-2017 and n = 6,017 in 2016-2017), by on average $4,500 an $3,900, respectively ($p < 0.001$). Mortality decreased in NT teaching hospitals [aOR 0.7 (95% CI: 0.6-0.8)] and slightly decreased in NT non-teaching hospitals [aOR 0.7 (95% CI: 0.5-1.0)]. In transplant hospitals, there was no change in mortality over time in the unadjusted model. In the propensity-matched cohort involving LT versus non-LT patients (n = 30 in each group), there was a 13% absolute reduction in in-hospital mortality, but this came at about a four-fold higher cost ($p < 0.001$) and a two-fold longer length of stay ($p < 0.001$). **Conclusion:** The severity of AH has been increasing over time, yet mortality has declined, after adjusting for severity of disease. All patients who underwent LT survived. However, there is a considerable healthcare burden associated with optimizing patients for potential transplant and performing LT itself.

Disclosures: The following people have nothing to disclose: Shahana Prakash, Tomohiro Tanaka

3616-C | THE MECHANISMS OF ZHIZI DAHUANG DECOTION IN THE TREATMENT OF ALCOHOLIC LIVE DISEASE BY INHIBITING THE OXIDATIVE STRESS IN NEUTROPHILS

Junhua Feng, Yiwen Hou, Jiaxin Tan, Qian Li, Rongjie Zhang, Yueqiu Gao and Man Li, Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine

Background: Zhizi Dahuang Decotion (ZZDHD) is a traditional Chinese formula, which have effects on treating alcoholic liver disease(ALD) , but its mechanisms are still poorly understood.We aim to study the mechanisms of ZZDHD in the treatment of alcoholic liver disease by regulating the oxidative stress in neutrophils, and to screen its effective monomers. **Methods:** An ALD model has been established in C57BL/6J mice treated according to the Gao-binge modeling method. We investigated the effects of ZZDHD on regulating levels of inflammation as well as oxidative stress in neutrophils in mice with ALD using biochemical assays, real-time PCR, and Western blot. Effective components in blood and liver tissue were screened by Ultra-High Performance Liquid Chromatography, analysis combined with Network Pharmacology to explore the potential therapeutic monomers for ALD and in mice validation. **Results:** l ZZDHD can alleviate inflammation response, reduce lipid deposition and oxidative stress in mice with ALD. a ZZDHD can alleviate neutrophil infiltration of liver in mice with ALD, and the effect was blocked by neutrophil depletion. b ZZDHD can inhibite expression of NADPH oxidases in neutrophils. c Geniposide can ameliorate liver damage in mice with ALD, as one of the effective components in ZZDHD. **Conclusion:** Our results suggests that ZZDHD can treat ALD by reducing lipid accumulation and oxidative stress in liver, the mechanism is related to inhibiting neutrophil infiltration of liver and expression of NADPH oxidases, Geniposide is an effective monomer in ZZDHD.

Disclosures: The following people have nothing to disclose: Junhua Feng, Yiwen Hou, Jiaxin Tan, Qian Li, Rongjie Zhang, Yueqiu Gao, Man Li

3617-C | THE MELD 3.0 IS NOT SUPERIOR TO THE MELD-NA IN PREDICTING THE SURVIVAL OF CHINESE PATIENTS WITH ALCOHOL-RELATED LIVER DISEASE: A RETROSPECTIVE COHORT STUDY

Chen Liu, Fangfang Duan, Hang Zhai, Min Quan, Jun Cheng and Song Yang, Beijing Ditan Hospital, Capital Medical University, Beijing, China

Background: The model for end-stage liver disease (MELD) 3.0 yields high prognostic performance for patients with end-stage liver disease (ESLD). However, its prognostic performance for patients with alcohol-related liver disease (ARLD) has not been determined. The aim of this study was to perform such an evaluation among Chinese patients. **Methods:** Patients hospitalized with ARLD in one institution from 2015 to 2018 were retrospectively included and followed up for 12 months. The original MELD, MELD-Na, MELD 3.0, and modified Maddrey discriminant function (MDF)

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

scores were calculated for each patient at baseline. Their prognostic performances for 1-year survival were assessed. Time-dependent receiver operating characteristic curves were constructed, and AUCs were calculated for each scoring system. **Results:** Among the 379 patients included in our analysis, 132 patients had alcoholic hepatitis (AH). By the 1-year follow-up, 22.7% (86/379) of all the patients and 38.6% (51/132) of those with AH had died. Overall, patients who had died had higher MELD, MELD-Na, MELD 3.0, and MDF scores (all $P < 0.001$) than those who did not. The same was true in the AH subgroup (MELD: $P < 0.001$, MELD-Na: $P < 0.001$, MELD 3.0: $P = 0.007$, MDF: $P = 0.017$). The AUC of the MELD 3.0 for prediction of 1-year survival among patients with ARLD was 0.704, lower than that of the original MELD (0.743, $P = 0.017$) and MELD-Na (0.751, $P = 0.001$). Moreover, among the AH subgroup, its AUC for prediction of 1-year survival was lower than that of the MELD-Na group (0.639 vs. 0.712, $P = 0.006$). **Conclusion:** The MELD 3.0 was not superior to the original MELD or the MELD-Na in predicting the prognosis of patients with ARLD.

3618-C | THE PROGNOSTIC IMPACT OF PSYCHIATRIC INTERVENTION ON ALCOHOL-ASSOCIATED LIVER DISEASE: A PROSPECTIVE STUDY OF UK BIOBANK COHORT

Keungmo Yang[1], Sunghwan Kim[1,2], Hyun Yang[1] and Si Hyun Bae[1], (1)The Catholic University of Korea, (2) Korea Advanced Institute for Science and Technology

Background: Alcohol-associated liver disease (ALD) is a public health concern, with a high morbidity and mortality rate. Psychiatric comorbidity is common among individual's with ALD and may negatively impact disease progression and outcomes. However, limited evidence exists regarding the prognostic impact of psychiatric interventions on ALD. This prospective study aims to investigate the survival benefits of psychiatric intervention in the treatment of ALD within the UK Biobank cohort. **Methods:** This prospective study included a total of 502370 participants. Among ALD patients, they were divided into two groups: those with psychiatric disorders and those without. Psychiatric disorders were defined based on the inclusion of ICD-10 code F10 (mental and behavioral disorders due to use of alcohol). Psychiatric intervention was determined by the consultation with psychiatrists during hospitalization or the history of medication related to alcohol use disorder (AUD). Survival analysis was performed to examine the prognostic impact of psychiatric intervention on ALD outcomes. **Results:** A total of 2417 ALD patients were included in the final analysis, with 1630 having F10 and 787 without F10. There were no significant differences in baseline characteristics, except for alcohol consumption, between the two groups. Patients with F10 had significantly lower average age of death compared to those without F10 ($P < 0.001$), indicating that having F10 is a poor prognostic factor for ALD patients. Among patients with F10, 221 received consultation for psychiatrists during hospitalization, and 221 had records of medication intake for AUD. Patients who received psychiatric consultation (Median OS 7.5 vs. 4.9 years; $P = 0.033$) and those who took related medications (Median OS 7.0 vs. 5.2 y; $P = 0.002$) presented a significant improvement in long-term overall survival (OS) rates. Psychiatric consultation and antidepressant intake were also identified as favorable prognostic factors in both univariate and multivariate analyses. **Conclusion:** This study demonstrates that psychiatric intervention has a favorable impact in ALD patients with psychiatric comorbidity. These findings emphasize the importance of integrated management for ALD patients, addressing both the medical and psychiatric aspects. The results support the potential benefits of psychiatric interventions in improving outcomes for individual's with ALD.

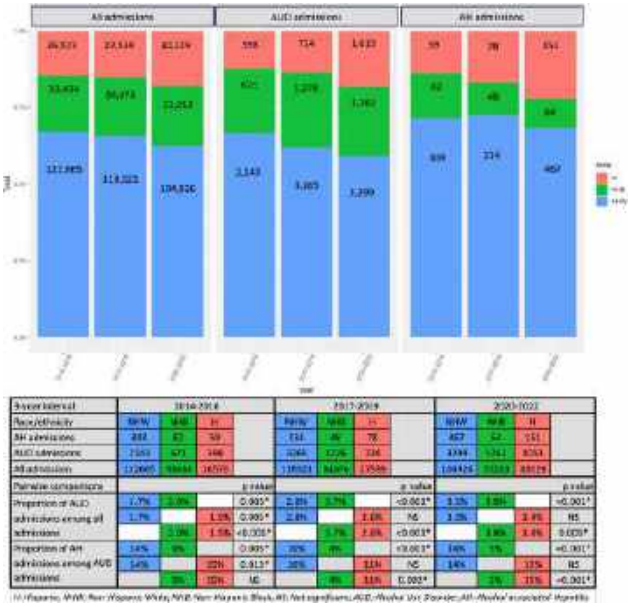
3619-C | THE ROLE OF RACE AND ETHNICITY ON THE CHARACTERISTICS AND OUTCOMES OF PATIENTS WITH ALCOHOL-ASSOCIATED HEPATITIS

Anahita Rabiee, Praveena Narayanan, Pramod K. Mistry and Tamar H. Taddei, Yale University, New Haven, CT

Background: Alcohol-associated Hepatitis (AH) is a major cause of alcohol related morbidity and mortality in the United States. Racial and ethnic differences may contribute to the presentation and outcome of AH, through cultural differences influencing alcohol use patterns, social support, access to health care, and genetic predispositions. Our goal was to explore the role of ethnicity and race in the prevalence, characteristics, severity, and outcomes of AH. **Methods:** We conducted a retrospective chart review of all patients with AH who were admitted to a single tertiary health system between 2014 and 2022. Patients had to have an AH ICD code *and* meet clinical criteria for AH (defined as total bilirubin $>=3$, AST to ALT ratio of >1.5, AST and ALT <400). Self-reported race and ethnicity data were used. Patients with no race or ethnicity data, or races representing $<1\%$ of the sample were excluded. To incorporate both race and ethnicity, patients were categorized as: Hispanic, Non-Hispanic White (NHW), and Non-Hispanic Black (NHB). In addition, the total number of all admissions and admissions related to alcohol use disorder (AUD) from 2014 to 2022 were obtained. Continuous variables with non-normal distributions were compared using Kruskal-Wallis rank sum test, and categorical variables were compared using Chi square test. **Results:** From a total of 530,976 admissions to our system between 2014 to 2022, 14,051 (3%) were AUD admissions, of which, 1,566 (11%) were AH admissions. A total of 921 unique patients with AH were identified, among whom, 683 (74%) were NHW, 143 (16%) were Hispanic, and 95 (10%) were NHB. Among Hispanics, 25% identified as White, and 3% as Black. Hispanic patients were significantly younger (median age: Hispanic: 45, NHW: 51, NHB: 55, $p=<0.001$) and had lower MELD-Na at presentation (median MELD-Na: Hispanic: 20, NHB: 22, NHW: 25, $p=<0.001$). Hispanic patients had significantly lower 30-day mortality (Hispanic: 7%, NHB: 9.5%, NHW: 15.4%, $p=0.014$) and 90-day mortality (Hispanic: 14%, NHB: 14.7%, NHW: 21.7%, $p=0.048$). There was a statistically significant association between race/ethnicity and AUD and AH admissions. The highest proportion of AUD admissions was among NHB compared to NHW or Hispanics. However, NHB patients had the lowest proportion of AH admissions among AUD admissions across all 3 historic intervals (Figure 1). **Conclusion:** Race and ethnicity are major factors affecting the severity and outcomes of AH, with NHW demonstrating more severe disease at presentation and higher short-term mortality compared to both Hispanics and NHB. The proportion of AUD admissions was highest in NHB compared to NHW and Hispanics in our health system. However, admissions for AH among AUD admissions, disproportionately affected NHW and Hispanic patients compared to NHB. Future research is needed to investigate the underlying reasons for these findings.



Disclosures: The following people have nothing to disclose: Anahita Rabiee, Praveena Narayanan
Disclosure information not available at the time of publication: Pramod K. Mistry, Tamar H. Taddei

3620-C | THE SIGNIFICANCE OF FIRST-DEGREE FAMILY HISTORY OF ALCOHOL CONSUMPTION AS A MAJOR PREDICTOR FOR RELAPSE IN PATIENTS ADMITTED FOR ALCOHOL ASSOCIATED HEPATITIS

Adalberto Guzman[1], Evelyn Calderon Martinez[1], Wern Lynn Ng[1], Anas Atrash[1] and Douglas M. Levin[2], (1) UPMC, (2)Ohio State University, Columbus, OH, United States

Background: Alcohol associated hepatitis is characterized by inflammation and liver damage resulting from excessive alcohol consumption. Despite advancements in treatment, the risk of relapse remains high among patients with alcohol associated hepatitis, leading to poor outcomes. Identifying predictors of relapse is crucial for developing effective intervention strategies and improving patient outcomes. **Methods:** This study aimed to

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

investigate the significance of first-degree family history of alcohol consumption as a major predictor for relapse in patients admitted for alcohol associated hepatitis. A comprehensive analysis was conducted on a cohort of 47 patients diagnosed with alcohol associated hepatitis and followed up for 3 months after discharge. **Results:** Among the enrolled patients, 33 (70%) who experienced relapse had a first-degree family history of alcohol consumption, revealing a significant association between familial alcohol consumption and a higher likelihood of relapse during the follow-up period. This finding suggests that patients with a positive family history were 2.5 times more susceptible to relapse compared to those without such a family history. Notably, patients with a first-degree family history exhibited a shorter time to relapse, approximately 17 to 23 days, in contrast to patients without such familial influences. These results, derived from a cohort of 47 patients, offer valuable insights into the link between a first-degree family history of alcohol consumption and relapse in alcohol associated hepatitis. The observed shorter time to relapse in patients with a positive family history underscores the importance of targeted interventions and heightened support for this specific subgroup of patients. By recognizing the influence of familial factors on relapse risk, healthcare providers can develop personalized strategies to enhance treatment outcomes and prevent relapses in individual's with alcohol associated hepatitis and a family history of alcohol consumption. **Conclusion:** Further research is warranted to delve into the underlying mechanisms that connect a family history of alcohol consumption to the increased risk of relapse in individual's with alcohol associated hepatitis. Understanding the specific genetic, environmental, and psychosocial factors involved can provide valuable insights into the complex interplay between familial influences and relapse vulnerability. Additionally, investigating the effectiveness of interventions tailored specifically to patients with a positive family history is essential for optimizing relapse prevention strategies and improving the overall management of alcohol associated hepatitis.

3621-C | THE TREATMENT EDUCATION FOR ALCOHOL MISUSE (TEAM) STUDY: A NOVEL INTERACTIVE VIDEO MODULE ABOUT ALCOHOL USE DISORDER FOR HOSPITALIZED PATIENTS

Patrick Twohig[1], Zachary Benton-Slocum[1], Anna Willet[1], Makayla Schissel[1], Alena Balasanova[1], Kyle Scholten[1], Joshua Warner[1], Tomoki Sempokuya[2,3], Nathalie Khoury[1], Allison Ashford[1] and Thoetchai (Bee) Peeraphatdit[1], (1)University of Nebraska Medical Center, (2)Queen's Medical Center, Honolulu, HI, (3) University of Hawaii

Background: Alcohol-associated liver disease (ALD) accounts for 50% of all liver-related deaths and is the most common reason for liver transplantation in the United States. Despite the availability of efficacious treatment for alcohol use disorder (AUD), very few patients are offered treatment. Providers endorse a lack of knowledge surrounding available treatments and how to prescribe them. **Methods:** Prospective single-center cohort study evaluating the impact of a novel, interactive patient educational video module (EVM) at increasing treatment rates for hospitalized patients with AUD and ALD from December 2022 to March 2023. Patients < 18 years old, who declined education, were unable to provide consent, or not hospitalized were excluded. Treatment was defined as receiving medication or participating in behavioral treatment within 30 days of discharge. Primary aim was to improve AUD treatment rates compared to a retrospective control cohort of AUD/ALD patients at our medical center from 2018-2020. AUD treatment rates, alcohol consumption patterns, and 30-day readmission/relapse rates were evaluated within the TEAM group and compared to control. We also received patient feedback on the EVM. **Results:** Of 62 eligible patients, 52 consented to participate (83.8%), and 42 were included in the analysis (5 died, 4 were lost to follow-up, and 1 received a liver transplant). Mean age 45 years, 50% female, mean MELD-Na 15.5. More patients in the TEAM cohort received any AUD treatment compared to control (85.7% vs. 51.3%, $p = 0.0001$). There were no significant differences in AUD treatment rates based on demographics, liver disease severity, or having received prior treatment. AUD treatment rates significantly increased for pharmacologic (22% to 50%, $p = 0.0008$) and behavioral treatment (44% to 73.8%, $p = 0.001$, and thirty-day relapse was significantly lower compared to control (7.9% vs. 35.6%, $p = 0.003$). After viewing the EVM, patients had significant reductions in self-reported number of drinks per day ($p < 0.0001$) and serum pETH levels ($p = 0.008$), and significant increases in pharmacologic ($p = 0.02$) and behavioral ($p = 0.003$) treatment rates at 30-day follow-up. 92.5% of patients found the EVM helpful and 100% would recommend it to others. **Conclusion:** Standardized EVM about AUD treatment can significantly increase treatment rates while reducing 30-day relapse. Most patients consented to participate, found the EVM helpful, and unanimously would recommend it to others. Increased efforts should be made to educate patients about AUD and available treatment options while hospitalized.

3622-C | THE UTILITY OF LILLE SCORE IN PREDICTING 30-DAY SURVIVAL IN STEROID-TREATED ACUTE ALCOHOLIC HEPATITIS

Geetha Ramalingam[1], Marcus Allen Healey[1], Yiwei Hang[1], Ekaterina Smirnova[2], Amon Asgharpour[3], Vaishali Patel[3], Hannah Lee[3], Velimir A. Luketic[2], Scott C. Matherly[3], Mohammad S. Siddiqui[4], Joel P. Wedd[4], Arun Sanyal[5] and Richard K. Sterling[3], (1) VCU Health, (2)Virginia Commonwealth University, Richmond, VA, (3)Virginia Commonwealth University Health System, (4)Virginia Commonwealth University, (5)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: In acute alcoholic hepatitis (AAH), steroids are considered if Discriminant Function (DF) is ≥ 32 or Model for End-Stage Liver Disease (MELD) is > 20 and no contraindications are present. However, not all patients respond favorably to steroids. The Lille score was created to assess futility of steroids in AAH. However, the utility of the Lille score and impact on 30-day (30-d) survival is needed. Our aim is to compare the utility of the Lille score on 30-d survival in those with AAH treated with steroids. **Methods:** Retrospective chart review of patients hospitalized with AAH who got steroids was performed (n = 272). Those with data to calculate Lille score < 0.45 on day 4 (n = 26) or 7 (n = 86) who continued steroids were compared to 83 patients with Lille scores ≥ 0.45 on day 4 (n = 18) or 7 (n = 65) who stopped steroids. Data on age, gender, race, ethnicity, BMI, and weight were gathered. Laboratory markers were obtained to include aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin (TB), internationalized normalized ratio (INR), prothrombin time (PT), albumin, and creatinine (Cr). DF on admission, and MELD upon admission and discharge was calculated. The primary outcome was 30-d survival. **Results:** Demographic and clinical characteristics of patients with Lille score < 0.45 and ≥ 0.45 are found in Table 1. Those with Lille Score < 0.45 were found to be younger (p = 0.001) with lower TB (p = 0.001), higher albumin (0.001), lower Cr(p = 0.001), and lower INR (p = 0.001). MELD and DF upon admission were found to be statistically significant, but MELD at discharge was not significant between cohorts (p = 0.104). In patients with Lille score < 0.45, survival was higher at 30-d (94.9% vs. 80.72%; p = 0.002). By comparison, a contemporary cohort hospitalized with AAH eligible but not receiving steroids (n = 206; 57% male, mean age 50, DF 47, MELD 24) had a 30-d survival of 87%. The sensitivity, specificity, PPV, and NPV of Lille score (< 0.45) to predict 30-d survival was 95%, 19%, 63%, and 73%, respectively. **Conclusion:** Our study shows that in AAH those with Lille score < 0.45 receiving steroids have improved 30-d survival (95%) that was better than those with Lille score ≥ 0.45 (81%). In those receiving steroids, Lille score on day 4 or 7 has excellent sensitivity but poor specificity to predict 30-d survival. Thus, while Lille score is sensitive to predict 30-d survival, its poor specificity implies a need for better scores to determine outcomes in this population.

3623-C | TIMING OF INITIATION OF CORTICOSTEROIDS IN SEVERE ALCOHOL-ASSOCIATED HEPATITIS HAS NO IMPACT ON SURVIVAL

Claire Durkin, University of Pennsylvania, David E. Kaplan, Division of Gastroenterology and Hepatology, Department of Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA and Therese Bittermann, Hospital of the University of Pennsylvania, Philadelphia, PA

Background: Although corticosteroids are recommended for the treatment of severe alcohol-associated

hepatitis (AH) to reduce short-term mortality, few data inform the urgency of steroid initiation. In clinical trials, steroid initiation occurred after 6-14 days, but in clinical practice there is perceived urgency to initiate steroids earlier. No studies to date have compared early versus delayed initiation of steroids on mortality in this population. **Methods:** This was a retrospective cohort study of patients on their first admission for severe AH (Maddrey's Discriminant Function $\geq$ 32) treated with corticosteroids in the Veteran's Health Administration from 1/3/2005-6/1/2022. Admissions were identified via a validated algorithm using International Disease Classification discharge codes and laboratory values. Time-to-event analyses evaluated the association between timing of steroid initiation (early, intermediate, and late initiation starting 0-5, 6-10, and >10 days after admission, respectively) and overall survival. Multivariable Cox models were adjusted for age, sex, race/ethnicity, body mass index, treatment year, Alcohol Use Disorders Identification Test (AUDIT-C) score, Model for End Stage Liver Disease (MELD-Na) score, cirrhosis, ascites, and hepatic encephalopathy on admission. **Results:** 1,932 patients on their first admissions for severe AH were identified during the study period, of which 843 (43.6%) received corticosteroids. 723 (85.8%), 82 (9.7%), and 38 (4.5%) of these patients had early, intermediate, and late corticosteroid initiation, respectively. Patients with early initiation had significantly higher AUDIT-C scores, lower rates of hepatic decompensation and ascites, and shorter lengths-of-stay compared to those with intermediate or late initiation (all $p<0.05$). Timing of steroid initiation was not significantly associated with all-cause unadjusted mortality ($p=0.35$, Figure). Overall survival ranged from 70.8-74.2%, 49.2-58.3%, and 34.4-45.8% at 28-days, 90-days, and 365-days after steroid initiation among the study groups, respectively. Compared to early initiation, intermediate and late initiation were not associated with worse overall survival (adjusted hazard ratio [aHR] 1.04 and 1.09, respectively; $p=0.94$). Worse survival was associated with older age (aHR 1.01 per year; $p=0.04$), later admission year (aHR 1.14 per year; $p<0.001$), and higher MELD-Na score (aHR 1.06 per point; $p<0.001$). **Conclusion:** In a large multi-center AH cohort, there was no difference in survival related to early, intermediate, or late initiation of corticosteroids. If steroids are associated with a survival benefit, delaying to allow for exclusion of infection and/or optimization of patient selection for corticosteroid treatment has no negative impact.

Figure:

3624-C | TRANSCRIPTOMIC ANALYSIS IDENTIFIES SENESCENCE-RELATED MECHANISMS ASSOCIATED WITH DISEASE SEVERITY IN ALCOHOL-ASSOCIATED HEPATITIS

Daniel Rodrigo-Torres[1], Alastair M Kilpatrick[1,2], Stephen R Atkinson[2], Sofia Ferreira-Gonzalez[1,3], Luke D Tyson[2], Nikhil Vergis[2], Mark R Thursz[2], Laura Martinez-Gili[2] and Stuart J Forbes[1], (1)Centre for Regenerative Medicine, Institute for Regeneration and Repair, the University of Edinburgh, (2)Imperial College London, (3)Centre for Inflammation Research, Institute for Regeneration and Repair, the University of Edinburgh

Background: Cellular senescence, a state of irreversible cell cycle arrest, has been associated with progression and outcomes in some chronic liver diseases (NASH, PSC, PBC). Its role in alcohol-related liver disease (ALD) and alcohol-associated hepatitis (AH) remains comparatively under-studied. We investigated the role of senescence in AH patients and an *in vitro* model of ethanol-induced toxicity. **Methods:** RNA sequencing (RNA-seq) data of liver biopsies from two ALD cohorts was analyzed: InTEAM (normal $n = 10$; early ALD $n = 12$; AH $n = 18$; AH explants $n = 11$), and a novel RNA-seq dataset of baseline biopsies from patients with severe AH from ISAIAH clinical trial ($n = 30$). Differential expression analysis by disease stage (InTEAM) or Model for End-Stage Liver Disease (MELD) score adjusted for age and sex (ISAIAH) was performed with DESeq2. Gene set enrichment analysis was computed with fgsea and FDR < 0.05 was used to define statistical significance. VL-17A cells (HepG2 cell line overexpressing ethanol metabolizing enzymes CYP2E1 and ADH1) were treated *in vitro* with 100mM ethanol for 48h. **Results:** Senescence markers (e.g. CDKN1A [p21], TP53) were significantly upregulated in AH compared to normal liver and early ALD patients in the InTEAM cohort. No additional upregulation was seen in liver explants from patients with AH compared to AH biopsies. In the ISAIAH cohort, whilst expression of these specific senescence markers did not vary significant with MELD the activity of senescence-related genes sets did. Pathways including stabilization of P53, TP53 regulation of metabolic genes, SCF/SKP2 mediated degradation of P27/P21 and mechanistic target of rapamycin complex (mTORC1) were all significantly enriched with worsening AH. Key enrichment drivers significantly downregulated with worsening AH included several subunits of the proteasome and cytochrome c oxidase (e.g. COX6C, COX18), two senescence-related complexes. *In vitro,* we observed a reduction of cell growth in ethanol-treated cells accompanied by an upregulation of senescence markers (e.g. CDKN1A, CDKN2A), and a downregulation of the key enrichment drivers identified in the ISAIAH cohort. **Conclusion:** Severe AH is associated with increased expression of senescence markers. Transcriptomic activation of these pathways correlates with the severity of liver dysfunction and can be recapitulated in vitro using an ethanol-metabolising liver cell line. Cellular senescence may be important in the pathogenesis of severe AH and present a promising target for interventional therapies.

3625-C | TRANSCRIPTOMIC ANALYSIS OF HIGH-GRADE FIBROSIS IN ALCOHOL-INDUCED LIVER DISEASE

Gopal Krishna R. Krishna Ramadas Dhondalay[1], Alastair M. Kilpatrick[1], Laura Martinez-Gili[1], Nikhil Vergis[1], Luke D. Tyson[1], Stephen R. Atkinson[1], Robert C. Glen[1], Timothy Md Ebbels[1], Ramon Bataller[2] and Mark R. Thursz[1], (1)Imperial College London, (2) Barcelona Clinic, Barcelona, Spain

Background: Liver fibrosis is the accumulation of hepatic collagen occurring in response to repeated injury and inflammation. The degree of fibrosis is a key determinant of morbidity and mortality in almost all chronic liver diseases including alcohol-related liver disease. Despite its clinical importance, no therapies exist which successfully modulate hepatic fibrosis necessitating better markers and druggable targets for this aspect of disease. This study aims to delineate the transcriptomic signature of high-grade fibrosis in alcohol-induced hepatitis. **Methods:** Bulk RNA-seq was performed on liver biopsies ($n = 20$) from patients with a clinical diagnosis of severe alcoholic hepatitis. Patients had a median age of 56 years; were predominantly male (14/20) and either fibrosis grade 3 ($n = 4$) or 4 ($n = 16$). Total mRNA was paired-end sequenced using an Illumina HiSeq2000 and mapped

to GRCh37/hg19 reference genome using STAR aligner with RSEM for gene expression quantification. A negative binomial model was fitted using DESeq2 to identify genes differentially expressed by fibrosis stage whilst adjusting for age and sex. Genes with log2(fold change) > 1 and adjusted p-value > 0.05 were considered statistically significant. Pathway and gene set enrichment analysis was done using fgsea packages. **Results:** The DE analysis identified 313 genes (51 up-regulated; 262 down-regulated) between grades 3 and 4 fibrosis. Among differentially expressed genes, in high-grade fibrotic samples, the drug metabolism genes (*CYP2A6*. *CYP2A7*, *CYP2C8*, *CYP2C9*, and *CYP39A1*) were found to be significantly downregulated, plasma cell markers like *CD38*, *CD19*, *CD45*, and *CXCR4* were also found to be differentially expressed and immunoglobulin genes (*IGHA1*, *IGHG1*, and *IGHM*) were significantly down-regulated. The fatty acid metabolism (5.57x) and bile acid and bile salt metabolism (16.52x) pathways were significantly enriched in high-grade fibrosis. Furthermore, we also investigated the relation of components of MELD score (Albumin, Bilirubin, and INR) with fibrosis and found cholangiocyte markers and hepatic dysfunction to be highly enriched. **Conclusion:** Gene expression analysis of high-grade fibrotic alcohol-induced liver disease confirms a previously known correlation between bile-acid secretion and reduced drug metabolism. The involvement of plasma cells and immunoglobulins in high-grade fibrosis with other clinical outcomes needs further investigation and could be potential for drug targeting.

3626-C | TRANSIENT ELASTOGRAPHY INCREASES READINESS FOR CHANGE IN INPATIENTS WITH ALCOHOL USE DISORDER: A PROSPECTIVE PILOT STUDY (ELISA)

Stephanie Rutledge[1], Rohit R Nathani[2], Patricia Miguez Arosemena[2], Daniel Suter[3], David Lehman[3], Timothy Brennan[3] and Gene Y. Im[1], (1)Icahn School of Medicine at Mount Sinai, (2)Mount Sinai Morningside and West Hospital, (3)Mount Sinai West Hospital

Background: Alcohol use disorder (AUD) is rising, especially with the COVID-19 pandemic. New approaches to the treatment of alcohol use disorder (AUD) are needed for harm reduction or abstinence. Teachable moments (TMs) are health events that can motivate individual's to adopt risk-reducing behaviors. Our aim was to determine the impact of vibration-controlled transient elastography (VCTE) and its interpretation as a TM on psychological scores (PS) in patients with AUD. **Methods:** This is a prospective, investigator-initiated, proof-of-concept pilot study: Evaluating LIver Stiffness and steatosis as a TM in patients with AUD (ELISA). Patients without known liver disease or prior VCTE were enrolled from an inpatient addiction unit at Mount Sinai West. At baseline, four validated PS assessing alcohol use, insight, and readiness to reduce drinking were administered (AUD Identification Test [AUDIT-C], revised Readiness Ruler [RR] (preset value of 0, range –5 to +5), Stages Of Change Readiness And Treatment Eagerness Scale [SOCRATES-8A], and Hanil Alcohol Insight Scale [HAIS]). VCTE was performed with FibroScan™ (Echosens), and results given in real-time via pre-scripted interpretations. PS were repeated immediately after. Follow up was every 3 months for 2 years. The primary endpoint was a change in PS. Secondary endpoints included prevalence of significant fibrosis, return to drinking, heavy drinking days, and linkage to hepatology care when recommended. **Results:** From May 2022, 21 study subjects were enrolled, all providing consent. Mean age was 53 (+/- 13) years, mostly male (76%) and racially diverse (62% White, 19% Black, 5% Hispanic). All had severe AUD, with a mean of 20.4 (+/-9.9) daily drinks for 16.7 (+/-11.2) years. Fourteen (67%) had comorbid psychiatric diagnoses and 16 (76%) had a family history of AUD. Significant fibrosis was detected in 7/21 (33%): three with stage 2 and four with stage 4 fibrosis. Steatosis stages 1, 2 and 3 were present in 11/21 (52%), 2/21 (10%), and 6/21 (28%), respectively. Mean AUDIT-C score was 11.6 (+/- 1.1). Mean scores for SOCRATES-8A (range 19-95), and HAIS (range -20 to +20) were high at baseline, 81.8, and 11.6, respectively with nonsignificant increases of 2.8 and 0.57 after VCTE, respectively. Mean revised RR score increased significantly after VCTE by 3.8 points ($p < 0.001$). No subjects were successfully contacted for follow-up. **Conclusion:** In this prospective pilot study, we demonstrate that VCTE increases readiness for change as measured by revised RR in inpatients with AUD. There was high baseline motivation and existing PS may not capture TM interventions appropriately. One-third had significant fibrosis, but loss to follow-up has concerning implications for linkage to

3627-C | TRANSPLANTATION OF DYSBIOTIC FECAL MICROFLORA FROM ALCOHOL-ASSOCIATED-HEPATITIS (AAH) PATIENTS, LEADS TO MALLORY-DENK BODY FORMATION AND PATHOGENESIS OF ALCOHOLIC HEPATITIS IN A MOUSE MODEL.

Smita Ghare, Paula Chilton, Manicka Vadhanam, Ben Charpentier, Richa Singhal, Scott Myers, John Greenwell, Jingwen Zhang, Mary Proctor, Leila Gobejishvili, Swati Joshi-Barve, Craig J. McClain and Shirish Barve, University of Louisville, Louisville, KY

Background: Hepatic Mallory-Denk bodies (MDBs) which indicate the histologic severity of alcoholic liver disease are observed with high prevalence in alcohol-associated hepatitis (AAH) patients. Several mechanisms have been proposed in the pathogenesis of MDBs; however, the role of gut microbiota in the development of MDBs has not been investigated. **Methods:** Fecal microbiome transplants (FMT) were performed in conventional mice using well-characterized fecal specimens from AAH patients (AAH-FMT, MELD scores > 22) and controls (N-FMT) 2X/week for 5 weeks. Along with FMT, the mice were pair-fed or 5% ethanol-fed (EF) with the Lieber-DeCarli diet for last 2 weeks. Transplanted microbiome was assessed by 16S rRNA gene sequencing. Histopathological analysis of mouse livers for the presence of MDB along with hepatic steatosis, inflammation, and injury was performed on H&E-stained tissues and were scored by a pathologist blinded to the study. MDB formation was assessed using immunofluorescent staining and mRNA levels of MDB associated proteins in mouse livers were assessed by qPCR. **Results:** Transplantation of dysbiotic fecal microbiome from AAH patients demonstrating a marked loss of butyrate-producing bacteria led to the development of MDBs in livers of recipient mice. Formation of MDBs was further exacerbated upon ethanol-feeding. There was a complementary increase in gene expression levels of MDB components including p62, CK8-18 and transglutaminase-2 in mice receiving AAH-FMT and ethanol. Further, higher aggregation and colocalization of MDB associated proteins was observed by immunofluorescent staining in FMT recipient mice after ethanol feeding. Notably, control mice, either non-FMT or FMT recipient mice given fecal transplants from controls, did not have increased incidence of hepatic MBDs with or without ethanol-feeding. Importantly, intervention with oral supplementation of tributyrin (TB), a butyrate prodrug, remarkably attenuated ethanol induced MDB development along with hepatic steatosis, inflammation, and injury in FMT recipient mice. **Conclusion:** These data strongly suggest that the dysbiotic microflora characterized by a decrease in butyrate producing bacteria plays a causal role in MDB formation and pathogenesis of AAH. Moreover, the data also suggest that TB supplementation could be a significant therapeutic strategy in the management of the alcohol-associated liver disease.
Disclosures: The following people have nothing to disclose: Smita Ghare, Paula Chilton, Manicka Vadhanam, Ben Charpentier, Richa Singhal, Scott Myers, John Greenwell, Jingwen Zhang, Mary Proctor, Leila Gobejishvili, Swati Joshi-Barve, Craig J. McClain, Shirish Barve

3628-C | Two hit hypotheses of alcohol-associated hepatitis (AAH): The role of genes in AAH

Anand V. Kulkarni[1], Ravikanth Vishnubotla[2], Govardhan Bale[2], Sameer Shaik[1], Sasikala Mitnala[2], Mithun Sharma[1], Nageshwar D Reddy[1] and Padaki Nagaraja Rao[1], (1)Aig Hospitals, Hyderabad, India, (2) Asian Healthcare Foundation

Background: Progression of liver disease in individual's with similar levels of alcohol consumption is variable, suggesting the contributory role of genetics. Whether such genetic associations exist in patients with alcohol-associated hepatitis (AAH), a disease associated with high mortality, and alcoholic cirrhosis (ALC), a slowly progressive disease, has not been evaluated. **Methods:** In this pilot study, we aimed to compare the genetic

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

variants of patients with AAH and ALC through whole exome sequencing. The analysis of the samples was performed after alignment using the SSV5UTR panel (74,557,381 bp), which covers 23690 genes. **Results:** 29 patients (ALC-15; AAH-14) were included. The mean age of ALC patients was higher (42.6 ± 5.55 yrs) than AAH patients (37.9 ± 5.9 yrs;P = 0.03). The amount of alcohol consumed (85 ± 28.73 g/d vs. 112.8 ± 51.2 g/d; P = 0.07) and the proportion of patients binging alcohol (26.7% vs. 64.3%;P = 0.06) was lower in ALC group than AAH group. However, the duration of alcohol intake was longer in ALC (12.33 ± 7.11 yrs vs. 4 ± 1.6 yrs; P < 0.001). A total of 10,10,247 variants were identified that predominantly comprised of exonic, intronic, and UTR (3` and 5` UTR) variants. Of these, missense (N = 4020), start loss (N = 7), and 2 kb upstream (N = 34) were identified as damaging and deleterious. Deleterious variants in genes, namely *ZFAT* (p.Gly64Arg; associated with waist-hip ratio in South Asians), *TAS2R19* (p. Leu235Arg-novel variant; sensory perception of taste), *CECR2* (p.Pro674Leu; DNA damage response), *FANCI* (p.Pro55Leu; DNA damage), *ATG9B* (p.Asn493Ser; associated with CT imaging-derived hepatic fat), *OR8D4* (p.Leu55Arg; Olfactory reception) and *PCDHA9* (p.Val508Met; neuronal connections) were exclusively found in AAH group. Higher frequency of variants in the AAH group as compared to the ALC group were identified in genes, namely *OR2G3* (p.Ile289Val; olfactory reception; p = 0.04), *STING1* (p.Arg293Gln; immune-related; p = 0.02), *OR8B4*(p.Cys178Arg; p = 0.04 and p.Tyr131His; p = 0.04; olfactory reception), *MAP1S* (p.Ser411Cys; p = 0.03; neutrophil differentiation and autophagy control). (Figure) **Conclusion:** We propose a two-hit hypotheses that leads to AAH: first hit where individual's with variants in genes related to chemosensory perception (taste and olfaction) tend to consume relatively higher amounts of alcohol and have a risk of addiction, and second hit in the form of variants in genes related to lipid metabolism, apoptosis, autophagy, and neutrophil infiltration leading to impaired functions culminating in alcoholic hepatitis. Further large population-based cohort needs to be assessed to validate the findings.

3629-C | UNDERUTILIZATION OF PHARMACOLOGIC THERAPY FOR ALCOHOL USE DISORDER (AUD) IN PATIENTS HOSPITALIZED WITH ALCOHOL-ASSOCIATED HEPATITIS

Christine Tien[1], Mimi Xu[1], Niwen Kong[1], David Lehoang[1], Michael Pimienta[2], Divya Ayyala[1], Rachan Narala[1] and Norah Terrault[1], (1)University of Southern California, (2)Stanford University

Background: Abstinence from alcohol plays a key role in reducing mortality in alcohol-associated liver disease, and medication-assisted treatment (MAT) for AUD is recommended to support sobriety. Studies of MAT utilization and efficacy in patients with alcohol-associated hepatitis (AH), a clinical entity with high short-term mortality, are lacking. **Methods**: This was a single-center retrospective study of adults (> 18 y) with an index hospitalization for probable/definite AH (per NIAAA criteria) at an urban safety net hospital from 2016-2022. Primary outcome was MAT prescription on discharge. **Results**: 240 patients were included in this study (median age 42 y, 84% male, 88% Hispanic, MELD-Na 27, IQR 22-31), and 12% (n = 28) were prescribed MAT (TABLE). Gabapentin was prescribed most frequently (64%, n = 18), followed by dual gabapentin/naltrexone therapy (25%, n = 7). The proportion prescribed MAT rose over time (4% 2016-2019 vs 18% 2020-2022, p < 0.001). The MAT group was younger, had lower MELD-Na scores, lower incidence of cirrhosis, fewer median cirrhotic decompensation traits, and were less likely to receive corticosteroids (TABLE). Rate of MAT prescription was higher in patients without decompensated cirrhosis (17% if no traits vs 6% if > 1 trait, p < 0.01) and in those with MELD-Na < / = 25 (17% if < / = 25 vs 7% > 25, p < 0.02). Apart from total bilirubin values on discharge (8 vs 13 mg/dL, p < 0.01), ALP, AST, and ALT were similar. The MAT group had shorter length of stay (3.5 vs 5 d, p = 0.02) but similar days since last drink (3 vs 5, p = 0.19), social work referral (65% vs 72%, p = 0.48), and hospitalizations within 90 days (1 vs 1). Ninety-day readmission rates (39% vs 42%, p = 0.46) and mortality (4% vs 13%, p = 0.12) rates were not significantly different in MAT vs. no MAT groups. In adjusted multivariable analysis, older age (aOR 0.95, 95% CI 0.90-1.00, p = 0.03), more decompensation traits (aOR 0.30, 95% CI 0.11-0.82, p = 0.02), corticosteroid treatment (aOR 0.35, 95% CI 0.14-0.88, p = 0.03) and higher MELD-Na score (aOR 0.89, 95% CI 0.83-0.96, p < 0.01) were associated with lower odds of MAT therapy. MAT prescription was not associated with 90-day readmission (OR 0.88, 95% CI

0.39-1.96, p = 0.75). **Conclusion**: Pharmacologic therapy for AUD is underutilized in AH patients upon discharge and represents a missed opportunity to support post-discharge sobriety. There is urgent need to identify and address barriers in both provider and patient awareness and enhance utilization of MAT, particularly in this high-risk patient population.

Table 1. Characteristics of individuals prescribed versus not prescribed MAT

	Total N=240	MAT N=28	No MAT N=212	P value
Age, years, median (IQR)	42 (35-51)	39 (31-45)	43 (36-51)	**0.05**
Male	84%	86%	84%	0.51
Hispanic	88%	96%	87%	0.13
Cirrhosis	63%	46%	65%	**0.05**
MELD-Na, median (IQR)	27 (22-31)	22 (19-27)	27 (23-32)	**<0.001**
Decompensation traits[a], median (IQR)	0 (0-1)	0 (0-1)	1 (0-2)	**0.003**
Corticosteroid therapy	66%	43%	69%	**0.006**
Alcohol duration >10 years	62%	42%	64%	**0.03**
Unhoused	18%	15%	18%	0.50
Substance use[b]	20%	25%	19%	0.32

Wilcoxon rank sum and Fisher's exact tests were used to compare median and mean values respectively.

3630-C | UNRAVELING THE ROLE OF REDUCTIVE STRESS IN HEPATIC TRANSCRIPTIONAL REGULATION OF FATTY LIVER DISEASE

Byungchang Jin[1], Charandeep Singh[1], Gloria Alvarez Sola[1], Valentin Cracan[2] and Russell P. Goodman[3], (1) Massachusetts General Hospital and Harvard Medical School, (2)Scintillon Institute, (3)Massachusetts General Hospital

Background: Hepatic reductive stress, which refers to an elevated cytosolic NADH/NAD$^+$ ratio, is a shared metabolic feature of both alcohol-related and non-alcoholic fatty liver disease, though how it directly affects hepatic fat accumulation is poorly understood. We aimed to investigate possible transcriptional regulation of hepatic fat accumulation by characterizing how direct modulation of reductive stress using a combination of alcohol, which increases reductive stress, and the metabolic tool *Lb*NOX, which decreases reductive stress, influences the hepatic transcriptome. **Methods:** To examine the role of hepatic reductive stress *in vivo*, mice were tail-vein injected with adenovirus either expressing *Lb*NOX or luciferase (control), and gavages with water or ethanol. Total hepatic RNA was isolated, and RNAseq was performed. For cell culture experiments, HEK293T cells were transfected with either plasmid expressing *Lb*NOX, with lowers reductive stress, or *Ec*STH, a new metabolic tool which increases reductive stress. Liquid-chromatography mass-spectroscopy (LC-MS) was used to characterize the metabolite changes, and RNAseq was used to characterize the resulting changes in the transcriptome. A luciferase reporter assay was designed to measure ChREBP activity. **Results:** Hepatic RNASeq showed that modulating reductive stress using alcohol and/or *Lb*NOX significantly altered *de novo* lipogenic gene expression *in vivo*, which was largely mediated by activation of the transcriptional factor Carbohydrate Response Element Binding Protein (ChREBP). Strikingly, *Lb*NOX transfected HEK293T cells, which had decreased reductive stress, showed an 84 % decrease in ChREBP activity, whereas increasing reductive stress using *Ec*STH increased ChREBP activity by 169%. Notably, we found that glyceraldehyde 3-phosphate and glycerol 3-phosphate are among the top metabolites that positively correlate with ChREBP activity and reductive stress. This observation is consistent with previous research, which has suggested that triose-phosphates can stimulate ChREBP and activate *de novo* lipogenesis. **Conclusion:** Our study demonstrates that ChREBP is a reductive-stress responsive transcription factor that contributes to hepatic fat accumulation in both alcohol and non-alcohol related fatty liver disease. Our findings suggest that targeting ChREBP activity via modulating reductive stress might be a novel paradigm for the treatment of fatty liver diseases.

3631-C | UPTAKE OF SECONDARY PREVENTIVE DRUGS AFTER MYOCARDIAL INFARCTION IN PATIENTS WITH ALCOHOL-RELATED LIVER DISEASE IS LOW: A NATIONWIDE POPULATION-BASED STUDY

Axel Wester[1], Hannes Hagström[1,2] and Peter Jepsen[3], (1)Department of Medicine, Huddinge, Karolinska Institutet, Stockholm, Sweden, (2)Unit of Hepatology, Department of Upper GI Diseases, Karolinska University Hospital, Stockholm, Sweden, (3)Aarhus University

Background: Secondary prevention with antiplatelets, statins, betablockers, and renin-angiotensin inhibitors improves clinical outcomes after myocardial infarction (MI), but the uptake of these therapies in patients with co-existing alcohol-related liver disease (ALD) is unclear. **Methods:** All patients with ALD and a first-time MI between 2006 and 2020 were identified from Swedish national healthcare registers (n = 362) and matched with up to ten controls from the general population with a first-time MI for age, sex, and year of MI (n = 3,155). Adjusted odds ratios (aOR) for filling prescriptions of four-drug secondary prevention (antiplatelets, statins, betablockers, and renin-angiotensin inhibitors) within 30 days after MI were calculated with logistic regression. Adjustments were made for the matching variables, socioeconomic factors, and a range of comorbidities. **Results:** The median age in the patients with ALD was 68 years and 271 (75%) were men. Cirrhosis was present in 189 of the patients with ALD (52%), of whom 78 had decompensated cirrhosis (41%). Complete four-drug secondary prevention was less common in patients with co-existing ALD (39%) compared to controls (67%, $p < 0.001$) (aOR = 0.30, 95% confidence interval [CI] = 0.23-0.38). The largest difference between patients with ALD and controls was seen for statins (62% vs 92%, $p < 0.001$, aOR = 0.17, 95%CI = 0.13-0.22). Among individual's who filled prescriptions for four-drug secondary prevention within 30 days and survived the first two years after MI, fewer patients with ALD were still taking their medications at that timepoint compared to controls (52% vs 62%, $p = 0.045$). **Conclusion:** Patients with ALD had a lower uptake of secondary preventive drugs compared with the general population following MI, in both short- and long-term perspectives. These results suggest that patients with ALD might be undertreated following MI.

3632-C | UTILITY OF N-ACETYLCYSTEINE IN THE TREATMENT OF ALCOHOLIC HEPATITIS

Noor Hassan[1], Ifrah Fatima[1], Islam Mohamed[1], Vinay Jahagirdar[1], Jennifer Von Ende[1], Jagadish Koyi[1], Abbas Bader[1], Mohamed Refaat[1], Mohamed Ahmed[1], Mir Zulqarnain[2], Adel Muhanna[3], Esmat Sadeddin[1] and Hassan Ghoz[1], (1)University of Missouri- Kansas City, (2)University of Missouri Kansas City, Department of Gastroenterology and Hepatology, Kansas City, MO, (3) University of Missouri-Kansas City

Background: Alcoholic hepatitis (AH), the most severe form of alcoholic liver disease, typically carries a very grim prognosis. N-acetylcysteine (NAC) is an antioxidant which counteracts free radicals and can help reduce inflammation, especially in the liver. Studies have shown a modest benefit with the addition of NAC to glucocorticoids for treatment of severe AH. In this study, we investigated the value of NAC in patients with AH. **Methods:** This is a retrospective study performed in a community center between January 2014 and December 2022. Patients older than 18 years admitted to the hospital for acute AH who received intravenous NAC for at least 72 hours were included in this study. The patients' length of hospitalization, mortality rate, and Mayo End-Stage Liver Disease Sodium (MELD-Na) scores were recorded. Mild to moderate AH was defined as a MELD score $\leq$ 20, and severe AH was defined as MELD > 20. We used historical data from prior publications as control groups. Chi square and Fisher exact tests were used to compare categorical variables, and t-test for continuous variables. **Results:** A total of 30 patients admitted to the hospital with AH who received intravenous NAC were identified. Based on the MELD score cutoff of 20, 15 patients of our cohort presented with severe AH and the other 15 presented with mild/moderate AH. The average length of hospitalization in our 30 patients with AH on NAC was 10.7 $\pm$ 11.7 days which was significantly longer when compared to 6.5 $\pm$ 7.7 days in a historical control cohort of 3,881 subjects with AH, $P = 0.003$. As expected, on sub-analysis, our patients with severe AH had a longer average length of hospitalization of 15 $\pm$ 14.5 days compared to 6.6 $\pm$ 5.7 days in patients with mild/moderate AH, $P = 0.046$. Regarding mortality, the 90 day mortality rate did not differ between our cohort which comprised of 9 out of the 30 patients (30%) when compared to historic control patients (997/3437, 29%), $P = 0.1$. In the mild to moderate AH cohort, there was only 1 death (6.67%) recorded within 90 days compared to 8 patients (53.3%) with severe AH, $P = 0.0053$. Only 5 out of the 15 patients with severe AH were prescribed

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

prednisolone, while other patients did not receive steroids due to contraindications. **Conclusion:** In our study, NAC did not seem to affect length of hospitalization nor 90-day mortality in patients with AH. Patients with AH and MELD score less than 20 had shorter length of stay and lower mortality rates when compared to patients with AH and MELD score of more than 20, while both groups were on NAC therapy. Our next step is to incorporate our control subjects stratified by AH severity in order to further expand this study and clarify utility of NAC in mild/moderate and severe AH.

3633-C | VALUE OF NUTRITION AND DIETARY SUPPORT IN ALCOHOLIC HEPATITIS

Kevin Yang, Naren Srinath Nallapeta, Alexander Mark Carlson, Nariman Hossein-Javaheri, Brian Quigley and Thomas Mahl, University at Buffalo

Background: Nutritional status is an often-overlooked component in alcoholic hepatitis. Almost all patients presenting with severe alcoholic hepatitis have a degree of protein calorie malnutrition, which is associated with worse clinical outcomes. Appropriate dietary support in this setting may influence the hospital course. **Methods:** We designed a retrospective study on all patients admitted to a tertiary care center from 2020 to 2022 with a diagnosis of alcoholic hepatitis. Complications and outcomes investigated included hepatic encephalopathy (HE), gastrointestinal bleeding (GIB), acute kidney injury (AKI), hepatorenal syndrome (HRS), bacterial infections, readmissions, and mortality at 28 and 90 days. We conducted a series of logistic regression analyses using a backward step procedure to identify significant predictors of various outcomes. The predictors included nutrition consultation (yes/no), albumin level at day 1 of treatment, and percent meal intake (continuous measure). Linear regression was also used to analyze the relationship between percent meal intake and the predictors. **Results:** The study included 425 patients who fit the criteria for alcoholic hepatitis. In the analysis examining 28-day mortality as the outcome, the significant predictors were percent meal intake and albumin level at day 1. For every 10% increase in meal percent intake, patients were 2 times less likely to die. For every 1 unit increase in albumin, patients were 5.8 times less likely to die. Higher percent meal intake was also a significant predictor for lower rates of HE, AKI, HRS, infection, and 90-day mortality. Higher albumin at day 1 was associated with lower rates of HE, GIB, AKI, HRS, infection, and 90-day mortality, but higher rates of readmission. Nutrition consults were associated with lower rates of GIB (OR = 0.44, 95% CI = 0.23/0.84), higher rates of AKI (OR = 2.03, 95% CI = 1.14/3.62), and more readmissions (OR = 2.49, 95% CI = 1.56/3.68). Patients who received nutrition consultation had higher percentage of meal intake as well (B = 10.51, 95% CI = 5.41/15.62). **Conclusion:** We found that nutritional status, specifically percentage meal intake during hospitalization and day 1 albumin, was significantly associated with lower rates of complications and short-term mortality in alcoholic hepatitis. The mortality benefit of nutrition consults was not evident in this study, perhaps because sicker patients were more likely to require dedicated support.

	Hepatic Encephalopathy	Gastrointestinal Bleeding	Acute Kidney Injury	Hepatorenal Syndrome

3634-C | VINYL CHLORIDE POTENTIATES LIVER INJURY CAUSED BY CHRONIC ALCOHOL CONSUMPTION IN MICE

Charis-Marie Vanderpuye, Olivia B. Bannister, Jiang Li, Gavin E. Arteel and Juliane I. Beier, University of Pittsburgh

Background: Vinyl chloride, an industrial chemical and environmental contaminant, causes liver injury at

high concentrations, but low-level exposure (< 1 ppm) is currently considered safe. The consequences of sub-OSHA exposure on human health are not well understood, especially in the context of VC as a risk-modifying agent. Previous work from this group confirms the role of VC in exacerbating experimental nonalcoholic fatty liver disease (NAFLD) caused by a Western diet. Both NAFLD and alcohol-associated liver disease (ALD) have similar liver pathologies, and the impact of VC exposure in ALD has not been investigated. Moreover, the prevalence of ALD worldwide raises concerns about how VC exposure can enhance disease progression to more severe stages of injury. The purpose of this study was to determine if VC exposure worsens liver damage caused by chronic alcohol (EtOH) consumption. **Methods:** C57Bl/6J mice, pair-fed or fed a Lieber-DeCarli EtOH diet, were exposed to VC (< 1 ppm), or room air for 6 hrs/d, 5 d/wk for 5 weeks. Plasma and liver samples were collected for determination of injury. **Results:** VC exposure exacerbated EtOH-induced liver damage and oxidative stress, and moderately increased inflammation. VC exposure, however, did not affect hepatic lipid content (Oil red-O, triglycerides and cholesterol). Although the increase in lipids caused by ethanol was not impacted by VC exposure, the pattern of steatosis shifted to more micro-vesicular fat, which is often indicative of mitochondrial dysfunction. In line with that VC also changed mRNA expression of genes regulating metabolism. **Conclusion:** Various environmental toxicants are known to modify or enhance liver injury in NAFLD models. Findings from the present study suggest that VC interacts also with other lifestyle factors such as alcohol consumption resulting in exacerbated alcohol-associated liver damage. This emphasizes that environmental chemical exposure, such as to VC, potentially drives inter-individual risk for developing or enhancing disease.

f 3635-C | VIRAL EXPOSURE PREDICTS MORBIDITY AND MORTALITY IN ALCOHOL-ASSOCIATED HEPATITIS

Cynthia Hsu[1], Limin Wang[2], Evan Maestri[2], Aleesha Jacob[2], Susan Mayo[3,4], Xin Wei Wang[2], Bernd Schnabl[3,4] and AlcHepNet Clinical Investigators, (1) University of California San Diego, La Jolla, CA, (2) National Institutes of Health, (3)University of California San Diego, (4)VA San Diego Healthcare System

Background: Alcohol-associated hepatitis (AH), or severe liver inflammation secondary to heavy alcohol use, is associated with very high mortality even despite abstinence from alcohol; up to forty percent of patients die within 6 months. Patients with AH are especially prone to infections, which can lead to dysfunction of other organs and poorer prognosis. **Methods:** In this study, we performed serological profiling of the viral infection history of 25 healthy controls (HC), 32 patients with alcohol used disorder (AUD) with no apparent liver disease, and 195 patients with AH. AH samples were obtained from two multicenter observational studies, InTeam and AlcHepNet. We used systematic viral epitope scanning by VirScan to comprehensively analyze antiviral antibodies and to better identify serologic biomarkers to predict patient outcomes. Briefly, VirScan is a phage-display immunoprecipitation and sequencing technology that detects the human virome epitopes recognized by antibodies in a serum sample. **Results:** We found significant differences in the serological profiles of these three patient populations, and specifically, we detected a significantly decreased number and diversity of viral antibody targets in the sera of patients with AH (p-value HC vs. AH = 0.002, p-value AUD vs. AH = < 0.001). When the sera of patients with AUD during active alcohol use and after two weeks of abstinence were compared, we detected a significantly increased number of viral epitopes in the sera of abstinent patients (p-value = 0.013), indicating a more robust immune response with abstinence. In patients with AH, a lower number of detectable serum viral antibody targets was correlated with a higher Maddrey's discriminant function score (*p*-value = 0.022) and decompensation events, such as hepatic encephalopathy (*p*-value Control vs. HE Grade 1 = 0.18, p-value Control vs. HE Grade 2 = 0.007, p-value Control vs. HE Grade 3 = 0.008), and a decrease in the diversity of the serum antibody repertoire was correlated with development of ascites (*p*-value < 0.001). Mortality at 30 and 90 days were also associated with a lower number of detectable serum viral antibody targets (p-value mortality at 30 d = 0.018, at 90 d = 0.032). Further, viral exposure to Human herpesvirus 6B and Rhinovirus A was significantly decreased in patients with AH who experienced mortality at 90 days compared to those who survived (*p*-value = 0.041 and 0.0046 respectively). **Conclusion:** We found that abstinence from alcohol is associated with a significant increase in the number of detectable anti-viral antibodies. A decrease

in the number of detectable anti-viral antibodies is predictive of decompensation of liver disease and mortality in patients with AH.

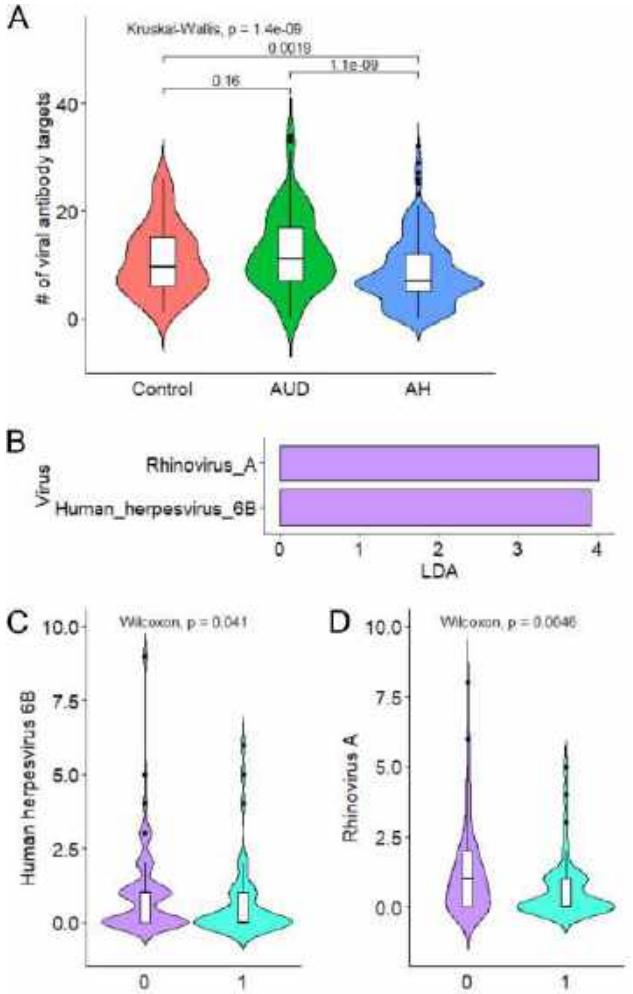

Figure 1. (A) Total number of viral antibody targets in sera of control subjects, patients with alcohol use disorder (AUD), and patients with alcohol-associated hepatitis (AH). (B) Linear discriminant analysis (LDA) of viruses targeted by serum antibodies of patients with AH. (C, D) Total number of epitopes recognized against Human Herpesvirus 6B (C) and Rhinovirus A (D) by serum antibodies of patients with AH.

3700-C | ASSESSMENT OF HOSPITAL READMISSION RATES, RISK FACTORS, CAUSES AND COST AFTER DISCHARGE WITH CHRONIC LIVER DISEASE: ANALYSIS OF THE US NATIONWIDE READMISSIONS DATABASE

James M. Paik[1], Rebecca Cable[1], Linda Henry[1,2,3], Leyla De Avila[1], Huong Pham[1] and Zobair M. Younossi[1,2,3], (1)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (2)Inova Medicine, Inova Health System, Falls Church, VA, (3)Center for Liver Disease, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, VA

Background: 30-day readmission data for patients with chronic liver disease (CLD) and contribution to healthcare burden are sparse. Aim: To assess trends, predictors, reasons, cost, in-hospital mortality, timing of 30-day readmission after discharged with CLDs. **Methods:** Data from all-adult hospitalizations (all-payer) in Nationwide Readmission Database (NRD, 2010-2017) with a diagnosis of CLD [hepatitis B (HBV) and C (HCV), alcoholic liver disease (ALD) and non-alcoholic fatty liver disease (NAFLD)] were analyzed. **Results:** During the 2010-2017, the number of patients discharged with NAFLD increased by +103% from 10,638 to 21,544; ALD increased by +82.2% from 16,023 to 29,188; HCV increased by +63.3% from 21,733 to 35,488; and HBV increased by +63.0% from 2,619 to 4,270. The 30-day readmission rate for NAFLD increased (17.8% in 2010 to 19.9% in 2017, $p < 0.001$), whereas those for HCV decreased (18.1% to 16.8%, $p < 0.001$) and those for HBV (18.6% to 16.7%, $p = 0.162$) and ALD (19.7% to 20.5%, $p = 0.128$) leveled off. Multivariable cox model showed that patients with NAFLD had a significantly higher risk of 30-day readmission (Hazard ratio = 1.06, 95%CI: 1.01-1.11). In addition to ascites, hepatic encephalopathy, and higher number of coexisting comorbidities, independent comorbidities associated with a higher risk of 30-day readmission included cirrhosis for NAFLD and HCV; acute kidney injury for NAFLD, HCV, and ALD; HCC for HCV, and peritonitis for ALD. Among readmitted patients, substantial differences in cost and in-hospital mortality between $\leq$30-day and > 30-day readmission were observed ($16,986 vs. $14,648 and 8.2% vs. 5.2% for NAFLD; $16,590 vs. $15,036 and 7.4% vs. 4.3% for HCV; and $19,152 vs. $16,487 and 8.5% vs. 6.3% for HBV; and $17,351 vs. $15,114 and 8.5% vs. 6.3% for ALD). These differences remained significant only for

NAFLD after controlling for patient's demographic, hospital-level and clinical characteristics. Hepatic reasons explained the majority of 30-day readmission. However, a large proportion of patients (43.7% for NAFLD; 28.4% for HCV, 39.0% for HBV, and 29.1%) were readmitted for extrahepatic reasons. Of 30-day readmissions, a disproportionately high number of readmissions occurred during days 1-15 (62.8% for NAFLD, 63.7% for HCV, 74.3% for HBV, and 72.9% for ALD) (Figure). **Conclusion:** Early readmissions for NAFLD were prevalent, causing economic and clinical burden.

3701-C | EVALUATING HOSPITAL LENGTH OF STAY, READMISSION, AND COST OF CARE IN CIRRHOTICS WITH HEPATIC ENCEPHALOPATHY

Natalia Salinas Parra[1,2], Adnan Khan[3], Heather M Ross[2] and Manish Thapar[4], (1)Hospital of the University of Pennsylvania, (2)Thomas Jefferson University Hospital, (3)Thomas Jefferson University, (4)Einstein Healthcare Network

Background: Hospital readmissions are a cause of significant cost burden to the health system. Rifaximin is prescribed to prevent recurrent episodes of Hepatic Encephalopathy in patients with Cirrhosis. The purpose of our study is to compare the hospital length of stay (LOS), re-admission rates, and hospital cost in patients prescribed Rifaximin during hospital stay and on discharge compared to those who were not prescribed Rifaximin. **Methods:** We used the Vizient Clinical Database (VCD) to collect data on patients diagnosed with Hepatic Encephalopathy and Cirrhosis between 2019-2021. The hospital length of stay (in days), re-admission rates, and hospital costs were compared between patients who were treated with rifaximin versus those not treated with rifaximin. Further, we compared the above outcomes in patients with Medicare and Medicaid insurance. Patients younger than 18 years old and those that required hospice, rehabilitation, or nursing facility placement were excluded from our study. Categorical variables were analyzed using the Chi-Square test. All statistical analysis was completed by STATA. P-values < 0.05 was considered statistically significant. **Results:** 29,999 patients with Medicaid were prescribed Rifaximin during hospital stay and on discharge. These patients had a higher mean LOS of 11.88 days as compared to 8.91 days in 22,985 Medicaid patients who were discharged without Rifaximin, and a higher mean direct cost of stay at $31,766 in the Rifaximin cohort versus $27,869 in the cohort not on Rifaximin on discharge. Similarly, the 30-day readmission rate was higher at 28% in the group on Rifaximin compared to the group discharged without Rifaximin at 24%, which is statistically significant ($P = 0.037$). Both groups had a higher observed LOS compared to the expected LOS. During the same period, 29,183 Medicare patients who were prescribed Rifaximin during hospital stay and on discharge had a mean LOS of 8.95 days, a 26% 30-day readmission rate, and a mean direct cost of $17,830. 20,054 Medicare beneficiaries discharged without Rifaximin

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

had a mean LOS of 8.26 days, 22% 30-day readmission rate, and mean direct cost of $21,702. Medicaid cohort on Rifaximin had a higher 30-day admission (28% vs 22%), mean LOS (11.8 vs 8.95) and higher mean direct hospital cost (31,766$ vs 21,702$) compared to the Medicare cohort. **Conclusion:** Our analysis of the VCD shows that in the Medicaid cirrhotic population, Rifaximin use is associated with a higher LOS, hospital cost, and readmission rates as compared to the Medicare population. This paradox of higher LOS could be explained by the challenges associated with prescription drug coverage and other psychosocial determinants of health. A possible target for reducing the length of stay and readmissions would entail use of dedicated case managers and a less restrictive prior authorization requirements.

3702-C | FINANCIAL BURDEN AFTER HCC DIAGNOSIS IN A LARGE US NATIONAL PATIENT COHORT

Ruchi Desai[1], Yue Jiang[2], Darine Daher[3], Karim Seif El Dahan[3], Lisa B. VanWagner[3], Amit G. Singal[3] and Sarah Rosanna Lieber[3], (1)UT Southwestern Medical Center, (2)Duke University, (3)University of Texas Southwestern Medical Center

Background: High financial burden of cancer care has been reported for multiple cancer types, although there are fewer data in patients with hepatocellular carcinoma (HCC). We aimed to characterize the financial burden to patients diagnosed with HCC using a large national database and to identify correlates of higher patient financial liability. **Methods:** Adults aged 18-64 diagnosed with HCC (ICD–9/10 codes 155.0, C22.0) from 2006 through 2021 were identified using IQVIA PharMetrics Plus, a nationally representative U.S. database of commercial medical and pharmacy claims. Patients were required to have at least 12 months of continuous medical and pharmacy benefits post diagnosis of HCC. Patient financial liability was defined as the difference between allowed and paid amounts from adjudicated insurance claims. We reported total and HCC-related financial liabilities. Multivariable logistic regression modeling was used to identify variables associated with high ($>=3000) vs. low (<$3,000) total financial liability post HCC diagnosis. **Results:** We identified 12,098 eligible patients with HCC, with median age 56 years and 58% were male. Of the 40% with at least one HCC therapy during the first year after HCC diagnosis, 18% received TACE or TARE, 10% external beam radiation, 9% ablation, 8% resection, and 4% liver transplantation (Table 1). The median total financial liability during the year after HCC diagnosis was $2,623 (25-75% interquartile range (IQR): $863 - $5,627). Despite all patients having some financial liability, only 15% (n = 1,837) experienced HCC-related liability. Among those with non-zero HCC liability, the median liability was $555 (Q1-Q3: $162 - $1,584). In multivariable analysis, older age, higher comorbidity, having alcohol-related cirrhosis, living in non-East regions, and receiving HCC-related treatment were each significantly associated with high total patient liability (≥ $3,000). **Conclusion:** In this privately insured population, patients' total financial liability after HCC diagnosis was high despite low direct HCC-related costs. There was significant variability in individual financial liability based on patient age, geography, treatments received, HCC etiology, and comorbidity. Patients with a diagnosis of HCC may need financial counseling tailored to their individual risk factors for greater financial liability, especially related to insurance coverage.

3703-C | INCREASE IN POINT-PREVALENCE AND COSTS OF LIVER CIRRHOSIS IN THE NETHERLANDS – A NATIONWIDE HEALTH CLAIMS DATA ANALYSIS

Koos De Wit[1], Gwen Masclee[1], Minneke Coenraad[2], Frans J. C. Cuperus[3], Matthijs Kramer[4], Raoel Maan[5], Bart Takkenberg[1] and Marten Alexander Lantinga[1], (1) Amsterdam University Medical Center, Amsterdam, Netherlands, (2)Leiden University Medical Center, (3) University Medical Center Groningen, Groningen, (4) Maastricht University Medical Center, (5)Erasmus University Medical Center

Background: Chronic liver injury ultimately progresses to the development of cirrhosis. Patients with cirrhosis can be in a compensated or decompensated phase, the latter marked by clinical events such as ascites, hepatic encephalopathy and variceal bleeding. These events are associated with significant morbidity and mortality and the management is challenging and labor-intensive. Due to ongoing unhealthy lifestyle factors resulting in chronic liver injury, the burden of cirrhosis on healthcare systems in Europe is increasing. There is however limited data on the impact of cirrhosis on Dutch healthcare resources. **Methods:** We aimed to determine the point-prevalence and claimed health costs of adults ($\geq$ 18 y) registered as patients with cirrhosis at Dutch hospitals. To this end we extracted health claims data (timeframe 2017-2021) from the records of the Dutch health claims database (Vektis), which covers almost all inhabitants of the Netherlands. We used diagnosis codes 'compensated cirrhosis' and 'decompensated cirrhosis' to identify patients. **Results:** The point prevalence of patients with cirrhosis increased from 48,7 patients per 100.000 adult Dutch inhabitants in 2017 to 75,2 per 100.000 in 2021 (+54%). The point-prevalence for cirrhosis was highest in the province of Limburg with 105,6 patients per 100.000 adult Dutch inhabitants. The annual increase in unique new patients for which hospitals claimed costs was n = 3.725 in 2018, n = 3.840 in 2019 (+3%), n = 3.749 in 2020 (-2%) and n = 3.695 in 2021 (-1%). The largest increase was observed in the province of Zuid-Holland (approximately 5 new patients per 100.000 adult Dutch inhabitants per year). Total number of hospital admissions increased with 19% from 2.443 admissions in 2017 to 2.899 admissions in 2021. The median length of stay for admitted patients with cirrhosis in 2017-2021 was four days [IQR 2-7 d]. The annual reported costs for patients with cirrhosis increased from €35 million in 2017 to €78 million in 2021 (+120%). **Conclusion:** The point-prevalence of Dutch adults registered as a patient with cirrhosis in Dutch hospitals increased by more than fifty percent, with remarkable regional differences. Consequently, the total healthcare costs claimed for these patients more than doubled in less than five years.
Disclosures: The following people have nothing to disclose: Koos De Wit, Matthijs Kramer, Bart Takkenberg

3704-C | TRENDS IN MEDICAID SPENDING ON NUCLEOSIDE/ NUCLEOTIDE ANALOGUES FOR HEPATITIS B: 2012-2010

Stephen E. Congly[1], Mayur Brahmania[2] and Carla S. Coffin[2], (1)University of Calgary, (2)Cumming School of Medicine, University of Calgary, Calgary, AB, Canada

Background: There is no cure for chronic hepatitis B infection and many individual's require expensive, long-term nucleoside and nucleotide analogues (NA) therapy. In the United States, individual's over the age of 65 or who are living with disability are eligible for Medicare and can obtain coverage of their drugs through Medicare Part D. The aim of this study was to assess the number of patients receiving NA monotherapy for HBV in the United States through Medicare and the direct costs associated with coverage. **Methods:** The Centers for Medicare & Medicaid Services Part D database was accessed from 2012-2020 to identify NA used to treat HBV including lamivudine, adefovir, telbivudine, entecavir, tenofovir disoproxil fumarate and tenofovir alafenamide. Emtricitabine/tenofovir was excluded from the analysis as it is often used for treatment of HIV, and the underlying disease being treated could not be determined from this database. Data extracted included the number of beneficiaries, number of claims and amount spent, classified by originator (brand name) and generic versions of each compound. **Results:** In 2012, a total of 32,112 individual's submitted 237,735 claims for NA monotherapy therapy for HBV at an estimated cost of $194 million USD. The number of individual's receiving NA monotherapy has overall increased from 2012 to 2020 by 49% with annual spending growing until 2017 before beginning to decrease related to a drop in the spending on originator drugs. From 2012-2018, the highest annual expenditure for NA was tenofovir disoproxil fumarate representing 58-68% of the annual total spend on NA. From 2019 and beyond, this highest expenditure

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

has shifted to tenofovir alafenamide which represents 65% of NA spending in 2020. There was no payment for telbivudine through the study period. **Conclusion:** There is a significant cost to Medicare for NA monotherapy therapy for HBV, but this economic burden is decreasing despite an increased number of patients treated, likely due to increased access to generic formulations. Understanding how medications are being utilized as well as the impact of generic medications is important for future planning for drug coverage to address and important cause of liver disease in the US.

