1889-A | REAL WORLD EXPERIENCE IN TREATMENT OF CHRONIC HEPATITIS C IN PATIENTS WITH CIRRHOSIS AT A SAFETY-NET HOSPITAL

Francois Rollin, Jennifer E. Lom, Maeve McNamara, Lana Aleuy, Siri Chirumamilla, Alexander Molinari, Lesley S. Miller and Shelly-Ann Fluker, Emory University School of Medicine

Background: Outside of clinical trials, there is limited data on the safety and efficacy of direct acting antivirals (DAAs) in patients with chronic hepatitis C (HCV) with cirrhosis. The CREST study recently described real world experience with glecaprevir/pibrentasvir in Canada, Israel, and Europe in treatment naïve patients with compensated cirrhosis. We sought to add to this knowledge by evaluating a large cohort of medically underserved patients in the US (United States) with compensated and decompensated cirrhosis treated with a variety of DAA regimens. **Methods:** We performed a retrospective chart review of patients with HCV cirrhosis treated with DAAs at the Grady Liver Clinic (GLC). The GLC is a primary care-based HCV treatment clinic at a safety net hospital in Atlanta, GA. We reviewed electronic health record charts of patients treated at the GLC between 2015 and 2019. Charts were abstracted for patient demographics and characteristics, treatment regimen, and treatment outcomes. We performed an intention to treat (ITT) analysis for all patients who took at least one dose of a DAA regardless of completion, and a per protocol (PP) analysis of those who completed treatment and were tested for sustained virologic response (SVR). **Results:** 451 patients with cirrhosis were treated during the study period. The median age was 62 and they were primarily male (59.0%), black (82.0%), and 90.5% had compensated cirrhosis. The primary HCV genotype was 1 (90.0%). Patients were treated according to AASLD guidelines, and we compared outcomes for compensated vs. decompensated cirrhosis. The most common regimens were ledipasvir/sofosbuvir (65.9% vs. 34.8%), sofosbuvir/velpatasvir (13.4% vs. 11.63%), glecaprevir/pibrentasvir (2.21% vs. 0%), and sofosbuvir/velpatasvir/voxilaprevir (2.7% vs. 0%). The majority of both groups had a high rate of adherence with no missed doses (66.4% vs. 65.1%) or 1 - 7 d missed (23.3% vs. 20.9%). The most common adverse effects between both groups were fatigue (33.3% vs. 39.0%), headache (30.3% vs. 29.3%), and nausea (11.6% vs. 14.6%). In the ITT analysis, 88.5% of compensated and 86.0% of decompensated achieved SVR and in the PP analysis, 94.0% of compensated and 90.2% of decompensated achieved SVR. For the entire cohort, ITT SVR was 88.2% and PP SVR was 93.6%. **Conclusion:** In this retrospective study, patients with compensated and decompensated HCV cirrhosis at a safety-net HCV clinic achieved high SVR rates using a variety of DAAs. Our study is among the first to report such results from a real-world cohort of medically underserved patients in the US.

1890-A | REAL-WORLD EFFECTIVENESS AND SAFETY OF SOFOSBUVIR/VELPATASVIR (SOF/VEL) IN PATIENTS WITH CHRONIC HEPATITIS C VIRUS (HCV) GENOTYPE 3b

Zhiyan Nan, China Medical University and Aihua Jiang, Infectious Hospital of Fushun

Background: To analyze the effectiveness and safety of SOF/VEL in real-world treatment of patients with HCV genotype 3b infection. **Methods:** A retrospective study of 22 patients with HCV genotype 3b admitted to our hospital from January 2020 to January 2023. Patients were treated with SOF/VEL for 12 weeks, and patients with hepatitis C cirrhosis, both hepatic compensated and decompensated, received a 12-week regimen of SOF/VEL ± ribavirin (RBV) to observe SVR12 and adverse events. **Results:** At the end of treatment, the sustained virological response rate (SVR12) was 95.4% in 22 patients, including 5 patients with compensated cirrhosis with 100% SVR12 and 5 patients with decompensated cirrhosis with 100% SVR12;there were no serious adverse events and death. **Conclusion:** SOF/VEL ± RBV regimen for genotype 3b HCV infection can achieve high sustained virological response (SVR) rates, especially in patients with cirrhosis, including compensated and decompensated stages, can still achieve good effectiveness and safety, but further sample size expansion is needed to validate.

1891-A | REAL-WORLD EFFECTIVENESS OF VOXILAPREVIR/VELPATASVIR/SOFOSBUVIR IN DAA FAILURE PATIENTS: AN INTEGRATIVE ANALYSIS

Christiana Graf[1], Roberta D'Ambrosio[2], Elisabetta Degasperi[2], Stefania Paolucci[3], Jordi Llaneras[4], Johannes Vermehren[1], Georg Dultz[1], Kai-Henrik Peiffer[1], Eva Herrmann[5], Stefan Zeuzem[1], Maria Buti[4], Pietro Lampertico[2], Julia Dietz[1] and Christoph Sarrazin[1,6], (1)Department of Internal Medicine 1, University Hospital, Goethe University, Frankfurt, Germany, (2)Division of Gastroenterology and Hepatology, Foundation Irccs Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, (3)Microbiology and Virology Department, Foundation Irccs San Matteo, Pavia, Italy, (4)Hospital Universitari Vall d'Hebron, Department of Medicine of the UAB (Universitat Autònoma de Barcelona), Spain, (5)Institute of Biostatistics and Mathematical Modeling, Goethe University, Frankfurt, Germany, (6)St. Josefs-Hospital, Wiesbaden, Germany

Background: The currently approved re-treatment regimen for prior DAA failure is a combination of voxilaprevir/velpatasvir/sofosbuvir (VOX/VEL/SOF), although data on its clinical use especially in difficult-to-treat patients are limited. The aim of the present study was to analyze the effectiveness of VOX/VEL/SOF in a real-world setting. **Methods:** All patients with HCV, starting antiviral treatment with VOX/VEL/SOF between 2016 and 2021 in 227 centers of the European Resistance study group in Austria, Belgium, Germany, Italy, Spain and Switzerland were enrolled in a retrospective multicenter real-life study. Sustained virological response (SVR) was defined as undetectable HCV RNA 12 (SVR12) weeks after the end-of-treatment. **Results:** A total of 746 patients were included: median age was 55 (21-84) years and 79% were male. Most were infected with HCV genotype (GT) 1 (56%) or 3 (32%). 87% of patients carried resistance associated substitutions (RAS) in the NS3, NS5A and NS5B region. The most common prior DAA combinations were ledipasvir/sofosbuvir (LDV/SOF), velpatasvir/sofosbuvir (VEL/SOF) and glecaprevir/pibrentasvir (G/P). Overall, per protocol (PP) SVR was 96.4% (683/716). Treatment effectiveness was significantly lower in patients with advanced liver disease ($p < 0.001$), hepatocellular carcinoma (HCC; $p < 0.001$), higher baseline alanine aminotransferase (ALT) levels ($p = 0.02$), HCV GT 3 ($p < 0.001$) and prior VEL/SOF experience ($p = 0.01$). However, in a multivariate analysis only HCV GT 3, HCC and liver cirrhosis turned out to be independent predictors of a treatment failure. RASs as well as the presence of rare genotypes did not impact treatment outcome of VOX/VEL/SOF. RBV was added in 8% of treatment courses and increased overall SVR rates (97%) as well as SVR rates in difficult-to-treat patients with HCV GT 3a (100%), liver cirrhosis (92.6%) and liver cancer (90%) insignificantly. Moreover, treatment effectiveness of rescue therapy with G/P+SOF, which was initiated in 9 patients after VOX/VEL/SOF failure, was found to be high (SVR 12: 100%). **Conclusion:** VOX/VEL/SOF represents an effective retreatment for patients with HCV and prior DAA treatment failure. The addition of ribavirin or alternative retreatment with G/P+SOF, which was found to be effective in VOX/VEL/SOF treatment failures, may be considered in difficult-to-treat patients with HCV GT 3a, liver cirrhosis and liver cancer.

1892-A | SAFETY AND IMMUNOGENICITY OF COVID-19 VACCINE IN PATIENTS WITH HCV RELATED LIVER DISEASE

Zhang Jing and Haiqing Guo, Beijing Youan Hospital Capital Medical University, Beijing, China

Background: Due to the high mortality of patients with severe liver disease who infected with SARS-CoV-2, vaccination was strongly recommended to those patients. However, there was little data on safety and antibody level after whole course vaccination by domestic vaccine. The present study evaluated the safety and immunogenicity of domestic COVID-19 vaccine in patients with HCV related liver disease aimed to provide evidence of vaccination strategy

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

adjustment. **Methods:** This observational study recruited 211 patients with HCV related liver disease who never infected with SARS-CoV-2. All patients received 3 doses of domestic COVID-19 vaccines within 7 months. The adverse reactions of vaccination were recorded. Liver function before and after vaccination, serum level of neutralizing antibody after the whole course vaccination were determined. **Results:** Among them, 81 were chronic hepatitis C, 117 were cirrhosis and 13 were hepatocellular carcinoma (HCC). Patients with cirrhosis and HCC were analyzed as one group. No serious adverse events were reported by patients. Hemoglobin, bilirubin, albumin, creatinine and prothrombin time worsened after vaccination but hadn't clinical significance. The negative response rate (40.8%) of cirrhosis and HCC group was comparable to chronic hepatitis C group (32.1%, $p = 0.206$). However, neutralizing antibody titer (median titer 24.2, range 11.2-65.5 IU/ml) was significantly lower in patients with cirrhosis and HCC than chronic hepatitis C (median titer 38.9, range 16.0-198.9 IU/ml, $p = 0.031$). **Conclusion:** The domestic COVID-19 vaccine appears to be safe and has a certain protective effect in patients with HCV related liver disease.

1893-A | SAFETY AND TOLERABILITY OF AN ORAL CONTRACEPTIVE CONTAINING LOW-DOSE ETHINYL ESTRADIOL COMBINED WITH GLECAPREVIR/PIBRENTASVIR TREATMENT IN HEALTHY PREMENOPAUSAL WOMEN: RESULTS OF A PHASE 1 STUDY

Dee-Dee Shiller[1], Betty B. Yao[1], Mong-Jen Chen[1], Amelia Orejudos[1], Nael M. Mostafa[1], John F. Marcinak[1], Margaret Burroughs[1] and Craig Boyle[2], (1)Abbvie, Inc., (2)PPD Phase 1 Clinic

Background: Glecaprevir/pibrentasvir (GLE/PIB) is an approved and guideline-recommended treatment for chronic hepatitis C virus infection. Current product labels do not recommend co-administration of GLE/PIB with ethinyl estradiol (EE)-containing medications such as oral contraceptives (OC) due to alanine aminotransferase (ALT) elevations observed in an earlier study. Specifically, Grade 2-3 ALT elevations were reported in 2/12 women co-treated with 35 µg/250 µg EE/norgestimate for 11 days; however, no Grade **e** 2 ALT elevation was reported in 14 women co-treated with low-dose EE (20 µg) and 100 µg levonorgestrel (LNG) for 11 days. Therefore, this Phase 1, single-arm, open-label study was designed to assess the safety of GLE/PIB co-administered with an OC containing low-dose EE and LNG, with a larger sample size and longer treatment duration than the earlier study. **Methods:** Healthy premenopausal women aged 18-49 years received 20 µg/100 µg EE/LNG alone during cycles 1-2, followed by co-administration with 300 mg/120 mg GLE/PIB during cycles 3-4. The main safety event of special interest was confirmed Grade **e** 2 ALT elevation. Adverse events (AEs) and steady-state trough concentrations of EE/LNG and GLE/PIB were also assessed. **Results:** Of 85 enrolled women, 72 received combined GLE/PIB+EE/LNG treatment and 66 completed the study; 16 discontinued the study due to non-safety reasons and 3 due to AEs deemed unrelated to GLE/PIB. No serious or Grade **e** 3 AEs were reported. No AEs of Grade **e** 2 ALT or aspartate aminotransferase (AST) elevation were reported. No ALT levels observed met the safety criterion of special interest of confirmed Grade **e** 2 elevation. Two women had Grade 2 bilirubin increase (EE/LNG, $n = 1$; EE/LNG +GLE/PIB, $n = 1$), which was considered representative of isolated hyperbilirubinemia, as neither woman had ALT/AST elevation reported during the study. EE/LNG and GLE/PIB concentrations (**e** 20-hour interval, binned data) were within the expected ranges. **Conclusion:** No Grade **e** 2 ALT elevation or evidence of drug-induced liver injury was observed during combined treatment with low-dose EE-containing OC and GLE/PIB in this robust Phase 1 study with a 2-cycle treatment duration and sample size of 72 women receiving the combined treatment. The combined treatment was generally well tolerated in this study, with no pattern to reported AEs and no new safety issues identified. *Note: Glecaprevir was identified by AbbVie and Enanta.*