	Spending			Claims			Beneficiaries

3705-C | UPPER LIMIT OF NORMAL ALT LEVELS IN HEALTH AND METABOLIC DISEASES: POOLED ANALYSIS OF 484,177 INDIVIDUALS WITH BOOTSTRAP MODELLING

Eunice Tan[1], Daniel Q Huang[2], Natasha Tang Sook Yee[3], Wan Zi Hui[3], Sanjna Nerurkar[3], Justin Yk Chua[3], Kang Shiong Goh[4], Cheng Han Ng[5], Mark Dhinesh Muthiah[2], Yu Zhou[6], Amanda Woodward[7], Michael H Le[7], Yee Hui Yeo[8], Scott D. Barnett[9], Ramsey Cheung[9] and Mindie H. Nguyen[9], (1)Nuhs, (2)National University Health System (NUHS), (3)National University of Singapore, (4)National University Health System, Singapore, (5)Yong Loo Lin School of Medicine, National University of Singapore, (6)Adelaide Medical School, the University of Adelaide, (7)Stanford University, (8)Cedars-Sinai Medical Center, Culver City, CA, (9)Stanford University Medical Center, Palo Alto, CA

Background: At present, physician practice in regards to evaluation for potential liver disease are largely driven by upper limit of normal (ULN) of serum alanine aminotransferase (ALT) by local laboratories, which may not be drawn from a healthy population without liver disease. However, obesity-related metabolic diseases such as type 2 diabetes mellitus (T2DM) have become increasingly prevalent in the recent decades and may affect the "normal" range of ALT. Thus, there remains an unmet need for updated reference ranges of ALT in individual's with no liver disease with and without metabolic diseases. **Methods:** We performed two separate searches of the PubMed, Embase, and Cochrane databases up to March 2020 and April 2021 to identify studies that included individual's with metabolic diseases and those without respectively. We included studies that provided data for mean or median ALT levels and demonstrated absence of hepatic steatosis on ultrasonography. We excluded those

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

with hepatitis B, C infection and/or excessive alcohol consumption. To identify individual's without metabolic diseases, we excluded those who had T2DM, dyslipidemia, and/or were overweight/obese. The mean ALT (U/L) was estimated using a random-effects mixed model and the ULN level (95th-percentile value, U/L) via a bootstrap model with 10,000 resamples. **Results:** 12 articles (349,367 individual's) were included in the analysis for healthy individual's. For studies which included individual's with metabolic disease, 35 articles were included in the analysis: 26 studies by weight status (187,069 normal weight individual's in 13 studies and 85,898 overweight/obese individual's in 13 studies), 15 studies by the presence of T2DM (9,245 individual's with T2DM in 12 studies and 20,904 individual's without T2DM in 3 studies). In healthy individual's, the ALT ULN levels were 32 U/L overall, and higher in males than females: 36 U/L and 28 U/ respectively (Fig 2A). In analyses that included individual's with metabolic diseases, the ALT ULN levels were 40 U/L in overweight/obese compared to 29 U/L in normal weight (Fig 2B); and 36 U/L among those with T2DM compared to 33 U/L in no T2DM (Fig 2C). On meta-regression of study-level factors, body mass index (coefficient 1.49, 95% CI 0.11-2.86, $P = 0.03$), high-density lipoprotein (coefficient -0.47, 95% CI -0.85-(-0.08), $P = 0.02$), and triglycerides (coefficient 0.19, 95% CI 0.12-0.25, $P < 0.0001$) correlated with ALT levels. **Conclusion:** We provide an updated reference ALT ULN levels for healthy individual's without known liver disease and in subgroups of individual's with or without T2DM, and those with normal weight or overweight/obesity. Our updated ALT ULN cutoffs from this study are less stringent than those proposed two decades ago and can inform current practice to streamline investigations of elevated ALT.

3706-C | A HEPATITIS C (HCV) TEST AND TREAT INITIATIVE IN RESIDENT ASSOCIATED ACADEMIC PRIMARY CARE CLINIC: UPDATES IN AN ERA OF EXPANDED SCREENING GUIDELINES

Eleanor Aubrey Belilos[1], Zoe Post[1], Matthew Eganhouse[1], Agnieszka Maniak[1], Raeesh Vahora[1] and Nancy Reau[2], (1)Rush University Medical Center, (2) Rush Medical College, Chicago, IL

Background: The WHO has tasked health systems to eliminate HCV as a public health threat by 2030, and as such 2020 USPTF guidelines changed to recommend a one-time screen for all adults aged 18-79. Given this, HCV screening responsibility now falls more than ever to primary care. Prior to the expanded guidelines, data from our institution examined resident HCV screening practices and found that consistent care from one primary care physician was associated with improved HCV screening, though rates were still ~50%. Most providers that screen for HCV have little experience in treatment; this new study examined the feasibility and efficacy of teaching residents to both screen and treat HCV in their primary care clinics in an era of expanded screening guidelines. It also explored the utility of a live dashboard in tracking screening rates and treatment practices, with the goal to expand HCV treatment in the primary care setting. **Methods:** A teaching session was held in early 2023 for residents at a single academic center to review updated HCV screening guidelines and teach them to effectively treat HCV in their primary care continuity clinics. A screening and treatment protocol was posted in the resident workroom for reference. A live dashboard was developed to automatically pull EMR data on resident HCV screening and treatment practices from 1/2021-present, to track data prospectively in 3-month intervals. All patient encounters for which HCV screening was incomplete were included. **Results:** From 1/2021-5/2023, 4,121 encounters in resident clinic had HCV screening due; of these, 671 were screened (16.3%) and 12 were HCV antibody positive; 1 had positive RNA and was referred to hepatology (prior to the teaching session). 3 months after the teaching session, the HCV screening rate improved from 14.99% to 21.67% ($p < 0.0001$) and antibody positivity rate increased from 1.53% to 2.56%. Residents also felt significantly more comfortable prescribing HCV treatment if indicated (mean comfort level on a scale of 1-5 increased from 1.7 to 3.9, $p < 0.0001$). **Conclusion:** Educating residents to both identify and treat HCV in their primary care continuity clinics is an easy strategy to increase the provider pool necessary to achieve WHO eradication goals. However, current HCV screening rates are inadequate and have notably decreased since the denominator of patients to be screened was expanded

in 2020. Residents are amenable to learning how to effectively screen and treat HCV, and implementation of a live tracking dashboard can motivate and hold resident clinicians accountable. Next steps include continuing to monitor the dashboard in regular intervals and implementing additional teaching sessions to include incoming residents, APPs, and precepting attending physicians to further increase comfort with HCV treatment.

3707-C | A NOVEL HOMELESS HEPATITIS C CARE MODEL: CLINICAL, PATIENT-REPORTED AND HEALTH ECONOMIC OUTCOMES FROM THE END C STUDY

Adele Mourad[1,2], Rona McGeer[1,2], Emma Gray[2], Anna-Marie Bibby-Jones[3], Vikki Charles[2], Natasha Sanderson[2], Thomas Bird[4], Margaret O'Sullivan[2], Lidia Salvaggio[2], Heather Gage[5] and Sumita Verma[1,6], (1) Brighton and Sussex Medical School, Brighton, United Kingdom, (2)University Hospital Sussex NHS Trust, (3) Sussex Partnership NHS Foundation Trust, (4)Royal Surrey NHS Foundation Trust, (5)University of Surrey, (6)University Hospitals Sussex NHS Foundation Trust, Brighton, UK

Background: Approaching hepatitis C virus (HCV) elimination we are left with an increasing complex and marginalised cohort such as people who are homeless (PWAH). We aimed to assess not only clinical but patient reported outcomes (PRO) and health economic outcomes of a novel community-based care model for PWAH. **Methods:** The END C study (2019-2023) based at multiple community homeless sites in southeast England provided point of care HCV testing, transient elastography (TE), onsite direct acting antiviral (DAA) treatment, peer mentor support, and contingency management (supermarket vouchers). Generic (SF-12v2 and EQ-5D-5L) and liver-specific (SFLDQoL) health related quality of life (HRQoL) was assessed before and at end of HCV treatment. Costs/HCV case detected and cured were calculated. Primary outcome measure was sustained virological response (SVR12) (intention to treat ITT). **Results:** A total of 418 individual's were recruited, mean age 44 ± 10.6, 78% male, 74% being homeless at initial assessment. Prevalence of current injecting drug use (IDU), alcohol use and positive HCV RNA were 25% (95% CI 21%-29%), 65% (95% CI 60%-69%) and 28% (95% CI 24%-33%) respectively. Forty-seven percent of the cohort had previously been incarcerated. Of the 344 individual's with a valid TE result, prevalence of cirrhosis (LSM ≥ 12kpa) was 12 %. Of the n = 116 with a positive RNA, n = 105 (91%) received DAAs of whom 91% were currently homeless, current IDU and current alcohol use being 88% and 93% respectively. ITT SVR12 rates were 81% (95% CI 72%-88%). The only predictor of non-SVR 12 was ≥ 80% adherence (OR 0.04, 95% CI 0.012-0.148, $p < 0.001$). Reinfection data awaited. HRQoL improved significantly at end of treatment in those with SVR12: SFLDQoL: symptoms ($p = 0.0043$), effect on daily life ($p = 0.0031$), memory ($p = 0.2403$), distress ($p = 0.0155$), loneliness ($p = 0.0126$), hopelessness ($p = 0.2476$), sleep ($p = 0.0164$) and stigma ($p = 0.0055$); SF-12 v2 :physical ($p = 0.0023$) and mental health domains ($p = 0.0374$); and EQ-5D-5L composite profile score ($p = 0.0037$) and visual analogue scale ($p < 0.001$). Cost (British pounds 2022) per case detected was £279; mean cost per cure (excluding DAA costs) being £137. Mortality in the treated cohort was 9.5%, the most common cause being drug overdose. **Conclusion:** With novel engagement strategies, excellent SVR12 rates can be achieved in PWAH at modest costs. In addition, SVR12 is associated with significant improvement in both generic and liver specific HRQoL.

3708-C | A PROSPECTIVE MULTIMODAL EDUCATION INTERVENTION FOR PROVIDERS TO INCREASE HEPATIC ENCEPHALOPATHY TREATMENT RATES

Patrick Twohig[1], Thoetchai (Bee) Peeraphatdit[1], Kaeli Samson[1], Makayla Schissel[1], Lynette Smith[1], Allison Ashford[1], Laura Freese[1] and Timothy M. McCashland[2], (1)University of Nebraska Medical Center, (2)University of Nebraska Medical Center, Omaha, NE

Background: Over 50% of hospitalizations from hepatic encephalopathy (HE) are preventable, but many patients do not receive guideline recommended treatment. Our aim was to use a multimodal education intervention (MMEI) for providers to increase HE treatment rates. We evaluated 1) trends in HE treatment, 2) predictors of receiving treatment, and 3) the impact of HE treatment on hospitalization outcomes. **Methods:** Prospective single-center cohort study of patients hospitalized with HE from July 1, 2021 – September 30, 2022. The MMEI included three phases: 1) Prior authorization resources for HE medication coverage, 2) Standardized electronic order set with suggested HE diagnostic workup and medications, and 3) In-person provider education session on HE treatment and resources from #1 and #2. Treatment was defined as receiving any drug (lactulose or rifaximin), or combination therapy (lactulose and rifaximin) while hospitalized. We compared treatment rates from the 15-month MMEI to a 15-month pre-MMEI control group from April 1, 2020 – June 30, 2021. Adjusted odds ratios (AOR) were generated from logistic regression. **Results:** 471 patients were included - 236 pre-MMEI and 235 during the MMEI. After adjustment, there is a significantly lower odds of receiving any drug post-MMEI compared to pre-MMEI (AOR = 0.61, 95% CI: 0.38, 0.96, p = 0.03). There was no significant difference in receiving combination therapy pre- or post-MMEI (AOR = 0.77, 95% CI: 0.46, 1.29, p = 0.32). Predictors of receiving any drug included alcohol-related or cryptogenic cirrhosis ($p < 0.001$), and the presence of ascites (p = 0.005) and/or portal hypertension (p = 0.003), while the only significant predictor of not receiving any drug treatment was having autoimmune cirrhosis ($p < 0.001$). Among those receiving lactulose, patients who were seen by internal medicine (p = 0.01) or were intoxicated (p = 0.02). Any HE treatment was associated with higher 30-day readmission ($P < 0.001$). **Conclusion:** The MMEI used in our study did not increase HE treatment rates. Despite the benefits of HE treatment, current prescribing patterns at our institution suggest that barriers other than prior authorization resources, standardized electronic order sets, or provider education are limiting the prescription of HE medications. Further efforts are needed to identify and address barriers to drug treatment by providers for patients, especially in subgroups of the population with low treatment rates.

3709-C | ALCOHOL USE DISORDER AND ALCOHOL RELATED LIVER DISEASE PREVALENCE IN OBSTETRICS AND GYNECOLOGY CLINICS

Mary Thomson, Elizabeth Aby, Thomas M. Leventhal and Nicholas Lim, University of Minnesota

Background: Early identification of alcohol use disorder (AUD) can prevent alcohol related liver disease (ARLD). Young female patients often seek care through an Obstetrician/Gynecologist (OB/GYN), rather than a traditional primary care provider (PCP). The aim of this study is to identify the prevalence of AUD and ARLD in young patients seeking OB/GYN care to better inform AUD screening in this population. **Methods:** A retrospective review of female patients aged 18-45 seen in

the University of Minnesota OB/GYN clinics between 10/1/2015-10/1/2021 was conducted. AUD and ARLD were defined using ICD-10 coding. **Results:** 71,853 female patients were included. Median age at first OB/GYN visit was 31 years. The majority (73.8%) were white. The median follow up period was 1,410 days, during which 42.8% had a pregnancy related visit (median 10 visits), and 88.3% had a gynecologic visit (median 2 visits). 4.0% of the cohort had coding for AUD or ARLD (Table 1). Patients with AUD/ARLD were more often white (81.0% v. 73.6%, $p < 0.000$), more likely to have Medicaid insurance (48.3% v. 23.1%, $p < 0.000$), and were older (OR 1.01 (95% CI 1.002-1.014, $p = 0.003$). 6.9% of those with AUD had coexisting ARLD. Patients with ARLD with labs had a median total bilirubin of 0.8 IU/mL (IQR 0.5-1.8) and median AST of 90.9 IU/mL (IQR 44.4-132.8). Median FIB-4 score was 2.0 (IQR 0.9-3.5). Patients with a pregnancy related visit, compared to those only seen for gynecologic issues, were younger, less often white, and more often on Medicaid. They were also less likely to be diagnosed with AUD (2.8% v. 4.0%, $p = 0.000$) and ARLD (0.2% v. 0.4%, $p = 0.000$). 72.4% concurrently saw a PCP. These patients were more likely to have a diagnosis code for AUD (4.1% v. 1.8%, $p < 0.000$) and ARLD (0.3% v. 0.2% $p = 0.003$). They were also older, more often white and on Medicaid compared to those who had not seen a PCP. **Conclusion:** Approximately one in thirty young patients in OB/GYN clinic had evidence of AUD. 6.9% of those with AUD had ARLD; median FIB-4 scores in those with ARLD were concerning for fibrosis. AUD/ARLD were less commonly coded for in those with an obstetrics visit, which may reflect reduced consumption or stigma of alcohol use during pregnancy. AUD and ARLD were more commonly coded for in those with a PCP, indicating these conditions may be under-recognized in OB/GYN clinics. Further work needs to be done to help OB/GYN providers identify harmful alcohol use, particularly in patients who only seek their care.

3710-C | AMSETY DATABASE: AN AI-POWERED NOVEL WAY TO RECRUIT MOTIVATED LIVER PATIENTS FOR CLINICAL STUDIES

Tarek I. Hassanein[1], Fatma Barakat[1], Michael Tunkelrott[2], Victoria Aksakovska[2], Jutta Kurz[2], Mustafa Behan[2], Kevin Li[3] and Guy W. Neff[3], (1)Southern California Liver Centers, (2)Amsety Gmbh, (3)Covenant Metabolic Specialists, LLC

Background: Recruiting eligible liver subjects for clinical studies faces numerous challenges. Be it for broader diseases like non-alcoholic steatohepatitis (NASH) or for smaller patient populations like liver cancer, finding motivated subjects is difficult, time-consuming, and costly. As a result, completing clinical trials is complicated by marked delays and missed time points. The novel Amsety digital recruiting program consists of the Amsety Database and the Amsety-AI, an Artificial Intelligence for subject selection. This novel recruiting program shows marked benefits towards identifying trial subjects. Amsety-AI introduces an alternative to the liver disease clinical states - enhancing trial recruitment and improving subject retention. **Methods:** Amsety's database contains a highly motivated population with liver conditions. Around 500,000 subjects were collected through digital education towards liver health, nutrition, and a liver healthy lifestyle – such as the Liver Health Score, a proprietary instrument to assess lifestyle. The data encompasses vast demographic information, allowing clinical trial networks cursory pre-screening analysis and lowering of screening failure rates. **Results:** We collected Amsety-AI patients across the United States since 2016, including zip codes, age, gender, lifestyle and diet patterns, primary liver conditions as well as comorbidities. The data showed 66% were females, 56% had chronic liver disease; 41% were 50-65 years old and 35% were over 65 years of age. 71% reported some alcohol use on weekly basis and 13% were regular smokers. 21% of the participants had diabetes. Details of their diet is captured as well as level of exercise and self-reported quality of sleep. Attendance of scheduled medical care was self-reported in 90% of individual's over 65 years versus 65% under 40 years of age. 21% of the participants reported family history of liver disease. More granular data is available. Currently the database grows by around 10,000 individual's per month. **Conclusion:** Prescreening subjects has shown vast benefits and improvement in screening failure rates, decreasing research networks resources, while markedly reducing time to complete trial recruitment. Amsety-AI is a model for improving subject selections for NASH clinical trials and can help to reach motivated individual's for Liver Health Care beyond clinical studies.

3711-C | ASSESSING ADHERENCE RATES TO QUALITY MEASURES IN HOSPITALIZED PATIENTS WITH CIRRHOSIS

Katherine Ni[1], Zoe Verzani[2], Kimberline Chew[1], Jang Hyun Kim[1], Lewis Paulino[1], Danielle Garfunkel[1], Max Schechter[3], Lital Aliasi-Sinai[4], Daniel Alvarez[1], Clara Tow[1] and Brett Fortune[1], (1)Montefiore Medical Center, (2)Weill Cornell Medical Center, (3)Albert Einstein College of Medicine, (4)Sackler School of Medicine

Background: Cirrhosis is associated with frequent complications and hospitalizations, including hepatic encephalopathy (HE), variceal bleeding, ascites, infection, and renal injury. It is crucial to provide evidence-based care for these complications. In this study, we assessed adherence rates to the AASLD Practice Metrics Committee's cirrhosis quality measures during hospitalizations of cirrhotic patients. **Methods:** We retrospectively reviewed cirrhotic patients admitted to the hospital at a single, academic liver transplant center in a diverse urban neighborhood. We collected admission data for the index admission in 2021, including sociodemographics, characteristics of cirrhosis-related complications, laboratory values, medications, procedures, readmissions, and follow-up appointment data. The primary endpoint was rate of adherence to cirrhosis quality measures. Secondary outcomes were comparison of quality measure adherence in patients with or without subsequent 90-day readmission or death, as well as in patients who did or did not receive hepatology/gastroenterology (GI) consultation. Wilcoxon rank sum, Chi-squared, or Fisher's exact tests were used for the secondary analyses. **Results:** 265 hospitalized cirrhotic patients were included. The median age was 63 years, 58% male, 16% White, 59% Hispanic, and 44% with alcohol related cirrhosis (Table 1). The median MELD-Na was 16. 102 patients (39%) were readmitted or died within 90 days of index admission. Among patients with ascites, 57% were treated with diuretics, 73% were given a low-sodium diet, and paracentesis was performed in 40%. In patients with HE, 80% were given lactulose or rifaximin. In patients with upper GI bleeding, 76% were given antibiotics and 81% had an upper endoscopy (EGD). 37% of patients with varices received band ligation, and 67% were treated with beta-blockers after discharge. Patients who were readmitted or died within 90 days were more likely to have a post-discharge hepatology appointment scheduled ($p = 0.035$); otherwise, there were no differences in quality measure adherence between groups. Inpatient GI/hepatology consultation was associated with higher rates of Hepatitis B testing ($p = 0.005$), rifaximin use ($p = < 0.001$), transplant evaluation ($p = < 0.001$), and hepatology follow-up appointments ($p = < 0.001$). **Conclusion:** In this study of a diverse urban liver transplant center population, adherence to quality measures for hospitalized cirrhotic patients was overwhelmingly poor. While there were no notable differences impacting 90-day readmission/death (likely due to small sample size), we did observe higher quality measure adherence when inpatient GI/hepatology consultation was performed. Further investigation on factors that impact quality measure adherence is warranted in order to develop program improvement initiatives to provide high value care for hospitalized patients with cirrhosis.

f 3712-C | ASSESSMENT OF HEPATOCELLULAR CARCINOMA URBAN/RURAL DIFFERENCES IN AFRICA USING SATELLITE SPATIAL SCALING

Erin Mann[1], Manaswita Tappata[2], Joseph Akambase[3], Kelly Searle[1] and Jose D. Debes[1,4], (1)University of Minnesota, (2)University of Minnesota, Minneapolis, Minnesota, Minneapolis, MN, (3)Hennepin Healthcare, Rochester, MN, (4)Erasmus University Medical Center

Background: Sub-Saharan Africa carries one of the highest burdens of hepatocellular carcinoma (HCC) in the world, with hepatitis B (HBV) as the most common cause. Globally, there is evidence that rural communities experience disproportionate cancer morbidity compared to urban ones. However, no study has examined these differences in Africa. **Methods:** We performed a systematic review of studies on HCC in Africa, later completing a meta-analysis using data from those studies to assess mean age, proportion of males, and of HBV positive patients in relation to location of the study. Using land-use/land cover data available from European Space Agency sentinel imagery on Africa, we categorized locations and calculated the distance in kilometers from each study site to the closest rural area (agricultural land). These distances were divided into quartiles. Logistic regression models were fit to estimate 1) the association between distance to the closest rural area and HBV and 2) the association between distance to the closest rural area and gender. Weighted mean age was calculated for each quartile. **Results:** 978 studies were retrieved through electronic database search. After removing duplicates and reviewing for relevance, fifty-seven articles were included. Data on 10,608 patients was used in the meta-analysis across 19 countries in Africa. 74% of patients were male and the weighted mean age was 52.5 years. Proximity to a rural areas was associated with increased odds of HBV after controlling for country, with locations closest to a rural region (<3.2km) having 3.1 times higher odds of HBV-HCC (95% CI 2.65 - 3.60, $p<0.001$) compared to patients in locations furthest from rural areas (>9.5km). When analyzing only studies in West Africa, those in locations closest to rural areas also showed higher odds of HBV-HCC (OR: 1.43, 95% CI 1.15-1.76, $p<0.001$) compared to those furthest from rural areas. However, patients in studies between 6.3 and 9.5km had decreased odds of HBV (OR: 0.42, 95% CI 0.28 – 0.63, $p<0.001$). No association was found between proximity to a rural areas and gender or age (50, 53, 47 and 53 y/o respectively per distance quartile). **Conclusion:** We found an association between proximity to a rural areas and odds of HBV-associated HCC in Africa in a first study of its kind. Further research is needed to understand the burden of HBV-related HCC in Africa across rural and urban areas.

3713-C | ASSOCIATION OF PSYCHOSOCIAL RISK FACTORS AND LIVER TRANSPLANT EVALUATION OUTCOMES IN NON-ALCOHOLIC STEATOHEPATITIS

Roy X. Wang[1], Danielle Mirda[1], Jason J. Lee[1], Marina Serper[2] and Therese Bittermann[1], (1)University of Pennsylvania, (2)University of Pennsylvania, Philadelphia, PA, United States

Background: The Stanford Integrated Psychosocial Assessment for Transplantation (SIPAT) score is a standardized metric to assess psychosocial risk for transplant candidates. To date, the role of SIPAT in liver transplantation (LT) has largely focused on patients with alcohol-associated liver disease. A recent study demonstrated that SIPAT may also be a useful tool for patients with metabolic syndrome being evaluated for bariatric surgery, in whom issues of surgical readiness, self-care, and social support are equally relevant. This study evaluates the association of SIPAT with metabolic syndrome severity and outcomes in a large cohort of patients with non-alcoholic steatohepatitis (NASH) evaluated for LT. **Methods:** We performed a single-center retrospective cohort study of all patients with NASH evaluated for LT between January 2014-December 2021. SIPAT was obtained at the time of LT evaluation for all candidates. Clinical data from patients' electronic medical record was linked to center-specific transplant registry data. Metabolic syndrome severity was compared descriptively between validated SIPAT score groups: <21 (excellent/good candidate) vs >21 (minimally acceptable/high risk). Multivariable logistic regression, adjusting for demographic and metabolic syndrome factors, evaluated the association of SIPAT score with achieving active LT listing. **Results:** We identified 482 patients with NASH cirrhosis evaluated for LT, among whom 90.5% had SIPAT score <21 and 9.5% SIPAT score >21. The SIPAT >21 group had greater average contribution of the psychopathology domain, while the opposite held true for the lifestyle/substance abuse domain ($p=0.001$ and $p=0.003$, respectively; Figure A). The high SIPAT group was younger (56.8 vs 62.7 y for SIPAT <21; $p<0.001$) and more often female (63.0% vs 41.1%, respectively; $p=0.004$; Figure B). Metabolic factors including composite of cardiovascular disease, uncontrolled diabetes (A1c $>7\%$), uncontrolled hyperlipidemia (LDL >100mg/dL), and class II obesity were not different between groups (all $p>0.05$). Rates of hepatic decompensations and Model for End-stage Liver Disease Sodium score were also not different (all $p>0.05$). Overall, 41% of patients were actively listed, 7% were deferred, and 51% were declined. In multivariable analyses, increasing SIPAT score was independently associated with decreased odds of active LT listing (adjusted OR: 0.82 per 5-point increase, 95% CI: 0.71-0.95, $p=0.009$). **Conclusion:** SIPAT score was not associated with degree of metabolic syndrome or liver disease severity at LT evaluation in the largest cohort to date of patients with NASH cirrhosis. Increasing SIPAT score was associated with reduced odds of active LT listing. Identifying patients with high SIPAT scores may allow for targeted social and behavioral interventions to improve opportunities for LT in the NASH population.

Coffin[3], (1)Division of Gastroenterology, University of British Columbia, BC, Canada, (2)The Ottawa Hospital, Ottawa, ON, Canada, (3)Cumming School of Medicine, University of Calgary, Calgary, AB, Canada, (4)Department of Medicine, University of Alberta, Edmonton, AB, Canada, (5) University Health Network, Toronto, Ontario, Canada, (6)Department of Medicine, University of Toronto, Toronto, ON, Canada, (7)Haskayne School of Business, University of Calgary, AB, Canada, (8)Toronto Liver Center, Toronto, Ontario, Canada, (9)Pacific Gastroenterology Associates, Vancouver, BC, Canada, (10)Cisss Laurentides, St-Jerome, Clinique Médicale Urbaine Du Quartier Latin, QC, Canada, (11) Department of Medicine, McGill University Health Centre, Montreal, QC, Canada, (12)Mcmaster University, Hamilton, on, Canada, (13)Cité-De- La-Santé De Laval, Laval, QC, Canada, (14)Division of Gastroenterology, Health Sciences, Dalhousie University, NS, Canada, (15)National Microbiology Laboratory, Public Health Agency of Canada, Winnipeg, MB, Canada, (16)Department of Medicine, McGill University Health Centre, Westmount, QC, Canada

Background: Although Canada has a universal health care system, this does not include prescription drug benefits and provincial drug coverage formulary is variable. There are systemic factors impacting access to treatment leading to poor outcomes. Our previous study has demonstrated undertreatment in patients with chronic hepatitis B (CHB) who meet treatment guideline criteria. The goal of this survey study was to determine barriers to CHB treatment from the physician's perspectives. **Methods:** An on-line physician survey was sent to members of the Canadian Association for the Study of Liver. Analyses were performed using SPSS. **Results:** Of 50 respondents, 77% (n = 37) were in the 31-50 age group, 54% (n = 27) were male and 52% (n = 26) had been in practice for over 10 years. 32% (n = 16) were gastroenterologists, 30% (n = 15) hepatologists and 30% (n = 15) infectious disease specialists. 38% (n = 19) had more than 200 CHB patients in their practice and 94% (n = 47) had access to transient elastography. 88% (n = 44) followed the Canadian/American treatment guidelines most to all the time, but 70% (n = 35) felt that treatment reimbursement criteria should be broadened especially in those patients with family history for hepatocellular carcinoma. 36% (n = 18) found the provincial medication reimbursement process cumbersome and 20% (n = 10) found that there was a clinically relevant long delay in response from reimbursement authorities. The proportions of CHB patients who were untreated or did not accept treatment and had financial difficulty affording antiviral therapy (Figure 1). 26% (n = 13) of the respondents ranked high medication costs and the need for long-term treatment as the most concerning factors for the patients. Lower medication costs, broadened provincial reimbursement criteria, and improved patient education were identified as the top three strategies that could potentially improve treatment rates among treatment-eligible CHB patients . **Conclusion:** Canadian physicians surveyed report a high proportion of treatment-eligible CHB patients do not receive antiviral therapy due to mediation costs and the need for long-term treatment. Lower drug costs, patient education, and broadened reimbursement criteria could reduce barriers and increase treatment rates for patients with CHB.

3715-C | BREAKING BARRIERS IN HEPATITIS C – A REAL-WORLD EXPERIENCE IN AN ECONOMICALLY DISADVANTAGED POPULATION

Gregory Churchill[1], Landen Burstiner[1], Abbey Johnston[1], Avni Agrawal[1], Oshin Rai[1], Reshmi Mathew[1], Alexis Kailey Goodman[2], Darby Allison[3] and Maged Peter Ghali[1], (1)University of Florida College of Medicine Jacksonville, (2)University of Florida, (3)Nova Southeastern University College of Osteopathic Medicine

Background: The WHO in 2016 projected global elimination of Hepatitis C by 2030. Despite highly efficacious direct-acting antiviral therapy, 2.3 million Americans remain infected. The United States budgeted 11 billion dollars this year to achieve eradication. It behooves local researchers to identify barriers to treatment, which differ depending on the population targeted. We sought to identify barriers in a frontline safety-net institution treating some of the most economically disadvantaged individual's. **Methods**: We identified all patients at our University hospital

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

hepatology clinic who were started on treatment for Hepatitis C (46% Medicaid/Uninsured patients). For patients who did not complete the treatment protocol, chart review was employed to identify reasons for discontinuing therapy and to analyze pertinent associations regarding demographics, medication type, and insurance. **Results**: From 2016-2023, 1648 patients were referred to our clinic and 574 patients were enrolled in our treatment program. Of these, 51 (9%) did not complete treatment. The predominant reasons for discontinuation were missed appointments (24), side effects (12), and cost (9). The highest rates of discontinuation were for Epclusa (14.89%), Mavyret (8.95%), then Harvoni (3.75%) (Fisher's Exact Test: $p = 0.003$). There was no clinically significant difference in patients who discontinued due to side effects. ($p = 0.837$). Uninsured completion rate was 97%, Medicare 95%, Medicaid 88%, and private insurance 84% ($p = 0.007$). Neither sex ($p = 0.884$) nor race ($p = 0.282$) significantly influenced the rate of therapy completion. **Conclusion**: In a population with significant healthcare disparities, excellent adherence to treatment protocols can be achieved even in uninsured charity cases. Non-adherence to follow-up is the predominant reason for not completing the treatment protocol. This may reflect challenges in contacting patients. Travel incentives or assistance with communication devices may improve compliance. Epclusa may be inferior to Mavyret due to its longer treatment course and periodic prescription with ribavirin, a medication with a poor side effect profile. Harvoni's lower discontinuation rate may represent an era effect; the most motivated patients sought treatment in the earlier era of therapy. Medicare's superiority over Medicaid may reflect patient level differences in these two populations and deserves further study. Once patients initiate therapy, the majority (89%) complete treatment successfully, but this represents only 35% of those referred. Further study is needed to determine how to better capture those who do not engage in therapy if elimination is to be achieved. Disclosures: The following people have nothing to disclose: Gregory Churchill, Landen Burstiner, Abbey Johnston, Avni Agrawal, Oshin Rai, Reshmi Mathew, Alexis Kailey Goodman, Darby Allison, Maged Peter Ghali

3716-C | BREAKING THE CHAIN OF TRANSMISSION THROUGH DIAGNOSIS AND CURE OF PWID LIVING WITH HCV IN HARYANA, INDIA

Kanudeep Kaur[1], Rajashree Sen[1], Parveen Boora[2], Usha Gupta[2], Vinod Kumar[2], Sanjay Sarin[1] and Sonjelle Shilton[1], (1)Find, (2)Directorate of Health Services

Background: The World Health Organization (WHO) has set a target of reducing HCV incidence by 80% and mortality by 65% by 2030. The cornerstone of HCV elimination is the availability of highly effective direct-acting antiviral therapy. However, several challenges remain in achieving HCV elimination, including reaching marginalised populations, improving testing and diagnosis rates, and ensuring access to treatment. To achieve HCV elimination, a comprehensive approach is needed, including screening, diagnosis, and treatment, as well as harm reduction efforts for people who inject drugs. In the light of above FIND, in collaboration with the National Viral Hepatitis Control Program and Haryana State AIDS Control Society, initiated a program aimed at eliminating HCV among people who inject drugs (PWIDs) in Haryana. Prior to this, PWIDs had to visit the nearest hospital to avail HCV testing. This program's primary objective is to disrupt the chain of transmission, thereby achieving the goal of HCV elimination in the targeted population. **Methods:** Participants from 10 Oral Substitution Treatment (OST) and 8 Targeted Intervention (TI) sites were enlisted for the study. They underwent screening for Anti-HCV antibody using a rapid diagnostic test (RDT). PWIDs who tested positive for HCV on RDT were requested to provide a blood sample for HCV RNA testing and pre-treatment investigations. The staging of liver disease was determined using the APRI score, where an APRI score below 2 indicated non-cirrhotic status, while a score above 2 indicated cirrhosis. Non-cirrhotic patients were initiated on treatment directly at the OST/TI sites under the supervision of the medical officer, with the medication dispensed by the trained staff nurse. Cirrhotic cases were referred to medical specialists at tertiary hospitals for further evaluation. **Results:** A total of 2830 PWIDs were screened at the 10 OST and 8 TI during the project period, from December 2022 to April 2023. Of the 28.9% ($n = 818$) HCV antibody-positive, 93.8% ($n = 768$) had a confirmatory viral load test, 61.7% ($n = 474$) were HCV RNA-positive. Notably, treatment was initiated in 62.2% ($n = 295$) of the HCV RNA-positive cases, and these individual's are currently receiving ongoing treatment. The treatment initiation for the remaining is ongoing. **Conclusion:** Demonstrated a one stop centre for HCV care at the existing harm reduction service centres among the PWIDs of Haryana through a decentralised approach by setting up treatment centres at the OST /TI facilities.Overall, this approach increased equitable access of HCV care to vulnerable groups reducing risk of transmission and disease burden. The outcomes across the entire care process have been positive, and the decentralization of treatment at the easy-to-approach sites has led to enhanced acceptance and successful completion of treatment among PWIDs. A satisfactory level of patient retention within the HCV care process was reported.

3717-C | CHARACTERIZING PRACTICE VARIATIONS IN THE CARE OF HOSPITALIZED PATIENTS WITH CIRRHOSIS ACROSS THE UNIVERSITY OF CALIFORNIA HEALTH

Jin Ge[1], Albert Lee[1], Oksana Gologorskaya[1], Chiung-Yu Huang[1], Mark J. Pletcher[1] and Jennifer C. Lai[2], (1) University of California, San Francisco, (2)University of California-San Francisco

Background: Despite publicly available practice guidelines and quality metrics published by AASLD and AGA, cirrhosis care remains highly variable. Investigating variations in guidelines-adherence could identify key opportunities to improve clinical outcomes, but prior studies have largely been based on administrative claims and limited by the lack of patient-level data. We aimed to overcome these limitations by leveraging a novel multicenter EHR database, the University of California Health Data Warehouse (UCHDW), with high-dimensional patient-level data to quantify adherence to national guidelines for inpatient cirrhosis care. **Methods:** UCHDW is an Observational Model Outcomes Partnership (OMOP)-based database with EHR data from the five major medical centers of the University of California Health System (UCH). We identified all adult patients with cirrhosis (based on a well-defined methodology of 1+ concept for chronic liver disease and 1+ concept for cirrhosis or its complications) from 2012 through 2022 in the de-identified version of UCHDW. We evaluated for adherence to five AASLD/AGA quality metrics applicable to inpatients with cirrhosis (Table 1, Column A). To determine pairwise differences between individual UCH sites, we conducted pairwise chi-squared tests with Bonferroni correction. **Results:** We identified 24,628 patients who were hospitalized for cirrhosis or its complications at the five UC Health medical centers. The patient population was gender and racially/ethnically diverse: 40% (9,877) women, 42% (10,448) White, 29% (7,136) Hispanic, 11% (2,620) Asian, 8% (1,864) Black, and 10% (2,555) Other/Unknown. Median (IQR) age was 59 years (IQR 50-67). Adherence to five quality metrics applicable to inpatients with cirrhosis differed significantly between the five UCH sites (Table 1, Column E, $p < 0.01$ for all comparisons). In pairwise comparisons between individual UCH sites (e.g., UC-3 versus UC-5), we found systematic differences between UC-1 versus other sites across all five metrics. When UC-1 is excluded from analyses, we found guideline-adherence rates remained significantly different across all metrics except for Metric 3, which recommends the use of antibiotics/albumin in the treatment of spontaneous bacterial peritonitis (Table 1, Column F). **Conclusion:** We found systematic differences in AASLD/AGA quality metrics across the five UC Health medical centers, and lower apparent quality particularly at one site (UC-1), indicating specific opportunities for improvement. Analyses of high-dimensional EHR data, such as UCHDW, will enable comprehensive evaluations of multi-level factors for potential interventions in the future.

Table 1 – AASLD/AGA Quality Metrics Applicable to Inpatient Admissions and UCH Site Performances

Background: Celiac disease (CeD) is emerging as a multisystem disease with involvement of the liver. While patients with CeD have been found to have hypertransaminasemia; patients with cryptogenic hypertransaminasaemia, cryptogenic cirrhosis, and autoimmune liver diseases have also been found to be associated with CeD. We assessed the prevalence of Celiac disease in all-cause cirrhosis. **Methods:** In a prospective study, consecutive patients with cirrhosis, irrespective of the underlying etiology, presenting between March 2022 and February 2023 to Gastroenterology clinic were recruited. All of them were screened for CeD using IgA anti-tissue transglutaminase antibody (anti-tTG Ab) and if found positive, they were subjected to anti-endomysial antibody (EMA) testing and duodenal mucosal biopsy examination. A diagnosis of CeD was established if they had anti-tTG Ab titers > 2 times the ULN in the presence of villous abnormalities of modified Marsh grade > 2 and/or had EMA positive. **Results:** Of 1126 patients with cirrhosis of all causes, 22 (1.9%) had high titers of anti-tTG Ab. EMA was positive in 9 of 15 patients in whom it could be done. Seventeen patients had a villous abnormality of modified Marsh grade ≥ 2. The prevalence of biopsy-confirmed CeD in them was 1.5%. The mean (SD) anti tTG Ab titer fold rise in them was 18.4 + 5.5 folds. Patients with cirrhosis having CeD, when compared to patients with cirrhosis without CeD, were younger, with a higher proportion being males. The median liver stiffness measurement (23.05 vs 29.71 Kpa, P = 0.75), mean CTP (8.9 vs 9.3) and MELD-Na (18.4 vs 19.2), respectively were comparable in patients with and without CeD. The etiology of cirrhosis in patients with associated CeD were alcohol in 7 (31.8%), autoimmune hepatitis in 6 (27.2%), non-alcoholic steatohepatitis in 4 (18.1%), chronic hepatitis B in 2 (9%), Wilson's disease in 1 and a combination of Alcohol+AIH and NASH+AIH in 1 each. The median delay in diagnosis of co-existent CeD was 201 days (range 54 to 886). All patients with co-existent CeD are being followed up prospectively to look for the effect of GFD on liver functions. **Conclusion:** The sero-prevalence and the prevalence of biopsy-confirmed CeD in patients with all-cause cirrhosis were 1.9% and 1.5% which is higher than the prevalence of CeD in the general population. Most of these patients with cirrhosis having CeD already had a known etiology of the cirrhosis. Therefore, all patients with cirrhosis should be screened for CeD as it can result in the diagnostic delay of a potentially reversible cause of chronic liver disease and may improve prognosis.

Figure: Individual patient characteristics of all cause cirrhosis of liver with CeD

Francisco, (3)Arusha Lutheran Medical Center, (4) Erasmus University Medical Center, Netherlands, (5) Hennepin Healthcare, (6)University of Minnesota

Background: Hepatitis B virus (HBV) and hepatocellular carcinoma (HCC) are associated with higher morbidity and mortality in Africa, particularly in rural areas, in part due to lack of identification of patients with HBV and lack of feasible surveillance programs for HCC. In this study, we implemented a community-based combined HBV and HCC screening program in rural Tanzania to increase awareness and early detection. **Methods:** We partnered with regional doctors and public health workers conducting mobile primary care clinics in rural villages in Tanzania at local hospitals and clinics to screen for HBV and HCC between March 2021 and February 2023. Patients who presented to the clinics underwent informed consent and completed a study questionnaire related to HBV. Testing for HBV was conducted with rapid point-of-care (POC) assay requiring a fingerstick which tested for HBsAg (hepatitis B surface antigen). Patients who were HBsAg positive underwent POC ultrasound to screen for HCC, POC for hepatitis C (HCV) antibody, and were referred to HBV clinic for further management. We measured the number of HBV diagnoses (primary outcome) and the number of liver masses (secondary outcome). Data were analyzed with descriptive statistics. **Results:** A total of 501 patients were screened for HBV with rapid antigen testing in four villages, and of these, 63% (n = 303) were female with median age of 40 (IQR 28-55). Only 6% (n = 30) were vaccinated against HBV, 92% (n = 453) were not vaccinated, and 2.4% (n = 12) reported not knowing vaccination status. 73% (n = 310) of respondents reported that they did not know they should get vaccinated against HBV and 3.8% (n = 16) reported that vaccination was too expensive. 41% (n = 182) knew how HBV was transmitted, and 4.1% (n = 18) of patients had at least one household member with HBV. There were 2.4% (n = 11) of patients who were positive for HBsAg, and over half were female (54.5% n = 6) with a median age of 36 years (IQR 34-43). All patients who tested positive were not vaccinated against HBV. All HBsAg positive patients were negative for HCV, and 3 patients were tested for hepatitis B e antigen (HBeAg) with all three being positive. One patient had a mass detected on ultrasound and one patient had ascites detected on ultrasound. **Conclusion:** We found that community-based HBV and HCC screening can be implemented sustainably in Africa with local partnerships. This model could be used in regions with high HBV endemicity and low rates of HCC screening.

3720-C | COULD NEW LAWS RESTRICTING RIGHTS AFFECT HEPATOLOGY TRAINING SLOTS IN AREAS OF NEED?

Alan Hutchison, University of Chicago, Medicine, Gautham Reddy, University of Chicago Medicine, Chicago, IL, Anna Mae Diehl, University of Chicago, Medicine, Durham, NC and Sonali Paul, University of Chicago Medical Center

Background: In recent years many states have passed laws limiting reproductive rights such as abortion and access to birth control and rights of transgender individual's to avoid discrimination. This may negatively impact where hepatologists train and live. Given predictions of a shrinking hepatology workforce, it is important to evaluate the impact of these state laws on current disparities and future workforce in hepatology care. **Methods:** We reviewed the Scientific Registry of Transplant Recipients data for centers that performed ≥20 liver transplants (LT) per year and identified if these programs had TH fellowships through manually visiting the websites associated with those centers. We compared this with the list of states that California will not let its employees use state funds to travel to due to a law that "California must take action to avoid supporting or financing discrimination against lesbian, gay, bisexual, and transgender people." (AB 1887). We also compared this with a list of states with active bans on abortion up to 20 weeks after gestation compiled by the New York Times. We compared this data to the hepatology existing workforce predictions from Russo et al. 2020. **Results:** We found that the 16 states with permissive transgender and reproductive laws accounted for 3855 DDLTs and 337 LDLTs across 48 centers with 56 training slots. We found that the 21 states with laws restricting reproductive or transgender rights accounted for 3943 DDLTs and 136 LDLTs across 43 centers with 38 training slots. By regions as defined by Russo et al., the Southeast (SE), Great Lakes (GL), and Northeast regions have the highest projected workforce loss. The SE has 13 centers, 8 centers with 10 TH slots, with all the centers in states with laws restricting both transgender and reproductive rights. The GL has 16 centers, 14 with 16 TH slots in states with permissive laws and 3 with 5 TH slots in states that restrict either transgender or reproductive rights. The NE has 12 centers, 7 with 14 TH slots, all of which are in states with permissive laws. **Conclusion:** New laws restricting reproductive and transgender rights are present in states accounting for half of the national transplant volume and centers and 40% of the training slots. Laws in these states may impact interest in obtaining training or hepatology positions. Workforce

projections show significant shortages in regions heavily impacted and slightly affected by the new laws. Future workforce surveys should incorporate questions about these laws to understand their potential to impact changes in the hepatology workforce.

3721-C | Creation of a population health disease management strategy for NAFLD in the Veterans Healthcare Administration

Heather M. Patton[1,2], Timothy R. Morgan[3], Jennifer Anwar[3], Vera Yakovchenko[4], Sandra Gibson[4], Gyorgy Baffy[5], Michael Fuchs[6], Karine Rozenberg-Ben-Dror[7], Christine M. Hunt[8,9], Dawn Scott[10], Nsikak Ekanem[11], Yiwen Yao[12] and Shari S. Rogal[4,13], (1)VA San Diego Healthcare System, (2)University of California, San Diego, (3)VA Long Beach Healthcare System, (4)VA Pittsburgh Healthcare System, (5)VA Boston Healthcare System, Boston, MA, (6)Mcguire Veterans Affairs Medical Center, Moseley, VA, (7)Veterans Health Administration, (8)Duke University School of Medicine, Chapel Hill, NC, (9)Durham VA Medical Center, Durham, NC, (10)Central Texas VA Healthcare System, (11)VA Northern Indiana Healthcare System, (12)VA Salt Lake City Healthcare System, (13)University of Pittsburgh

Background: The VA is the largest U.S. provider of liver disease care. In anticipation of ongoing innovation in nonalcoholic fatty liver disease (NAFLD) care and in recognition of disease burden and underdiagnosis, VA hepatology leadership aimed to develop a blueprint for NAFLD population level management. **Methods:** VA hepatology leaders developed a multifaceted approach to address NAFLD as a public health problem in VA. An advisory board of hepatology experts and an interdisciplinary group of providers from across specialties were convened. These stakeholders created an evidence based guidance document for the diagnosis, evaluation and treatment of NAFLD. Simultaneously, a data management plan was developed, evaluating how to extract data about Veterans at risk and the care delivered to this population. Subsequently, we conducted a national survey of resources, knowledge, and current practices to identify and address barriers to providing care. A dashboard was created to track patients with potential NAFLD. **Results:** Over 4 million Veterans had risk factors for NAFLD; 207,529 (4.9%) had a diagnosis of NAFLD and 71,169 (1.7%) had a diagnosis of cirrhosis. Of 124 station survey respondents, most reported that NAFLD patients were managed in hepatology/GI (68, 55%) or in primary care (61, 50%). Patients were followed in GI/liver clinic either long term (14%) or based on having abnormal blood tests (38%) or fibrosis (60%). The most frequent interventions included provider recommendation for weight management and counseling on alcohol abstinence, followed by referral for weight loss or nutrition services. Bariatric services were infrequently used. Vitamin E was the most common pharmacotherapy, followed by pioglitazone, then semaglutide (Table 1). A primary care algorithm for NAFLD diagnosis and risk assessment to guide specialty referral was developed. Ongoing efforts include NAFLD dashboard utilization for case finding, refining data management systems, designation of quality metrics, patient and provider education, and dissemination of resources. **Conclusion:** In preparation for novel pharmacotherapies and rapidly evolving care guidance, VA developed a population management blueprint for NAFLD. This approach began with drafting interdisciplinary consensus guidance, identifying high rates of baseline undiagnosed disease, examining patterns of field-based care, and developing a dashboard to facilitate population management. Interventions underway include dissemination of information addressing NAFLD diagnosis and management, establishing quality metrics for

3722-C | DECREASED COMPLETION OF ORDERED LABS AND IMAGING IN TELEHEALTH COMPARED TO IN-PERSON ENCOUNTERS

Jacqueline B. Henson, Yuval A. Patel, April Wall and Andrew Joseph Muir, Duke University

Background: One important aspect of successful outpatient care is patient completion of ordered testing, including labs and imaging. For telehealth visits, which have become a more routine modality of healthcare delivery since the COVID-19 pandemic, these generally must be performed at a different time and place than the encounter. Whether completion of ordered labs and imaging in telehealth encounters differs from in-person visits, however, is unknown. The aim of this study was to compare order completion in telehealth and in-person encounters and to identify factors associated with lack of completion. **Methods:** Telehealth and in-person encounters in hepatology clinics at our center from 1/1/2021-12/31/2022 were identified. Completion of associated orders for labs and imaging was assessed and compared by visit modality. Encounter- and patient-level factors associated with telehealth order completion were evaluated. Comparisons were performed using chi-square tests or Cochrane-Armitage tests for trend across ordered groups. **Results:** A total of 2489 telehealth visits were conducted, 10.8% of all encounters (23147) for 9925 patients. Telehealth encounters were less likely to have labs (42.2% vs. 69.4%, $p < 0.001$) and imaging ordered (28.4% vs. 40.9%, $p < 0.001$). They were also less likely to have ordered labs completed within 14 days (37.2% vs. 77.8%), 30 days (47.6% vs. 78.1%), and 90 days (59.3% vs. 78.7%; all $p < 0.001$). Ordered imaging was similarly less likely to be performed within one year (57.8% vs. 66.0%, $p < 0.001$), particularly liver ultrasounds (58.9% vs. 67.6%, $p = 0.001$). Among encounters for cirrhosis, liver ultrasounds (55.3% vs. 66.4%, $p = 0.004$) and abdominal computed tomography (52.9% vs. 66.7%, $p = 0.046$) were less likely to be completed after telehealth visits. Return telehealth visits and encounters in patients more remote from the center had a lower proportion of labs completed (Table). When stratified by diagnosis, telehealth encounters for decompensated cirrhosis were most likely to have labs completed, though 43.6% were still not completed within 30 days. Telehealth encounters in patients with Medicaid or without health insurance were less likely to have ordered imaging completed (Table). **Conclusion:** In our population, telehealth encounters had lower completion of ordered labs and imaging compared to in-person visits. More than half did not have labs collected within a month, and liver imaging studies were less likely to be completed in patients with cirrhosis. Though one of the potential benefits of telehealth is improving access for patients more remote from specialty care, increasing distance was associated with decreased lab completion. Further research is needed to better understand the barriers to order completion for telehealth visits and ways to optimize this to improve effectiveness of this visit modality.

Table. Factors associated with lab and imaging completion after telehealth encounters.

	Labs Completed within 30 Days, % (n)	Labs Not Completed within 30 Days, % (n)	p-value	Imaging Completed within 1 year, % (n)	Imaging Not Completed within 1 Year, % (n)	p-value

3723-C | DEMOGRAPHIC COMPARISON OF NONALCOHOLIC STEATOHEPATITIS (NASH) PATIENT POPULATIONS IN A LARGE ELECTRONIC MEDICAL RECORDS DATABASE VS. CLINICAL TRIAL POPULATIONS

Paola Figueroa Barojas, Alessandra Vignola, Sigrunn Blacoe and Stephen Peroutka, Clinical Research, Thermo Fisher Scientific

Background: Recent Food and Drug Administration (FDA) guidance stressed the importance of studying trial populations that are similar to the patient population likely to use the treatment being developed, if approved. However, the FDA has not provided specific guidance on how to define demographic goals for trial populations. **Methods**: The demographics for age, gender and race were analyzed in the TriNetX Analytics Network database of more than 140 million patients who have received care at 73 health care organizations in the United States within the past two years. Demographic data were assessed for individual's with an ICD-10 K75.81 diagnosis of nonalcoholic steatohepatitis (NASH). **Results**: There were 87,390 individual's in the TriNetX database with an ICD-10 K75.81 diagnosis of NASH, aged 18 or older. The demographic characteristics included age distribution, median age (59 years), gender (58% female; 42% male) and racial distribution (White = 76%, Black or African American = 5%, Asian = 3%, Other or unknown = 16%). Ethnicity data showed that 68% of patients were identified as Not Hispanic or Latino, 22% as Hispanic or Latino and 10% as Unknown. These data were then compared to demographic data from (U.S. only) industry trials available in the clinicaltrials.gov database. There were 35 identified completed NASH trials with gender data on 2,372 subjects, of whom 59% were female and 41% male. Race data were available from 20 studies with 1,884 subjects: White = 87%, Black or African American = 3%, Asian = 3%, Other or unknown = 7%. In terms of Ethnicity, data from 16 studies with 1,432 subjects reported that 64% were Not Hispanic or Latino and 36% were Hispanic or Latino. **Conclusion:** Large electronic medical record databases provide an unprecedented opportunity to rapidly identify the "real world" gender, race and ethnicity demographics of patients receiving health care for conditions such as NASH. These data can be used to guide the appropriate selection of NASH clinical trial study populations, as recommended by the FDA. Based on the current data from completed adult NASH (U.S. only) industry trials, there appears to be a moderate under-representation of Black subjects and overrepresentation of Hispanic or Latino subjects in comparison to the "real world" data in the TriNetX database. It is well documented that NASH is more prevalent in the U.S. Hispanic population[1] and therefore we would expect to see a higher proportion of Hispanic patients in the "real world" data. The observed difference in the data set may be due to complex social factors such as lack of understanding and/or willingness to identify with race or ethnic demographics categories, and medical care access. Future studies are needed to investigate the demographic observations. 1. Rich NE, et al. Racial and ethnic disparities in nonalcoholic fatty liver disease prevalence, severity, and outcomes in the United States, Clin Gastroenterol Hepatol 2018;16:198-210.e192

3724-C | DESIGN OF A CLINICAL DECISION SUPPORT (CDS) SYSTEM FOR CIRRHOSIS MANAGEMENT

Jin Ge[1], Ana Buenaventura[1], Beth Berrean[1], Jory Purvis[1], Valy Fontil[2], Jennifer C. Lai[3] and Mark J. Pletcher[1], (1)University of California, San Francisco, (2) NYU-Langone Medical Center, (3)University of California-San Francisco

Background: Electronic health record (EHR)-based CDS systems are potentially scalable interventions that could help standardize clinical care. CDS systems, however, have not been extensively investigated in liver disease and cirrhosis management. Human-centered and user-centered design are approaches that systematically engage with potential users in the development of an intervention. In this study, we applied principles from these approaches to design a CDS system for cirrhosis management, called *CirrhosisRx*. **Methods:** We conducted initial focus groups that included clinicians, user-experience designers, informaticists,

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and programmers to construct a low-fidelity wireframe of the potential CDS system. We then convened six co-design workshops with (N = 4-7 per workshop, and N = 20 total) clinicians from diverse practice background (residents, fellows, hospitalists, gastroenterologists, hepatologists, and advanced practice practitioners) via a snowballing sampling method. Practice settings included a major academic medical center, Veterans Administration hospital, and community-based academic inpatient practice. We elicited approaches and workflows for managing patients with cirrhosis, assessed gaps and needs in existing EHR systems, evaluated potential features, and refined the design prototype for *CirrhosisRx*. At the conclusion of each of the 6 co-design workshops, we analyzed recordings and transcripts for overarching themes. **Results:** Feedback from co-design workshops indicated that aggregation of relevant clinical information into cirrhosis decompensation domains and linkages with prescribed order sets were the most important. Detection of clinical events based on inference from EHR data was not well accepted due to concerns about accuracy. Calculators and visualizations for commonly used risk stratification scores, such as MELD, were helpful but not necessary. The final design for CirrhosisRx is in Figure 1. **Conclusion:** This is one of the first applications of design methods to construct electronic interventions in hepatology. The co-design processes with potential users significantly altered features for *CirrhosisRx*, overall design of the interface, and likely improved the overall usability of the *CirrhosisRx* application. This work provides a framework model for the creation and design of future EHR-based interventions in hepatology care.

3725-C | DIRECT ACCESS COLONOSCOPY AS A TIME TO CONSIDER HEPATITIS B TRIPLE SCREENING

Eric A. Wien[1], Catherine Freeland[2] and Jonathan M. Fenkel[1], (1)Thomas Jefferson University Hospital, (2) Hep B Foundation

Background: On March 10, 2023, the CDC released new recommendations to offer one-time triple screening for hepatitis B virus (HBV), including HBsAb, HBsAg, and HBcAb total, to all adults age 18+. Patients presenting for the first time to a gastroenterologist/hepatologist (GI/Hep) for colon cancer screening via direct access colonoscopy (DAC) are all age 18+. A possible barrier to implementation of the HBV triple screening recommendation in primary care is that HBV serologies can be difficult to interpret. GI/Hep providers should be able to interpret the results of these tests and provide guidance on management, minimizing the barrier of linkage to care primary care providers may face when implementing HBV screening recommendations. We sought to examine a snapshot of patients coming to our division for DAC over a 2-week period to assess whether a care gap exists and whether DAC may be a time to consider HBV triple screening. **Methods:** All patients presenting for DAC at any of our division's three Pennsylvania-based endoscopy units with any GI/Hep provider during the first two

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

weeks of April 2023 were included in this quality improvement (QI) initiative. The institutional EPIC chart and EPIC's CareEverywhere platform were reviewed for hepatitis B serologies and keyword searched for "HBV" and "hepatitis" to identify any hepatitis B testing obtained prior to the DAC encounter. Descriptive statistics were utilized to measure the outcomes. **Results:** 108 patients underwent DAC during the evaluation period. The cohort was 52.7% female, 50% Caucasian, 37% African-American, 6.5% Asian, and 4.6% Hispanic with a median age of 54 ± 8.99 years. Of the 108 DAC patients, only 9 patients (8.3%) had complete HBV triple screen results for HBsAg, HBsAb, and HBcAb total on their charts. 24 patients (22.2%) had prior HBsAg testing, 24 (22.2%) had prior HBsAb testing, and 12 patients (11.11%) had been tested for HBcAb total. Health disparities in screening could not be assessed due to the small number of patients with complete triple screening in our evaluation cohort. **Conclusion:** Offering HBV triple screening at DAC encounters may offer an excellent QI opportunity to screen patients for HBV. More data is needed to confirm this potential QI care gap and assess potential health disparities in screening, but this snapshot at least suggests this population of patients holds promise for screening.

3726-C | EFFECT OF PHYSICIAN TURN-OVER IN JULY ON CLINICAL OUTCOMES IN HOSPITALIZED CIRRHOSIS PATIENTS: A US NATIONWIDE STUDY USING DIFFERENCE-IN-DIFFERENCES ANALYSIS

Melis Gokce Celdir[1], Shahana Prakash[1] and Tomohiro Tanaka[2], (1)University of Iowa Hospitals and Clinics, (2) University of Iowa Hospitals and Clinics, Iowa City, IA

Background: Adverse clinical outcomes in US teaching hospitals in July, attributed to the relative inexperience of new trainees, have been referred to as "The July Effect." Studies investigating the July Effect on surgical outcomes and in-hospital myocardial infarction mortality have yielded conflicting results. In this study, our aim was to evaluate the causal effect of physician turnover in July on the clinical outcomes of hospitalized patients with cirrhosis in the United States. **Methods:** Using data from the National (Nationwide) Inpatient Sample (NIS) database from 2016 to 2019, we identified hospitalized cirrhosis patients with and without severe liver-related complications (variceal bleeding, hepatorenal syndrome, or acute-on-chronic liver failure) in both teaching and non-teaching hospitals. We compared the changes in in-hospital mortality and length of stay (LOS) between May and July admissions in teaching hospitals to those in non-teaching hospitals using a Differences-in-Differences analysis with logistic and Poisson regression models. The models included confounders such as sex, age, race, hospital region, and hospital size to account for factors that could have affected the parallel trends assumption. **Results:** Our analysis included 78,373 hospitalizations in teaching hospitals and 23,519 in non-teaching hospitals during May and July. In the analysis of baseline characteristics, we found no significant differences except for age; patients were slightly younger in July (58.1 vs. 57.6 years in teaching hospitals [$p = 0.047$]; 59.0 vs. 58.3 in non-teaching hospitals [$p = 0.12$]). The only cirrhosis-related complication that varied between July and May in teaching hospitals was hepatorenal syndrome (61.8% vs. 63.9% in May vs. July; $p = 0.015$). LOS was longer in teaching hospitals, with a 14% increase in duration (95% CI 13-15%), and in-hospital mortality was higher (odds ratio 1.20; 95% CI 1.12-1.29) compared to non-teaching hospitals. Using the difference-in-difference models, the increase in LOS associated with teaching hospitals was 3% greater (95% CI 2-5%) for all cirrhosis-related admissions and 9% greater (95% CI 6-12%) when only admissions with severe complications were included. No significant "July effect" on mortality was found in teaching hospitals ($p > 0.05$ for adjusted and unadjusted models). **Conclusion:** Our study revealed a significant effect of physician turnover in July on LOS, but not on mortality, in nationwide cirrhosis hospitalizations, particularly when there are complications related to cirrhosis. Appropriate supervision of new trainees may alleviate the healthcare burden associated with the care of hospitalized patients with cirrhosis.

f 3727-C | ELIMINATING DISPARITIES IN LIVER TRANSPLANT ACCESS THROUGH MARKET ANALYSIS, STRATEGIC DESIGN, AND EXECUTION

Richard Gilroy, Derek Ginos, Joanna Stephens, Sophie Hansen, Nate Peterson and Jean Botha, Intermountain Health

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: An extensive body of literature and substantial controversy exists regarding disparities in access to a life-saving liver allograft. Most reports and analyses focus upon socioeconomic factors, OPTN policies, and geography. To date, little has been written on how transplant centers might design their actions to mitigate disparity. This study details how market analysis, strategic design, and a graduated implementation of outreach, with continuous performance review and optimization, can eliminate disparities associated with geographic location. **Methods:** In 2017 a market analysis was completed in 6 regional markets (Utah, Nevada, Idaho, Montana, Wyoming and Colorado). Data sources for these analyses were generated from population charts, physician and gastroenterology demographics, hospital demographics, insurance payer mix data sources and center contracting data. OPTN registry data and SRTR offer and acceptance data were reviewed both within the center and at regional centers. A robust Quality Assessment and Performance Improvement department within the system, with numerous quality dashboard, was then created for each performance domain of interest. Within the program, new policies for organ offer and acceptance, remote patient management tools, and interstate high quality networks of physician partners and institutions were established. Sequentially, markets were then developed based upon internal resources, barriers to market development, and the absolute market potential. **Results:** Between 2008 and 2018 the center averaged 36 transplants per year. Market analysis led to 3 markets being identified for development: Utah, Idaho, and Nevada. The disparity between actual transplant rates were 68, 23 and 46 adult residents in 2019 vs predicted 112, 63, and 106 residents per year (30 transplants/million). Following the initiation of our activities transplant rates, in these states, increased to 107, 52, and 56 were respectively in 2022. Specific to Idaho, a remote location with patients living over 300 miles on average from the center, transplants by this center increased from 3 to 27 patients over the 4 years, while in Nevada the numbers only increased from 2 to 6 patients. Organs derived from donation after cardiac death increased from 5% in 2018 to 29% in 2022. One year patient survival with original allograft (Table 7 SRTR: UTLD) was 96.35% (observed) vs 91.73% (predicted) for January 2023. Center transplant volumes increase from 39 to 104 over 5 yrs. **Conclusion:** While OPTN policies and geography do impact center operational performance and transplant rates, a center's behavior and practices has a clinically significant impact upon transplant rates and a patient's access to transplantable organ offers. Transplant programs must consider their design, internal policies, and practices if we seek to mitigate organ transplant disparities within our communities and between US states.

f 3728-C | EMERGENCY DEPARTMENT UTILIZATION AND OUTCOMES IN PATIENTS WITH CIRRHOSIS: A NATIONAL COHORT STUDY

Hirsh Elhence[1], Jennifer L. Dodge[2], Norah Terrault[2] and Brian P. Lee[2], (1)Keck School of Medicine of USC, (2) University of Southern California

Background: While hospitalizations for cirrhosis are well-characterized, the emergency department (ED) reflects an upstream point of care that is understudied. We aimed to describe the national landscape of ED utilization among patients with cirrhosis, and assess factors associated with ED outcomes. **Methods:** We retrospectively analyzed a large national insurance registry (Optum) between 2015-2019, including adults with at least 180 days of enrollment. Liver transplant recipients were censored at the year of transplant. ED visits (stratified by liver vs. non-liver related) were identified using validated billing code definitions. Negative binomial regression was used to assess ED visits per year and a linear discriminant model was used to assess 90-day mortality rates, with models adjusted for individual-level demographic and clinical characteristics. **Results:** Among 26,190,668 patients, 103,475 were with cirrhosis (median age 65 [IQR 58-72]; 46% female; 62% white). In age-adjusted analysis, ED visits per year were 2.02 [95CI 2.00-2.05] with cirrhosis vs 0.52 [0.52-0.52] without cirrhosis, 1.80 [1.80-1.81] for congestive heart failure (CHF), and 1.43 [1.43-1.44] for chronic obstructive pulmonary disease (COPD). Age-adjusted 90-day mortality rates were 11.1% [11.1-11.2] with cirrhosis vs 4.8% [4.8-4.8] without cirrhosis, 9.0% [9.0-9.0] for CHF, and 6.9% [6.9-6.9] for COPD. The most common diagnoses were abdominal pain (12%), septicemia (10%) and alcohol-related disorders (10%) for liver-related visits; and chest pain (6%), lower respiratory disease (4%), and hypertension (4%) for non-liver visits. Patients with decompensated (vs compensated) cirrhosis had more ED visits, were more likely to have their ED visit be liver-related, to be hospitalized, and had higher 90-day mortality rates after non-liver and liver-related ED visits (summarized in Fig. 1). In multivariable analysis, decompensation [+8.0%, +7.6 to +8.4], dialysis [+3.1%, +1.8 to +4.5], and age [+2.5% per 10 years, +2.3 to +2.7] were associated with increased 90-day mortality. **Conclusion:** In this national study, we show that patients with cirrhosis visit the ED more frequently than those with CHF, COPD, and without cirrhosis, and are often discharged home. Despite visiting the ED, high 90-day mortality rates are seen after both liver-related and non-liver related visits. These findings suggest that the ED may be an important site for high-yield, pre-hospitalization interventions in patients with cirrhosis.

3729-C | EMPOWERING THE FRONTLINE: ENHANCING HEPATITIS C TREATMENT ACCESSIBILITY IN PRIMARY CARE THROUGH PROCESS DESIGN AND RESIDENT EDUCATION

Rita Auro, Michael Schwartz and Alexandra Lane, Cooper University Health Care

Background: In 2022, the World Health Organization (WHO) recommended simplifying the hepatitis C virus (HCV) care pathway to improve treatment access, advocating for diagnosis and management in primary care (PC) settings. Approximately 2.7 million adults in the United States have HCV, with roughly 17,000 new cases annually, particularly among adults with intravenous drug use (IVDU). Despite over 95% of patients being curable with 8-12 weeks of oral direct-acting antiviral (DAA) therapy, treatment rates remain low. Our project aimed to improve treatment access by 1) developing an HCV treatment process in an academic PC clinic and 2) enhancing resident familiarity and confidence in HCV management. **Methods:** The project comprised of two phases. Phase 1 involved specialty pharmacy collaboration, EMR utilization, and content development. DAA therapies, only available at specialty pharmacies, require prior authorization. Hence, coordination with hepatitis C therapy representatives was necessary to identify pharmacies that process authorizations and dispense DAAs. EMR technical specialists assisted in creating an order set encompassing all requisite tests for drug approval. The set coordinates with an EMR template that automatically extracts data for prior authorization, facilitating swift approval processing. Phase 2 entailed education and implementation. After an educational session, residents could commence in-clinic HCV treatment, referring patients to specialists only when necessary. **Results:** Figure 1 demonstrates the comprehensive process flow for HCV treatment, from patient identification through therapy completion. Next steps involve anonymous surveys conducted pre and post-HCV educational session to assess resident confidence in treatment. The results are anticipated this fall. Survey items, rated on a Likert scale, will cover guideline familiarity and comfort with various components of HCV management. The data will undergo descriptive statistical analysis. **Conclusion:** This initiative developed an HCV treatment process in an academic PC clinic, potentially increasing access to timely care. It focused on equipping residents with the resources needed for confident HCV management, especially in an area disproportionately impacted by the virus. This model, effective where HCV infections are typically managed by specialists, may be replicated in other PC clinics to better serve patient populations facing challenges such as active IVDU, economic, or social barriers that can limit access to care.

HIIT HBV peer consortium, (1)Institute of Liver Studies, King's College Hospital, London, United Kingdom, London, United Kingdom, (2)Institute of Liver Studies, King's College Hospital, London, United Kingdom, (3) NHS South East London Clinical Commissioning Group, (4)National Organisation for People Living with Hepatitis B, (5)Hepatitis B Foundation, (6)King's College Hospital

Background: Hepatitis B virus (HBV) is a global health problem with more than 290 million people affected worldwide. For successive generations, there has been insufficient infrastructure in place to address issues such as inter-sectional stigma and digital misinformation, whilst the focus on health optimisation and education has been unsatisfactory. Over time, this has eroded confidence in healthcare providers, triggering resentment and disengagement with the clinical service. **Methods:** At King's College Hospital, we recognise the limitations of our current system and are pioneering an improved, patient-focused model of care [I REACH OUT (Figure 1)]. This is founded on six core principles, namely Identification of affected individual's, Risk Stratification, Education & Empowerment, Advocacy & Peer Support, Collaborative Networking and Health Optimisation. By mobilising the multidisciplinary team and working closely with our international partners, we anticipate an Opportunity for Upward Social Mobility, Tackling inequalities and building Trust with healthcare professionals. **Results:** Over the past few years, we have invested in local service development and optimised different aspects of this model. From an education perspective, we have delivered content through our Extension for Community Healthcare Outcomes (ECHO) programme and plan to diversify our interfaces with artificial intelligence platforms. We have also secured funding for a full-time HBV peer and their remit will be to share lived experiences and help shape the service from a user's perspective. Additionally, we have strengthened collaborations with other research institutions and built a robust platform for validating prognostic biomarkers. More broadly, we have modernised our non-alcoholic fatty liver disease (NAFLD) service by improving community access to transient elastography and incorporating lifestyle practitioners into the team, and will align these services with the viral hepatitis division. Adherence to a constructivist research paradigm will allow us to evolve this model and sustain high levels of engagement. **Conclusion:** Elimination of viral hepatitis as a global health problem will require a framework of care in which individual's feel empowered to express their autonomy, engage with healthcare providers and embrace a healthy lifestyle. The I REACH OUT model provides a platform to transform care in diverse clinical settings and address underlying social factors.

Medicine, (3)University of Miami Miller School of Medicine, (4)MetroHealth Medical Center, (5)Ochsner Medical Center, (6)Medical Technology and Practice Patterns Institute, (7)University of Miami, (8)Metrohealth Medical Center, (9)University of California, San Francisco, (10)University of Texas Southwestern Medical Center

Background: Hepatocellular carcinoma (HCC) surveillance in cirrhosis patients remains under-utilized, particularly among vulnerable safety-net populations, who are mostly ethnic minorities with existing barriers in healthcare access. We evaluated provider-level factors that may contribute to disparities in HCC surveillance across 4 U.S. safety-net health systems. **Methods:** 1,036 providers (attending physicians, advanced practice providers, and residents/fellows) in primary care (PC) and gastroenterology/hepatology (GI-Hep) across 4 safety-net health systems were invited to participate in an anonymous online survey to assess knowledge, attitudes, beliefs, perceived challenges, and COVID-19-related disruptions in HCC surveillance in cirrhosis patients, using a 4-point Likert scale. Knowledge questions were scored from 0 to 6 based on number of questions answered correctly. Multivariable logistic regression models evaluated for predictors of adequate HCC surveillance knowledge (score >5). **Results:** Of 202 provider respondents (19.5% response rate) (46.0% female, 46.5% white, mean age 42.3 $\pm$ 11.7 years, 56.9% PC, 13.1% GI-Hep), only 55.7% had adequate HCC surveillance knowledge, more so among GI-Hep vs. PC (70.0% vs. 52.9%, $p<0.05$). On multivariable regression, those with perceived barriers or challenges to HCC surveillance had lower odds of adequate HCC surveillance knowledge (OR 0.29, 95% CI 0.10-0.81, $p<0.01$). Providers reported challenges with HCC surveillance, including not feeling up to date with HCC guidelines (41.0%), difficulty identifying cirrhosis patients (31.1%), inadequate time during visits (14.3%), and language barriers (8.4%). Providers reported perceived patient factors that may impact adherence (12.3% had concerns about patients' out-of-pocket costs, 8.9% about adherence, 8.4% about patient transportation barriers). Health system issues were identified: 10.4% cited shortage of radiology facilities, 7.9% had concerns about capacity for timely diagnostic testing, 6.4% cited challenges with arranging HCC treatment. Pandemic-related disruptions in timely HCC surveillance were reported by 63.8%; over 30% noted persistent delays in HCC surveillance for cirrhosis patients. **Conclusion:** Survey of PC and GI-Hep providers in safety-net health systems identified important provider-level factors contributing to suboptimal HCC surveillance practices in cirrhosis patients, including gaps in knowledge, as well as attitudes, barriers, and persistent disruptions in care due to COVID-19 pandemic.

3733-C | EXPANDING ACCESS TO HEPATITIS C CARE AMONG PEOPLE WHO USE DRUGS: HCV TELEHEALTH TOOLKIT

Lauren Walker[1], Charlotte Miller[1], Linda Wang[2] and Jeffrey Weiss[3], (1)Mount Sinai Institute for Advanced Medicine, (2)Icahn School of Medicine at Mount Sinai, (3)Icahn School of Medicine at Mount Sinai (ISMMS)

Background: The Clinical Education Initiative's Hepatitis C and Drug User Health Center of Excellence (the Center) offers continuing medical education to enhance the capacity of New York State medical providers. Between May 2021 and April 2023, the Center delivered 25 hepatitis C virus (HCV)-focused webinars that trained 566 unique individual's. During the same time period, the Center facilitated HCV-focused ECHO™ sessions, offered a clinical HCV preceptorship program and developed the Hepatitis C Telehealth Toolkit (the Toolkit). **Methods:** The Toolkit was developed in collaboration with the New York Hepatitis Clinical Education Collaborative, a group of organizations dedicated to optimizing viral hepatitis clinician education. In March 2022, the group identified the need for a resource on HCV telehealth to increase access to HCV treatment among persons who inject drugs and convened experts to participate in monthly workgroup meetings to develop the Toolkit. The workgroup consisted of clinicians and non-clinicians from government, academia and harm reduction agencies. To develop the Toolkit, the workgroup reviewed existing resources and engaged additional experts to review specialized content. **Results:** The Toolkit, finalized in December 2022, is a flexible, practical guide that is intended to support both traditional and non-traditional settings interested in providing HCV care via telehealth. The Toolkit describes three models of HCV telehealth (tele-harm reduction and facilitated telehealth with *or* without an onsite clinician), and includes role descriptions, patient workflows, best practices, minimum requirements and billing considerations for each. The Toolkit was disseminated to workgroup members' professional networks and various state- and nation-wide groups. Toolkit dissemination coincided with delivery of a webinar on models of HCV telehealth. Evaluation data from the webinar's attendees demonstrated an increase in self-reported knowledge about models of HCV telehealth, and one attendee stated that they will use learnings from the webinar to implement HCV care in the syringe services program where they work. **Conclusion:** Further evaluation is needed to determine whether and how the Toolkit can best be implemented in clinical settings. With continued dissemination and application, this unique resource for implementing HCV telehealth can serve as a key tool to achieving HCV elimination.

3734-C | EXTERNAL VALIDATION OF AN ICD-10 CONSENSUS CODE SET TO IDENTIFY PATIENTS WITH CIRRHOSIS USING ELECTRONIC HEALTH RECORDS IN AN ASIAN POPULATION

Jason Pik Eu Chang[1], Pooi Ling Loi[2], Jeanette Pei-Xuan Ng[1], Hong-Yi Lin[3], Wei Quan Teo[4], Amber Chung[4] and Prema Raj[4], (1)Singapore General Hospital, (2)Department of Gastroenterology & Hepatology, Singapore General Hospital, Singapore, (3) Yong Loo Lin School of Medicine, National University of Singapore, (4)Singhealth-Duke Nus Transplant Centre

Background: Electronic health records (EHR) are commonly used for large, multi-institutional studies in liver cirrhosis. Central to such studies is the development of an algorithm to correctly identify patients with cirrhosis using ICD-10 diagnosis codes. A recent systematic review by Shearer et al proposed a consensus set of nine ICD-10 codes to identify cirrhosis patients. This "9-code set" showed a high positive predictive value (PPV) between 83-89% in European and North American populations. However, its performance in an Asian population has not been studied. We aimed to externally validate the performance of Shearer's 9-code set to identify cirrhosis patients in an Asian population from a tertiary hospital in Singapore, and to explore alternative code sets to improve case-finding. **Methods:** We used an initial algorithm of 25 ICD-10 codes that covered all potential diagnosis codes related to cirrhosis. When applied to the EHRs of all patients admitted to the Singapore General Hospital from 1 January to 31 December 2018, this broad algorithm identified 1733 Asian patients who potentially had liver cirrhosis. We manually reviewed the EHRs of all subjects to confirm the diagnosis of cirrhosis. Next, we evaluated the performance of Shearer's 9-code set in this cohort to determine the sensitivity, specificity, PPV

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and NPV to identify subjects with cirrhosis. We then examined alternative sets of codes that could potentially improve the identification of cirrhosis patients in our population. **Results:** From the manual review of 1733 subjects' EHRs, 937 (54.1%) were confirmed to have liver cirrhosis. Median age at diagnosis of cirrhosis was 64 years (IQR 55-74), with 65.6% males. The main etiologies of cirrhosis were chronic hepatitis B (30.1%), non-alcoholic fatty liver disease (26.2%) and cryptogenic (15.6%). 59.0% were Child A, 32.7% Child B and 8.3% were Child C. Shearer's 9-code set identified 856 cirrhosis subjects, of which 713 were truly cirrhotic, providing a PPV of 83.3%, NPV 74.5%, sensitivity 76.1%, specificity 82.0%. We identified a set of 10 ICD-10 codes comprising individual and combinations of codes that had marginally better performance compared to Shearer's 9-code set. This "Solidarity-10" code set identified 838 cirrhosis subjects, of which 717 were truly cirrhotic, providing a PPV of 85.6%, NPV 75.4%, sensitivity 76.5%, specificity 84.8%. The replacement of "hepatic failure" with "biliary cirrhosis" and the addition of the combination code of "hepatocellular carcinoma (HCC)" and "ascites" in Solidarity-10 identified an additional 15 cirrhotic patients that were not identified by Shearer's 9-code set. **Conclusion:** The 9 ICD-10 code consensus set proposed by Shearer et al to identify patients with cirrhosis maintains a high PPV of 83.3% in an Asian population. We identified a 10 ICD-10 code set (Solidarity-10) with potentially better performance in populations with high rates of HCC.

3735-C | FACT OR FICTION: UNDERSTANDING THE QUALITY AND RELIABILITY OF LIVER CIRRHOSIS INFORMATION ON YOUTUBE

Rajmohan Rammohan[1], Sai Greeshma Magam[1], Melvin Joy[2], Dilman Natt[1], Achal Patel[1], Abhishek Tadikonda[1] and Paul Mustacchia[3], (1)Nassau University Medical Center, (2)Nassau University Medical Center, East Meadow, NY, (3)Nassau Univeristy Medical Center

Background: The internet, particularly YouTube, is a popular health information source for many. However, studies suggest that patient information on YouTube is often of poor quality. This study aims to evaluate the content and quality of YouTube videos on fibromyalgia. With over a billion users, YouTube's widespread use doesn't guarantee quality, as videos, including those on liver cirrhosis, aren't subjected to an editorial process. This can lead to misinformation, potentially skewing users' understanding of their health conditions. **Methods:** We searched YouTube for liver cirrhosis videos using "liver cirrhosis" and "alcoholic hepatitis" as keywords. Videos were excluded if they weren't in English, weren't relevant, or lacked audio. We recorded video characteristics such as views, subscriptions, likes, dislikes, comments, and whether they were academic or private. Videos were then categorized as reliable or not based on the accuracy of their scientific information. To assess overall video quality, we used DISCERN, the Global Quality Score (GQS), and the Patient Education Materials Assessment Tool (PEMAT). The level of agreement between seven investigators on DISCERN, GQS, and PEMAT was calculated using intraclass correlation. **Results:** We reviewed 36 YouTube videos that appeared in the search results, of which 16 (44.4%) were academic and 20 (55.5%) were private. Academic videos received higher DISCERN scores than private ones (35 ± 14.5 vs. 26.64 ± 15.07, $p = 0.028$). The Global Quality Score was also higher for academic videos (4.1 vs. 3.2, $p < 0.01$), as was the PEMAT score (4.5 vs. 2.9, $p = 0.032$). Furthermore, academic videos were found to have a positive correlation with the number of likes (OR: 0.65, $P < 0.001$), subscribers (OR:0.78, $P < 0.0001$), and views (OR:1.12, $P < 0.001$). **Conclusion:** Our study shows that the quality of YouTube videos on liver cirrhosis varies widely. Videos from academic sources provided more accurate and high-quality information than private ones, reflected in higher DISCERN, Global Quality Score, and PEMAT ratings. This indicates a positive correlation between academic sources and the number of likes, subscribers, and views. The results underscore the importance of guiding patients toward academically sourced health information, thereby reducing the chance of misinformation.

3736-C | FIBROSIS-4 (FIB-4) INDEX AS A PREDICTOR FOR MECHANICAL VENTILATION AND 30-DAY MORTALITY ACROSS COVID-19 VARIANTS

Priyanka Parajuli[1], Roy Sabo[2], Rasha Alsaadawi[2], Amanda Robinson[3], Evan French[1] and Richard K. Sterling[4], (1)Virginia Commonwealth University, (2) Virginia Commonwealth University, Department of Biostatistics, Richmond, VA, (3)Virginia Commonwealth University, C. Kenneth and Dianne Wright Center for Clinical and Translational Research, Richmond, VA, (4) Virginia Commonwealth University Health System

Background: The evolution of the severe acute respiratory syndrome coronavirus has led to new variants of concern that vary in transmissibility, severity or change in clinical presentation. Recent studies of the Omicron variant have shown reduced odds of hospitalization with Omicron vs. the prior Delta variant. The Fibrosis-4 (FIB-4) index, a simple index that includes age, liver enzymes, and platelet count has been studied as a risk-stratification tool for front-line health care professionals to quickly identify patients at a risk of requiring mechanical ventilation (MV) from Coronavirus disease 2019 (COVID-19) due to its high negative predictive value (NPV). The main objective was to determine if FIB-4 can predict MV requirements and 30-day mortality from COVID-19 across variants including Alpha, Delta, and Omicron. **Methods:** This was a retrospective cohort analysis of 232,364 COVID-19 positive patients between April 27, 2020 and June 25, 2022 within the National COVID Cohort Collaborative database. Simple logistic regression (SLR) and multiple logistic regression (MLR) models were utilized to investigate potential bivariate associations between MV use and various patient characteristics including age, liver enzymes, platelet counts, sex, and comorbid conditions. MLR models were fit between categorical FIB-4 covariates (FIB-4 > 2.67, > 3.04, > 3.25) and MV use for each COVID variant. The sensitivity, specificity, positive predictive value (PPV), NPV, and the area under the receiver operating characteristic (AUROC) curve were calculated. The primary outcome was association of FIB-4 and need for MV. Secondary measures included the association of FIB-4 with 30-day mortality. **Results:** Of the cohort, 12,207 were hospitalized during the Alpha wave, 38,187 during the Delta wave, 34,871 during the Omicron-initial wave, and 6,915 during the Omicron-subsequent wave. A FIB-4 > 2.67 had 1.8 times higher odds ratio (OR) of requiring MV across all variants of COVID-19 (OR 1.81; 95% CI: [1.76,1.86]). A FIB-4 > 3.04 and a FIB-4 > 3.25 also had a 1.8x higher odds overall across all variants. The AUROC curve showed a high sensitivity ranging from 0.78 to 0.80 for the initial variant, 0.74 for Alpha, 0.76-0.78 for Delta, 0.70-0.71 for Omicron, and 0.67-0.71 for the subsequent Omicron variant. The specificity ranged from 0.83 to 0.84 across all variants. The NPV ranged from 0.96 to 0.97 overall across all variants. Simple logistic survival regression (SR) and multiple logistic survival regression (SR) modeling for FIB-4 as a continuous variable showed an increased odds of 30-day mortality (OR 1.21; 95% CI: [1.20, 1.21]) throughout all waves without significant variability between variants. **Conclusion:** The FIB-4 index was consistently associated with both increased utilization of MV and 30-day mortality among COVID-19 patients across all waves in both adjusted and unadjusted models, solidifying its utility amongst COVID-19 patients.

f 3737-C | GEOGRAPHIC OPPORTUNITIES FOR GROWTH IN THE TRANSPLANT HEPATOLOGY TRAINING WORKFORCE★

Alan Hutchison, University of Chicago, Medicine, Gautham Reddy, University of Chicago Medicine, Chicago, IL, Sonali Paul, University of Chicago Medical Center and Anna Mae Diehl, University of Chicago, Medicine, Durham, NC

Background: The US hepatology workforce is predicted to shrink in the coming decade, with this differential regional impact. As a result, it is important that the hepatology community identify opportunities for physician growth, especially in resource limited settings, such as transplant hepatology (TH) fellowship programs. **Methods:** We reviewed the Scientific Registry of Transplant Recipients data for programs that performed ≥ 20 liver transplants (LTs) per year (the minimum volume required to have a TH fellowship [ACGME 2022]). We identified if these programs had TH fellowships by searching the center websites as well as the AASLD TH application portal. We compared this

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

data to existing hepatology workforce predictions from Russo et al. 2020. **Results:** Among 107 centers there were 92 TH slots. The median number of LTs was 81, with an inter-quartile range of 50-127, with the most being 226. Among the 64 centers that have the 92 TH slots, a median of 105.5 LTs were performed, with inter-quartile range (IQR) of 73.5-139, with a range of 25-226. Per training slot, the median was 72.25 with IQR of 51-108, with a range of 17-195. Thirty-eight centers with TH slots performed living donor LTs (LDLTs), with median of 7.5 LDLTs, with IQR of 2-16.25 (max 66). Among 27 centers without TH slots, 9 of which do LDLTs and 24 of which have gastroenterology (GI) fellowships, a median of 42 LTs were performed, with IQR of 31-71.5 (max 148). Of the 92 available TH slots, there are 37, 71, and 10 eligible slots for H1B, J1, and E3 visas, respectively. The region with the highest projected workforce loss is the Southeast, losing 352 Full-Time-Equivalent (FTE) hepatology positions from 2018 to 2033. Of its 14 centers, 5 do not have a TH fellowship, though 4 of those have GI fellowships indicating GME infrastructure. These 5 account for 382 deceased donor transplants (DDLT) and 8 LDLTs. Eight centers with 11 TH slots performed 1029 DDLTs and 17 LDLTs; they include 7, 6, and 2 eligible slots for H1B, J1, and E3 visas, respectively. The Great Lakes region has the second highest projected workforce loss of 297 FTE. Of its 16 centers, 3 do not have TH slots, though they have GI programs. Of the 13 training centers that performed 1221 DDLTs and 70 LDLTs with 19 training slots, they include 11, 18, and 2 eligible slots for H1B, J1, and E3 visas, respectively. Projected workforce loss rankings change when normalizing for TH slots. The Southeast has projected losses of 32 FTE per annual TH slot from 2018 to 2033, while the Great Lakes has projected losses of 16 FTE per slot. The Northwest only has a projected loss of 93 FTE, the lowest of the regions, but that translates to a region-high of 46.5 FTE per slot. **Conclusion:** Several opportunities exist to grow the hepatology workforce. Many centers could start or expand TH fellowships still meet ACGME requirements, especially in regions of high need. Finally, visa acceptance among training programs is limited and could be broadened to attract trainees.

3738-C | HEPATITIS B VIRUS (HBV) AND HEPATITIS D VIRUS (HDV) LABORATORY-BASED REFLEX TESTING CASE STUDIES

Jana Manning[1], Lindsey Hiebert[1], Weiming Tang[2], Philippa Easterbrook[3], Niklas Luhmann[3] and John W. Ward[1], (1)The Task Force for Global Health, (2) University of North Carolina at Chapel Hill, (3)World Health Organization

Background: A global laboratory survey was undertaken by the Coalition for Global Hepatitis Elimination and the University of North Carolina in collaboration with WHO to investigate the scope, use, and implementation experience of reflex viral load for HBV DNA and also reflex HDV serology and RNA testing. **Methods:** A comprehensive web-based survey was conducted using SmartSheet to gather quantitative and qualitative data on HBV DNA and HDV reflex testing. The survey was shared with over 1,000 participants. Reflex laboratory testing was defined as either immediate HBV DNA testing and/or reflex HDV serology testing of persons with positive HBsAg test results using an existing blood specimen, based on a single clinical interaction and one blood sample or immediate testing of positive HDV serology samples for HDV RNA. The survey was in five sections and those that offered reflex testing for either HBV DNA and/or HDV serology addressed reasons for offering reflex testing, specimen collection process, testing protocol, costs, the impact on care, and key challenges in implementation. **Results:** A total of 26 laboratories from 19 countries responded to

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

the survey – 8 (42%) were from high income countries and 11(58%) were from low-middle income countries. Six labs performed HBV DNA reflex testing (China, Ghana, Myanmar, Nigeria,Italy and Spain), and 8 HDV serology reflex testing (USA, China, Egypt, Malawi, Italy, Spain). Of the 6 labs performing HBV DNA reflex testing, all reported initiating this option to improve linkage to care. All six reported securing buy-in from administrators as a key step in implementation, followed by training clinicians (n = 2) and laboratory staff (n = 4). Of the 8 labs performing HDV reflex testing, 3 conducted reflex testing of HBsAg positive specimens, and 4 labs tested for HDV RNA, of which 3 conducted reflex testing of positive HDV serology samples. Of the 5 labs, 3 reported securing a reliable supply of high-quality and approved tests as a challenge. **Conclusion:** Though the number of respondent laboratories is low, our survey demonstrates that laboratories in both high-income and low- and middle-income settings have implemented HBV DNA and HDV reflex testing. More data from diverse settings are needed to guide the implementation of reflex testing. This data can inform planning to scale up HBV and HDV testing and treatment programs.

3739-C | HEPATITIS C ELIMINATION IN RURAL ARIZONA THROUGH A PHARMACIST-LED TREATMENT MODEL

Katherine Halza[1], Kristen Nelson-Rowan[1], Edmund Evangelista[2], Rhet Pond[3], Richard A. Manch[4], Anthony Santarelli[1], Diana Lalitsasivimol[1] and Linda Williams[1], (1)Kingman Regional Medical Center, (2)Cour College of Pharmacy, (3)Roseman University, (4)Arizona Liver Health, Phoenix, AZ

Background: The World Health Organization (WHO) global hepatitis strategy aims to eliminate Hepatitis C (HCV) by 2030. Innovative models are needed to reach underserved and hard to access patient populations that have historically been undertreated. Mohave County, Arizona is identified as a high priority area, being in the top 5% of United States counties at risk for a HCV outbreak, with an average annual rate of 211 new cases per 100,000 people (2017-2021), but lacks traditional access to HCV care due to the rural health disparities of distance to care, lower median income, and lack of healthcare providers. To address these issues, a pharmacist-led HCV program was implemented via a collaborative practice agreement (CPA) model at the Disease Management Clinic (DMC) within a rural community health system. The purpose of this study is to compare outcomes of the DMC Hepatitis C Program model to the Traditional Care Model (TCM). **Methods:** Our retrospective cohort study of adult patients who were screened for HCV used EMR data from 2020-2023. Patients were stratified into Group A: Referral to the DMC Hepatitis C Program; Group B: Traditional Care Model. We analyzed patients with a positive HCV antibody test, confirmed HCV RNA, and achieved sustained virologic response after 12 weeks post-treatment (SVR12). We compared treatment cascade progression and treatment outcomes among each group. **Results:** Within the DMC treatment cascade, 161 patients were identified HCV antibody+, 147/161 (91%) were connected to care, 107/161 (66%) had a confirmed HCV RNA, 101/161 (63%) were prescribed HCV medication, 86/161 (53%) completed treatment, and 71/161 (44%) achieved SVR12 cure. The average time from outreach to first visit was 31 days, from first visit to start of treatment was 28 days, and from RNA+ to SVR12 was 30 weeks. Within the DMC group, 66% were diagnosed, 63% were treated, and 44% were cured, compared to WHO 2023 targets of 64%, 51%, and 49% respectively. **Conclusion:** This innovative care model can reach WHO HCV elimination goals by improving access and linkage to care, improving time to treatment, and increasing HCV cure rates. Pharmacist-led programs for HCV management leverage the underused group of pharmacists as health care extenders in rural communities to overcome the barriers of difficulty accessing traditional care and provider shortages. Pharmacist CPAs can be used across other populations with health disparities to improve HCV long term outcomes.

3740-C | HEPATITIS C TREATMENT ACCESS IN ILLINOIS: A LONG AND CIRCUITOUS PATH

Anjana Bairavi Bairavi Maheswaran, Cammeo Mauntel-Medici, Melanie Izquierdo, Heather Lee, Michelle Martin and Janet Lin, University of Illinois at Chicago

Background: Hepatitis C (HCV) is a curable infectious disease that affects over 2.4 million Americans. The CDC reports the number of patients accessing HCV treatment has declined despite favorable policy changes around HCV treatment access. In November 2018, IL Medicaid removed the need for advanced

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

fibrosis of the liver as a criterion for being eligible for HCV treatment. Published data following important policy changes in Illinois is lacking. **Methods:** We retrospectively reviewed charts of the first 100 HCV RNA-positive patients (Jan-Mar 2021). Demographic information (race, ethnicity, sex assigned at birth, insurance type) was collected via EPIC query reports. Manual chart reviews provided data on diagnosis status, care linkage, HCV labs, treatment initiation, substance use, and mental health. Excel (Version 2304) was used for descriptive analysis. We assessed the proportion and demographic composition of patients linked to HCV treatment after a positive HCV RNA test. **Results:** The final sample included 86 treatment-naive HCV patients (avg. age: 57). Most were Male (64%), African American (57%), and publicly insured (Medicaid: 59%, Medicare: 29%). Sixty-five patients (75%) reported ever substance use (excluding alcohol/tobacco), and 20% reported recent use. Among 59 patients with documented risk factors, 30 reported drug use. Of 86 patients, 71 (83%) underwent liver fibrosis staging, and 53 (62%) initiated treatment. Forty nine patients completed treatment (92%), and 40 achieved sustained virologic response (75%). Most who initiated treatment were Male (64%), African American (60%), Medicaid insured (51%), with F0-F1 fibrosis (75%). Among 33 non-treated patients, 16 (48%) were lost to follow-up, 8 deferred treatment (3 undergoing cancer treatment, 3 awaiting kidney transplantation, 2 with ongoing substance use), 3 were referred elsewhere, 2 deceased, 2 relocated, 1 was denied prior-authorization, and 1 declined treatment. **Conclusion:** The exploratory analysis showed higher treatment uptake in the sample compared to national estimates. A prior study on the hospital's chronic HCV population, demonstrated lower treatment initiation rate (39%) especially among Medicaid recipients (36%). The prior study also highlighted disparities in treatment access ; Medicaid recipients with advanced liver fibrosis were more likely to initiate treatment compared to their counterparts with lower fibrosis scores. In our study, among those who initiated treatment, 55% were Medicaid-insured and 60% of them had little to no liver fibrosis. However, these results are not generalizable. Over 45% of the sample were tested for HCV RNA at a Liver / Infectious Disease specialty clinic indicating care referral. As a nation, we still have significant strides to make and milestones to reach to eradicate HCV. Updating policies and innovating care strategies to align with current HCV trends is crucial towards achieving equitable care nationwide.

3741-C | HIGH RATES OF NON-INDICATED PROTON PUMP INHIBITOR PRESCRIPTION IN PATIENTS WITH CIRRHOSIS AT A LARGE ACADEMIC MEDICAL CENTER

Jeff K. Than[1], Clare Kane[2] and Daniel R. Ganger[2], (1) Northwestern University Feinberg School of Medicine, (2)Northwestern University

Background: The adverse effects of proton pump inhibitor (PPI) use in patients with cirrhosis has been an area of active discussion. While recent studies have demonstrated no association between PPI use and all-cause or cause-specific mortality, a growing body of literature supports a correlation between PPI use and increased rates of serious infection including spontaneous bacterial peritonitis (SBP) and liver related mortality in patients with cirrhosis. These effects are thought to be mediated by alterations in gut microbiome due to acid suppression which can lead to bacterial translocation, subsequent infection, and higher rates of hospital readmission. Our study aims to further characterize the PPI prescription patterns at a large tertiary medical center. **Methods:** All patients with a diagnosis of cirrhosis between August 2020 and August 2022 with an active PPI prescription were included in the study. Demographics, PPI formulation with dose, frequency, and duration were extracted from the Northwestern University Enterprise Data Warehouse (EDW). Prior history of SBP, PPI indication, and etiology of cirrhosis were determined using ICD-10 codes. Appropriate indications for PPI use were determined based on a recent practice update from the American Gastroenterological Association. Chi-squared testing was used to compare the rates of new inpatient PPI prescriptions without appropriate indication. **Results:** Of the 10,863 encounters for 2,538 unique patients

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

included in the analysis, 10,070 encounters (92.7%) had a PPI prescription that preceded the study period (Table 1). Pantoprazole was the most commonly prescribed and 193 patients (7.5%) had a prior history of SBP. The indication for PPI use was documented in 6,326 encounters (58.2%) with GERD (n = 5,127, 47.2%), gastric or duodenal ulcer (n-1,453, 13.4%), and multiple indications (n = 1,627, 15.0%) as the most common indications. Of the 793 patients with a new PPI prescription during the study period, only 362 (45.6%) had an appropriate indication for PPI use (Table 1). The median duration of new PPI prescriptions was 161 days. As with analysis of the complete dataset, GERD, gastric or duodenal ulcer, or multiple indications were the most common indications of PPI use. The difference in rates of new inpatient PPI prescriptions without appropriate indication between internal medicine, surgery, and cardiology providers was not statistically significant (p = 0.99). **Conclusion:** Our study highlights both the prevalence and prolonged duration of non-indicated PPI use in patients with cirrhosis at a large tertiary medical center. Future quality improvement initiatives should aim to limit PPI use in patients with cirrhosis to those with clinical indications and educate prescribers on limiting PPI exposure by using the lowest dose and shortest frequency.

Table 1. Demographic and PPI use information in baseline and new PPI prescription groups

Variable	N	N (%)
Age (years)	10,863	63 ± 13
Sex (female)	10,863	5,127 (47%)
Cirrhosis etiology	10,863	
Alcohol-associated cirrhosis		4,516 (42%)
Cardiac cirrhosis		1,784 (16%)

3742-C | HOME HOSPITAL FOR PATIENTS WITH CIRRHOSIS: A CASE SERIES

Olivia Kahn-Boesel[1], Henry Mitchell[2], Lucinda Li[3], Teresa Indriolo[3], Areej El-Jawahri[3], David Levine[2] and Nneka Ufere[3], (1)Harvard Medical School, (2)Brigham and Women's Hospital, (3)Massachusetts General Hospital

Background: Novel care delivery models are needed to address the rising costs and reduce healthcare utilization for patients with cirrhosis. Home hospital (HH) is the delivery of hospital-level care at home, including continuous vital sign monitoring, daily physician and twice daily nurse/paramedic visits. HH reduces cost, utilization, and readmissions for general medical patients, but its feasibility for patients with cirrhosis is unknown. **Methods:** We performed a retrospective case series to describe the experience and outcomes of patients with cirrhosis enrolled in HH at a large tertiary hospital between 2018-2022. We examined patient demographic and clinical characteristics, services provided during HH, and outcomes including adverse events, disposition, readmission and mortality rates. **Results:** 22 patients with cirrhosis (32% male, 45% Hispanic, 27% White, 23% Black) with a median age of 70 (IQR: 60-74) were enrolled in HH. The majority of patients had non-alcoholic steatohepatitis (NASH, 36%) or combination of alcohol-related liver disease and NASH (27%). Median MELD-Na was 12 (IQR: 10-16); 50% of patients had ascites and 36% had hepatic encephalopathy. In total, 59% were admitted to HH directly from the emergency department (ED), 36% from an inpatient floor, and 5% directly from home. The most frequent admission diagnoses were decompensated cirrhosis (27%), heart failure exacerbation (27%), and infection (27%). The most common interventions provided by HH were: monitoring lab chemistries (82%), intravenous medications including diuretics, antibiotics, and albumin (77%), medication reconciliation and teaching (91%), dietary counseling (72%), and specialist consultation (23%). While enrolled in HH, patients could additionally be transported from home to ambulatory facilities for diagnostics/procedures: 3 (14%) had imaging, 2 (9%) underwent serial paracenteses, and 1 (5%) underwent endoscopy. The median length of stay in HH was 7 days (IQR: 4-12). 2 patients (9%)

experienced adverse events (acute kidney injury) that resolved prior to discharge. No patients required escalation of care to the hospital. 2 patients (9%) were readmitted 30 days after discharge, 1 patient (5%) died within 90 days of discharge. **Conclusion:** In this single-site study, we found that HH was safe and effective for patients with cirrhosis and holds promise as a hepatology care delivery model. Future prospective studies are needed to evaluate the quality of HH care for this patient population.

Table. Key Home Hospital data

Key characteristic	Patients n (%)
Admission Diagnosis	
Decompensated cirrhosis	6 (27)
Heart failure exacerbation	6 (27)

3743-C | IDENTIFICATION AND QUANTIFICATION OF JAUNDICE BY TRANS-CONJUNCTIVA OPTICAL IMAGING USING A HUMAN BRAIN-LIKE ALGORITHM: A CROSS-SECTIONAL STUDY

Takuya Kihara, Takaaki Sugihara, Suguru Ikeda, Yukako Matsuki, Hiroki Koda, Takumi Onoyama, Tomoaki Takata, Takakazu Nagahara and Hajime Isomoto, Tottori University

Background: Jaundice is caused by excess circulating bilirubin, known as hyperbilirubinemia. This symptom is sometimes caused by a critical hepatobiliary disorder, and is generally identified as yellowish sclera when bilirubin levels increase more than 3 mg/dL. It is difficult to identify jaundice accurately, especially via telemedicine. This study aimed to identify and quantify jaundice by transconjunctiva optical imaging. **Methods:** Patients with jaundice (total bilirubin ≥ 3 mg/dL) and normal control subjects (total bilirubin < 3mg/dL) were prospectively enrolled from June 2021 to July 2022. We took bilateral conjunctiva imaging with a built-in camera on a smartphone (1st generation iPhone SE) under normal white light conditions without any restrictions. We processed the images using an Algorithm Based on Human Brain (ABHB) (Zeta Bridge Corporation, Tokyo, Japan) and converted them into a hue degree of Hue Saturation Lightness (HSL) color space. **Results:** A total of 26 patients with jaundice (9.57 $\pm$ 7.11 mg/dL) and 25 control subjects (0.77 $\pm$ 0.35 mg/dL) were enrolled in this study. The causes of jaundice among the 18 male and 8 female subjects (median age 61 yrs.) included hepatobiliary cancer ($n = 10$), chronic hepatitis or cirrhosis ($n = 6$), pancreatic cancer ($n = 4$), acute liver failure ($n = 2$), cholelithiasis or cholangitis ($n = 2$), acute pancreatitis ($n = 1$), and Gilbert's syndrome ($n = 1$). The maximum hue degree (MHD) optimal cutoff to identify jaundice was 40.8 (sensitivity 81% and specificity 80%), and the AUROC was 0.842. The MHD was moderately correlated to total serum bilirubin (TSB) levels ($rS = 0.528$, $p < 0.001$). TSB level (≥ 5 mg/dL) can be estimated by the formula $21.1603 - 0.7371 \times \sqrt{>}(56.3 - \text{MHD})^2$.

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Conclusion: The ABHB-based MHD of conjunctiva imaging identified jaundice using an ordinary smartphone without any specific attachments and deep learning. This novel technology could be a helpful diagnostic tool in telemedicine or self-medication.

Disclosures: The following people have nothing to disclose: Takuya Kihara, Takaaki Sugihara, Suguru Ikeda, Yukako Matsuki, Hiroki Koda, Takumi Onoyama, Tomoaki Takata, Takakazu Nagahara, Hajime Isomoto

3744-C | IMPACT OF COVID-19 VACCINATION ON LIVER TRANSPLANT RECIPIENTS. EXPERIENCE IN A REFERENCE CENTER IN MEXICO

Daniel Azamar Llamas[1], Josealberto Sebastiano Arenas-Martinez[1], Antonio Olivas-Martínez[2], Eric Kauffman Ortega[1], Jose Victor Jimenez[3], Cristian De Jesús García-Carbrera[1], Fabian Esteban Rivera-Lopez[1], Bruno Papacristofilou-Riebeling[1], Luis Federico Uscanga[1] and Ignacio García Juárez[1], (1)Instituto Nacional De Ciencias Medicas y Nutricion, (2)University of Washington, (3)Yale New Haven Hospital, Stamford, CT

Background: COVID-19 vaccination has proved to be effective to prevent symptomatic COVID-19 infection and severe disease. However, the risk in liver transplant patients has not been widely investigated. We aim to assess the impact of COVID-19 vaccination on the mortality and development of severe and critical disease. **Methods:** A retrospective cohort study where we used the data from LT individual's who attended a reference center between March 2020 and February 2022. Demographic data, cirrhosis etiology, time on liver transplantation, immunosuppressive therapies, and vaccination status were recorded at the time of diagnosis. The primary outcome was death due to COVID-19, and secondary outcomes included the development of severe COVID-19 and intensive care unit (ICU) requirement. **Results:** One-hundred and fifty-three of 324 LT recipients developed COVID-19, in whom the main causes of cirrhosis were HCV infection and metabolic-associated fatty liver disease. The vaccines used were BNT162b2 (48.6%), ChAdOx1 nCoV-19 (21.6%), mRNA-1273 vaccine (1.4%), Sputnik V (14.9%), Ad5-nCoV-S (4.1%) and CoronaVac (9.5%). Case fatality and ICU requirement risk were similar among vaccinated and unvaccinated LT patients who developed COVID-19 (adjusted relative case fatality for vaccinated versus unvaccinated of 0.68, 95% CI 0.14 – 3.24, p = 0.62; adjusted relative risk [aRR] for ICU requirement of 0.45, 95% CI 0.11 – 1.88, p = 0.27). Nonetheless, vaccination was associated with a lower risk of severe disease (aRR for severe disease of 0.32, 95% CI 0.14 – 0.71, p = 0.005). **Conclusion:** Vaccination reduces the risk of severe COVID-19 in LT patients, regardless of the scheme used. Vaccination should be encouraged for all LT recipients.

3745-C | IMPACTING PATIENT RECRUITMENT FOR NASH STUDIES WITH AI-POWERED AMSETY DATABASE

Guy W. Neff[1], Kevin Li[1], Michael Tunkelrott[2], Victoria Aksakovska[2], Jutta Kurz[2], Mustafa Behan[2], Fatma Barakat[3] and Tarek I. Hassanein[3], (1)Covenant Metabolic Specialists, LLC, (2)Amsety Gmbh, (3) Southern California Liver Centers

Background: Recruiting liver subjects for clinical trials is challenging. The Amsety Database, an artificial intelligence (AI) powered recruiting program, offers an

effective process to improve recruitment for clinical trials. Developed to market the Amsety Liver Health Nutrition Bar, the self-selected database contains a highly motivated population with liver and related metabolic conditions. Amsety-AI has a growing database of around 500,000 patients across the US, including zip codes, age, gender, lifestyle and diet patterns, primary liver conditions as well as comorbidities. The project aim is to demonstrate Amsety-AI for identifying potential liver trial subjects. **Methods:** From November 2022 to May 2023, a pilot initiative with large clinic research network started to recruit subjects with NASH. Amsety-AI had 30,000 individual's in Florida of whom 2,347 were close to the study center. The initial prescreening survey resulted in 200 individual's that met predetermined qualifications. Candidates were referred to the study center for evaluation and digital pre-screening. **Results:** Of the 200 Amsety candidates, 43 (21.5%) met the criteria of the study and were invited for liver detailed screening. 56% of the respondents were female, and 44% male. The average age is 55 years. Average weight of the female respondents is 166lbs and 194lbs for males. 44% have a family history of liver disease. 13% have cirrhosis; 6% have hepatitis B; 6% have liver cancer. 75% have co-morbidities. 31% have hypertension, 25% are diagnosed with type 2 diabetes, 31% suffer from sleep apnea, 19% have gastroesophageal reflux disease and 13% have cardiovascular problems. Lifestyle habits: 56% exercise less than once/week, 25% consume high density food at least 2-3 times/week, and 13% consume alcohol every day. 31% have experienced recent weight gain. The center is in the process of evaluating the 43 candidates for screening and trial inclusion. The pilot is ongoing and new sites are being added in California and Texas. **Conclusion:** The data shows Amsety-AI creating a highly engaged population database with high potential for clinical trial enrollment. Combining Amsety digital and AI tools will improve speed and decrease costs of patient recruiting in large numbers.

f 3746-C | INEQUITIES IN LIVER TRANSPLANT AND LIVER RELATED MORTALITY IN THE UNITED STATES

Anshul Bhatnagar[1], Tzu-Hao (Howard) Lee[2], Ruben Hernaez[2], John A. Goss[1], Abbas Rana[1], Hashem B. El-Serag[1], Fasiha Kanwal[1] and George Cholankeril[1], (1) Baylor College of Medicine, (2)Baylor College of Medicine, Houston, TX

Background: Despite the increasing number of liver transplants (LT) in the U.S. over time, mortality from end-stage liver disease remains disproportionately high. Geographic, racial, sex, and age disparities in access to LT may widen the mortality burden. We aim to measure access to LT and assess disparities within diverse subpopulations using transplant to mortality (TM) ratio, defined by ratio of LT rate to mortality rate. **Methods:** Using population-level data from the United Network for Organ Sharing (UNOS) and Multiple Cause of Death files from the National Vital Statistics System (NVVS), we examined the trends in TM ratios for cirrhosis- and HCC-related mortality for patients with two common chronic liver diseases (hepatitis C (HCV) or alcohol-associated liver disease (ALD)) from 2011 to 2020. Our primary outcome was the TM ratio calculated for each subpopulation and stratified by age, sex, race/ethnicity, geographic region, and number of LT centers within the states. **Results:** There were 36,114 LTs and 181,406 cirrhosis or HCC-related deaths from 2011 to 2020. In the cirrhosis-related mortality group, patients

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

with HCV had a higher TM ratio than those with ALD, indicating greater transplant access among HCV patients compared with ALD patients. Regardless of mortality cause, patients living in states with more than 3 LT centers had significantly higher TM ratios than those in states with no LT centers. Patients who lived in the Northeast had the highest TM ratios, while those in the West had the lowest. Asians had the highest TM ratios compared to other races/ethnicities. Native Americans had the lowest TM ratio, followed by Hispanics in the cirrhosis group and Blacks in the HCC group. Women had higher TM ratios in the HCC group, while the opposite was true in the cirrhosis group. For example, black women with ALD in Nevada had a TM ratio of 0.029, indicating a lower chance to transplant and higher mortality compared to Asian men with HCV in New York that had a TM ratio of 1.00. **Conclusion:** There are significant disparities in access to LT in the US. Blacks, Native Americans, and patients living in the South, West, or states without LT centers suffer the greatest challenges in accessing LT. Strategies are needed to mitigate the multi-level barriers to life-saving LT and to better serve vulnerable populations across the country.

	Cirrhosis-Related Mortality	HCC-Related Mortality

3747-C | INPATIENT CLINICAL DIETICIAN IS ASSOCIATED WITH ACHIEVING NUTRITIONAL GOALS AMONG PATIENTS WITH SEVERE ALCOHOLIC-ASSOCIATED HEPATITIS

Tiange Zhang[1], Cara Joyce[2], Stephanie Betcher[1], Fillippa Trikantzopoulou[3] and Steven J. Scaglione[1], (1) Loyola, (2)Loyola University Chicago, (3)Loyola University Medical Center, Chicago, IL

Background: Protein-calorie malnutrition (PCM) is present in nearly all patients with alcoholic hepatitis. An assessment of PCM is simple tool that has prognostic value in patients with severe alcoholic hepatitis (sAH). Nutritional therapy is of likely benefit to patients with sAH. The European Society for Clinical Nutrition and Metabolism (ESPEN) developed evidence based guidelines recommending an energy intake of 35–40 kcal/kg BW/d and protein intake of 1.2–1.5 g/kgBW/d. Adherence to the ESPEN guidelines for total calorie or protein intake remains unclear. Therefore, the aim of this study was to compare clinical characteristics and outcomes of patients with sAH by achievement of ESPEN goals. **Methods:** We used international classification of diseases, 9th and 10th revision codes for alcohol related liver disease and alcohol use disorder between 2012-2021 at three hospitals identifying 1287 potential cases. After detailed chart review, we identified 298 patients that met the NIAAA definition of sAH. Demographic and clinical variables including complications of liver disease, comorbidities, opioid use, and baseline and day 7 nutritional variables were extracted from the EMR. Outcomes of interest were 1) achieving ESPEN guidelines for calorie or protein 2)30 day overall survival. Adjusted odds ratio (aOR) were estimated from multivariable logistic regression analysis. **Results:** The median age of our cohort was 47 +/- 11 years, 62.8% male, 71.5% white, 7.4% African American, and 19.1% Hispanic, 6% other. Chronic opioid use was present in 11.2%. Only 10.4% of patients with sAH achieved ESPEN nutritional goals. Spontaneous recovery occurred in 56.7%, while 16.5% died, and 6.9% received liver transplant. Patients achieving ESPEN goals were more likely to have had a variceal bleed (EVB) (21.4% vs 6.3% ($p < 0.01$), hepatic encephalopathy (58.1% vs 34.5%, $p < 0.010$), and had a dietician involved in their inpatient care (93.5% vs 64.4%, $p < 0.01$). Factors significantly associated with achieving ESPEN goals were a dietician consult (aOR 6.2 95% CI 1.76-39.5, $p < 0.002$) and EVB (aOR 5.4, 95%CI

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

1.6-16.6, $p > 0.006$), adjusting for age and BMI on admission. Achieving ESPEN goals was not associated with improved 30 day overall survival. **Conclusion:** Nutritional therapy is important therapy in patients with sAH, but achieving well-known goals occurs in only a tenth of patients. Having a dietician involved in the care of patients with sAH is associated with achieving ESPEN goals.

3748-C | INTEGRATION OF HCV TESTING AND TREATMENT INTO PEER DELIVERED SYRINGE EXCHANGE SERVICES USING TELEHEALTH FOR PEOPLE WHO INJECT DRUGS

Jeffrey Weiss[1], Abigail Hunter[1], David Kalinoski[2], Amanda Clay[2], Caro Bolanos Ordonez[2], Arash Diba[2], Linda Wang[1], Ponni Perumalswami[3], Larissa Wilberschied[4] and Colleen Flanigan[4], (1)Icahn School of Medicine at Mount Sinai, (2)Vocal-NY, (3)VA Ann Arbor Healthcare System, (4)New York State Department of Health

Background: In 2019, VOCAL-NY, a harm reduction agency, and Mount Sinai Hospital expanded their partnership to co-locate hepatitis C virus (HCV) treatment at VOCAL-NY for persons who inject drugs. Due to the COVID pandemic and VOCAL-NY being without a brick and mortar site, co-location of services was delayed until 2023. In the interim, a model of integrating HCV testing into peer delivered syringe exchange services and HCV treatment using telehealth was developed and implemented. **Methods:** VOCAL-NY's HCV point of care testing was integrated into peer delivered syringe exchange community outreach in several neighborhoods in Brooklyn, New York. HCV treatment was conducted via telehealth by a nurse practitioner from Mount Sinai Hospital working collaboratively with the VOCAL-NY team to arrange for laboratory testing, care coordination, treatment visits, and adherence monitoring. HCV testing and treatment were incentivized. De-identified client-level data was reported to the program funder, the New York State Department of Health AIDS Institute, for analysis. **Results:** From July 2019-June 2022, 709 people who use drugs were tested for HCV antibodies using OraQuick® rapid HCV antibody tests and HCV RNA using dry blood spot . Sixty-five of the 709 (9.2%) had detectable HCV RNA. Forty-five of the 65 persons (69.2%) were provided the HCV RNA test results and offered engagement in HCV treatment. Thirty-four clients were interested in treatment and enrolled in the program (70.6% male; 47.1% Hispanic, 32.4% black, 20.6% white; 79.4% injecting drug use in past 12 mo). Twenty-one clients attended the first telehealth visit, 15 initiated treatment, 13 completed treatment, 10 were assessed for SVR12 and 9 achieved SVR12. **Conclusion:** In the context of the COVID pandemic and the absence of a physical site for the harm reduction agency, the feasibility of using a street outreach telehealth model of HCV testing, linkage to care, and treatment was demonstrated with significant drop off at each step of the care cascade. The most significant challenge was remaining in contact with clients who were often (1) unstably housed/street homeless; (2) lacked reliable cell phone service; (3) had multiple competing priorities including food insecurity and inadequately treated medical and psychiatric comorbidities. Lessons learned from the initial phase of the collaboration were used to plan for the co-located model of onsite HCV services to be evaluated in VOCAL-NY's new physical home.

3749-C | INTERVENTION FIDELITY MONITORING FOR PAL LIVER, A COMPARATIVE EFFECTIVENESS TRIAL OF MODELS OF PALLIATIVE CARE DELIVERY FOR END STAGE LIVER DISEASES

Manisha Verma, Einstein Medical Center, Tamar H. Taddei, Yale University, New Haven, CT, Michael Volk, Loma Linda University, Andrzej Kosinski, Duke Clinical Research Institute, Marie Bakitas, University of Alabama at Birmingham and Victor J. Navarro, Md, Albert Einstein Medical Center, Doylestown, PA

Background: Palliative care (PC) comprises multiple elements which may work independently or interdependently to contribute to health outcomes. The generalizability of a PC intervention depends on the fidelity of its implementation. Intervention fidelity (IF) refers to the use of strategies to assess accurate implementation of interventions to maintain their validity, reproducibility, and reliability. PAL LIVER is a comparative effectiveness trial comparing two models: delivered by PC Providers versus Hepatologists trained with primary PC skills. PC delivery is guided by an intervention checklist in both models. This study aims to describe the method of IF monitoring in this ongoing trial, using the first three key

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

domains of the National Institute of Health Behavior Change Consortium 1) intervention design, 2) training providers, 3) delivery of intervention. **Methods:** We developed a PC training program and a PC intervention checklist based on the elements of primary PC using American Society of Clinical Oncology guidelines. All hepatology intervention providers were required to complete the training prior to launch of intervention. All the interventionists (PC providers and Hepatologists) are required to complete the PC checklist after each intervention visit. In addition, clinical notes are documented as a part of standard clinical care. Periodically, selected clinical notes at each site are reviewed and compared to the PC checklist to validate the accuracy of the latter. If there is lack of congruency, the provider is alerted and given additional training. A score is calculated by summing allocated points (Figure). We report the initial visit data as the trial is ongoing. Since the study enrolls dyads, there are separate checklists for patients and caregivers. **Results:** Of the 714 initial patient visits completed, the mean (SD) IF score is 83 (17). Of the 427 initial caregiver visits, the mean (SD) IF score is 77(29). Time spent during the initial visit was between 31-50 min in 50% patients and 21% of caregivers. In > 90% of patient visits, these elements were discussed and documented: assess patients understanding of disease and prognosis; distress; depression and symptom assessment; and assess social support. Health care proxy identification was done during initial visit in 71%, and advance directive discussion in 29%. Caregiver burden assessment was performed in 86% of initial visits. In > 70% of initial visits, caregivers were educated on symptom triggers, complications of liver disease, and role of health proxy. Providers found checklists to be easy to complete and useful at the time of intervention delivery. Completion of checklists was facilitated by integrating checklists within EMRs and by coordinators directly handing checklists to providers following the visit. **Conclusion:** A combination of checklist and clinical note documentation is a feasible and pragmatic approach to maintain IF in multi-site PC intervention trials.

3750-C | LIVER TRANSPLANT WAITLISTING IS LOWER AMONG PATIENTS EVALUATED AT SATELLITE CLINICS

Kevin Tang[1], Jason J. Lee[1], Marina Serper[2], Ethan M. Weinberg[1] and Therese Bittermann[1], (1)University of Pennsylvania, (2)University of Pennsylvania, Philadelphia, PA, United States

Background: Satellite liver transplant clinics are increasingly common at transplant centers to improve access to liver transplantation. However, their impact on liver transplant waitlisting is not known. We investigated whether liver transplant evaluation at a satellite clinic was associated with liver transplant waitlisting in a large transplant center. **Methods:** This was a retrospective cohort study of adults evaluated for liver transplant in 2018 and 2021 to compare pre- and post-COVID-19 pandemic characteristics. We abstracted sociodemographic factors, psychosocial risk, comorbidities, liver disease severity, and listing requirements. Covariate adjusted multivariable logistic regression analysis evaluated the association of liver transplant evaluation location and not being waitlisted. **Results:** Of 472 patients evaluated for liver transplant, 19% were evaluated at a satellite clinic. Sex, age, MELD-Na, comorbidities, psychosocial risk, malnutrition, education, and etiology were not different by evaluation location or year. A greater Hispanic (13.2% vs 5.0%) and fewer Black (10.8% vs 4.4%) proportion of patients were seen at satellite clinics ($p = 0.025$ overall). Psychiatric disease was more prevalent in the satellite group (35.2% vs 19.2%; $p = 0.001$). The satellite group had shorter travel distance from home to evaluation location (median 28.5km vs 61.1km; $p < 0.001$) and commute time (median 24min vs 58min; $p < 0.001$). Overall, 43% of the cohort was not waitlisted because of medical/surgical (42%) or psychosocial (14%) contraindications, loss to follow-up (11%), and other (33%), with no difference by location. Patients evaluated at a satellite clinic were more likely to be not waitlisted (57% vs 39%; $p = 0.003$). This difference was most pronounced in 2018 (72% vs 46%; $p = 0.002$) versus 2021 (35% vs 29%; $p = 0.198$). Among patients not waitlisted, time to evaluation decision was shorter at satellite clinics (median 99d vs 166d; $p = 0.002$). There were no differences observed for patients accepted for waitlisting. In multivariable analysis (Table), satellite clinic

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

evaluation was independently associated with higher odds of no waitlisting (OR, 2.31, 95% CI, 1.35-3.94; p = 0.002). **Conclusion:** In a large liver transplant center, patients evaluated at a satellite clinic were less likely to be waitlisted for liver transplant compared to patients evaluated at the main center after adjusting for multiple confounders despite shorter travel distance and commute times. Future studies should examine the factors that guide waitlisting decisions at satellite clinics to inform quality improvement and improve equitable access to liver transplantation.

Table. Factors associated with not being listed for liver transplantation

Covariate	OR, (CI)	*P* value
Evaluation location		**.002**
Main center clinic	**Reference**	
Satellite clinic	**2.31 (1.35, 3.94)**	
Female sex	1.35 (0.87, 2.10)	.177

3751-C | MODELS OF CARE OF PEOPLE LIVING WITH CHRONIC HEPATITIS B: SYSTEMATIC REVIEW AND META-ANALYSIS

Alexander J. Stockdale[1], Bethany Holt[2], Ajeet Bhadoria[3], Daniel Ikeda[2], David Duong[2], Todd Pollack[2], Gibril Ndow[4], Vy H. Nguyen[2], Janus Ong[5], Thuy Pham[6], Abhishek Sadasivan[7], Roger Chou[8] and Philippa Easterbrook[9], (1) Malawi-Liverpool-Wellcome Trust Clinical Research Programme, (2)Harvard Medical School, (3)All India Institute of Medical Sciences, Rishikesh, (4)Lshtm, (5) National Institute of Health, Manila, Philippines, (6)Health Advancement in Vietnam (HAIVN) and Beth Israel Deaconess Medical Center, Hanoi, Vietnam, (7)AIIMS Rishikesh, (8)Oregon Health & Science University, (9) World Health Organization

Background: Globally, less than 10% of 296 million with chronic hepatitis B virus (HBV) infection had been diagnosed and only 2% treated. Increasing access to HBV care and treatment requires simplified service delivery models. A global systematic review and meta-analysis was conductedidentify range of service delivery models for HBV testing, care, and treatment, and compare outcomes achieved across the HBV care continuum. **Methods**: We searched PubMed, Embase, and Scopus for studies published in last 10 years that evaluated service delivery models and care cascade for HBV. Models were categorised as hospital-based, primary care/co-managed, integrated with HIV/NCD/ harm reduction sites, or for other special populations. Key outcomes across the HBV care cascade (linkage to care, treatment uptake, viral load suppression, adherence and retention to care) were pooled using random-effects meta-analysis and nested elements confidence intervals calculated using parametric bootstrapping. **Results**: Our search identified 3989 reports; 69 met the eligibility criteria. 17 (25%) were from LMICs. Most were observational (41 or 61%) or non-randomized interventional designs (24 or 35%), with very few RCTs (3 or 4%). In total, 9 (13%) described hospital/specialist-based models (Hosp), 22 (32%) were primary care/co-managed or screening only (Prim), and the remainder related to integrated models (e.g., harm reduction, PLHIV) or tailored for special populations (e.g., migrants, pregnancy). Only 4% of studies reported outcomes across the complete cascade of care; 33% on early outcomes (testing and linkage) and 6% across late cascade outcomes (treatment and retention). Among those reporting late cascade outcomes, antiviral treatment initiation among eligible patients was 37%, viral suppression 9%, and retention in care 16%. There were higher rates of treatment eligibility assessment following diagnosis for Hosp vs Prim care (74% [95% CI 66–81] vs 55.5% [41.7–68.6]), and for treatment initiation (69.3% [54.1–81.2] *vs* 57.3% [39.3–73.5]. Retention in care was similar (~42%) between models, but greater in those on antiviral therapy (70.3% [58.7–79.7]) than those only monitored (37.5% [21.0–57.6]). Adherence to treatment and DNA suppression rates were rarely reported. **Conclusion**: We identified a wide range of hospital and primary care-based service delivery models for HBV care and treatment in high and low income settings. Few reported data across the full cascade of care, especially for assessing treatment response. Linkage to care, uptake

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

of treatment and retention in care was sub-optimal, and especially for reported primary-care based models. Interventions to improve adherence and retention in care are urgent across all models. Future studies should capture data across the cascade of care and utilize standardised definitions for linkage, eligibility assessment and retention.

3752-C | NATIONAL SURVEY OF SECOND OPINIONS FOR HOSPITALIZED PATIENTS IN NEED OF LIVER TRANSPLANTATION

Alyson Kaplan[1], Grace Lee-Riddle[2], Yael R. Nobel[3], Lorna M. Dove[2], Akhil Shenoy[2], Russell Rosenblatt[4], Benjamin Samstein[5], Jean C. Emond[6] and Robert S. Brown Jr[7], (1)Weill Cornell Medical Center, (2)Columbia University Medical Center, New York, NY, (3)Columbia University Irving Medical Center, New York, NY, (4)Weill Cornell Medicine, NY, (5)Newyork-Presbyterian/Weill Cornell Medical Center, (6)Columbia University, New York, NY, (7)Cornell University

Background: Decisions by liver transplant (LT) centers about patient candidacy can be the difference between life or death. Center practices of receiving and referring for second opinion for inpatients declined for LT is not well understood. We aimed to survey LT centers across the United States (US) to assess their perceptions of and barriers to second opinion referrals for this population. **Methods:** The medical and surgical directors of 100 unique LT programs that had done > 20 LTs in the year 2021 were surveyed with a 33-item questionnaire including both multiple choice and free response questions. **Results:** The response rate was 60% (60 LT centers) and included 28 large (≥ 100 LTs in 2021) and 32 small volume programs (< 100 LTs in 2021). 62% of responses were from hepatologists and 38% from surgeons. The top 3 reasons for inpatient denial for LT included lack of social support (20.9%), too physically frail (20.3%), and too short remission from alcohol (11.3%). The most common etiology of liver disease for which patients were referred for a second opinion was alcohol-associated hepatitis (38%). 25% of programs reported "frequently" facilitating a declined inpatient for a second opinion, 51.8% of programs reported "sometimes" doing so, and 6.67% of programs reported never doing so. The most common barriers to referral identified were that other centers had similar psychosocial criteria (20.2%), insurance limitations (19.0%), and patients being too sick for transfer (18.4%). 100% of programs reported that they receive referrals for second opinions, but only 25% reported transplanting these referrals over 20% of the time. Neither program size nor program location statistically impacted the findings. When asked if centers would be in favor of standardizing the medical and psychosocial evaluation process for inpatients to eliminate the need for second opinions, 37.5% of centers would be in favor, 39.3% would not be, and 23.2% were unsure for varied reasons (Table 1). **Conclusion:** Practices and perceptions of second opinions for hospitalized patients evaluated for LT varied widely across the US. Centers report ambivalence regarding the next step towards facilitating referrals. Working to achieve equity in LT, while still maintaining individual program autonomy, seems to be a goal of many programs. Policy development for second opinions of inpatient evaluations will require further stakeholder engagement if there is to be community consensus on optimizing LTs for this particular population.

Table 1. Themes Regarding Standardization of the Medical and Psychosocial Evaluation for Liver Transplant

Reasons to Standardize	Representative Quotes
Better use of resources	• "It avoids wasting time transferring a poor candidate who would be denied elsewhere anyways." • "Better use of resources." • "That would avoid unnecessary transfers."
More equitable organ allocation	• "Helps allocate organs equitably." • "Decrease misallocation, better consensus amongst centers."
Less ambiguous	• "Relieves ambiguity in process." • "It would seem less arbitrary to patients." • "It is also a large source of angst and stress for patients and teams (nobody wants to feel that a different advocate or center would have resulted in a better patient outcome)."
Reasons Not to Standardize	
Inability to achieve consensus	• "Almost impossible to reach agreement." • "We might disagree with other centers as to what is appropriate." • "I do not believe that transplant programs will ever be able to walk in lock-step." • "Not sure the community could come to a consensus about a common transplant evaluation and decisions to list are necessarily nuanced."
Different risk tolerance	• "Different centers can take different risks at different times." • "While much of the evaluation process should be standardized across centers, different centers have different priorities and levels of risk tolerance." • "Each center has its own set of values and community values as well as ability to take risk which makes standardization very difficult."

3753-C | NATIONWIDE SURVEY OF THE IMPACT OF COVID-19 ON THE CLINICAL PRACTICE AND CARE OF PATIENTS WITH LIVER DISEASE IN JAPAN★

Hiroko Setoyama, Faculty of Life Sciences, Kumamoto University, Noriko Oza, Saga-Ken Medical Center Koseikan, Tetsuro Shimakami, Kanazawa University, Junko Tanaka, Department of Epidemiology, Infectious Disease Control and Prevention, Graduate School of Biomedical and Health Sciences, Hiroshima University, Japan, Yasuhito Tanaka, Graduate School of Medical Sciences, Kumamoto University and Tatsuya Kanto, The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan

Background: The COVID-19 pandemic has had various effects on medical care, including changes in care-seeking behavior and postponement of tests and surgeries. Comprehensive investigation into the pandemic's effects on liver disease care is also necessary. Since 2017, we have been developing clinical indicators for hepatitis and cirrhosis care at regional core centers for the management of liver disease as a part of the Policy Research for Hepatitis Measures of the Ministry of Health, Labor and Welfare in Japan. In this study, we used these indicators to assess the impact of the pandemic on liver disease care at regional core centers nationwide. **Methods:** The survey regarding 29 clinical indicators (hepatitis CIs) was conducted with 71 regional core centers. The hepatitis CIs consisted of 6 indicators related to general hepatitis and cirrhosis, 10 related to hepatitis C, 6 related to hepatitis B, 3 related to cirrhosis, and 4 related to subsidy systems. Results of surveys from 2018 to 2022 were compared to assess changes in indicators between the pre- (2018) and the pandemic periods (Early phase: 2020,2021, Late phase: 2022). We also analyzed the association between trends in these indicators and the data related with COVID-19 infection such as the number of severe cases and deaths due to COVID-19, vaccination rate and policy responses to the pandemic. **Results:** From 2018 to 2022, 17,707-20,960 patients/year (average 19,517) were enrolled for the analysis in 71 institutions in Japan. In the early phase of the pandemic period, compared to pre-pandemic period, there was a downward trend in many hepatitis CIs, with particularly large changes in indicators related to imaging and endoscopy. 16 indicators showed improvement in the 2022 survey, most of them related to hepatitis C and hepatitis B. In the evaluation using standardized scores, indicators related to antiviral treatment for hepatitis C and hepatitis B increased compared to 2021 (hepatitis C: -0.79 to 0.19, hepatitis B: -0.22 to -0.07), suggesting that the impact of the COVID-19 is being overcome. In addition, improvements in these indicators were more associated with the government stringency index and the proportion of vaccinated persons than with the number of severe cases or deaths. **Conclusion:** Trends in each indicator over time allowed us to evaluate the impact of COVID-19 on hepatitis care in Japan. Our survey showed that the spread of the COVID-19 infections has adversely affected liver disease treatment, however, the impact of pandemic on antiviral therapy for hepatitis B and C is reducing. The fluctuation in hepatitis clinical indicators were associated with vaccination coverage and policy responses to the pandemic.

3754-C | OBSTETRICIAN AND GYNECOLOGIST PERSPECTIVES ON SCREENING FOR AND MANAGEMENT OF ALCOHOL USE DISORDER AND ALCOHOL RELATED LIVER DISEASE

Mary Thomson, Cresta Jones and Nicholas Lim, University of Minnesota

Background: There has been a dramatic rise in female mortality due to alcohol-related liver disease (ARLD). Early identification and treatment of alcohol use disorder (AUD) could reduce future development of ARLD in these patients. Female patients may only see an Obstetrics/Gynecology (OB/GYN) provider for their health needs, providing a unique opportunity to screen for AUD and ARLD. **Methods:** An anonymous survey was distributed to 143 OB/GYN providers at the University of Minnesota and affiliated sites who participate in routine outpatient care to understand their experience and comfort with screening for and management of AUD and ARLD. **Results:** 39 (27.3%)

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

eligible providers completed this survey: median age, 41; 53.8% were MD/DO, 43.6% were certified nurse midwives; 35.9% were within 5 years of training. More than 90% of providers reported routinely screening for diabetes mellitus, colon cancer, breast cancer, and tobacco use. 59% cared for someone with ARLD and 28.2% had cared for someone who died from this. More than 60% reported screening for harmful alcohol use in both OB and GYN visits (Table 1). Reasons for not screening for harmful alcohol use during GYN visits included inability to effectively screen (28.6%), counsel (28.6%), or refer (28.6%) patients with harmful alcohol use. Reasons for not screening for harmful alcohol use at OB visits included time constraints (33.3%), worries about legal consequences for the patient (33.3%), and not feeling able to effectively refer patients with harmful use (33.3%). In patients identified with harmful alcohol use, 89.8% providers counseled on safe alcohol use, 41.0% referred to an addiction specialist, 41.0% recommended discussing with their primary care provider, and 35.9% referred to a social worker. A minority had ordered labs (41.0%) or imaging (25.6%) on patients suspected of having ARLD. Only 30.8% felt they received adequate education on harmful alcohol use and ARLD during their training, 41.0% felt there were adequate resources on ARLD for OB/GYNs while 92.3% were interested in learning more about ARLD **Conclusion:** Almost all OB/GYNs provide aspects of traditional primary care, but have limited comfort with screening and management of patients with AUD or ARLD. Improving education on AUD and ARLD for OB/GYN providers can potentially boost screening and early intervention in female patients with AUD and ARLD.

Table 1:

How often do you perform standardized screening for alcohol use?	Gynecology Visits (n=33/39)	Obstetrics Visits (n=34/39)
Never	9.1%	2.9%
Rarely	15.2%	17.7%
Sometimes	15.2%	14.7%
Most of the time	42.4%	29.4%
All of the time	18.2%	35.3%
How comfortable are you screening for alcohol use?		
Not at all comfortable	0%	0%
Not very comfortable	18.2%	8.8%
Somewhat comfortable	42.4%	41.2%
Very comfortable	39.4%	50.0%
How do you screen for alcohol use? (Select up to 3)		
The patient fills out a questionnaire directly quantifying alcohol use	27.3%	41.2%
The patient fills out an intake questionnaire using alcohol screening methods (CAGE, AUDIT-C)	6.1%	2.9%
MA/LPN/RN directly quantifies alcohol use during intake	36.4%	2.9%
MA/LPN/RN uses alcohol screening methods (CAGE, AUDIT-C)	0%	5.9%
I directly quantify alcohol use during my interview	60.1%	70.6%
I use alcohol screening methods (CAGE, AUDIT-C) during my interview	15.2%	11.8%
What do you recommend as the safe upper limit of alcohol use?		
I do not feel any alcohol use is safe	0%	94.1%
No more than 1 drink a week	0%	2.9%
No more than 1 drink a day, up to 4 days a week	45.5%	2.9%
No more than 1 drink a day, up to 7 days a week	27.3%	0%
No more than 2 drinks a day, up to 4 days a week	6.1%	0%
No more than 2 drinks a day, up to 7 days a week	3.0%	0%
I do not have a recommendation	18.2%	0%

3755-C | OPPORTUNITIES TO REDUCE HBV-RELATED DISPARITIES THROUGH HARM REDUCTION ORGANIZATIONS

Amy B. Jessop, Heptrec, Melissa Lam, University of Pennsylvania and Catherine Freeland, Hepatitis B Foundation

Background: Approximately 40% of new hepatitis B (HBV) infections in the U.S. occur among people who inject drugs (PWID). To meet hepatitis elimination goals and reduce HBV's impact, we must prevent infections and identify and care for existing infections in PWID. Harm reduction organizations (HROs) engage this "hard-to-reach" group regularly with trusted, low barrier services and are obvious, positive partners for public health and healthcare systems. HROs, however, have not been key players in these efforts. This study examines HBV-related interests and actions of select U.S.-based HROs and identifies opportunities for engagement with traditional healthcare systems and providers. **Methods:** We conducted semi-structured interviews with 20 leaders of HROs in the Northeast (8), South (4), Midwest (3), Southwest (1), Northwest (4) regions of the U.S. using an interview guide developed through consideration of published manuscripts and expert consultation. Researchers reviewed transcripts with an inductive thematic analysis. A code book was developed (> 80% agreement) and data were analyzed with NVivo software. **Results:** Few HROs conducted HBV activities and few considered HBV as a priority, even though HIV and HCV are primary concerns. Legal statutes and relationships with public health agencies positively and negatively influenced actions. Among HROs with HBV activities, there was strong collaboration with healthcare centers and with providers dedicated to serving PWID. HBV testing was rare, generally only at HROs with onsite medical providers (reportedly due to need for phlebotomy and lab orders) and is often limited to participants with HIV or HCV. Vaccination occurred more frequently but still limited to on-site medical services or through public health outreach. To improve HBV actions, HROs need increased staff education, prioritization at health departments, culturally appropriate materials, revised government and insurance policies for vaccination, point-of-care testing, and engagement of more healthcare providers. **Conclusion:** To improve HBV actions, HROs need increased staff education, prioritization at health departments, culturally appropriate materials, revised government and insurance policies for vaccination, point-of-care testing, and engagement of more healthcare providers.

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Engagement of healthcare providers is essential to reduce HBV transmission, infection and related hepatocellular carcinoma. To address the identified gaps in HBV within HROs healthcare providers are needed for engagement for vaccination, testing, and follow up care. Provider support is also necessary for advocacy efforts to revise immunization policies, push point-of-care testing approval, reduce insurance-related barriers to treatment and monitoring, reduce PWID-related stigma and to expand capacity for treatment of PWID.

Disclosures: The following people have nothing to disclose: Amy B. Jessop, Melissa Lam, Catherine Freeland

3756-C | PATIENTS WITH HEPATITIS B AND D ARE MORE OFTEN LINKED TO MEDICAL CARE THAN PATIENTS WITH HEPATITIS C

Elena Vargas-Accarino[1], Anna Feliu-Prius[2], Adriana Palom[1], Ariadna Rando[1], Ana Barreira[1], Joan Martínez Camprecios[3], Judit Vico-Romero[1], Juan Carlos Ruiz Cobo[3], Jordi Llaneras[3], Mar Riveiro[3], Francisco Rodriguez-Frias[1], Rafael Esteban-Mur[4] and Maria Buti[5], (1)Vall D'hebron Research Institute (VHIR), (2)Hospital Universitari Vall D'hebron, (3)Vall D'hebron Universitary Hospital, (4)Hospital Universitario Vall D'hebron, (5)Hospital Universitari Vall d'Hebron, Department of Medicine of the UAB (Universitat Autònoma de Barcelona), Spain

Background: To achieve the WHO goals for viral hepatitis elimination is crucial to identify people living with hepatitis B and C. The objective of this study was to retrieve individual's with hepatitis B, C and D lost to follow-up and to deepen the reasons why they were not linked to care. **Methods:** Retrospective and prospective search of serum samples with hepatitis C (HCV-RNA+), hepatitis B (HBsAg+) and hepatitis D (anti-HDV+) from the microbiology database of the northern area of Barcelona (450,000 inhabitants). Individual's with a positive serum sample were identified and their medical records were reviewed to identify those lost to follow-up and the reasons of lack of linkage to care. Candidates to contact were telephoned a maximum of five times to offer them a medical visit. **Results:** A total of 3,407 medical records were reviewed between January 2019 and June 2022. Among them, 1,540 (45%) were HBsAg+, 53 (2%) anti-HDV+, and 1,814 (53%) HCV-RNA+. A total of 433 patients (28%) of the HBsAg+, 13 (24%) of the anti-HDV and 191 (10%) of those HCV-RNA+ were not linked to care. The reasons why the patients were not linked to care were: poor adherence to treatment, not attending the medical visit, treatment rejection and patients that were lost by the system. The main reasons of non-previously linked to care differs in relation to the type of viral hepatitis infection; the percentage of patients that rejected treatment and with poor adherence to treatment was higher in patients with hepatitis C (28% and 18% respectively) than in patients with hepatitis B (8% and 5%) or D (0 and 8%). Moreover, individual's with hepatitis C had significantly more advanced age or comorbidities (703 patients (23%)), compared to patients with hepatitis B or D (17 (1%) and 1 (2%)) ($p < 0.0001$) (median age of patients with hepatitis C, B and D was 60, 43 and 40 y old respectively). After the telephone calls, 226 HBsAg+ patients, 12 anti-HDV+ (2 of them HDV-RNA+) and 54 HCV-RNA+ were finally linked and treated; being HCV-RNA+ patients significantly less linked to care ($p < 0.0001$). 670 (20%) out of the 3,407 patients reviewed could not be contacted due to missing personal data. **Conclusion:** 292 (19%) patients have been linked to care, suggesting this is an effective strategy. Patients with hepatitis D are more linked and predisposed to be linked to care than patients with hepatitis C. The primary reasons for non-prior linkage to care vary depending on the type of viral hepatitis infection and the biggest challenge of this strategy has been the lack of contact details.

3757-C | PREDICTING LIVER-RELATED EMERGENCY ADMISSIONS IN CIRRHOSIS: A MULTI-CENTRE STUDY

Alan J. Wigg[1,2], Peter D. Rose[1,2], Sumudu Narayana[2], Richard J Woodman[1] and ALFIE Investigator Group, (1) Flinders University, (2)Southern Adelaide Local Health Network

Background: Rates of hospital readmission for patients with cirrhosis is high. These patients have increased overall mortality and contribute to significant healthcare costs. Many liver-related emergency admissions (LREA) are potentially preventable, thus identifying predictors of LREA may provide a target for intervention. There is currently no Australian multicentre data looking at LREA in cirrhosis. The primary aim of this study was therefore to determine predictors of LREA in cirrhosis across a multicentre, multi-state Australian database. **Methods:** The patient cohort studied was from the ALFIE dataset. This was a multicentre (5 centres across SA, WA and NSW) randomised controlled trial occurring between 2018 and 2022, with 1:1 randomization between a nurse coordination model and standard of care. All patients were recruited following an inpatient admission with a complication of chronic liver failure (CLF) (including ascites, encephalopathy, variceal bleeding, SBP, AKI-HRS, and alcohol-related acute on chronic liver failure) with planned follow up of 2 years. Baseline covariates studies included: randomization group, age, gender, aetiology, MELD and Child Pugh score, type of index cirrhosis complication, site, Charlson Comorbidity Index, SEIFA score, ARIA score, presence at baseline of carer or GP, dietician and pharmacy reviews and attendance rates at planned outpatient care. A variety of baseline scores assessing patient knowledge, self-management ability and quality of life were also used as covariates. Multivariate analysis was performed using negative binomial regression to identify covariates associated with LREA. LREA were defined as readmissions due to one or more complications of cirrhosis. **Results:** A total of 146 patients were analysed. The cohort had the following characteristics: mean age 54.9 years, 68% male, median MELD score 19.0 and median Child-Pugh score 9.0. The main causes of CLF were alcohol (68%), MAFLD (16%) and HCV (11%). A total of 384 LREA admissions occurred over a median follow up of 2.0 years, with a mean of 2.63 LREA per patient. 116 patients (79%) had at least one LREA over the study period. Table 1 shows the covariates that were significant predictors of LREA on multivariate analysis. **Conclusion:** Cirrhotic patients who are male, with HCV or MAFLD, who miss follow-up appointments and with lower baseline quality of life scores are more likely to have LREA. Interventions targeting cirrhotic patients with these higher risk features may help reduce LREA.

Covariate	Incident rate ratio (95% CI)	P value
Female vs male gender	0.50 (0.29-0.86)	0.011
HCV vs. alcohol	2.20 (1.00-4.86)	0.049
MAFLD vs. alcohol	3.04 (1.66-5.52)	<0.001
Nonattendance	1.19 (1.05-1.35)	0.007
Baseline CLDQ score	0.73 (0.55-0.97)	0.032

Table 1: Covariates significant for prediction of LREA on multivariant analysis.

3758-C | PREDICTION MODELS OF EARLY READMISSIONS IN CIRRHOSIS: A SCOPING REVIEW

Peter D. Rose[1,2], Richard J. Woodman[2] and Alan J. Wigg[1,2], (1)Southern Adelaide Local Health Network, (2)Flinders University

Background: Patients hospitalised with cirrhosis have high rates of early readmissions within 30 days. These patients have increased overall mortality and represent a significant cost to healthcare systems. Many of these readmissions are potentially preventable, thus prediction of patients at high risk of early readmission may provide an opportunity for quality improvement and intervention. Our aim was to perform a scoping review of the literature predicting early readmissions in cirrhosis to determine which variables are incorporated into prediction models, the type of prediction models used and the performance of these models. **Methods:** Relevant literature from electronic references databases were searched from inception to March 2023. A total of 33 studies were incorporated into the final review. All variables included in univariate and multivariate analyses were examined. Prediction models were analysed for model type, presence of a validation and derivation cohort, and discrimination ability. **Results:** Out of the 33 studies, there were 13 nationwide databases, 4 multi-centre studies and 16 single centre studies. There were 30 retrospective studies and 3 prospective studies. Regarding patient cohort, 13 studies only included patients with decompensated cirrhosis, including 3 with specifically hepatic encephalopathy. The pooled early readmission rate was 22.7%. Table 1 demonstrates the frequency of major variables reported. Models of prediction were proposed in 11 studies, with 10 of these incorporating linear regression models and 1 incorporating Cox regression models. Only 5 studies provided both a derivation and validation cohort, 2 of which were externally validated. Only 3 studies yielded a derivation model with at least reasonable discrimination (concordance index greater than 0.7) and no study yielded a validation model with at least reasonable discrimination. Machine learning was used as a prediction tool in one study, however it did not demonstrate reasonable discrimination, and no social, functional, frailty or quality measure variables were

incorporated. **Conclusion:** Social, functional, frailty, and quality measure variables are underrepresented in models predicting early readmission in cirrhosis and these models demonstrate suboptimal discrimination. Incorporation of these important variables into a machine learning model may enhance its performance and better identify cirrhotic patients at high risk of early readmission who may benefit from further intervention.