1894-A | SOFOSBUVIR/VELPATASVIR WITH OR WITHOUT RIBAVIRIN FOR CHRONIC HEPATITIS C VIRUS INFECTED PATIENTS WITH LIVER CIRRHOSIS AND CHRONIC KIDNEY DISEASE: REAL-WORLD EXPERIENCE FROM SOUTHWEST CHINA

Yang Yong Rui, Kang Huang, Zhirong Zhao, Jinsong Bai, Lei Wu, Junyi Li, Shenghao Li, Liu Li, Haiwen Li and Yingrong Du, The Third People's Hospital of Kunming City

Background: Evidence of direct-acting antiviral (DAA) treatment for refractory chronic hepatitis C (CHC) patients with liver cirrhosis and chronic kidney disease (CKD) was limited . We aimed to evaluate the safety and effectiveness of Sofosbuvir/Velpatasvir (SOF/VEL) with or without Ribavirin (RBV) treatment in this special population in Southwest China. **Methods:** From June 2018 to March 2023, CHC patients with liver cirrhosis (diagnosed by imaging examination and clinical manifestation) and CKD (eGFR < 90 ml/min/1.73m2) at The Third People's Hospital of Kunming City were retrospectively enrolled. All patients received SOF/VEL ± RBV (dosage of RBV depending on weight and renal function) for 12 weeks. The primary endpoints were change of renal function during treatment. Sustained virologic response at 12 weeks off-therapy (SVR12,defined as HCV RNA < 20 IU/mL), change of liver function and adverse events (AEs) were also assessed. **Results:** A total of 65 CHC patients with liver cirrhosis and CKD were included. The mean age was 52.31 ± 8.02 years and 76.92% (50/65) were male. HCV genotype distribution: 6.15%(4/65) patients were GT2a, 28 %(18/65) were GT3a, 55%(36/65) were GT3b,.4.6%(3/65) were GT6n and 6.15%(4/65) were unknown genotype. Baseline CKD stage: 49 (75.4%) in CKD stage 2, 12 (18.5%) in stage 3, 2 (3%) in stage 4 and 2 (3.1%) in stage 5. Cirrhosis status: 41.54% (27/65) were compensated cirrhosis(CC) and 58.46% (38/65) were decompensated cirrhosis (DCC). Regarding the safety profile, mean eGFR increased significantly from 68.45 ± 20.56 ml/min/1.73m^2 at baseline to 84.24 ± 56.97ml/min/1.73m^2 at the end of treatment ($P = 0.073$). There were no patients in CKD stage 1 at baseline but 21.5% (14/65) of patients improved to stage 1 after 12 weeks off-treatment. For liver function, mean ALT (from55.57 ± 38.18 U/L to 25.23 ± 20.97 U/L, $P < 0.05$) and AST (from 59.38 ± 33.24 U/L to 35.54 ± 18.99 U/L, $P < 0.05$) also decreased significantly after treatment. 38.5% (25/65) patients reported AEs during treatment (including 20 hemolysis,1 pruritus, 1 rash, 2 dizziness and 2 fatigue) and recovered after supportive treatment. No serious AEs were reported. For the efficacy profile, 96.9% (63/65) patients achieved SVR12 after SOF/VEL ± RBV for 12 weeks, including 100%(18/18) in GT3a , 94.44% (34/36) in GT3b, 100% (11/11) in other GTs patients with CKD. 100% (27/27) patients with CC and 94.74%(36/38) patients with DCC achieved SVR12. 2 patients with GT3b and DCC with CKD stage 2 failed treatment. **Conclusion:** SOF/VEL ± RBV treatment was effective and well tolerated in CHC patients with liver cirrhosis and CKD. Both renal and liver function were improved after DAA treatment.

1895-A | STANDARD VERSUS MINIMAL MONITORING FOR HEPATITIS C DIRECT ACTING ANTIVIRAL (DAA) THERAPY AT AN ACADEMIC MEDICAL CENTER

Anita Yang, University of North Carolina Health, Jane Giang, University of North Carolina at Chapel Hill and Neel Swamy, University of North Carolina Eshelman School of Pharmacy

Background: Several publications have shown safety and efficacy data with minimal Hepatitis C Virus (HCV) monitoring during treatment with direct acting antivirals (DAA). However, many practices have not implemented this change. The coronavirus disease 2019 (COVID-19) pandemic has shifted care from an in-person to virtual platform in a short period of time. Despite these events, there continues to be limited real-world data regarding the impact of minimal HCV monitoring approaches. Thus, the purpose of this study was to assess if minimal monitoring approaches in HCV direct acting antiviral (DAA) therapy can overcome clinic and patient burden while maintaining undetectable HCV RNA 12 weeks after the end of treatment (SVR12). **Methods:** A 12-month, single-center retrospective chart review was conducted in treatment-naïve HCV-infected adults who received DAA therapy from May 1st, 2020, to April 30th, 2021. Patients in Cohort 1 had standard monitoring with > 1 in-person clinic visit during DAA treatment. Patients in Cohort 2, minimal monitoring, had entirely virtual visits during treatment. Both groups received telephonic touch points throughout DAA treatment from a Clinical Pharmacist Practitioner (CPP) and Nurse

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Care Coordinator (NCC). The primary outcome was SVR12 rate. Student t-tests were conducted for continuous variables and chi-square tests for categorical variables. **Results:** From 5/1/2020 to 4/30/2021, 133 HCV patients met inclusion criteria and were treated with DAA (Cohort 1: n = 56; Cohort 2: n = 77). There were no differences in baseline demographics and most patients received Epclusa or Mavyret for 8-12 weeks. Total encounters remained significantly higher in Cohort 1 compared to Cohort 2 (Cohort 1: 3.1 ± 1.0 vs Cohort 2: 2.8 ± 1.2; p = 0.047), whereas Cohort 2 had more telephonic CPP and NCC touch points (Cohort 1: 2.1 ± 1.2 vs Cohort 2: 2.5 ± 1.9; p = 0.045). Although Cohort 2 had non-significantly higher loss to follow-up rates (Cohort 1: 7.1% vs Cohort 2: 18.2%; p = 0.06), ultimately, there were no differences in SVR rate between cohorts (Cohort 1: 91.1% vs Cohort 2: 77.9%; p = 0.13). **Conclusion:** This single-center study demonstrates that minimal monitoring during HCV treatment through post-treatment week 12 is as effective in achieving SVR cure rates compared to standard monitoring. Eliminating required in-person clinic visits during DAA therapy alongside a collaborative approach may play a major role in overcoming barriers to HCV care in select patients.

1896-A | THE EFFICACY AND SAFETY OF 12-WEEK SOF/VEL REGIMEN COMBINED WITH PROPHYLACTIC USE OF TAF FOR TREATMENT-NAIVE genotype1-6 HCV/HBV CO-INFECTION ADULT PATIENTS WITH OR WITHOUT COMPENSATED CIRRHOSIS IN CHINA: A MULTI-CENTER PROSPECTIVE, SINGLE-ARM, OPEN-LABEL TRIAL

Hongyu Chen[1], Xiaoyuan Xu[1], Qian Kang[2], Yifan Han[1], Jiali Pan[1], Zhan Zeng[1] and Yanyan Yu[1], (1)Peking University First Hospital, (2)Beijing Friendship Hospital, Capital Medical University, Beijing, China

Background: When humans are co-infected with the Hepatitis B virus (HBV) and Hepatitis C virus (HCV), HCV can inhibit the replication of HBV in HCV/HBV co-infected patients. Therefore, it may put patients at increased risk of HBV reactivation after they receive anti-HCV therapy. This study will evaluate the safety and efficacy of SOF/VEL in Chinese patients with HBV/HCV co-infection and assess the preventive effect of TAF on HBV reactivation during direct-acting antiviral (DAA) treatment. **Methods:** We performed a multicenter, prospective, single-arm, open clinical trial to evaluate the safety and efficacy of SOF/VEL 12-week regimen and prophylactic use of TAF in patients with GT1-6 HCV/HBV co-infection in China. All patients included in the study were divided into a non-cirrhotic group (group 1) and a compensated cirrhotic group (group 2). Patients were given 7 months of TAF (from day 0 to week 28) and 3 months of SOF/VEL (from week 4 to week 16) antiviral therapy. The primary endpoint of the study was the proportion of subjects achieving sustained virological response to HCV 12 weeks (SVR12) after discontinuation of SOF/VEL therapy. **Results:** 60 patients (47 patients in group 1, 13 patients in group 2) with hepatitis B and C co-infection were included in the study, with 17 (28.3%), 11 (18.3%), 7 (11.7%), 10 (16.4), and 15 (25%) patients with HCV genotypes 1, 2, 3a, 3b, and 6, respectively (Figure A). 59 patients achieved SVR12, and 1 patient (group 1, HCV genotype 1b) converted to HCV RNA positive after 12 weeks end of SOF/VEL treatment, with an overall SVR12 of 98.3% (Figure B and C). 28 patients were HBV DNA positive at baseline and 2 patients were HBV DNA positive at week 28. HBV DNA decreased after antiviral therapy in all patients and no HBV reactivation occurred (Figure D). No deaths and 6 adverse events (5 in group 1, 1 in group 2) occurred. There was no significant difference in the degree of decrease in liver stiffness between group 1 and group 2 patients after 16 weeks of antiviral therapy [6.9 (5.6-9.8) vs 6.8 (5.7-8.9), p = 0.690], [20.5 (16.4-37.1) vs 17.2 (10.9-24.9), p = 0.246]. **Conclusion:** In the present study, the HCV genotype distribution rates differed significantly from those previously reported for HCV genotypes. Patients demonstrated high SVR rates after 12 weeks of SOF/VEL combined with TAF anti-HCV therapy, and all patients did not experience HBV DNA reactivation during the treatment period. Although there was an overall decrease in liver stiffness measurement values in both groups, the difference was not statistically significant. Most patients did not experience significant adverse events during treatment. (ClinicalTrials.gov no: NCT04997564).

1897-A | TOTAL HCV PATIENTS TREATED WITH DIRECT ACTING ANTIVIRALS SINCE 2014

Alexis Voeller, Devin Razavi-Shearer, Sarah Blach, Ivane Gamkrelidze, Kathryn Razavi-Shearer and Homie Razavi, Center for Disease Analysis Foundation

Background: With the second generation direct-acting antiviral (DAAs) treatments taking over as the gold standard for hepatitis C virus (HCV) treatment circa 2014, there has been an exponential increase in HCV treatment patterns globally. The aim of this analysis is to quantify the increase in cumulative HCV treatment in 2014-2021. **Methods:** Experts in over 100 countries provided HCV treatment data from 2014-2021 via the Polaris Observatory annual surveys. These surveys included regimen data starting in 2019. Prior to that, the average sustained viral response (SVR) rate was used to determine the percentage of all patients treated with DAAs in each country. National registration dates of sofosbuvir (SOF), ombitasvir + paritaprevir + ritonavir, glecaprevir + pibrentasvir, and elbasvir + grazoprevir based treatments were used to allocate treated patients to specific regimens. Outside of Egypt and Georgia, most treated patients were in high-income countries in years 2014-2018 where drug sales data were available and analyzed to determine annual treated patients by regimen. **Results:** Between 2014-2021, 12.4 million HCV patients have been treated cumulatively, globally with DAAs, of which, 10.1 million were treated with SOF based regimens accounting for an estimated 81% of the total. The increase in treatment was accompanied by an increase in the use of other DAAs over the past 4 years. Most HCV treatments were in lower-middle income countries (7.3 million) with high income countries following (3.4 million). The peak in percentage of SOF based regimens in 2019 was due to the substantial uptake in HCV treatment in the Egyptian elimination program. **Conclusion:** The access to DAAs in low- and middle-income countries (LMIC) has had a profound impact on the total number of HCV patients treated globally with generic sofosbuvir + daclatasvir being the preferred treatment. With 89% of all HCV infections in LMIC, immediate access to generic versions of the latest drugs is needed to achieve the global elimination targets. The high-income countries have been very proactive in treating their HCV infected populations and removing all restrictions. For the global elimination of HCV, there needs to be a continued exponential increase in cumulative treated patients in LMIC along with continued expansion of generic access to medications.

1898-A | TOWARDS ULTRA-SHORT THERAPY TO ERADICATE HCV INFECTION?