	Number of studies variable reported	Percentage of studies variable reported
Gender	33	100%
Age	33	100%
Comorbidity indices*	21	63%
Aetiology of cirrhosis	28	85%
Cirrhosis severity scores†	18	55%
Ascites	22	67%
Hepatic encephalopathy	22	67%
Hepatocellular carcinoma	20	61%

3759-C | PREVALENCE AND PREDICTORS OF PROBLEMATIC ALCOHOL USE AMONG TRANSPLANT HEPATOLOGISTS

Christopher L. Coe[1], Nicole Prause[1], Jihane N. Benhammou[1,2], Jasleen Singh[1], Akshay Shetty[1], Hirsh Trivedi[3], Beshoy Yanny[1], Kamron Pourmand[4] and Arpan Arun Patel[1,5], (1)University of California, Los Angeles, (2)VA Greater Los Angeles Healthcare System, (3)Cedars-Sinai Medical Center, Los Angeles, CA, (4)Mount Sinai Hospital, (5)Greater Los Angeles VA Healthcare System

Background: In the United States (U.S.), problematic alcohol use is common not only among the adult population but also physicians, 15.3% of whom screen positive for alcohol abuse/dependence. Male and younger physicians may be at higher risk, and specialty-specific estimates of use vary widely. The aim of this study is to describe the prevalence and predictors of problematic alcohol use among transplant hepatologists in the U.S., which is not known. **Methods:** This was a secondary analysis of a 69-item survey sent to practicing transplant hepatologists in the United States in 2019, which assessed prevalence and predictors of burnout. It included 22 items from the Maslach Burnout Inventory, as well as items related to demographics, practice characteristics, and psychological factors, including the 3-item Alcohol Use Disorders Identification Test-Concise (AUDIT-C). We used well-established cutoffs to define problematic drinking (3 or higher for women; 4 or higher for men) and alcohol abuse/dependence (4 or higher for women; 5 or higher for men). A working group of transplant hepatologists narrowed predictors in our analysis to those hypothesized to be associated with problematic alcohol use. We used generalized linear models to describe associations between predictors and AUDIT-C scores (Table). **Results:** A total of 185 responses were analyzed. Forty-seven (25.4%) respondents met criteria for problem drinking and 20 (10.8%) screened positive for alcohol abuse/dependence. There was no difference in sex, age, or career stage between those with negative or positive screens for problematic drinking. Our final model demonstrated that having higher feelings of personal accomplishment (standardized beta coefficient [β_{std}]: 1.52, 95% confidence interval [CI]: 1.20-1.93) and depersonalization (β_{std}: 1.38, 95% CI: 1.01-1.87) were independently associated with higher AUDIT-C scores. Compared with being single, being married or divorced (β_{std}: 0.8, 95% CI: 0.67-0.95) was independently associated with lower AUDIT-C scores. **Conclusion:** One in four surveyed transplant hepatologists in the U.S. screened positive for problematic alcohol use. Traditional risk factors, such as age and sex, were not associated with greater alcohol use; however, transplant hepatologists who experience depersonalization, report being high-achieving, or have never been married may be at a higher risk. This should inform efforts to destigmatize problematic alcohol use and ensure access to substance use resources for hepatologists. For interested colleagues, a list of confidential physician health programs is published online (http://www.fsphp.org/state-programs).

3760-C | PREVALENCE OF VIRAL HEPATITIS AND SEROLOGIC EVIDENCE OF IMMUNITY AMONG INJECTION DRUG USERS IN US ADULTS FROM 2009 TO 2018

Javeria Khalid[1], Yinan Huang[2] and Rajender Raj Aparasu[1], (1)University of Houston, (2)University of Mississippi

Background: In the United States (US), illicit drug users continue to rise, with an estimated 43.5 million people (19.4%) exposed to illicit drugs. Globally, viral hepatitis (A, B, C, D & E) among illegal drug users is a public health concern due to concerns of disease transmission through social and sexual interactions. Moreover, there are limited data on the recent prevalence of viral hepatitis in US adults who inject illicit drugs. Therefore, this study aims to analyze the prevalence and predictors of viral hepatitis and hepatitis-B immunization among adults in the US who inject illicit drugs from 2009 to 2018. **Methods:** This retrospective, cross-sectional study used the National Health and Nutrition Examination Survey (NHANES) from 2009-2018. The study included adults aged 18 to 69 who filled out questionnaires for drug use information (including heroin, amphetamines, buprenorphine, benzodiazepines, barbiturates, cocaine, and methamphetamine). Viral hepatitis (A, B, C, D & E) infections among these populations were identified based on serological laboratory tests. Adults were considered immunized for HBV if serological HBV-antibody titer was > 10mIU/Ml. Trend analysis evaluated prevalence trends of viral hepatitis and vaccine-induced immunity among injection drug users across five survey-year cycles. **Results:** According to NHANES (2009-2018) survey, an estimated 18.23% (95%CI:15.64%-20.04%) injection drug users had HBV infection, and 33.02% (95%CI:30.96%-34.45%) had HCV infection, while infection rate for HBV and HCV was 3.9% and 1.13% among non-injection drug users, respectively. Among all injection drug users, the prevalence of HBV infection has increased significantly from 16.7% in 2009-2010 (95%CI: 9.23%-20.6%) to 24.46% in the 2017-2018 cycle (95% CI:15.1%-28.3%) ($P < 0.001$). However, the prevalence of HCV infection did not change significantly during the study period (HCV infection: 2009-2010 cycle (35.9% [95% CI, 33.5%-37.15%]) to the 2017-2018 cycle (34.48% [95% CI, 18.59%-41%]; P-value = 0.56). Moreover, the odds for HCV infection were 26.79 (95% CI:17.07-42.2) among injection drug users and 7.2 (95%CI:5.2-10.1) for HBV infection. The odds for HBV vaccination were similar for injection drug users (high-risk adults) compared to non-injection drug users (OR: 1.05, 95%CI: 0.8-1.378). **Conclusion:** Despite periodic releases of guidelines for controlling blood-borne infection, viral hepatitis is still high among injection drug users, while vaccine-induced immunity remains low. Concerted efforts are needed to maintain the rate of blood-borne diseases and improve the HBV immunization rate among injection drug users in the U.S.

3761-C | PRIMARY CARE AND ENDOCRINE SPECIALTY CLINICIAN KNOWLEDGE AND PERSPECTIVES ON SCREENING FOR NON-ALCOHOLIC FATTY LIVER DISEASE IN AN URBAN, SAFETY-NET SETTING

Arpan Mohanty, Kathryn Fantasia, Kirsten Austad, Allan J. Walkey and Mari-Lynn Drainoni, Boston Medical Center, Boston, MA

Background: Nonalcoholic fatty liver disease (NAFLD) is a highly prevalent cause of chronic liver disease and a public health problem. Even though the incidence of NAFLD and related complications such as cirrhosis and liver cancer are rising, it remains underdiagnosed in primary care and endocrinology clinics. The aim of this study is to understand clinician perspectives on the current status of NAFLD screening and risk stratification so as to inform future implementation strategies to improve NAFLD care. **Methods:** In 2022, we conducted a sequential exploratory mixed-methods study at a large, urban US safety-net hospital. A survey was deployed to 299 clinicians from adult primary care and related subspecialties (geriatrics, infectious disease/HIV primary care) and endocrinology. A subset participated in semi-quantitative interviews. Survey and interview questions were on knowledge, attitude, and practice around NAFLD screening and risk stratification. The interviews were designed to gain a deeper understanding on barriers and facilitators and perspectives on electronic health record (EHR) integrated tools to improve NAFLD screening. **Results:** Survey response was 36.5% (109 respondents). Survey findings indicate that most clinicians (83%) recognize NAFLD as a significant health problem though most underestimate its prevalence (69%). Only 34% of the respondents reported using fibrosis prediction scores such as FIB-4 and 47% reported using transient elastography for

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

NAFLD risk stratification, with more frequent use among primary care clinicians as compared to sub-specialities. Barriers to screening for NAFLD include competing patient issues (75%), lack of confidence in screening (63%), limited time during clinic visit (59%) and the perceived lack of effective therapies (34%). Half the clinicians (55%) felt that they did not have enough resources to address NAFLD and a quarter felt that patients with suspected NAFLD should be referred to gastroenterology. Thirteen survey respondents participated in qualitative interviews (9 primary care, 2 geriatrics, 2 endocrinology). The following themes about knowledge and attitude about NAFLD emerged: clinicians were concerned about under-recognition of NAFLD; they perceived that NAFLD had fewer complications than other liver diseases; across specialties, they believe screening should occur in primary care; they acknowledge that currently screening and risk stratification for NAFLD is not normative or encouraged. In addition to barriers identified in the survey, clinicians felt that availability of easy to use and unobtrusive EHR tools would facilitate NAFLD diagnosis and risk stratification. **Conclusion:** Our findings suggest implementation strategies to improve clinician knowledge and to deploy well-defined easy-to-use EHR tools, especially in primary care clinics, can bolter NAFLD screening and risk stratification practices.

3762-C | PRIMARY CARE SCREENING FOR NAFLD AMONG PEOPLE WITH HIV: A REAL-WORLD PROVIDER SURVEY

Jennifer C. Price[1], Kyoko Hirose[1], Naga P. Chalasani[2], Holly Crandall[3], Sonya Heath[4], Rohit Loomba[5], Susanna Naggie[6], Richard K. Sterling[7], Mark S Sulkowski[8], Laura Wilson[9] and Jordan E. Lake[10], (1) University of California, San Francisco, (2)Indiana University Medical Center, Indianapolis, IN, (3)Indiana University, (4)University of Alabama at Birmingham, (5) University of California, San Diego, San Diego, CA, (6) Duke Clinical Research Institute, Durham, NC, (7) Virginia Commonwealth University Health System, (8) Johns Hopkins University School of Medicine, Division of Infectious Diseases, (9)Johns Hopkins School of Public Health, (10)Division of Infectious Diseases, Department of Medicine, Indiana University School of Medicine, Indianapolis, Indiana, USA

Background: Nonalcoholic fatty liver disease (NAFLD) is highly prevalent in people with HIV (PWH) and increases the risk of hepatic fibrosis and hepatocellular carcinoma. To better inform recommendations for NAFLD screening among PWH, we surveyed HIV providers on their NAFLD screening patterns and management needs. **Methods:** An online survey was sent to American Academy of HIV Medicine (AAHIVM) member and non-member HIV providers 3 times over 6 weeks Jan-Feb 2023. The survey was restricted to physicians and advanced practice providers working in the US, Puerto Rico, and US Virgin Islands (n = 2,753). Questions assessed NAFLD screening and referral practices, barriers to screening, and attitudes toward support tools. **Results:** Of respondents (n = 215, 8% response rate), 60% were physicians, 27% nurse practitioners, 12% physician assistants, and most (52%) had been in practice for > 10 years. Sixty-five percent reported screening for NAFLD in PWH, with 28% routinely screening all patients (Figure). The most cited reasons for screening were persistently elevated liver enzymes, metabolic syndrome, obesity, and pre-diabetes/diabetes. Liver enzymes (90%) and abdominal ultrasound (71%) were the most common modalities used for NAFLD screening, with vibration controlled transient elastography (VCTE, 33%) and MRI (3%) less commonly used. The majority of respondents refer patients to hepatology if work-up suggests another co-existing liver disease or abdominal imaging suggests cirrhosis, with the primary goals of referral being additional diagnostic testing (60%) or specific treatments (75%). The most common barriers to NAFLD screening were not feeling sure of what tests to order (28%) and not knowing when there is enough data to make the diagnosis (29%). A low proportion reported screening being a low priority (17%), not having enough time to screen (7%) or not having access to hepatology referrals (7%) as barriers. When asked what tools would help in diagnosing and managing NAFLD in PWH, the majority were interested in society guidelines (73%) and NAFLD education for patients (57%) and providers (55%). A high proportion also reported interest in electronic medical record tools to assist NAFLD work-up and referral. **Conclusion:** Two-thirds of survey respondents reported screening for NAFLD in at least some of their patients, and the most common reason for hepatology referral was for treatment options. The majority believed society guidelines and increased education would help with NAFLD diagnosis and

management. Our findings support the development of NAFLD clinical practice guidelines for HIV providers and the inclusion of PWH in clinical trials of novel agents.

3763-C | PROTOCOLIZED HEPATITIS B VACCINATION TO INCREASE VACCINATION RATES AND IDENTIFY BARRIERS TO CARE IN PATIENTS UNDER LIVER TRANSPLANT EVALUATION

Andreas Zori[1], Maya Jordan[2], Ismael Media[2], Juan Gonzalez[2], Divya Devabhaktuni[2], Calvin Kiani[2] and Roniel Cabrera[2], (1)University of Florida, Gainesville, FL, (2)University of Florida

Background: Shortage of appropriate donor livers is an obstacle for liver transplantation in the United States, therefore there is significant interest in expanding the pool of potential donors. Use of donors that are hepatitis B (HBV) positive is a potential source of donors, however there is risk of causing chronic HBV infection in the recipient. This risk can be reduced significantly if the recipient is immune to HBV. Nationally only about 25% of adults show serologic evidence of HBV immunity whereas at our center about 52% of liver transplants candidates were immune at the time of evaluation. Although it is recommended for all liver transplant candidates to be vaccinated if they are not immune to HBV, there are significant logistic and financial obstacles to completing the vaccine series. At our center historically only 7.14% of non-immune patients evaluated for liver transplant completed the vaccine series. Therefore we sought to identify barriers to vaccination at our center and create workflow to improve our vaccination rate **Methods:** Under the historic protocol at our center patients were responsible for obtaining required vaccines independently. Under the new protocol, HBV serology was obtained prior to transplant evaluation. This was followed by financial screening for vaccine coverage and patients scheduled during their transplant evaluation if they were not HBV immune. The vaccines were administered during their pharmacy consultation. Vaccine completion was evaluated and causes for failure to vaccinate recorded. **Results:** During this period vaccination rates increased from 7.14% prior to implementation of a standardized HBV vaccination protocol to 32% after implementation. The primary barrier to vaccination was inability to obtain financial/insurance authorization for vaccination either in specialty (hepatology) clinic or through the pharmacy and was the reason for non-vaccination in 73% of candidates. Of the patients who were denied coverage for vaccination, 12/14 had Medicare as their primary insurance and two had Medicaid. None of the 12 patients with private insurance were denied coverage for HBV vaccination. **Conclusion:** Protocolized HBV vaccination can improve immunity among liver transplant candidates but despite this, significant barriers remain to universal vaccination. The primary barrier at our center is lack of insurance authorization and

coverage for vaccination in specialty clinics and pharmacies.

3764-C | PUBLIC HEALTH STRATEGIES AND EARLY DETECTION PROGRAMS SHOULD FOCUS ON INDIVIDUALS AT RISK OF ALCOHOL RELATED HARM TO REDUCE MORBIDITY AND MORTALITY FROM DECOMPENSATED CIRRHOSIS IN THE UK

The Trainee Collaborative for Research and Audit in Hepatology UK, Torch-UK

Background: In the natural history of chronic liver disease (CLD), the onset of decompensation is associated with a significant increase in patient mortality. However, strategies aiming to reduce the prevalence of CLD and complications of advanced disease have had limited success to this point. We aimed to characterise index presentations of decompensated cirrhosis to hospitals in the United Kingdom (UK) and understand differences between those with known and unknown liver disease. **Methods:** Patients admitted to hospitals with decompensated cirrhosis between 1/11/2019-30/11/2019 from across the UK were included in this analysis. Admission clinical, demographic and laboratory data were collected with outcome and trust-specific data. Data regarding the presence of a local community early detection program was also supplied. Univariable and multivariable analyses were performed. **Results:** 1224 admissions from 104 hospitals across the UK were included. There were regional variations in the proportion of admissions with index presentations and with unknown liver disease (Figure 1). Index presentations were more likely to consume alcohol regularly (67.78% v 49.67%, $p < 0.0001$*), present with jaundice (24.38% v 10.58%, $p < 0.0001$*) and less likely to present with encephalopathy (9.2% v 21.17%, $p < 0.0001$*) than patients with established disease. No other differences were reported in demographic, aetiological, deprivation or clinical data between these cohorts. Patients with index presentations of previously unknown liver disease were more likely to regularly drink alcohol (75.16% v 61.36%, $p = 0.01$*) and had significant worse prognostic scores than index presentations with known liver disease. No other differences were reported in demographic, aetiological, deprivation or clinical data between these cohorts. The presence of a local community early detection program was not associated with a significantly lower proportion of admissions with index presentations or unknown liver disease. Inpatient mortality was high in index presentations (17.77%) and highest in the those with unknown liver disease (19.89%) but this was not significant when adjusted for patient age, critical care admissions and MELD score. **Conclusion:** Public health strategies are required to reduce alcohol use across the UK in order to reduce morbidity and mortality from decompensated cirrhosis. These likely include Minimum Unit Pricing and increased funding for alcohol services. Early detection programs should focus on identifying those at risk of alcohol related harm.

3765-C | RAPID HEPATITIS B VIRUS TESTING AND HEPATOCELLULAR CARCINOMA SCREENING THROUGH AN EMERGENCY DEPARTMENT IN TANZANIA

Manaswita Tappata[1], James Ford[2], Johnstone Kayandabila[3], Joseph Morrison[4], Samwel Seth[3], Aliasghar Mukhtar[3], Michael Schick[4], Larissa May[4] and Jose D. Debes[1,5], (1)University of Minnesota, (2) University of California, San Francisco, (3)Arusha Lutheran Medical Center, (4)University of California Davis, Sacramento, CA, (5)Erasmus University Medical Center, Netherlands

Background: Africa suffers from a high burden of hepatitis B virus (HBV) and hepatocellular carcinoma (HCC). Novel screening strategies are needed to achieve The World Health Organization goal of detecting 90% of global cases of HBV by 2030. In this study, we assessed the utility of an emergency department (ED)-based combined HBV and HCC screening program in Tanzania. **Methods:** We conducted a study in a combined HBV and HCC screening program at an ED in Arusha, Tanzania at a regional referral hospital

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

between April and June 2022. All patients who presented to the ED (primary or from clinic) were approached for enrollment, underwent informed consent, and completed a study questionnaire with the aid of study staff. HBV testing was conducted via fingerstick using a rapid point-of-care assay to detect HBV surface antigen (HBsAg). Patients who were HBSAg positive underwent point of care ultrasound to screen for HCC, and were referred to HBV clinic for further management. We trained local ED and critical care providers who had prior ultrasound experience on how to systematically screen the liver for masses. We measured the number of HBV diagnoses (primary outcome) and the number of liver masses (secondary outcome). Data were analyzed with descriptive statistics. **Results:** A total of 846 patients were tested for HBV during the study period (primary ED: 761, clinic-referral: 85). Median age of patients was 44 ± 15 years, and 66% were female. Only 15% of patients reported having a primary care doctor. 13% of patients had been previously vaccinated for HBV. 65% of patients did not know how HBV is transmitted. 6% of patients had a family member with a known HBV infection. There were 17 new HBV diagnoses (primary ED: 16, clinic-referral: 1), which corresponds to a seroprevalence of 2.0% [95% CI 1.2, 3.2]. No patients had liver masses detected on point of care ultrasound. **Conclusion:** We found that an ED-based, combined HBV and HCC screening protocol can be feasibly implemented with short-interval training of local providers and minimal time. This study could serve as a model for HBV/HCC screening in regions with high HBV endemicity and low rates of community screening.

3766-C | REPEATED EMERGENCY DEPARTMENT UTILIZATION BY INDIVIDUALS WITH CIRRHOSIS IS PREDICTABLE AND MAY BE AVOIDABLE WITH HEALTHCARE DELIVERY REFORM

Swetha Parvataneni[1], Yara Sarkis[2], Brittany Baker[2], Michelle Haugh[1], Qing Tang[1], Lauren D. Nephew[1], Marwan S. Ghabril[1], Naga P. Chalasani[3], Raj Vuppalanchi[2], Nicholas Eric Harrison[1], Eric S. Orman[1] and Archita Parikh Desai[1], (1)Indiana University, (2) Indiana University School of Medicine, (3)Indiana University Medical Center, Indianapolis, IN

Background: Emergency Department (ED) care is often required to manage cirrhosis related complications and utilization of the ED by individual's with cirrhosis has not been well described. We aimed to describe ED care utilization and compared the outcomes of high ED utilizers versus not in individual's with cirrhosis. **Methods:** We retrospectively reviewed charts for adults with cirrhosis without prior liver transplant (LT) presenting to any ED from 01/2021 – 12/2021 in a large, state-wide healthcare system (16 EDs) associated with a LT center. Patient characteristics and features of the first ED visit during 2021 as well as 90-day health-care use and outcomes were collected. Charts were adjudicated to determine if the ED visit could have been avoided based on pre-determined criteria. Predictors of being a high ED utilizer (HEDU, > 2 visits during 90-day follow-up) were assessed using multivariable logistic regression models. **Results:** The study cohort (n = 1850) is described in the Table. Return visits were common (41%, mean visits 1.9 ± 1.3) with 19% of the cohort being a HEDU. Compared to non-HEDUs, HEDUs were younger, were more likely to have active alcohol use, complications of cirrhosis and a higher MELD score (Table). Rates of ED interventions were not significantly different between the groups, including receipt of paracentesis (Table). Upon expert review, 20% of initial visits could have been avoided, of which 33% deemed avoidable with an urgent visit in hepatology, urgent paracentesis (24%), improved medical management at home (23%) and/or non-emergent weekend/holiday services (16%). In those with a repeat ED visit, 32% were deemed avoidable. The 5 most frequent reasons for initial ED visit were: abdominal pain, 19%; shortness of breath, 16%; fall/generalized weakness, 13%; altered mental status, 12%; and ascites, 10%. In those with a subsequent visit for these top reasons, presentation for the same symptom occurred in 12-23% of non-HEDU vs. 13-23% of HEDUs ($p > 0.05$ for each). Considering 90-day outcomes by HEDU status, HEDUs returned sooner than non-HEDUs (Table). While HEDUs had a similar risk of 90-day mortality (16.7% vs. 13.4%, $p = 0.131$), they were more likely to undergo LT within 90-days (0.8% vs. 2.3%, $p = 0.038$). Independent predictors of being a HEDU were: weekday presentation (OR 0.74, 0.56, 0.98), lack of clear etiology of cirrhosis (OR 3.05, 95% CI: 1.81, 5.16), ascites (OR 1.5, 95% 1.13, 1.94), higher number of prior ED visits (1.22, 95%CI: 1.12-1.32) and prior hospitalizations (1.18, 95% CI: 1.07-1.31). **Conclusion:** Individual's with cirrhosis seek ED care, often for liver-related conditions, of which 1 out of 5 can be prevented. Furthermore, these individual's are at high-risk for repeated ED use, hospitalization and mortality. Prior health-care use is an important predictor of HEDU and should be incorporated discharge planning to

prevent subsequent returns to the ED, possibly through improved outpatient services.

3767-C | RESULTS OF A UNIVERSAL HEPATITIS B SCREENING AND LINKAGE TO CARE PROGRAM IN A LARGE, URBAN HEALTH SYSTEM

Anna Mageras[1], Caroline Romano[1], Tasnim Bhuiyan[1], Francina R. Collado[1], Brooke Wyatt[2], Rebecca Roediger[1], Eric Woods[1] and Douglas T. Dieterich[3], (1) Icahn School of Medicine at Mount Sinai, (2)Icahn School of Medicine at Mount Sinai (ISMMS), (3)Icahn School of Medicine at Mount Sinai, New York, NY

Background: In March 2023, the CDC updated its screening guidelines for hepatitis B virus (HBV) from risk-factor-based to universal one-time screening for adults. In anticipation of this change, in October 2022 we implemented universal one-time HBV screening for adults in our multi-center hospital system serving metro-NYC, where HBV prevalence is 2.9%. We describe modifications to the electronic medical record (EMR), changes in screening rates, and the cohort of patients identified as HBsAg+. **Methods:** We met with population health, ambulatory, EMR IT, and laboratory teams to build the EMR modification and provider education materials. The screening consists of three lab orders: HBsAg, anti-HBs, and anti-HBc (all with one click), in line with updated CDC guidance. To complement the EMR alert, we conducted outreach to PCPs and implemented navigation for patients who tested HBsAg+, with the goal of connecting them to care. HBsAg+ cohort demographics were summarized descriptively and compared using chi square tests across patients already versus not yet receiving care. **Results:** Since implementation of the EMR alert, the average HBV screening rate has increased from 4% at baseline in September 2022 to 23% in March 2023 across our pilot clinics that received education (n = 3) and from 3% to 15% in clinics that did not (n = 2). From September 2022 to March 2023, we identified 231 HBsAg+ patients who were screened or had an encounter at one of our pilot clinics. Of these, 24 (10%) were screened for the first time during this period, and 207 (90%) had a previous HBsAg+ test on record. Of these patients, 90 (39%) were not engaged in HBV care. Among these, 54% attended at least one liver appointment by May 19, 2023, largely due to patient navigation; 27% were still being engaged by our navigators; and 19% declined care or were lost to follow-up. The HBsAg+ cohort was 50% male; 73% < 65 years old; 22% born in a country with ≥ 2% HBV prevalence; 35% Black, 28% Asian, 12% Latino, 10% White, and 15% unknown race. There were no statistically significant differences across these demographics when comparing patients already in care to those not yet linked. **Conclusion:** Many patients with HBV are undiagnosed or diagnosed but not receiving liver care. Policy changes, automatic prompts in the EMR, and outreach to providers can promote universal HBV screening and diagnosis. Preliminary results indicate that provider engagement and patient navigation enhance the positive effect of EMR alerts on screening rates and linkage to care for patients with chronic HBV. Future directions include investigating barriers to care.

Background: Chronic liver disease is a leading global cause of death and disability. To improve prognosis, several recent studies focus on population screening for liver fibrosis to enable early detection and timely intervention to halt disease progression. Liver stiffness by transient elastography (TE) above 8 kPa is considered the reference screening cut-off value. Yet, the variability of TE is unknown when used in low-prevalence populations. We, therefore, aimed to investigate short-term variation in TE measurements in a screening setting. **Methods:** We included screening positive participants from two screening cohorts: The European LiverScreen project which screens for fibrosis using TE in a general population aged 40 or above, and the Danish DECIDE project which screens an at-risk population with excessive use of alcohol, obesity or type 2 diabetes, aged 30-75. All those screening positive (TE $\geq$8 kPa) were offered a second visit with a repeated TE within three months. We tested absolute and relative changes in TE from the first to second visit, and intervals of TE 8, 10, 15, 20, and 25 kPa. Finally, we explored potential causes for short-term variation including time between measurements, transaminases, BMI, probe size, and lifestyle changes. **Results:** We included 294 subjects from the general population and 177 subjects at-risk (median age 60 y (IQR 53-66), 67% male, 88% Caucasian, 62%, BMI $\geq$30 kg/m^2). The median TE was 10.7 kPa (IQR 9.1-15.2) at screening and 8.9 kPa (IQR 6.5-12.9) at the second visit after an average of 32 days. At screening, 186 (40%) had a TE 8-9.9 kPa, 166 (35%) had a TE 10-14.9 kPa, 46 (10%) had a TE 15-19.9 kPa and 73 (15%) had a TE $\geq$20 kPa. At the second visit, 44% dropped below 8 kPa with 43% dropping from TE $\geq$ 10 kPa at screening (figure). Almost half (46%) of the study population dropped more than 20% in TE measurements between the first and second visits. In a multivariable regression analysis, delta-TE did not correlate with age, gender, ALT/AST ratio, high BMI or probe size. **Conclusion:**

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Elevated transient elastography is prone to significant variation in populations where fibrosis prevalence is low. Lifestyle changes between the first and second visit may have an influence on the observed changes. Yet although known predictors can explain a small degree of short-term TE variance, regression towards the mean plays an important role in the selection of screening positives. High liver stiffness should be confirmed with a second measurement when used as a screening tool.

Background: Hepatocellular carcinoma (HCC) is the third most common cause of cancer-related deaths worldwide. The aims of the study were to explore HCC-related population-wide public health policies (PHP) in terms of prevention, treatment availability, epidemiological surveillance, and awareness campaigns worldwide. **Methods:** We conducted a 43-item survey about HCC: policies and civil society (18 questions), clinical guidelines (5 questions), epidemiology (7 questions), and care management (13 questions). We invited 249 gastroenterologists, hepatologists, oncologists, surgeons, radiation therapists, and public health experts from 74 countries/territories. The survey was carried out using an electronic form between May 2022 and January 2023. Data were collected in a spreadsheet, revised by two independent reviewers, and verified with governmental institutions, regulatory agencies, scientific societies, and scientific publications. We classified policies into eight dimensions, including criteria for low, moderate, and strong PHP establishment. We estimated an index using multiple correspondence analysis. **Results:** We obtained 134 responses from 66 countries/territories (Africa N = 16, the Americas N = 18, Asia N = 10, Europe N = 21, and Oceania N = 1). The median index was 43.7 [IQR: 30.9–59.3]. The lower scores were observed in Sierra Leone (0), Lebanon (5.5), and Pakistan (5.5), while Italy (79.7), Brazil (94.1), and Sweden (100) obtained the highest scores (Figure). In particular, 46 (69.7%) countries had a written national cancer strategy or action plan, but only 5 (7.6%) had a specific written national strategy or action plan on HCC. Thirty-two (48.5%) countries had national clinical practice guidelines on HCC and 54 (81.8%) countries had a national disease registry that included HCC. The most common strategies for staging of HCC were Barcelona Clinic Liver Cancer (BCLC) (85%) and TNM classification (10%). The survey reflects important differences in the availability of treatments, including surgery (98.4%), tyrosine kinase inhibitors (95.1%), chemoembolization (85.2%), radiofrequency or alcohol ablation (82%), immunotherapy plus anti-VEGF (82%), liver transplant (74.2%), stereotactic body radiation therapy (42.6%), and radioembolization (36.4%). **Conclusion:** Existence of PHP on HCC is insufficient worldwide. The most common strategy for staging is BCLC, but there are important differences in treatment availability across countries, especially regarding curative therapies.

3770-C | THE EFFECT OF IMPLEMENTING GAMIFICATION IN HEPATOLOGY CURRICULUM FOR MEDICAL STUDENTS

Chelsea Edirisuriya, Jason Goldenberg, Zachary Breslin, Anita Wilson, Steven K. Herrine, Christina Tofani and Danielle Tholey, Thomas Jefferson University Hospital

Background: Gamification, or the incorporation of game theory into curriculum, has been correlated with improved knowledge retention compared to standard didactics. Gamification appeals to current medical students given their technical savvy and desire for a diverse educational experience. Application of gamification to a hepatology curriculum has not yet been studied. Our study aims to determine the impact of gamified hepatology modules on medical student knowledge retention and exam performance. **Methods:** We created 3 web-based, gamified hepatology modules on liver anatomy, evaluation of jaundice, and elevated liver function tests (LFTS) with 15 question pre and post-tests. Differences in each module's pre and post test scores were compared using paired t-tests, with students serving as internal controls. We also compared medical school exam scores in students who did and did not complete the modules using independent 2 sample t-tests. Both total exam score (n = 120 items) and hepatology item specific exam scores (n = 11 items) were assessed. **Results:** In total 13% of students (n = 36) completed the modules and 87% of students (n = 240) did not use the modules. Module users scored 1.2 points higher on the total exam score and 2 points higher on hepatology exam score. However, there was no significant difference in total exam score between module users (M = 86%, SD = 8.67) and non-module users ((M = 84.8%, SD = 8.04); t(274) = [-0.85], p = 0.4). There was also no difference in hepatology score between module users (M = 88.1%, SD = 11.25) and non-module users (M = 86.1%, SD = 10.68; t(274) = [-1.02], p = 0.31, Table 1). Module completion yielded significant increases in pre to post test scores for the Jaundice (Mean Pre-test = 57% vs. Mean post-test = 69%, SD = 3.02; t(37) = [-3.42], p = 0.002) and Anatomy modules (Pre-test = 61% vs. post-test = 72%, SD = 2.57; t(50) = [-4.31], p = < 0.001), but score improvement was not significant in the LFT module (p = 0.06, Table 2). When evaluating a combined module score, module completion demonstrated significant improvement in pre vs post test scores (Pre-test = 59% vs. post-test = 68%, SD = 2.82; t(107) = [-5.09], p < 0.001). **Conclusion:** Compared to non-module users, module users had higher hepatology exam and total exam scores, yet this difference was not statistically significant. However, the lack of difference in exam scores may be due to a type 2 error, as module pre and post test scores were significantly improved overall and in all modules except the LFT module. Students who chose to participate in the modules may have a common characteristic that is inherently different than students who chose not to complete the modules. This study suggests that gamification may be beneficial in aiding hepatology knowledge recall. Larger sample studies and investigation of student characteristics are needed to further define the role of a gamified hepatology curriculum.

Table 1: Descriptive statistics and Independent T-test results of Hepatology-specific and Total exam scores in module and non-module users

Group	Hepatology Score							Total Score						
	N	Mean score (%)	Std Dev	Std. Err	T-score	Df	p	N	Mean score (%)	Std Dev	Std. Err	T-score	Df	p
Modules	36	88.13	11.25	0.69	-1.02	274	0.3	36	86.04	8.67	0.52	-0.85	274	0.4
No Modules	240	86.17	10.68	1.88				240	84.81	8.04	1.45			
Total	276	86.43	10.76					276	84.97	8.13				
Difference		-1.96	10.76	1.92					-1.24	8.13	1.45			

Table 2: T-test paired two sample means of Module Pre and Post test scores

	N	Mean Pre-Test Score	Mean Post-Test Score	Mean Difference	Std Dev	Std Err	T-score	Df	P*
All Modules	36	59%	68%	1.38	2.82	0.27	-5.09	107	**<0.001**

3771-C | THE ENHANCED LIVER FIBROSIS TEST IMPROVES EARLY DIAGNOSIS OF ALCOHOL RELATED LIVER DISEASE IN COMMUNITY SETTINGS

Charlotte Turner[1], Alexander J. Hung[1,2], Freya Rhodes[2], Jennifer M. Ryan[2] and William M. Rosenberg[2,3], (1)University College London, (2)Royal Free Hospital, (3)University College London, United Kingdom

Background: Alcohol-related liver disease (ArLD) is a leading cause of cirrhosis and death, but affects a minority of people with alcohol use disorder (AUD). Early detection of ArLD allows specialists to intervene and alter disease trajectory, whilst those without ArLD may be best served by community alcohol services. We assessed the effectiveness of a primary care referral pathway using the enhanced liver fibrosis (ELF) test to stratify patients with AUD and facilitate specialist referral of those with ArLD. **Methods:** The ELF ArLD pathway was established in January 2020, and evaluated over the subsequent 3 years. Patients assessed using the pathway were compared to those referred to the Royal Free Hospital using standard care (SC). Laboratory ELF tests for AUD were used to identify patients assessed in primary care, and their outcomes determined from primary care and hospital electronic medical records. The clinical status of all patients assessed in specialist liver clinics was determined using a composite clinical judgement (examination, blood tests, elastography, imaging and biopsy if performed) from electronic records. An “appropriate” referral was deemed to constitute the presence of at least steatosis. **Results:** Using SC, 132 patients were referred, of which 98.5% (n = 130) were appropriate. At least advanced fibrosis was present in 68.9% (n = 91), 56.5% (n = 74) had cirrhosis, and 30.3% (n = 40) were decompensated at referral. On the ELF pathway, 30 patients (29.1%) with AUD avoided referral. Of the 69 patients referred using ELF, 89.9% (n = 62) were appropriate; 29% (n = 20) had advanced fibrosis and 10.1% (n = 7) were cirrhotic. Patients referred via SC were 91% more likely to be cirrhotic (OR = 0.088; CI = 0.038-0.201) and 82% more likely to have advanced fibrosis (OR = 0.184;CI = 0.097-0.348). **Conclusion:** The majority of patients referred using SC had established cirrhosis when first seen compared to 10% of ELF referrals, indicating that use of the pathway facilitated specialist intervention before liver damage was irreversible. Use of ELF avoided unnecessary specialist referral in 30% of cases. In patients with AUD, the ELF pathway may be used for early detection of ArLD to permit specialist intervention and avoid unnecessary referral of people with AUD without ArLD. The low uptake of the pathway has been attributed to poor dissemination of the pathway impacted by the COVID-19 pandemic, necessitating better implementation.

3772-C | THE IMPACT OF COVID-19 OUTBREAK BETWEEN FEBRUARY AND JUNE 2022 ON MANAGEMENT OF CHB OUTPATIENTS IN SHANGHAI:A CROSS-SECTIONAL STUDY

Shaowen Jiang, Simin Guo and Qing Xie, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine

Background: An outbreak of coronavirus disease 2019 (COVID-19) caused by Omicron BA.2 variant occurred from February to June 2022 in Shanghai, China, which severely disrupted citizens' daily life and work. However, little is known about the impact of this COVID-19 outbreak on the management of outpatients with chronic hepatitis B(CHB). **Methods:** A structured questionnaire was designed to learn about the continuity of antiviral treatment and HCC surveillance during the pandemic. CHB outpatients in our hospital were invited to answer this questionnaire online via WeChat app or in a face-to-face interview from November to December 2022. **Results:** Totally 487 responders were included in our analysis, comprising 394 on NA (nucleos/tide analogs) monotherapy, 40 on IFN (interferon)+NA therapy, 5 on IFN monotherapy and 48 without any antiviral therapy. From February to June 2022, interruption of NA occurred in 13.4% (58/434) of responders on NA therapy, 31% of whom suffered from > 4 weeks of NA discontinuation. Internet hospital was the main source of accessing NA during the lockdown phase, accounting for 43.5% (189/434). Interruption of IFN occurred in 57.8% (26/45) of responders on IFN ± NA therapy, 57.6% of whom suffered from > 4 weeks of IFN discontinuation. Multivariate logistic regression analysis showed that interferon-containing treatment and age were independently associated with interruption of antiviral therapy during this special period (OR = 8.338, 95%CI: 4.170-16.672, p < 0.001; OR = 0.964, 95%CI: 0.939-0.989, p = 0.005). Movement restriction ranked first (63.0%, 307/487)in all

reasons for delayed or unmet medical needs (accessing antivirals and outpatient review). 48.4% (236/487)of responders had an interval of > 6 months between two liver ultrasonic examinations, and COVID-19 pandemic was the top reason (34.7%, 82/236) for a delayed HCC surveillance. After the lockdown measure was lifted, 3.7% (18/487) of responders were found to develop HCC, 4.1% (20/487) had an abnormal liver function test, 5.1% (25/487) had a HBV-DNA rebound and 9.2% (45/487) have not performed any outpatient review so far. **Conclusion:** COVID-19 outbreak between February and June 2022 caused by Omicron BA.2 variant had a negative impact on management of CHB outpatients in Shanghai. Some measures should be taken to maintain the continuity of antiviral treatment and HCC surveillance in the future pandemic of COVID-19 and other diseases.

Disclosures: The following people have nothing to disclose: Shaowen Jiang, Simin Guo, Qing Xie

3773-C | THE LIVER TRANSPLANT CASCADE OF CARE AMONG PATIENTS REFERRED FROM A SAFETY NET HOSPITAL

Sarah Wang[1], Matt Sumethasorn[2], Mark Chang Wang[3], Jihane N. Benhammou[4], Christopher Wong[3], Kali Zhou[1] and Saroja Bangaru[3], (1)University of Southern California, Los Angeles, CA, (2)Keck Medical Center of USC, (3)University of Southern California, (4)University of California, Los Angeles, Los Angeles, CA

Background: Safety-net hospitals provide essential care to low-income adults in the United States (US), who have high burden of end-stage liver disease yet face significant barriers to accessing life-saving liver transplantation (LT). We aimed to describe the LT cascade of care in a large US safety-net system and determine predictors of completing an initial evaluation. **Methods:** This was a multi-site retrospective study of adult patients with end-stage liver disease who received outpatient hepatology care at LA General (LAG) Medical Center (2nd largest county hospital in the US) and were referred to USC or UCLA transplant centers for LT evaluation between 2016-2022. Primary outcome was completing a LT evaluation defined as an initial visit with a transplant hepatologist. Logistic regression was performed to determine clinical and sociodemographic predictors of outcome. Covariates with univariate $p < 0.1$ were included in multivariate models, with additional adjustment for age, race and ethnicity, and LT evaluation site. **Results:** Results: 318 patients were referred from LAG for LT evaluation. The mean age was 58 years; 64% were male, 81% Hispanic, 75% foreign born; 33% reported English as primary language, and 80% had Medicaid insurance. 55% had ETOH-assoc. cirrhosis, 17% had HCV, and 14% had NASH cirrhosis. The mean MELD-Na was 16. 80% had history of clinical decompensation. 238 (75%) were evaluated; 135 (58%) were listed, and 64 (48%) were transplanted (Figure 1). Of 80 patients not evaluated, most were due to lack of financial clearance followed by death (Figure 1). Per univariate analysis, patients completing evaluation were more likely to be married, have NASH vs. HCV, prior variceal hemorrhage or SBP; less likely to have unstable housing or shorter than 6-months sobriety. NASH cirrhosis (OR 5.60, 95% CI 1.47-21.34), over 6 months sobriety (OR 3.60, 95% CI 1.39-9.34) and unstable housing (OR 0.30, 95% CI 0.10-0.93) were significant predictors of completing LT evaluation. Patients who were evaluated had higher 1-year (84.4% vs. 67.0%) and 5-year (52.3% vs. 36.8%) survival ($p < 0.001$). **Conclusion:** One out of four safety-net patients referred for LT did not complete an initial evaluation, over half of which were due to financial clearance. Our data suggest optimizing insurance pathways in safety-net systems is critical to tackling referral drop-offs for LT and improving survival.

3774-C | THE NUTRITION IN CIRRHOSIS GUIDE AND ITS POTENTIALLY BENEFICIAL IMPACT ON PATIENTS WITH CIRRHOSIS

Manila Sophasath[1], Mélanie Tremblay[2], Christopher F. Rose[3] and Chantal Bémeur[1], (1)Université De Montréal, (2)Hepato-Neuro Laboratory, Centre De Recherche Du Centre Hospitalier De l'Université De

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Montréal, (3)Université De Montréal, Montreal, QC, Canada

Background: Liver disease affects 1 in 4 Canadians. One of the most common complications of chronic liver disease is malnutrition, associated with decreased quality of life. Very few studies have focused on nutritional education resources for this population rendering their development and evaluation essential. The general objective is to assess the potential impact of the evidence-based *Nutrition in Cirrhosis Guide* on cirrhotic patients followed at the CHUM's liver outpatient clinic. The first specific objective is to quantitatively assess nutritional knowledge, quality of life and nutritional status. The second is to qualitatively assess the patients' satisfaction of the *Guide*. **Methods:** A randomized controlled study including 100 cirrhotic patients in 2 groups: Guide+ (n = 50) and Guide- (n = 50), is on-going. All patients are assessed for nutrition knowledge, quality of life and presence of malnutrition at baseline, 3 and 6 months. The *Guide* is taught to Guide+ patients for 6 months. Guide- patients do not use the *Guide*. The qualitative part evaluates patients' satisfaction of the *Guide* through 5 focus groups 3 patients) to assess general appreciation, complexity and applicability of the *Guide*. A patient-partner participates in focus groups. Preliminary **Results:** To date, 23 patients have completed the study: Guide+ (n = 12) and Guide- (n = 11). The preliminary results show a trend of improvement of nutrition knowledge for Guide+ patients (from 76.0% to 80.4%) after 3 months, not maintained at 6 months (down to 76.4%; $p > 0.05$). The Guide- patients' knowledge remains unchanged throughout the study. There is a trend of improvement in malnutrition in the group Guide+ (58.3% of patients initially malnourished, 41.7% at 3 months and 20.0% at 6 months; $p > 0.05$), which worsened in the group Guide- (from 36.4% to 54.5% at 3 months, to 45.5% at 6 months). Preliminary results from focus groups suggest an overall satisfaction towards the content, but a need to lighten and better divide the concepts. **Conclusion:** A trend of improvement is denoted in patients' nutritional knowledge over 3 months, not maintained at 6 months, and a decrease in the presence of malnutrition after 6 months. The results of this project will help optimize the quality of care for cirrhotic patients.

3775-C | TRAVEL TIME TO LIVER TRANSPLANTATION CENTERS IN THE UNITED STATES

Xiaohan Ying[1], Walter Mathis[2], Emily Smith[1], Peter Kahn[2], Arun Jesudian[1], Russell Rosenblatt[1] and Brett Fortune[3], (1)Weill Cornell Medicine, NY, (2)Yale School of Medicine, New Haven, CT, (3)Montefiore Medical Center

Background: Currently, over 11,000 patients are waiting to have a liver transplant (LT) in the United States. Despite recent emphasis on improving equity in access to LT, gender, racial, and socioeconomic disparities persist. One additional contributor to unequal access is geographic distance; increased distance from liver transplant centers (LTCs) is associated with lower transplant rates and increased mortality. However, travel time has emerged as a more accurate measure of geographic access. To our knowledge, this is the first study to examine geographic access to LTCs in the US using travel-time. **Methods:** Organ Procurement & Transplantation Network was queried for LTCs. Population and coordinates of every census block in the Continental US were extracted from the 2020 US census. Travel-times were computed using an Open-Source Routing Machine server built on Open Street Network data. For map representations, we computed population-weighted mean travel-times for each census tract. **Results:** In the US, 143 LTCs performed 9,236 total transplants in 2021. 55.4% of the US population lives within 60 minutes of the nearest LTC, and 67.3% and 76.8% live within 90 and 120 minutes, respectively. 23.2% (76.5 million people) live more than 2 hours away from the nearest LTC. (Figure 1) On a state level, Connecticut is the only state where over 90% of the population resides within 60 minutes of the nearest transplant center, and 6 additional states have more than 75% of the population living within 60 minutes. In nine states, more than 75% of the population lives beyond 120 minutes from the nearest center, including six where more than 75% of inhabitants lives further than 180 minutes. Of the ten most populous states, New York (69.0%) has the highest percentage of its population living within 60 minutes of the nearest LTC, while North Carolina (41.2%) has the lowest percentages. **Conclusion:** While proximity to LTC by travel time appears adequate on a national level, state-to-state variability is profound. Given the highly specialized and resource-heavy nature of liver transplantation, it is not feasible to reduce geographic disparities by establishing new LTCs. Alternative solutions must

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

be explored; one possible solution is to expand telemedicine infrastructure, as access to virtual care has been demonstrated to reduce wait time between initial referral and formal evaluation. Additionally, it is crucial to strengthen partnerships between LTCs and local primary care specialist providers.

3776-C | TRENDS IN ORAL MEDICATIONS FOR HEPATITIS C IN MEDICARE POPULATION FROM 2013 TO 2020

Xiaohan Ying, Emily Smith, Rochelle Wong, Nicole Palmer, Russell Rosenblatt and Arun Jesudian, Weill Cornell Medicine, NY

Background: Chronic hepatitis C (CHC) is a major cause of liver-related morbidity and mortality globally, and there are an estimated 2.4 million people in the United States living with CHC. Since 2013, the FDA has approved numerous oral medications for CHC with curative intent. We aim to analyze Medicare Part D utilization and spending on oral antiviral medications for CHC. **Methods:** We used publicly available Medicare Part D data (2013-2020) to determine the number of beneficiaries who received these medications and the associated total annual spending. Join-Point Regression was used for annual percent change (APC) and trends analysis. **Results:** Eight medications were included in our study: Solvaldi®, Harvoni®, Epclusa®, Zepatir®, Mavyret®, Vosevi®, generic ledipasvir-sofosbuvir, and generic sofosbuvir-velpatasvir. Between 2013 and 2020, total Medicare spending was $29.8B; $18B (60.4%) was spent on Harvoni®, followed by $5.8B (19.6%) for Sovaldi®, and $3.5B (11.8%) for Epclusa. Total Medicare spending increased significantly from 2013 to 2015 (APC 1868%, 95% CI: 1450% to 2399%, $p < 0.001$) followed by a steady decline after 2015 (APC -35.7%, 95% CI: -39.1% to -32.2%, $p < 0.001$). Figure 1. Within the same period, a total of 412,680 Medicare beneficiaries received these medications with similar observable trends over time (2013-2015: APC: 1059%, 95% CI: 709% to 1561%, $p < 0.001$; 2015-2020: APC -23.7%, 95% CI -29.6% to -17.3%, $p = 0.002$). Over the study period, Medicare spending was ~$70,000 per person treated, with Sovaldi® costing ~$90,000 per person and Harvoni® ~ $83,000. In 2019, two generic medications were introduced (ledipasvir-sofosbuvir, sofosbuvir-velpatasvir) both costing ~$22,000 per person. Medicare spending on Sovaldi® and Harvoni ® within the first two full years of their respective approval accounted for over 50% of total Medicare Part D spending on CHC medications during our 2013 – 2020 study period. **Conclusion:** The introduction of highly effective oral medications has revolutionized CHC treatment. It is estimated that approximately half of the CHC infected Medicare population was treated between 2013 and 2016. While a significant number of Medicare beneficiaries with CHC has been treated, reduced cost of treatment with the introduction of generic medications has the potential to expand access considerably.

3777-C | UNLOCKING THE POWER OF LIVER TRANSPLANT REFERRALS: A JOURNEY THROUGH A PENNSYLVANIA COMMUNITY HOSPITAL

Adalberto Guzman[1], Evelyn Calderon Martinez[1], Wern Lynn Ng[1], Anas Atrash[1] and Douglas M. Levin[2], (1) UPMC, (2)Ohio State University, Columbus, OH, United States

Background: Cirrhosis accounts for about 34,000 deaths annually in the United States. Access to Liver transplantation (LT) has shown a profound improvement in the management of advanced liver disease. Liver transplant is indicated for severe acute or advance chronic liver diseases when the limits of medical therapy have been reached. About 95% of patients with end stage liver disease are not referred for transplant evaluation, even when the criteria are met. We present the results of the retrospective phase of a quality improvement project to increase liver transplant referral rates in our hospital. **Methods:** Using Epic's SlicerDicer function, patients admitted during November and December of 2022 with a diagnosis of cirrhosis of any type were identified using ICD-10 codes. Those with incomplete information or duplicated were excluded obtaining a total of 71 patients. We used chi-square test to analyze between group differences for mortality and readmission analysis. The Fisher exact test was employed when any of the expected frequencies was five or less. We used the Wilcoxon rank-sum test or Kruskal-Wallis test to analyze the differences in length of stay, as appropriate. A p value less than 0.05 was considered statistically significant. All the analyses were done by SAS 9.4 (SAS Institute, Cary NC). **Results:** From the 71 patients, 46 (64.7%) were male. More than 70% had either Medicare or Medicaid as primary insurance. The readmission rate at 7 days was 14% and at 30 days was 35.2%. In our population the mortality rate for 3 months was 21%. There was a statistically significant difference in mortality when comparing patients that were referred to a liver transplant center (independent from transplant status) vs those who were not referred ($p = 0.0375$). The mortality rate was higher in patients that had an outpatient follow-up (with either PCP or GI/hepatology specialist) in comparison with those who did not ($p = 0.0005$). **Conclusion:** The access to a liver transplantation referral, a close follow-up after discharge can make a significant difference in mortality in patients with end-stage liver disease. Multiple reasons have been identified for a lack of referrals. This project aims to create a medical health record order set for clinicians to refer potential liver transplant candidates based on the American Association of Liver diseases

Patient Demographics

3778-C | "HAVING ANOTHER OUTLET TO DISCUSS THEIR DISEASE, THEIR WORRIES, THEIR FEARS…WITH SOMEBODY WHO ISN'T THEIR HEPATOLOGIST" PALLIATIVE CARE CLINICIANS' EXPERIENCE FROM THE PAL LIVER STUDY

Nicholas Hoppmann[1], Manisha Verma[2], Stephanie Ford[3], Margaret Armstrong[3], Macy Stockdill[4], Victor J. Navarro, Md[5] and Marie Bakitas[3], (1)Columbia VA Healthcare System, Columbia, SC, (2)Einstein Healthcare Network, (3)University of Alabama at Birmingham, (4)National Institute of Health, (5)Albert Einstein Medical Center, Doylestown, PA

Background: Palliative care (PC) is an integral part of managing patients with chronic illness and high symptom burden including end-stage liver disease

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

(ESLD). Given the limited PC workforce, as a part of the Pal-Liver comparative effectiveness trial, we compared ESLD patient outcomes between patients who received PC provided by PC-trained hepatologists vs. PC specialists (PCORI-NCT03540771). As part of a larger qualitative interview study of patients, caregivers and clinicians participants, we describe PC specialists' experiences caring for patients with ESLD and their caregivers as part of the Pal-Liver study. **Methods:** We conducted qualitative interviews with PC specialist participants within the 18-institution cluster-randomized comparative effectiveness trial of PC delivered by PC-trained hepatologists (10 sites) vs PC specialists (8 sites) to ESLD patients and caregivers. Trained interviewers used a semi-structured guide to interview hepatologists (n = 13) and PC specialist (n = 15) participants to explore pre- and post-study experiences, challenges, and benefits, in providing specialty PC for patients with ESLD. Phone interviews were digitally-recorded, transcribed verbatim, coded, and analyzed aided by NVIVO 12 software. We constructed a consensus-driven code book of emergent manifest and latent themes. Here we report preliminary analysis of PC specialist's perspectives. **Results:** PC specialist participants (n = 15) from the 8 PC specialist-provided institutions had a mean age of 49.8 years and were mostly female (93.3%) and white (86.6%). Main themes included: 1) patients and caregivers appreciated having a non-transplant clinician with whom to discuss their concerns 2) patients and caregivers lacked awareness of the role of PC 3) early PC referral and increased collaboration occurs with PC-minded hepatologists; 4) the study raised PC clinicians' awareness and desire for hepatology and transplant-specific education; 5) true primary PC integration in ESLD requires hepatologists' training as well as additional time for implementation during patient encounters. **Conclusion:** Pal-Liver PC clinician participants identified patient and caregiver's appreciation of communication with a non-transplant clinician, the need to clarify the role of PC, the value of hepatologists PC champions, but also recognized that primary PC training alone will not increase PC implementation until additional time is available during patient encounters. Future analysis will compare hepatology and PC specialist perspectives to inform pragmatic PC delivery models.

3779-C | A REMOTE INTERACTIVE EXERCISE PROGRAM FOR PATIENTS WITH CIRRHOSIS AND FRAILTY: THE FITNESS IMPROVEMENT WITH TELEHEALTH (FIT) PILOT EXPERIENCE

Eric S. Orman[1], Andrea Burkhardt[1], Kelsey Green[2], Archita Parikh Desai[1], Niharika R. Samala[3], Naga P. Chalasani[4] and Malaz Boustani[1], (1)Indiana University, (2)Indiana University School of Medicine, (3)Indiana University, Indianapolis, IN, (4)Indiana University Medical Center, Indianapolis, IN

Background: Individual's with cirrhosis are often physically frail and may benefit from exercise. However, in-person supervised programs may have limited reach, and home-based self-directed programs have been plagued by poor adherence. We developed a video telehealth-based exercise program for patients with cirrhosis and frailty to overcome obstacles limiting previous programs. **Methods:** Patients with cirrhosis seen in outpatient hepatology clinics at Indiana University were screened for frailty. Those with frailty (Liver Frailty Index [LFI] $\geq$ 4.5) were invited to participate in a 12-week interactive two-way video telehealth exercise program (Fitness Improvement with Telehealth [FIT]), consisting of 45-minute seated exercise sessions three times weekly. Pre- and post-program LFI, quality of life (SF-36), anxiety (GAD-7), depression (PHQ-9), and feedback (Net Promoter Score [NPS]) were compared. **Results:** 90 patients were screened, of whom 24 were frail. Eight participated, 6 completed all sessions, and 7 provided end-of-study measures. The median participant age was 60, 50% were female, and 63% were members of a racial or ethnic minority group. 75% were on Medicare and/or Medicaid, and none were employed (3 disabled). The median BMI was 36 kg/m^2, median Charlson comorbidity score was 5, 38% had impaired basic ADLs, and 63% had impaired instrumental ADLs. Comparing scores pre- and post-intervention, LFI did not change (pre 5.2 vs. post 5.1), and there were no significant differences in SF-36 scores: vitality (pre 17.5 vs. post 35, p = 0.62), physical function (27.5 vs. 50, p = 0.73), bodily pain (46 vs. 75, p = 0.13), general health (37.5 vs. 47, p = 0.80), physical role (75 vs. 75, p = 0.44), emotional role (100 vs. 100, p = 0.86), social role (68.8 vs. 76, p = 0.97), mental health (84 vs. 84, p = 0.13), physical component score (28.7 vs. 36.6, p = 0.18; Figure), and mental component score (56.3 vs. 55.6, p = 0.24). GAD-7 was also unchanged (pre 5 vs. post 2, p = 0.63), as was PHQ-9 (10 vs. 8, p = 0.80). On

the NPS, 4 rated FIT a "10," and the overall NPS was 28.6. **Conclusion:** Patients with cirrhosis and frailty who participated in the FIT program had high completion rates and satisfaction with the program. However, initial participation rates were low. Future work is needed to identify ways to spur initiation of behavior change in those with cirrhosis and frailty. After initiation, the FIT program may be a scalable and sustainable way to maintain physical exercise in this population.

3780-C | ADDRESSING HEPATITIS C (HCV) MICRO-ELIMINATION GOALS: AN IMPLEMENTATION SCIENCE INITIATIVE IN PARTNERSHIP WITH STATE AND LOCAL HEALTH DEPARTMENTS

Ricardo A. Franco[1], Seema Gupta[2], Jeffrey Carter[3], Melissa Rodriguez[3], Laura Simone[3] and Leah Molloy[3], (1)University of Alabama at Birmingham, (2)Marshall University Joan C Edwards School of Medicine, (3) PRIME Education

Background: The elimination of Hepatitis C virus (HCV) infections is a national priority. State and local health departments play critical roles in HCV prevention and treatment, but setbacks in outreach activities related to the COVID-19 pandemic have restricted the availability and accessibility of these services. To support HCV micro-elimination goals, we partnered with state and county departments of health in two states - West Virginia (WV) and Alabama (AL) - to improve healthcare professional (HCP) and patient engagement in the HCV care cascade through education designed to identify and close local and regional gaps in HCV awareness, knowledge, screening, and linkage to care. **Methods:** Between September 2021 and December 2021, 6 live patient education programs were led by HCPs in community centers and clinics in West Virginia. Surveys were administered before and after each session. The initiative was scaled up to deliver three additional sessions in Alabama in April 2022. **Results:** Surveys were conducted amongst the 385 participating patients. 13% of the 71 patients in WV and 55% of the 314 patients in AL reported a past diagnosis of HCV. Patient knowledge about HCV and hepatocellular carcinoma, symptoms, cure, and reinfection improved after the sessions (Figure). Amongst the 61 participating HCPs (23 in WV and 38 in AL), confidence in counseling patients improved following the program. More providers felt confident in counseling patients on HCV test results ($\mathbf{p = 0.009}$; 100% in WV; 78% in AL) and linking newly diagnosed patients ($\mathbf{p = 0.003}$; 95% in WV; 89% in AL) than at baseline (76% in WV; 58% in AL and 76% in WV; 61% in AL, respectively). When asked what they thought would keep patients from starting or adhering to HCV treatment, HCPs identified inability to pay (37%) or patient perceptions that medications are not effective or necessary (21%), while patients reported fear of negative judgment (23%) and uncertainty of where to get medication (23%) as their top barriers. Following the programs, HCPs identified increasing patient awareness and access to HCV screening as their top goal to improve care (84% in WV and 78% in AL). **Conclusion:** Patient knowledge and attitudes about HCV varied, as did provider perceptions about patients' barriers to care. Educational sessions can help to narrow knowledge gaps among patients and improve provider confidence in patient counseling, increasing the potential for changes in behavior related to HCV awareness and management.

3781-C | ADVANCED CARE PLANNING FOR PATIENTS WITH CIRRHOSIS, THE FIRST EXPERIENCE OF TERTIARY LIVER UNIT

Daniel Ján Havaj[1], Karolina Kristina Sulejova[1], Jana Vnencakova[1], Beáta Škvarková[1], Simona Zemanová[2], Svetlana Adamcova Selcanova[1] and Lubomir Skladaný[1], (1)University Hospital of F. D. Roosevelt, (2)No

Background: Cirrhosis is a leading cause of mortality and morbidity across the world. The clinical trajectory is unpredictable and the development of acute decompensation with complications is associated with a significant lowering of median survival in the absence of liver transplantation. These barriers impair the patient's ability to participate in decision-making, leading to invasive life-sustaining therapies during their end-of-life. Advanced care planning represents the process over the course of illness trajectory involving the assessment of goals, values, and preferences, designation of a surrogate decision-maker, and documentation of patient will. The aim of this pilot study is to evaluate the portrait of patient goals of care in our register of cirrhosis, including end-of-life. **Methods:** In the following period, we evaluated patient goals of care by the validated ACP questionnaire in all patients first time hospitalized in our liver unit and enrolled into the local register of cirrhosis. **Results:** The questionnaire was proposed to 268 patients between May 2022 and 2023, 237 patients (88%) were accepted to participate (140 men (59%), 97 women (41%), mean age 55,4 years, CHP 8,6, MELD-Na 19,3). 41% were admitted because of acute decompensation and nearly half of them (49%) because of ACLF. 19% were evaluated as candidates for liver transplantation. The mean quality of life was 8,1 (EQ-5D), the mean LFI was 4,1 and overall mortality was approximately 20% (28 d 12,7%, 90 d 17,8%, 365 d 20,76%). The majority of patients in case of acute deterioration prefer an active approach, only 7% don't want to be admitted and approximately 7% don't want to receive antibiotics and intravenous therapy. More than a quarter of patients disagree with artificial feeding via a tube through the nose (30%) or into the stomach (25%). 4% of patients don't want to be resuscitated. The majority of patients prefers to spend their last few days at home, and only 11% prefer hospital or hospice care. 98% of patients identified a surrogate decision maker, and 15% gave someone a power of attorney. 10% of patients were assigned a decision to refuse treatment. The majority of patients (97%) made the decision to formally share goals of care with healthcare providers. 70% of patients would like to discuss their wishes for future care in the end stage of their life. When we looked at the different attitudes on the questions about don't resuscitate, identification of a surrogate decision maker, and readiness for discussion about end-of-life, there was no difference in terms of age, sex, etiology, disease severity, quality of life, and frailty index. **Conclusion:** ACP is crucial for providing healthcare consistent with patient goals and values, especially at the end of life. This study described the first experiences with advanced care planning in our tertiary liver unit and reveals the patient's wishes for health care.

3782-C | ALCOHOLIC LIVER DISEASE AND NON-ALCOHOLIC FATTY LIVER DISEASE WERE THE MAIN DRIVERS OF CIRRHOSIS RELATED DEATHS BEFORE AND DURING THE COVID-19 PANDEMIC IN THE UNITED STATES

James M. Paik[1,2,3], Dipam Shah[4], Katherine Elizabeth Eberly[4], Pegah Golabi[1,2,3], Linda Henry[1,2,4] and Zobair M. Younossi[1,2,3], (1)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (2)Center for Liver Disease, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, VA, (3)Inova Medicine, Inova Health System, Falls Church, VA, (4)Inova Health Systems Medicine Service Line, Falls Church, VA

Background: Although liver mortality increased during the COVID-19 pandemic, the impact may differ according to the etiology of liver disease [hepatitis B virus (HBV), hepatitis C virus (HCV), alcoholic liver disease (ALD), and non-alcoholic liver disease (NAFLD). **Aim:** To assess changes in liver-specific deaths attributable to HBV, HCV, ALD, and NAFLD after the COVID-19 Pandemic start. **Methods:** We assessed liver-specific deaths in the U.S. using death data (2011-2021) obtained from National Vital Statistics System (NVSS). The average annual percentage change (AAPC) from the models selected by Joinpoint regression analysis over the pre-pandemic (2011-2019) and then from 2019-2021 were reported because non-linear trend in death rates were observed over the 2011-2021. Liver-specific death was defined as an underlying cause of death. **Results:** During the pre-pandemic, age-standardized hepatocellular carcinoma (HCC)- and cirrhosis-related

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

death rates increased by AAPC = +1.18% (95% confidence interval, 0.34% to 2.03%) and AAPC = +1.95% (1.56% to 2.35%). In this context, during the 2019-2021, the AAPC in age-standardized cirrhosis-related death rate (per 100,000) accelerated: AAPC = +11.25% (15.23 in 2019 to 18.86 in 2021) whereas that in age-standardized HCC-related death rate slowed down to AAPC = -0.39% (-1.32% to 0.54%). According to the etiology of liver disease, during the 2019-2021, the age-standardized cirrhosis-related death rates from ALD and NAFLD increased by AAPC = +17.29% (12.21% to 20.38%) and AAPC = +8.21% (3.52% to 10.42%). In contrast, the age-standardized cirrhosis-related death rates from HCV and HBV decreased: AAPC = -3.07% [-4.83% to -1.53%]) and AAPC = -0.88% [-2.98% to 1.31%]).After pandemic start to 2021, ALD was responsible for 47.32% of the increase in cirrhosis-related deaths followed by NAFLD (40.85%), HCV (2.51%); and HBV (0.16%). Interestingly, a differential increase in ALD-cirrhosis deaths and NAFLD-cirrhosis deaths were observed according to age: ≥ 65 years (ALD 69.86% and NAFLD 53.32%), 45-64 years (29.35% ALD and 39.13% NAFLD), and 20-44 years (ALD 0.79% and NAFLD 7.55%). **Conclusion:** Increases in cirrhosis-related deaths were driven by ALD and NAFLD. ALD predominantly affected patients ≥ 65 years old while NAFLD affected the younger population.

3783-C | ASSOCIATION BETWEEN CIRRHOSIS AND SEVERE COVID-19 OUTCOMES: A POPULATION-BASED COHORT STUDY IN CANADA

Héctor Alexander Velásquez García[1,2], Prince Adu[2], Dahn Jeong[1], Jean Damascene Makuza[1,2], Georgine Cua[2], Mawuena Binka[1,2], James Wilton[2], Hind Sbihi[2] and Naveed Zafar Janjua[1,2,3], (1)University of British Columbia, (2)British Columbia Centre for Disease Control, (3)St. Paul's Hospital

Background: Population-level evidence for the association between cirrhosis and COVID-19 severe outcomes remains an important knowledge gap. We assessed the association between cirrhosis and COVID-19-related severe outcomes (hospitalization and intensive care unit [ICU] admission) among individual's who have tested positive for COVID-19. **Methods:** We used data from the British Columbia (BC) COVID-19 Cohort, a population-based surveillance platform that integrates data on all individual's tested for COVID-19, with data on hospitalizations, medical visits, emergency room visits, prescription drugs, chronic conditions, and deaths in the Canadian province of BC. We included all individual's aged 18 or above who tested positive for SARS-CoV-2 by real-time reverse transcription-polymerase chain reaction, from January 01 to December 31, 2021. Multivariable logistic regression models were used to assess the associations between cirrhosis status and COVID-19 related hospitalization and ICU admission, adjusting for age, sex, variant of concern, comorbidities, area-level income, geographic area, and vaccination status. Cirrhosis was identified with a validated algorithm using relevant ICD-9/10 codes. Hospitalization was defined as admission to a BC acute care facility within 14 days after a positive SARS-CoV-2 test, and ICU was defined as admittance to ICU during hospitalization. **Results:** This analysis included 162,509 individual's of whom 768 (0.5%) had cirrhosis. Compared to individual's without cirrhosis, those with cirrhosis had a higher rate of ICU (12.8% v. 1.5%) and hospital (17.2% v. 3.6%) admission. In the adjusted models, cirrhosis was associated with increased odds of hospitalization (excluding ICU cases, aOR = 1.97, 95%CI: 1.58–2.47; including ICU cases, aOR = 2.55, 95%CI: 2.11–3.08) and ICU admission (aOR = 3.33, 95%CI: 2.56–4.35). Cirrhosis was also associated with increased odds of ICU admission among individual's who were already hospitalized (aOR = 1.84, 95%CI: 1.38–2.46). Stratified analyses by age showed increased odds of hospitalization and ICU among people with cirrhosis across all age-groups (18-49, 50-69 and ≥ 70 y). **Conclusion:** Cirrhosis is associated with greater odds of hospitalization and ICU admission among COVID-19 patients. These findings emphasize the importance of timely monitoring, prioritization of COVID-19 vaccination, and early treatment for people living with cirrhosis to prevent and mitigate severe COVID-19 outcomes.

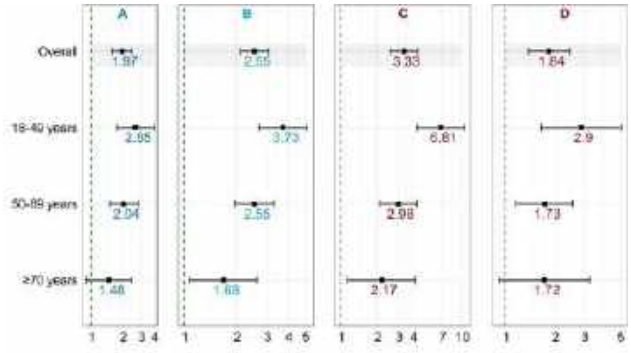

Figure 1. Cirrhosis overall and age-stratified adjusted odds ratios for COVID-19-related hospitalization and ICU admission.

A: Outcome hospitalization: Hospitalization (excludes ICU admissions) vs. non-hospitalization.
B: Outcome hospitalization: Hospitalization (includes ICU admissions) vs. non-hospitalization.
C: Outcome ICU: ICU admissions vs. non-hospitalization.
D: Outcome ICU: ICU admissions vs. hospitalization.

3784-C | CENTERING THE PATIENT VOICE IN MULTI-STAKEHOLDER ENGAGEMENT TO DEVELOP A STRATEGIC RESEARCH PLAN FOR THE PSC COMMUNITY

Jessie D. Kirkpatrick[1,2], Mahesh Krishna[1,3], Sarah Curup Callif[1], Mary Pressley Vyas[4], Rachel Gomel[1], Matthew McMurtry[1], Willie McKinney[1], Christopher L. Bowlus[5], Daniel S. Pratt[6], Joshua R. Korzenik[7], Ricky Safer[1], Joanne Hatchett[1], Stephen J Rossi[1] and Ruth-Anne Pai[1], (1)PSC Partners Seeking a Cure, (2) Massachusetts Institute of Technology, (3)Johns Hopkins Medical School, (4)PSC Partners Seeking a Cure Canada, (5)University of California Davis, Sacramento, CA, (6)Massachusetts General Hospital, (7)Brigham and Women's Hospital

Background: Primary sclerosing cholangitis (PSC) is a rare, progressive immune-mediated liver disease with no Food Drug and Administration (FDA) approved treatments available. Drug development is limited due to poor understanding of the pathophysiology of PSC, with no surrogate endpoints or validated patient-reported outcomes. PSC Partners Seeking a Cure aimed to generate an organizational research plan with patient and researcher input to better understand and address these gaps. **Methods:** Our interdisciplinary team of PSC Partners representatives and clinical researchers led a two-year process to develop a strategic research plan (SRP) with 4 stages: 1) Organization of an externally-led patient-focused drug development (EL-PFDD) meeting with the FDA. 2) A series of focus groups to discuss symptoms, patient-reported outcomes, research, natural history, and drug development. 3) Review of the scientific literature and interviews with 9 PSC researchers to capture gaps in understanding of PSC. The first three steps informed the development of the draft research agenda. 4) Discussion of the draft research agenda within focus groups at the PSC Partners Annual Conference in 2022. Participants provided research recommendations which were analyzed by our interdisciplinary team and scored using a standardized rubric. Both qualitative and quantitative data guided generation of the SRP. **Results:** These efforts incorporated the voices of more than 500 unique PSC patients and caregivers. More than 100 patients and caregivers participated in 15 focus groups and contributed 65 community recommendations across 6 diverse topics for future research directions. PSC researchers contributed 59 recommendations for future research directions, 22 of which (37%) aligned with the 65 community recommendations. Assessment of multi-stakeholder recommendations formed 4 pillars of focus for PSC Partners and the structure of the SRP: 1) Improve understanding of the mechanisms contributing to the development and progression of PSC, 2) Further understanding of the gut-liver connection in PSC, 3) Develop safe and effective treatments to slow progression and reduce symptom burden for those with PSC, and 4) Provide support and education through patient engagement and knowledge translation. **Conclusion:** This initial round of prioritization resulted in PSC Partners' efforts to develop surrogate endpoints and patient-reported outcome measures for clinical trials. Future support and new partnerships will further work across the 4 pillars as PSC Partners plays an active role in research and drug development to find a cure for PSC.

Figure 1: Novel approach to generating a strategic research plan consolidating researcher and patient priorities led by PSC Partners Seeking a Cure.

3785-C | CIRRHOSIS INCIDENCE AMONG YOUNG ADULTS (18-44) AND IN FEMALES - A POPULATION-BASED STUDY FROM 2010 TO 2019

Nabiha Faisal[1], Lisa Lix[1], Randy Walld[1], Alexander Singer[1], Eberhard Ludwig Renner[1], Harminder Singh[1], Leanne Kosowan[1] and Alyson Mahar[2], (1)University of Manitoba, (2)Queen's University

Background: The past decade has witnessed significant changes in the risk factors associated with cirrhosis that underscore the importance of ongoing efforts to prevent and manage this critical and potentially life-threatening condition. To facilitate the development of these strategies, our study aimed to investigate the temporal trends of cirrhosis incidence in Manitoba, Canada, as well as assess changes in these estimates across different age groups and between males and females. **Methods:** Individual level administrative healthcare data from Manitoba was used to identify individual's with cirrhosis between 2010-2019 using a validation algorithm (≥ 1 hospitalization or ≥ 1 physician claims; sensitivity, specificity, positive and negative predictive values include 68%,98%,19% and 99% respectively). To establish incident cases, we used a five-year look back window. Annual incidence rates were estimated using a generalized linear model and generalized estimating equations with a negative binomial distribution adjusting for age and sex. Linear trends of incidence by calendar year, overall and by age and sex, were tested using linear regression models. **Results:** Between 2010-2019, a total of 24,303 incident cases of cirrhosis were identified. Mean age at diagnosis was 50 years SD 15.8 and 51% were males. Age and sex adjusted incidence increased by 50% between 2010-2019 (264 vs 389/100,000). Incidence increased by 2-fold over the study period for aged 18-44 (144 vs 289/100,000) more among females than males (Figure 1). Cirrhosis incidence increased on average per year by 6% (95% confidence interval (CI) 5% to 7%, ($p < 0.001$), with the largest increase of 8% per year (95% CI 7% to 9%) $p < 0.0001$ in those aged 18-44 years. The youngest age group (ages 18-44 y) also exhibited the highest rate of increase in the incidence of cirrhosis compared to other age groups ($P < 0.001$). The incidence of cirrhosis showed a greater annual increase in females, with a rate of 7% per year (95% CI 5% to 8%), compared to males, who had a rate of 5% per year (95% CI 4% to 6%) ($p < 0.0001$). In addition, females demonstrated a significantly higher rate of change in cirrhosis incidence compared to males ($p = 0.0025$).