Alberto Grassi[1], Natascia Celli[2], Silvana Maccariello[2], Gabriele Donati[3], Angela Fabbri[2] and Giorgio Ballardini[2], (1)Internal Medicine Unit, Cervesi Hospital, Cattolica (RN), Italy, (2)Internal Medicine, Infermi Hospital, Rimini, Italy, (3)Internal Medicine, San Marino Hospital, RSM

Background: Direct Antiviral Agents (DAA) permit HCV eradication with short-time therapy (8-12 weeks) in the vast maiority of cases. **Methods:** From 2018 to 2022, 271 HCV-RNA positive patients completed antiviral treatment with glecaprevir/pibrentasvir (G/P) and 12 weeks post treatment follow up. **Results:** Sustained virological response (SVR) was globally obtained in 267 patients (98.5%). Nine patients (3.3%) prematurely suspended treatment, mainly for side effects: six of them anyway resulted SVR, two were HCV RNA negative at the end of treatment but relapsed 12 weeks later and one resulted non responder. Clinical data of patients are reported in the table. **Conclusion:** There is general agreement about the fact that at least 8 weeks of therapy are necessary to achieve definitive HCV eradication. In this series of patients, HCV eradication was obtained with (even extremely) reduced duration of treatment (4-28 d only) with G/P. Nowadays, probably, the real impact of DAA in HCV replication is not yet completely known. More studies about this topic would be important to eventually permit ultra-short scheduled of treatment to eradicate HCV infection: this could have paramount impact in the WHO program to eliminate HCV infection within 2030.

1899-A | TREATING CHRONIC HEPATITIS C VIRUS-INFECTED PATIENTS IN SARS-COV-2 GLOBAL PANDEMIC ERA IN AN URBAN MEDICAL CENTER IN TAIWAN: 'CALL-BACK' STRATEGY NEEDED

Hsin-Ju Tsai, Cheng-Che Chen, Teng-Yu Lee, Shao-Wu Lee, I-Ta Lu, Chung-Hsin Chang and Sheng-Shun Yang, Taichung Veterans General Hospital

Background: Hepatitis C virus (HCV) can be eliminated by all-oral direct-acting antivirals (DAA) nowadays, here we report real-world data on the effectiveness and safety of pangenotypic DAAs namely sofosbuvir/velpatasvir (SOF/VEL) and glecaprevir/pibrentasvir (G/P) in a hospital applying 'call-back' strategy during SARS-CoV-2 global pandemic era. **Methods:** A total of 832 chronic HCV-infected patients with different liver disease severity completed 8 or 12 weeks DAAs treatment are retrospectively enrolled. The effectiveness was determined by a sustained virologic response at off-treatment 12 weeks (SVR12). Baseline patient characteristics, laboratory data, and adverse events were analyzed and compared between two antiviral regimens and 'call-back' vs. 'non-call-back' populations. **Results:** By per-protocol analyses, the overall SVR12 rate was 98.0% with SOF/VEL 98.9% vs. G/P 97.2%, 'call-back' 98.6% vs. 'non-call-back' 97.8% respectively (Table 1 & 2). Twenty patients died and 14 patients discontinued treatment due to non-virologic causes throughout the antiviral therapy course, none with SVR12 data available. The median age was 64.0 (vs. 59.0, $p < 0.001$), > 65 y/o 45.9% (vs. 32.4%, $p < 0.001$), fewer male patients (48.5% vs. 56.2%, $p = 0.044$), more treatment-experienced (9.5% vs 5.2%, $p = 0.021$), less FIB-4 < 1.45 and more FIB-4 > 3.25 (26.2% vs. 36.6%, and 31.9% vs. 24.0%; $p = 0.008$) in 'call-back' compared to 'non-call-back' subjects. Aged, history of HCC, more genotype 1b and less genotype 2, higher FIB-4 scores, poorer laboratory data (AST, ALT, T. bil., INR, and albumin), while less CKD subjects noted in patients receiving SOF/VEL compared to G/P (Table 1). A total of 332 (40.4%) experienced any adverse event, of them fatigue (19.6%) and pruritus (15.4%) were the most common AEs in SOF/VEL and G/P respectively (Table 1). Elevated ALT or T. bil. level during the treatment course was mild and did not lead to treatment discontinuation. **Conclusion:** Real-world data in HCV management were heterogeneous and we found several baseline patient characteristics which might lead to different pangenotypic DAA choices by the physicians. While in our 'call-back' cohort, age, female, prior antiviral treatment failure, and FIB-4 score were significantly more or higher than the 'non-call-back' cohort, and both with the same favorable SVR12 rate and tolerable AEs to the two pangenotypic DAA regimens.

f 1900-A | TREATMENT OF RECENT INJECTION DRUG USERS WITH CHRONIC HCV INFECTION IN U.S. LIVER REFERRAL CLINICS: A PROSPECTIVE, OBSERVATIONAL COHORT STUDY AND CONTEMPORANEOUS THERAPY COHORT WITHOUT INJECTION DRUG USE

Brian Pearlman[1,2,3], Michael Perrys[1], Carole Ehleben[2] and Andrew Hinds[2], (1)Medical College of GA, (2) Wellstar, (3)Emory

Background: It is estimated that nearly 3.7 million people, or 1.5% of the U.S. population injected drugs in 2018, which is five times more prevalent than had been in 2011. With the advent of COVID, those numbers are expected to be even higher. Although there have been studies of people who inject drugs (PWID's) who underwent successful HCV treatment in opiate substitution therapy (OST) clinics/harm reduction centers, correctional settings, mobile health units and primary care clinics, few have studied active injection drug users at liver referral clinics, and the relative success in this setting has been questioned. **Methods:** Chronically HCV-infected participants were recruited and treated at two liver referral clinics in GA, but had been referred from OST clinics, primary care + GI clinics, neighboring hospitals, and correctional centers. Once consented, each participant was assigned to a nurse navigator was responsible for all subjects' appointments, and med supplies. Drug testing was mandated at specified intervals. Patients with recent injection drug use (within 6 mo) were assigned to the PWID arm, and those who hadn't injected within 6 months but agreed to be in the study and signed consents, were assigned to the non-PWID arm. Both groups were treated with velpatasvir (100 mg) and sofosbuvir (400 mg) once daily for 12 weeks (brand or branded generic). Adherence was assessed by pill counts. Mandatory treatment visits were scheduled for baseline, 4 and 12 weeks (+/- 2 weeks) and follow-up (FU) week 12 (+ 4 mo). Long-term FU was flexible and could be virtual, but was mandated once yearly with HCV RNA testing. **Results:** Between March, 2018 and September, 2020, 128 subjects were enrolled, 72 PWIDS and 56 non-PWIDS. Baseline characteristics are shown in the Table. In PWID and non-PWID, respectively, SVR rates (ITT) were 94%(68) and 96%(54) ($p = 0.62$), and SVR rates (as treated) were 97%(70) and 100%(56) ($p = 0.09$); adverse events were 46%(33) and 41%(23), and serious adverse events were 4%(3) and 7%(4), including one drug overdose/death and one suicide in the PWID arm. The FU period was 32 months (mean). Adherence differed between PWID group (73%) and non-PIWD (95%) ($p = 0.007$). Reinfection rate was 2% in the PWID and 0% in the non-PWID groups. Moderate alcohol use declined in the PWID group but increased in the non-PWID group. In the PWID group, relative to baseline at the end of FU, the OST rate increased (42% to 68%), and the rates of other drug use and injection drug use in the preceding month and six month period likewise declined (76% to 58% and 100% to 79%, respectively). **Conclusion:** Active PWIDS were successfully treated in liver referral clinics with comparable rates of SVR as concurrently treated non-PWIDS (non-significant differences) . Using a nurse navigator, retention rates were excellent. In the PWID arm, alcohol and drug use diminished and OST increased during follow-up. Reinfection was rare and consistent with PWID reinfection rates globally.

	PWID (72)	Non-PWID (56)	p value

1901-A | CELL-FREE NUCLEIC ACIDS VARY BY DISEASE SEVERITY AND BODY COMPARTMENTALIZATION IN CHRONIC HEPATITIS C VIRUS INFECTION

Nicole San-Dee Minerva[1], Rownock Afruza[1], Christina Park[2], Moumita Chakraborty[1], Adekanyinsola Onitiri[1], Maleeha F Ahmad[1], Rabab Ali[1], Elliott Levy[3], Ohad Etzion[1], David E Kleiner[4], Christopher Koh[5] and Theo Heller[1], (1)Translational Hepatology Section, National Institutes of Health, (2)Clinical Research Section, National Institutes of Health, (3)Radiology & Imaging Sciences Department, National Institutes of Health, (4) Laboratory of Pathology, National Cancer Institute, National Institutes of Health, (5)National Institute of Diabetes and Digestive and Kidney Diseases, Nih

Background: Circulatory cell-free nucleic acids (ccfNAs), comprised of both ccfDNAs and ccfRNAs, play roles in signaling, immunity, and gene regulation. ccfNAs are an active area of research given their role in disease progression and ease of measurement. The aim of this study is to explore composition and concentration of ccfNAs in both portal vein and peripheral plasma, before and after HCV clearance. **Methods:** HCV patients had a liver biopsy with portal vein cannulation before (HCVi, n = 29) and 1 year after DAA therapy (SVR, n = 23) (NCT02400216). Peripheral blood was collected from HCVi patients, before and 1 year after DAA therapy. Total ccfRNAs and ccfDNAs were extracted from plasma and measured using a TBS-380 Mini-Fluorometer. For significance $p < 0.05$. **Results:** Concentrations of ccfNAs were lower after SVR in portal plasma compared to peripheral plasma (median 83.11 vs. 108.9 ng/ml plasma, n = 22 pairs). During HCVi, portal (median 99.92 vs. 210.1 ng/ml plasma, n = 13 cirrhotic and 15 non-cirrhotic) and peripheral (median 100.5 vs. 210 ng/ml plasma) ccfNA levels were lower in cirrhotic (C) compared to non-cirrhotic (NC) patients. ccfRNA concentration was lower in portal plasma (median 84.87 vs. 108.4 ng/ml plasma, n = 23 pairs) compared to peripheral plasma after HCV clearance. During HCVi, both peripheral (median 203.435 vs. 82.40 ng/ml plasma, n = 15 NC and 13 C) and portal ccfRNA (median 207.6 vs. 81.88 ng/ml plasma, n = 15 NC and 13C) concentrations were higher in non-cirrhotic compared to cirrhotic patients. After SVR, ccfDNA concentrations reduced (median 5.980 vs. 12.86, n = 21 pairs) in portal plasma compared to HCVi patients. There were correlations between portal and peripheral ccfRNAs ($r = 0.9299$, and $r = 0.8854$) and between portal and peripheral ccfDNAs ($r = 0.4800$, and 0.4839) during both HCVi and after SVR. The concentration of ccfRNA was higher than its accompanying ccfDNA in all patients (HCVi and after SVR) and all body compartments (peripheral and portal plasma) (n = 29 HCV and 23 SVR). **Conclusion:** The concentration and pattern of ccfNAs differ between mild and severe forms of liver disease as well as in different compartments of the body, with ccfRNA concentrations being higher than ccfDNA concentrations. After SVR, significant reduction of portal ccfRNAs compared to peripheral suggests that a deeper understanding of cell-free nucleic acids will provide insight into disease pathogenesis.

1902-A | DIRECT-ACTING ANTIVIRALS INDUCE LYMPHOPROLIFERATIVE DISEASE RESPONSE IN HEPATITIS C VIRUS-INFECTED PATIENTS WITH INDOLENT B-CELL NON-HODGKIN'S LYMPHOMA: A PROSPECTIVE OBSERVATIONAL STUDY

Monica George, Khalis Mustafayev, Sairah Ahmed, Sheeba K. Thomas, Ying Jiang, Krina Patel and Harrys A. Torres, The University of Texas MD Anderson Cancer Center

Background: Chronic hepatitis C virus (HCV) infection has been associated with an increased risk of different types of B-cell non-Hodgkin's lymphoma (NHL). Case reports and retrospective case series have suggested that HCV eradication with direct-acting antivirals (DAA) favorably impacts the oncologic outcome of patients with indolent NHL. We aim to prospectively evaluate the oncologic impact of DAA treatment on HCV-infected patients with indolent NHLs not yet requiring initiation of systemic cancer therapy. **Methods:** HCV-infected patients with NHL seen at MD Anderson Cancer Center between 01/01/2014 and 01/31/2021 were enrolled in a prospective observational study. Only chemotherapy naïve patients treated with DAAs were further analyzed. The primary endpoints were lymphoproliferative disease responses classified as complete response, partial response, stable disease, and progressive disease. The secondary endpoints were overall survival (OS) and progression-free survival (PFS) at 2 years after achieving sustained virologic response at week 12 without DAAs (SVR12). Response evaluation was based on the 2014 Lugano criteria. **Results:** Forty HCV-infected patients with indolent NHL were enrolled. Seven of them fulfilled the study criteria and were

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

further analyzed. Most patients had HCV genotype 1 (4/7, 57%), and were less than 65 years of age (4/7, 57%), male (5/7, 71%), white (4/7, 57%), and non-cirrhotic (6/7, 86%). Two patients had failed prior interferon-based treatment (follicular lymphoma [n = 1] and marginal zone lymphoma [n = 1]). All patients were treated with a sofosbuvir-based regimen, with an SVR12 rate of 100%. The total follow-up period from DAA initiation was 32 months (range 32-60 mo). At 2 years after achieving SVR12, most patients (4/7, 57%) experienced either complete or partial response, 2 had NHL progression requiring chemotherapy, and 1 had stable disease (Table 1). Two years after SVR12, rates of OS and PFS were 100% and 71% respectively. **Conclusion:** This is the first prospective study evaluating the impact of treatment with DAAs alone on the oncologic outcomes of HCV-infected patients with indolent NHL. Most patients experienced lymphoproliferative disease response after HCV eradication.

Table 1. Characteristics of HCV-infected patients with Indolent B-Cell Non-Hodgkin's Lymphoma treated with direct-acting antivirals without cancer treatment.

Total number of patients	7

1903-A | IS CHRONIC HEPATITIS C INFECTION ASSOCIATED WITH AN INCREASED RISK OF DISSEMINATED COCCIDIOIDOMYCOSIS? A RETROSPECTIVE ANALYSIS

Humzah Iqbal, Nam Huynh, Geetha Sivasubramanian and Marina M. Roytman, UCSF Fresno

Background: Coccidioidomycosis, a fungal infection caused by *Coccidioides spp.* is endemic to the southwestern United States. Most cases are limited to the respiratory system, however a small subset of patients may develop disseminated coccidioidomycosis (DCM). Liver cirrhosis is associated with an increased risk for infections, with some studies suggesting it may be a risk factor for developing DCM as well as worse outcomes. There is a paucity of literature regarding DCM in patients with chronic liver disease. Our study explored risk factors and attributes of patients with chronic liver disease who developed DCM. **Methods:** We conducted a retrospective study including patients over the age of 18 from January 2010 to December 2020 with chronic liver disease who developed DCM. DCM was defined as positive serum *Coccidioides* immunoglobulin G (IgG) titers, culture, or polymerase chain reaction (PCR) along with compatible clinical syndrome with evidence of extrapulmonary coccidioidal infection. Data were collected at the time of DCM diagnosis and included age, gender, ethnicity, type of liver disease, co-morbidities, hepatitis B (HBV) and hepatitis C (HCV) viral loads, presence of cirrhosis and site of coccidioidal dissemination. **Results:** We identified 32 patients with chronic liver disease who developed DCM. Median age at diagnosis was 49 years and 87.5% were men. Hispanic patients accounted for 65.6%, while 12.5% were Black, 12.5% Caucasian, and 6.3% were Asian. Causes of liver disease included: HCV in 37.5%, alcohol-related liver disease (ALD) in

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

28.1 % and metabolic associated liver disease (MAFLD) in 18.8% of patients. Of the patients with chronic HCV, 83% had a positive viral load, and 25% had progressed to cirrhosis. Diabetes was noted in 16.7% of patients with chronic HCV, compared to 47% in all patients. Sites of coccidioidal dissemination included central nervous system (CNS) (34.4%), bone (31.3%), visceral organ (28.1%), skin/soft tissue (18.8%), hematogenous (6.3%), and multiple sites (15.6%). **Conclusion:** Although ALD and MAFLD are known to be the most common driving factors of liver disease in our population, our study found that DCM is more commonly seen in patients with chronic HCV. Majority of patients had a positive viral load bringing up a possibility of immune dysfunction in patients with active HCV potentially playing a role in developing DCM. Further studies are needed to determine if chronic HCV predisposes patients to coccidioidal dissemination to the CNS.

1904-A | LOCAL ELIMINATION PROGRAMS LEADING TO GLOBAL ACTION IN HCV(LEGA-C): OUTCOME OF STUDIES AND THE IMPACT FOCUSING ON ACTIVITIES WITHIN UNITES STATES

Kyung Min Kwon and Efe Johnson, Gilead Sciences, Inc.

Background: Since 2016 Gilead Sciences, Inc., has committed to support studies and grants for programs focused on hepatitis C virus (HCV) elimination under LEGA-C (Local Elimination programs leading to Global Action in HCV) initiative. Focusing on Investigator Sponsored Studies (ISR) and collaborative studies under LEGA-C initiative, > 120 studies in > 30 countries were funded from Gilead until now. Here we aim to report the relative impact of these studies that took place in the United States. **Methods:** We aim to measure the impact of these studies from 3 aspects; scientific communications, number of individual/patients reached and the changes made in guidelines. We describe the types of studies supported, the populations and the treatment patterns emerging from the studies. To assess the potential impact in science, we catalogued the number and impact factors (IF) of studies' publications and the numbers of citations of study papers. For the measurable impact made to patients' lives, we collected the number of individual's reached within each presentation/publication. To gauge potential impacts, we reviewed recent AASLD and EASL guidelines to identify mentions of LEGA-C supported studies in the US. **Results:** Globally, total of 120 studies were conducted in 6 continents. 67 studies were conducted in the United States as of July 2022.

The types of approaches varied in ways to overcome the barriers of screening and linkage to care ; Test and treat (n = 10), Simplified screening/Minimal monitoring (n = 4), epidemiology (n = 3), outreach/callback (n = 3), modeling/cost effectiveness (n = 4), and patient/HCP education (n = 2).

Of the 67 studies, 30 (45%) focused on special populations such as persons who inject drugs (n = 14), men who have sex with men (n = 3), persons with concomitant HIV infection (n = 6), and homeless population (n = 4).

Roughly 200,000 individual's were reached with the studies and among those who were identified as HCV infected, 1941 patients were treated with DAAs.

Publications include 32 journal articles with mean IF of 9.2 (1.4 - 45.0). 26 papers were cited a total of 335 times.

Changes in clinical practices were made with 2 studies on EASL and AASLD recommendations regarding universal HCV screening in pregnancy women and implementation of minimal monitoring to reduce the time to treat.

AASLD 2019 HCV screening guidance and the EASL 2020 acute HCV treatment guideline cited the LEGA-C–supported paper on cost-effectiveness of universal screening of pregnant women for HCV infection, recommending that such screening be adopted. **Conclusion:** Since 2016, LEGA-C initiative has supported 67 studies in the US that led to advance in science,

1905-A | MODELING HCV KINETICS FROM INOCULATION TO STEADY STATE IN SCID HUMANIZED MICE PREDICTS A PARTIAL BLOCK OF VIRAL PRODUCTION POSSIBLY DUE TO AN EARLY STAGE OF INNATE IMMUNE RESPONSE

Ari Josephson[1], Yuji Ishida[2,3], Zhenzhen Shi[1], Adquate Mhlanga[1], Chise Tateno[2,4], Jordan J. Feld[5], Harel Dahari[1] and Kazuaki Chayama[2,6,7], (1)The Program for Experimental and Theoretical Modeling, Division of Hepatology, Department of Medicine, Stritch School of Medicine, Loyola University Chicago, Maywood, Illinois, USA, (2)Hiroshima Institute of Life Sciences, (3)R&D, Phoenixbio Co., Ltd., (4)Phoenixbio Co., Ltd., (5)Viral Hepatitis Care Network (VIRCAN), Toronto, Canada, (6) Collaborative Research Laboratory of Medical Innovation, Hiroshima University, (7)Riken Center for Integrative Medical Sciences

Background: Understanding of HCV early evolution and the interplay between HCV and the mammalian host will help to identify key aspects of early HCV infection that is crucial for the design of an urgently needed prophylactic HCV vaccine. In this study, we investigated HCV kinetics from inoculation to steady state in uPA-SCID chimeric mice with humanized livers and developed a mathematical model to provide insights into early HCV-host dynamics. **Methods:** Five PXB uPA-SCID mice with hepatocyte donor: JFC (1 y, male Caucasian) and human albumin > 9mg/mL, inoculated intravenously with HCV (genotype 1a)-infected serum of $1x10^6$ copies/animal. Viral levels were frequently measured from blood samples up to 35 days post infection (p.i.). We modified our previous HCV acute mathematical model in chimpanzees (Gastroenterology.2005;128(4):1056-66) to account for the lack of adaptive immune response and hepatocytes proliferation in the uPA-SCID mouse model. **Results:** After an initial rapid viral decline, the virus resurged in a biphasic manner i.e., rapid phase during the first 2 to 6 days p.i. followed by a slower phase, with a transient decline (in 3 mice) in between), that eventually stabilized at high steady state levels [Fig. 1]. The modified model was able to account for the initial rapid viral decline, assuming that the inoculated virus was less infectious (~100-fold) compared to the newly produced virions from infected human hepatocytes. Modeling suggests that the biphasic viral increase (with [Fig. 1a] or without [Fig. 1b] a transient decline), can be best explained by assuming blockage in viral production [Fig. 1, solid lines] over blocking of infection [Fig. 1: dashed lines]. **Conclusion:** The multiphasic HCV kinetic patterns observed in uPA-SCID mice were reminiscent of our previously reported early acute HCV kinetics in chimpanzees (ibid). The biphasic viral increase seen in mice can be explained by a partial block of virion production possibly due an early stage of innate immune response, reminiscent of the observed biphasic increase in chimpanzees that was suggested due to an endogenous type I interferon response (ibid). The nature of the innate immune response in humanized mice requires further study.

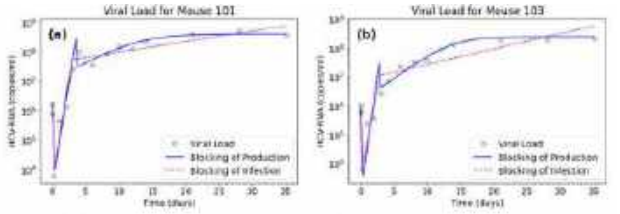

Fig 1: Modeling fit curves (lines) with measured HCV vire load (symbols in uPA/SCID humanized mice. [a] representative mouse (out of 3) with an observed transient viral decline. [b] representative mouse (out of 2) without an observed transient viral decline. Model parameter estimates in (a) and (b) respectively were: HCV clearance rate constant 22.3 and 20.6 day^{-1}, viral production of 51.5 and 168 copies/cell, blocking of virion production of 92.5% and 91% that was initiated 3.5 and 2.8 days p.i.. Blocking of infection (dashed lines) was ruled out due to poor goodness of fit compared to blocking of viral production (solid lines). Modeling fits were done using Python 3.7.3.

2000-A | 3D SPATIAL BIOLOGY ASSESSMENT OF LIVER BIOPSIES FROM PATIENTS WITH NASH AND NAFLD

Alexandra Alvarsson[1], Brandy Olin[1], Caleb Stoltzfus[1], Rohit Loomba[2], Seema Singh[2], Mark A Valasek[2] and Nicholas Reder[1], (1)Alpenglow Biosciences, (2) University of California, San Diego

Background: Liver fibrosis and steatosis are hallmark features of non-alcoholic steatohepatitis (NASH) and non-alcoholic fatty liver disease (NAFLD). 2D histopathological examination of biopsies is the gold standard for the assessment of steatosis and fibrosis in liver disease. However, this traditional method is subject to significant undersampling, interobserver variability and interpretative errors. Here we present a method for comprehensive 3D assessment of intact biopsies to evaluate the severity of liver damage based on the quantity and spatial distribution of fibrosis and steatosis. **Methods:** Formalin-fixed paraffin embedded liver biopsies were obtained from human subjects with/without varying degrees of NASH and NAFLD. The samples were processed using a modified iDISCO+ protocol, stained with To-Pro-3 and eosin and optically cleared. Entire biopsies (average dimensions: 0.5 x 1 x 10 mm) were imaged using an open-top light-sheet microscope (3D*i*, Alpenglow Biosciences) at a resolution of 2 µm/px. High-resolution images (0.33 µm/px) were acquired from select regions of interest to capture specific pathological features. Steatosis, fibrosis, hepatocyte ballooning and inflammation were segmented across complete 3D datasets using Aivia. CytoMAP and python were used to quantify and localize the radius, volume and clustering of lipid droplets, the degree of fibrosis, and their spatial relationships. **Results:** High field of view images of entire biopsies were obtained within 11-63 min depending on sample volume. Steatosis and fibrosis were readily visualized and recognizable in 2D optical sections of the 3D datasets, and we found that their 3D distribution varied substantially throughout the volume of each biopsy. This variability may cause sampling and interpretative errors when biopsies are processed using conventional 2D histology. Qualitative pathologist 3D assessment revealed a preponderance of fine collagen fibers interdigitating with larger fat droplets in the lobules of NASH biopsies. **Conclusion:** This novel method enables identification and quantification of pertinent parameters such as the percentage of fibrosis and steatosis across an entire biopsy. Further sampling and 3D reconstruction may enable us to develop a new and more accurate scoring system which can correlate better with clinical disease severity. Quantitative assessments, including zonal variation in collagen fiber size and fat-collagen distance measurements, are underway.