Conclusion: The incidence of cirrhosis substantially increased over the study period, signaling an alarming shift in the disease burden towards younger individual's and females. Public health action is required to implement an effective multi-faceted approach encompassing prevention, early detection, and the provision of high-quality healthcare.

f 3786-C | CIRRHOSIS PATIENT PERSPECTIVES ON PALLIATIVE CARE: A SURVEY PROJECT

Alan Noll[1], Rachel Hannum[1], Shalini Sivathasan[2], Nneka Ufere[3], Jennifer C. Lai[4] and Shari S. Rogal[2,5], (1) University of Pittsburgh Medical Center, (2)University of Pittsburgh, (3)Massachusetts General Hospital, (4) University of California, San Francisco, (5)VA Pittsburgh Healthcare System

Background: Despite a high physical and psychological symptom burden, patients with cirrhosis underutilize specialty palliative care (PC) services. When used, PC is often introduced late in the disease course, limiting potential benefit. While there has been an increasing call for earlier integration of PC into cirrhosis care, patients' preferences and needs have not been fully explored. We therefore aimed to understand the physical and psychological symptom burden, PC needs, and preference for PC among an outpatient cohort of patients with cirrhosis. **Methods:** From November 2022 to April 2023, patients with cirrhosis at a tertiary care center were recruited to complete a one-time survey. Survey items included: the Edmonton Symptom Assessment Scale (ESAS), questions about how often the 8 domains of PC (see Fig. 1) are addressed in hepatology clinic, and their preferences for PC. **Results:** N = 59 patients responded to survey questions ($M_{age} = 57 \pm 12$ y, 42% women, $M_{MELD} = 11 \pm 5$). Over half (61%) had decompensated cirrhosis, 5% had hepatocellular carcinoma, and none had previously seen PC. Top etiologies of liver disease were: Alcohol = 36%, NASH = 32%, hepatitis C = 8% and primary biliary cholangitis = 8%. Patients with decompensated cirrhosis reported more severe pain, lack of appetite, difficulty falling asleep, itchiness, leg swelling and overall symptoms ($ps < 0.05$). Patients universally wanted hepatology providers to ask about each of the 8 domains of PC at least once (Fig. 1). Prognosis and mental health were addressed significantly *less* than respondents preferred ($p < 0.05$). While most patients wanted hepatology providers to address the various domains of their PC needs, only 19% of respondents wanted to see specialists in PC; 35% reported that the most appropriate time to refer to PC was only once they were too sick to care for themselves. Older age was significantly associated with desire for PC ($p < 0.01$) among those with compensated cirrhosis, while female sex ($p = 0.007$) and higher symptom burden ($p < 0.01$) were significantly associated with desire for PC among patients with decompensated cirrhosis ($p = 0.01$). **Conclusion:** Almost all patients with cirrhosis wanted their hepatology providers to address the various domains of PC. While relatively few wanted to see PC specialists, those who did were more likely to be women, older, and those with higher symptom burdens.

3787-C | COINCIDENT LIVER DISEASE INCREASED THE RATE OF ICU CARE, ENDOTRACHEAL INTUBATION AND IN-HOSPITAL DEATH IN PATIENTS HOSPITALIZED WITH COVID-19

Jessica Ann Musto[1], Thomas M. Piasecki[1], Wendy S Slutske[1] and Michael R. Lucey[2], (1)University of Wisconsin, (2)University of Wisconsin School of Medicine and Public Health, Madison, WI

Background: The interaction of liver disease with COVID-19 infection has not been well elucidated. This study employed a national multi-center prospective database of patients with COVID-19 to compare mortality rates in hospitalized COVID-19 patients with and without liver disease. **Methods:** Data from all patients with COVID-19 who were hospitalized at 21 participating healthcare systems between February 1, 2020 and January 31, 2022 were recorded. Subjects were followed until hospital discharge or death. The main outcome of interest was in-hospital mortality. Secondary outcomes of interest were endotracheal intubation and ICU admission. The analyses used generalized linear mixed model logistic regression including random intercepts to account for the clustering of patients within healthcare systems. **Results:** Among 145,940 patients hospitalized for COVID-19, 48.9% male, ages 18-90+ years-old with median age 63 years-old, 7,217 (4.9%) had some form of liver disease. The presence of liver disease was associated with increased odds of all tested adverse outcomes in patients hospitalized with COVID-19. Of those patients with liver disease, 1,519 (21%) died while hospitalized with COVID-19 compared to 11,517 (8.3%) without liver disease (aOR 3.58, 95% CI 3.35, 3.82, $p < 0.001$). The presence of liver disease was also associated with increased odds of endotracheal intubation (aOR 3.03, 95% CI 2.87, 3.21, $p < 0.001$) and ICU admission (aOR 2.30, 95% CI 2.18, 2.42, $p < 0.001$). There was a clear gradient of mortality according to severity of liver disease (fibrosis OR < cirrhosis OR < decompensated cirrhosis OR) and each category of liver disease was associated with adverse outcomes compared to no liver disease. On multivariable analysis, liver disease, male gender, increasing age, higher BMI and former smoking status were all associated with increased mortality from COVID-19. **Conclusion:** In this large, observational cohort of hospitalized patients with COVID-19, mortality in patients with liver disease was triple that seen in patients without liver disease, and the rate of severe complications such as transfer to the ICU and endotracheal intubation were significantly more common in liver patients.

3788-C | COMPREHENSIVE CARE OF PATIENTS WITH CIRRHOSIS DECREASES LIVER DECOMPENSATION AND NEED FOR LIVER TRANSPLANTATION

Tarek I. Hassanein[1], Julian Diaz-Moreno[2], Noora Alqassim[2], Ahmed Atalla[2], Abdul Rahman Khan[2], Fatma Barakat[2], Anna Marie Hefner[2] and Deanna Oliver[1], (1)Gateway Comprehensive Medical Group, APC, (2)Southern California Liver Centers

Background: Chronic liver injury results in progressive fibrosis and ends in cirrhosis with decompensation and/or HCC. The primary goal in caring for patients with cirrhosis is to eliminate the primary liver injury and control other co-morbidities to prevent liver decompensation. In 2010, our Center deployed a systematic program of care for patients with cirrhosis. **Methods:** Between January 2010 and December 2022, 5352 patients (pts) with cirrhosis were seen. Primary liver disease, co-morbidities, medications, vital signs, outpatient visits, hospital admission, disposition, laboratory and imaging results amongst other variables were retrieved for all the patients. **Results:** The initial analysis included 750 consecutive cirrhotic patients and shows the following: 398 (53.1%) females. Mean age was 65.8 $\pm$ 10.6 years. 63% Hispanics and 89% whites. Visits: Median follow-up: 67 (1-156) months. Median number of outpatient visits at Hepatology practice is 21.5 visits (1-201) Underlying etiology of liver disease was primarily history of HCV (60%), Alcoholic liver disease (30%), and NASH (25%). Classification: Refer to table for Child Pugh classification and MELD changes from initial visit to last visit. Platelets count: 75% had platelets count < 150 at the initial visit versus 68% at their last visit. Disposition: 71.6% alive. 17% received a liver transplant. **Conclusion:** Eliminating primary liver injury, supported by managing co-morbidities in a closed intense care

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

program results in 1) minimizing liver decompensation, 2) prolonging survival, 3) decreases rates of hospitalization, 4) decreases need for liver transplantation and ultimately decreases cost of cirrhosis care. Further analysis of the data is underway.

Table		Last Visit	
		Compensated	Decompensated
Initial Visit	Compensated	88.6%	11.4%
	Decompensated	33.4%	66.6%
		MELD <15	MELD>15
Initial Visit	MELD <15	76.7%	23.3%
	MELD >15	21.4%	78.6%

f 3789-C | CROSS-SECTIONAL AND LONGITUDINAL ASSESSMENT OF THE EDMONTON SYMPTOM ASSESSMENT SYSTEM IN PATIENTS WITH DECOMPENSATED CIRRHOSIS

John Donlan[1], Chengbo Zeng[2], Teresa Indriolo[3], Lucinda Li[3], Joyce Zhou[3], Kedie Pintro[3], Nora Horick[3], Maria Edelen[2], Areej El-Jawahri[3] and Nneka Ufere[4], (1) Harvard Medical School, (2)Brigham and Women's Hospital, (3)Massachusetts General Hospital, (4) Massachusetts General Hospital, Boston, MA

Background: Understanding the symptom burden of patients with decompensated cirrhosis (DC) is critical for improving their health-related quality of life (HRQOL). The Edmonton Symptom Assessment System (ESAS) is a simple 10-item measure assessing physical and psychological symptoms that has been validated in patients with serious illnesses. This prospective longitudinal study aims to assess the face validity of the ESAS among outpatients with DC who concurrently completed the Short-Form Liver Disease Quality of Life (SF-LDQOL) questionnaire. **Methods:** Outpatients with DC were prospectively recruited from a single liver transplant center and completed the ESAS and SF-LDQOL at baseline and at 3 months. For both scales, we calculated the total scores for each timepoint and change in scores from baseline. We examined the correlations in total scores and change in scores between ESAS and SF-LDQOL. We employed regression analysis to examine whether change in ESAS scores was associated with change in SF-LDQOL scores, with adjustment for age, baseline MELD-Na, etiology of DC, transplant status, and history of ascites, hepatic encephalopathy (HE), variceal bleeding (EVB) and hepatocellular carcinoma (HCC). **Results:** From 7/2018-9/2022, we enrolled 218 patients with DC (median age 60 [IQR 51-65], median MELD-Na 16 [IQR 11-22], 48% alcohol-related liver disease, 50% listed for transplant, 92% ascites, 74% HE, 33% history of EVB, 12% HCC). At baseline, the mean total ESAS score was 37.7 (SD 19.9). The total ESAS score was significantly and negatively correlated with the SF-LDQOL total score ($r = -0.65$, $p < 0.01$) but was not correlated with MELD-Na score. At 3 months, 83 patients were unavailable for analysis due to death, liver transplant, or loss to follow-up. Of the remaining 135 patients, the change in SF-LDQOL scores was moderately correlated with changes in ESAS scores at 3 months ($r = -0.47$, $p < 0.01$) but not baseline MELD-Na scores. In bivariate analysis, the change of ESAS score explained 23% of the change of SF-LDQOL. In multivariable analysis, the change in total ESAS score was a significant predictor of the change in SF-LDQOL ($\beta = -0.34$, $p < 0.001$) (Table). **Conclusion:** The ESAS is a simple tool for longitudinally assessing symptom burden among patients with DC. The change in ESAS total score can account for the change in SF-LDQOL at 3 months. Future directions include implementation of ESAS in research and clinical practice as a key outcome measure in cirrhosis care.

Table. Predictors of change in SF-LDQOL by ESAS, controlling for MELD-Na score and other covariates

Outcome variable:	Predictor variable:	Univariate analysis			Multivariable analysis		
Change in		β (SE)	R^2	p	β (SE)	R^2	p
Baseline to Month 3 SF-LDQOL (N=135)						0.30	
	Age at baseline	-0.01 (0.12)	0.00	0.970	0.08 (0.12)		0.483

3790-C | DECOMPENSATED CIRRHOTICS WITH COVID-19 INFECTION HAVE A HIGHER POST HOSPITALIZATION MORTALITY COMPARED TO COMPENSATED CIRRHOTICS OR THOSE WITHOUT CIRRHOSIS

Ethan Berman[1], Alexa Giammarino[1], Jeffrey Lowell[1], Pratik Patel[2], Hassam Ali[3], Maham Ghani[1], Akash Singh[4], Edgewood Warner[1], Salima Makhani[1] and Sanjaya Kumar Satapathy[5], (1)Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, (2) Northwell Health, Forest Hills, NY, (3)East Carolina University, (4)Einstein Healthcare Network, (5)Division of Hepatology, Northwell Health, and Donald and Barbara Zucker School of Medicine at Hofstra/ Northwell, Hempstead, NY, USA.

Background: The COVID-19 pandemic had a profound and immediate worldwide effect resulting in significant mortality. Over three years from the first COVID-19 diagnosis in the United States, we are beginning to see the long term effects of the disease. There is an array of short term data published on the mortality of patients with chronic liver disease (CLD) and COVID-19; however, we lack sufficient long term follow-up information for CLD patients who survived COVID-19 infection. **Methods:** We retrospectively analyzed 192 patients admitted to any Northwell Health hospital in the state of New York for a COVID-19 infection who also had an ICD-10 diagnosis of chronic liver disease. We included 96 of the 143 patients with confirmed COVID-19 infection who survived their hospitalization and were discharged between March 2020 through April 2020. Of this final cohort of CLD patients, 87 had cirrhosis and 56 did not have cirrhosis. Patients without known follow up data were excluded (n = 47). Follow up was censored on November 22, 2022. Post hospitalization follow up data was analyzed to assess survival probability using Kaplan-Meier survival curves. **Results:** In patients with COVID-19 infection, those with CLD with cirrhosis had significantly higher age (p = 0.053) at admission, bilirubin (p = < 0.001), AST (p = 0.009), ALP (p = < 0.001), lactate (p = 0.028), INR (p = < 0.001), MELD (p = < 0.001) and lower platelet count (p = < 0.001) and albumin (p = 0.001) than patients with CLD without cirrhosis. Patients with cirrhosis had significantly lower ferritin (p = 0.053) and d-dimer (p = 0.023) compared to patients without cirrhosis. When evaluating follow up data, cirrhotic patients had higher post-hospitalization mortality than non-cirrhotic patients (p = 0.055). Patients with Child-Pugh class A cirrhosis had no mortality at day 900 post- hospitalization, which is similar to the mortality rate of chronic liver disease patients without cirrhosis. Survival probability in patients with Child-Pugh class A cirrhosis (100.00%) and no cirrhosis (89.71%) were significantly higher than those with Child-Pugh classes B (52.66%) and C cirrhosis (50.00%) (p = 0.006) (Graph 1). **Conclusion:** Patients with CLD (well compensated cirrhosis or no cirrhosis) who survived a COVID-19 hospitalization had significantly better post hospitalization survival than patients with decompensated cirrhosis. Greater efforts should be made to ensure adequate follow up for patients with CLD who are hospitalized with COVID-19, particularly in decompensated cirrhosis.

Graph 1: Survival among COVID-19 patients with chronic liver disease with and without varying degrees of cirrhosis

f 3791-C | Development and Validation of Prognostic Model to Predict Risk of Sepsis Among Patients With Cirrhosis

Somaya Albhaisi, Department of Internal Medicine, Virginia Commonwealth University, Richmond, VA, Ekaterina Smirnova, Virginia Commonwealth University, Richmond, VA and Arun Sanyal, Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Patients with cirrhosis are at risk for developing sepsis which is associated with high mortality. Prognostic tools estimating a patient's risk of sepsis could inform management. The aims of this study were to investigate predictors of sepsis and to develop a prognostic model among patients with cirrhosis. **Methods:** A total of 4045 adult patients with cirrhosis were included in the analysis from a retrospective single-center cohort. The demographic, clinical, and laboratory data were collected at baseline. A simplified prognostic model was developed using multiple logistic regression after identifying significant predictors of 30-day sepsis risk. **Results:** The 30-day overall risk of sepsis was 12.2%. Baseline characteristics of study population are summarized in table 1. Age, diabetes, hypertension, white blood cell count (WBC), hemoglobin (Hgb), creatinine, total bilirubin, and albumin were identified as independent risk factors for sepsis in cirrhosis patients. A new logistic model was developed from independent prognostic factors using multivariate analysis and calculated using the equation (0.97 x age) + (1.3 x diabetes) + (1.3 x hypertension) + WBC + (0.88 x Hgb) + (1.1 x creatinine) + (0.97 x total bilirubin) + (0.70 x albumin). This model's area under the receiver operating characteristics (AUROC) was 0.67. Validation analysis showed that the AUROC values were consistent (0.67) (figure 1). **Conclusion:** Our new simplified model can be used to predict the 30-day risk of sepsis among patients with cirrhosis which can lead to early identification of high-risk patients who might benefit from greater attention and early targeted interventions thus improving survival and patient care.

Table 1. Baseline characteristics of overall study population, and patients with and without sepsis.

3792-C | EFFECT OF DIFFERENT RADIOLOGIC MODALITIES FOR SURVEILLANCE OF HEPATOCELLULAR CARCINOMA ON SURVIVAL OF HIGH RISK CIRRHOTIC PATIENTS.

Ahmed El Sabagh[1,2], Islam Mohamed[1,2], Megha Bhongade[1], Nikita Rao[1], Eunji Jo[3], Susan G. Hilsenbeck[3] and Prasun K. Jalal[1], (1)Baylor College of Medicine, (2)Faculty of Medicine, Ain Shams University, (3)Dan L Duncan Comprehensive Cancer Center at Baylor St. Luke's Medical Center

Background: American Association for the Study of Liver Diseases (AASLD) recommends that patients with high risk of developing hepatocellular carcinoma (HCC) undergo regular surveillance with ultrasonography (US) every 6 months with or without Alpha-feto protein (AFP). However, compared to cross-sectional imaging modalities -Computed tomography (CT) and Magnetic resonance imaging (MRI) - US has lower efficacy for detection of early HCC. To our knowledge, there are no studies evaluating the overall survival and receipt of curative treatment for patients who received surveillance using the different imaging modalities. **Methods:** We retrospectively reviewed all patients who were diagnosed with HCC at Baylor Saint Luke's Medical Center Hospital between January 2011 and June 2021. Patients who underwent regular surveillance were identified. Data retrieved from electronic medical records and radiology reports included demographic and laboratory features, surveillance modality, tumour characteristics, treatments received and survival data. We estimated survival using the Kaplan-Meier method and compared the different modalities using the Log Rank test. We used univariate and multivariate Cox model to evaluate factors affecting survival. **Results:** A total of 183 patients developed HCC while on biannual surveillance program (115 with MRI, 34 with CT and 34 with US). Patients were similar regarding with respect to age, sex, comorbid diseases. However, our cohort shoed statistically significant differences regarding race and ethnicity, with more African American and Hispanic population undergoing surveillance with US. Moreover, Race and ethnicity were associated with lower survival rates. The initial survival analysis showed that compared to other modalities MRI had statistically significant association with longer survival (p-value = 0.034). However, cox-multivariate regression model with adjustment for race, ethnicity, MELD score and total tumor size at time of diagnosis shows that surveillance modality has no statistically significant association with

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

survival (MRI: HR 1.80, p-value = 0.095) (CT: HR 0.71, p-value = 0.26). **Conclusion:** For cirrhotic patients with high risk for HCC, surveillance with MRI or CT was not associated with higher survival rate compared. This result shed the light on importance of adherence to surveillance irrespective of modality. Additionally, racial and ethnic disparities may affect the access to the HCC surveillance.

3793-C | IMPACT OF ATEZOLIZUMAB + BEVACIZUMAB THERAPY ON HEALTH-RELATED QUALITY OF LIFE IN PATIENTS WITH ADVANCED HEPATOCELLULAR CARCINOMA

Masako Shomura[1], Haruka Okabe[1], Emi Sato[2], Koichi Shiraishi[3], Yoshitaka Arase[3], Kota Tsuruya[3], Yusuke Mishima[2], Shunji Hirose[3] and Tatehiro Kagawa[3], (1) Faculty of Nursing, Tokai University School of Medicine, (2)Department of Advanced Medical Science, Tokai University Graduate School of Medicine, (3)Division of Gastroenterology, Department of Internal Medicine, Tokai University School of Medicine

Background: Health-related quality of life (HRQoL) is an essential consideration for patients with hepatocellular carcinoma (HCC) and is becoming an important endpoint in evaluating new therapies such as atezorizumab+bevacizumab (Atez+Bev) for advanced HCC. HRQoL can be affected by cancer symptoms and adverse events (AEs) of therapies. This study aimed to identify factors associated with treatment efficacy, treatment duration, and overall survival (OS) in HCC patients receiving Atez+Bev, based on their characteristics, including AEs and HRQoL at 3 months. **Methods:** The consecutive HCC patients who received Atez+Bev from Nov 2020 to Apr 2023 were followed up until Apr 21, 2023, or death. Treatment efficacy was assessed according to modified RECIST at 6-9 weeks. HRQoL was monitored every month by EORTC-QLQ C30. The relationship of baseline characteristics, AEs, and HRQoL with efficacy, OS, and treatment duration was analyzed by multivariate logistic regression models and Cox's hazards models with a landmark method. A nursing intervention program was provided to all patients, including education regarding self-monitoring and AEs management, and telephonic consultations. **Results:** A total of 52 patients were enrolled; the majority of patients were men (87%), aged 70 years or older (50%), and had a Child-Pugh score of 5 (48%) and Barcelona Clinic Liver Cancer Stage C (44%). The disease control and response rate (RR) were 78.4% and 37.3%, respectively, with a median treatment duration of 10.8 and OS of 17.9 months. The commonest AEs (all grades) were hypoalbuminemia (90%), fatigue (86%), and thrombocytopenia (75%). HRQoL scores of five functional domains such as general health, physical function (PF), role function, emotional function, and cognitive function (CF), and seven symptoms such as fatigue, nausea, pain, dyspnea, insomnia, and financial difficulties significantly worsened during the first three months. CF < 80 (Odds ratio [OR] 0.16, 95% confidence interval [CI]: 0.03–0.87, p = 0.03) at month 3, extrahepatic invasion (OR 0.11, 95% CI: 0.02–0.58, p < 0.00) and TNM stage IV (OR 0.24, 95%CI: 0.07–0.83, p = 0.02) were associated with lower RR. History of liver resection (OR 4.35, 95%CI: 1.09-16.67) and grade ≧ 2 skin toxicities (OR 10.00, 95%CI: 1.03-100.00, p < 0.05) contributed to higher RR. Factors predictive of shorter OS were PF < 80 (Hazard ratio [HR] 2.52, 95%CI: 1.05-6.03, p = 0.04), grade ≧ 2 hypoalbuminemia (HR 4.37, 95% CI: 1.50–12.76, p = 0.01), and DCP value > 1000 (HR 2.81, 95% CI: 1.22–6.51, p = 0.02). **Conclusion:** The HRQoL scores significantly deteriorated at month 3 after the beginning of Atez+Bev therapy in HCC patients. Declining CF and PF scores were associated with poor prognosis. Thus, maintaining HRQoL during anticancer therapy by appropriately managing AEs with multidisciplinary team support would contribute to a better prognosis.

3794-C | MENSTRUAL AND REPRODUCTIVE HEALTH IN LIVER TRANSPLANT CANDIDATES: A CROSS SECTIONAL SURVEY

Katherine M. Cooper[1], Navine Nasser-Ghodsi[2], Anita Krishnarao[3], Mary Flynn[1], Monika Sarkar[4] and Deepika Devuni[1], (1)UMass Chan Medical School, (2)UMass Chan Medical School, SOUTHBOROUGH, MA, (3) Lahey Clinic Medical Center, (4)University of California, San Francisco

Background: Menstrual and reproductive health is affected by chronic liver disease (CLD). Patients with advanced CLD often become oligo- or amenorrheic, which typically resolves after liver transplant (LT). There are limited gynecologic and obstetric data in LT candidates that would inform appropriate reproductive health counseling in transplant clinics. Thus, we designed a cross-sectional women's health survey for patients presenting for pre-LT clinical care. **Methods:** We distributed a 25-question survey querying gynecologic and obstetric history to all pre-LT patients assigned female gender at birth (hereto called women) between 1/16/23-5/2/23. Menstrual status was determined by the response to the following yes or no question: "Are you still having menstrual periods?". Subgroup analysis was reported by age at time of survey (≤ 50 vs > 50 y) and by menstrual status. Data are reported as: percentage, (# or positive responses/# of total answers for specific question). **Results:** The survey was completed by 50 of 56 patients. Mean age of respondents was 55 +/-12 years; 16 patients were $\leq$ 50 years of age. Of those who reported disease etiology, most had alcohol-related liver disease (62%, 22/36), followed by NAFLD (16%, 6/36), PBC or AIH (16%, 6/36) and HCV (6%, 2/36). Most patients (82%, 36/50) reported amenorrhea (100% of those > 50 vs. 43.8% ≤ 50 y). On a Likert scale characterizing menstrual regularity, 36% (16/44) selected always normal periods, 30% (13/44) selected fairly normal periods, and 34% (15/44) selected irregular periods; 58% and 44% reported prior heavy or painful menses, respectively. Of those no longer menstruating, 20.5% (8/39) and 17.9% (7/39) reported

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

last menstrual period at age < 40 and between 40-45, respectively. Regarding why menses stopped, 70% (29/41) reported menses stopped at random, 10% (4/41) reported menses stopped due to a medication or procedure, and 20% (7/41) did not know why menses stopped. The majority (77%, 36/47) reported prior contraceptive use (27 oral contraception, 7 intrauterine device, 2 not specified). Of the menstruating, 22% (2/9) were using contraception at time of visit. 86% of patients (47/50) reported a prior pregnancy of which 60% (28/47) reported more pregnancy events than deliveries. The average age of first and last pregnancy were 23 and 30, respectively. Approximately one quarter (23%, 8/35) reported difficulty conceiving when desired. **Conclusion:** Women with CLD experience irregular and painful menses. Further, 40% of participants reported LMP < age 45, compared to the nationwide prevalence of 12%. Importantly, self-reported menopause in these young women likely reflects secondary amenorrhea, a condition which typically resolves following transplant. This population is thus at risk for early and unplanned pregnancy if reproductive counseling is not conducted throughout the pre and post-transplant time periods.

	Question: Are you still having periods?		
	No	Yes	Total
Subject Number	41	9	50

f 3795-C | OUTCOMES OF CIRRHOSIS PATIENTS ADMITTED FOR INFLUENZA COMPARED TO SARS-Cov2 ADMISSIONS IN THE UNITED STATES

Yasmeen Obeidat[1], Renuka Verma[2], Kamleshun Ramphul[3], Hemamalini Sakthivel[4] and Tejas Joshi[1], (1) Marshall University, (2)Guru Gobind Singh Medical School, (3)Independent Researcher, (4)One Brooklyn Health System/Interfaith Medical Center Program

Background: Several studies have highlighted the impact of cirrhosis on the immune system, contributing to a weaker response and poorer prognosis following infections. We wanted to compare the outcomes and healthcare burden these now endemic viruses have on adult cirrhosis patient population. We conducted an in-depth retrospective analysis via one of the largest hospitalization databases from the United States, with a primary objective of understanding the differences in characteristics, complications and outcomes among adults with a diagnosis of cirrhosis that were admitted for either Influenza or COVID-19. **Methods:** Patients who also had a diagnosis of influenza were included from the 2016-2019 NIS. For the 2020 NIS, we included patients with a diagnosis of COVID-19. A diagnosis of cirrhosis was also identified. We proceeded to evaluate for potential complications and outcomes during their hospitalization (death, non-invasive ventilation, mechanical ventilation, septicemia, acute kidney injury), and the adjusted odds ratios (aOR), while considering for confounders, were estimated via different logistic regression models. Completed propensity matched analysis, set at a 1:1 ratio and caliper width of 0.20. The various outcomes were further compared and a secondary logistic regression model was also used to estimate the events in cirrhosis patients. **Results:** In 2020, there were an estimated 1628110 cases of COVID-19 in the United States. A total of 48810 (3.0%) cases also had cirrhosis. 4690 (9.6%) of cirrhosis patients required non-invasive ventilation (aOR 1.460, 95% CI 1.413-1.508, $p < 0.01$), 17850 (36.6%) needed mechanical ventilation (aOR 4.375, 95% CI 4.286-4.467, $p < 0.01$), 23200 (47.5%) developed septicemia (aOR 2.705, 95% CI 2.653-2.757, $p < 0.01$), and 26180 (53.6%) reported Acute kidney injury (aOR 2.983, 95% CI 2.922-3.045, $p < 0.01$). Unfortunately, 18305 (37.5%) of cirrhosis patients did not survive their hospitalization for COVID-19 (aOR 4.265, 95% CI 4.176-4.356, $p < 0.01$) (table 1, figure 1). **Conclusion:** Cirrhosis patients have various physiological changes which can alter their immune response to infection. Our study confirms that they are at higher risk for several complications and poor outcomes, including death, compared to those without cirrhosis. Several differences were noted in outcomes between cirrhosis patients with COVID-19 as compared to influenza, as highlighted by our study. Better understanding these outcomes can help tailor our vigilance and management approach when managing cirrhosis patients with each specific viral infection.

3796-C | OVERVIEW OF INTERIM FINDINGS FROM A SURVEY ON PATIENT ATTITUDES TOWARD CLINICAL TRIAL PROCESSES IN CHRONIC LIVER DISEASES

Shavonne Temple[1], Frhaan Zahrawi[2], Farzaneh Dashti[2], Tamar H. Taddei[2], Joseph K. Lim[2], Wajahat Z. Mehal[2] and Bubu A Banini[2], (1)LSU Health Shreveport, (2)Yale University, New Haven, CT

Background: Chronic liver disease (CLD) affects 1.5 billion people worldwide and over 30 million people in the United States. However, there is insufficient information about patients' knowledge of clinical trials in CLD. We aimed to achieve a better understanding of patient awareness of clinical trials in CLD by surveying a diverse patient population with various etiologies of CLD. **Methods:** A 26 questions survey was designed and administered to adult patients aged ≥ 18 years with a diagnosis of CLD. The study was reviewed and approved by local Review Board (IRB). A bilingual (English and Spanish) recruitment message was sent through the Electronic Medical Record (EMR). The survey included questions on: general information (8 questions [Q]); current health status (2Q); clinic accessibility (2Q); and clinical research knowledge and opinions (14Q). The QR code for the survey was also distributed outside of the EMR via social media. **Results:** Between June 2022 and May 2023, a total of 299 responses were obtained comprising 61% women and 39% men. Respondents were 86% Caucasian, 4% African American, 2% Asian American, 1% American Indian, and 7% Other. Respondents identified as 9% Hispanic and 91% non-Hispanic. The etiology of CLD was 38% NAFLD, 13% ALD, 11% HCV, 11% autoimmune hepatitis, 6% primary biliary cholangitis, 4% HBV, 1% primary sclerosing cholangitis, and 16% other liver diseases. Only (41%) indicated that their medical provider had informed them about clinical trials. The majority of respondents (88%) were very likely or likely to participate in clinical trials if given the opportunity. The commonest motivating factors for clinical trial participation were: desire to contribute to medical science (28%); help others (28 %); and receive treatment (21%). The majority (61%) of respondents strongly agreed or agreed that they preferred in-person visits over video or telephone visits. Regarding frequency of imaging procedures, 27% thought monthly liver ultrasound was reasonable; 25% preferred every 3 months. For MRI, 24% indicated a preference for yearly imaging; 20% indicated every 6 months. For liver biopsy, 29% indicated yearly;16% indicated every 6 months. For liver stiffness measurement, almost half (47%) of respondents were not sure or had no opinion regarding preferred frequency. **Conclusion:** Our interim report from a bilingual system-wide electronic survey of patients with CLD indicates that the majority of patients are interested in clinical trial participation due to the potential to improve their health or those of others. Areas for improvement include providing more education and information to patients regarding ongoing clinical trials, efforts to disseminate information to diverse patient populations, and increased patient education on liver-related procedures such as liver stiffness measurement.
Disclosures: The following people have nothing to disclose: Frhaan Zahrawi, Wajahat Z. Mehal

3797-C | PAIN IN US ADULTS WITH LIVER DISEASE: INSIGHTS FROM THE NATIONAL HEALTH INTERVIEW SURVEY

Grace Zhang[1], Aly Cortella[1], Jennifer C. Lai[2] and Jessica Beth Rubin[3,4], (1)UCSF, (2)University of California-San Francisco, San Francisco, CA, (3) University of California, San Francisco, San Francisco, CA, (4)San Francisco VA

Background: Pain is common in patients with chronic liver disease, impairing their daily functioning and quality of life. However, our limited understanding of patterns of pain in this population, as well as differences compared to patients with other chronic conditions, hinders the development of effective cirrhosis-specific pain management strategies. **Methods:** Using cross-sectional data from 2016-2021 National Health Interview Survey, we

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

examined pain rates, severity, and functional limitations due to pain in respondents with self-reported liver disease (i.e. viral hepatitis, cirrhosis, or liver cancer), compared to the general population and those with other chronic conditions associated with pain (arthritis, diabetes, chronic kidney disease [CKD]). We defined pain and functional limitation outcomes by report of symptoms on most or all days. Categorical and continuous variables were compared by χ^2 and t-test, respectively. **Results:** Our liver disease cohort comprised of 5330 participants (63% viral hepatitis, 49% cirrhosis, 2% liver cancer), among whom 42% reported pain, 42% severe pain, and 28% functional limitations by pain. Only 22% of non-liver disease patients reported pain, 30% severe pain, and 13% functional limitations by pain. Compared to liver disease respondents without pain, those with pain were older (60 y vs 57 y old), more often female (52% vs 46%), less often Asian (2% vs 8%) or Hispanic (10% vs 16%), and had lower levels of education (40% vs 33% high school or less) and employment (71% vs 52% unemployed) ($p < 0.001$ for all). The proportion of liver disease respondents reporting pain remained stable over the study period. Liver disease respondents were less likely to have pain than those with CKD or arthritis ($p < 0.001$ for both) but had similar rates as those with diabetes ($p = 0.8$) (Figure). Liver disease respondents had similar rates of *severe pain* compared to all 3 other chronic conditions and were more likely to be functionally limited by pain than those with arthritis ($p < 0.001$). **Conclusion:** The prevalence of pain in liver disease is higher than in the general population, and the prevalence of severe pain and resulting functional limitations is similar to or higher than among those with other painful chronic conditions. Future research should focus on elucidating mechanisms of this disproportionately severe pain in liver disease patients to develop safe and effective treatment options that improve their quality of life.

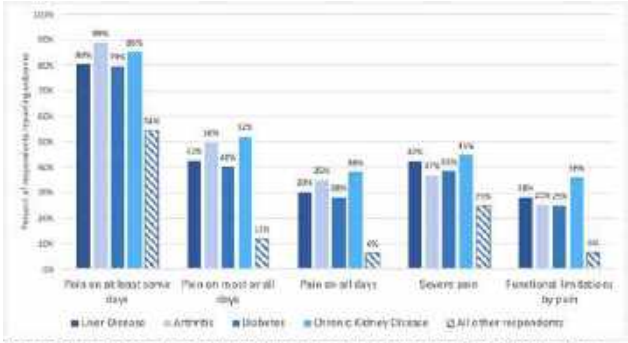

Figure. Comparing reports of pain frequency, severity, and functional limitations for liver disease and other chronic conditions including arthritis, chronic kidney disease, diabetes mellitus, and the general population.

3798-C | PATIENT EXPERIENCE WITH A SMARTPHONE-ENABLED INTERACTIVE CARE PLAN FOR MANAGEMENT OF CIRRHOSIS

Kathryn A. Schmidt[1], Daniel Penrice[1], Sarah Harper[2], Jordan Coffey[2], William Harmsen[2], Julianne Lunde[2], Barbara Copeland[2], Rachel Gullerud[2], Winnie Fan[2], Hugo E. Vargas[3], Blanca Lizaola-Mayo[3] and Douglas A. Simonetto[1], (1)Mayo Clinic Rochester, Rochester, MN, (2)Mayo Clinic, (3)Mayo Clinic Arizona, Phoenix, AZ

Background: Patients with cirrhosis are at increased risk for disease-related hospitalizations and reduced quality of life. An interactive care plan (ICP) – a smartphone-enabled self-care application for monitoring and managing cirrhosis – was developed and implemented at Mayo Clinic. We sought to understand the impact of this novel interactive digital platform by evaluating patients' willingness to engage, usage, satisfaction, and potential barriers. **Methods:** Patients 18 or older who receive longitudinal care for cirrhosis at Mayo Clinic in Rochester and Arizona were enrolled. The ICP delivered daily flowsheets, questionnaires, and self-management education to the online patient portal over 12 months. Cirrhosis-related symptom tracking and educational content were developed by the hepatology team. Surveys using a 5-point Likert scale were sent to participants at the midway point (6 mo) of their care plan. **Results:** Of the 98 participants (47% male, median age 66 (range 30-83), 60% in Rochester, 40% in Arizona) enrolled in the ICP for 1 year, 26 completed the mid-point survey. Themes include patient communication with the care team, education/understanding of their condition, and

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

usefulness/accessibility of educational materials. Communication: Most patients felt confident using the ICP (85%) and interacting with the care team (96%). A majority also felt that the app was easy to use (88%), and that it improved communication with their care team (85%). Education/understanding of condition: Most patients felt the ICP helped them to better understand their condition (73%), how to care for themselves (69%), and what steps they could take to improve their health (69%). Quality of Educational Materials: Most patients agreed that the educational materials were easy to understand (88%). Fewer patients felt that the materials matched their personal needs (58%) or information they received from their care team (62%). Most were comfortable with how often they received educational materials (79%) and were able to find the materials when needed (69%). Overall, most patients would recommend the ICP to others with similar conditions (73%) and were satisfied with the ICP (88%) underscoring the need for and benefit of a care plan in high-risk patient populations. **Conclusion:** Tailoring an ICP program to the unique needs of patients with cirrhosis has the potential to improve satisfaction with their care. Most patients had a positive experience, benefitting from the communication and education as well as empowering them to be more engaged in their cirrhosis care. With additional surveys upon completion of the program, we will better characterize unique phenotypes and tailor educational content to specific needs.

3799-C | PATIENT KNOWLEDGE AND ATTITUDES ABOUT VALUE OF HEPATOCELLULAR CARCINOMA (HCC) SURVEILLANCE

Darine Daher[1], Karissa D. Kao[2], Karim Seif El Dahan[1], Dala Eloubeidi[2], Austin J. Fobar[2], Lisa Quirk[1], Nishi Patel[3], Megha Bhongade[4], Islam Mohamed[4], Ahmed El Sabagh[4], Sean Woolen[5], Jonathan P Troost[2], Prasun Jalal[4], Maarouf A. Hoteit[6], Amit G. Singal[1] and Neehar Dilip Parikh[2], (1)University of Texas Southwestern Medical Center, (2)University of Michigan, (3)University of Pennsylvania, (4)Baylor College of Medicine, (5) University of California San Francisco, (6)Hospital of the University of Pennsylvania

Background: Society guidelines recommend HCC surveillance for patients with cirrhosis and chronic hepatitis B; however, suboptimal adherence in clinical practice impairs effectiveness. Patient knowledge and attitudes regarding the value of HCC screening can contribute to underuse of surveillance so are essential to understand as potential intervention targets. **Methods:** We administered a survey evaluating knowledge and attitudes about HCC surveillance practices and value among patients with cirrhosis at four medical centers in the US. We included adult patients with Child-Pugh A or B cirrhosis (defined by histology, imaging, elastography, or laboratory indices) who were eligible for HCC surveillance. We excluded patients with a history of HCC, liver transplantation, or Child Pugh C cirrhosis. **Results:** Participants (n = 175) had a median age of 60 years, 51% were female, 77% White, 10% Black, and 19% Hispanic. Patients' knowledge of surveillance logistics was high, with > 75% of patients correctly answering knowledge questions. Self-assessment of HCC risk varied widely, with 39% believing they had a less than 1% annual risk and 18% believing they had an annual risk exceeding 5%. Most (75%) reported their provider had discussed benefits of HCC screening, but only 59% reported a discussion of potential harms. Respondents largely agreed that surveillance improves early detection (79%), curative therapy (84%), and survival (75%), although over half (55%) believed surveillance prevented HCC from developing. Early detection was a priority for 83% of patients, independent of improved survival. However, most respondents (> 80%) acknowledged that a discussion of potential harms was important and that false positive results would cause anxiety. Two-thirds (66%) also believed that financial harms should also be considered when considering HCC screening. Over half of patients (52%) reported tolerating false positives in less than 20% of cases over a time frame where HCC risk approached 10%. When presented with the pictogram (Figure), 91% of respondents indicated they would undergo HCC surveillance. **Conclusion:** Patients with cirrhosis undergoing HCC screening displayed high levels of knowledge about HCC screening but have misconceptions that are potential educational targets. Patients acknowledge the importance of screening harms but prioritize early detection as the primary driver of surveillance value.

3800-C | PATIENT PREFERENCES FOR HEPATOCELLULAR CARCINOMA SCREENING ATTRIBUTES

Karissa D. Kao[1], Jonathan P. Troost[1], Dala Eloubeidi[1], Karim Seif El Dahan[2], Darine Daher[2], Austin J. Fobar[1], Lisa Quirk[2], Nishi Patel[3], Megha Bhongade[4], Islam Mohamed[4], Ahmed El Sabagh[4], Sean Woolen[5], Maarouf A. Hoteit[6], Prasun Jalal[4], Amit G. Singal[2] and Neehar Dilip Parikh[1], (1)University of Michigan, (2) University of Texas Southwestern Medical Center, (3) University of Pennsylvania, (4)Baylor College of Medicine, (5)University of California San Francisco, (6) Hospital of the University of Pennsylvania

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer related mortality in patients with cirrhosis. Ultrasound and alpha fetoprotein (AFP) are the most commonly recommended surveillance tools; however, several alternate emerging modalities have been proposed, including imaging- and blood-based strategies, each with its own performance and logistical attributes. Understanding patient preferences regarding surveillance attributes can help identify which strategies will be well accepted when implemented in practice. **Methods:** We conducted a choice-based conjoint survey among patients with cirrhosis undergoing HCC surveillance at 4 medical centers in the US. Participants were provided 15 scenarios in which they were asked to choose surveillance modalities based on six test attributes: benefits (i.e., sensitivity for early HCC), physical harms (i.e., false positives requiring additional testing), financial harms (i.e., out-of-pocket costs), test logistics (i.e., blood draw vs. imaging), test location (i.e., in-clinic vs. separate appointment) and duration of testing (Table). Hierarchical Bayes discrete choice conjoint analysis was used to derive attribute importance. **Results:** We surveyed 255 patients, with a median age of 60 years, 51% male, 82% White, 8% Black, and 15% Hispanic. The highest priority attribute was surveillance benefits (42.9%; 95%CI: 40.6-45.1%), followed by financial harms (19.4%; 95%CI: 18.1-20.7%). Patients placed less priority on test logistics (12.3%; 95%CI: 11.5-13.2%), test location (9.2%; 95%CI: 8.5-10.0%), time duration (8.3%; 95%CI: 7.8-8.7%), and physical harms (7.9%; 95%CI: 7.2-8.6%). In subgroup analyses, Black and Hispanic patients placed lower importance on sensitivity and more on financial harms than White ($p = 0.01$) and non-Hispanic ($p < 0.001$) patients, respectively. Hispanic participants prioritized convenient testing locations compared to non-Hispanic patients ($p = 0.03$). Participants with less than a high school education ($p = 0.004$) and annual income less than $25,000 ($p = 0.001$) placed higher importance on financial harms. **Conclusion:** Patients with cirrhosis prioritize high test sensitivity and low financial harms, while placing less importance on test logistics and risk of physical harms; however, preferences significantly differed by race, ethnicity, and socioeconomic status. These data suggest patient acceptance of and adherence to surveillance may improve with increased options for surveillance modalities.

Table: Test attributes for available hepatocellular carcinoma screening tests

Domains	AFP alone	Novel Biomarker Panel	Ultrasound alone	Ultrasound+ AFP	CT scan	aMRI	MRI
Benefits (Sensitivity for early stage)	35%	70%	45%	63%	80%	85%	89%
Harms (false positive rate)	40%	10%	10%	16%	15%	20%	18%
Test logistics	Blood draw	Blood draw	Imaging	Imaging/Blood draw	Imaging	Imaging	Imaging
Test location	In clinic	In clinic	Separate	Separate	Separate	Separate	Separate
Out of pocket costs	$4.14	$35.95	$28.47	$32.61	$54.71	$61.05	$99.76
Time investment (minutes)	10	10	45	55	75	45	90

3801-C | PATIENT-REPORTED FUNCTIONAL STATUS AND PHYSICAL FUNCTION HAVE WEAK CORRELATIONS WITH PHYSICAL MEASURES AND MAY NOT IMPROVE PREDICTION OF SHORT-TERM OUTCOMES IN CIRRHOSIS

Archita Parikh Desai[1], Thomas Cerri[1], Timothy Stump[1], Jake McCarty[1], Janeth Castano[1], Lauren D. Nephew[1], Patrick Monahan[1], Naga P. Chalasani[2], Marwan S. Ghabril[1] and Eric S. Orman[1], (1)Indiana University, (2) Indiana University Medical Center, Indianapolis, IN

Background: Physical frailty can be measured by batteries of physical tests such as the Liver Frailty Index (LFI), but these require physical capacity and specialized equipment. Patient-reported outcome measures (PROMs) of physical function and electronic health record (EHR) data may be used as surrogates for physical frailty. We aimed to measure the correlations between these different measures and assess their ability to predict 30-day outcomes in hospitalized individual's with cirrhosis. **Methods:** From a prospective inpatient cirrhosis cohort, 191 adults enrolled from 7/2020-4/2023 completed the Functional Status Questionnaire, FSQ; Patient-Reported Outcomes Measurement Information System, PROMIS Profile-29 v2.1; and LFI. The Hospital Frailty Risk Score (HFRS) was calculated using EHR data. Scores range from 0-100 for all measures except LFI which ranges from 1-7. Spearman's correlation coefficients were assessed between these measures. Predictors of 30-day readmission and mortality were assessed using multivariable logistic regression models. **Results:** The cohort had a mean age of 53.5 ± 12.5 years and was 55% male, 80% White, and 10% Hispanic. Mean Charlson comorbidity index of 5.6 ± 2.5 and mean MELD-Na score of 23 ± 8. Primary reasons for admissions were ascites/volume overload (37%), abdominal pain (26%), and acute kidney injury (23%). Figure A summarizes LFI, PROMIS physical function (PF), fatigue, and ability to participate in social roles (APSR) and HFRS scores. The correlations between LFI, PROMs and HFRS were weak ($r \leq 0.30$, Figure B). There were moderate correlations between FSQ and PROMIS PF ($r = 0.66$) and APSR ($r = 0.50$). Median days between LFI assessment and PROMs was 0 days (IQR: 0). Those with a 30-day readmission (34%) were not significantly different from those not re-admitted except for active alcohol use (79% vs. 64%, $p = 0.05$). Those who died within 30-days ($n = 18$, 9.4%) were older (59 vs. 53, $p = 0.055$), less likely to have hepatitis C (0% vs 18%, $p = 0.47$) and had a higher MELD-Na (29 vs. 22, $p = 0.002$) compared to survivors. LFI, PROM scores and HRFS were not significantly different between these groups. In multivariable models, LFI, PROMs and HRFS did not independently predict 30-day readmission or mortality (Figure C) although PROMIS APSR was marginally associated with 30-day mortality (OR 0.93, 95% CI 0.85, 1.00). **Conclusion:** In patients with decompensated cirrhosis, patient report of physical functions is poor, comorbidity is high and physical frailty is common; however, there is poor correlation between these measures. Further, these measures have limited value in predicting 30-day readmissions beyond markers of liver disease in advanced cirrhosis. Future work should assess if change in PROs overtime can predict cirrhosis-related outcomes.

3802-C | PATIENTS WITH CIRRHOSIS RAPIDLY REVIEW POTENTIALLY ABNORMAL HCC SURVEILLANCE RESULTS VIA THE PATIENT PORTAL

Jeremy Louissaint[1], Jonathan Melendez-Torres[1], Robert Turer[1], Timothy P. Hogan[1], Elliot B. Tapper[2], Sruthi Yekkaluri[1] and Amit G. Singal[1], (1) University of Texas Southwestern Medical Center, (2) University of Michigan Medical Center

Background: Patients with cirrhosis have an increased risk of hepatocellular carcinoma (HCC) and undergo surveillance every six months. Historically, abnormal imaging findings were first communicated to patients via direct patient-provider communication in clinic or by telephone. However, since implementation of the 21st Century Cures Act, patients can immediately review test results through the electronic patient portal. We investigated how often and how rapidly patients view ambulatory liver imaging results through the patient portal. **Methods:** We identified patients with cirrhosis who were enrolled in the patient portal and had at least one ambulatory ultrasound or triphasic CT/MRI between 1/1/2021 and 5/1/2023. Reasons for exclusion included a history of liver transplantation or history of HCC. Patient follow-up was censored at time of HCC diagnosis or liver transplantation. We extracted dates and times that imaging results were released to patients via the patient portal and times that results were viewed by the patient. For each result, we calculated the median (IQR) time between result release and patient review. **Results:** The cohort (n = 169) was demographically diverse (median age 62.2 years, 41% female, and 25.4% Hispanic ethnicity). Of 346 ambulatory imaging studies performed during the study period, abnormal imaging findings were reported in 58 (16.8%): 14 on ultrasound (5 US-2 and 9 US-3) and 44 on CT or MRI (24 LR-3, 9 LR-4, 10 LR-5, and 1 LR-M). Over 90% (n = 312; 90.2%) of results were viewed by the patient. Only 12 (7.1%) patients (comprising 19 imaging studies) never viewed their results via the portal. Overall, the median time from result release to patient review was 3.6 (IQR 0.79-27.9) hours. **Conclusion:** Most patients with cirrhosis enrolled in the patient portal view their HCC imaging results via the patient portal, typically within a few hours of release. Given the risk of abnormal imaging findings, our study highlights a potential source of distress for patients accessing high-risk imaging results prior to result-related provider communication.

3803-C | PERSONALIZING HEPATOLOGY: THE ROLE OF CHATBOTS IN TAILORED TREATMENT PLANS IN THE FIELD OF HEPATOLOGY

Rajmohan Rammohan[1], Melvin Joy[2], Dilman Natt[1], Achal Patel[1], Abhishek Tadikonda[1] and Paul Mustacchia[3], (1)Nassau University Medical Center, (2) Nassau University Medical Center, East Meadow, NY, (3)Nassau Univeristy Medical Center

Background: Chatbot's like ChatGPT and Google Bard have significantly impacted healthcare, particularly hepatology, enhancing liver disease diagnosis and treatment. These advanced solutions interpret ultrasound images, analyze various samples, streamline administrative tasks, and aid in medical imaging and device automation. By enabling personalized treatments and side-effect predictions, they have considerably improved hepatology disorder management. Integrating these AI tools provides patients with tailored treatment evaluations, promoting informed decision-making. However, the effectiveness of these chatbots still warrants further scrutiny. **Methods:** The study set out to evaluate the precision of two prominent Chat Bots - Chat GPT and Google BARD - in addressing medical management queries. Both bots were tasked with a series of questions, and their responses were evaluated on a 1-10 Likert scale, with 1 indicating utmost accuracy. Two unbiased evaluators examined each bot's responses to ensure objective evaluation. The research aimed to provide insight into these Chat Bots' capabilities via a structured performance appraisal, focusing on accuracy and dependability. The dual-

evaluator system and the Likert scale approach helped minimize possible bias, thereby lending credibility to the findings. **Results:** Our research contrasted the effectiveness of Chat GPT and Google BARD in the realm of liver disease management. Chat GPT excelled, scoring 74% in the accuracy of information compared to Google BARD's 49% ($p = 0.015$) and 48% vs.29% in medical information reliability ($p = 0.032$). This study emphasizes the critical role of accuracy, and dependability, in developing liver disease-oriented chatbots. While Chat GPT displayed impressive performance, indicating its potential as a reliable tool, it also underscored the necessity for continued research and development in this field. **Conclusion:** This research revealed the relative strengths of Chat GPT and Google Bard in liver disease management, with Chat GPT outperforming in both accuracy and reliability. As AI technologies continue to permeate healthcare, ensuring their accuracy is crucial. While Chat GPT demonstrated promising potential as a reliable hepatology tool, it also highlighted the continuous need for research and development in this domain. The significant disparity in performance emphasizes the importance of rigorous testing and validation before integrating AI tools into medical practice.

3804-C | PHASE ANGLE NEGATIVELY CORRELATES WITH LIVER FRAILTY INDEX AND MAY HELP PREDICT LIKELIHOOD OF DISCHARGE HOME AFTER LIVER TRANSPLANT

Nabeel Wahid, Northwestern Medicine, Fawzy Barry, University of California-San Francisco, Pamela M. Bloomer, University of Pittsburgh Medical Center, Jennifer C. Lai, University of California-San Francisco, San Francisco, CA and Andres Duarte-Rojo, Northwestern University Feinberg Scho

Background: Liver frailty index (LFI) is a clinical tool consisting of 3 performance-based tests (grip strength, chair stands, and balance) used to assess frailty in liver transplant (LT) candidates and has been associated with pre- and post-transplant mortality. Phase angle (PhA) from bioimpedance spectroscopy is an easily measured composite of tissue resistance and reactance to an electric current, which directly reflects muscle mass. Although PhA has been associated with frailty, it is unclear how well PhA correlates with LFI and whether the association is affected by outpatient (OP) or inpatient (IP) status. We examined the correlation of PhA with LFI in both OP and IP settings and explored their association with post-LT disposition. **Methods:** We utilized a prospective cohort of OP/IP being evaluated for LT at two transplant centers in the United States with available LFI and PhA measurements. LFI and PhA were measured between April 2021 and October 2022, and patients were followed until May 2023. Associations between PhA and LFI was assessed using Spearman rank or Mann-Whitney U tests. **Results:** A total of 82 patients, including 51 OP and 31 IP, were included in the study with a total of 36 patients (44%) proceeding to LT. Compared to IP, OP tended to have a higher BMI (27 vs 30, $p = 0.05$), lower MELD (15 vs 21, $p > 0.001$) and were more likely to identify as Hispanic (48% vs 2%, $p < 0.001$). PhA negatively correlated with LFI overall (Spearman's rho -0.34, $p = 0.003$) though this was driven by OP (Spearman's rho -0.57, $p < 001$) (Table). When broken down by LFI components, PhA correlated with grip strength in both OP and IP but only correlated with chair stands in OP. Although 55% of IP could not complete all the components of LFI (i.e., the chair stands/balance sections), there were no differences in PhA between those who completed and did not complete the chair stands/balance sections (median PhA 4.8 [IQR 3.4-5.4] vs 5.0 [IQR 3.9-6.8], respectively, $p = 0.35$). Yet, a patient's inability to complete the chair stands/balance sections conferred higher LFI scores (6.0 [5.9-6.4] vs 3.6 [3.3-4.6], $p < 0.001$). Neither LFI nor PhA were associated with LT ($p = 0.95$ and $p = 0.30$). However, lower OP LFI and higher OP PhA were observed in patients who were discharged home after LT vs. discharged elsewhere (median LFI 2.9 [IQR 2.3-3.4] vs 3.8 [IQR 3.4-4.8] respectively, $p = 0.008$; median PhA 5.3 [IQR 4.4-5.3] vs 3.2 [IQR 2.7-4.6] respectively, $p = 0.009$), with no relationship observed in IP. **Conclusion:** Expectedly, PhA negatively correlated to LFI, reflecting how higher muscle mass corresponds with a less frail profile. Both PhA and LFI were predictive of post-LT discharge when measured in the ambulatory setting. The association between PhA and LFI in IP was likely affected by assumptions made for patients unable to complete all LFI components. Further studies are needed to assess if PhA and LFI may be used as

3805-C | PREDICTING 90-DAY MORTALITY IN PATIENTS WITH DECOMPENSATED CIRRHOSIS USING THE "SURPRISE QUESTION": A PROSPECTIVE COHORT STUDY

Lucinda Li[1], Justin Yun[1], Chengbo Zeng[2], Teresa Indriolo[1], Alyson Kaplan[3], Nancy Mason[1], Michaela Rowland[1], Kirsten Engel[1], Dio Kavalieratos[4], Kedie Pintro[1], Nora Horick[1], Maria Edelen[2], Areej El-Jawahri[1], Kei Ouchi[2] and Nneka Ufere[1], (1)Massachusetts General Hospital, (2)Brigham and Women's Hospital, (3)New York-Presbyterian/Weill Cornell Medical Center, (4)Emory University

Background: The Surprise Question (SQ) has been previously used to predict mortality in patients with serious illnesses such as cancer and congestive heart failure. We aimed to assess the predictive accuracy of the SQ for hospitalized patients with decompensated cirrhosis (DC). **Methods:** We conducted a prospective cohort study of consecutive patients with DC admitted to a large academic medical center between 2/2022-1/2023. Internal medicine (IM) and/or hepatology clinicians (attendings and/or trainees/advanced practice providers [APP]) were approached within the first 72 hours of patients' admission. Clinicians were asked to provide a "surprised" (SQ+) or "not surprised" (SQ-) response to the following question: "would you be surprised if this patient were to die in the next 90 days?". To assess the performance of the 90-day SQ in predicting 90-day mortality, we calculated the sensitivity, specificity, positive and negative predictive values (PPV/NPV), positive and negative likelihood ratios (LR+/LR-), and accuracy. **Results:** The full cohort included 80 hospitalized patients with DC (mean age 58 (SD 13), median MELD-Na 21 [IQR 14-27], 13% on liver transplant waitlist). Response rates were 77% (54/70) among hepatology clinicians and 65% (110/168) among IM clinicians. Hepatology clinicians provided responses to the SQ for 35 patients of whom 12 (34%) had died by 90 days. IM clinicians provided responses for 79 patients of whom 19 (24%) had died by 90 days. Among hepatology clinicians, the 90-day SQ had the following test characteristics: sensitivity (8% [95%CI: 0-24%]), specificity (65% [95%CI: 46-85%]), PPV (11% [95%CI: 0-32%]), NPV (58% [95%CI: 39-77%]), LR+ (0.24 [95%CI: -0.23-0.71]), LR- (1.41 [95%CI: 0.92-1.89]), and accuracy (46% [95%CI: 29-62%]). Among IM clinicians, the 90-day SQ had the following test characteristics: sensitivity (26% [95%CI: 7-46%]), specificity (38% [95%CI: 26-51%]), PPV (12% [95%CI: 2-22%]), NPV (62% [95%CI: 47-78%]), LR+ (0.43

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

[95%CI: 0.10-0.76]), LR- (1.92 [95%CI: 1.12-2.73]), and accuracy (35% [95%CI: 25-46%]). There was similar diagnostic accuracy of the 90-day SQ between hepatology attendings and trainees/APPs (47% vs. 46%) and IM attendings and trainees/APPs (37% vs. 36%) (Table). **Conclusion:** The surprise question's accuracy was poor in predicting 90-day mortality of patients with DC based on hepatologist or IM clinician response. This underscores the difficulty with prognostication in the context of DC.

Table. Performance of Surprise Question (SQ) in Predicting 90-Day Mortality of Patients with Decompensated Cirrhosis

	Hepatology Attendings n = 30	Hepatology Trainees/APPs n = 24	IM Attendings n = 68	IM Trainees/APPs n = 42
SQ+ (n, %)†	1 (9.1)	1 (12.5)	4 (22.2)	2 (20)
SQ- (n, %)†	10 (90.9)	7 (87.5)	14 (77.8)	8 (80)
Total death (n, %)*	11 (36.7)	8 (33.3)	18 (26.5)	10 (23.8)
Total sample (n, %)	30 (100)	24 (100)	68 (100)	42 (100)
Sensitivity (95% CI)	9 (0, 26)	13 (0, 35)	22 (3, 41)	20 (0, 45)
Specificity (95% CI)	68 (48, 89)	63 (39, 86)	42 (28, 56)	41 (24, 58)
PPV (95% CI)	14 (0, 40)	14 (0, 40)	12 (1, 23)	10 (0, 22)
NPV (95% CI)	57 (36, 77)	59 (35, 82)	60 (44, 76)	62 (41, 83)

f 3806-C | PREDICTING LIVER-RELATED OUTCOMES IN PATIENTS WITH CIRRHOSIS: THE PROGNOSTIC VALUE OF CLINICAL FACTORS AND NONINVASIVE TESTS

Somaya Albhaisi[1], Rasha Alsaadawi[2], Amanda Robinson[3], Roy Sabo[2] and Arun Sanyal[4], (1) Department of Internal Medicine, Virginia Commonwealth University, Richmond, VA, (2)Virginia Commonwealth University, Department of Biostatistics, Richmond, VA, (3)Virginia Commonwealth University, C. Kenneth and Dianne Wright Center for Clinical and Translational Research, Richmond, VA, (4)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Patients with cirrhosis are at risk for developing complications which are associated with high mortality. Prognostic tools estimating a patient's risk of adverse liver outcomes based on cirrhosis etiology could inform disease management. The aims of our study were to investigate predictors of adverse liver outcomes and to develop simplified prognostic models by disease etiology among patients with cirrhosis. **Methods:** Six prognostic models were developed using proportional hazards regression, classified by cirrhosis etiology, after identifying meaningful predictors of 5-year risk of ascites, hepatic encephalopathy (HE), and variceal bleeding (VB) among patients with cirrhosis due to nonalcoholic steatohepatitis (NASH) or viral hepatitis (table 2). The predictors for each model were selected via LASSO regression. **Results:** A total of 4045 adult patients with cirrhosis were included in the analysis from a single U.S. center retrospective cohort. The 5-year rates were 31.6%, 22.9%, and 30.7% for ascites, HE, and VB, respectively. Baseline characteristics of study population are summarized in table 1. Multivariable analyses showed that independent predictors in cirrhosis due to NASH and viral hepatitis were: (a) ascites: albumin and international normalized ratio (INR); (b) HE: albumin, INR, total bilirubin, platelet count; (c) VB: albumin, platelet count, hemoglobin. No variables were significantly associated with outcomes in patients with alcohol-associated liver disease. Validation analyses based on 30-day risk showed that these models were reasonably predictive (table 3). **Conclusion:** Our new, simplified models accurately and consistently predicted 5-year risk of ascites, HE, and VB among patients with cirrhosis due to NASH or viral hepatitis using simple routinely available variables measured at baseline. These models could be employed to identify high-risk patients who might benefit from greater attention and more aggressive treatments.

3807-C | PREVALENCE AND PREDICTORS OF LIVER FIBROSIS IN A HOUSTON COMMUNITY CLINIC

Jessica P. Hwang[1], Natalia I. Heredia[2], Sumeet Asrani[3], Jessica T. Foreman[1], Carla L. Warneke[1], Johannah Abraham[4], Caroline Ankoma-Sey[4], Victor Ankoma-Sey[5], Karen Basen-Engquist[1], Aleah R. Booker[4], Carol Gambrill[4], Kara W. Green[4], Cassandra L. Harris[1], Anh Le[4], Jacqueline Ma[4], Lorna H. McNeill[1], Lynne Nguyen[1], Harrys A. Torres[1] and Andrea Caracostis[4], (1) The University of Texas MD Anderson Cancer Center, (2)The University of Texas Health Science Center at Houston School of Public Health, (3)Baylor University Medical Center, Dallas, TX, (4)HOPE Clinic, (5)Houston Methodist Hospital, Houston, TX

Background: Liver fibrosis may lead to hepatocellular carcinoma (HCC). Hepatitis B virus (HBV) infection, hepatitis C virus (HCV) infection, metabolic syndrome, and alcohol use disorder (AUD) are risk factors for fibrosis. Early screening for fibrosis using serum biomarkers in community settings is not well established. **Methods:** Adult patients at the HOPE Clinic, a federally qualified health care center in Houston, were enrolled from January 2021 through May 2023 and surveyed about risk factors for liver fibrosis. We measured vital signs and waist circumference, calculated body mass index (BMI), and performed blood testing. We defined chronic HBV infection as positivity for hepatitis B surface antigen; chronic HCV infection as detectable HCV RNA; metabolic syndrome as the presence of at least 3 of 4 conditions: hyperglycemia, hypertension, dyslipidemia, and obesity; and AUD as an AUDIT-C score of ≥ 4 for men and ≥ 3 for women. Transient elastography was performed to assess for fibrosis, with scores ≥ 8 kPa indicating $\geq$F2 fibrosis. Serum biomarkers of fibrosis were defined as Fibrosis-4 (FIB-4) score ≥ 2.67 (based on ALT, AST, platelets, age); NAFLD Fibrosis Score (NFS) ≥ 0.675 (based on ALT, AST, platelets, albumin, age, BMI, diabetes); and Fatty Liver Index (FLI) ≥ 30 (based on triglycerides, gamma-glutamyl transferase, waist circumference, BMI). We described the prevalence of fibrosis risk factors and tested the associations of risk factors and serum biomarkers with $\geq$F2 fibrosis using Fisher's exact test. Logistic regression was used to model the outcome of $\geq$F2 fibrosis. **Results:** We enrolled 977 patients, 409 men (42%) and 568 women (58%). The median age was 48 years (IQR = 22). A total of 483 patients (50%) were White, 252 (27%) were Asian, and 210 (22%) were Black. Among all patients, 394 (41%) were Hispanic. Forty-three percent of patients (n = 416) had BMI ≥ 30. Six percent of patients (57/944) had chronic HBV infection, $< 1\%$ (1/939) had chronic HCV infection, 48% (440/912) had metabolic syndrome, and 13% (125/971) had AUD. Of 891 patients who completed transient elastography, 86 (10%) had $\geq$F2 fibrosis. Among patients with metabolic syndrome, FIB-4 score ≥ 2.67 (OR 26.2, 95% CI 5.3-129.7) and NFS ≥ 0.675 (OR 8.9, 95% CI 2.3-34.3) were predictive of $\geq$F2 fibrosis, but FLI ≥ 30 (OR 4.5, 95% CI 0.7-27.6) was not. The receiver operating characteristic curve for

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

the model was 0.74 (95% CI 0.68-0.80). After controlling for age and sex, we found that metabolic syndrome (1.89, [95% CI 1.09-3.26]), AUD (1.15 [95% CI 1.02-1.30]), NFS ≥0.675 (1.54 [95% CI 1.21-1.96]), and FIB-4 ≥2.67 (1.33 [95% CI 1.07-1.66]) were statistically significant predictors of fibrosis > F2 (see Table). **Conclusion:** In this community-based study, 1 in 10 patients had fibrosis. Metabolic syndrome and AUD were significant predictors of ≥F2 fibrosis, along with FIB-4 and NFS. Incorporating these predictors into clinical algorithms will be useful to prevent HCC.

Table. Predictors of >F2 Fibrosis

Odds Ratio Estimates			
Effect	**Point Estimate**	**95% Wald Confidence Limits**	
Age	0.993	0.971	1.015
Male vs female sex	1.141	0.685	1.899
Metabolic syndrome	1.889	1.094	3.264
AUD	1.145	1.015	1.291
NFS ≥0.675	1.542	1.213	1.961
FIB-4 ≥2.67	1.332	1.067	1.662

AUD: alcohol use disorder; AUDIT-C score ≥4 for men and ≥3 for women. NFS: NAFLD fibrosis score. FIB-4: Fibrosis-4 score.

3808-C | PSYCHOSOCIAL PREDICTORS OF REQUIRING EXPEDITED INPATIENT LIVER TRANSPLANT EVALUATION

Katherine M. Cooper[1], Hau Nguyen[1], Alessandro Colletta[2] and Deepika Devuni[1], (1)UMass Chan Medical School, (2)Umass Chan Medical School

Background: Failure to refer for liver transplant evaluation (LTE) in a timely manner may lead to expedited LTE in the setting of acute decompensation. It has been historically difficulty to identify risk factors for late referral, particularly psychosocial risk factors. We analyzed patients undergoing inpatient LTE (I-LTE) versus outpatient LTE (O-LTE) to identify psychosocial risk factors for expedited LTE at our center. **Methods:** Patients completed LTE for cirrhosis over a 4-year period were included. Psychosocial data was collected from social work and psychiatry LTE assessments. 15 variables were compared between I-LTE and O-LTE: age, sex, education, proximity to center > 50 miles (proximity) marital status (MS), insurance status (IS), living with family, being dependent on others for housing (housing dependent), military history (military), employment within 1-month, stable income, social security income (SSDI), depression history, English as a second language (ESL), and birthplace (in vs. out of US). Univariable logistic regression (LR) was used to identify psychosocial variables associated with I-LTE. A multivariate LR model was built and backward LR was used to identify potential independent predictors of transplant; probability to enter = 0.05 and probability to remove = 0.10. Models were assessed using Hosmer Goodness of Fit (GoF). **Results:** 624 patients were included (25.6% I-LTE vs 74.3% O-LTE). I-LTEs were more likely to be women, Hispanic, and to have autoimmune or genetic liver disease. Death was more common and transplant less common in I-LTE. Multivariate LR using all factors had excellent GoF (0.97). Potential independent predictors of LTE location on backward LR included military, SSDI, ethnicity, ESL and living with family (right panel). Adding disease etiology did not affect these findings. Predictors differed between men and women. Predictors of I-LTE in men included: military (OR 0.41), MS (OR 0.47), SSDI (OR 3.0), and housing dependent (OR 1.8). Predictors in women included MS (2.6), SSDI (2.4), Hispanic ethnicity (1.6), proximity (2.4), ESL (3.6). Models had higher GoF in men than women (0.75 vs. 0.40). **Conclusion:** Expedited LTE is associated with increased risk of mortality in men and women. Psychosocial variables may strengthen models aiming to identify patients at risk for expedited LTE at individual centers. Housing situation and SSDI were strongly associated with increased risk of I-LTE for men and women at our center. However, having a stable relationship was protective against I-LTE in men but not in women. Psychosocial factors differ by sex in patients seeking LT and should be considered when referring patients for LTE.

3809-C | QUALITY OF LIFE, SYMPTOM BURDEN, PSYCHOLOGICAL DISTRESS, AND PROGNOSTIC PERCEPTIONS AMONG PATIENTS WITH DECOMPENSATED CIRRHOSIS

Nneka Ufere[1], Lucinda Li[1], John Donlan[2], Teresa Indriolo[1], Joyce Zhou[1], Alyson Kaplan[3], Alan Noll[4], Nancy Mason[1], Michaela Rowland[1], Kirsten Engel[1], Jennifer C. Lai[5], Maria Edelen[6], Chengbo Zeng[6], Kedie Pintro[1], Nora Horick[1] and Areej El-Jawahri[1], (1) Massachusetts General Hospital, (2)Harvard Medical School, (3)New York-Presbyterian/Weill Cornell Medical Center, (4)University of Pittsburgh Medical Center, (5) University of California-San Francisco, San Francisco, CA, (6)Brigham and Women's Hospital

Background: Patients with decompensated cirrhosis (DC) struggle with a life-limiting illness course. Yet, data describing patients' quality of life (QOL), symptom burden, psychological distress, and illness and prognostic understanding in this population are lacking. **Methods:** We conducted a cross-sectional study in which outpatients with DC completed assessments of quality of life (Short-Form Liver Disease Quality of Life scale, SF-LDQOL, range 0-100, higher scores = higher QOL), symptom burden (Revised Edmonton Symptom Assessment Scale, ESAS-r), depression (Patient

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

Health Questionnaire 9, PHQ-9) and anxiety symptoms (Hospital Anxiety and Depression Scale, HADS-A). Patients also completed the Prognostic Treatment Perceptions Questionnaire to assess their readiness to discuss prognosis and self-reported health status. We used linear regression analyses to examine the associations of patients' self-reported health status (terminally ill vs. not terminally ill) and their quality of life, symptom burden, and psychological distress. **Results:** Between July 2018 and September 2022 we prospectively enrolled 66% (218 of 330) of eligible outpatients with DC (mean age 57.5 [SD 10.2], median MELD-Na 16 [IQR 11-22], 50% listed for transplant). To date, the cohort has had 1-year and 2-year mortality rates of 12.3% (27/218) and 19.3% (42/218), respectively. Mean SF-LDQOL score was 57.8 (SD 16.4). Patients reported a high frequency of moderate-to-severe tiredness (77%), drowsiness (68%), pain (50%) and muscle cramps (48%). In total, 42% reported moderate-to-severe depression and 44% reported clinically significant anxiety symptoms. Almost all (93%) indicated that knowing their prognosis was "extremely important" or "important". However, 81% had never discussed their end-of-life care wishes with their hepatologist. Overall, 34% self-reported a terminally ill health status. Patients who reported a terminally ill health status had worse quality of life (SF-LDQOL; $B = -7.27$, $p = 0.002$), symptom burden (ESAS; $B = 8.54$, $p = 0.003$), anxiety (HADS-A; $B = 1.89$, $p = 0.002$) and depression (PHQ-9; $B = 2.64$, $p = 0.001$). **Conclusion:** Patients with DC struggle with poor QOL and immense symptom burden and psychological distress. Despite patients reporting the importance of knowing their prognosis, self-reported terminally ill health status was associated with lower QOL and mood. Interventions to improve patients' prognostic understanding while providing adequate psychosocial support are warranted.

3810-C | SERIOUS ILLNESS COMMUNICATION SKILLS TRAINING FOR GASTROENTEROLOGY FELLOWS: A PILOT STUDY

Nilofar Najafian[1], Anne Walling[1], Karen Spritzer[1], Janet Gripshover[2], Shirley Otis-Green[1], Lin Chang[1], Neil Wenger[1] and Arpan Arun Patel[3], (1)University of California-Los Angeles, (2)Geisinger Medical Center, (3)Greater Los Angeles VA Healthcare System

Background: Patients with decompensated cirrhosis and their treating clinicians rarely engage in goals of care discussions, despite recommendations. Participation in serious illness communication skills training may help clinicians improve their confidence and skills for such discussions, but gastroenterologists (GIs) and hepatologists lack training opportunities individualized to their practice. Investment in such training during GI fellowship is ideal, as standardized assessments show deficiencies in end-of-life communication among GI fellows, and GIs/hepatologists cite insufficient training as a major barrier to conversations. Normalization of such conversations among GIs/hepatologists can help ensure that care delivered is more patient and caregiver-centered. Our aim is to report the results of a pilot training program on serious illness communication skills for GI fellows. **Methods:** The 2.5-hour training included didactics on advance care planning and serious illness communication (1 hour) and practice delivering serious news to standardized patients (1.5 hours, sharing with a patient with cirrhosis that they are not a transplant candidate). Adaptation of training materials, development of cases, and training of standardized patients were conducted by the interdisciplinary UCLA Advance Care Planning Program (https://www.uclahealth.org/programs/advance-care-planning). Fellows were asked to complete surveys pre- and post-training, which included questions about demographics and prior training [pre-, $N = 6$], session feedback [post-, $N = 7$], and validated items assessing self-reported clinician barriers to goals of care communication [pre- and post-, $N = 36$]. We analyzed results using descriptive statistics and performed paired *t*-tests to assess the relationship between communication skills training and self-reported barriers. **Results:** A total of 21 fellows (20 GI, 1 transplant hepatology) completed training and the assessments. Little over half (12/21 = 57%) reported

prior training consisting of observation and structured feedback. Domains that significantly improved after training included: self-reported knowledge, skills, beliefs about capabilities, attitudes about organizational support and social/professional role regarding having discussions. All fellows reported the program format and selection of topics as very good or excellent. Qualitative feedback supported these findings (Figure). Conclusion: A 2.5-hour serious illness communication training was highly acceptable and significantly improved multiple domains, including GI fellows' self-reported knowledge, skills, capabilities for communication, and attitudes about organizational support and social/professional role. Such programs should be adapted using trainee feedback, scaled, and disseminated.

f 3811-C | SEX DIFFERENCES IN POST LIVER TRANSPLANT ALCOHOL RELAPSE IN PATIENTS EVALUATED WITH EARLY SOBRIETY

Katherine M. Cooper[1], Alessandro Colletta[2] and Deepika Devuni[1], (1)UMass Chan Medical School, (2) UMass Chan Medical School, Worcester, MA

Background: Alcohol associated liver disease (ALD) is an increasingly prevalent transplant indication in the United States for both acute and chronic forms of liver failure. Risk factors for alcohol relapse have been studied but are poorly understood, particularly in patients with early liver transplant evaluation (e-LTE) after alcohol cessation We aimed to assess risk factors for relapse in patients with e-LTe with a focus on identifying sex differences in risk factors for relapse. **Methods:** We retrospectively analyzed patients with ALD and early alcohol sobriety (< 6 mo) who completed e-LTE between 2018 and 2021 (n = 162). Patients were further categorized by 0-3 mos (very early) and 3-6 mos sobriety (early). Clinical, demographic, and psychosocial factors were collected at time of LTE. Psychosocial predictors of post LT alcohol relapse were evaluated in the total cohort and by patient gender. Backward logistic regression was used to identify potential predictors of relapse amongst all variables in the total group (See table 1 for list). Subsequently, data was compared by relapse status in men and in women using Fishers Exact and Students t-tests. Odds ratios were calculated with logistic regression. A trend was evaluated at p = 0.10 and significance was evaluated at p = 0.05. **Results:** 162 patients were identified (82 very early LTE and 80 early LTE). 67 patients (42.1%) underwent LT and this was more common in very early sobriety group (50.0% vs. 32.1%, p = 0.02). Post LT relapse rate was 10% overall; the strongest potential predictors of relapse were sex (0.05), marital status (0.11), and number of standard drinks per day (p = 0.05). Of note, there were no differences in post-LT treatment for alcohol use disorder (not shown). Relapse was 3.5x more common in women overall (27.3% vs. 8.9%, p = 0.05). On subgroup analysis, this relationship persists in the very early sobriety group (35.7% vs. 7.4%, p = 0.02), but does not in the early group (12.5% vs. 11.1%, p = 0.91). Women with post LT relapse were younger, but not significantly, than those without relapse. Marriage status, employment, depression and PTSD history, prior alcohol use treatment, and number of daily drinks were similar by relapse status for men and women. However, women with post LT relapse were more likely to have children than women without relapse (p = 0.05). Further, women with relapse had more children under the age of 18 years on average than those without post-LT relapse. This relationship was generally persevered when controlling for age, race, and education status on multivariate logistic regression (OR 3.8, p = 0.07). **Conclusion:** Women with ALD who have children, particularly younger children, may be at increased risk of relapse. The more negative effect on women compared to men may be due to increased caregiving responsibility. There is significant opportunity to better understand this relationship and improve interventions to reduce relapse in this high-risk population.