2001-A | A MULTI-OMICS STUDY REVEALS A MECHANISTIC LINK BETWEEN ADENOSINE DEAMINASE 2 AND LIVER FIBROSIS IN NONALCOHOLIC FATTY LIVER DISEASE

Scott Brian Minchenberg[1], David Guardamino Ojeda[1], Yered Pita-Juarez[1], Sebastian Niezen[2], Yusuf Yalcin[3], Shilpa Tiwari-Heckler[4], Russell Tracey[5], Peter Durda[5], Kent Taylor[6], Craig Johnson[7], Xiuqing Guo[6], Matthew Budoff[6], Namrata Gupta[8], Stacy Gabriel[8], Francois Aguet[8], Kristin Ardlie[8], Clary Clish[8], Thomas Blackwell[9], Robert Gerszten[1], Kenneth Mukamal[1], Stephen S Rich[10], Jerome I Rotter[6], Ioannis Vlachos[1], Yongmei Liu[11] and Z. Gordon Gordon Jiang[1], (1)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (2)University of Pittsburgh Medical Center, (3)Carney Hospital, (4)Heidelberg University Hospital, (5)University of Vermont, (6)The Lundquist Institute for Biomedical Innovation at Harbor-UCLA Medical Center, (7)University of Washington, (8)Broad Institute, (9) University of Michigan, (10)University of Virginia, (11) Duke University Medical Center

Background: Adenosine deaminase 2 (ADA2) is an ecto-enzyme secreted by monocytes and macrophages that catalyzes the conversion of extracellular adenosine to inosine, thus regulating circulating ATP, AMP, and adenosine. We have previously discovered a correlation between serum ADA2 enzymatic activity and fibrosis in patients with nonalcoholic fatty liver disease (NAFLD). The mechanism underscoring this link remains elusive. In this study we use a multi-omics approach to determine the relationship of ADA2 activity with metabolic and inflammaotry pathways associated with macrophage activation and fibrosis. **Methods:** Individual's with NAFLD were identified based on the liver-to-spleen density ratio on CT scan and medical history from the Multi-Ethnic Study of Atherosclerosis (MESA). Serum ADA2 activity and biochemical

components of Enhanced Liver Fibrosis (ELF) score were measured in serum samples from exam 5. Serum proteomics from SomaScan, metabolomics from mass spectrometry, and peripheral blood mononuclear cell (PBMC) transcriptomics from RNA-seq were obtained through the Trans-Omics for Precision Medicine (TOPMed) Whole Genome Sequencing Program. We used multiple regression models and clustering analysis to determine how ADA2 activity is related to liver fibrosis, purine metabolism, cytokine/chemokine profiles, and PBMC transcriptomics. **Results:** From a total of 427 participants with NAFLD, we demonstrate an association between circulating ADA2 activity and ELF score ($r = 0.484$; $p < 0.0001$), a non-invasive marker of fibrosis. Using hypothesis-free clustering analysis, high ADA2 activity was associated with high inosine and its downstream metabolites, hypoxanthine, and xanthine. Based on serum proteomics data, high ADA2 activity was associated with elevated levels of IL13, IL23, but reduced levels of IL10, suggesting a proinflammatory phenotype. PBMC transcriptomics data further revealed upregulation of interferon (IFN)-induced genes (IFI27, IFIT3, IFI6, IGLV7-46), and cell migration regulators (CXCL10, CCR9, ITGA1, MIF). Monocyte subset transcriptome analysis trended toward NF-kB activation. Finally, we evaluated the impact of ADA2 on glycolysis and the Krebs cycle using both cluster analysis and regression, and determined that ADA2 is associated with increased circulating Krebs cycle metabolites and decreased glycolytic metabolites. **Conclusion:** We developed a multi-omics approach to determine the impact of ADA2 on liver fibrosis in NAFLD. Elevated ADA2 activity in the circulation is associated with increased purine metabolites with a shift toward an accumulation of inosine and its downstream metabolites. There is also an association with proinflammatory cytokines, activation of IFN genes, and chemokine-mediated immune cell migration. These findings support emerging mechanistic framework of how ADA2 regulates inflammation and provides insight on how ADA2 may be implicated in liver fibrosis.

2002-A | A NOVEL PATIENT DECISION AID SYSTEM FOR EARLY RISK STRATIFICATION IN NAFLD: METHODOLOGY, AND RESULTS

Adam Hall[1], Jonathan G. Stine[2], Wayne Eskridge[3], Henry E Chang[3], Neeraj Mistry[3], Jaap Oosterbroek[1], Anne Kim[1] and Kanchana Padmanabhan[1], (1)Secure AI Labs, Cambridge MA, USA, (2)Penn State Health Milton S. Hershey Medical Center, Hershey, PA, USA, (3)Fatty Liver Foundation, Boise, ID, USA

Background: Nonalcoholic fatty liver disease (NAFLD) affects billions worldwide, however, most individual's are asymptomatic until a late-stage of the disease. This makes early identification and risk stratification challenging at both the individual level for clinicians and the population health level. Current methods for identifying NAFLD are limited by access, cost and are often invasive. Patient Decision Aid Systems (PDAS) aim to improve outcomes through early risk stratification. The objective of this study was to develop a PDAS for early risk stratification of patients with NAFLD. **Methods:** This study includes 940 individual's from Houston and Galveston County, Texas who completed a survey questionnaire regarding clinical and lifestyle variables deemed important to metabolic disease. as a part of the Screening for Undiagnosed Nonalcoholic Steatohepatitis and NAFLD (SUNN-1) study. A number of classification models were tested on data contained in SUNN-1. These classifiers included logistic regression, support vector machine, neural network, decision tree, random forest and XGBoost (eXtreme Gradient Boosting). XGBoost was the most performant and was selected for fine tuning. As a result, an XGBoost-based PDAS was developed using data in SUNN-1. Features were selected through iterative feature exclusion and model re-training ordered by feature information gain. The PDAS was designed to separate NAFLD from non-NAFLD individual's, with its performance evaluated using the Area Under the Receiver Operating Characteristic (AUROC) curve. **Results:** In the subsection of the population included in SUNN-1, the median age group was 40-49 years of age with the majority of

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

patients between 40 and 59 years of age. Of the population that was surveyed, 2 in 3 were female and 61% were Hispanic. 80% of those who took the survey were classed as either overweight or obese and 1 in 4 were diabetic. The model demonstrated an AUROC of 0.81 on test data, indicating its effectiveness in identifying NAFLD patients who have entered severe steatosis (S3). The chosen model identified S3 positive patients with 0.7 precision and 0.7 recall. In identifying negative cases, the model scored 0.77 and 0.77 precision and recall respectively. The average accuracy across both classes was 0.74. **Conclusion:** The developed PDAS shows promise for early risk stratification of NAFLD patients based on results. Importantly, the developed PDAS offers tremendous potential to screen for NAFLD in the general population and improves upon previous machine learning developed models for population screening which require input from a treating clinician in the form of physical examination findings and blood testing. If prospectively validated, this novel tool offers potential to improve patient outcomes and doctor-to-patient time efficiency at the population level.

Robert J. Wong[6] and Manisha Verma[7], (1)American Liver Foundation, San Diego, CA, (2)American Liver Foundation, (3)Henry Ford Health, (4)Yale University, New Haven, CT, (5)University of Miami Miller School of Medicine, Schiff Center for Liver Diseases, (6)Stanford University School of Medicine, (7)Einstein Healthcare Network

Background: Nonalcoholic fatty liver disease (NAFLD) prevalence is estimated to be 80-100 million in the US. NAFLD is highly under-diagnosed due to inadequate screening programs, and as a result can progress to non-alcoholic steatohepatitis (NASH), liver cirrhosis, liver cancer, the need for liver transplantation, and death. NAFLD is often asymptomatic and disproportionately affects disadvantaged communities. Although early detection allows for timely intervention to improve disease course, screening for fatty liver diseases is not offered as part of routine medical care outside of hepatology clinics. To address this gap, the American Liver Foundation (ALF) launched a pilot NAFLD Screening Program for high-risk individual's in Texas. **Methods:** ALF consulted with public health professionals in Houston to identify a non-profit community-based clinic (Fundación Latinoamericana De Acción Social) providing essential healthcare services to those with limited access. The clinic completed steps necessary to become a screening site to conduct LIVERFASt tests, a blood test that measures 10 biomarkers for liver health (Figure 1). Clinic staff were trained, screening tests were performed on at-risk individual's (Figure 1), and results were analyzed for evidence of steatosis and fibrosis. **Results:** A total of 448 individual's participated in the NAFLD screening program (62% females, mean age = 43 y), among whom 63% had a steatosis score of S1 or higher, with moderate to severe steatosis (S2-S3) in 32%. Importantly, most participants with S2-S3 had little evidence of fibrosis, signaling an opportunity to potentially halt or reverse disease. Participants with scores **e** S1 were given educational resources on NAFLD and healthy lifestyle choices and linked to healthcare providers for follow-up care. After the pilot program concluded in 2021, the established processes were sustained to continue screening at the clinic. Based on lessons learned, ALF has expanded screening through ALF's National Public Health Campaign, *Think Liver Think Life*, in Federally Qualified Health Centers and Community Clinics in 21 states. **Conclusion:** NAFLD/NASH is an emerging under-diagnosed healthcare crisis, and our pilot program demonstrates the feasibility of widespread screening in high-risk individual's. The ALF plans to expand the *Think Liver Think Life* campaign to all 50 states within 5 years, with the goal to improve education, early diagnosis, and access to care for people with liver disease.

Laboratoire Hifih, Sfr Icat 4208, Université D'angers, Angers, France, (3)Echosens, (4)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Agile3+ and Agile4 are two elastography-based tests respectively designed for the non-invasive diagnosis of advanced fibrosis and cirrhosis in NAFLD. We aimed to evaluate whether these two tests designed for different diagnostic targets synergize for the prediction of liver-related events (LRE) in NAFLD. **Methods:** This retrospective study included adults with NAFLD from a tertiary care center. The main study outcome was LRE, a composite endpoint combining cirrhosis complication or hepatocellular carcinoma. All patients had FIB4, vibration-controlled transient elastography (VCTE) with FibroScan device, Agile3+ and Agile4 available at baseline. Each non-invasive test stratified patients in three risk groups (low-risk, intermediate risk, high-risk) according to their published thresholds: < 1.30 and > 2.67 for FIB4; < 10 kPa and > 15 kPa for VCTE; $<$ 0.451 and **e** 0.679 for Agile3+; < 0.251 and **e** 0.565 for Agile4. **Results:** 341 patients were included (median age: 58 y, male sex: 65%, diabetes: 36%). The rate of patients included in the low / intermediate / high-risk groups with FIB4, VCTE, Agile3+ and Agile4 were, respectively: 43%/46%/11%, 57%/23%/20%, 56%/15%/29%, and 83%/9%/8%. LRE occurred in 27 (8%) patients after a median follow-up of 5.2 years (IQR: 2.9-7.2). Agile3+ and Agile4 provided higher time-dependent ROC curves than VCTE or FIB4 for LRE prediction (Panel A). Most of the patients who experienced LRE during the follow-up were included in the high-risk group with Agile3+ (23 of 27 patients, 85%), versus only 10 (37%) in the high-risk FIB4 group, 15 (56%) in the high-risk VCTE group, and 12 (44%) in the high-risk Agile4 group. Because Agile3+ and Agile4 can be calculated at the same time, we evaluated a stratification based on their combination: low-risk group (Agile3+ < 0.679), high-risk group (Agile3+ **e** 0.679 and Agile4 < 0.565), and very high-risk group (Agile3+ **e** 0.679 and Agile4 **e** 0.565). Rate of patients included in these three groups were respectively 71%, 21% and 8%. LRE occurred in 4 patients (1.7%) from the low-risk group, 11 patients (15%) from the high-risk group, and 12 patients (44%) from the very high-risk group. Therefore, the Agile3+/Agile4 combination provided the best risk stratification, with Agile4 splitting the Agile3+ high-risk group in two high-risk and very-high groups (Panel B). **Conclusion:** Agile3+ and Agile4, two elastography-based noninvasive tests respectively designed for the diagnosis of advanced fibrosis and cirrhosis, both synergize for a better stratification of the liver-related risk in NAFLD.

2005-A | AI-ASSISTED GUBRA HISTOPATHOLOGICAL OBJECTIVE SCORING TECHNIQUE (GHOST) FOR UNBIASED, FAST AND ACCURATE ASSESSMENT OF DISEASE SEVERITY IN RODENT MODELS OF NASH

Anitta Kinga Sarvari[1], Susanne E. Pors[1], Jacob Nøhr-Meldgaard[1], Casper Salinas[1], Denise Oró Bozzini[1], Henrik B. Hansen[1] and Michael Feigh[2], (1)Gubra, (2) Gubra Aps

Background: Efficacy studies in animal models of non-alcoholic steatohepatitis (NASH) include histopathological endpoints. Clinical-derived NAFLD Activity Scoring (NAS) and Fibrosis Staging system, outlined by Kleiner et al., is reproducible in preclinical models of NASH. Manual histopathological scoring is prone to observer variability which can influence robustness and reproducibility of study results. To enable objective and unbiased histopathological assessment in liver biopsies, we developed GHOST, an deep learning-based digital imaging analysis pipeline for automated NAS and fibrosis scoring. **Methods:** Liver biopsies were obtained from two NASH rodent models, GAN diet-induced obese (GAN DIO-NASH) mouse and choline-deficient L-amino acid-defined high-fat diet (CDAA-HFD) rat. Age-matched chow-fed mice and rats served as normal controls. Automated GHOST deep learning computational analysis of NAS and fibrosis scores was performed on hematoxylin-eosin (HE) and picrosirius red (PSR) stained sections. GHOST module was extended to enable automated analysis of fibrosis severity in CDAA-HFD rats using the Ishak fibrosis scoring system. All GHOST data were validated by manual scoring by expert histopathologists. Quantitative morphometrics, derived from scoring variables, includeddensity of hepatocytes with lipid droplets, number of inflammatory foci, and %-area of fibrosis. **Results:** GHOST accurately and reproducibly detected hepatic central veins and portal areas in GAN DIO-NASH mice and CDAA-HFD rats , enabling segmentation of zones for clinical histopathological scoring. In HE stained sections, hepatocytes, inflammatory cells, and ballooned hepatocytes were identified. Inflammatory foci were considered as clusters of **e** 4 inflammatory cells. NAS was computed and validated using 338 mouse liver biopsies with a Cohen´s Kappa value of 0.72, indicating agreement between AI-assisted and manual scoring of NAS. PSR-stained collagen fibers were localized in the sinusoidal and periportal space by GHOST, identifying collagen forming bridges and branch points. Kleiner fibrosis stage was computed and validated using 537 mouse liver biopsies, achieving

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

a Kappa value of 0.84 between AI and manual scores. For Ishak scores, PSR-stained sections were segmented into smaller tiles, classified using convolutional neural network (CNN) analysis. The output of the CNN model was used in a machine learning algorithm to predict fibrosis stage achieving Kappa value of 0.82, based on86 liver biopsies from CDAA-HFD rats. **Conclusion:** Accuracy of GHOST-automated histopathological scoring in the GAN DIO-NASH and CDAA-HFD models of NASH was in close agreement with expert histopathologist assessment. Using GHOST for automated assessment of NAS and fibrosis scores provides fast, accurate and reproducible histopathological scoring, hence highly instrumental for the assessment of test drug effects in preclinical models of NASH.

2006-A | AI-BASED CELLULAR-LEVEL CHARACTERIZATION OF TISSUE MICROARCHITECTURE IN NON-ALCOHOLIC STEATOHEPATITIS

Neel Patel[1], Pratik Mistry[1], Adam Stanford-Moore[1], Robert Egger[1], Michael G. Drage[1], Murray Resnick[1], Jonathan Glickman[1], John Abel[1], Nidhi Chandra[1], Dinkar Juyal[1], Dana Lau-Corona[1], Ilan Wapinski[1], Timothy R. Watkins[2], Andrew N. Billin[2] and Janani Iyer[1], (1)Pathai, Inc., (2)Gilead Sciences, Inc.

Background: Non-alcoholic steatohepatitis (NASH) is traditionally evaluated via ordinal scoring of tissue patterns in liver biopsies. While these scoring systems facilitate pathologist evaluation, they do not afford the granularity and sensitivity required to detect subtle yet meaningful histologic changes. To address this unmet need, we trained machine learning (ML) models to characterize the morphological architecture of H&E NASH liver biopsies at the cellular level, and tested the biological validity of model-generated, quantitative Human Interpretable histologic Features (HIFs) by comparing them against ML-derived NASH Clinical Research Network (CRN) scores. **Methods:** An ML model was trained using whole slide images (WSIs) of H&E NASH biopsies to detect all cell nuclei present and assign a cell label (Fibroblast, Macrophage, Lymphocyte, Neutrophil, Eosinophil, Plasma Cell, Ballooned Hepatocyte, Normal Hepatocyte, Other Hepatocyte, Macrovesicular Steatotic Cell, or Other cell; Fig. 1A) to each nucleus. We deployed the resulting cell model alongside a previously developed ML-based Tissue Model on WSIs from a subset of enrolled participants in the Stellar-3 (ST3; Baseline [BL] N = 391, Week 48 [Wk48] N = 384) and Stellar-4 (ST4; BL N = 1117, Wk48 N = 548) clinical trials to characterize tissue composition in the form of cellular HIFs. In addition, ordinal and continuous ML-derived NASH CRN scores for each sample were generated via the AI-based Measurement of NASH Histology tool (AIM-NASH, PathAI, Inc.; previously described). We used Kendall's tau (T) or Pearson's correlation (R) to measure the association between cellular composition of tissue samples and AIM-NASH scores. **Results:** We found moderate correlations between cell HIFs and AIM-NASH CRN ordinal and continuous scores in BL WSIs from both ST3 and ST4 (Fig.1B). The cell density features that best correlated with the AIM-NASH CRN components were Ballooned Hepatocytes with Ballooning Grade, Steatotic Hepatocytes with Steatosis Grade, Macrophages with Lobular Inflammation Grade, and Fibroblasts with Fibrosis Stage (FDR-corrected $p < 0.001$ for these comparisons), suggesting that the ML model is accurately capturing relevant cellular histology. **Conclusion:** Here we report an ML model that delivers insight into the cellular architecture of NASH liver biopsies. We found biological validity of model predictions by showing correlations of quantitative HIFs with the gold standard NASH CRN grading and staging system. Future work should aim to characterize the cellular patterns that uniquely predict histologic response to individual drug classes or indicate mechanisms of action, in addition to interrogating the spatial relationships between these cell types in advancing versus regressing fibrosis in NASH.

2007-A | ALANINE TRANSAMINASE LEVEL DOES NOT AFFECT THE PREDICTABILITY OF CLINICALLY SIGNIFICANT OR ADVANCED FIBROSIS BETWEEN NONINVASIVE SCORING SYSTEMS

Maham Ghani[1], Salima Makhani[1], Alexa Giammarino[1], Ethan Berman[1], Justin Lin[2], Jeffrey Lowell[1], Mark Patrick Cubillan[2], Pratik Patel[3], Hassam Ali[4], Michael Ramada[1], James S. Park[3] and Sanjaya Kumar Satapathy[5], (1)Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, (2)Northshore University Hospital/Long Island Jewish Hospital, (3)Northwell Health, Forest Hills, NY, (4)East Carolina University, (5) Division of Hepatology, Northwell Health, and Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, Hempstead, NY, USA.

Background: Serum alanine transaminase (ALT) levels are regarded as a sensitive and reliable marker of liver disease, however patients with chronic liver disease can have normal or slightly elevated ALT. Non-invasive validated scoring systems such as FIB-4, APRI and NAFLD fibrosis score (NFS) can assist in predicting severity of disease. Our study aims to determine whether stratification by ALT level can improve accuracy of non-invasive fibrosis scores. **Methods:** We retrospectively analyzed 444 biopsy proven NAFLD cases from 2015-2020. Fibrosis score > 1 was defined as clinically significant fibrosis and while a score > 2 was defined as advanced fibrosis. Performances of each score for advanced fibrosis were determined for low ALT (< 40 U/L) and high ALT (> 40 U/L) levels by calculating the area under the receiver operating characteristic (ROC) curve and their 95% confidence intervals (CI). We used two-sided tests with $\alpha = 0.05$. Statistical analyses were performed using SAS version 9.4 (SAS Institute, Cary, NC). **Results:** Of 444 biopsy proven NAFLD patients, 187 had serum ALT levels < 40 whereas 257 had serum ALT levels > 40. The average APRI, FIB4 and NFS for all patients were 0.77, 1.81, and -0.96, respectively; for the normal ALT cohort were 0.36, 1.57, and -0.27 respectively; and for the elevated ALT cohort were 1.08, 1.99, and -1.46, respectively. In the advanced fibrosis cohort, there were 37 patients in the normal ALT cohort and 77 patients in the elevated ALT cohort. ROC scores for the FIB4, APRI, and NFS in clinically significant fibrosis were approximately 0.83 (95% CI 0.74-0.93, p = 0.21), 0.83 (95% CI .73-94, p = 0.21), and 0.78 (95% CI .67-0.89 p = 0.18), for the normal ALT cohort and 0.76 (95% CI 0.70-0.83, p = 0.22), 0.70 (95% CI 0.63-0.77, p = 0.16), 0.71 (95% CI 0.65-0.78, p = 0.18) for the elevated ALT cohort. When stratifying for advanced fibrosis, defined as fibrosis score > 2, ROC scores for the FIB4, APRI, and NFS were approximately 0.88 (95% CI 0.77-0.98, p = 0.18), 0.86 (95% CI .74-97, p = 0.17), and 0.86 (95% CI .75-0.96 p = 0.17), for the normal ALT cohort and 0.84 (95% CI 0.78-0.90, p = 0.18), 0.76 (95% CI 0.69-0.84, p = 0.14), 0.80 (95% CI 0.72-0.87, p = 0.15) for the elevated ALT cohort. **Conclusion:** Our analysis demonstrated that all three non-invasive fibrosis scores (FIB-4, APRI, and NFS) are highly predictive for fibrosis, regardless of normal or elevated serum ALT level. FIB-4, APRI and NFS equally predict both clinically and advanced fibrosis in patients with normal ALT level levels. FIB-4 and the NFS are slightly better predictors of the degree of fibrosis in patients with elevated ALT levels. Larger prospective studies are needed to validate the stratification of non-invasive fibrosis scores based on serum ALT level.

2008-A | APPLICATION OF LIVERFAST BIOMARKERS TO PREDICT STEATOSIS IN CHRONIC HEPATITIS B PATIENTS WITH METABOLIC SYNDROME

Mati Ullah Dad Ullah[1], Mansoor Rahman[1], Mehdi Sakka[2], Rana Alkouri[2], Muhammad Asad Raza[1], Mukarram Jamat Ali[1], Karen Campoverde Reyes[1], Maxime Deregnaucourt[2], Dominique Bonnefont-Rousselot[2,3], Ronald Quiambao[4], Mona Munteanu[4] and Daryl T. Y. Lau[1], (1)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (2) Metabolic Biochemistry Department, Pitié-Salpêtrière Hospital, Public Assistance Paris Hospitals,Aphp Sorbonne University, France, (3)Pharmacy Training and Research Unit (UFR), Paris Cité University; Cnrs, Inserm, Utcbs, France, (4)Fibronostics US Inc, USA

Background: Chronic hepatitis B (CHB) and non-alcoholic fatty liver disease (NAFLD) are both common liver conditions. Approximately 30-40% patients with CHB also have NAFLD. Patients with coexisting CHB and NAFLD have high risk of liver disease progression and hepatocellular carcinoma. In this study, we evaluated LIVERFASt as a noninvasive biomarker in detecting hepatic steatosis among CHB patients with and without metabolic syndrome. We also correlated LIVERFASt steatosis scores with the Controlled Attenuation Parameter (CAP) scores of FibroScan. **Methods:** This is a retrospective, cross-sectional study in a single tertiary liver center. We identified 82 patients who met the study criteria and had available fasting sera in the biorepository. The MS-HBV group consisted of 36 (44%) CHB patients with metabolic syndrome or known diabetes mellitus; the C-HBV group had 46 (56%) patients with CHB alone. Metabolic syndrome was defined according to the criteria of the national cholesterol education program. LIVERFASt ™ (Fibronostics) scores were computed for each sample using the defined clinical and laboratory values. Medical chart review was performed to record demographics, clinical and HBV status. **Results:** Asians were predominant in both the MS-HBV (83%) and C-HBV (67%) groups with similar mean age of 50 and 46 years, respectively. BMI (28 vs. 25 kg/m^2, $p = 0.001$), HbA1c (6.1 vs. 5.2%, $p < 0.0001$), ALT (42 vs. 27 U/L, $p = 0.002$) and AST (30 vs. 25 U/L, $p = 0.01$) were significantly higher in the MS-HBV group. The proportions of patients on antiviral therapy for CHB in the MS-HBV (42%) and C-HBV (37%) groups were similar. About 15% of patients in each group had HBV DNA levels > 2000 IU/ml. 7 (19%) patients in MS-HBV and only 2 (4%) patients in C-HBV groups were identified to have steatosis ($p = 0.03$) [Figure]. LIVERFASt steatosis score most strongly correlated with BMI ($r = 0.58$, $p < 0.00001$), followed by HbA1c ($r = 0.32$, $p = 0.004$) and lipo-protein insulin resistance index (LP-IR) ($r = 0.33$, $p = 0.002$). In a linear regression model, steatosis can be predicted using the formula: *Steatosis score = (0.02199 x BMI)-0.3985*. Fewer than 10% of subjects in each group had advanced fibrosis. There was no significant correlation between steatosis and fibrosis scores. 54 (66%) patients had BMI change < 2 kg/m^2 and had FibroScan with CAP in an average follow up of 2 years. Their steatosis scores significantly correlated with their CAP scores ($r = 0.56$, $p = < 0.00001$). **Conclusion:** LIVERFASt has prognostic value in detecting steatosis among CHB patients with metabolic syndrome. LIVERFASt steatosis score had the strongest correlations with BMI and CAP score by fibroScan in this study. Noninvasive methods to identify patients with NAFLD are important for timely interventions and management. These positive observations and the steatosis prediction model need to be validated with larger, racially diverse cohorts of chronic hepatitis B patients in further studies.