Research Cardiac Surgery, (42)Center for Outcomes Research in Liver Diseases, Washington, DC, (43) Barcelona Institute for Global Health (ISGlobal), Hospital Clínic, University of Barcelona, Barcelona, Spain

Background: Stigma can be associated with impairment of patients' quality-of-life. Aim: Evaluate the association between stigma and HRQL among NAFLD patients. **Methods:** NAFLD patients were invited to complete the Chronic Liver Disease Questionnaire-NAFLD (CLDQ-NASH; 36 items, 6 domains, range 1-7, higher scores = better HRQL) and a stigma survey about history of stigmatization or discrimination due to chronic conditions, various aspects of disease burden [Liver Disease Burden (LDB) instrument; 35 items, 7 domains including Stigma, range 1-4, higher scores = greater disease burden], and perception of various diagnostic terms. **Results:** The CLDQ-NASH and the stigma surveys were completed by 377 NAFLD patients (9% < 35 years, 52% male, 47% with ≥2 chronic comorbidities, 45% type 2 diabetes, 20% severe fibrosis or cirrhosis) from 12 countries (47% USA). Of included patients, 15% reported having experienced stigma or discrimination (at least sometimes) due to their liver disease (NAFLD) and 42% due to being overweight/obese. In addition, 26%, 35%, 23%, 25% reported feeling uncomfortable with the diagnostic terms "NAFLD", "fatty liver", "NASH" and "MAFLD", respectively. All aspects of NAFLD stigma (self-reported history of stigmatization due to the liver disease of NAFLD and having LDB Stigma score in top quartile) were associated with lower HRQL scores in all domains ($p \leq 0.01$) (Figure). In multivariate analysis adjusted for country of enrollment, history of stigmatization or discrimination due to the liver disease of NAFLD was the strongest independent predictor of lower HRQL scores in all domains (beta -0.63 to -0.92, $p < 0.001$) while history of stigmatization due to being overweight/obese was associated with lower Activity domain (beta = -0.36, $p = 0.01$). Negative perception of the diagnostic terms "NAFLD" or "NASH" was not associated with HRQL scores (all $p > 0.05$) while that of "fatty liver" or "MAFLD" was associated with impairment in Emotional, Fatigue, and Worry domains of CLDQ-NASH ($p < 0.01$). Other predictors of lower HRQL scores included female sex, lack of college education, having ≥2 chronic comorbidities, history of weight loss due to medical reasons, and having severe fibrosis or cirrhosis ($p < 0.05$). **Conclusion:** In this survey, 15% of NAFLD patients reported having experienced stigma or discrimination due to their liver disease and this was an independent predictor of impaired HRQL. Efforts should be made to better understand and reduce the sources of stigmatization or discrimination in patients with NAFLD.

3813-C | SYMPTOM BURDEN, QUALITY OF LIFE, AND PALLIATIVE CARE IN END-STAGE LIVER DISEASE

Joel P. Wedd[1], Danielle Noreika[1], Irma Hashmi[1], Stephanie Taylor[1] and Richard K. Sterling[2], (1)Virginia Commonwealth University, (2)Virginia Commonwealth University Health System

Background: End-Stage Liver Disease (ESLD) is a growing cause of mortality, suffering, and healthcare cost, all potentially modifiable by palliative care (PC) even with aggressive goals. PC is underutilized in ESLD, and actionable guidelines are lacking owing to lack of trial data. We conducted a pilot study of ESLD patients undergoing PC evaluation to guide future interventions. **Methods:** We enrolled patients admitted to our center for ESLD complications from 1/2022 to 11/2022. Demographic and clinical data were collected; surveys on symptom burden, quality of life (QOL), psychologic symptoms, and caregiver burden were conducted at baseline and at follow-up within 60 days; and readmission and mortality were collected. Every enrollee underwent PC evaluation regardless of care goals. Those readmitted within 60 days were compared to those who were not. **Results:** Twenty-eight patients were enrolled in the pilot. Mean age was 58 years, 61% were female, and 11% were Black. Etiology of liver disease was NASH in 36%, alcohol in 68%, and complications of portal hypertension, hepatic encephalopathy, ascites, and variceal bleed were present in 96%, 75%, 93%, and 21%, respectively with a median MELD-Na of 24.5. Median symptom burden measured by ESAS was moderate for pain (3.5), tiredness (5.5), and wellbeing (5). Median anxiety was mild by GAD 7 (7.5), and HADS Depression Score showed a median of 7.2. Mean QOL using the Short-Form Liver Disease QOL Survey was worst in Health Distress and Sleep domains (36.1 and 40.5, respectively), and highest in the Loneliness domain (82.3), with Symptoms, Effects, Concentration, Sexual functioning, Hopelessness, and Stigma domains ranging from 54.1 to 68.7). Mean caregiver burden by the Zarit Burden Interview was high (36.1). Mortality was 7%, and 47% were readmitted within 60 days of enrollment. Patients who were readmitted within 60 days had higher BMI, more burden in 7 out of 9 symptoms by ESAS, have more anxiety by GAD7, and have worse QOL in 7 out of 9 domains (Table 1). **Conclusion:** In a pilot study, symptom burden was high, quality of life was low, and readmitted patients appear to have more suffering and worse quality of life compared to patients who were not. This study supports the ability to offer PC to admitted patients in our institution and underscores its need from symptom burden, quality of life, and resource utilization perspectives. Next steps include creating and studying

3814-C | TAILORED MESSAGE INTERVENTION BY NUDGE THEORY INCREASES THE NUMBER OF THE VIRAL HEPATITIS SCREENING FOR JAPANESE WORKERS AND CONSULTATION BEHAVIOR OF POSITIVE PATIENTS FOR HCV ANTIBODY- CONSIDERATION OF 1.8 MILLION GENERAL CHECK-UP PARTICIPANTS.

Masaaki Korenaga[1], Chieko Ohe[2], Keiko Kamimura[2], Keiko Korenaga[3], Tatsuya Ide[4] and Tatsuya Kanto[5], (1) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, (2) Japan Health Insurance Association, (3)National Center for Global Health and Medicine, (4)Kurume University School of Medicine, (5)The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan

Background: Although the overall number of hepatitis B virus (HBV) and hepatitis C virus (HCV) carriers in Japan has decreased, actions against hepatitis at work sites in Japan have not yet been fully implemented. In Japan Health Insurance Association (JHIA), which is belonged to more than 40 million Japanese who are working in Medium and Small Sized Companies, the number of hepatitis screening were less than 2 million from 2008 to 2016 even the cost of only $ 6. The aim of this study was to investigate the effectiveness of a tailored message intervention using nudge theory promoted the numbers of viral hepatitis screening and how many of those found to be positive for HCV antibody have been followed up with examinations and hospital treatment. **Methods:** About 1.8 million Japanese workers at Fukuoka branch of the JHIA who wish to get annual general checkup from 2017 to 2021 received client reminders by using nudge theory for an optional hepatitis virus screening. For control subjects, we enrolled general checkup applicants with typical message condition in 2016. The main outcome measure was attendance rates in HBV and HCV screening which were examined HBs antigen (HBsAg) and Anti-HCV antibody (HCVAb), respectively. In addition,12 months after the checkup, we analyzed how many workers who were positive for HCVAb visited to physicians by medical prescription system. **Results:** There was a significant difference in viral hepatitis screening attendance rates between the client reminders by using nudge theory ($n = 124,148$, 6.9%) and the control ($n = 4,791$, 1.2%; $p < 0.001$). One thousand one hundred thirty workers (0.91%) were positive of HBsAg ($n = 683$, 0.55%) and HCVAb ($n = 447$, 0.36%), respectively. The positive rate of HCV Ab in the 50s (0.59%) were higher than those in 60s (0.49%). Two hundred seventy-seven with HCVAb positive patients (61%) were confirmed to visit specialists 12 months after the screening. One hundred seventy (38%) were treated with IFN-free direct-acting antivirals and four males (0.8%) in 60s were detected hepatocellular carcinoma. **Conclusion:** There were still many positive patients with viral hepatitis at work sites. A simply modifying the client reminders using nudge theory could increase the viral hepatitis screening rates. Promoting hepatitis virus screening for workers at general checkup can rescue hepatitis virus carriers who are unaware of their infection and require to therapy for viral elimination and liver cancer.

3815-C | The associations between MELD, CTP and Quality of Life scores for patients with End Stage Liver Disease.

Manisha Verma[1], Alfred Sidney Barritt IV[2], Maya Balakrishnan[3], Marina M. Roytman[4], Binu V John[5], Andrzej Kosinski[6], Yang Yue[6] and Victor J. Navarro, Md[7], (1)Einstein Medical Center, (2)University of North Carolina, (3)Baylor College of Medicine, Houston, TX, (4)UCSF Fresno, (5)University of Miami and Miami VA, (6)Duke Clinical Research Institute, (7)Albert Einstein Medical Center, Doylestown, PA

Background: Patient reported quality of life (QoL) has increasingly been recognized as an important clinical parameter and research end point in palliative care (PC) and hepatology research. This study investigates 1) the associations between baseline liver function (MELD, CTP scores) and QoL measures (Patient Reported Outcomes Measurement Information System/ PROMIS-29 domain scores and FACT-Hep total score), and 2) provides estimates of PROMIS-29 domain scores for ESLD patients participating in the ongoing PAL LIVER trial. **Methods:** PAL-LIVER is a multi-site cluster randomized PC intervention trial enrolling patients with decompensated cirrhosis, and/or Hepatocellular Cancer (HCC). Pearson correlation coefficient was used to summarize the association between the baseline MELD, CTP and FACT-Hep total scores. To identify any moderation effect of HCC on the MELD and FACT-Hep association, linear regression with FACT-Hep as an outcome, and covariates including HCC status, MELD, as well as interaction between these two variables was done. In addition, we evaluated the relationship between FACT-Hep total score and PROMIS-29 domain scores, as well as HCC moderation effect on this relationship in the same way as described above. **Results:** Recruitment into this study is ongoing. 821 patients have been enrolled (mean age 62.8, 28% females, 79% Caucasians), with 29% having HCC. Mean baseline MELD score is 11.4 (SD 6.1), CTP score 8.3 (1.9) and FACT-Hep total score 116.2 (SD 28.1) respectively. There is a statistically significant correlation between MELD and FACT-Hep total score at baseline, although the magnitude is small ($r = -0.13$, $p < 0.001$). CTP score correlates better with FACT-Hep (-0.19, $p < 0.001$). Mean (SD) PROMIS- 29 T scores are- Physical function 38.4 (9.6), Anxiety 53.5 (10.9), Depression 53.3 (10.7), Fatigue 57.6 (11.5), Sleep disturbance 54.4 (10.8), Social roles 45.4 (10.6), and Pain interference 57.0 (11.0). Among all domain scores, physical function scores are the worst when compared to general population mean of 50 (SD = 10). All PROMIS-29 domain T scores correlate strongly with FACT-Hep total score (Table). The relationship between MELD and baseline FACT-Hep total score was stronger for HCC when compared to patients without HCC, but this differential effect was not statistically significant (interaction $p = 0.058$). Patients without HCC showed differential relationship of the FACT-Hep total score with Depression (interaction $p < 0.001$) and Fatigue (interaction $p = 0.029$) scores as compared to those with HCC. **Conclusion:** The correlation between MELD, CTP scores and QoL is moderate. CTP correlates better with QoL than MELD scores. FACT-Hep total score correlates strongly with all PROMIS-29 domains, thus future research can utilize either one. Given moderate correlation between liver function and QoL, there's probably other factors that contribute to QoL. There are differences in relationships in HCC Vs. no HCC patients.

Table: Correlation between FACT-Hep Total Score and PROMIS-29 Domain scores.

PROMIS 29 Domain scores	FACT-HEP baseline total score[1]	p-value
Physical function domain T-score[2]	0.52	<.001
Anxiety domain T-score[3]	-0.62	<.001
Depression domain T-score[3]	-0.64	<.001
Fatigue domain T-score[3]	-0.67	<.001
Sleep disturbance domain T-score[3]	-0.50	<.001
Social roles and activities domain T-score[2]	0.59	<.001
Pain interference domain T-score[3]	-0.60	<.001
Pain intensity score[3]	-0.49	<.001

[1]- Higher score is better; [3]- Lower score is better (e.g. lower anxiety score means less anxiety, and Higher physical function means better physical function)

3816-C | THE HOSPITAL FRAILTY RISK SCORE IDENTIFIES LIVER CIRRHOSIS PATIENTS AT RISK OF FRAILTY AND MORTALITY

Marianne De Roza[1], Jason Pik Eu Chang[2], Kalki Rajamanickam Chandrasekaran[1], Hiang Keat Tan[2], Rahul Kumar[3], Kevin Kim Jun Teh[2], Amber Chung[4], Wei Quan Teo[4], Prema Raj[4], Chanda Kendra Ho[2] and Singhealth Solidarity Liver Group, (1)Sengkang General Hospital, (2)Singapore General Hospital, (3)Changi General Hospital, (4)Singhealth-Duke Nus Transplant Centre

Background: Frailty in older adults and in liver cirrhosis is a predictor of worse outcomes and high resource utilization.[1] Validated assessments of frailty in liver cirrhosis include tests on physical function which may not be carried out routinely in real world clinical practice.

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

The hospital frailty risk score (HFRS)[2] uses administrative data from a set of weighted ICD10 codes to identify frailty. While the HFRS was originally designed as a geriatric assessment tool, our study aims to validate the HFRS in the cirrhotic population as a prognostic predictor of mortality and hospital readmissions. **Methods:** Patients with liver cirrhosis and at least 1 hospital admission in 2018 from 2 large public hospitals in Singapore were identified using ICD-10 codes. The diagnosis of cirrhosis was confirmed using imaging, liver stiffness measurement or histology. A 2-year lookback period, as utilized in the Gilbert study, was used to calculate the HFRS using the cumulative sum of a weighted ICD10 code set. Patients were categorized into low risk (HFRS < 5) or higher risk (HFRS ≥ 5). Patient outcomes were tracked from 2016-2020. **Results:** A total of 1037 patients with liver cirrhosis and at least 1 hospital admission or emergency department (ED) visit in the year 2018 were included. During the two-year lookback period for the 1037 patients, there were 8965 hospital admissions or ED visits where 286 distinct patients had visits with ICD-10 codes identified in the Gilbert study. Based on the weighted HFRS calculation, only 2.3% patients in the study cohort were in the higher risk (HFRS ≥ 5) group. However, these patients had a significantly higher mortality rate (79.2% vs. 35.1% HFRS < 5; $p = 0.008$). Additional subgroup analysis by age (< 65, 65-75, age > 75) was performed and showed a trend of increased mortality with each age category when comparing the two groups. The mortality data are as follows: Age < 65 (57.1% vs. 41.9% HFRS < 5); age 65-75 (75% vs. 55.7% HFRS < 5; Age > 75 (92.3% vs. 59% HFRS < 5). **Conclusion:** Our study shows that a Hospital Frailty Risk Score ≥ 5 is a significant predictor of frailty and mortality among patients with cirrhosis. Early identification of at-risk patients is necessary to implement interventions known to improve frailty, especially as we care for a globally aging population living with chronic disease. The HFRS is a useful cost-effective tool that can be leveraged using administrative data to identify at-risk patients with cirrhosis to help improve health outcomes.

f 3900-C | ABSENCE OF BILIARY ATRESIA CANDIDATE GENE PKD1L1 IMPAIRS BILIARY DEVELOPMENT

Dominick Hellen[1], Ashley Bennett[1], Caroline Klindt[1], David Lee[1], Paul A. Dawson[1] and Saul Karpen[2], (1) Division of Pediatric GI/Hepatology, Children's Healthcare of Atlanta & Emory University School of Medicine, (2)Children's Healthcare of Atlanta & Emory University School of Medicine, Atlanta, GA

Background: Biliary atresia (BA) is the most prevalent serious liver disease of infancy, yet limited progress has been made in understanding the causes and contributors to its etiopathogenesis. Recently, applying data acquired from human BA DNA analyses, a liver-restricted deletion of the BA candidate gene *Pkd1l1* in mice led to histologic features akin to that seen in BA livers including ciliopathy, ductal plate expansion, and enhanced peribiliary fibroinflammation. To better delineate *Pkd1l1*'s role in developing cholangiocytes, we studied embryonic, postnatal, and isolated cholangiocytes from a developmentally-focused *Pkd1l1* knockout line. **Methods**: We generated *Pkd1l1*$^{null/Fl}$ (null/Fl), and *null/Pkd1l1*-deficient mouse (null/LKO) models, respectively. From embryonic day 18 (E18) through postnatal day 30 (P30), null/Fl and null/LKO mice were evaluated with standard serum chemistries, and whole slide liver histology, with a focus on developmental biliary structures, junctional complexes, and transcription factors. At P30, bile duct ligation (BDL) was performed for 7 days of null/Fl and null/LKO mice followed by standard serum and liver analytics. Isolated intrahepatic *Pkd1l1*$^{Fl/Fl}$ (CTL) and *Pkd1l1-deficient* (KO) cholangiocytes were studied in vitro for structural features and reactive phenotype. **Results**: Histological analyses at ages E18, P5, and P30 revealed delayed biliary maturation, a significant increase in immature *Sox9*+ cholangiocytes, and a reduction of mature Ck19+ cholangiocytes and bile ducts in null/LKO compared to null/Fl livers (see Figure). Disordered tight junctional complexes were evident at ages P5 and P30 by disordered ZO-1 and β-catenin staining in null/LKO vs null/Fl cholangiocytes. Following BDL, peribiliary fibroinflammation, and necrosis were markedly increased in null/LKO compared to null/Fl livers. Isolated KO cholangiocytes revealed perturbed tight junctions, reduced cilia, altered β-catenin signaling, and decreased rates of proliferation in contrast to CTL. **Conclusion**: Developing cholangiocytes deficient in *Pkd1l1* exhibit ductal immaturity, with tight junction and intracellular structural disturbances. The absence of *Pkd1l1* in young cholangiocytes leads to enhanced susceptibility to obstructive damage from BDL. In sum, the null/LKO mouse provides a novel and useful model to explore the consequences of absent *Pkd1l1* with indication that its absence can induce the developmental cholangiopathy that leads to the BA phenotype. Figure: Delayed and reduced Ck19+ bile ducts at all time points throughout development in null/LKO compared to null/Fl livers. N = 4-6/group. $^{**}p < 0.01$, $^{****}p < 0.0001$.

3901-C | IL-17 SIGNALING IN PRIMARY SCLEROSING CHOLANGITIS PATIENT-DERIVED ORGANOIDS

Ana Sofia Garcia Moreno[1], Gregory J. Gores[1], Maria Eugenia Guicciardi[1], Erik Jessen[1], Alexander Q. Wixom[1], Filippo Pinto E Vairo[1], Jingchun Yang[1], Sumera I. Ilyas[2], Jackie K Bianchi[1] and Konstantinos N. Lazaridis[1], (1)Mayo Clinic, (2)Mayo Clinic, Rochester, Rochester, MN

Background: IL-17 signaling has been implicated in the pathogenesis of Primary Sclerosing Cholangitis (PSC). However, a direct assessment of IL-17 signaling in PSC cholangiocytes is lacking. **Methods:** Cholangiocytes obtained from bile and brushing samples collected during endoscopic retrograde cholangiography (ERC) from PSC (n = 9) and non-PSC (n = 7) patients were cultured as organoids. These extrahepatic cholangiocyte organoids (ECO) were treated with vehicle or IL-17A (100 ng/mL for 24 hours) and analyzed by NanoString and single cell RNA sequencing (scRNA-seq). In addition, ECO from 9 PSC patients were subjected to whole genome sequencing (WGS), to determine if somatic mutations are implicated in IL-17 signaling dysregulation. **Results:** ScRNA-seq analysis confirmed the ECO were cholangiocytes and were not contaminated by hepatocytes or fibroblasts. The ECO abundantly expressed the IL-17 receptors A, C, and E. Unsupervised clustering identified 8 cholangiocyte clusters in the ECO; however, there were no differences between PSC and non-PSC ECO. PSC ECO respond differently to IL-17 stimulation as compared to non-PSC ECO. When comparing PSC to non-PSC ECO after IL-17 treatment, there was an enhanced expression of 33 genes such as TLR2, KLRB1, BTLA, FCGR2A/C and IL22. In particular, PSC ECO had a robust response to IL-17 in all of the clusters, with the differential expression of genes associated with protein processing, prion, and Huntington diseases, bladder cancer, rheumatoid arthritis, AGE-RAGE, and HIF-1 signaling pathway. After rigorous filtering, WGS identified the presence of somatic mutations on the RUNX and MAPK pathways that were shared between 3 and 4, respectively in the 9 PSC patients. However, no somatic mutations dysregulating genes in the IL-17 pathway were identified. **Conclusion:** PSC- as compared to non-PSC derived ECO respond differently to IL-17A stimulation suggesting dysregulation of this pathway in PSC, implicating IL-17 signaling in PSC disease modulation.

f 3902-C | MRP9 IS A NOVEL REGULATOR OF CHOLANGIOCYTE MITOCHONDRIA METABOLISM

Anit Shah[1], Ramesh Kudira[1], Hannah Nartker[1], Bryan Donnelly[1], Wujuan Zhang[1], Manavi Singh[1], Maria E. Moreno-Fernandez[1], Alexander G. Miethke[1] and Chunyue Yin[1,2], (1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)University of Cincinnati

Background: In an effort to discover new genes causal for cholestatic liver disease, we recently reported a biallelic frameshift variant in *ABCC12* in a patient with intrahepatic cholestasis and bile duct paucity. *ABCC12* encodes the ATP-binding cassette protein MRP9, whose function is poorly understood. Studies conducted on zebrafish and mice have demonstrated that MRP9 loss renders cholangiocytes susceptible to bile acid-induced apoptosis, but the underlying mechanism is unclear. MRP9 has been implicated to mediate sperm mitochondrial function in mice. Its role in cholangiocyte mitochondria remains unknown. **Methods:** We performed immunofluorescent staining to investigate the subcellular localization of MRP9 in the H69 human cholangiocyte cell line. *Abcc12-/-* mice and zebrafish show progressive abnormalities in bile duct profiles during juvenile and adult stages. To determine the initial cause of bile duct defects, we focused on larval zebrafish and neonatal mice. We compared transcriptomes of cholangiocytes isolated from wildtype and *abcc12-/-* neonatal mice. We examined the ultrastructure of zebrafish and mouse cholangiocytes using transmission electron microscopy. We assessed mitochondrial energetic metabolism in neonatal mouse

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

cholangiocytes through Seahorse assay. **Results:** In human H69 cells, MRP9 was localized in proximity to the plasma membrane and mitochondria. Bulk RNAseq analysis showed that pathways associated with cholangiocyte development during the embryonic stages were upregulated in *Abcc12-/-* neonatal mice, indicating a less mature phenotype compared to wildtype cells. The mutant cholangiocyte transcriptome indicated increased lipid and glucose metabolism, as well as dysregulated mitochondrial metabolism. Ultrastructural analyses of larval zebrafish and neonatal mice revealed vacuolization, loss of cristae, and mitophagy in the mitochondria of mutant cholangiocytes (Fig. A). Seahorse mito stress test demonstrated impaired mitochondrial energetic metabolism in the mutant cholangiocytes, as evidenced by decreased basal respiration, maximal respiration, ATP-linked respiration, and non-mitochondrial respiration, along with increased proton leak compared to controls (Fig. B). **Conclusion:** These findings identify mitochondria dysfunction as a potential cause for apoptosis in *Abcc12-/-* cholangiocytes. They connect MRP9 to cholangiocyte mitochondria metabolism for the first time, highlighting the link between cell-specific mitochondrial function and susceptibility to bile duct paucity and neonatal cholestasis.

f 3903-C | OVEREXPRESSION OF OSTEOPONTIN (SPP1) IN BILIARY EPITHELIAL CELLS CAUSES DUCTULAR REACTION

Sai Santosh Babu Komakula, Xiaodong Ge, Zhuolun Song, Hui Han, Sukanta Das, Ines Barahona, Daniel Lantvit and Natalia Nieto, University of Illinois at Chicago

Background: Osteopontin (OPN, encoded by *SPP1*) is implicated in chronic liver disease. OPN expression increases in chronic liver disease including, non-alcoholic fatty liver disease (NAFLD), alcoholic liver disease (ALD), fibrosis, and hepatocellular carcinoma (HCC). Biliary epithelial cells (BECs) maintain the structural integrity of the bile ducts (BDs) and form a continuous barrier between hepatocytes and bile. Moreover, BECs play a major role in bile acid (BA) composition and secretion, which in turn influences intestinal physiology. Proliferation of BECs occurs in cholangiopathies. OPN is highly expressed in BECs, however the role of BEC-derived OPN is still unknown. **Methods:** we analyzed publicly available human liver scRNAseq data sets. We generated mice with BECs-specific OPN overexpression ($Spp1^{KI\ BEC}$) or ablation ($Spp1^{\Delta BEC}$) using $Sox9\text{-}Cre^{ER}$ mice and injecting tamoxifen (75 mg/kg body weight) at 8 weeks of age. Mice were sacrificed 1 and 4 weeks later. Histology of liver and intestine was performed. Intestinal transit rate was analyzed using the carmine red assay. **Results:** *SPP1* expression increased in BECs from NAFLD and ALD patients compared to healthy subjects. Homozygous $Spp1^{KI\ BEC}$ mice died 10 days after tamoxifen injection, indicating that overexpression of OPN in BECs is deleterious. $Spp1^{KI\ BEC}$ mice had significant body weight loss (~25%) and the ratio of liver-to-body weight decreased. Moreover, $Spp1^{KI\ BEC}$ mice had significantly increased intestinal transit rate. Histological analysis of liver revealed greater number of bile ducts per portal triad, indicating ductular reaction. H&E staining showed damaged duodenal epithelium. Since homozygous $Spp1^{KI\ BEC}$ mice died early, we then used heterozygous ($Spp1^{KI\ (+/-)\ BEC}$) mice for further analyses along with $Spp1^{\Delta BEC}$ and $Sox9\text{-}Cre^{ER}$ mice

and they were sacrificed 4 weeks after tamoxifen injection. H&E staining showed increased ductular reaction in liver from *Spp1*$^{KI\ (+/-)\ BEC}$ compared to control (*Sox9-Cre*^{ER}) mice. Of note, the intestinal transit rate significantly increased in *Spp1*$^{KI\ (+/-)\ BEC}$ mice and decreased in *Spp1*$^{\Delta BEC}$ mice compared to control mice. **Conclusion:** expression of OPN in BECs is elevated in NAFLD and ALD patients. Overexpression of OPN in BECs increases ductular reaction, alters the intestinal epithelium, and lengthens the intestinal transit rate.

3904-C | REGNASE-1 DYSFUNCTION PROMOTES INTRAHEPATIC CHOLANGIOCARCINOMA DEVELOPMENT VIA MYELOID CELL-MEDIATED HEPATOCYTE TRANSDIFFENTIATION

Yu Sato[1], Takahiro Kodama[2], Shuhei Yamamoto[1], Yuto Shiode[3], Hayato Hikita[1], Tomohide Tatsumi[1] and Tetsuo Takehara[2], (1)Osaka University, Graduate School of Medicine, (2)Osaka University Graduate School of Medicine, (3)National Cancer Institute Laboratory of Human Carcinogenesis

Background: Etiology of Intrahepatic cholangiocarcinoma (ICC) is still unclear, but chronic liver inflammation is considered as the risk factor. An endoribonuclease Regnase-1(Reg1) controls inflammation by degrading mRNAs of inflammatory mediators. Herein, we investigated the role of Reg1 in ICC. **Methods:** We analyzed spontaneous ICC models including the liver-specific Pten/Traf3 double knockout (DKO) mice and wild-type mice with hydrodynamic injection of transposon-based Yap and Akt expression vectors. We generated liver-specific Reg1 KO mice, liver-specific Reg1/Pten DKO (LDKO), hepatocyte-specific Reg1/Pten DKO (HDKO) and chorangiocyte-specific Reg1/Pten DKO (CDKO) mice. They were also crossed with ROSA-LacZ mice for lineage tracing. We performed scRNA-seq of the liver of WT and Reg1 KO mice and tumor and non-tumor liver tissue of an ICC patient. Association of intratumor Reg1 expressions and prognosis was evaluated in 40 ICC patients. **Results:** Reg1 expression levels were lower in tumors than in non-tumor liver tissues in two ICC models. Reg1 KO mice showed cholangiocyte hyperplasia with CD11b$^+$ cell infiltration, resulting in spontaneous ICC development. Liver-specific Reg1 deletion also significantly accelerated ICC formation in the absence of Pten. ICC developed in HDKO but not in CDKO mice. Lineage tracing of HDKO mice showed that proliferative cholangiocytes were derived from hepatocytes. scRNA-seq analysis revealed a predominant intrahepatic immune cell cluster expressing CD11b and TNF not in WT mice but Reg1 KO mice. Similar unique cluster was also found only in tumor sites but not in non-tumor liver tissue of ICC patients. Antibody-mediated depletion of CD11b$^+$ cells or genetic TNF deletion suppressed the cholangiocyte neoplastic growth in Reg1 KO mice, suggesting that TNF secreted from CD11b$^+$ cells was responsible for ICC formation by Reg1 loss. Mechanistically, Reg1 deletion in hepatic cells upregulated expressions of CXC chemokines important for CD11b$^+$ cell recruitment and RIP-Seq analysis showed direct binding of Reg1 to these mRNAs. Reg1 deletion in hepatic cells promoted migration of co-cultured CD11b$^+$ cells and upregulated their TNF expressions. Conversely, CD11b$^+$TNF$^+$ cells upregulated cholangiocyte markers of co-cultured Reg1-deficient hepatocytes. Lastly, intratumor Reg1 expression was negatively correlated with the number of infiltrated CD11b$^+$ cells and poor prognosis in ICC patients. **Conclusion:** Regnase-1 dysfunction promotes myeloid cell-mediated ICC development.

3905-C | TRANSCRIPTOME ANALYSIS REVEAL CONJUGATED BILE ACID INDUCED DUCTAL PROLIFERATION VIA YAP1-PITX1-NRAS AXIS IN BILIARY ATRESIA

Surya Amarachintha[1], Stacey S. Huppert[2], Arul Thason[1] and Anh-Hue Tu[1], (1)Georgia Southwestern State University, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, OH

Background: Biliary atresia (BA) is a severe inflammatory and fibrosing cholangiopathy of neonates. Despite successful hepatoportoenterostomy, the liver continues to progress with fibrosis and cirrhosis towards liver failure requiring organ transplantation. We hypothesize that elevated levels of conjugated bile acids in BA livers augments pathologic activation of *YAP1*, loss of *PITX1*, and *NRAS* induction to abnormally proliferate intrahepatic bile ducts. **Methods:** To identify gene signature responsible for elevated conjugated bile acids in BA, first, we analyzed publicly available curated gene expression datasets (GSE46960, GSE122340, GSE136270) of liver biopsies collected from normal and BA patients. Next, we compared gene datasets (GSE186444) of cholangiocyte organoids (CO)

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

generated from livers of normal donor (ND) and BA patients at diagnosis (Dx) or transplant (Tx) to identify pathways that would induce ductular proliferation. **Results:** Bile acid-CoA:amino acid N-acyltransferase (*BAAT*), an enzyme producing conjugated bile acids was found elevated in BA livers compared to normal controls (0.33 ± 0.9 vs -0.47 ± 0.49; $p < 0.001$), (164.9 ± 68.7 vs 93.7 ± 67.6; $p < 0.05$), and (4841 vs 1888; $p < 0.05$) in all three data sets. Analyzing dataset of CO, we found an increased expression of *YAP1* in Tx compared to Dx (89.9 ± 17 vs 54.2 ± 24.5; $p < 0.05$) along with its downstream targets *TEAD1* (36.2 ± 5.8 vs 18.8 ± 10; $p < 0.01$), and *SMAD2* (87.2 ± 23.3 vs 47.8 ± 15.8; $p < 0.05$). This increased expression of *YAP1* could be a direct effect of increased conjugated bile acids or an indirect effect with loss of *CRB3,* an inhibitor of *YAP1,* in Tx compared to Dx (45.6 ± 10.3 vs 58.7 ± 5.9; $p < 0.05$). Identifying a pathway that induces cholangiocyte proliferation with disease progression, we found loss of *PITX1* in Dx and Tx (ND, 7.3 ± 5.6 vs Dx, 0.45 ± 0.6, $p < 0.05$; vs Tx, 0.74 ± 0.8, $p < 0.05$) that could be a result of *YAP1* activation. Following the loss of *PITX1,* a suppressor of *RAS* further analysis revealed activation of *NRAS* pathway in Tx compared to Dx (*NRAS*, 18.5 ± 4.3 vs 11.7 ± 2.9, $p < 0.05$; *RAF1*, 58.2 ± 7.1 vs 45.2 ± 6.4, $p < 0.05$; *p38*, 39.7 ± 5.8 vs 27.1 ± 7.7, $p < 0.05$; *ERK2*, 96.1 ± 12 vs 49.5 ± 21.2, $p < 0.01$). Finally, proliferation of cholangiocytes can be confirmed with activation of *NOTCH2* in Tx compared to Dx (19.3 ± 3 vs 12.8 ± 5.9, $p < 0.05$). **Conclusion:** Based on the bioinformatic analysis and published data we conclude that activation of *YAP1* by conjugated bile acids results in stimulation of *NRAS,* potentially via loss of *PITX1* that would uncover a novel mechanism in abnormal bile duct proliferation with disease progression in BA (Figure 1). However, this remains to be experimentally/functionally tested.

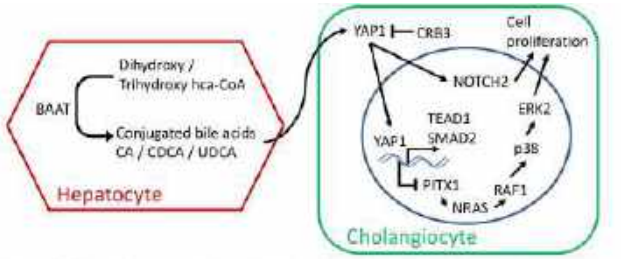

Figure 1. Schematic representation of intrahepatic bile duct proliferation with disease progression in Biliary atresia. BAAT, bile acid-CoA:amino acid N-acyltransferase; CA, cholic acid; CDCA, chenodeoxycholic acid; UDCA, ursodeoxycholic acid; YAP1, Yes1 associated transcriptional regulator; CRB3, crumbs cell polarity complex component 3; TEAD1, TEA domain transcription factor 1; SMAD2, SMAD family member 2; PITX1, paired like homeodomain 1; NRAS, NRAS proto-oncogene, GTPase; RAF1, Raf-1 proto-oncogene, serine/threonine kinase; p38, mitogen -activated protein kinase 14; ERK2,mitogen-activated protein kinase 1.

3906-C | VANISHING BILE DUCT SYNDROME (VBDS): HOW DO DUCTS DISAPPEAR?

Jose R. Russe, Joseph Cotton, Li Liu and Anurag Maheshwari, Institute for Digestive Health and Liver Disease at Mercy Medical Center

Background: Vanishing Bile Duct Syndrome (VBDS) is an acquired condition characterized by prolonged cholestasis and more than 50% progressive loss of bile ducts on liver biopsy (LBx). Common causes of VBDS are antibiotics (Abx) and herbal intake. Reported cases of VBDS have been scarce, leading to a poorly understood pathophysiology thought to be immune-mediated cholangiolar damage in response to direct injury by drugs, metabolites, and prolonged stagnant bile salt exposure. We aim to provide evidence to clarify VBDS pathophysiology further. **Methods:** A 63-year-old woman with recurrent Lyme arthritis was treated, in November, with Cefdinir (CFD), minocycline (MNC), and Flagyl (FLG) for ten days. A week later, her symptoms were unresolved, and she took Bactrim and Lamictal for five days. Unfortunately, her symptoms continued, and she started Malarone and Artemisinins in addition to resuming CFD, MNC, and FLG. Finally, in February, she saw her provider for fatigue, nausea, constipation, pruritus, icterus, jaundice, and abdominal pain. **Results:** Routine biochemistry (BCH) showed elevated liver enzymes (LFTs) and bilirubin (TB) of 4.9, and she was sent to the hospital (H), where new BCH showed an alkaline phosphatase (ALP) of 488 and TB of 11. The ABx were stopped after a suspected drug-induced injury and started Ursodiol with tapered steroids. Imaging (IMG), autoimmune, and viral serology were all normal. She was discharged to a specialized liver clinic, where a LBx showed lymphohistiocytic portal inflammation and ductal damage (Figure 1A). In March, her ALP was 515, TB was 32.1, and IMG showed hepatosteatosis, no obstruction, and cholestatic inflammation, resolved on repeat IMG in May. In August, ALP was 510, TB was 3.9, and repeat LBx showed persistent inflammation, worsened ductal damage, and pericholangitis (Figure 1B). Nearly two years after stopping ABx, the LFTs were normal, except ALP was 341, and repeat LBx showed ductopenia with numerous sinusoidal macrophages (Figure 1C). **Conclusion:** Progressive cholestatic injury supporting an early ductopenic process is seen in adverse drug reactions, particularly persistent ductal loss without portal fibrosis, despite withdrawing the offending drug (Figure 1). Furthermore, our findings demonstrate that chronic T-cell-mediated cholestatic injury, bile duct destruction by circulating leukocytes, and hepatic repair and resolution by Kupffer cells, maintaining hepatic

homeostasis, were the driving forces for the emergence of VBDS. The highlighted case and objective data provide evidence for the natural history of VBDS, prompting further research.

3907-C | A HIGH FAT DIET MODULATES BILE ACID COMPOSITION AND GUT MICROBIOTA LEADING TO SEVERE CHOLANGITIS AND CIRRHOSIS IN A MURINE MODEL OF PBC

Masahiro Umemura[1], Akira Honda[2], Maho Yamashita[1], Takeshi Chida[1], Hidenao Noritake[1], Kenta Yamamoto[3], Takashi Honda[3], Mayuko Ichimura-Shimizu[4], Koichi Tsuneyama[4], Patrick S.C. Leung[5], M Eric Gershwin[5] and Kazuhito Kawata[1], (1)Hepatology Division, Department of Internal Medicine, Hamamatsu University School of Medicine, Japan, (2)Division of Gastroenterology and Hepatology, Tokyo Medical University Ibaraki Medical Center, Japan, Japan, (3) Nagoya University Graduate School of Medicine, (4) Department of Pathology and Laboratory Medicine, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, (5)Division of Rheumatology, Allergy and Clinical Immunology, University of California at Davis School of Medicine, 451 Health Sciences Drive, Davis, CA, 95616, USA

Background: The obesity epidemic has increased the number of patients with primary biliary cholangitis (PBC) suffering from metabolic syndrome. Indeed, the complication of fatty liver disease complicates the pathology of PBC and reduces the efficacy of ursodeoxycholic acid. We hypothesized that alterations in bile acid (BA) composition and gut microbiota by a high-fat diet (HFD) would influence cholangitis and hepatic fibrosis in PBC. **Methods:** We took advantage of a unique PBC hepatic fibrosis mouse model, Cyp2c70/Cyp2a12 double knockout (DKO) mice, which have human-like BA composition, and develop progressive PBC following immunization with a PDC-E2 mimic, 2-octynoic acid (2OA). We serially studied 2OA-treated DKO mice or control mice, each of which was fed an HFD (60% kcal from fat) or a normal diet (ND) for 10 weeks by comparing pathological changes, hepatic expression of inflammatory cytokines, chemokines, and fibrosis markers, BA composition, and gut microbiota. **Results:** 2OA-treated DKO mice fed an HFD had significantly exacerbated portal and lobular inflammation and bile duct damage, and cirrhotic change compared with those mice fed ND. Hepatic expression of Th1 cytokines/chemokines and fibrotic markers were predominantly induced in 2OA-treated DKO mice fed an HFD. The ratio of chenodeoxycholic acid + lithocholic acid (LCA) to cholic acid (CA) + deoxycholic acid and the BA hydrophobicity index in the liver were significantly increased by an HFD, which was associated with reduced expressions of Cyp8b1, a key enzyme in the CA biosynthetic pathway, and Cyp3a11 and Sult2a1, enzymes metabolizing LCA. In addition, there was a higher relative abundance of secondary BA-producing bacteria with 7α-dehydroxylation activity (*Bacteroides*, *Acetatifactor*) in 2OA-treated DKO mice fed an HFD, correlating with the increase in LCA. **Conclusion:** Increased hepatic BA hydrophobicity associated with the alteration of hepatic BA metabolism and gut microbiota by an HFD exacerbated cholangitis and critically progressed to cirrhosis in this murine PBC model. These data demonstrate that diet-induced changes in gut microbiota and BA composition influence cholangitis and the progression of hepatic fibrosis. These features have the potential for understanding not only hepatic pathology in patients with PBC suffering from metabolic syndrome but also the natural history and role of diet-induced inflammation in all patients with PBC.

Ghanekar[6] and Binita M. Kamath[7], (1)Hospital for Sick Children, (2)University of Cambridge, (3)Cambridge Stem Cell Institute, (4)Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, (5)Children's Healthcare of Atlanta, (6)Toronto General Hospital, (7)The Hospital for Sick Children, Toronto, ON, Canada

Background: After injury, cholangiocytes develop a reactive phenotype involving secretion of cytokines and chemokines which recruit immune cells that promote inflammation and biliary fibrosis. The underlying mechanisms are not completely understood and may involve the bile acid-activated Sphingosine-1-phosphate receptor 2 (S1PR2). To better model the molecular pathogenesis of human cholangiopathy and S1PR2, we developed a human extrahepatic cholangiocyte organoid (ECO) injury model that mimics the cholestatic microenvironment. We explored ECO responses to hydrophobic bile acids and cytokines, and focused on the role of S1PR2 signaling in injury and rescue with therapeutic bile acids NorUDCA and UDCA. **Methods:** Human ECOs were exposed to 1 mM TCA, 1 mM GCA or 0.5 mM GCDCA ± 20 ng/ml TNFα for 24 hours to initiate injury. Treatment with 250 μM NorUDCA or 62.5 μM UDCA were initiated 8 hours after injury induction. Outcome measures included ECO diameter change, cell proliferation, LDH activity and mRNA quantitation of reactive phenotype markers MCP-1, IL-8, TNF-α, Vimentin and TGF-β1. To test the role of S1PR2 pathway, S1PR2 agonist Sphingosine-1-phosphate (S1P), antagonist JET-013 (JET), and ERK-1/2 inhibitor were utilized. **Results:** Exposure to TCA, GCA or GCDCA with TNF-α had synergistic effects; with combined exposure ECO diameters were reduced 3.5 ± 0.6, 4.8 ± 0.6 and 5.4 ± 0.6 fold; cell proliferation decreased 29 ± 3.8%, 27.4 ± 3.8% and 30.2 ± 3.8 %; while LDH activity increased 5.9 ± 0.4%, 4.6 ± 0.5% and 12.3 ± 0%; respectively compared to control ($P < 0.05$), together with marked increase in all reactive phenotype marker mRNAs. Both NorUDCA and UDCA treatments improved all measured ECO effects from the bile acid TCA +TNF-a treatment and suppressed reactive phenotype marker mRNAs. S1P stimulation reproduced cholangiocyte injury and reactive phenotype, which was inhibited by JET, ERK1/2 inhibitor, and NorUDCA and UDCA. S1PR2 inhibition with JET partially suppressed cholangiocyte reactive phenotype after injury. S1PR2 downstream mediators ERK1/2 phosphorylation and COX2 expression were suppressed by JET and by NorUDCA and UDCA treatment after injury. **Conclusion:** We modeled the reactive state in human ECOs. In response to cholestatic conditions we demonstrated a contributory role of S1PR2 in injury and therapeutic response via NorUDCA and UDCA. This new cholangiocyte injury model provides a valuable tool to further understand the role of bile acids in human cholangiopathies.

3909-C | ABLATION OF OSTEOPONTIN (SPP1) IN HEPATOCYTES AND BILIARY EPITHELIAL CELLS PROTECTS FROM PRIMARY SCLEROSING CHOLANGITIS

Ines Barahona, Hui Han, Zhuolun Song, Xiaodong Ge, Sukanta Das, Sai Santosh Babu Komakula, Daniel Lantvit and Natalia Nieto, University of Illinois at Chicago

Background: primary sclerosing cholangitis (PSC) is a rare chronic cholestatic liver disease characterized by strictures of the intrahepatic or extrahepatic biliary system, inflammation, and portal fibrosis, all of which lead to impaired bile formation, cirrhosis, and liver failure. Osteopontin (OPN, encoded by *SPP1*), is highly expressed in hepatocytes and biliary epithelial cells (BECs), regulates extracellular matrix (ECM) turnover, and increases in cholestatic disorders, however the role of OPN in PSC is unknown. Our aim was to investigate the effect of OPN from hepatocytes and BECs in PSC. **Methods**: we analyzed *SPP1* expression in publicly available RNA-seq datasets and in liver biopsies from PSC patients. To investigate the role of OPN from hepatocytes and BECs, we ablated *Spp1* in these cells in *Mdr2*$^{-/-}$ mice, a mouse model of PSC, and sacrificed them at 1 month of age. **Results**: *SPP1* mRNA and OPN protein expression were higher in patients with advanced PSC. *Mdr2*$^{-/-}$*Opn*$^{\Delta Hep}$ and *Mdr2*$^{-/-}$*Opn*$^{\Delta BEC}$ had reduced liver injury (ALT and AST) compared to *Mdr2*$^{-/-}$ mice. H&E staining, immunohistochemistry and qPCR analyses demonstrated that *Mdr2*$^{-/-}$*Opn*$^{\Delta Hep}$ and *Mdr2*$^{-/-}$*Opn*$^{\Delta BEC}$ showed less DR, number of bile ducts per portal triad, atrophied bile ducts, SOX9 expression, and *Krt19, Epcam,* and *Krt7* mRNAs compared to *Mdr2*$^{-/-}$ mice. Sirius red/fast green staining revealed that *Mdr2*$^{-/-}$*Opn*$^{\Delta Hep}$ and

Mdr2$^{-/-}$*Opn*$^{\Delta BEC}$ had less fibrotic onion-like structures compared to *Mdr2*$^{-/-}$ mice. Immunohistochemistry, flow cytometry, and qPCR analyses unveiled that *Mdr2*$^{-/-}$*Opn*$^{\Delta Hep}$ and *Mdr2*$^{-/-}$*Opn*$^{\Delta BEC}$ mice had decreased portal inflammation (F4/80^{+} cells, CD8^{+} T-cells, CD4^{+} T-cells, and B-cells) and lower expression of proinflammatory genes (*Il6, Ifn, Tnfa*) compared to *Mdr2*$^{-/-}$ mice. **Conclusion**: ablation of *Spp1* from hepatocytes and BECs decreases DR, fibrosis, and inflammation in livers from *Mdr2*$^{-/-}$ mice and protects from PSC.

3910-C | AGGRAVATING EFFECT OF LCA ADMINISTRATION ON CHOLANGITIS OCCURRING IN A MOUSE MODEL WITH HUMAN-TYPE BILE ACID COMPOSITION

Teruo Miyazaki[1], Hajime Ueda[2], Tadashi Ikegami[2] and Akira Honda[1,2], (1)Joint Research Center, Tokyo Medical University Ibaraki Medical Center, (2) Gastroenterology, Tokyo Medical University Ibaraki Medical Center

Background: Fibrosis around the large intrahepatic bile ducts characterized as the onion-skin lesion is a typical lesion of sclerosing cholangitis. Bile acids (BAs) might be involved in the pathogenesis, but still not well understood because no mouse models have been established to evaluate the role of BAs. One reason for this is the species difference in BA metabolism between humans and mice. In mice, a human-type hydrophobic BA, chenodeoxycholic acid (CDCA), is metabolized to mouse-specific BAs (muricholic acids; MCAs) by Cyp2c70, and also, the secondary BAs (lithocholic acid and deoxycholic acid; LCA and DCA) are converted back to the primary BAs by Cyp2a12, and consequently, the hydrophilic BAs as cholic acid (CA) and MCAs are the predominance. The present study evaluated the frequency of cholangitis and its possible onset factors in the mouse model with human-type BA composition by gene double knockouts (DKO) of *Cyp2c70* and *Cyp2a12* as well as the influences of LCA (the most hydrophobic BA) treatment. **Methods:** Wild-type (WT) C57BL/6J and DKO mice (5 weeks of age) were treated with or without LCA solution (75 mg/L) for 15 weeks in drinking water (Male/Female = 8/8 in each group). We evaluated hepatic BA profile, histological images, and gene and protein expressions of integrins (Itg) β6 and αV. ItgαVβ6 activates TGFβ and highly expresses in the epithelial cells in the colon with ulcerative colitis, which is often concurrent with primary sclerosing cholangitis. **Results:** The BA composition in the DKO livers changed to the human-type BAs (CA, CDCA, DCA, LCA) from the WT livers mainly occupied by CA and MCAs. Particularly, LCA content in the DKO livers was significantly increased by the LCA treatment. In histological observations, the frequency of onion-skin lesions with inflammatory cells around the large intrahepatic bile ducts was 88% (severe 63%; mild 25%) in the DKO livers and increased to 100% (severe 100%) by the LCA treatment, while no observations in the WT livers with and without LCA treatment. However, severe inflammation and damage in the parenchymal cells were not observed in WT and DKO groups and by LCA treatment. The mRNA expressions of *Itgβ6* and *ItgαV* were significantly higher in the DKO livers than in the WT livers, and the highly expressed Itgβ6 protein was observed in the portion of the fibrotic bile duct in the DKO livers by the immunohistochemical stain. **Conclusion:** Severe fibrosis with inflammation around the large intrahepatic bile ducts was induced in the DKO livers, and further aggravated by LCA administration at a low dose that does not cause acute and serious liver damage. The human-type hydrophobic BAs, particularly in LCA, are strongly suggested to be related to the onset of sclerosing cholangitis associated with Itg αVβ6.

3911-C | CHOLESTATIC DECREASE OF BILE SHEAR STRESS PROMOTES AKT ACTIVATION AND AGGRESSIVE FEATURES IN CHOLANGIOCARCINOMA

Andrew M. Oleksijew[1], Henry C. Drvol[2], Ashley M. Mohr[2] and Justin L. Mott[2], (1)Univeristy of Nebraska Medical Center, (2)University of Nebraska Medical Center

Background: Cholestasis, altered or absent bile flow, is associated with poor survival in patients with cholangiocarcinoma, an aggressive cancer of the biliary epithelium. Changes in bile flow often result from remodeling of bile duct geometry due to strictures or obstruction. Experimental cholestasis promoted tumor growth and progression. However, studies are needed that directly assess the mechanical interaction between bile flow, or bile shear stress, and cancer signaling. We hypothesized that cholestasis and absent bile shear stress increases cancer signaling and aggressive cellular behavior. **Methods:** KMCH cells, a human cholangiocarcinoma cell line, were used. Fluid shear stress was applied by orbital plate method approximating shear from bile flow and compared to identical culture conditions without media flow. Kinase activation

in shear versus early and late stasis was assessed by sandwich-ELISA for phosphokinase activity. Subcellular fractionation and immunoblot were used to identify protein localization and levels. Migration was assessed with wound-closure where the scratch was positioned at 0, 45, and 90 degrees to the direction of shear stress. Proliferation was assessed by cell count. **Results:** Transition of cells from shear stress pre-treatment to stasis (2 hours) increased levels of PRAS40 and β-catenin, proteins associated with cancer cell survival and epithelial-to-mesenchymal transition (EMT). Longer stasis increased β-catenin and it's regulators phospho-GSK3β and phospho-Akt. Consistently, intracellular and nuclear β-catenin increased with increased time in stasis. Tumor cells showed increased migration and proliferation with time in stasis providing additional evidence of mechanical responsiveness. Migration was not dependent on the direction of shear stress **Conclusion:** We demonstrated the regulation of cholangiocarcinoma by mechanical forces modeling cholestasis, activating Akt and increasing nuclear β-catenin. Restoring mechanosensory responses to cholestatic environments provides a novel therapeutic approach in cholangiocarcinoma and new understanding of mechanical interaction between bile and the biliary epithelium.

Baumert[1,10,11], (1)Université De Strasbourg, Inserm, Institut De Recherche Sur Les Maladies Virales Et Hépatiques Umr-S1110, 67000 Strasbourg, France, (2) Department of Imaging and Pathology, University of Leuven, 3000 Leuven, Belgium, (3)Department of Immunology, University of Toronto, Canada, (4)Ajmera Transplant Center, University of Toronto, Toronto, ON, Canada, (5)University of Toronto, (6)Donnelly Centre for Cellular and Biomolecular Research, (7)Alentis Therapeutics, 4123 Allschwil, Switzerland, (8)Division of Chronic Inflammation and Cancer, German Cancer Research Center, 69120 Heidelberg, Germany, (9)M3 Research Institute, Eberhard Karls University Tübingen, Tübingen, Germany, (10)Institut Hospitalo-Universitaire (IHU), Pôle Hépato-Digestif, Hôpitaux Universitaires De Strasbourg, 67000 Strasbourg, France, (11)Institut Universitaire De France, 75006 Paris, France

Background: Cholangiopathies are biliary diseases progressing to end-stage liver disease, fibrosis, and hepatobiliary cancers. Clinical care of most cholangiopathies lacks effective therapeutic strategies other than liver transplantation. Claudin-1 (CLDN1) is a transmembrane protein expressed in tight junctions. CLDN1 is also expressed non-junctionally mediating cell plasticity and signaling. We have previously developed a monoclonal antibody (mAb) targeting CLDN1 outside the tight junctions exhibiting an excellent safety profile (Roehlen et al. Science Transl. Med. 2022). The aim of this study was to investigate the functional role of CLDN1 as a mediator and therapeutic target for cholangiopathies. **Methods:** CLDN1 expression in liver tissues of patients with cholangiopathies was analysed using RNAseq, multicolor immunofluorescence, and spatial transcriptomics. Proof-of-concept studies using CLDN1-specific mAb H3L3 were performed in state-of-the-art mouse models for cholangiopathies. The HepaRG progenitor cell model and primary human cholangiocytes were used to study cell plasticity and signaling. **Results:** CLDN1 expression is significantly upregulated in primary sclerosing cholangitis (PSC), primary biliary cholangitis, biliary atresia, and the Alagille syndrome. Expression analysis of PSC patient-derived liver tissues revealed CLDN1 expression in cholangiocytes, reactive ductular biliary epithelial cells, and peri-portal hepatocytes, as well as fibroblasts and macrophages. scRNA analyses showed that CLDN1 is highly expressed by EPCAM+ progenitor cells and cholangiocytes. CLDN1 expression in PSC co-localizes with other known disease drivers at the periphery of scar lesions, such as p21, NF-kB, EGFR, and IL-8 in spatial transcriptomics analyses of patient tissues. Proof-of-concept studies showed that monoclonal anti-CLDN1 mAb H3L3 improved survival, cholestasis and liver function in the bile duct ligation mouse model and markedly and significantly reduced hepatobiliary fibrosis and its porto-portal progression without detectable adverse effects in the DDC biliary fibrosis model. Mechanistic studies showed that anti-CLDN1 mAb induced maturation of liver progenitor cells and inhibited NF-kB and MAPK signaling in vivo and cell-based models including human cholangiocytes. **Conclusion:** Our results uncover a previously unknown role of CLDN1 in the pathogenesis of cholangiopathies and provide preclinical proof-of-concept for a CLDN1 as a target to treat PSC and cholangiopathy-induced liver fibrosis.

f 3913-C | CONDITIONAL LOSS OF B-CATENIN LOWERS TOXIC BILE-INDUCED HEPATIC INJURY AND IMPROVES CHOLESTATIC OUTCOME IN MURINE MODEL★

Chhavi Goel[1], Rong Zhang[1], Silvia Liu[2], Pamela Cornuet[1], Xiaochao Ma[3] and Kari Nejak-Bowen[4], (1) University of Pittsburgh, (2)Pittsburgh Liver Research Center, (3)University of Pittsburgh School of Pharmacy, (4)University of Pittsburgh, Pittsburgh, PA

Background: Primary sclerosing cholangitis is a chronic fibrosing cholangiopathy partly attributed to toxic bile insults for which there is no medical treatment with proven efficacy. A high concentration of lithocholic acid (LCA) in primary sclerosing cholangitis patients is associated with hepatotoxicity and adverse clinical outcomes. We previously reported that conditional loss of β-catenin prevents the development of cholestatic liver injury after bile duct ligation by decreasing bile acid synthesis. To ascertain our findings, we tested if loss of β-catenin can elicit protection in toxic bile acid model of hepatobiliary injury. **Methods:** Age-matched wild-type control (Con) and liver-specific β-catenin knockout (KO) mice were fed LCA-supplemented diet. Mice were euthanized and liver tissues analyzed by histology, qPCR, RNAseq, immunostaining, Western blot and liquid chromatography-mass spectrometry. Serum biochemistry was measured to assess liver injury parameters. **Results:** Morphological comparison depicted significant necrotic lesions in Con livers following LCA diet which were remarkably reduced in the β-catenin KO livers. Serum analysis showed significant decrease in hepatic and biliary injury in KO compared to Con. Gene expression evaluation by qPCR revealed decreased bile acid uptake transporters, increased apical and basolateral efflux transporters, and increased expression of detoxifying cytochrome P450 enzymes in the KO group with the net result of decreased accumulation of toxic bile acid in KO livers. Additionally, bile acid composition was slightly altered in KOs after LCA diet, with a predominance of TbMCA over TMDCA. Pan-cytokeratin immunostaining showed increased ductular response in KO livers, likely as a compensatory mechanism for mediating enhanced bile clearance. RNA-seq analysis showed decreased proinflammatory genes in the KO livers compared to Con. Immunostaining analysis further confirmed significant activation of IL-33 in the hepatocytes of Con but not in KO. **Conclusion:** As observed previously in our bile duct ligation model, our current study in toxic bile acid model further supports that loss of β-catenin reduces hepatotoxicity and offers protection from hepatobiliary injury. This is achieved through increased transport and hydroxylation of toxic bile acid. IL-33 seems to be an important target of β-catenin and its secretion from hepatocytes may contribute to hepatic injury induced by the toxic bile LCA.

f 3914-C | DEFINING THE WNT SIGNALING LANDSCAPE OF THE EXTRAHEPATIC BILE DUCT AT HOMEOSTASIS AND IN OBSTRUCTIVE CHOLANGIOPATHY★

Ashley Calder[1], Mirabelle Peter[1], Erik Wamsteker[1], John Tobias[2] and Nataliya Razumilava[1], (1)University of Michigan, (2)University of Pennsylvania

Background: Understanding the mechanisms that drive quiescent cholangiocytes to become proliferative in acute injury and chronic biliary diseases such as primary sclerosing cholangitis and cholangiocarcinoma are necessary for the discovery of new therapeutic targets. WNT signaling has been implicated in cell fate determination, proliferation, and disease progression in GI organs, including liver; however, its role in cholangiocyte biology is not as well understood. WNT ligands can activate canonical (β-catenin mediated) or non-canonical pathways with antagonists (secreted frizzled-related protein, sFRP), and potentiators (R-spondins, Rspo) modulating WNT signaling. We aim to understand the WNT signaling landscape in the extrahepatic bile duct (EHBD) in homeostasis and injury. **Methods:** To investigate these questions, we performed single-cell (scRNA-seq) and bulk RNA-seq of the EHBD in mice and bulk RNA-seq in human biliary organoids. We used bile duct ligation (BDL) to model acute obstructive injury. We interrogated samples of cholangiocarcinoma (CCA) from The Cancer Genome Atlas (TCGA) for WNT signaling. We used mouse organoids to examine WNT effects on cholangiocyte proliferation and a porcupine (PORC) inhibitor to prevent WNT secretion. **Results:** Our transcriptomic analysis of mouse EHBD and human organoids revealed *WNT7B* as the predominant ligand in cholangiocytes. Both *Wnt4/7b* (canonical or non-canonical)

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

were upregulated and *Wnt5a* (noncanonical) was downregulated post-BDL. Upregulated WNT target genes (*Birc5*, *Ccnd1*, etc.) and *β-catenin* are expressed in cholangiocytes. WNT antagonists sFRP 1/5 are downregulated post-BDL. Fibroblasts are the primary source of sFRPs and Rspos. While organoids can be maintained in WNT-free media, loss of endogenous WNT secretion (via PORC inhibitor) resulted in decreased organoid growth. Similar to BDL, human CCA samples (TCGA) show increased proliferation (*KI67*) and *WNT7B*. **Conclusion:** These data indicate that 1) *WNT7B* is upregulated in acute and chronic biliary diseases. 2) WNT signaling enhances cholangiocyte growth *in vitro*. 3) sFRP1/5 may attenuate WNT effects at homeostasis. 4) Fibroblasts secrete both inhibitors and potentiators of WNT signaling. 5)The opposing expression of WNT ligands in biliary injury indicates a potential interplay between canonical and non-canonical signaling. Further studies elucidating the role of WNT signaling may provide further insight into the mechanisms driving cholangiocyte proliferation in biliary diseases and provide new therapeutic targets.

3915-C | DELETION OF INTERLEUKIN-17A AUGMENTS PORTAL FIBROSIS IN A MOUSE MODEL OF CHOLESTATIC LIVER INJURY

Takashi Kitagataya[1], Kirsta Olson[1], Michelle Baez-Faria[1], Begum Ozturk[1], Kaiyel Cutshaw[1], Anuradha Krishnan[2], Maria Eugenia Guicciardi[1], Kevin D. Pavelko[2] and Gregory J. Gores[1], (1)Mayo Clinic, (2) Mayo Clinic Rochester, Rochester, MN

Background: The underlying mechanism contributing to cholestatic liver injury remains unclear. The proinflammatory cytokine interleukin-17A (IL-17A) has been implicated in human cholestatic liver injury. However, mechanistic insights on how IL-17A modulates cholestatic liver injury are lacking and require further exploration in preclinical models. Herein, we examined the effects of IL-17A genetic deletion in a mouse model of cholestasis. **Methods:** Age- and gender-matched littermate WT and *Il-17a*$^{-/-}$ were fed intermittently on 0.1% 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) diet or control diet (n = 10, each) and standard diet for 21 days to induce cholestatic liver injury. We assessed liver inflammation, ductular reaction, and fibrosis using complementary approaches. **Results:** DDC-fed mice displayed significant increases in liver weight/body weight ratio and histological and serological characteristics of cholestatic liver injury compared to control-diet-fed mice in both WT and *Il-17a*$^{-/-}$ mice; however, there were no differences between WT and *Il-17a*$^{-/-}$ DDC-fed mice. Immunofluorescence staining for Desmin and Collagen I and Sirius red indicated portal fibrosis was significantly increased in DDC-fed *Il-17a*$^{-/-}$ mice compared to DDC-fed WT mice. Immunofluorescence staining for IBA1 (a pan macrophage marker) and myeloperoxidase (a neutrophil marker) displayed an increase in macrophages and neutrophils in DDC-fed *Il-17a*$^{-/-}$ mice vs. DDC-fed WT mice. Mass cytometry (CyTOF) on intrahepatic leukocytes confirmed this observation. Gene expression profiling and pathway analysis of intrahepatic leukocytes subjected to Nanostring analysis displayed upregulation of multiple profibrogenic genes and enrichment of fibrosis-relating pathways in both WT and *Il-17a*$^{-/-}$ mice. Compared to DDC-fed WT mice, the profibrotic gene *Tnfsf14* was significantly upregulated in DDC-fed *Il-17a*$^{-/-}$ mice. Taken together, these data suggest deletion of *Il-17a* in the mouse model of cholestatic liver injury results in upregulating profibrogenic pathways and alteration of immune cell populations within the liver, promoting fibrosis. **Conclusion:** IL-17A appears to restrain liver inflammation and fibrosis by suppressing *Tnfsf14* expression.

Background: Cholemic nephropathy (CN) is a severe complication of cholestasis-associated liver diseases, and no specific treatment is available. We revisited the pathophysiology to investigate the role of bile acids (BAs) and test new therapeutic strategies. **Methods:** The liver-kidney axis was time-dependently analysed in wild type (WT) mice for up to 12 weeks after bile duct ligation (BDL) or sham operation. BA flux in kidneys and livers was spatio-temporally visualized by intravital imaging, and further quantified by MALDI-MSI and LC-MS/MS. AS0369, a systemically bio-available apical sodium-dependent bile acid transporter (ASBT) inhibitor was synthesized and its specificity and pharmacokinetic properties characterized in mice. AS0369 was administered twice daily after BDL and its effects on liver and kidney were quantified using RNA-sequencing, histological, and serum and urine biochemistries. Translational relevance was evaluated by ASBT immunostaining in kidney biopsies from two cohorts of CN patients. **Results:** Enhanced reabsorption of BAs from the renal tubular lumen into proximal renal tubular epithelial cells (TEC) and a progressive increase in kidney BA tissue levels is observed after BDL. BA enrichment in TEC is followed by cell death, damage of peritubular capillaries, massive leakage of BA into the renal interstitium, and increased kidney fibrosis. Renal ASBT expression is restricted to the TEC and maintained after BDL. ASBT inhibition by AS0369 blocked BA uptake in renal TEC, massively increased urinary nonsulfated BA excretion, prevented BDL-associated mortality, and almost completely prevented kidney injury up to 6 weeks after BDL as evidenced by intravital imaging and MALDI-MSI, kidney histology, transcriptomics, urine and serum biomarkers (urea and NGAL). Preserved ASBT expression in human TEC was demonstrated in renal biopsies from CN patients, including at late-stage disease, highlighting the translational potential of treating CN by targeting ASBT. **Conclusion:** BA enrichment in TEC followed by cell death is an early key event in CN and consistent with an impaired kidney adaptive response to cholestasis. Inhibiting renal ASBT preserves the TEC and prevents CN even under conditions where serum and urinary BA concentrations are massively increased.

3917-C | LEUKEMIA INHIBITORY FACTOR (LIF) AS TRIGGER SIGNAL TO IMMUNE ACTIVATION IN AUTOIMMUNE CHOLESTATIC DISEASE

Cristina Di Giorgio[1], Ginevra Urbani[1], Martina Bordoni[1], Michele Biagioli[1], Carmen Massa[1], Silvia Marchianò[1], Rachele Bellini[1], Eleonora Distrutti[2], Angela Zampella[3] and Stefano Fiorucci[1], (1)University of Perugia, (2) Azienda Ospedaliera Di Perugia, (3)University of Naples, Federico II

Background: Primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC) represent primary autoimmune cholestatic liver diseases characterized by the chronic inflammation and progressive loss of the hepatic bile ducts. The pathogenesis of the disease is still unclear, although autoimmune mechanisms have been partially elucidated. The interaction between self-reactive immune cells, hepatic stellate cells (HSCs), sinusoidal endothelial cells (SECs) and cholangiocytes contributes to the perpetuation of chronic inflammation and fibrosis development. Recent evidence demonstrates that the Leukemia inhibitory factor (LIF) is expressed at low levels in normal human liver, whereas is greatly increased in fibrotic liver, suggesting its role in liver disease and immune response. LIF exerts its biological function through its binding to a heterodimeric receptor complex, LIFR and is expressed by several type of differentiated cells such as immune cells, epithelial cells, endothelial cells and fibroblasts. However, the role of LIF in PBC is highly debated. **Methods:** In vitro

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

assays were performed on a normal human cholangiocyte cell line (NHC). In vivo, Abcb4$^{-/-}$on C57BL/6 background and C57BL/6 congenic littermates, were monitored for for 16 weeks. At the time of sacrifice, liver were excised and analyzed. **Results:** LIFR and LIF, mRNA and protein expressions, were detected in NCH. LIF and IL-6 was upregulated by 100 ng/ml LPS, while LIFR appeared downregulated. Abcb4$^{-/-}$ mice, which spontaneously developed PBC/PSC-like disorders, showed an increment of biochemical parameters across time compared to Abcb4$^{+/+}$ mice, the fibrosis score (Syrius red) and the expression of pro-fibrotic markers Tgfβ and Col1a1 mRNA. Consistent with in vitro results, Lif and Il-6 expression were increased, while showed low levels of Lifr and Il-10 mRNA expression. RNAseq analysis of liver samples revealed high dissimilarities between Abcb4$^{+/+}$ and Abcb4$^{-/-}$. Finally, we have demonstrated that NHC exposure to 10 ng/ml LIF exacerbated the effect of LPS trigger, upregulating the expression the pro-inflammatory markers and LIF and downregulating the expression of the LIFR in activated NHC. **Conclusion:** Our data demonstrated that LIF exert an additive effect to that LPS, exacerbating the inflammatory pattern. In this contest the antagonism of LIFR might mitigate the LPS-induced NHC activation.

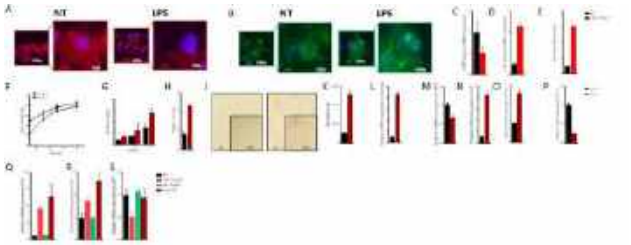

Figure 1. LIF was upregulated in vitro and in vivo models of PBC, moreover LIF exposure exacerbated the effect promoted by LPS challenge on normal human cholangiocytes. NHC cells were exposed to 100 ng/ml LPS alone or left untreated for 24 h. Data presented are immunofluorescence analysis of **(A)** LIFR (red) and **(B)** LIF (green) in left untreated (on left) and LPS-challenged (on right) NHC cells. Relative mRNA expression levels of **(C)** LIFR **(D)** LIF and the pro-inflammatory cytokine **(E)** IL-6. Data are normalized to GAPDH mRNA. Results are the mean ± SEM of 3 samples per group. *p < 0.05. Abcb4-/- male mice spontaneously develop biliary damage and liver fibrosis. They were monitored for 16 weeks. At the time of sacrifice, liver was excised and analyzed. **(F)** Body weight (g) changes across time. **(G)** Bilirubin (mg/dL) changes. **(H)** Number of circulating White Blood Cells (WBC) (10x3/μL). **(I)** Sirius-Red staining of liver sections (5x and 10x Magnification) with **(K)** fibrosis score in arbitrary units and relative liver mRNA expression of the pro-fibrotic marker gene, **(L)** Col1a1 **(K)**, **(M)** Lifr, **(N)** Lif, **(O)** Il-6, **(P)** Il-10. Data are normalized to Gapdh mRNA. Results are the mean ± SEM of 5 mice per group. *p < 0.05. NHC cells were exposed to 100 ng/ml LPS, 10 ng/ml LIF alone or in combination of both, or left untreated for 24 h, then RNA was extracted and analyzed. Relative mRNA expression of the pro-inflammatory cytokines **(O)** IL-6, **(R)** LIF and **(S)** LIFR. Data are normalized to GAPDH mRNA. Results are the mean ± SEM of 3 samples per group. *p < 0.05.

Disclosures: The following people have nothing to disclose: Cristina Di Giorgio, Ginevra Urbani, Martina Bordoni, Michele Biagioli, Carmen Massa, Silvia Marchianò, Rachele Bellini

3918-C | MODULATION OF GPBAR1 ATTENUATES LIVER FIBROSIS IN A MOUSE MODEL OF AUTOIMMUNE CHOLESTATIC LIVER DISEASE

Cristina Di Giorgio[1], Ginevra Urbani[1], Martina Bordoni[1], Michele Biagioli[1], Carmen Massa[1], Silvia Marchianò[1], Rachele Bellini[1], Eleonora Distrutti[2], Angela Zampella[3] and Stefano Fiorucci[1], (1)University of Perugia, (2) Azienda Ospedaliera Di Perugia, (3)University of Naples, Federico II

Background: Primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC) represent the main forms of autoimmune cholestatic liver characterized by chronic inflammation and progressive bile ducts loss. The etiology of PBC and PSC results from complex interactions between a genetic background, environmental trigger and immune dysregulation. Macrophages play a role in the pathogenesis of autoimmune cholestasis at the interface between the innate and adaptive immunity. The GPBAR1 (also known as TGR5) is a cell membrane receptor for secondary bile acids. GPBAR1 is highly expressed in Kupffer cells, liver endothelial cells and cholangiocytes and its expression is reduced PBC patients. Whether GPBAR1 plays a mechanistic role in PBC, however, remains poorly defined. BAR501 is a GPBAR1 agonist that exerts anti-inflammatory effects. **Methods:** In vitro assays were performed on a normal human cholangiocytes (NHC) cell and U937, a monocyte line. In vivo, Abcb4 $^{-/-}$ male mice were administered with BAR501 (10 mg/Kg) for 16 weeks. ANIT model on Il10$^{-/-}$ mice adminestred with BAR501 (10 mg/Kg). **Results:** GPBAR1 expression, mRNA and protein, was detected in NCH, and its activation with BAR501 (10 μM) reverted the pro-inflammatory phenotype promoted by LPS (100 ng/ml) as demonstrated by downregulation of pro-inflammatory markers. Administered in vivo to Abcb4$^{-/-}$, BAR501 attenuated hepatic damage as documented by reduced of AST, ALT and bilirubin plasma levels and the number of plasmatic WBC counts. BAR501 reduced the severity of liver fibrosis and expression of the Col1a1 and αSMA mRNAs. Moreover, BAR501 decreased the CDK19 positive area, as well the expression of Il-6 and Gpbar1 mRNAs. RNAseq analysis of liver samples reveal major dissimilarities between Abcb4$^{-/-}$ left untreated or administered with BAR501, downregulating the expression of many genes belonging to inflammatory and pro-fibrotic pathways. BAR501 reversed the developed of a pro-inflammatory phenotype induced by challenging U937 cells with NHC supernatants (LPS induction), reversing the M1 phenotype and IL-6 production. Because of Abcb4$^{-/-}$ mice showed reduced levels of Il-10 mRNA, Il-10$^{-/-}$ mice were challenged with ANIT and the administration of BAR501 didn't revert the disease. **Conclusion:** GPBAR1 agonism, counter-regulates the development of a pro-inflammatory phenotype of liver macrophages, this reducing development of inflammation, fibrosis and bile duct damage in models of cholestasis.