AMERICAN ASSOCIATION FOR THE STUDY OF LIVER DISEASES

2009-A | ARTIFICIAL INTELLIGENCE/NEURAL NETWORK SYSTEM THAT ACCURATELY DIAGNOSES HEPATOCELLULAR CARCINOMA IN NONALCOHOLIC STEATOHEPATITIS

Kanji Yamaguchi[1], Toshihide Shima[2], Yasuhide Mitsumoto[3], Yuya Seko[1], Yoshito Itoh[1] and Takeshi Okanoue[3], (1)Kyoto Prefectural University of Medicine, (2)Saiseikai Suita Hospital, Suita, Osaka, Japan, (3) Saiseikai Suita Hospital

Background: The aim of this study was to develop a novel noninvasive test using an artificial intelligence/neural network system (called HCC-Scope) to diagnose early stage hepatocellular carcinoma (HCC) in nonalcoholic steatohepatitis (NASH). **Methods:** One hundred and seventy-five NASH patients and 55 patients with NASH-HCC were enrolled for training and validation studies. Of the 55 NASH-HCC, 27 had very early stage HCC, and six had early stage HCC based on the Barcelona Clinic Liver Cancer staging system. Diagnosis with HCC-Scope was performed based on 12 items: age, sex, height, weight, aspartate aminotransferase level, alanine aminotransferase level, gamma-glutamyl transferase level, cholesterol level, triglyceride level, platelet count, diabetes status, and immunoglobulim M-free apoptosis inhibitor of macrophage level. The FMVWG2U47 hardware (Fujitsu Co. Ltd, Tokyo) and the originally developed software were used. **Results:** HCC-Scope had 100.0% sensitivity, 100.0% specificity, 100.0% positive predictive value (PPV), and 100.0% negative predictive value (NPV) for differential diagnosis between non-HCC and HCC in a training study with and without gray zone analysis. It was also excellent in the validation study (95.0% sensitivity, 100.0% specificity, 100.0% PPV, and 97.1% NPV with gray zone analysis and 95.2% sensitivity, 100.0% specificity, 100.0% PPV, and 97.1% NPV without gray zone analysis). HCC-Scope had significantly higher sensitivity (85.3%) and specificity (85.1%) than alpha-fetoprotein (AFP) level, AFP-L3 level, des-gamma-carboxy prothrombin (DCP) level, and the gender–age–AFP-L3–AFP–DCP (GALAD) score. **Conclusion:** HCC-Scope is easy to use and can accurately differentially diagnose between non-HCC NASH and NASH-HCC, including very early stage NASH-HCC.

Background: Histologic scoring systems for NASH have suboptimal inter-reader agreement, even amongst expert hepatopathologists (HPs). Misclassification of NAFLD activity and fibrosis staging impacts NASH clinical trial enrollment and endpoint assessment with inaccurate and imprecise measurement of histologic change over time. High variability limits comparison of results between clinical trial phases and between drug classes. In this study, AIM-NASH (PathAI) was evaluated for accuracy alone and for use as an assistive tool to HPs in assessment of liver biopsies in a NASH clinical trial population. **Methods:** In a clinical validation (CV) study1, de-identified biopsy samples representing cirrhotic and non-cirrhotic subjects were collected from multiple Phase II and Phase III NASH trials. A panel of expert HPs established ground truth (GT) NASH scores. Cases were also digitally evaluated by at least 3 other experienced HPs who independently provided NAS activity grades and CRN fibrosis stage. After a minimum 2-week washout period, individual HPs AI-assisted scores were collected. Accuracy of AIM-NASH alone and HP's manual reads was assessed for the full CV population against GT. Accuracy and inter-reader agreement was assessed with and without AI-assistance, and was performed on a subset of cases where either (a) cases where the same HP read with and without AI-assistance (ranging from 86-216 samples per HP or (b) cases were scored with AI-assistance by multiple HPs (ranging from 10 to 83 slides; Table 1). **Results:** AIM-NASH alone demonstrated superior accuracy to HPs for hepatocellular ballooning and lobular inflammation (weighted kappa [WK] differences of 0.119 and 0.148; both $p < 0.0001$) and non-inferior accuracy for steatosis and fibrosis (WK differences of 0.002; [$p < 0.0001$] and -0.009; [$p < 0.001$]). AI-assistance improved HPs' accuracy for lobular inflammation and hepatocellular ballooning (WK difference of 0.088, and 0.11, respectively), while HPs' accuracy for fibrosis and steatosis compared to GT were largely unchanged with AI-assistance (WK difference of 0.012 and 0.000). AI-assistance decreased inter-pathologist variability for all features with a WK difference ranging in 0.314-0.771. Inter-reader agreements with AI-assistance were higher than published literature for all features (Table 1). **Conclusion:** AIM-NASH is an accurate tool for NASH assessment for all histologic features. In a subanalysis where the same readers performed assisted and manual reads, AI-assisted HPs displayed improved accuracy for assessment of lobular inflammation and hepatocellular ballooning and showed higher inter-reader agreement for all features. These data show that AIM-NASH may help to standardize histologic scoring by increasing accuracy and reducing inter-reader variability in those features most difficult to score in clinical trial populations, allowing for a more reliable assessment of therapeutics under development.

Table 1: Inter-pathologist agreement rates with and without AI (for cases with >10 reads for comparison)

Histologic Feature	Mean WK Inter-reader agreement with AI assistance (range)	Mean Inter-reader agreement without AI assistance (range)	Average Inter-reader WK from literature[2]
Steatosis	0.986 (0.958-1)	0.672 (0.503-0.734)	0.609
Lobular Inflammation	1	0.229 (-0.047-0.466)	0.328
Hepatocellular Ballooning	0.995 (0.973 - 1)	0.383 (0.281-0.448)	0.517
Fibrosis	0.958 (0.906 - 1)	0.493(0.091-0.735)	0.484

2011-A | ASSESSING THE REPEATABILITY AND REPRODUCIBILITY OF LIVERMULTISCAN METRICS cT1 AND PDFF

Cayden Beyer[1], Anneli Andersson[1], Elizabeth Shumbayawonda[2], Andrea Dennis[1] and Kathleen E. Corey[3], (1)Perspectum Ltd, (2)Perspectum Ltd., (3) Massachusetts General Hospital, Somerville, MA

Background: Multi-parametric magnetic resonance imaging (mpMRI)-derived metrics iron-corrected T1 (cT1) and proton density fat-fraction (PDFF) have proven to be excellent non-invasive biomarkers for diagnosis and monitoring of non-alcoholic steatohepatitis (NASH). They are both commonly utilized as efficacy endpoints in NASH trials to assess therapy-induced changes in liver health, and cT1 additionally predicts clinical outcomes. Here we assess the robustness of both metrics by investigating their test-retest variability in a NASH population. **Methods:** Patients were recruited at Massachusetts General Hospital. All participants underwent two LiverMultiScans within the same scanning session, five minutes between scans without exiting the scanner, (timepoints A and B, respectively) to assess the measurement variability of

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

cT1 and PDFF. Additionally, patients histologically classified as having at-risk NASH (NAS > = 4 and fibrosis > = 2) were invited back for a third scan 2-4 weeks after their first visit (timepoint C) to test the biological/physiological variability. Bland-Altman analysis was performed, and the coefficient of variance (CoV), repeatability coefficient (RC), bias and upper/lower limits of agreement (LoA) were calculated, PDFF values are reported in relative percentages, rather than absolute. **Results:** Of the patients included in this study (n = 22; age = 48 years; BMI = 36.1 kg/m^2; cT1 = 858 ms; PDFF = 12.8%; 50% female, 41% diabetic), 7 had histologically confirmed at-risk NASH and were scanned 2-4 weeks following the initial scan. cT1 demonstrated high repeatability across timepoints A and B (CoV: 1.5%; RC: 32.1ms; bias: -6.2ms; 95% LoA: –36.6 to 24.2ms), and high reproducibility across timepoints A and C (CoV: 2.6%; RC: 65.2ms; bias: 6.3 ms; 95% LoA: –63.8 to 76.5ms). PDFF also demonstrated high repeatability across timepoints A and B (CoV: 1.9%; RC: 5.1%; bias: 1.1%; 95% LoA: –3.7 to 5.8%%), and high reproducibility across timepoints A and C (CoV: 6.9%; RC: 19.5%; bias: -1.1%; 95% LoA: –22.0 to 19.7%). **Conclusion:** Both cT1 and PDFF are used as efficacy endpoints in clinical trials with meaningful changes aligning with approved endpoints of NASH resolution and/or fibrosis regression reported to be > 80 ms for cT1 and **e** 30% relative change for PDFF. In this study of test-re-test variability, both metrics showed measurement variability well under the clinical meaningful change thresholds, both within session and two-weeks later With excellent repeatability and reproducibility, and proven correlations with respective histopathological features of NASH, cT1 and PDFF represent robust and reliable metrics for characterizing and assessing changes in liver tissue.

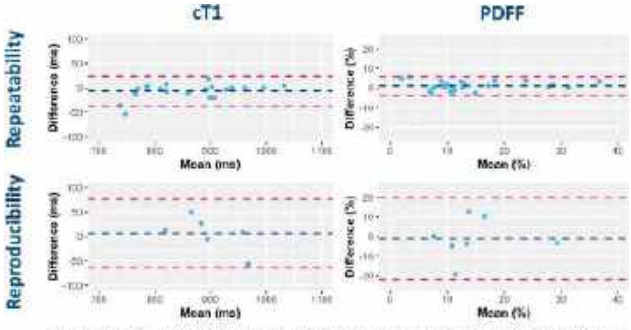

Figure 3. Bland-Altman plots showing the cT1 and PDFF differences between baseline (timepoint A) and follow-up (timepoint B for repeatability and timepoint C for reproducibility). The dashed lines represent the the upper 95% LoA (top), the mean (middle) and the lower 95% LoA (bottom).

2012-A | ASSESSMENT OF HEPATIC FIBROSIS SCREENING IN PRIMARY CARE USING AUTOMATIC CALCULATION OF THE FIB-4 SCORE, FOLLOWED IN SECOND LINE BY AN ELF (ENHANCED LIVER FIBROSIS) TEST

Denis Ouzan, Institut Arnault Tzanck; Rhecca, Guillaume Penaranda, Hopital Europeen, Malik Jlaiel, Bioesterel BIO Group and Jeremie Corneille, Bioesterel Biogroup

Background: Screening for liver fibrosis in the general population is a public health issue. We have shown in a previous study that FIB-4, a simple score combining age, ALT, AST, and platelet, can detect liver fibrosis in general practice and identify a possible cause of liver disease (1). The objective of our work was to evaluate the screening of hepatic fibrosis in general practice using the FIB-4 score automatically calculated, followed in second line if **e** 1.3 by an ELF test. **Methods:** The FIB-4 score was calculated from March to September 2022 in all consecutive patients seen by 15 general practitioners, outside the emergency. When the FIB-4 was **e** 1.3, it was defined as positive and ELF test was systematically performed. FIB-4 positivity was confirmed when the ELF test was **e** 9.8. **Results:** Among the 3427 patients included, 869 (25%) had a positive FIB4 score: 784 (22.5%) at intermediate (FIB-4:1.3-2.67) and 85 (2.5 %) at high risk of fibrosis (FIB-4 > 2.67). Among the 869 FIB-4 positive patients, 509 (59%) were confirmed by the ELF test. FIB-4 positivity was significantly linked to age over 65 years, AST, AST/ALT ratio and platelets levels $p < 0.001$. Confirmation by ELF was observed in 80% of the patients at high risk and 56 % at intermediate risk of fibrosis ($p < 0.0001$). Clinical information's were collected in 755/869 (87%) FIB-4 positive patients. The percentage of confirmation was significantly higher in patients over 65 years (84 vs 58%, $p < 0.0001$), in those with FIB-4 > 2.67 (80 vs 56%, $p < 0.0001$), BMI > 25 (47 vs 38%, $p = 0.010$), and with a diabetes (24 vs 14%, $p = 0.001$), but not in those with excessive alcohol consumption (14 vs 15%, $p = 0.8284$). In patients without known liver disease (92%), the general practitioner defines a cause of liver disease in 27% of cases: NAFLD 67 %, Alcohol 23%, FLD+ Alcohol 9%, other 5% and requires a specialized advice in 1/2 cases. **Conclusion:** Liver fibrosis was suspected by FIB4 score in 25 % of patients who consulted a general practitioner. The ELF test performed as a second-line test improves the screening of hepatic fibrosis by FIB-4 in primary care and in

particular for FIB-4 indetermined results which are confirmed in one out of two cases. The FIB-4 score, automatically generated, represents a warning that allows the general practitioner to identify a risk factor and a cause of liver disease on which it can intervene at an early stage. 2013-A | ASSESSMENT OF RESMETIROM-MEDIATED REDUCTIONS OF STEATOSIS AND CONCOMITANT BALLOONING UTILIZING QUANTITATIVE SECOND HARMONIC GENERATION IMAGING