3919-C | OVEREXPRESSION OF TNFα CONTRIBUTES TO INCREASED HEPATIC INFLAMMATION AND CHOLANGIOCYTE PROLIFERATION IN MICE

Colin T. Shearn[1], Aimee Anderson[2], Michael Devereaux[1], Samuel D. Koch[1], David J. Orlicky[3], Calen Steiner[1], Sean Colgan[1] and Ronald J. Sokol[4], (1) University of Colorado Anschutz Medical Campus, (2) Department of Pediatrics, University of Colorado School of Medicine, (3)Department of Pathology, University of Colorado, (4)Children's Hospital of Colorado and University of Colorado School of Medicine

Background: Intestinal inflammation is common factor in approximately 70% patients diagnosed with Primary Sclerosing Cholangitis. The TNF$^{\Delta ARE}$ mouse carry mutations that result in nearly 20-fold increases in circulating TNFα. These mice spontaneously develop ileitis early after weaning and intestinal fibrosis by 24 weeks of age. The impact of genetic TNFα overexpression on the liver has not been explored. The aim of this study was to examine the influence of TNFα overexpression on hepatic injury, fibrosis, inflammation and bile acid synthesis in mice. Furthermore, the impact of increased intestinal inflammation and fibrosis on ileal FXR signaling was examined. **Methods:** Using serum, hepatic and ileal tissue isolated from 24-week old C57BL/6 and TNF$^{\Delta ARE+/-}$ (N = 4-6 per condition) mice, fibrosis, inflammation, ductal proliferation and regulation of bile acid synthesis was assessed by immunohistochemical and quantitative PCR methods. **Results:** Compared to age matched C57BL/6mice, TNF$^{\Delta ARE+/-}$ mice exhibited increased biochemical injury as evidenced by increased serum AST (2.00 ± 0.30-fold increase) which corresponded to increased hepatic picrosirius red staining and an increase in mRNA expression of *Timp1, Col1a1* and *Mmp9* supporting induction of fibrosis. Examining inflammation, immunohistochemical staining revealed a significant periportal increase in MPO+ neutrophils and a panlobular increase in F4/80+ macrophages and CD3+ lymphocytes. Importantly, periportal inflammation corresponded to a significant increase in Cytokeratin 7 staining supporting increased ductular proliferation. In the liver, mRNA expression of *Nr0b2* (Shp) and *Abcc2* (Mrp2) correlating with suppression of *Cyp7a1*, *Cyp7b1*, *Cyp27a1* but no significant differences were evident in the bile acid transporter *Abcb11* expression supporting dysregulation of bile acid homeostasis. In the ileum, increased inflammation correlated with increased *Fgf15* and *Nr0b2* mRNA expression, supporting a role for intestinal injury-dependent changes in FXR signaling. **Conclusion:** Increased TNFα expression is sufficient to promote both intestinal and hepatocellular fibrotic injury and contributes to hepatic dysregulation of FXR signaling and bile acid homeostasis. Overall, these results suggest that the TNF$^{\Delta ARE}$ mouse may be a useful model for studying inflammatory cholangiopathies such as human PSC.

3920-C | PARENTERAL NUTRITION UNCOUPLES ILEAL TO HEPATIC CIRCADIAN EXPRESSION IN MICE

Colin T. Shearn[1], Aimee Anderson[2], Michael Devereaux[1] and Ronald J. Sokol[3], (1)University of Colorado Anschutz Medical Campus, (2)Department of Pediatrics, University of Colorado School of Medicine, (3)Children's Hospital of Colorado and University of Colorado School of Medicine

Background: We have developed a mouse model of Parenteral Nutrition Associated Liver Disease in which PN infusion results in increased liver injury. In the liver, the master genes Clock and Arntl/Bmal drive rhythmic gene expression and regulate circadian expression of hepatic functions including bile acid synthesis. Once activated, Bmal/Clock are negatively regulated by

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

several transcription factors including Nr1d1, Dbp, Dec1/2, Cry1/2 and Per1/2. The aim of this study was to examine the effect of PN on expression of ileal and hepatic of circadian regulatory (CR) genes, FXR signaling and bile acid synthesis in mice. **Methods:** First, WT mice were exposed to continuous soy oil lipid emulsion based PN infusion through a central venous catheter for 4 days (PN). Water was provided ad libitum, but no nutrients were provided enterally. On d4, mice were sacrificed, serum harvested, and ileal and hepatic tissue obtained at 7AM and 7PM. From tissue samples, gut permeability, relative expression of circadian transcription factors and FXR signaling was assessed. **Results:** Administration of 4d PN increased hepatic injury, inflammatory cytokine expression and gut permeability as evidenced by increased serum AST, TNFa mRNA expression and FITC dextran fluorescence. In the ileum, increased expression of the FXR target genes *Fgf15*, *Nr0b2*, *Slc51a* (OSTα) corresponded to suppression of *Slc10a2* (ASBT) supporting ileal FXR activation. Interestingly, ileal FXR expression decreased suggesting a feedback inhibition of FXR expression. In the liver, hepatic expression of *Abcb11* was increased whereas *Abcc2* decreased following 4d PN. Although *Abcb11* mRNA was increased, no significant differences were evident in hepatic *Nr0b2* or *Nr1h4* mRNA expression supporting dysregulation of FXR signaling. Marked hepatic and ileal desynchrony of mRNA expression of circadian transcription factors was evident. Finally, a comparison of ileal with hepatic circadian transcription factor expression demonstrated significant uncoupling following PN administration. **Conclusion:** Dysregulation of circadian regulatory machinery is in part due to uncoupling of the gut-liver circadian axis. Pharmacologic targeting of CR as a therapeutic strategy for PNAC thus deserves further investigation.

3921-C | ROLE OF OSTEOPONTIN (SPP1) IN BILIARY ATRESIA ONSET AND PROGRESSION

Zhuolun Song, Hui Han, Xiaodong Ge, Sukanta Das, Sai Santosh Babu Komakula, Ines Barahona, Romain Desert, Dipti Athavale, Wei Chen, Daniel Lantvit and Natalia Nieto, University of Illinois at Chicago

Background: biliary atresia (BA) is a devastating neonatal cholangiopathy that leads to cholestasis and progressive hepatic failure. Our poor understanding of the onset and progression of BA results in compromised transplant-free survival. Osteopontin (OPN, encoded by *SPP1*), is highly expressed in biliary epithelial cells (BECs) and is involved in chronic liver disease, however whether OPN participates in BA is unknown. Here we investigated the role of OPN in the onset and progression of BA. **Methods:** *SPP1* gene expression in BA patients was analyzed using publicly available datasets of scRNA-seq, RNA-seq, and microarrays. OPN protein expression in BA livers was analyzed by immunohistochemistry. OPN concentration in serum was measured by ELISA. To induce BA in mice, we inoculated i.p. rhesus rotavirus (RRV) to BALB/c pups as well as pups with *Spp1* depletion in the liver within 24 hours of birth. Symptoms of BA were monitored after RRV inoculation and mice were sacrificed on day 11. Growth rate was evaluated, activity of transaminases and levels of total bilirubin were measured in serum, and histopathological changes were assessed. **Results:** in humans, *SPP1* is predominantly expressed in BECs in healthy individual's and is highly increased in cirrhosis. Notably, *SPP1* gene expression is significantly higher in livers from BA patients compared to non-BA cholestatic liver disease or control pediatric liver donors (GSE122340, GSE46960). *SPP1* gene expression highly correlates with *KRT7*, *KRT19* and *MMP7*, all markers of BECs. BA patients with fibrosis exhibit higher *SPP1* expression than those with inflammation only (GSE15235). Liver tissue from BA patients shows prominent expression of OPN. The OPN concentration in serum is significantly higher in BA patients compared with patients with other cholestatic liver diseases. BALB/c mice with BA show delayed development, jaundice and acholic stools. Moreover, they have increased transaminases and higher levels of total bilirubin. H&E staining reveals massive ductular reaction and hepatic inflammation. The concentration of OPN in serum and urine and the hepatic expression of OPN are significantly increased in mice with BA compared to controls. Mice lacking *Spp1* in the liver exhibit significant body weight reduction as well as more inflammatory response in liver tissue 11 days after RRV injection compared with control littermates. **Conclusion:** hepatic *SPP1* gene expression and serum OPN concentration differentiate BA from patients with other cholestatic liver disease. OPN is highly expressed in serum, urine, and liver tissue in a mouse model of BA. Depletion of *Spp1* from liver results in significant grow retardation and an inflammatory response after RRV injection.

f 3922-C | SINGLE NUCLEUS RNA SEQUENCING UNVEILS A KEY IMMUNOLOGICAL PATHWAY INVOLVED IN LNCRNA H19-MEDIATED CHOLESTATIC LIVER INJURY

Xixian Jiang[1,2], Grayson Way[1], Jing Zeng[1], Derrick Zhao[1,2], Yun-Ling Tai[1], Lianyong Su[1,2], Xuan Wang[1], Phillip B. Hylemon[1,2] and Huiping Zhou[1,2], (1)Virginia Commonwealth University, (2)Richmond Veterans Affairs Medical Center

Background: Primary sclerosing cholangitis (PSC) remains a major clinical challenge due to the limited understanding of its pathogenesis and lack of effective treatments. Multidrug resistance 2 knockout (Mdr2$^{-/-}$) mouse is a well-accepted PSC model. Single-cell/nucleus transcriptomics has transformed the current understanding of the cell-type-specific role in liver disease. Our previous snRNA-seq studies reported that long non-coding RNA H19 (H19) is a critical regulator of cholestatic liver fibrosis, especially through regulating cholangiocyte differentiation, proliferation, and senescence. However, the cell type-specific role of H19 in modulating immune response in cholestatic liver disease remains unclear and is the focus of this study. **Methods:** C57/BL6 wild type (WT), Mdr2$^{-/-}$, H19$^{-/-}$ and Mdr2$^{-/-}$/H19$^{-/-}$ mice (female, 6-month-old) were used. The liver tissues were processed for snRNA-seq. Seurat package in R was used to analyze the snRNA-seq data. Cell-type-specific marker genes were used for the identification of cell types and the subsequent statistical analysis. QIAGEN Ingenuity Pathway Analysis (IPA) was used to identify both whole liver and cell-type-specific pathways regulated by H19 in Mdr2$^{-/-}$ mice. **Results:** All major hepatic cell types were successfully identified, including hepatocytes, cholangiocytes (CHO), hepatic stellate cells (HSCs), lymphocytes (Lyms), monocyte-derived macrophages (Md-MQs), Kupffer cells (KCs), myofibroblasts (MyoFs) and endothelial cells (ECs). The identification of cell types enabled us to compare the involvement of different cell types from different samples in chemokine signaling. As shown in Fig.1, Cxcl16 is markedly upregulated in Md-MQs and CHO of Mdr2$^{-/-}$ mice but downregulated in the Md-MQs and CHO of Mdr2$^{-/-}$/H19$^{-/-}$ mice. Cxcl16 is a chemokine that acts as a chemoattractant for the recruitment of various immune cells, including cytotoxic lymphocytes (CD8+ NKT cells and potentially NK&Th1 cells) through chemokine receptor Cxcr6. In Mdr2$^{-/-}$, Cxcr6 was significantly upregulated in Lyms, which was abrogated by the deletion of H19. **Conclusion:** Cxcl16 has diverse functions and has been implicated in various diseases by modulating immune cell migration and activation as well as the production of pro-inflammatory cytokines. Our study uncovered a cell-type-specific immunological pathway regulated by H19. These findings have the potential to identify new therapeutic targets or strategies for cholestatic liver injury.

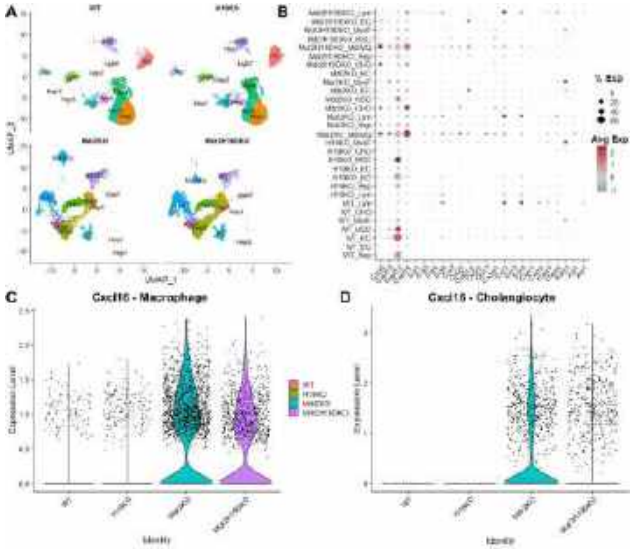

Fig 1. (A)Uniform Manifold Approximation And Projection (UMAP) of all identified cell types from all samples. (B)Dotplot of important chemokine signaling related genes in all cell types across all samples. (C)Violin plot of Cxcl16 expression in macrophage (KC & Md-MQ) populations cross all samples. (D)Violin plot of Cxcl16 expression in cholangiocyte populations cross all samples.

3923-C | A STRUCTURAL AND MECHANISTIC MODEL FOR BSEP DYSFUNCTION IN SEVERE CHOLESTATIC DISEASE

Clemence Gruget[1], Bharat Reddy[2], Patrick Stoiber[2] and Jonathan Moore[1,2], (1)MIT, (2)Rectify Pharmaceuticals

Background: Bile salt efflux pump (BSEP, *ABCB11*) transports bile salts across the canalicular membrane of hepatocytes, for incorporation into bile. Biallelic mutations in BSEP can cause Progressive Familial Intrahepatic Cholestasis Type 2 (PFIC2), a pediatric disease characterized by hepatic bile acid accumulation leading to hepatotoxicity, and ultimately, liver failure. Missense variants comprise the preponderance of pathogenic genotypes but vary significantly in their degree of dysfunction, in a manner that predicts onset and severity of disease. Understanding the mechanism underlying the molecular dysfunction of disease-causing variants is important for the development of targeted pharmacotherapeutics that can rescue BSEP function as disease-modifying therapies for PFIC2. Here we undertake a biophysical characterization of 13 distinct PFIC2-associated variants. **Methods:** To characterize the effects of disease-causing mutations on protein

thermodynamic stability, we have carried out in-cell thermal shift (CETSA) measurements for 13 different PFIC2 mutations, including the most prevalent BSEP mutations E297G and D482G. Using a novel split luciferase detection method, shifts in aggregation temperature (T_{agg}) could be classified into three groups based on the degree of thermal destabilization, 1) no effects on T_{agg}, 2) mildly destabilizing thermal shifts of -2-4 °C, and 3) severe destabilization of 9-11°C. Furthermore, to support the structural basis for BSEP protein destabilization, we determined the cryo-EM structure of wild-type BSEP to 3.0 Å resolution. **Results:** All group 3 variants were localized to the NBD2-ICL2 interface of BSEP. Confocal microscopy indicated cytoplasmic versus plasma membrane localization in HEK293 cells, confirming that these mutations result in defective protein trafficking. Focusing on mutations in NBD and ICL2, our high-resolution cryo-EM model provided a structural framework for rationalizing the thermal destabilization of these mutants, suggesting a novel, NBD2-localized mechanism through which the most severe missense patient mutations drive severe cholestatic disease. **Conclusion:** These data provide critical insight into the molecular dysfunction of 13 PFIC2-associated trafficking mutations. Moreover, our novel CETSA approach and cryo-EM models support a rationalized drug discovery approach for the development of small molecule PFIC2 precision therapeutics that would address the underlying cause of disease.

3924-C | HEPATIC INSULIN RESISTANCE INCREASES RISK OF GALLSTONE DISEASE IN SOUTHWESTERN INDIGENOUS AMERICANS

Beyza N Aydin, Nih

Background: Recent animal models indicate that hepatic insulin resistance directly promotes cholesterol gallstones. Gallstone disease (GSD) is linked with surrogate markers of whole-body insulin resistance, but the impact of insulin resistance specifically within the liver is unclear. Thus, we sought to determine whether hepatic and whole-body insulin resistance in humans, both measured with reference methods, are associated with the development of GSD in a prospective cohort. **Methods:** Healthy Southwestern Indigenous American adults without GSD and diabetes at baseline were included (n = 450). At baseline, participants had a 2-step hyperinsulinemic-euglycemic clamp with ^{3}H-labelled glucose tracer at submaximal and max insulin stimulation (240 and 2400 pmol/m^2/min) for measurement of whole-body insulin sensitivity (M-low and M-high; submaximal and max insulin stimulation, respectively) and hepatic glucose production (HGP) before and during the submaximal insulin infusion (HGP-basal and HGP-insulin). Body composition and glucose area under the curve (AUC) from a 3-h oral glucose tolerance test were also measured. Incident GSD was identified by clinical history and chart review during follow-up visits conducted at ~2-year intervals. The separate associations of HGP (basal, insulin, and % suppression), M-low, and M-high (per 1-SD change) with risk of GSD were assessed by Cox regression models adjusted for age, sex, body fat (%), glucose AUC, and plasma insulin (corresponding to time of HGP or M). **Results:** During median follow-up of 11.6 years, 60 participants (13%) developed GSD. Participants who developed GSD were of similar age (26 ± 6 vs. 27 ± 6 y) and whole-body insulin sensitivity (M-low: 2.5 ± 0.7 vs. 2.8 ± 1.2; M-high: 8.3 ± 1.9 vs. 8.6 ± 2.2; mg/kg-metabolic body size/min) as those who did not develop GSD, but were more likely to be female (82% vs. 32%, $p < 0.0001$), have higher body fat (37 ± 7 vs. 31 ± 8%), higher HGP-basal and HGP-insulin (1.99 ± 0.27 vs. 1.90 ± 0.24, $p = 0.01$; 0.50 ± 0.41 vs. 0.35 ± 0.42 $p = 0.01$; mg/kg-metabolic body size/min), and lower % suppression of HGP (74 ± 22 vs. 82 ± 22, $p = 0.01$). In separate adjusted models, higher HGP-insulin and lower % suppression of HGP (i.e., hepatic insulin resistance) were associated with increased risk for GSD (hazard ratio [HR] per SD: HR 1.38, 95% CI 1.12, 1.69, $p = 0.002$; HR 1.41 95% CI 1.16-1.72, $p = 0.0007$). HGP-basal, M-low, and M-high were not associated with GSD in adjusted models (p's > 0.22). **Conclusion:** Using a direct measure of HGP, higher absolute HGP during insulin infusion and lower suppression were associated with development of GSD, but whole-body insulin resistance was not associated. Insulin resistance within the liver may have a specific role in the pathogenesis of GSD and is a potential therapeutic target for prevention of the disease.

3925-C | HEPATIC NONVESICULAR CHOLESTEROL TRANSPORT IS CRITICAL FOR SYSTEMIC LIPID HOMEOSTASIS

Xu Xiao, UCLA

Background: In cell models, changes in the 'accessible' pool of plasma membrane (PM) cholesterol are linked with the regulation of endoplasmic reticulum sterol synthesis and metabolism by the Aster family of

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

nonvesicular transporters; however, the relevance of such nonvesicular transport mechanisms for lipid homeostasis in vivo has not been defined. **Methods:** To study Aster function in the liver, we generated mice with hepatocyte-specific deletion of either Aster-A (L-A knockout (KO)), Aster-C (L-C KO) or both (L-A/C KO) and conducted lipidomic analysis with in vivo tracer studies with [14C]cholesterol. **Results:** Here we reveal two physiological contexts that generate accessible PM cholesterol and engage the Aster pathway in the liver: fasting and reverse cholesterol transport. During fasting, adipose-tissue-derived fatty acids activate hepatocyte sphingomyelinase to liberate sequestered PM cholesterol. Aster-dependent cholesterol transport during fasting facilitates cholesteryl ester formation, cholesterol movement into bile and very low-density lipoprotein production. During reverse cholesterol transport, high-density lipoprotein delivers excess cholesterol to the hepatocyte PM through scavenger receptor class B member 1. Loss of hepatic Asters impairs cholesterol movement into feces, raises plasma cholesterol levels and causes cholesterol accumulation in peripheral tissues. **Conclusion:** These results reveal fundamental mechanisms by which Aster cholesterol flux contributes to hepatic and systemic lipid homeostasis.

3926-C | INOSITOL-REQUIRING ENZYME 1a/X-BOX BINDING PROTEIN 1 (IRE1a/XBP1) PATHWAY REGULATES HEPATIC BILE ACID METABOLISM

Mahmoud Khalafalla[1], Andrew Benintende[2], Xiaoying Liu[2], Alyssa Kriegermeier[3], Brian LeCuyer[2] and Richard M. Green[4], (1)Feinberg School of Medicine, Northwestern University, Chicago, IL, United States, (2) Feinberg School of Medicine, Northwestern University, (3)Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, (4)Feinberg School of Medicine, Northwestern University, River Forest, IL

Background: Cholestasis causes hepatic ER stress that can activate the IRE1α/XBP1 pathway of the unfolded protein response and can regulate bile acid synthesis. We developed liver-specific tet-on, TRE promoter-IREα (TG-IRE1α) mice which have doxycycline (DOX)-induced increases in hepatic IRE1a and XBP1. The aim of this study is to use TG-IRE1α mice to determine the regulation of hepatic IRE1α/XBP1 signaling on bile acid metabolism. **Methods:** Male 8-12 wk old TG-IRE1α mice were treated with ip DOX (50 mg/kg) or saline for 4 or 48 hrs; or were fed DOX-supplemented chow (200mg/kg) or chow-alone for 48 hrs. Gene and protein expression were measured with qPCR and western blotting, and bile acid concentrations were measured spectrophotometrically. **Results:** TG-IRE1α mice treated with ip DOX for 4 hrs had a 2.6-fold increase in hepatic IRE1α gene expression ($P < 0.001$). Hepatic pIRE and XBP1s protein expression increased 1.25- and 2-fold ($P < 0.04$ and $P < 0.01$, respectively) versus saline controls. Gene expression for the XBP1 downstream target *ERdj4* also increased 2-fold ($P = 0.02$). DOX-treated mice had > 90% reduction in hepatic gene expression of *Cyp7a1* from 1.13+/-0.63 to 0.1+/-0.06 ($P < 0.003$), and 33% and 29% reductions of *FXR* ($P < 0.005$) and *Abcb11* ($P < 0.03$), respectively. Hepatic gene expression of the bile acid synthesis genes *Cyp8b1* and *Cyp27a1*, *PERK* and *ATF6* pathways, and RIDD targets (*Blocs1, Angptl3)* were unchanged. In contrast, 48 hrs of ip DOX treatment resulted in a 2.1-fold increase of CYP7A1 protein ($P < 0.03$), and all other above changes resolved. Ileal FGF15 gene expression was unaltered at 4 and 48 hrs. 4 hrs of ip Dox reduced hepatic bile acid concentrations from 256+/-135 to 92+/-50 nmol/g liver ($P < 0.02$), which normalized at 48 hours. Feeding Dox-supplemented chow for 48 hours increased *Cyp7a1* hepatic protein expression 1.8-fold ($P < 0.05$), and gene expression of *Cyp8b1*, *Cyp27a1* and *Abcb11* 5-, 2.5-, and 2.2-fold, respectively ($P < 0.03$ for all). Hepatic bile acids were higher in DOX-fed mice (803+/-1125 to 222+/-288 nmol/g), but this did not reach significance. **Conclusion**: TG-IRE1α mice treated with ip DOX for 4 hrs have hepatic IRE1α/XBP1 pathway activation, markedly reduced Cyp7a1 gene expression and lower hepatic bile acids, which normalize by 48 hrs. In contrast, DOX-chow feeding for 48 hrs increases expression of bile acid synthesis genes and Abcb11. We speculate that IRE1α/XBP1 signaling is important in the pathogenesis of cholestatic liver disease.

3927-C | TAUROCHOLATE ADMINISTRATION TO PIGS ENHANCES PORTAL VENOUS BLOOD FLOW AND HEPATIC OXYGEN CONSUMPTION, BUT NOT PREHEPATIC SPLANCHNIC OXYGEN CONSUMPTION

Susanne Keiding[1,2], Kim Frisch[3], Frank Viborg Mortensen[1], Aage Kristian Olsen Alstrup[1], Ole L Munk[1] and Michael Sørensen[4], (1)Aarhus University, (2) Department of Nuclear Medicine and PET Center, Aarhus University, (3)University of Aarhus, Health, (4) Viborg Regional Hospital

Background: In a placebo-controlled study of patients with PBC, administration of the synthetic bile acid obeticholic acid enhanced hepatic blood flow (*Kjærgaard, J Hepatol 2021*). In the present study in anaesthetized pigs, we examined if administration of the natural bile acid taurocholate increases blood flows in the portal vein and/or hepatic artery – and hepatic and/or prehepatic oxygen consumption. **Methods:** Eight 40-kg propofol-anaesthetized female pigs were used. Taurocholate was given as IV bolus and infusion of 0−0.2 mmol/min via a catheter in a femoral vein. Oxygen concentration was measured in blood sampled from catheters in a femoral artery, a hepatic vein (via a jugular vein) and in portal vein via a 30-cm long incision below the right curvature. This incision was also used to place ultrasound transit-time flow meter probes around the portal vein and hepatic artery/arteries for continuous blood flow rate measurements. Hepatic oxygen consumption was estimated as the sum of portal vein and hepatic arterial blood flow rates multiplied with the difference between flow-weighted oxygen concentration in arterial and portal vein blood and oxygen concentration in hepatic vein. Prehepatic splanchnic oxygen consumption was estimated as portal venous blood flow multiplied with difference between oxygen concentration in arterial and portal venous blood. **Results:** Hepatic oxygen consumption was increased by taurocholate and in experiments with high doses of taurocholate, it was 2−3 times higher than in experiments with no taurocholate (mean 2 mmol/min versus 0.7 mmol/min; $P < 0.01$). There was no significant effect of taurocholate on prehepatic splanchnic oxygen consumption (mean 1.4 mmol/min). Portal venous blood flow was increased by taurocholate and in experiments with high doses of taurocholate, it more than doubled compared to experiments with no taurocholate (mean 1.9 L/min versus 0.8 L/min; $P < 0.01$) with no significant effect on hepatic arterial blood flow (mean 0.22 L/min). **Conclusion:** The main findings of this study are instant and big enhancements in hepatic oxygen consumption and portal venous blood flow by high-dose infusion of the bile acid taurocholate. We ascribe these effects to energy-requiring transport of taurocholate through the liver, leading to increase in the hepatic oxygen consumption, and portal venous blood flow. These effects may be ascribed to the so-called "metabolic requirement," the mechanism of which is an exciting subject for further investigation.

3928-C | THE ADDITION OF OMEGA-3 TO FIBRATES: A PROMISING WAY TO REDUCE HEPATIC BILE ACID

Audrey-Anne Lavoie, Université Laval and Olivier Barbier, Université Laval, Faculty of Pharmacy, Québec, Canada, Quebec, QC, Canada

Background: The accumulation of toxic bile acids (BA) in the liver is a key factor in the pathogenesis of primary biliary and sclerosing cholangitis (PBC and PSC), two autoimmune liver diseases deprived of any curative options. While PBC and/or PSC treatment are currently limited to Ursodiol® (UDCA) and Ocaliva® (OCA), fibrates, such as fenofibrate and bezafibrate, are currently tested in off-labeled trials. Since we already reported that omega-3 polyunsaturated fatty acids, such as the eicosapentaenoic (*EPA*) and docosahexaenoic acids (DHA), improve the response to UDCA and OCA, we sought to test the possibility that similar improvement also occurs with fenofibrate and bezafibrate. **Methods:** Human HepG2 cells were treated for 24H with vehicle (DMSO-ethanol 0.01%/0.01% v/v), 100μM fenofibrate and 100μM bezafibrate, in the presence or absence of EPA/DHA (50:50μM). Total RNA was purified, and the expression of essential genes related to BA transport, synthesis and detoxification was quantified by qRT-PCR. **Results:** When used alone fenofibrate and bezafibrate caused 37% and 34% reduction in CYP7A1 transcript levels, respectively. While in the presence of EPA/DHA mRNA levels of this rate-limiting enzyme for BA synthesis were 58% and 52% reduced by the same dosage of fenofibrate and bezafibrate. Similarly, the addition of EPA/DHA to fenofibrate reinforced the overexpression of the export gene MRP2 from 1.5 to 29-fold over control. Interestingly, the combinations EPA/DHA+fenofibrate ($p < 0.001$) and +bezafibrate ($p < 0.01$) caused 58% and 47% reduction of CYP27A1 transcripts a BA-synthesizing enzyme. When used alone the 2 drugs failed to modulate this gene expression. A similar inhibition was also observed for the Ntcp transcript but only with the EPA/DHA+bezafibrate combination. **Conclusion:** The

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

addition of EPA/DHA to fibrates seems to be a promising way to reduce the hepatic BA concentration. Further analysis is, however, required to validate this hypothesis.

3929-C | THE BIOACTIVE OMEGA-3 DERIVATIVE, PROTECTIN DX, IMPROVES THE ABILITY OF LOW DOSES OCALIVA TO REDUCE BILE ACID SYNTHESIS AND SECRETION IN LIVER CELLS.

Audrey-Anne Lavoie[1,2,3], Mélanie Verreault[4], Jocelyn Trottier[4], René Maltais[5], Jean-Yves Sancéau[5], Donald Poirier[6], André Marette[7] and Olivier Barbier[4], (1) Université Laval, (2)CHU De Québec - Université Laval, (3)Nutriss Center - Nutrition, Health and Society, (4) Université Laval, Faculty of Pharmacy, Québec, Canada, (5)CHU De Québec Research Center, (6) Université Laval, Faculty of Medicine, Québec, Canada, (7)Centre De Recherche De L'institut Universitaire De Cardiologie Et De Pneumologie De Québec

Background: The toxic bile acids (BA) that accumulate in the liver during cholestasis play a crucial role in the destruction of epithelial cells and hepatocytes in patients with cholestatic autoimmune liver diseases, such as primary biliary and sclerosing cholangitis (PBC and PSC). Their reduction is therefore a major drug target for PBC and PSC treatments. Ocaliva® (OCA) is an FDA-approved treatment with limited clinical use due to the occurrence of severe dose-related side effects. In the presence of omega-3 fatty acids such as EPA and DHA, the OCA dose allowing an optimal reduction of BA toxicity is reduced by 20 times in liver cells. The present study aimed at investigating whether the bioactive omega-3 derivative, protectin DX (PDX), is also an improver of Ocaliva's ability to reduce the hepatic BA concentration. **Methods:** Human hepatoma HepG2 cells were treated with vehicle (DMSO/ethanol; 0.01%/0.01% v/v), and 1µM OCA in the presence or absence of EPA/DHA (50:50µM) or PDX (5µM) for 24 hours. Total RNA was purified, and gene expression was analyzed by qRT-PCR. Experiments were performed twice in quadruplicates. BA secretion was also assessed by liquid chromatography with tandem mass spectrometry (LC-MS/MS) in culture media. **Results:** In the presence of EPA/DHA and PDX, liver cells exhibited a stronger response to Ocaliva 1µM when compared to the drug alone. Indeed, OCA 1µM caused a 54.3% reduction in CYP7A1 transcript levels, a gene coding for the rate-limiting enzyme in BA synthesis, while in the presence of PDX, the same amount of drug led to a stronger ($p < 0.05$) reduction of this transcript to 64.7%. PDX also significantly enhanced the ability of OCA to increase the mRNA expression of BA export transporters such as OSTα and β, MRP2 and 3 ($p < 0.001$). Interestingly, both combinations of OCA with EPA/DHA ($p < 0.01$) and PDX ($p < 0.05$) led to a stronger reduction of chenodeoxycholic acid (CDCA) secretion in cell media. **Conclusion:** These experiments indicate that, as EPA/DHA, protectin DX improves the ability of a low OCA dose to inhibit BA synthesis and export in HepG2 cells. Considering the toxic and pro-inflammatory roles played by bile acids during cholestatic autoimmune liver diseases such as PBC and PSC, the use of PDX+low OCA dose combinations may provide an alternative pharmacological option for these diseases. Further analyses are, however, required to validate this hypothesis.

3930-C | THE LOSS OF INTESTINAL MICROBIOME IMPACTS BILE ACID SYNTHESIS, TRANSPORT, AND METABOLISM IN THE GUT-LIVER AXIS

Elena Maria Haddad, Mélanie Verreault, Jocelyn Trottier and Olivier Barbier, Université Laval, Faculty of Pharmacy, Québec, Canada

Background: Bile acids (BAs) are steroid acids synthetized in the liver, with essential roles in the control of lipid and vitamin absorption in the intestines. These molecules undergo an enterohepatic cycle, with 95% of BA being reabsorbed in the ileum and sent back to the liver. The remaining 5% are metabolized by intestinal bacteria of the large intestine. To fully grasp the systemic impact of this bacterial metabolism on BAs homeostasis, we investigated how the expression and/or activity of key genes is affected in the liver and intestine of germ-free (GF) mice. **Methods:** GF mice were generated using Swiss Webster strain at the animal facility of the CHU de Québec-Université Laval research centre (Québec, Canada). Samples from 8-month-old GF male and female mice were analyzed in comparison to sex- and age-matched conventionally raised (CONV-R) SP1 Elite animals. Hepatic BA levels were quantified using LC-MS/MS. Tissular transcript and protein levels involved in synthesis (*Cyp7a, 27a1, 8b1, and 2c70*), metabolism (*Cyp3a11, Sult2a1, Ugt1a1, Fxr, Vdr*), transport (*Asbt, Bsep, Ostα, Ostb, Mrp2, Mrp3, Ibabp, Ntcp*) and regulation of BAs were determined using qRT-PCR and western-blotting,

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

respectively. Sulfonation assays were performed using liver homogenates and the lithocholic acid as a substrate. **Results:** In the liver, male GF animals exhibited higher total, unconjugated and primary BAs levels ($p < 0.001$). These parameters remained unchanged in female GF mice when compared to control animals. *Cyp8b1* mRNA and proteins were increased ($p < 0.01$) in livers from male GF, but not in female, while the same gender specificity also applied to the reduction of *Cyp3a11* mRNA levels in GF male livers ($p < 0.01$). In contrast to that, the mRNA, protein, and activity levels of the BA-sulfonating enzymes *Sult2a1* were increased only in female livers. The same applies to transcript levels of *Ugt1a1, Bsep, Ntcp, Ostb, Mrp2, Mrp3* and *Fxr*. In the intestine similar gender- and gene-, and tissue-specific regulatory events were observed. For example, *Asbt* mRNA expression was up-regulated in small and large intestine of male GF mice ($p < 0.01$), while *Vdr* mRNAs were increased in both male and female samples, but only in the duodenum **Conclusion:** These analyses reveal that the loss intestinal microbiome affects both hepatic and intestinal determinants of BA homeostasis, thus supporting the idea that microbial activities exert systemic impacts. Such regulatory events display a major gender-related sexual dimorphism.

3931-C | THE X-BOX BINDING PROTEIN 1 (XBP1s) AGONIST IXA4 REGULATES HEPATIC BILE ACID METABOLISM

Andrew Benintende[1], Mahmoud Khalafalla[1], Micaela Naibryf[1], Xiaoying Liu[2], Alyssa Kriegermeier[3], Enrique Saez[4], R. Luke Wiseman[4] and Richard M. Green[5], (1) Northwestern University Feinberg School of Medicine, (2)Feinberg School of Medicine, Northwestern University, (3)Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, (4)Scripps Research, (5)Feinberg School of Medicine, Northwestern University, River Forest, IL

Background: Cholestasis can cause increased hepatic bile acid concentrations and ER stress, with activation of the unfolded protein response IRE1α/XBP1 signaling pathway. Furthermore, the hepatic IRE1α/XBP1 pathway can also regulate bile acid metabolism. However, the complex regulation of ER stress and bile acid synthesis and metabolism is not fully understood. IXA4 is a newly developed XBP1s agonist that activates liver XBP1s signaling and has been shown to be beneficial in murine models of fatty liver disease. In this study we aimed to use IXA4 to determine the regulation of XBP1 signaling on bile acid metabolism. **Methods:** 8-12 week old C57BL/6J mice were treated with IXA4 (50 mg/kg ip) or vehicle-alone (DMSO/EtOH/Kolliphor El) for 2 or 48 hrs. Hepatic gene expression was measured with RNASeq and qPCR and serum C4 levels were measured using LC-MS/MS. **Results:** Two hours after IXA4 treatment, there was a 1.7-fold increase in hepatic gene expression of the XBP1s downstream targets ERDJ4 ($P < 0.05$) and HRD1 ($P < 0.06$). Hepatic Cyp7a1 gene expression was decreased by over 55% in IXA4 treated mice compared to vehicle controls (0.49 +/- 0.31 vs. 1.13 +/- 0.49, respectively, $P < 0.05$). Cyp7a1 bile acid synthesis enzymatic activity measured by serum C4 was also reduced with IXA4 treatment, being 12.5 +/- 5.9 ng/mL vs. 25.7 +/- 1.5 ng/mL in IXA4 treated and control mice ($P < 0.05$). The hepatic gene expression of SHP, Cyp8b1, and HNF4-alpha were reduced by 42% ($P = 0.01$), 36% ($P = 0.03$) and 46% ($P = 0.01$), respectively. Hepatic FXR, Abcb11, and NTCP expression were unaffected. Liver ASBT gene expression increased 2-fold ($P < 0.005$), while there was no difference in ileal ASBT nor FGF15 gene expression. Hepatic bile acid concentrations were similar in both groups. After 48 hours of IXA4 treatment, hepatic SHP expression remained decreased ($P < 0.05$), while expression of the above suppressed genes returned to baseline. **Conclusion:** Treatment with the XBP1s agonist IXA4 for two hours reduced hepatic Cyp7a1 gene expression and Cyp7a1 bile acid synthesis activity. IXA4 administration also resulted in decreased expression of hepatic Cyp8b1, SHP, and HNF4-alpha. The reduction in Cyp7a1 gene expression resolved by 48 hours, although SHP expression remained lower. These data suggest that the UPR has an important role in bile acid synthesis and metabolism and is regulated, at least in part, by activation of hepatic XBP1s.

3932-C | VALIDATION OF THE MICE AS AN EXPERIMENTAL MODEL FOR STUDYING BILE ACID GLUCURONIDATION AND ITS POTENTIAL AS A TREATMENT TARGET IN AUTOIMMUNE AND CHOLESTATIC HEPATO-BILIARY DISEASES

Elena Maria Haddad, Jordan Grondin, Sarra Beji, Justine Chouinard, Mathilde Mouchiroud, Mélanie

Verreault, Jocelyn Trottier, Alexandre Caron and Olivier Barbier, Université Laval, Faculty of Pharmacy, Québec, Canada

Background: Glucuronidation is a phase II conjugation reaction involved in the detoxification of numerous exogenous and endogenous compounds such as bile acids (BAs). These acids play important roles for cholesterol, lipids and glucose metabolism and absorption. But their accumulation, as it occurs in cholestatic diseases such as primary biliary and sclerosing cholangitis (PBC and PSC), is toxic for liver cells and promotes inflammatory processes ultimately leading to liver failure, if not pharmacologically prevented. While the mechanisms governing human BA glucuronidation are well understood, this process occurring in mice has received less attention, thus limiting the access to well-known animal models for studying BA glucuronidation formation *in vivo*. **Methods:** Glucuronidation assays were conducted using recombinant Udp-glucuronosyltransferase (Ugt) enzymes and tissue homogenates from male and female CD1-Elite mice (n = 4/group). The enzymatic assays were performed at 37°C in presence of the UDP-glucuronic acid co-substrate with various BA substrates, and the formation of BA-Glucuronides (BA-G) was quantified using LC-MS/MS. LC-MS/MS was also used to profile BA-G in murine feces, intestinal contents, liver, and plasma. How environmental factors affect BA glucuronidation were investigated by exposing male C3H/HeJ mice (n = 8/group) fed with control or high fat diets to different temperatures (10°C and 30°C). **Results:** The β-muricholic acid (β-MCA)-24G was the most frequently detected BA-G in mice, while the murine Ugt2b34, 2b35 and 2b37 were the most reactive enzymes for BA-G formation. The most reactive tissues were the liver and colon, and female organs exhibited higher activity levels than male ones. HFD-fed mice livers exhibited significantly higher rates of glucuronidation of β-MCA. In contrast, the same diet caused a significant reduction in β-MCA-24G formation in the colon. **Conclusion:** These experiments revealed the BA-, Ugt-, tissue- and sex-dependent manner in which bile acids are glucuronidated in mice. We also demonstrated that the BA glucuronidation activity is regulated in a tissue- and stimuli (i.e diet or temperature factor)-dependent way. Overall, these observations support the idea that mice could be an adequate model for studying the role of BA glucuronidation in the context of PBC and PSC treatment.

4000-A | A META-ANALYSIS OF CUMULATIVE INCIDENCE OF HEPATOCELLULAR CARCINOMA AFTER THE FONTAN OPERATION

Sophie Hansen[1], Richard Gilroy[2], Ian Lindsay[1], John Doty[2], Ross Butschek[2] and Christopher Danford[3], (1) University of Utah, (2)Intermountain Health, (3) Intermountain Health, Millcreek, UT

Background: Hepatic complications are increasingly recognized after the Fontan operation. The development of hepatocellular carcinoma (HCC) is one of the most feared complications with high mortality when diagnosed,[1] but its incidence and risk factors are poorly understood. We conducted a systematic review and meta-analysis of the incidence of HCC after Fontan. **Methods:** We searched PubMed, CINAHL, and MEDLINE databases for articles reporting the incidence of HCC after the Fontan operation on March 21, 2023. We excluded cross-sectional studies, case reports, case series, or review articles. Studies were required to be retrospective or prospective cohort studies and report the cumulative incidence of HCC after Fontan. Two reviewers independently reviewed studies for inclusion and extracted variables of interest. A single-arm random effects meta-analysis was conducted in RStudio (version 1.3.1093). Meta-regression analysis was conducted to evaluate study-level effect of variables on the development of HCC. **Results:** We identified four studies including a total of 1,980 patients that met criteria for inclusion. The cumulative incidence of HCC at 10, 20, and 30 years after Fontan was 0% (95% CI 0.00-0.01), 2% (0.01-0.06), and 7% (0.03-0.17) respectively (Figure 1). Heterogeneity was low at 10 and 30 years ($I^2 = 0\%$), but moderate at 20 years ($I^2 = 67\%$). On metaregression, only duration of follow-up was significantly associated with HCC incidence (OR 1.31, 95% CI 1.1-1.57). Gender, manner of HCC diagnosis, prevalence of cirrhosis, anticoagulation use, Fontan type, and congenital anatomical diagnosis were not associated with HCC incidence. **Conclusion:** By 30 years after Fontan, cumulative incidence of HCC is high (7%). The only identifiable risk factor is duration of follow-up and not underlying cirrhosis or heart disease characteristics indicating screening should be considered based on time after the Fontan operation. Our findings are limited by an inconsistent definition used for HCC and cirrhosis in the literature and further research and cost-effectiveness analysis is needed to determine the optimal timing and modality for HCC screening in this population.

4001-A | A NATIONWIDE STUDY ON THE CURRENT TREATMENT STATUS AND NATURAL PROGNOSIS OF HEPATOCELLULAR CARCINOMA IN ELDERLY

Jeong-Ju Yoo[1], Dong Ah Park[2] and Jayoun Lee[2], (1) Soonchunhyang University Bucheon Hospital, (2)National Evidence-Based Healthcare Collaborating Agency

Background: The aim of this study was to identify the treatment status and natural prognosis of hepatocellular carcinoma (HCC) patients aged 65 years or older in South Korea. **Methods**: We analyzed 3,492 patients' data from linking the liver cancer stage data of the Central Cancer Registry of National Cancer Center (2011-2016) and the death data of the National Statistical Office. **Results**: The average age of the patients was 72 years. The most common etiology of HCC was hepatitis B (32.7%), followed by hepatitis C (18.9%). Among a total of 3,492 elderly patients, 2,624 patients (69.2%) received first-line active treatment for HCC, The most frequently selected treatment was transarterial chemoembolization (TACE), followed by surgical resection and radiofrequency ablation (RFA). The proportion of patients receiving supportive care increased with increasing age. Second-line treatment was performed in only 36.7% of cases, with all others choosing supportive care. Among the various treatments, liver transplantation was found to have the greatest effect in reducing the risk of death (HR 0.164, 95% CI 0.061-0.444), followed by resection (HR 0.231), RFA (HR 0.296), radioembolization (HR 0.447), and TACE (HR 0.503). The median survival for untreated HCC in BCLC stage 0/A/B/C/D was 3.7 years, 2.3 years, 7.9 months, 3.9 months, and 2.9 months, respectively. **Conclusion**: This study highlights the current status of elderly patients with HCC in South Korea. While the proportion of patients receiving supportive care is high among the elderly, effective treatment can improve their survival rate.

4002-A | A PHASE II STUDY OF AUTOLOGOUS NATURAL KILLER CELLS WITH HEPATIC ARTERIAL INFUSION CHEMOTHERAPY IN PATIENTS WITH LOCALLY ADVANCED HEPATOCELLULAR CARCINOMA

Woo Kyun Bae[1], Byung Chan Lee[1], Yang Hyun Baek[2], Jung Gil Park[3], Jeong Won Jang[4], Je Jung Lee[1], Sung Bum Cho[5] and Yangseok Koh[6], (1)Chonnam National University Medical School and Hwasun Hospital, (2) Dong-a University College of Medicine, (3)Yeungnam University College of Medicine, (4)The Catholic University of Korea, (5)Hwasun Chonnam National University Hospital, (6)Chonnam National University

Background: Patients with locally advanced HCC who were refractory to the standard treatment have a limited treatment option. We aimed to evaluate the efficacy and safety of autologous NK cell therapy combined with the hepatic artery infusion chemotherapy (HAIC) in patients with intermediate and/or locally advanced HCC. **Methods:** This was an open-label, multi-center, prospective Phase II study done at four centers in South Korea. Patients were eligible if they were aged 19 years or older and had locally advanced HCC unresectable and/or refractory to the standard treatments, macrovascular invasion, and no extrahepatic spread. Patients who had achieved SD or better after 2nd cycle of HAIC with 5-fluorouracil and cisplatin received Vax-NK/HCC therapy for 5 consecutive days every 4 weeks for up to 2 cycles (dose: 1×10^9 NK cells/injection) through hepatic arterial infusion following 2 additional cycles of HAIC. The primary endpoint was the objective response rate (ORR), and the secondary endpoints were disease control rate (DCR), time to progression (TTP), overall survival (OS), and safety. The clinical response was evaluated by modified Response Evaluation Criteria in Solid Tumors (mRECIST). **Results:** As of May 2023, 16 out of 17 patients enrolled were evaluable for the primary and secondary outcomes. The investigator-assessed ORR was 62.5% (complete response [CR]: 37.5%, partial response [PR]: 25%). Stable disease

(SD) was observed in six (37.5%) patients, resulting in a disease control rate (DCR) of 100%. There were no incidences of decompensation or severe adverse events during HAIC, and no adverse events related to NK cell infusion were noted. **Conclusion:** Although this phase II study is still in progress, its preliminary data suggest that the locoregional infusion of NK cells with cytotoxic chemotherapy is safe and feasible for locally advanced HCC refractory to the standard treatment. This result warrants further development of this novel treatment to establish its efficacy in this type of disease. 4003-A | A SINGLE CENTER ANALYSIS OF PATIENTS UNDERGOING LIVER RESECTION FOR INTRAHEPATIC CHOLANGIOCARCINOMA

Begum Ozturk and Laith H. Jamil, Beaumont Hospital, Royal Oak

Background: Intrahepatic cholangiocarcinoma (iCCA) is the second most common primary liver cancer with increasing rates of incidence and mortality. Surgical resection with negative margins and regional lymphadenectomy is the mainstay of the treatment for patients with resectable-iCCA. Because of its rarity and low resectability rate of iCCA, prognostic markers and outcomes of patients who undergo liver resection are not well defined. We aimed to evaluate the characteristics of patients undergoing liver resection for iCCA at our institution over ten years. **Methods:** All patients with iCCA who had liver resection between 3/2013-3/2023 at our institution were included in the study. An institutional review board approval was obtained by our institution. Patients who had neoadjuvant therapy prior to resection and patients with a history of malignancy were excluded. Demographic, clinical, radiological, and histological data were collected. Continuous variables are reported as median (interquartile range, IQR), and categorical variables by counts and percentages. **Results:** A total of 68 patients (36 female, 32 male) were included in the final analysis. The median age at resection was 66 years (57.2-74). Liver cirrhosis was present on histology in four patients (5.8%), of which three had non-alcoholic steatohepatitis, and one had primary sclerosing cholangitis. Of all patients, 52.9% had hypertension, 22% had diabetes mellitus, 8.8% had inflammatory bowel disease, 25% had clinically significant alcohol use history, and 47% had former or current tobacco use for more than 5 pack-years. The median pre-operative BMI was 27.84 kg/m^2 (25-32). Pre-operative values of albumin, total bilirubin, AST, ALT, ALP, CA19-9, CEA, and AFP are shown in table 1. The median tumor size was 4.2 cm (3.1-5.9), and 16.1% of the patients had satellite lesions. 36.7% of the patients had lymph node invasion, 30.8% had perineural invasion, and 16.1% had vascular invasion on liver histology. Positive surgical margins were present in 19.1% of patients. Progression of disease or recurrence was seen in 58.8% of patients in a median of 1.1 years (0.7-1.7), and 25% of the patients died during follow-up. Duration from liver resection to last follow-up or death was 1.5 years (0.8-2.9). **Conclusion:** Our results show that iCCA has a high risk of progression/recurrence despite curative resection. Predictive markers of recurrence and survival in patients vary in the literature and remain to be validated.

Table 1. Pre-operative laboratory values, median (IQR1-IQR3)	
Albumin (g/dL)	4.0 (3.4-4.3)
Total bilirubin (mg/dl)	0.6 (0.5-0.9)
Aspartate aminotransferase (IU/L)	34 (25-60)
Alanine aminotransferase (IU/L)	37 (22-88)
Alkaline phosphatase (IU/L)	139 (88.5-272.5)
Carbohydrate antigen 19-9 (U/ml)	28.9 (15-181.9)
Carcinoembryonic antigen (ng/ml)	2.25 (1.8-6.8)
Alpha fetoprotein (ng/ml)	2.1 (1.5-3.8)

4004-A | ABRIDGED NEW DIAGNOSIS OF HEPATOCELLULAR CARCINOMA (HCC) AMID COVID-19 OUTBREAKS: A TERRITORY-WIDE STUDY IN HONG KONG

Grace Lai-Hung C Wong[1], Vicki Wing Ki Hui[1], Yee-Kit Tse[1], Vincent Wai-Sun Wong[2] and Terry Cheuk-Fung Yip[3], (1) The Chinese University of Hong Kong, (2)The Chinese University of Hong Kong, Hong Kong, China, (3)The Chinese University of Hong Kong, Hong Kong, 91, China

Background: In the US, two national emergency declarations dealing with the COVID-19 pandemic are going to end on May 11, 2023. Over the last three years of COVID-19 pandemic, medical services had been seriously disturbed and had led to delays in achieving the goals set by the World Health Organization (WHO) of reducing of chronic viral hepatitis mortality by 65% by 2030. We aimed to evaluate the numbers of newly diagnosed hepatocellular carcinoma (HCC) from 2001 to 2022, with special interest amid the time of COVID-19 pandemic. **Methods:** This was a territory-wide retrospective observational cohort study in Hong Kong. We identified subjects who had newly diagnosed HCC based on diagnosis codes of the electronic database, Clinical Data Analysis and Reporting System (CDARS) of Hospital Authority which serves all public hospitals in Hong Kong. **Results:** We identified 35,647 subjects (78.3% men, mean age 63 y) who had HCC first diagnosed in 2001-2022. The median annual number of

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

new HCC increased from 1,563 (range 1,384-1,716) in 2001-2010, to 1,689 (range 1,662-1,736) in 2011-2019. This dropped dramatically during COVID-19 pandemic, from 1,649 in 2020 to 1,546 in 2021 and 1,473 in 2022 (Figure 1A). The monthly number of new HCC was time-sensitive to COVID-19 outbreaks; it dropped from approximately 140-150 to 114 right after the first COVID-19 case in February 2020. The drop was even more dramatic during the omicron outbreak in early 2022, with the monthly number of new HCC dropped down to 86 in February 2022, 98 in March 2022 and 112 in April 2022. It gradually increased to the close-to-usual numbers (range 116-148) in the 2nd half of 2022 (Figure 1B). **Conclusion:** COVID-19 pandemic significantly reduced the number of newly diagnosed HCC in the public healthcare system. Further studies are warranted to investigate if such reduction had led to delayed HCC diagnosis, or shift of medical service from public the private sector. Resumption of HCC surveillance programme is pivotal for early HCC diagnosis and hence higher chances of curative treatments in order to meet the WHO goal of reducing of chronic viral hepatitis mortality by 65% by 2030 Figure. Number of newly diagnosed HCC in A. 2001-2020 annually and B. 2020-2022 monthly during the COVID-19 pandemic.

4005-A | ABSENCE OF PULMONARY METASTASIS ON CHEST CT IN BCLC-A HCC

Thuy-Duyen Nguyen[1], Shanna Cheng[1], Melissa Chai[1], Christopher E. Slatore[2], Willscott E. Naugler[1] and Janice Jou[1], (1)Oregon Health & Science University, (2) VA Portland Hospital

Background: Barcelona Clinic Liver Cancer (BCLC) system is often used to stage hepatocellular carcinoma (HCC). Current AASLD guidelines recommend obtaining a CT chest regardless of BCLC stage. Recent studies suggest early stage or BCLC-A HCC pulmonary metastasis rates are low. This study's aim was to determine pulmonary metastasis incidence in BCLC-A HCC patients and assess utility in obtaining a CT chest. **Methods:** We conducted a retrospective study of patients with cirrhosis and newly diagnosed HCC, confirmed on imaging/biopsy, using Oregon Health & Science University's Multidisciplinary Liver Tumor database between January 2015–December 2021. The primary outcome was pulmonary metastasis detection rate on CT chest within 1 year of BCLC-A diagnosis and prior to HCC treatment. The secondary outcome was the identification of other pulmonary nodules. **Results:** We identified 413 patients with BCLC-A HCC. There were 330 patients (79.9%) who had a CT chest within 1 year of diagnosis of HCC and a minimum of 1-year follow-up after the initial CT. We excluded 75 patients (18.1%) with no CT chest within inclusion criteria timeline and 8 patients (1.9%) with no follow-up imaging to confirm nodule identification after initial CT chest showed incidental pulmonary nodules. The median age was 64.4 (±8.6) years and 94 (28.5%) were female. Cirrhosis etiologies were HCV 51.2% (n = 169), alcohol-associated 16.0% (n = 53), NAFLD 13.0% (n = 43), HCV/HBV 7.6% (n = 25), HBV 3.0% (n = 10), AIH 0.6% (n = 2) and other 8.5%

(n = 28). The median MELD 3.0 score was 11.0 (± 4.3). At time of diagnosis, 28.2% (n = 93) never smoked tobacco, 50.6% (n = 167) formerly smoked, and 21.2% (n = 70) were actively smoking at the time of diagnosis. 70.3% (n = 322) had one HCC lesion, 20.9% (n = 69) had two, and 8.8% (n = 29) had three. The median lesion size was 2.1 cm (± 1.6). Median AFP was 7.1 (range 0–3917.3). Of the 330 patients, none had findings consistent with pulmonary metastasis on CT chest. 71.5% (n = 236) did not have any lung nodules. 28.5 % (n = 94) had incidental pulmonary nodules. Of patients with pulmonary nodules, 54.3% (n = 51) had resolved/stable nodules suggesting a benign etiology, 35.1% (n = 33) were inflammatory nodules, and 10.6% (n = 10) were primary lung malignancies. **Conclusion:** In our study, no patients with BCLC-A HCC had pulmonary metastasis on CT chest within 1 year of diagnosis. Future studies are warranted to assess the cost effectiveness of routine CT chest at time of diagnosis of BCLC-A HCC and to examine potential predictors of pulmonary metastasis.

4006-A | ACHIEVEMENT OF COMPLETE RESPONSE AND DRUG-FREE STATUS BY ATEZOLIZUMAB PLUS BEVACIZUMAB COMBINED WITH LOCOREGIONAL THERAPY IN PATIENTS WITH TRANSARTERIAL CHEMOEMBOLIZATION-UNSUITABLE, INTERMEDIATE-STAGE HEPATOCELLULAR CARCINOMA: A MULTICENTER PROOF-OF-CONCEPT STUDY

Masatoshi Kudo[1], Tomoko Aoki[1], Kazuomi Ueshima[1], Kaoru Tsuchiya[2], Masahiro Morita[1], Hirokazu Chishina[1], Masahiro Takita[1], Satoru Hagiwara[1], Yasunori Minami[1], Hiroshi Ida[1], Naoshi Nishida[1], Chikara Ogawa[3], Tetsu Tomonari[4], Noriaki Nakamura[5], Hidekatsu Kuroda[6], Atsushi Takebe[1], Yoshifumi Takeyama[1], Masaaki Hidaka[7], Susumu Eguchi[7], Stephen Lam Chan[8], Masayuki Kurosaki[2] and Namiki Izumi[2], (1)Kindai University Faculty of Medicine, (2) Musashino Red Cross Hospital, (3)Takamatsu Red Cross Hospital, (4)Tokushima University Graduate School of Biomedical Sciences, (5)Shuuwa General Hospital, (6)Iwate Medical University, (7)Nagasaki University Graduate School of Biomedical Sciences, (8) State Key Laboratory of Translational Oncology, Department of Clinical Oncology, Sir Yue-Kong Pao Center for Cancer, the Chinese University of Hong Kong

Background: Atezolizumab plus bevacizumab therapy is extremely effective in the treatment of intermediate-stage hepatocellular carcinoma (HCC), with a response rate of 44%, as reported in the IMbrave150 trial. When tumor shrinkage is obtained, achieving complete response (CR) is possible in many cases using curative conversion with resection, ablation, or super selective transarterial chemoembolization (TACE) with curative intent. This concept, *i.e.*, curative conversion by combining systemic therapy and locoregional therapy, has not been reported before. This multicenter proof-of-concept study was conducted to show the value of curative conversion in immunotherapy-treated intermediate-stage HCC meeting TACE-unsuitable criteria. **Methods**: This study included 110 consecutive Child-Pugh A patients who received atezolizumab plus bevacizumab as first-line treatment for unresectable and TACE-unsuitable intermediate-stage HCC at seven centers in Japan. CR rate, drug-free rate, time to CR, change in liver function, efficacy in positron emission tomography (PET)-positive HCC, progression-free survival (PFS), and overall survival (OS) were assessed in patients who achieved CR using resection, ablation, super selective TACE with curative intent following atezolizumab plus bevacizumab or atezolizumab plus bevacizumab alone. **Results**: Clinical or pathological CR was achieved in 38 patients (35%) (median observation period: 21.2 mo). The modalities of curative conversion in 35 patients were as follows: resection, 7; ablation, 13; and superselective TACE, 15. Three patients achieved clinical CR with atezolizumab plus bevacizumab therapy alone. Among the 38 CR patients, 25 achieved drug-free status. PFS was not reached, and three patients experienced recurrence after reaching CR. Regarding OS, there were no deaths in any of the CR patients. The albumin-bilirubin score did not deteriorate after locoregional therapy or resection. Of seven PET-positive patients who achieved CR with atezolizumab plus bevacizumab followed by curative conversion, five achieved drug-free status. **Conclusion**: The achievement of CR rate by curative conversion in patients treated with atezolizumab plus

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

bevacizumab as the preceding therapy for unresectable and TACE-unsuitable intermediate-stage HCC was 35%. Overall, 23% of patients achieved drug-free status and no recurrence was observed from this patient subgroup with CR and drug free status. Thus, achieving CR and/or drug-free status should be a therapeutic goal for patients with intermediate-stage HCC without vascular invasion or extrahepatic spread.

4007-A | ADVERSE EVENTS AS PREDICTIVE FACTORS OF THERAPEUTIC ACTIVITY IN PATIENTS WITH HCC TREATED WITH ATEZOLIZUMAB PLUS BEVACIZUMAB

Yuri Tsujimoto[1], Toshifumi Tada[2], Takashi Kumada[3], Atsushi Hiraoka[3], Masashi Hirooka[3], Kazuya Kariyama[4], Ei Itobayashi[3], Tsuji Kunihiko[3], Toru Ishikawa[3], Hidenori Toyoda[5], Takeshi Hatanaka[6], Satoru Kakizaki[7], Hideko Ohama[8], Fujimasa Tada[9], Kazuhiro Nouso[3] and Yoichi Hiasa[10], (1)Japanese Red Cross Society Himeji Hospital, (2)Japanese Red Cross Himeji Hospital, Himeji, Japan, (3)Relpec Study Group and HCC 48 Group, (4)Okayama City Hospital, (5) Ogaki Municipal Hospital, (6)Gunma Saiseikai Maebashi Hospital, (7)National Hospital Organization Takasaki General Medical Center, Takasaki, Gunma, Japan, (8)Takarazuka City Hospital, (9)Ehime Prefectural Central Hospital, (10)Ehime, Toon-shi, Ehime, Japan

Background: To investigate the possible correlation between the occurrence of adverse events (AEs) and outcome in patients with unresectable hepatocellular carcinoma (HCC) treated with atezolizumab plus bevacizumab (Atezo/Bev). **Methods:** A total of 286 patients with unresectable HCC who were treated with Atezo/Bev as first-line systematic therapy were included. **Results:** For treatment-related AEs, decreased appetite of any grade, proteinuria of any grade, and fatigue of any grade were present more frequently than 20% of the time. In a multivariate Cox proportional hazards model adjusted for immune-related liver dysfunction, immune-related endocrine dysfunction, proteinuria, fatigue, decreased appetite, and hypertension, decreased appetite (hazard ratio [HR], 1.745; 95% confidence interval [CI], 1.093-2.786; $p = 0.020$) and hypertension (HR, 0.596; 95 CI, 0.373-0.954; $p = 0.031$) were independently associated with progression-free survival. Multivariate Cox proportional hazards modeling adjusted for the same AEs showed that fatigue (HR, 2.055; 95% CI, 1.092-3.869; $p = 0.026$) was independently associated with overall survival. Median progression-free survival was 8.3 months (95% CI, 6.6-not available (NA)) for patients with no appetite loss and

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

4.8 months (95% CI, 3.4-7.4) for those with appetite loss (p = 0.006). Median progression-free survival was 6.6 months (95% CI, 5.5-8.3) for patients without grade IV hypertension and 12.6 months (95% CI, 6.7-NA) for patients with grade IV hypertension (p = 0.041). For radiological best response rate, the disease control rate was significantly higher in patients who developed treatment-related hypertension (94.2%) than in those who did not (79.1%) (p = 0.009).
Conclusion: Treatment-related hypertension is associated with good outcomes in patients with unresectable HCC treated with Atezo/Bev.

4008-A | AGE DISPARITIES IN CLINICAL OUTCOMES AND TREATMENT UTILIZATION IN HEPATOCELLULAR CARCINOMA

Olgert Bardhi[1], Karim Seif El Dahan[1], Nicole E. Rich[1], Sarah Rosanna Lieber[1], Jeremy Louissaint[1], Thomas G. Cotter[2], Lisa B. VanWagner[1], Neehar Dilip Parikh[3], Anna Mae Diehl[4], Laura M. Kulik[5], Ju Dong Yang[6], Purva Gopal[1], Amit G. Singal[1] and Darine Daher[1], (1) University of Texas Southwestern Medical Center, (2) University of Texas Southwestern Medical Center, Dallas, TX, (3)University of Michigan, (4)University of Chicago, (5)Northwestern University, (6)Cedars-Sinai Medical Center, Los Angeles, CA

Background: Hepatocellular carcinoma (HCC) is the leading cause of cancer-related mortality in patients with cirrhosis. Prognosis significantly differs by tumor stage and treatment type; 5-year survival exceeds 70% for patients with early-stage HCC that undergo curative surgical therapy compared to < 10% for those with larger tumor burden treated with palliative therapies. Understanding the impact of older age on treatment eligibility and outcomes, including overall survival, is important to inform optimal surveillance and treatment recommendations. **Methods:** We performed a search of MEDLINE and EMBASE databases and national conference abstracts from January 2000 to July 2022 to identify studies reporting tumor stage, curative treatment receipt, or overall survival among patients with HCC, stratified by age category (younger vs. older) thresholds. Curative treatment was defined as liver transplant (LT), surgical resection, and ablative therapies; we excluded studies that only looked at non-curative therapies. We calculated pooled risk ratios (RR) and hazard ratios (HR) with the corresponding 95% confidence interval (CI) stratified by age using the DerSimonian and Laird method for random effects models. **Results:** We identified 139 studies (n = 191,582 patients) that investigated treatment receipt in young vs. old patients with HCC. Across all studies, curative therapy did not significantly differ between younger and older patients (RR 1.01, 95% CI 1.00 – 1.02), although age thresholds varied. However, in subgroup analyses, younger patients were more likely to undergo curative treatment among studies using an age cutoff of 65 years (RR 1.07, 95% CI 1.03 – 1.12) and 75 years (RR 1.10; 95% CI 1.00 – 1.21). Among the subset studies (n = 6) with 65-year age threshold that reported receipt of LT, younger patients were more likely to undergo transplantation (RR 2.81; 95% CI 0.89 – 8.87). Among all studies, younger patients had reduced mortality compared to older patients (HR 0.88; 95% CI 0.82 – 0.93). **Conclusion:** Patients > 65 years appear less likely to undergo curative treatment, particularly liver transplantion, and experience higher hazards of mortality. Studies need to identify underlying reasons for this disparity, including possible differences in tumor burden, liver dysfunction, comorbidities, or patient preferences. Improved selection tools are needed to identify elderly patients who can most benefit from surveillance programs and curative therapies.

4009-A | ARTIFICIAL INTELLIGENCE MODEL TO PREDICT DE NOVO HEPATOCELLULAR CARCINOMA AFTER 5 YEARS OF ANTIVIRAL THERAPY

Yeonjung Ha[1], Young Eun Chon[1], Joo Ho Lee[1], Kwan Sik Lee[1], Jinseok Lee[2] and Han Chu Lee[3], (1)CHA Bundang Medical Center, CHA University, (2)Kyung Hee University, (3)Asan Medical Center, Seoul, Korea, Republic of (South)

Background: Patients with chronic hepatitis B (CHB) receiving potent antiviral agent, such as entecavir (ETV) or tenofovir (TFV), achieve virological and biochemical stability after long-term (>5 y) therapy. Prediction of de novo hepatocellular carcinoma (HCC) in these patients is particularly important considering limited medical resources and relatively lower incidence of HCC compared with those treated for <5 years. Therefore, we aimed to construct an individualized artificial intelligence (AI) model to predict de novo HCC after 5 years of ETV/TFV therapy. **Methods:** From retrospective registry data from two university hospitals, 5,908 and 562 patients with CHB who were treated with ETV/TFV for >5 years and were not diagnosed with HCC during the first 5 years of therapy were selected, respectively. A total of 37 variables including baseline characteristics (age, sex, cirrhosis, and type of antiviral agent), laboratory parameters (albumin, bilirubin, prothrombin time, transaminases, platelet counts, HBeAg, HBV DNA, and Child-Pugh score) at baseline and at 5 years, aspartate aminotransferase to platelet ratio at 5 years, and derived time-varying variables (change in laboratory parameters) were used as input variables. From the training set (n=4,726), we applied five machine learning algorithms based on 100 datasets derived from repeated 5-fold cross-validation, including adaptive boosting, extreme gradient boosting, light gradient boosting machine, logistic regression, and random forest classifier. Internal validation was performed in a split dataset (n=1,182). The final model was tested in patients from another university hospital as external validation (n=562). **Results:** In the training set, logistic regression showed the highest area under the receiver operating curve (AUROC) of 0.803 and balanced accuracy of 0.735, which outperformed other AI algorithms (AUROC, 0.775-0.802 and balanced accuracy, 0.701-0.729). The sensitivity and specificity were 75.3% and 71.6%, respectively. An ensemble approach by soft voting technique demonstrated that the combined model with logistic regression and random forest classifier provided the best performance (AUROC, 0.811 and balanced accuracy, 0.754). The results derived from the test set also showed good performance metrics (AUROC, 0.784 and balanced accuracy, 0.712). In the external validation, our model showed an AUROC of 0.862 and balanced accuracy of 0.771. A web-based calculator was developed. **Conclusion:** Our AI model combining logistic regression and random forest classifier provides good performance in predicting de novo HCC occurrence after 5 years of ETV/TFV therapy. It can compute the estimated risk of HCC and facilitate individualized HCC surveillance based on risk stratification.

4010-A | ATEZOLIZUMAB PLUS BEVACIZUMAB THERAPY FOR HEPATOCELLULAR CARCINOMA – GERIATRIC NUTRITIONAL RISK INDEX AS A CONVENIENT PROGNOSTIC EVALUATION TOOL

Atsushi Hiraoka[1], Toshifumi Tada[2], Hideko Ohama[1], Masashi Hirooka[2], Fujimasa Tada[1], Kazuya Kariyama[2], Ei Itobayashi[2], Tsuji Kunihiko[2], Toru Ishikawa[2], Hidenori Toyoda[2], Takeshi Hatanaka[2], Satoru Kakizaki[2], Atsushi Naganuma[2], Tomomitsu Matono[2], Kazuhiro Nouso[2], Yoichi Hiasa[2] and Takashi Kumada[2], (1)Ehime Prefectural Central Hospital, (2)Relpec Study Group and HCC 48 Group

Background: The geriatric nutritional risk index (GNRI) is an easy-to-use tool for assessing nutritional status based on body weight and serum albumin. This study aimed to evaluate the prognostic predictive ability of the GNRI for patients with hepatocellular carcinoma (HCC) treated with atezolizumab plus bevacizumab (Atz/Bv). **Methods:** The GNRI was used to evaluate prognosis of 525 HCC patients who received Atz/Bv as first-line systemic chemotherapy (median age=74 years, male=420, HCV:HBV:HBV+HCV:alcohol:others=187:88:2:104:144, Child-Pugh A:B:C=484:40:1, BCLC 0:A:B:C:D=7:25:192:283:18). They were classified into normal, mild-, moderate-, and severe-decline GNRI groups, with muscle volume decline (MVD) used for sub-analysis. **Results:** Prognoses [median progression-free survival (mPFS)/median overall survival (mOS)] were stratified according to GNRI status (normal vs. mild- vs. moderate- vs. severe-decline=8.3/21.4 vs. 6.7/17.0 vs. 5.3/11.5 vs. 2.4/7.3 months) (P<0.001). mPFS and mOS according to Child-Pugh A, B, and C were 7.0/19.1, 4.3/6.4 and 0.4/

Symbols: ᶠ, Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

1.1 months, respectively ($P < 0.001$), and according to albumin-bilirubin (ALBI) grade 1, 2, and 3 were 9.3/21.4, 6.0/14.5 and 3.0/7.3 months, respectively ($P < 0.001$). For predicting PFS and OS, GNRI c-index values were higher than those of Child-Pugh class and ALBI grade (0.574/0.632 vs. 0.527/0.570 vs. 0.565/0.629). Time-dependent receiver operating characteristic curve (ROC) analysis was used to evaluate the area under the curve (AUC) for PFS and OS at 6 and 12 months. The AUC at 6 and 12 months for PFS was 0.616 and 0.594 for GNRI, 0.533 and 0.533 for Child-Pugh class, and 0.607 and 0.591 for ALBI grade, respectively, and for OS was 0.669 and 0.667 for GNRI, 0.622 and 0.580 for Child-Pugh class, and 0.654 and 0.661 for ALBI grade, respectively. MVD frequency increased as GNRI value declined (GNRI status: normal vs. mild- vs. moderate- vs. severe-decline = 17.6% vs. 29.2% vs. 41.2% vs. 57.9%, $P < 0.001$), with a GNRI value of 97.8 predictive of occurrence (AUC 0.715, 95%CI 0.649-0.781, specificity/sensitivity = 0.644/0.688). There was a significant relationship of GNRI with SMI for both genders (male: $r = 0.42$, 95%CI 0.302-0.526, $P < 0.001$, female: $r = 0.438$, 95%CI 0.169-0.646, $P = 0.002$) **Conclusion:** The present results suggest that GNRI is a useful prognostic tool for predicting both prognosis and MVD in HCC patients treated with Atz/Bv.

4011-A | BODY MASS INDEX IS NOT ASSOCIATED WITH POST-LIVER TRANSPLANT HEPATOCELLULAR CARCINOMA RECURRENCE

Meaghan Phipps, Yuan Zhang and Elizabeth Verna, Columbia University Irving Medical Center, New York, NY

Background: The number of patients undergoing liver transplantation (LT) for hepatocellular carcinoma (HCC) continues to rise. Post-LT HCC recurrence occurs in 15-20% of patients, with median survival of less than one year. Prior studies have suggested that obesity and increased visceral adipose tissue increase risk for HCC recurrence. However, the impact of body mass index (BMI) on risk of HCC recurrence after liver transplantation has not been studied in a large dataset in the setting of the current HCC-related Model for End Stage Liver Disease (MELD) exception pathway that includes a 6-month observation period. **Methods**: We performed an analysis of patients who underwent LT for HCC in the United Network for Organ Sharing (UNOS)/Organ Procurement and Transplantation Network (OPTN) with a waitlist registration date starting October 8, 2015 (marking the implementation of mandated 6-month waiting period for HCC exception points) and LT date through March 31, 2020 (to allow for minimum three years post-LT follow-up time). We assessed for patient and tumor characteristics associated with HCC recurrence after transplantation. **Results**: A total of 7,502 patients with HCC underwent LT in the study period, of whom 521 (6.9%) had post-LT HCC recurrence. The median age was 62 years, and the majority were male (77.2%) and non-Hispanic White (66.1%). Median BMI was 28.6, and most patients were normal weight (BMI 18.5-24.9, 22.6%), overweight (BMI 25-29.9, 35.8%), or obese (BMI 30-34.9, 26.2%). In univariable analysis, neither median BMI nor BMI category (compared to normal) was significantly associated with risk for HCC recurrence (Table 1). Alcohol-associated liver disease and nonalcoholic fatty liver disease (NAFLD) were associated with decreased risk for HCC recurrence. HCC identified on explant, increased number of tumors on explant, lymph node involvement, extrahepatic spread, vascular invasion, and poor tumor differentiation were all associated with increased risk for post-LT HCC recurrence. In multivariable analysis adjusting for patient and tumor characteristics, tumor characteristics including greater number of tumors on explant ($p < 0.001$) and the presence of vascular invasion ($p = 0.02$) were both associated with increased risk for post-LT HCC recurrence. BMI did not have a significant association with risk for post-LT HCC recurrence. **Conclusion**: Among patients who underwent LT for HCC after implementation of the mandated 6-month waiting period for HCC exception points, increased tumor burden and high risk tumor characteristics were associated with increased risk for HCC recurrence. Patient BMI and metabolic syndrome factors such as NAFLD or the presence of diabetes were not significantly associated with risk for recurrence in this large dataset.

4012-A | BRIDGING THERAPY FOR PATIENTS WITH HEPATOCELLULAR CARCINOMA AWAITING LIVER TRANSPLANTATION: A SYSTEMATIC REVIEW AND META-ANALYSIS

Ashwini Arvind[1], Karim Seif El Dahan[1], Darine Daher[1], Neehar Dilip Parikh[2], Anna Mae Diehl[3], Laura M. Kulik[4], Nicole E. Rich[1], Sarah Rosanna Lieber[1], Jeremy Louissaint[1], Thomas G. Cotter[5], Lisa B. VanWagner[1], Ju Dong Yang[6], Purva Gopal[1] and Amit G. Singal[1], (1) University of Texas Southwestern Medical Center, (2) University of Michigan, (3)University of Chicago, (4) Northwestern Medical Faculty Foundation, Chicago, IL, (5)University of Texas Southwestern Medical Center, Dallas, TX, (6)Cedars-Sinai Medical Center, Los Angeles, CA

Background: Liver transplantation (LT) is the curative treatment of choice for patients with early-stage hepatocellular carcinoma (HCC) and liver dysfunction. However, LT is limited by organ shortage and increasing wait times, so bridging therapy is recommended to reduce the risk of waitlist dropout. Given the association between viable tumor on explant and recurrence, bridging therapy may also improve post-transplant outcomes. However, data evaluating this association have been conflicting. **Methods:** We conducted a systematic review using the Medline and EMBASE databases of studies published between database inception and July 31, 2022, which reported post-transplant outcomes, stratified by receipt of locoregional therapy. Studies that investigated downstaging therapy were excluded. The exposure of interest was bridging therapy for HCC within Milan criteria. Primary outcomes were post-LT recurrence-free and overall survival. Pooled hazard ratios were calculated for each outcome using the DerSimonian and Laird method for random effects models. **Results:** We identified 34 studies, including 16,545 patients with and 19,280 patients without bridging therapy. Patients with bridging therapy had a larger pre-treatment tumor burden and longer wait times vs. those without bridging therapy. Overall, bridging therapy was not associated with post-LT recurrence-free survival (HR 0.91; 95%CI 0.77 – 1.08) or overall survival (HR 1.09; 95%CI 0.95 – 1.24). In subgroup analyses by study period, bridging therapy was associated with worse overall survival (HR 1.23; 95%CI 1.04 – 1.45), but no difference in recurrence-free survival (HR 0.85; 95%CI 0.58 – 1.24), among studies published between 2005 and 2014. Conversely, in latter studies, bridging therapy was not associated with overall survival (2015 – 2019: HR 1.08; 95%CI 0.83 – 1.41, and after 2019: HR 0.90; 95%CI 0.67 – 1.20), or recurrence-free survival (2015 – 2019: HR 0.96; 95%CI 0.76 – 1.21, and after 2019: HR 0.79; 95%CI 0.25 – 2.46). Most studies had a high risk of bias due to lack of adjusting for tumor burden, degree of liver dysfunction, or differences in transplant waiting times. **Conclusion:** Beyond known benefits of reducing risk of waitlist dropout, bridging therapy is not associated with improved post-transplant recurrence-free or overall survival in patients with HCC within Milan criteria. Bridging therapy may not be beneficial for patients in whom risk of waitlist dropout is low, such as those in regions with short wait times.

4013-A | CENTER EXPERIENCE AND OUTCOMES IN TRANSPLANTATION FOR CHOLANGIOCARCINOMA

Omar Bushara[1], Maarouf A. Hoteit[2], Therese Bittermann[1], Tarek Araji[1] and Matthew H. Levine[1], (1) Hospital of the Univerity of Pennsylvania, (2)Perelman School of Medicine, University of Pennsylvania

Background: Liver transplantation has been offered as a treatment for select patients with unresectable hilar cholangiocarcinoma since the 1990s at one center, and with UNOS approval of an exception point pathway, at a few centers nationally since 2009. With the implementation of the national liver review board in 2019, qualification for exception points was based on a standardized approval process of the selection criteria rather than regional review board review. It has previously been suggested that transplant centers who perform a higher volume of transplants for cholangiocarcinoma have improved patient outcomes. However, these studies were performed in the era of regional exception points. The goal of this study is to investigate the association between center experience and patient outcomes since the national standardization of exception point approval. **Methods:** Patients listed for transplantation using cholangiocarcinoma exception points from 5/2019-12/2022 were identified in the UNOS database. Transplant centers were grouped based on volume. Experienced centers were defined as having done at least 10 transplant during the time period. The remaining centers were grouped as less experienced. Recipient and donor characteristics, one-year graft survival, and hospital length of stay were compared between these groups using Wilcoxon ranksum, Fisher's exact, and log-rank tests were used where appropriate. **Results:** 166 patients listed based on cholangiocarcinoma exception points and were transplanted. Of these, 98 (59%) were performed at experienced centers (5) and 68 (41%) at less experienced centers (32). The groups did not differ in recipient age, BMI, gender, or MELD score. Donors at experienced centers were older (51.5 [39-62] vs 43.5 [31-50.5], $p = 0.002$), had higher BMI (29.6 [24.1-34.9] vs 26.7 [23.8-30.5], $p = 0.02$), and were more likely to be expanded criteria (55.9% vs 11.2%, $p = 0.008$). However, experienced centers had higher one-year survival. (91.8% vs 74.4%, $p = 0.02$). Hospital length of stay did not differ. Log-rank test showed experienced centers had improved post-transplant survival rate ($p = 0.03$). (Figure 1) **Conclusion:** These data suggest that more experienced with transplantation for cholangiocarcinoma is associated with improved outcomes, which is concordant with the current literature. However, it is unclear if this is driven by better patient selection for a complex protocol, or by added surgical or medical expertise in more experienced centers. Improved availability of explant pathology data from recipients of transplant for malignant disease would allow for further research in this field.

4014-A | CHALLENGES IN HEPATOCELLULAR CARCINOMA DURING COVID-19 PANDEMIC

Cristina Patoni[1,2], Mirela Chirvase[1], Bianca Oltean[3], Sandica Bucurica[1,2] and Florentina Radu-Ionita[1,2], (1) Central Military Emergency Hospital Dr.Carol Davila, (2)

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

University of Medicine and Pharmacy "Carol Davila" Bucharest, (3)County Clinical Emergency Hospital of Sibiu

Background: Hepatocellular carcinoma (HCC) is one of the most aggressive neoplasms and a leading cause of cancer-related deaths worldwide with an incidence that continues to increase. Data regarding epidemiology is heterogeneous worldwide. Even if viral hepatitis is known as an important risk factor for HCC development, non-alcoholic fatty liver disease (NAFLD) became a leading cause of HCC in developed countries. Despite the considerable improvements in diagnosis and therapy, the overall outcomes of HCC are still far from satisfactory. Data regarding epidemiology of HCC in Romanian population is scarce. This study aims to investigate HCC etiology, risk factors, the clinical impact of tumor location, and management of these patients. **Methods:** In this retrospective study, we used medical coding data to identify patients with a diagnosis of HCC from Central Military Emergency Hospital Dr. Carol Davila who were hospitalized between March 2020 and February 2023. Statistical analyses were carried out using SPSS 29.0.1.0. Continuous variables were compared using an analysis of variance (ANOVA) while the categorical variables were compared using the Chi-square test. **Results:** A total of 74 patients with a mean age of 65.29 (SD +/- 8.04) were diagnosed with HCC out of which 67.6% were males. Hepatitis C was the main cause of HCC (28.4%), followed by hepatitis B (25.7%) and alcoholic liver disease associated with hepatitis B (10.8%). Half of the patients found with HCC were known with cirrhosis. Furthermore, at the moment of the diagnosis, 25.7% of the patients were already stage IV, lung metastasis being the most frequent site of dissemination. The most frequent location of the tumor was the right liver lobe (64%). There was no association between the etiology of HCC and the location of the tumor. The sensitivity of AFP levels in detecting HCC with a cut-off value of 20 ng/ml was only 56.9%. **Conclusion:** Our analysis revealed that in Romania viral hepatitis is still a major health problem in comparison with the actual trend. HCC is still diagnosed in advanced stages, despite the screening programs for patients at risk. Difficulty regarding optimal management could have been determined by Covid-19 Pandemic. Data highlights that we should develop better prevention strategies and that we need to implement better monitoring programs for the early diagnosis of HCC.

4015-A | CHANGING EPIDEMIOLOGY OF HCC IN MELBOURNE, AUSTRALIA: PRIMARY OUTCOMES OF THE PROSPECTIVE HOMER-2 COHORT

Joan Ericka Flores[1], Alexander J. V. Thompson[1], Sheng Wei Lo[2], Thai Hong[1], Stuart Keith Roberts[3], Amanda J. Nicoll[4], Diana Lewis[2], Zina Valaydon[5], Siddharth Sood[6], Gauri Mishra[7], William W. Kemp[3], Ammar Majeed[3], James Haridy[6] and Jessica Howell[1], (1)St Vincent's Hospital Melbourne, Australia, (2) Northern Health, (3)Alfred Health, (4)Eastern Health, (5) Footscray Hospital, Footscray, Victoria, Australia, (6) Royal Melbourne Hospital, (7)Monash Health

Background: Surveillance for hepatocellular carcinoma (HCC) with six monthly ultrasounds for at-risk patients with cirrhosis or chronic hepatitis B is recommended is recommended, however rates of uptake remain unacceptably low internationally. With the HOMER-2 cohort, we aimed to describe the uptake of surveillance and the changes in HCC epidemiologic profile. **Methods:** HOMER-2 is a prospective, multi-site cohort of all incident adult HCC cases from Greater Melbourne, Australia identified through HCC multidisciplinary team meetings at the eight tertiary centres with HCC specialist units between 18 Oct 2021 and 17 Oct 2022. Surveillance uptake occurred where patients were known to health services, receiving follow up and scans in the two years preceding HCC diagnosis, to account for COVID-19 disruptions to care. Optimal surveillance was defined as completion of two scans in the preceding year, and suboptimal surveillance completed less. Variables were compared to the similar HOMER cohort of HCC cases from 1 July 2012 and 30 June 2013 using Chi square or Wilcoxon rank-sum test. **Results:** There were 202 incident HCC cases identified, 78% were male (n = 159), median age of 68 years (IQR 60-74 y), 61% born overseas (n = 116). Established cirrhosis was known in 47% (n = 96), 33% (n = 66) newly diagnosed with cirrhosis at time of HCC diagnosis, 20% (n = 41) non-cirrhotic. Early-stage HCC (BCLC 0-A) occurred in 47% (n = 95). Surveillance uptake occurred in 39% (n = 79). Of these, 53 % (n = 42) had optimal surveillance and 47% (n = 39) had suboptimal surveillance. In patients with known cirrhosis, 67% (n = 66) were undergoing surveillance and 45% (n = 21) of eligible patients with chronic hepatitis B. Having at least one abdominal scan in the preceding 12 months for any indication was associated with increased odds of early-stage HCC (OR 2.99, 95% CI 1.68-5.32, $p < 0.0001$). Surveillance through imaging +/- AFP was the most common mode of presentation at

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

37% (n = 75), then symptomatic disease (pain/decompensation) 34% (n = 69), clinician investigation of liver test derangement 16% (n = 32) and incidental findings 13% (n = 27). Compared to the original HOMER cohort (2012-13), there was an overall decrease in crude HCC incidence estimates from 6.57 to 4.11/100 000, a significant decrease chronic hepatitis C as a risk factor and increase in MAFLD; a higher proportion diagnosed with early-stage HCC, although there was no improvement in surveillance uptake over time (Table 1). **Conclusion:** The incidence of HCC in Melbourne, Australia has reduced between 2012-13 and 2021-22, temporally associated with the introduction of DAAs for HCV in 2016, and an increase in MAFLD-HCC reflecting the obesity epidemic. Early-stage HCC at diagnosis was more common in 2021-22, but rates of diagnosis in surveillance remained sub-optimal, highlighting the need for programs to promote community diagnosis of liver disease and enrolment in HCC surveillance.

Table 1: Comparison of selected clinical characteristics between HOMER-2 (2021-22) and HOMER (2012-13) cohorts	HOMER-2 N=202	HOMER N=272	p-value*
Early-stage HCC (BCLC 0-A)	95 (47)	70 (26)	<0.0001
Surveillance uptake	79 (39)	110 (40)	0.770
Early-stage HCC identified through surveillance	52 (66)	54 (49)	0.022
Risk factors for chronic liver disease			
Chronic Hepatitis B	48 (24)	60 (22)	0.683
Chronic hepatitis C	58 (29)	112 (41)	0.005
SVR at time of diagnosis	40 (70)		
Alcohol related liver disease	63 (31)	107 (39)	0.062
Metabolic associated fatty liver disease	76 (37)	39 (14)	<0.0001
More than one risk factor	60 (30)	73 (27)	0.238
*Chi square analysis

4016-A | CHARACTERISTICS AND OUTCOMES OF HEPATOCELLULAR CARCINOMA IN THE FONTAN SURVIVOR: A MULTICENTER RETROSPECTIVE STUDY EXAMINING LIVER OUTCOMES

Benjamin E. Rosenthal[1], Yuli Y. Kim[1,2], Annique Nyman[1], Gentian Lluri[3], Christiane Haeffele[4], Roger A De Freitas[5], Adam Lubert[6], Richard Krasuski[7], Fred Wu[8], Eric Krieger[9], Anita Saraf[10], Michael Earing[11], Matthew J. Lewis[12], Fred H. Rodriguez III[13], Ali Zaidi[14], Elisa Bradley[15], Ari M. Cedars[16], Wayne J. Franklin[17], Salil Ginde[18], Jasmine Grewal[19], Charlotte Schluger[2], Jungwon Min[2], Moira Hilscher[20], Jack Rychik[2], Elizabeth Rand[2] and Maarouf A. Hoteit[1], (1)Hospital of the University of Pennsylvania, (2)Children's Hospital of Philadelphia, Philadelphia, PA, (3)Ronald Reagan UCLA Medical Center, (4)Stanford University, (5)Robert H. Lurie Children's Hospital of Chicago, (6)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (7)Duke University Health System, (8)Boston Children's Hospital and Brigham and Women's Hospital, Boston, MA, (9)University of Washington Medical Center, (10)UPMC Children's Hospital of Pittsburgh, (11)Chicagoland Children's Health Alliance, (12)Columbia University Irving Medical Center, New York, NY, (13)Children's Healthcare of Atlanta, (14)Mount Sinai Hospital, (15)Ohio State University Hospital, (16)Johns Hopkins Hospital, (17)Phoenix Children's Hospital, (18)Children's Wisconsin and Froedtert Hospital, (19)University of British Columbia, (20)Mayo Clinic

Background: The Fontan operation is a surgical procedure to palliate single ventricle congenital heart disease. Hepatocellular carcinoma (HCC) is a rare and potentially fatal complication of Fontan-associated liver disease (FALD). We aim to describe tumor characteristics, including stage, treatment, and outcomes of HCC occurring in the context of FALD. **Methods:** This is a multicenter, retrospective case series of adult Fontan patients diagnosed with HCC between 2005 and 2022. Descriptive statistics were used to compare groups. Patient survival was evaluated using Kaplan-Meier curves and log-rank tests. **Results:** Fifty-eight patients (43% female, 79% White) were diagnosed with HCC at median age 31 (interquartile range 26, 38) years. Diagnoses were made by biopsy (45%), imaging (38%), explant/resection (16%), or autopsy (2%). Twenty-five (43%) patients had a single lesion and median tumor size was 3.9 cm. Metastatic disease was present in 3 patients (5%) and vascular invasion in 6 patients (10%). There were 42 patients (72%) classified as Child-Turcotte-Pugh class A, 16 (28%) as class B, and none in class C. Nine patients (16%) were Barcelona Clinic Liver Cancer (BCLC) stage 0, 30 patients (54%) stage A, 8 patients (14%) stage B, 6 patients (11%) stage C, and 3 patients (5%) stage D. Treatment modalities included surgery in 18 patients (31%, 9 resection, 9 combined heart-liver transplant), liver-directed therapy in 28 patients (48%, 6 percutaneous ablation, 22 transarterial chemoembolization, transarterial radioembolization or external radiotherapy), systemic therapy 3 patients (5%) and palliative care only in 9 patients (16%). Forty-four percent of BCLC stage 0 or A patients had surgical therapy and 15% had percutaneous ablation, while 13% of BCLC stage B patients had surgery and none had percutaneous ablation (p = 0.001). One- and 3-year survival were 79% and 64%, respectively. Three-year survival was higher in patients who received surgery or ablation (80%) compared to other liver directed therapy (64%), systemic therapy (0%), and palliative care (17%, p = 0.004; Figure). There was no recurrence or evidence of viable tumor after treatment following liver transplant or ablation, compared to 4 patients (44%) after surgical resection and 13 patients (59%) after non-ablation liver-directed therapy (p = 0.001). **Conclusion:** This is the largest case series describing staging, therapy and

Symbols: ᶠ, Poster of Distinction; ★, Foundation Award Recipient

outcome of HCC in the context of FALD. More than two-thirds of the cases were diagnosed at an early stage, of whom slightly more than half received potentially curative surgery or ablation. We demonstrate higher survival rates among patients who received these treatments. Survival was worse in the remaining one-third who were diagnosed at later stages and did not undergo curative therapy. Our findings underscore the importance of HCC screening for early detection in Fontan patients.

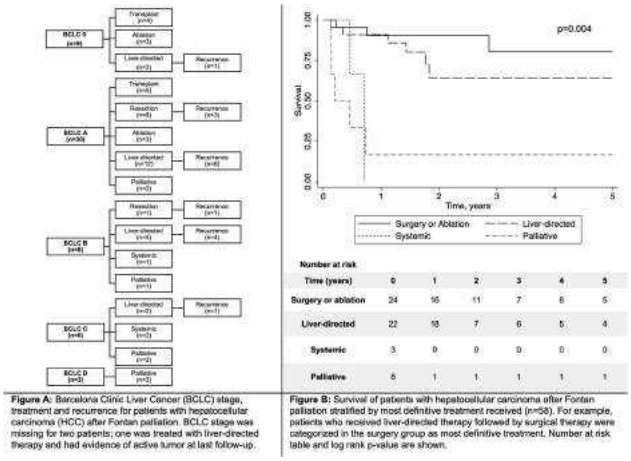

Figure A: Barcelona Clinic Liver Cancer (BCLC) stage, treatment and recurrence for patients with hepatocellular carcinoma (HCC) after Fontan palliation. BCLC stage was missing for two patients; one was treated with liver-directed therapy and had evidence of active tumor at last follow-up.

Figure B: Survival of patients with hepatocellular carcinoma after Fontan palliation stratified by most definitive treatment received (n=58). For example, patients who received liver-directed therapy followed by surgical therapy were categorized in the surgery group as most definitive treatment. Number at risk table and log rank p-value are shown.

4017-A | CHARACTERIZING THE IDENTIFYING MODALITY OF INELIGIBLE PATIENTS WHO PRESENTED FOR LIVER TRANSPLANTATION EVALUATION FOR COLORECTAL LIVER METASTASES

Eric Takoushian[1], Ellie Brandon[2], Mateo Noriega[2], Pashtoon Murtaza Kasi[2], Manish Shah[2], Juan P Rocca[2] and Benjamin Samstein[2], (1)Weill Cornell Medical College, (2)Newyork-Presbyterian/Weill Cornell Medical Center

Background: Liver transplantation is a novel therapy for patients with unresectable colorectal liver metastases (CRLM). 5-year survival using liver transplantation appears to be significantly better than systemic chemotherapy in selected patients. Despite strict criteria for transplantation, there is little guidance on the required workup prior to full transplant evaluation; as a result, most referred patients do not proceed to transplantation. The purpose of this study is to identify the necessary screening tests for patients with CRLM referred for liver transplant evaluation and describe the reasons many do not progress to transplantation. **Methods:** 23 patients were referred for CRLM evaluation for liver transplantation from 2018 to 2022. Demographic and transplant evaluation data was collected for all patients throughout evaluation. **Results:** The population was 91% male with median age 53.8 years at diagnosis. 52% had their primary intact at referral and the Sigmoid colon was the most common site of primary tumor. Number of liver metastases ranged from 3 to > 20 with a median of 10; 43% of patients had a largest tumor size > 5.5cm. 57% of patients had prior liver resection, ablation, or HAI pump. 30% of patients had CEA at referral > 80 and 22% had progression of disease on chemotherapy. 13% of patients had an Oslo Score of 0; 52% an Oslo score of 1, 30% an Oslo score of 2, and 4% an Oslo score of 3. 22% of patients had a KRAS mutation. Of the 23 patients that presented for evaluation, 6 were listed for transplant, and 4 received a liver transplant; 1 is currently in evaluation. For the 18 patients who are no longer eligible, we identified the reason evaluation was ended and how this was discovered in Table 1. Of the 11 patients determined to be ineligible by CT Chest, 27% were ruled out on their first CT Chest and did not have prior high resolution CT Chest. Follow-up data at 1 year was available for 10 of the patients ineligible for transplant and overall survival at 1 year for these patients was 60%. **Conclusion:** It is important to streamline the appropriate imaging and procedural screening among patients referred for liver transplantation for CRLM. Most patients referred were ruled out due to extra-hepatic disease during the evaluation. Employing the use of CT chest, PET/CT imaging, and lymphadenectomy appears essential to understanding why many do not progress to transplantation and is critical to refining referral criteria to improve access to transplantation for appropriate patients with unresectable CRLM.

Table 1: Reasons for ineligibility – patients no longer eligible for transplant (n=18)

Reason for ending evaluation, n (%)	
Metastasis outside the liver	16 (89)
Rendered NED on imaging	1 (6)
Patient opted against transplant	1 (6)
Scan to identify ineligibility, n (%)	
CT chest	11 (61)
PET/CT skull base to thigh	4 (22)
Lymphadenectomy	1 (6)
Peritoneal metastases on colonic resection	1 (6)

4018-A | CLINICAL CHARACTERISTICS AND RISK FACTORS OF EXTRAHEPATIC RECURRENCE AFTER HEPATECTOMY OF HEPATOCELLULAR CARCINOMA WITHOUT INTRAHEPATIC HEPATOCELLULAR CARCINOMA: A MULTI-INSTITUTIONAL 15-YEAR OBSERVATIONAL STUDY

Jae Hyun Yoon[1], Ga Ram You[2], Sung Bum Cho[2] and Sung Kyu Choi[1], (1)Chonnam National University Hospital, (2)Hwasun Chonnam National University Hospital

Background: Extrahepatic recurrence (EHR) is a well-known poor prognostic factor regarding hepatocellular carcinoma (HCC). Although EHR after hepatectomy of HCC may occur in high risk group of patients, little is known about EHR when there are no intrahepatic HCC. We investigated the clinical features and risk factors regarding EHR without remnant intrahepatic HCC at the time of EHR diagnosis. **Methods:** Among 1,069 treatment-naive patients who underwent curative hepatectomy for HCC at four tertiary academic hospitals from January 2004 to December 2019, 569 patients were enrolled. Multivariate analysis via Cox-regression was performed to identify the variables associated with EHR. **Results:** Thirty-eight patients developed EHR after hepatectomy without remnant intrahepatic HCC during median follow-up duration of 1.04 years. (Figure 1) Patients with EHR demonstrated significant early initial HCC recurrence than the patients without EHR; 1.73 vs. 4.43 years, respectively. On multivariate analysis, compared to patients without EHR, patients with EHR (without IHR) showed higher portion of venous/lymphatic involvement (HR 2.418, $p = 0.020$), tumor necrosis (HR 2.592, $p = 0.009$) and initial tumor stage beyond Milan criteria (HR = 3.008, $p = 0.001$). Also on analysis of factors related to survival after surgical resection of HCC, EHR was strongly associated with poor survival on multivariate analysis via Cox-regression (HR = 14.044, $p < 0.001$) (Figure 3). Not only the cumulative rates of EHR correlated with the numbers of risk factors but also the survival rates also exhibited step-wise relationship (Figure 2, and 3). **Conclusion:** EHR without remnant viable HCC may occur in considerable number of patients after hepatectomy for HCC. Patients with high risk for EHR are warranted for meticulous postoperative surveillance for timely EHR detection and positive clinical outcomes despite no intrahepatic HCC.

4019-A | CLINICAL FACTORS ASSOCIATED WITH THE THERAPEUTIC EFFICACY OF ATEZOLIZUMAB PLUS BEVACIZUMAB IN PATIENTS WITH UNRESECTABLE HEPATOCELLULAR CARCINOMA: A MULTICENTER PROSPECTIVE OBSERVATIONAL STUDY

Kazuki Maesaka[1], Hayato Hikita[1], Machiko Kai[1], Yuki Tahata[2], Kazuma Shinkai[1], Akira Doi[2], Kazuyoshi Ohkawa[3], Masanori Miyazaki[4], Hisashi Ishida[5], Kengo Matsumoto[6], Yasutoshi Nozaki[7], Takayuki Yakushijin[8], Ryotaro Sakamori[9], Takahiro Kodama[2], Tomohide Tatsumi[2] and Tetsuo Takehara[2], (1)Osaka University, Graduate School of Medicine, (2)Osaka University Graduate School of Medicine, (3)Osaka International Cancer Institute, (4)Osaka Police Hospital, (5)Ikeda Municipal Hospital, (6)Toyonaka Municipal Hospital, (7) Kansai Rosai Hospital, (8)Osaka General Medical Center, (9)National Hospital Organization Osaka National Hospital

Background: The treatment efficiency and predictors of atezolizumab plus bevacizumab therapy for unresectable hepatocellular carcinoma (uHCC) in real-world practice have not been established. This study aimed to assess the therapeutic efficacy of atezolizumab plus bevacizumab and investigate the clinical factors associated with progression-free survival (PFS) and overall survival (OS). **Methods:** Patients with uHCC treated with atezolizumab plus bevacizumab in 19 hospitals were registered before the treatment and observed prospectively. Of this prospectively observational cohort, the outcomes of 222 patients were analyzed. The therapeutic responses were assessed according to the Response Evaluation Criteria in Solid Tumor version 1.1. **Results:** The median age of study patients was 73 years. One hundred and forty-seven (66.2%) patients were treated as their first systemic chemotherapy, whereas 75 (33.8%) had received another regimen before the treatment. One hundred and sixteen (47.7%) patients had more than four intrahepatic tumors, 37 (16.7%) patients had macrovascular invasion, and 88 (39.6%) patients had extrahepatic metastasis. The hepatic etiologies were as follows: viral, n = 120 (54.1%); non-viral, n = 102 (45.9%). The median NLR was 2.44 (IQR 1.78–3.55). The objective response rate and disease control rate were 22.0% and 70.6%, respectively. The median PFS was 5.7 months and 7.8 months in all patients and in the first-line systemic treatment group, respectively. Independent risk factors for the shortened PFS were younger age (< 75) (3.9 mo vs. 8.6 mo; $p = 0.008$), a higher number of intrahepatic tumors (≥ 5) (4.0 mo vs. 7.9 mo; $p < 0.001$), macrovascular invasion (2.3 mo vs. 6.7 mo; $p < 0.001$), and higher NLR (≥ 3.03) (3.0 mo vs. 7.8 mo; $p < 0.001$). On the other hand, non-viral etiology of hepatitis and the presence of prior systemic therapy were not risk factors for the shorten PFS. The median OS was not reached; however, independent risk factors for the shortened OS were a higher number of intrahepatic tumors (≥ 5), macrovascular invasion, higher α-fetoprotein level (≥ 400), worse Child-Pugh score (≥ 6), and higher NLR (≥ 3.03). **Conclusion:** Patients with older age, a lower number of intrahepatic tumors, the absence of macrovascular invasion, and lower NLR were expected to have the prolonged PFS in atezolizumab plus bevacizumab therapy for uHCC.

4020-A | CLINICAL IMPACT OF DIRECT ACTING ANTIVIRALS ON PROGNOSIS OF PATIENTS WITH HEPATOCELLULAR CARCINOMA DUE TO HEPATITIS C VIRUS IN JAPAN

Hideko Ohama[1,2], Atsushi Hiraoka[1,2], Toshifumi Tada[2], Masashi Hirooka[2], Kazuya Kariyama[2], Ei Itobayashi[2], Tsuji Kunihiko[2], Toru Ishikawa[2], Hidenori Toyoda[2], Takeshi Hatanaka[2], Satoru Kakizaki[2], Atsushi Naganuma[2], Tomomitsu Matono[2], Fujimasa Tada[2], Kazuhiro Nouso[2], Yoichi Hiasa[2] and Takashi Kumada[2], (1)Ehime Prefectural Central Hospital, (2)Relpec Study Group and HCC 48 Group

Background: Direct acting antivirals (DAAs) capable of eliminating hepatitis C virus (HCV) sustained virological response SVR at a higher rate than interferon therapy has been available in Japan since 2014. This study examined the clinical impact of DAAs for hepatocellular carcinoma (HCC) due to HCV before and after the advent of these drugs. **Methods:** Enrolled were 1982 patients with HCC due to HCV treated at our institutions in Japan from January 2000 to January 2023. They were divided into two groups based on before and after DAA availability: pre-DAA (before 2013, n = 1181) and post-DAA (after 2014, n = 801). Changes in clinical features and prognoses were evaluated in a retrospective manner. **Results:** The groups did not show

significant differences for Liver Cancer Study Group of Japan tumor node metastasis stage or Japan integrated staging (JIS) score. However, the post-DAA group had higher frequencies of patients with SVR from anti-viral treatments (45.9% vs. 10.1%), elderly age (73 vs. 69 y old), lower AST (40 vs. 56 IU/L), ALT (31 vs. 46 IU/L), and AFP (11.2 vs. 23.6 ng/mL) levels, higher platelet count (13.6 vs. 10.8 x10^4/μL), longer prothrombin time (88.0% vs. 81.9%), better ALBI score (-2.53 vs. -2.36), and higher rate of curative treatment (surgical resection or radio frequency ablation) (73.7% vs. 65.0%) ($p < 0.001$, for all). Also, recurrence-free survival (RFS) after curative treatment was significantly better in the post-DAA group (median 2.9 vs. 2.1 y) as was overall survival (OS) [median: not applicable (NA) vs. 5.5 y) ($p < 0.001$, for all). After inverse probability weighting (IPW) adjustment using propensity scores based on multivariate analysis, OS was also better in the post-DAA group (median 7.0 vs. 5.7 y, $p < 0.001$). As a sub-analysis, comparisons of prognosis among three groups after dividing the post-DAA group into non-SVR ($n = 307$), pre-SVR (HCC developed after SVR, $n = 368$), and post-SVR (SVR developed after HCC, $n = 126$) showed that OS for the non-SVR group was significantly shorter (median 3.2 y vs. NA vs. NA, $P < 0.001$), with no significant difference noted between the pre- and post-SVR groups ($p = 0.19$). **Conclusion:** The prognosis of patients with HCC due to HCV was greatly improved after introduction of DAAs, with the resultant high rate of HCV elimination dramatically changing clinical practice for HCV-related HCC cases.

Disclosures: Takeshi Hatanaka – Eisai: Speaking and Teaching, Yes, No;

The following people have nothing to disclose: Hideko Ohama, Atsushi Hiraoka, Toshifumi Tada, Masashi Hirooka, Kazuya Kariyama, Ei Itobayashi, Tsuji Kunihiko, Toru Ishikawa, Hidenori Toyoda, Satoru Kakizaki, Atsushi Naganuma, Tomomitsu Matono, Fujimasa Tada, Kazuhiro Nouso, Yoichi Hiasa, Takashi Kumada

4021-A | CLINICAL OUTCOMES OF POROUS GLASS MEMBRANE PUMPING EMULSIFICATION DEVICE IN TRANSARTERIAL CHEMOEMBOLIZATION FOR HEPATOCELLULAR CARCINOMA

Fumitaka Mizuno, Norihiro Imai, Shinya Yokoyama, Kenta Yamamoto, Takanori Ito, Yoji Ishizu, Takashi Honda, Masatoshi Ishigami and Hiroki Kawashima, Nagoya University Graduate School of Medicine

Background: A porous glass membrane pumping emulsification device (GMD) enables the formation of a high-percentage water-in-oil emulsion with homogeneous and stable droplets. Although GMD is expected to improve local therapeutic effects in transarterial chemoembolization (TACE) for hepatocellular carcinoma (HCC), the clinical outcomes of GMD in TACE are limited to a few reports to date. **Methods:** From 2019 to 2023, 57 patients with unresectable HCC were treated with 72 TACE sessions using GMDs. All TACE procedures were performed according to the standard treatment protocol. Ethiodized oil was mixed with epirubicin solution using a GMD. The ratio of epirubicin solution to ethiodized oil was 1:2. The emulsion was injected into the tumor-feeding artery, followed by embolization. The treatment efficacy was evaluated by contrast-enhanced computed tomography 1–3 months after TACE using a GMD and every 2–3 months thereafter. Based on changes in the maximum diameter of viable lesions, the treatment responses of target tumor were categorized by the modified Response Criteria in Solid Tumors. The changes in liver function after the treatment and the treatment-related adverse events were analyzed retrospectively. **Results:** There were 47 males and 10 females; the median age was 73 years (range 45-89). Child–Pugh scores were A (score 5) in 36 patients, A (score 6) in 14 patients, B (score 7) in five patients, and B (score 8) in two patients. The Barcelona Clinic Liver Cancer stages were 0 (very early stage) in 13 patients, A (early stage) in 33 patients and B (intermediate stage) in 11 patients. The median size of treated HCCs was 23.5 (range 6–61) mm, and 44 nodules were solitary. The median dosage of ethiodized oil mixed with epirubicin solution was 3.0 (range 0.7–12) ml. Treatment effects of target tumors were complete response in 76% and partial response in 17%. The local recurrence rates at 6 months and 12 months were 84.2% and 59.2% respectively. The median time to recurrence after the treatment was 581 days. During the observation period, no major treatment related complications were observed. Multivariate Cox proportional hazards model analysis including emulsion dosage, localization, and enhancement pattern revealed that the number of HCC and first TACE were significantly associated with better local control. **Conclusion:** The use of GMD in TACE enables the tumor to accumulate ethiodized oil more densely, resulting in effective local control.

4022-A | CLINICAL SIGNIFICANCE OF CIRCULATING IMMUNE MOLECULE BIOMARKERS FOR PREDICTING THE EFFICACY OF ATEZOLIZUMAB PLUS BEVACIZUMAB THERAPY FOR UNRESECTABLE HEPATOCELLULAR CARCINOMA

Makoto Chuma[1], Haruki Uojima[2], Hidenori Toyoda[3], Atsushi Hiraoka[4], Masanori Atsukawa[5], Tomomi Okubo[6], Toshifumi Tada[7], Yoshitaka Arase[8], Hisashi HIdaka[2], Takashi Kumada[9], Tatehiro Kagawa[8] and Shin Maeda[10], (1)Yokohama City University Medical Center, (2)Kitasato University School of Medicine, (3)Ogaki Municipal Hospital, (4)Ehime Prefectural Central Hospital, (5)Nippon Medical School Hospital, (6)Nippon Medical School Chibahokusoh Hospital, (7)Japanese Red Cross Himeji Hospital, Himeji, Japan, (8)Division of Gastroenterology and Hepatology, Department of Internal Medicine, Tokai University School of Medicine, (9)Gifu Kyoritsu University, (10)Yokohama City University

Background: Atezolizumab plus bevacizumab (ATZ +BV) therapy has become a first-line therapy for unresectable hepatocellular carcinoma (u-HCC), but predictive biomarkers of the response of this therapy have not yet been clarified. The aim of this study was to identify clinically significant biomarkers of the response to ATZ+BV therapy in u-HCC. **Methods:** First, for the potential of cell-free DNA/circulating tumor DNA (ctDNA) as biomarkers for predicting the therapeutic outcome, we have extracted cell-free DNA from serum in 24 u-HCC patients treated with ATZ+BV therapy and AmpliSeq for Illumina Cancer Hotspot Panel v2 was used to detect and analyze mutations. Second, levels of specific immune-related cytokines reported in sera from HCC patients (i.e., CD274; LAG3; CCL2, 4, 5, and 20; CXCL1, 9, 10, 11, 12, and 13; CX3CL1, CCR5, IFNγ; and IL-6 and 8) were measured using enzyme-linked immunosorbent assays in blood samples from 130 u-HCC patients treated with ATZ+BV therapy. **Results:** Variant read frequency (VRF) mutations in TP53 (12.6%), APC (8.4%), PICK3CA (8.4%), and VHL (4.2%) were found as pathologically malignant genes at a VRF of ≥1%, but there was no correlation between these mutations and treatment response. CTNNB1 was also detected in two stable disease (SD) cases and two progressive disease (PD) cases, but at a low VRF of 0.5%. We measured 16 chemokines in 130 cases and found significant differences in expression among OR, SD, and PD cases, for CXCL9 and LAG3 which are related to recruitment of CD8 T-cell or CD8 T-cell exhaustion. Receiver-operating characteristic curve analyses of CXCL9 (402 mg/ml) and LAG-3 (3864 pg/ml) indicated areas of 0.739 and 0.707, respectively, to differentiate OR from non-OR and to differentiate PD from non-PD. The patients with high serum CXCL9 (CXCL9-H) exhibited significantly longer progression-free survival (PFS) and overall survival (OS) compared to patients with low serum CXCL9 (CXCL9-L) (adjusted hazard ratio [aHR] = 0.43, 95% confidence interval [CI] = 0.28-0.66, P < 0.001, and aHR = 0.42, 95% CI = 0.25-0.70, P < 0.001, respectively) (Figure A, B). Furthermore, patients with low serum LAG-3 (LAG-3-L) exhibited significantly longer PFS and OS compared to patients with serum LAG-3-H (aHR = 0.43, 95% CI = 0.28-0.66, P = 0.001, and aHR = 0.42, 95% CI = 0.25–0.70, P < 0.001, respectively) (Figure C, D). **Conclusion:** Although no ctDNA mutations were found to be related to the efficacy of ATZ+BV therapy, serum levels of CXCL9 and LAG-3 were associated with the efficacy of ATZ+BV therapy and both PFS and OS, suggesting the importance of CD8 T-cell function in predicting the effectiveness of this treatment in patients with unresectable hepatocellular carcinoma.

4023-A | CLINICAL USEFULNESS OF LENVATINIB AS SECOND-LINE TREATMENT FOR HEPATOCELLULAR CARCINOMA FOLLOWING ATEZOLIZUMAB PLUS BEVACIZUMAB FAILURE

Atsushi Hiraoka[1], Toshifumi Tada[2], Masashi Hirooka[2], Kazuya Kariyama[2], Ei Itobayashi[2], Tsuji Kunihiko[2], Toru Ishikawa[2], Hidenori Toyoda[2], Takeshi Hatanaka[2], Satoru Kakizaki[2], Atsushi Naganuma[2], Tomomitsu Matono[2], Hideko Ohama[1], Fujimasa Tada[1], Kazuhiro Nouso[2], Yoichi Hiasa[2] and Takashi Kumada[2], (1)Ehime Prefectural Central Hospital, (2)Relpec Study Group and HCC 48 Group

Background: Atezolizumab plus bevacizumab (Atez/Bev) is a standard first-line treatment for advanced hepatocellular carcinoma (HCC), though effective methods for post-progression systemic treatment have yet to be established. The present study investigated the potential of lenvatinib as second-line treatment after Atez/Bev failure. **Methods:** A total of 101 patients who received lenvatinib as second-line treatment between 2020 and 2022 were included. Median age was 72 years and the majority were male (77%). Most patients had Child-Pugh A (82%), while BCLC staging was A:B:C:D = 1:35:61:4. As controls, 29 patients who received another molecular targeting agent (MTA) as second-line treatment during the same period (sorafenib 14, ramucirumab 11, cabozantinib 4) were also enrolled. The therapeutic efficacy of lenvatinib given as second-line treatment was retrospectively evaluated. **Results:** Median progression-free survival (PFS) and median overall survival (OS) for all patients were 4.4 and 15.7 months, respectively. For those with Child-Pugh class A, median PFS was 4.7 months and median OS was not reached. When compared with patients who received another MTA, there were no significant differences in terms of PFS (3.5 months, $P = 0.557$) or OS (13.6 months, $P = 0.992$), and also no significant differences for clinical background factors. Modified RECIST findings revealed that objective response and disease control rates for patients treated with lenvatinib were 23.9% and 70.4%, respectively (CR:PR:SD:PD = 3:14:33:21), while those shown by RECIST ver. 1.1 were 15.4% and 66.2%, respectively (CR:PR:SD:PD = 1:10:36:24). The most common adverse events (any grade $\geq 10\%$) were appetite loss (26.7%), general fatigue (21.8%), proteinuria (16.8%), and hypertension

(13.9%). **Conclusion:** Lenvatinib treatment may not provide a pseudo-combination immunotherapy effect after Atez/Bev treatment failure, though the present results suggest that it can be an effective second-line treatment option for advanced HCC patients following such failure. These results provide important insights into the therapeutic potential of lenvatinib for this patient population and highlights the need for further research to optimize treatment strategies.

4024-A | CLINICOPATHOLOGIC AND TREATMENT OUTCOME DATA FROM 165 FIBROLAMELLAR CARCINOMA PATIENTS

Shadi Chamseddine[1], Sunyoung Lee[1,2] and Ahmed Kaseb[1], (1)The University of Texas MD Anderson Cancer Center, (2)Severance Hospital, Yonsei University College of Medicine

Background: Fibrolamellar carcinoma (FLC) is a rare subtype of liver cancer that primarily affects young adults and adolescents. The main objective of this study is to evaluate the association between survival outcomes and clinical factors of patients with FLC. **Methods:** We retrospectively collected clinicopathologic and treatment outcome data from 88 male and 77 female patients with a pathologic diagnosis of FLC. Median overall survival (OS) and progression-free survival (PFS) were calculated using Kaplan-Meier curves. Log rank test, univariable and multivariable Cox models were applied to evaluate the association between clinical outcomes and patients' characteristics. **Results:** Mean age at diagnosis was 27.4 years (age range: 9, 76), median OS was 42.6 months (95% CI: 36.5, 59.2). 50.3% of patients in our study were AJCC Stage IV at the time of presentation, with 67.5% having vascular invasion at diagnosis. 5% of patients had liver cirrhosis. 68.5% of patients received surgery, including metastasectomy. 30.9% received radiation therapy, and 77.5% received systemic therapy. Combination of 5-fluorouracil and interferon-alpha2 was the most frequently used systemic therapy (83 patients), with 45 patients receiving other forms of chemotherapy. The median OS of patients who underwent surgery was 59.2 months (95% CI [49.51, 89.68]) versus 20.34 months (95% CI [15.37, 26.02] in patients who did not. Of those who did not have surgery, 94.2% (49 patients) had AJCC stage > II. Higher tumor stage(> II) (HR = 2.841; 95% CI [1.309, 6.165]), lack of surgery (HR = 3.47; 95% CI [2.193, 5.488]) and lack of receipt of radiation therapy (HR = 1.685; 95% CI [1.059, 2.68]) were positively associated with worse OS. **Conclusion:** We identified prognostic factors in FLC. The associations of receipt of surgery and radiation with prolonged OS suggest that local control and cancer debulking in this disease is paramount.
Disclosures: The following people have nothing to disclose: Shadi Chamseddine, Sunyoung Lee, Ahmed Kaseb

4025-A | COMBINATION OF RADIATION THERAPY IMPROVE EFFICACY OF ATEZOLIZUMAB PLUS BEVACIZUMAB (ATE+BEVA) THERAPY IN ADVANCED HEPATOCELLULAR CARCINOMA WITH HIGH RISK FACTOR (HUGE TUMOR, BILIARY AND MAIN PORTAL VEIN INVASION)

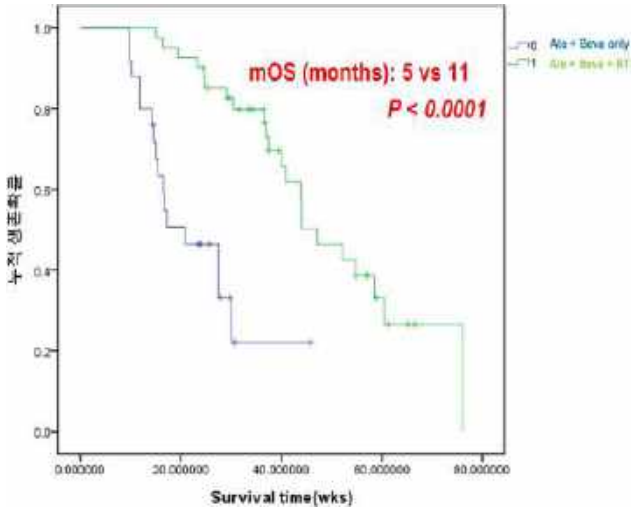
Sangyoun Hwang, Wan Jeon, Hyung Jun Kim, Jung Woo Im, Ki Jeong Jeon and Beom Jin Shim, Dongnam Institute of Radiological & Medical Sciences

Background: Atezolizumab plus bevacizumab (Ate +Beva) proved better efficacy compared to sorafenib as a first line systemic therapy for advanced hepatocellular carcinoma (HCC). However, there is unmet need in the so called "high risk population" (huge tumor, bile duct invasion, main portal vein invasion) because efficacy of Ate+Beva is worse in those group. Radiation therapy (RT) with immunotherapy could be expected synergic effect by immune stimulation. Therefore we describe the efficacy and safety of RT with immunotherapy in high risk population of advanced HCC. **Methods:** The clinical course of patients with advanced HCC who received Ate+Beva therapy in single cancer center from September 2020 to December 2021 was assessed until May 2022. Overall response rate (ORR) and disease control rate (DCR) per RECIST v1.1 and mRECIST, median overall survival (OS), and safety were analyzed.

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Especially we divided two groups (RT vs non-RT) in high risk population and analyzed OS of two groups. **Results:** 163 patients were treated with Ate+Beva therapy, Child A:B:C patients were 147:16:1, BCLC stage B:C patients were 23:140. Median OS of total patients was 10.2 months, ORR & DCR of total patients were 20.8%, 72.4%. Severe adverse event (AE) beyond grade 3 was 12.9%, AE of Grade 5 (hemoptysis, pneumonitis, variceal bleeding, duodenal ulcer perforation, autoimmune hepatitis) was 3.1%. Median OS of RT group and non-RT group in total patients were 10.7 vs 11.7 months ($p = 0.597$), however those of two groups in high risk population were 11 vs 5 months ($p < 0.0001$). SAE of two groups was not different significantly. **Conclusion:** This study demonstrates that RT combined with Ate+Beva could improve efficacy about 2 times ompared to Ate+Beva without RT in high risk population of HCC without difference of AE. Further validation with large cohort in prospective study are needed to prove efficacy of Ate +Beva combined with RT in high risk population.



Disclosures: The following people have nothing to disclose: Sangyoun Hwang, Wan Jeon, Hyung Jun Kim, Jung Woo Im, Ki Jeong Jeon, Beom Jin Shim

4026-A | COMPARATIVE ANALYSIS OF ATEZOLIZUMAB PLUS BEVACIZUMAB AND HEPATIC ARTERY INFUSION CHEMOTHERAPY IN UNRESECTABLE HEPATOCELLULAR CARCINOMA: A MULTI-CENTER, PROPENSITY SCORE STUDY

Si Hyun Bae[1], Jae-Sung Yoo[2], Pil Soo Sung[2], Jeong Won Jang[2], Jong Choi[2], Seung Kew Yoon[2] and Department of Gastroenterology and Hepatology, Seoul St Mary's Hospital, The Catholic University of Korea, Seoul, Republic of Korea, (1)The Catholic University of Korea, (2)Seoul St Mary's Hospital, the Catholic University of Korea, Seoul, Republic of Korea

Background: Patients who are not feasible for or cannot afford the first-line systemic chemotherapy, hepatic artery infusion chemotherapy (HAIC) may be proposed and can be used for treatment. Up to date, to our knowledge, there has been no study regarding the comparison between combination therapy, atezolizumab and bevacizumab, and hepatic artery infusion chemotherapy in advanced hepatocellular carcinoma (HCC) patients. The purpose of this study was to compare the prognosis and characteristics of the advanced HCC patients treated with the first-line combination therapy and hepatic artery infusion chemotherapy. **Methods:** We retrospectively assessed 174 patients treated with HAIC and 77 patients treated with atezolizumab/bevacizumab combination therapy between 2018 and 2022 in 5 university-affiliated hospitals in Korea. Firstly, we assessed the overall survival (OS), progression free survival (PFS), objective response rate (ORR) and disease control rate (DCR) between atezolizumab/bevacizumab combination therapy and hepatic artery infusion chemotherapy. Due to baseline characteristic differences between the two groups, we also analyzed results with propensity score matching (PSM) method **Results:** When we compared the baseline characteristics of the enrolled patients, we found that there were significant differences in age, tumor numbers, portal vein invasion and Child Pugh scores. HAIC treated patients were significantly younger, had significantly more single number of tumors, had more portal vein invasions and had worse Child-Pugh scores. Despite the fact that HAIC-treated patients had more portal vein invasions and worse Child-Pugh scores, however, there was no significant difference in overall survival or progression-free survival between the two groups. After adjusting for bias that could occur due to confounding variables by PSM method, patients treated with Ate/beva therapy has a significantly longer OS than patients treated with HAIC ($P < 0.05$), although there were no significant differences in progression-free survival and objective responses. **Conclusion:** According to our multi-center, propensity score study, patients treated with Ate/beva therapy has a significantly longer OS than patients treated with HAIC.

4027-A | COMPARATIVE ANALYSIS OF ATEZOLIZUMAB PLUS BEVACIZUMAB AND LENVATINIB ON LIVER FUNCTION IN HEPATOCELLULAR CARCINOMA PATIENTS: A MIXED-EFFECTS REGRESSION MODEL

Takeshi Hatanaka[1], Satoru Kakizaki[2], Atsushi Hiraoka[3], Toshifumi Tada[4], Masashi Hirooka[5], Kazuya Kariyama[6], Ei Itobayashi[7], Tsuji Kunihiko[8], Toru Ishikawa[9], Hidenori Toyoda[10], Atsushi Naganuma[2], Tomomitsu Matono[11], Hideko Ohama[12], Fujimasa Tada[3], Yutaka Yata[13], Kazuhiro Nouso[6], Yoichi Hiasa[5], Takashi Kumada[14] and The Real-life Practice Experts for HCC (RELPEC) Study Group, and HCC 48 Group (hepatocellular carcinoma experts from 48 clinics in Japan), (1)Gunma Saiseikai Maebashi Hospital, (2)National Hospital Organization Takasaki General Medical Center, (3) Ehime Prefectural Central Hospital, (4)Japanese Red Cross Himeji Hospital, (5)Ehime University Graduate School of Medicine, (6)Okayama City Hospital, (7)Asahi General Hospital, (8)Teine Keijinkai Hospital, (9) Saiseikai Niigata Hospital, (10)Ogaki Municipal Hospital, (11)St. Mary's Hospital, (12)Takarazuka City Hospital, (13)Hanwa Memorial Hospital, (14)Gifu Kyoritsu University

Background: The aim of the retrospective study was to compare the impact of atezolizumab plus bevacizumab (Atez/Bev) and lenvatinib (LEN) on liver function in patients with hepatocellular carcinoma. **Methods:** Between March 2018 to July 2022, we included 526 patients receive Atez/Bev and 731 patients received LEN in this study. We conducted a 1:1 propensity score matching analysis and identified 324 patients in each group for inclusion in the present analysis. We used non-linear mixed-effects regression models to compare the rate of ALBI score, serum albumin and total bilirubin in Atez/Bev and LEN group. **Results:** After the propensity score matching, the median age of the Atez/Bev and LEN groups were 74.0 [68.0-80.0] and 74.0 [69.0-79.0] years old, respectively. In the Atez/Bev group, 276 (85.2%) were male, while in the LEN group, 276 (85.2%) were male. There was no significant difference in the performance status between the two groups, with 274 (84.6%) having a status of 0, 41 (12.7%) having a status of 1, and 9 (2.8%) having a status of ≥ 2 in the Atez/Bev group, and 262 (80.9%), 54 (16.7%), and 8 (2.5%) in the LEN group, respectively ($p = 0.4$). The serum level of albumin was 3.8 (interquartile range [IQR] 3.4-4.1 g/dL) in the Atez/Bev group and 3.8 (IQR 3.4-4.0 g/dL) in the LEN group, showing no significant difference ($p = 0.9$). Similarly, the serum total bilirubin was 0.8 (IQR 0.6-1.0 mg/dL) in the Atez/Bev group and 0.8 (IQR 0.5-1.0 mg/dL) in the LEN group, with no significant difference observed ($p = 0.1$). The mean ALBI score in Atez/Bev and LEN groups were -2.41 ± 0.40 and -2.44 ± 0.42 at baseline, and -2.17 ± 0.56 and -2.19 ± 0.58 at 12 weeks, respectively. Although the ALBI score significantly worsened during treatment in both groups ($p < 0.001$), there was no significant difference in the rate of ALBI score deterioration between the two groups ($p = 0.06$). There was also no significant difference in the rate of decreasing serum albumin and increasing total bilirubin levels ($p = 0.5$ and 0.07). Subgroup analyses showed that LEN-treated patients with BCLC advanced stage ($p = 0.02$) and those who initially received the full dose ($p < 0.001$) had a significantly greater worsening of ALBI score compared to Atez/Bev treatment. **Conclusion:** There was no significant difference in the trend of liver function deterioration between both groups. Caution should be exercised for LEN-treated patients with BCLC advanced stage or those receiving a full dose of LEN.

4028-A | COMPARISON OF ATEZOLIZUMAB PLUS BEVACIZUMAB AND LENVATINIB FOR HEPATOCELLULAR CARCINOMA WITH PORTAL VEIN TUMOR THROMBOSIS

Jeayeon Park[1], Hyunjae Shin[1], Moon Haeng Hur[2], Min Kyung Park[1] and Yun Bin Lee[2], (1)Seoul National University College of Medicine, (2)Seoul National University Hospital

Background: Atezolizumab plus bevacizumab and lenvatinib are currently available as first-line therapy for the treatment of unresectable hepatocellular carcinoma (HCC). However, studies comparing the efficacy of atezolizumab plus bevacizumab and lenvatinib are still scarce. This study aimed to investigate the effectiveness of these treatments in HCC patients with portal vein tumor thrombosis (PVTT). **Methods:** We retrospectively included consecutive patients who received either atezolizumab plus bevacizumab or lenvatinib as first-line systemic therapy for the treatment of HCC with PVTT between October 2020 and July 2022 at a tertiary referral center. Primary endpoint was overall survival (OS), and secondary endpoints included progression-free survival (PFS) and disease control rate (DCR) determined by Response Evaluation Criteria in Solid Tumors, version 1.1. **Results:** A total of 52 patients were included: 30 received atezolizumab plus bevacizumab and 22 received lenvatinib. The median follow-up duration was 6.4 months (interquartile range,

3.9–9.8). The median OS was 10.8 months (95% confidence interval [CI], 5.7–not estimated) with atezolizumab plus bevacizumab and 5.8 months (95% CI, 4.8–not estimated) with lenvatinib ($P = 0.26$ by log-rank test; Figure 1A). There was no statistically significant difference in OS between patients treated with atezolizumab plus bevacizumab and those treated with lenvatinib (atezolizumab plus bevacizumab versus lenvatinib; adjusted hazard ratio [aHR], 0.53; 95% CI, 0.22–1.26; $P = 0.15$). The median PFS was similar between the two treatments ($P = 0.63$ by log-rank test; Figure 1B), with 4.1 months (95% CI, 3.3–7.7) for atezolizumab plus bevacizumab and 4.3 months (95% CI, 2.6–5.8) for lenvatinib (atezolizumab plus bevacizumab versus lenvatinib; aHR, 0.70; 95% CI, 0.34–1.56; $P = 0.34$). HRs were similar after balancing with inverse probability treatment weighting. The DCRs were 23.3% and 18.2% in patients receiving atezolizumab plus bevacizumab and lenvatinib, respectively ($P = 0.89$). **Conclusion:** The effectiveness of atezolizumab plus bevacizumab and lenvatinib was comparable for the treatment of HCC with PVTT.

4029-A | COMPARISON OF CLINICAL OUTCOME BETWEEN NIVOLUMAB AND REGORAFENIB AS SECOND-LINE SYSTEMIC THERAPY AFTER SORAFENIB FAILURE IN PATIENTS WITH ADVANCED HEPATOCELLULAR CARCINOMA

Jae Seung Lee[1,2], Hong Jun Lee[1], Hye Won Lee[1,2], Beom Kyung Kim[1,2], Seung Up Kim[1,2], Jun Yong Park[1,2], Sang Hoon Ahn[1,2] and Do Young Kim[1,2], (1) Yonsei University College of Medicine, Seoul, Republic of Korea, (2)Severance Hospital, Seoul, Republic of Korea

Background: Nivolumab and regorafenib are used as second-line therapies for patients with advanced hepatocellular carcinoma (HCC). We aimed to compare the effectiveness of nivolumab to regorafenib. **Methods:** We retrospectively reviewed HCC patients treated with nivolumab or regorafenib after sorafenib failure. Progression-free survival (PFS) and overall survival (OS) were analyzed. Inverse probability of treatment weighting (IPTW) using the propensity score (PS) was conducted to reduce treatment selection bias. **Results:** Among the recruited 189 patients, 137 and 52 patients received regorafenib and nivolumab after sorafenib failure, respectively. Nivolumab users showed higher Child-Pugh B patients (42.3% vs. 24.1%) and shorter median sorafenib maintenance (2.2 vs. 3.5 mo) compared to regorafenib users. Compared to regorafenib users, nivolumab users showed shorter median OS (4.2 vs. 7.4 mo, $P = 0.045$) and similar median PFS (1.8 vs. 2.7 mo, $P = 0.070$), respectively. However, median OS and PFS were not different between the two treatment groups after 1:1 PS matching yielded 34 pairs (log-rank $P = 0.810$ and 0.810, respectively), and after stabilized IPTW (log-rank $P = 0.445$ and 0.878, respectively). In addition, covariate-adjusted Cox regression analyses showed that the nivolumab (vs. regorafenib) use was not significantly associated with the PFS and OS after 1:1 PS matching and stabilized IPTW (all $P > 0.05$). **Conclusion:** Clinical outcomes in patients treated with nivolumab and regorafenib after sorafenib failure did not differ significantly.

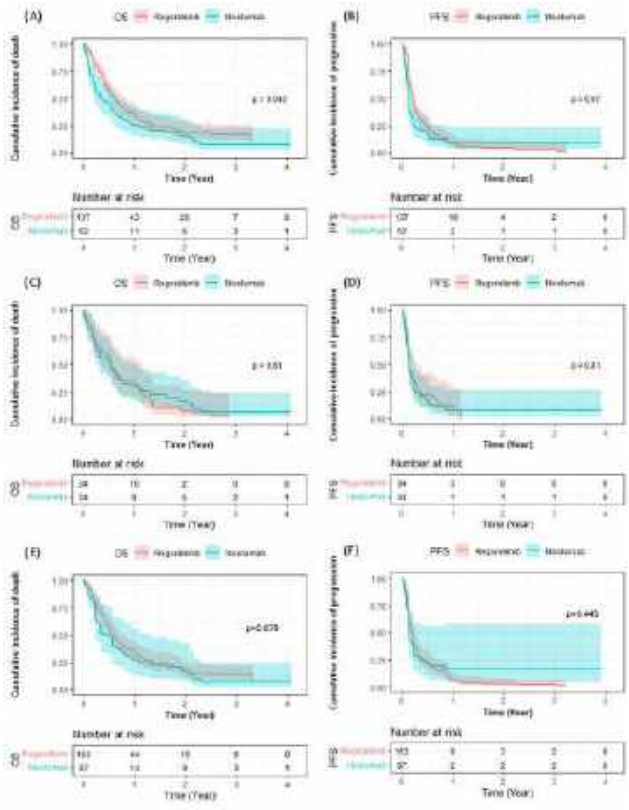

Figure. Kaplan–Meier curves with survival analysis for regorafenib and nivolumab users. (A) OS and (B) PFS of the unmatched cohort, (C) OS and (D) PFS of the 1:1 propensity score-matched cohort, and (E) OS and (F) PFS of the covariate-adjusted cohort after the stabilized inverse probability of treatment weighting. Abbreviation: OS, overall survival; PFS, progression-free survival.

4030-A | COMPARISON OF FIRST-LINE SYSTEMIC THERAPIES FOR ADVANCED HEPATOCELLULAR CARCINOMA: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS OF RANDOMIZED CONTROLLED TRIALS

Moon Haeng Hur[1], Youngsu Park[1], Yunmi Ko[1], Hyunjae Shin[1], Jeayeon Park[1], Ju Yeon Kim[1], Yun Bin Lee[1], Su Jong Yu[1], Yoon Jun Kim[2], Jung-Hwan Yoon[1] and Jeong-Hoon Lee[3], (1)Seoul National University College of Medicine, (2)Department of Internal Medicine and Liver Research Institute, Seoul National University College of Medicine, Seoul, South Korea, (3)Seoul National University College of Medicine, Seoul, South Korea

Background: Recently, several novel systemic therapies and their combinations have shown favorable outcomes in patients with advanced hepatocellular carcinoma (HCC). We performed a systemic review and network meta-analysis (NMA) to compare the efficacies of these treatments in relation to the current standards of care. **Methods:** A systematic literature search was conducted from inception to December 2022 on PubMed, EMBASE, Web of Science, and the Cochrane Controlled Register of Trials to identify phase III randomized controlled trials assessing the efficacy of systemic agents used as first-line therapies among patients with unresectable HCC. Studies investigating locoregional treatment or conventional cytotoxic chemotherapy were excluded. To focus on recently introduced systemic therapies, treatment regimens presented prior to 2018 (i.e., the year of lenvatinib introduction) were also excluded, except for sorafenib. Hazard ratios (HRs) with 95% confidence intervals (CIs) for overall survival (OS) and progression-free survival (PFS) were pooled and *P* score was calculated to rank treatment regimens. **Results:** A total of 5,038 studies were identified after duplicates removal and 12 trials (13 regimens) were included for NMA. Low level of heterogeneity ($I^2 = 0\%$) and inconsistency (Cochran's $Q = 0.01$, $P = 0.93$) was confirmed. Compared to sorafenib, sintilimab plus a bevacizumab biosimilar (Sint-IBI305) showed the greatest OS benefit (HR = 0.57, 95% CI = 0.43–0.75, *P* score = 0.944), followed by camrelizumab plus rivoceranib (Cam-Rivo; HR = 0.62, 95% CI = 0.49–0.79, *P* score = 0.892) and atezolizumab plus bevacizumab (Atezo-Bev; HR = 0.66, 95% CI = 0.52–0.84, *P* score = 0.834; Figure). The superiority of Sint-IBI305 was maintained in the subgroup of HCC with macrovascular invasion and/or extrahepatic spread and hepatitis B virus-related HCC. Regarding PFS, Cam-Rivo ranked first (HR = 0.52, 95% CI = 0.41–0.65, *P* score = 0.927), followed by Sint-IBI305 (HR = 0.56, 95% CI = 0.45–0.69, *P* score = 0.863) and lenvatinib plus pembrolizumab (Lenva-Pembro; HR = 0.57, 95% CI = 0.46–0.72, *P* score = 0.848). **Conclusion:** Novel systemic therapies including Sint-IBI305 and Cam-Rivo demonstrated promising results compared to the current standard regimens (sorafenib, lenvatinib, and Atezo-Bev); however, further validation is warranted.

4031-A | COMPARISON OF GAAD VERSUS GALAD SCORES FOR THE SURVEILLANCE OF HEPATOCELLULAR CARCINOMA – A PROSPECTIVE STUDY

Chee-Kiat Tan, Wei Lun Liou, Si-Yu Tan, Kaina Chen, Thinesh Krishnamoorthy, Jason Pik Eu Chang and Chin-Pin Yeo, Singapore General Hospital

Background: Hepatocellular carcinoma (HCC) is the 6th most common cancer and the 3rd leading cause of cancer death globally. HCC surveillance has been shown to improve outcomes. Alpha-fetoprotein (AFP)

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

is traditionally used in HCC surveillance but has suboptimal sensitivity. Hence, newer biomarkers, lectin-reactive AFP (AFP-L3) and des-γ-carboxy prothrombin (DCP), have been combined with AFP as a HCC risk algorithm, GALAD (gender/age/AFP-L3/AFP/DCP). Recently, GAAD (gender/age/AFP/DCP) which has the advantage of not having to do an additional AFP-L3 assay, has also been proposed as HCC risk algorithm. Our study aims to compare the performance of the GAAD and GALAD scores in a prospective cohort of at-risk individual's undergoing HCC surveillance. **Methods:** Patients undergoing HCC surveillance with 6-monthly ultrasonography (US) and AFP assay in Singapore General Hospital Department of Gastroenterology and Hepatology were enrolled between Dec 2017 and Oct 2018. Study sera were collected on the day of US for up to 3 consecutive visits. All the patients continued to receive HCC surveillance with 6-monthly US and AFP assay. The study sera were assayed by the Roche Elecsys® DCP and AFP kits, as well as the μTASWako® DCP, AFP and AFP-L3 kits, to calculate the GAAD and GALAD scores respectively using the algorithms provided by the manufacturers. The manufacturer's cut-off value for the GAAD score was 2.57 and -1.95 for the GALAD score (Japanese cut-off value). The study was IRB approved. **Results:** There were 180 patients. The median age was 59 years with 107 (59.4%) males. Hepatitis B was the most common chronic liver disease (83.9%). The median follow-up period was 49.6 months. By Feb 2023, 20 patients had developed HCC and they were all early stage disease. Median time between study sera and HCC was 20.5 months. The positive and negative predictive values for HCC detection by the GAAD (55.6%, 91.2%) and GALAD (45.5%, 93.7%) scores were similar. The GALAD score was able to predict 75% of HCCs developing within the next 1 year compared to 25% by the GAAD score. AUROC was 0.815 (95%CI: 0.713-0.916) for the GALAD score with an optimal cut-off value of -2.04 and 0.786 (95%CI: 0.679-0.893) for the GAAD score with an optimal cut-off value of 0.93. Thus, the performance of the GALAD score in our cohort was similar to the manufacturer's recommended cut-off value of -1.95, unlike that of the GAAD score (manufacturer's recommended cut-off value is 2.57). **Conclusion:** In our prospective study, the GALAD score performed better for HCC surveillance in our population compared to the GAAD score as it is better able to portend the development of HCC within a year using the manufacturer's recommended cut-off value.

4032-A | COMPARISON OF PROGNOSTIC IMPACT OF ATEZOLIZUMAB PLUS BEVACIZUMAB VERSUS LENVATINIB AS FIRST-LINE SYSTEMIC THERAPY IN PATIENTS WITH INTERMEDIATE-STAGE HCC

Toshifumi Tada[1], Takashi Kumada[2], Atsushi Hiraoka[3], Masashi Hirooka[2], Kazuya Kariyama[4], Ei Itobayashi[2], Tsuji Kunihiko[2], Toru Ishikawa[2], Hidenori Toyoda[2], Takeshi Hatanaka[2], Satoru Kakizaki[5], Fujimasa Tada[3], Hideko Ohama[6], Kazuhiro Nouso[7], Tomomitsu Matono[8], Yutaka Yata[9], Yoichi Hiasa[10] and Masatoshi Kudo[11], (1)Japanese Red Cross Society Himeji Hospital, (2)Relpec Study Group and HCC 48 Group, (3)Ehime Prefectural Central Hospital, (4)Okayama City Hospital, (5)National Hospital Organization Takasaki General Medical Center, Takasaki, Gunma, Japan, (6) Takarazuka City Hospital, (7)Okayama City Hosipital, (8)St. Mary's Hospital, (9)Hanwa Memorial Hospital, (10)Ehime, Toon-shi, Ehime, Japan, (11)Kindai University Faculty of Medicine, Osaka-Sayama, Japan

Background: The study goal was to compare the outcomes of patients with intermediate-stage (Barcelona Clinic Liver Cancer [BCLC]-B) hepatocellular carcinoma (HCC) who received atezolizumab plus bevacizumab (Atezo/Bev) or lenvatinib (LEN) as first-line systemic therapy. **Methods:** A total of 358 patients with BCLC-B HCC treated with Atezo/Bev (n = 177) or LEN (n = 181) as first-line systemic therapy were included. **Results:** The median progression-free survival (PFS) times in the Atezo/Bev and LEN groups were 10.8 months (95% confidence interval [CI], 7.8–12.6) and 7.3 months (95% CI, 6.3–8.5), respectively (p = 0.019). In the propensity score–matched cohort, the median PFS times in the Atezo/Bev (n = 151) and LEN (n = 151) groups were 10.2 months (95% CI, 7.0–12.3) and 6.9 months (95% CI, 5.9–8.1), respectively (p = 0.020). Restricted mean survival times of PFS were significantly higher in the Atezo/Bev group than in the LEN group at landmarks of 12 and 18 months (p = 0.031 and 0.012, respectively). In a subgroup analysis of patients with HCC beyond the up-to-seven criteria, the median PFS times in the Atezo/Bev (n = 134) and LEN (n = 117) groups were 10.5 months (95% CI, 7.0–11.8) and 6.3 months (95% CI, 5.5–7.3), respectively (p = 0.044). In addition, among patients with non-viral hepatitis (non-B, non-C), the median PFS

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

times in the Atezo/Bev (n = 100) and LEN (n = 85) groups were 10.6 months (95% CI, 7.0–19.1) and 6.9 months (95% CI, 5.4–8.5), respectively (p = 0.022). **Conclusion:** The use of Atezo/Bev as first-line systemic therapy in patients with BCLC-B HCC is expected to result in good outcomes.

4033-A | COMPARISON OF TREATMENT OUTCOMES BETWEEN LENVATINIB AND ATEZOLIZUMAB PLUS BEVACIZUMAB FOR HEPATOCELLULAR CARCINOMA IN PATIENTS AGED 80 YEARS OR OLDER: A MULTICENTER STUDY

Satoru Kakizaki[1,2], Takeshi Hatanaka[2,3], Atsushi Hiraoka[2,4], Toshifumi Tada[2,5], Masashi Hirooka[2,6], Kazuya Kariyama[2], Ei Itobayashi[2,7], Tsuji Kunihiko[2,8], Toru Ishikawa[2,9], Hidenori Toyoda[2,10], Atsushi Naganuma[1,2], Tomomitsu Matono[2,11], Hideko Ohama[2,12], Fujimasa Tada[2,4], Kazuhiro Nouso[2,13], Yoichi Hiasa[2,6] and Takashi Kumada[2,14], (1)National Hospital Organization Takasaki General Medical Center, (2)Relpec Study Group and HCC 48 Group, (3) Gunma Saiseikai Maebashi Hospital, (4)Ehime Prefectural Central Hospital, (5)Japanese Red Cross Himeji Hospital, (6)Ehime University Graduate School of Medicine, (7)Asahi General Hospital, (8)Teine Keijinkai Hospital, (9)Saiseikai Niigata Hospital, (10) Ogaki Municipal Hospital, (11)St. Mary's Hospital, (12) Takarazuka City Hospital, (13)Okayama City Hospital, (14)Gifu Kyoritsu University

Background: The optimal treatment strategy for older patients with hepatocellular carcinoma (HCC) is still controversial. In this study, we compared the treatment outcomes of lenvatinib (LEN) and atezolizumab plus bevacizumab (Atez/Bev) for HCC in patients aged 80 years and older. **Methods:** Between March 2018 and July 2022, there were 861 LEN-treated patients and 518 Atez/Bev-treated patients in our hospitals. Of these, 170 cases in the LEN group and 92 cases in the Atez/Bev group were aged 80 years or older and receiving first-line treatment. **Results:** The median ages of the LEN and Atez/Bev groups were 83 (81-86) years and 83 (82-86) years, respectively (p = 0.3); 119 cases (70.0%) and 64 cases (69.4%) were male, respectively (p = 1.0). There were no significant differences in background liver disease (p = 0.9), BCLC stage (p = 0.3), or Child-Pugh class (p = 0.8). The ALBI scores were -2.46 (-2.70 to -2.11) and -2.42 (-2.66 to -2.12) for the LEN and Atez/Bev groups, respectively (p = 0.5). The mALBI grades (1/2a/2b/3) were 65 (38.2%)/ 49 (28.8%)/ 51 (30.0%)/ 5 (2.9%) and 32 (34.8%)/ 25 (27.2%)/ 35 (38.0%)/ 0 (0.0%), respectively (p = 0.3). There were no significant differences in AFP levels (p = 0.4) or DCP levels (p = 0.3). Therefore, there were no significant differences in patient background. The best treatment effect evaluated by mRECIST (CR/PR/SD/PD/NE) was 4 (2.4%)/ 57 (33.5%)/ 46 (27.1%)/ 31 (18.2%)/ 32 (18.8%) in the LEN group versus 7 (7.6%)/ 24 (26.1%)/ 27 (29.3%)/ 14 (15.2%)/ 20 (21.7%) in the Atez/Bev group (p = 0.2); response rates were 35.9% and 33.7%, respectively (p = 0.8), and disease control rates were 62.9% and 63.0%, respectively (p = 1.0), with no significant differences. The median progression-free survival (PFS) was 6.3 (95% CI 4.3-7.3) months in the LEN group versus 7.2 (95% CI 4.8-10.6) months in the Atez/Bev group, which was not significantly different (p = 0.2). In multivariate analysis, only mALBI grade 2b or 3 (HR 1.43, 95% CI 1.05-1.95, p = 0.02) contributed to PFS. Treatment (LEN or Atez/Bev) was not a significant factor. Adverse events were similar in both groups, including anorexia, fatigue and malaise, increased blood pressure, and proteinuria. **Conclusion:** The outcomes and adverse events were generally similar between LEN and Atez/Bev in the elderly. It was suggested that LEN may be one of the treatment options for patients with autoimmune diseases and those at high risk of esophageal varices rupture.