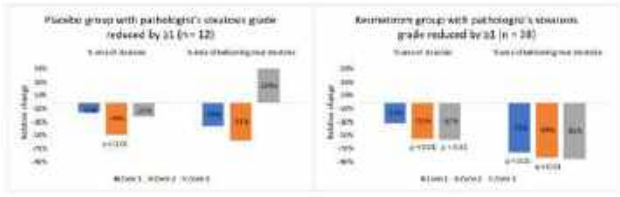
Dean Tai[1], Rebecca A. Taub[2], Ya-Yun Ren[3], Elaine Lay Khim Chng[1] and Stephen A Harrison[4], (1)Histoindex Pte Ltd, Singapore, (2)Madrigal Pharmaceuticals, (3) Histoindex Pte Ltd, (4)Pinnacle Clinical Research Center, San Antonio, TX

Background: Resmetirom is an oral, liver-targeted thyroid hormone receptor-β selective agonist that reduces biopsy component scores. As shown in a previous analysis of qSteatosis and qFibrosis in a Phase 2 serial liver biopsy study, reduction of collagen near steatosis associates with steatosis improvement in Zone 2. The aim of this analysis was to study the association between ballooning reduction and steatosis reduction in the resmetirom versus placebo group using second harmonic generation (SHG)/two-photon excited fluorescence (TPEF) microscopy imaging of paired biopsy samples with artificial intelligence (AI)-based algorithms. **Methods:** 102 paired biopsy samples from a 36-week, randomized, double-blind, placebo-controlled Phase 2 study with resmetirom (NCT02912260) were imaged using SHG/TPEF. Ballooning and steatosis were estimated as a continuous variable using an AI-based algorithm. Resmetirom-mediated changes of ballooning in relation to steatosis reduction were evaluated by simultaneous measurement of ballooning and hepatic fat in selected areas around the fat vacuoles in liver regions: portal tract (Zone 1), central vein (Zone 3), and transitional (Zone 2). **Results:** In patients who showed a reduction in steatosis grade, resmetirom-treated patients (n = 38) showed a decrease in percentage area of steatosis according to qSteatosis across all 3 zones with significance observed in Zone 1 and 2; as compared to placebo-treated patients (n = 13) who only showed significance in Zone 2. Concomitant analysis of ballooning around the steatosis revealed some ballooning reduction in Zones 1 and 2 for the placebo group, but these were not statistically significant. The resmetirom group clearly showed a significant ballooning reduction across all zones with significance in Zones 1 and 2. A relative decrease of 55% for percentage area of steatosis was associated with a relative decrease of 83% for percentage area of ballooning near steatosis in Zone 2 ($p < 0.01$). Similar observation of concomitant reduction in ballooning (85%) near steatosis (57%) was seen for Zone 3 too ($p < 0.01$). **Conclusion:** Qualitatively, a clear difference can be seen in the pattern of co-localization analysis of steatosis and ballooning in resmetirom-treated patients versus placebo-treated patients. The use of a continuous variable (qBallooning, qSteatosis) provides quantitation of zonal changes in ballooning and steatosis in serial liver biopsy studies which cannot be captured using the NASH CRN system.

Figure: Steatosis and ballooning co-localization plots for resmetirom-treated (right) versus placebo-treated groups (left) in patients whose steatosis reduced from baseline to end-of-treatment.



SHG/TPEF image showing co-localization of ballooned hepatocytes (pink) in close proximity to steatotic vacuoles (blue) versus ballooned hepatocytes (white) further away from steatotic vacuoles.

2014-A | ASSOCIATION BETWEEN RENAL FUNCTION AND NONALCOHOLIC STEATOHEPATITIS (NASH) SEVERITY: COMBINED DATA FROM MULTIPLE THERAPEUTIC TRIALS INCLUDING MORE THAN 6,000 PATIENTS (IN COLLABORATION WITH NAIL-NIT CONSORTIUM)

Stephen A Harrison[1], Julie Dubourg[2], Sophie Jeannin[2], Naim Alkhouri[3], Jörn M. Schattenberg[4] and Mazen Noureddin[5], (1)Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom, (2) Summit Clinical Research, San Antonio, TX, (3)Arizona Liver Health, Phoenix, AZ, (4)I. Department of Medicine, University Medical Centre Mainz, Johannes Gutenberg University, Mainz, Germany, Mainz, Germany, (5) Houston Research Institute, Houston, TX

Background: Previous reports have identified an association between chronic kidney disease (CKD) and nonalcoholic fatty liver disease (NAFLD). The prevalence and incidence of these two chronic conditions are rapidly increasing worldwide. Both conditions share cardiometabolic comorbidities including type 2 diabetes, obesity, hypertension, and metabolic syndrome. We aimed to assess the association between non-invasive biomarkers of fibrosis and NASH with renal function. **Methods:** We combined screening data from 8 NAFLD/NASH non-cirrhotic phase 2 trials. Estimated glomerular filtration rate (eGFR) was used as a marker of renal function with 5 categories (G1 **e** 90; G2 60-89; G3a: 45-59; G3b: 30-44; G4: 15-29; G5 < 15) where CKD is defined by eGFR < 60 mL/min/1.73m^2. We performed univariate linear regression analyses to describe the potential associations between noninvasive biomarkers and renal function. **Results:** Out of 6,558 patients, 5,343 with eGFR and non-invasive biomarkers data were included. Due to the clinical trials settings most patients were G1 (64%) or G2 (32%). A small proportion of patients were G3a (3%), G3b (< 1%) or G4 (< 1%). Liver biopsies were performed in 2,185 of these patients. Among patients without CKD, 59%, 40% and 32% had NASH, at-risk NASH (NASH + NAS **e** 4 + Fibrosis Stages 2 or 3), and advanced fibrosis (Fibrosis stages 3 or 4), respectively. This rises to 66%, 49% and 42% in patients with CKD. In univariate regression analysis, Fib-4 ($p < 0.001$, Figure), FibroScan liver stiffness measurement (LSM) ($p < 0.001$), AST ($p < 0.001$), ALT ($p < 0.001$) and type 2 diabetes ($p < 0.001$) were significantly associated with eGFR. **Conclusion:** A decrease in renal function is associated with higher NASH severity based both on non-invasive biomarkers and liver biopsy. Considering the low representation of CKD patients in this clinical trial population, further analyses are required to further confirm and explore this association. Enrichment with CKD population could be considered to help mitigate the high liver biopsy screen failure rate observed in NASH clinical trials.

Background: Early identification of those with NAFLD activity score **e** 4 (with at least 1 for steatosis, lobular inflammation, and ballooning) and significant fibrosis or "at-risk NASH" is a priority as these patients are at increased risk for disease progression and may benefit from therapies. Here we aim to study whether the MASEF score could be used alternatively to liver stiffness measurements (LSM) by transient elastography (VCTE) in the FIB-4+LSM by VCTE algorithm that is currently recommended by several guidance publications. **Methods:** This study included 310 participants that had undergone liver biopsy, LSM by VCT and MASEF score analysis. MASEF score is a highly specific metabolomics-driven score to identify at-risk NASH based on 12 lipids, body mass index, aspartate aminotransferase and alanine aminotransferase. We compared the performance of a FIB-4+MASEF algorithm to that of FIB-4+LSM by VCTE. **Results:** 133 (43%) of 310 patients had FIB-4 < 1.30 and were classified as low risk of having at-risk NASH, 37 (12%) of 310 patients had FIB-4 > 2.67 and were classified as high risk, and 140 (45%) of 310 were classified into the indeterminate or grey zone and then were further analyzed by MASEF score or LSM by VCTE. When using MASEF as the second test after FIB-4, 14% of patients had MASEF < 0.258 and were classified as not at-risk NASH, 41% had MASEF > 0.513 and were classified as at-risk NASH, and 45% fell into the indeterminate zone. Among patients with MASEF < 0.258, 79% were correctly classified and only 4 (21%) were misclassified (NAS **e** 4 with **e** F2). Among patients with MASEF > 0.513, 37 (65%) were correctly classified, and 20 (35%) were misclassified. When using LSM by VCTE as the second test after FIB-4, 25% of patients had LSM < 8 kPa and were classified as not at-risk NASH, 38% had LSM > 12 kPa and were classified as at-risk NASH, and 36% fell into the grey zone. Among patients with LSM < 8 kPa, 67% were correctly classified and 12 (33%) were misclassified. Among patients with LSM > 12 kPa, 32 (60%) were correctly classified, and 21 (39%) were misclassified. Complete classifications are shown in the table. The overall performance of both algorithms when using MASEF score or LSM by VCTE as the second test after FIB-4 did not show significant differences (p = 0.69). **Conclusion:** MASEF is a promising diagnostic tool for the assessment of at-risk NASH that can be used alternatively to LSM by VCTE in the FIB-4+LSM by VCTE algorithm that is currently recommended by the AGA and EASL.

2016-A | AUTOMATED AI-BASED MORPHOMETRIC ANALYSIS OF FIBROSIS REVEALS SIGNIFICANT FIBROSIS CHANGES IN T2DM VS NON-T2DM NASH PATIENTS WITH ADVANCED FIBROSIS

Cindy Serdjebi, Bastien Lepoivre, Florine Chandes and Yvon Jule, Biocellvia

Background: Non-alcoholic steatohepatitis (NASH) is the most severe form of fatty liver diseases. Type 2 diabetes mellitus (T2DM) is known as a major risk factor for fibrosis development, and drugs currently under development in NASH address both heath issues, with no drug approved so far. Knowing T2DM patients are at high-risk of severe fibrosis, we have compared fibrosis stages and characteristics of NASH patients according their T2DM status using MorphoQuant, a fully-automated user-independent morphometric software. **Methods:** 107 patients were enrolled in this study. Both untreated and treated patients for T2DM were considered as T2DM patients. Liver biopsies were scored by a blinded expert pathologist according to the NASH CRN for steatosis, inflammation, ballooning and fibrosis. Patients were considered NASH if NAS **e** 4. For MorphoQuant™ analysis, picrosirius red (PSR)-stained slides were prepared and scanned at X20 magnification. Steatosis, vesicle size, total collagen, periductular, perisinusoidal, perivascular and septal collagens, as well as collagen fiber width and length were assessed. TD2M and non-T2DM patients were compared for all readouts using a Mann-Whitney test. **Results:** Among the 107 patients, 53 patients had T2DM. Neither difference was seen in fibrosis stage distribution between T2DM and not-T2DM NASH patients, nor for steatosis, inflammation, and ballooning grades. When overall comparing TD2M versus non-T2DM NASH patients according to their fibrosis stage, nond ifference was seen for fibrosis-related endpoints and steatosis. Interestingly, in NASH patients with F3 stage, TD2M patients had significantly less steatosis, and more fibrosis, expressed as collagen content (p-values = 0.0075 and 0.0164, respectively). When looking at fibrosis distribution and features, TD2M patients had more perivascular and septal collagen than non-T2DM patients (p-values = 0.0145 and 0.006, respectively), their mean septa length was longer (0.036), as well as their maximal septa length and width (0.035 and 0.028). No changed was observed for perisinusoidal fibrosis, or for F1-F2 NASH patients. **Conclusion:** F3 T2DM NASH patients display significantly different features from F3 non-T2DM patients. These differences could be only captured using morphometric digital analysis of NASH and fibrosis features. Particularly, fibrosis was more developed and differently distributed between non-T2DM and T2DM patients. Such findings are in alignment with longer history of liver injury and more advanced fibrosis in T2DM patients and show the limitations of using scores for patient's risk stratification.

2017-A | BMI50+-FIBROSIS SCORE – A NEW NON-INVASIVE TEST FOR LIVER FIBROSIS IN PATIENTS WITH OBESITY AND A BMI > 50 KG/mβ

Maximilian Joseph Brol[1], Uta Drebber[2], Xiaojie Yu[2], Robert Schierwagen[1], Sabine Klein[1], Andreas Plamper[3], Margarete Odenthal[2], Wenyi Gu[1], Frank Erhard Uschner[1], Karl Peter Rheinwalt[3] and Jonel Trebicka[1,4], (1)University Hospital Münster, (2) University Hospital of Cologne, (3)St. Franziskus-Hospital Cologne, (4)European Foundation for the Study of Chronic Liver Failure and Grifols Chair, Barcelona, Spain

Background: Liver fibrosis is a hallmark of chronic liver disease. Especially in non-alcoholic fatty liver disease (NAFLD), awareness of liver fibrosis is key for patient stratification and planning of follow-up care. Current non-invasive tests (NIT) for liver fibrosis show poor performance in patients with obesity and to date no NIT

was validated in the rapidly growing cohort of patients with clinically severe obesity, defined by a body mass index (BMI) over 50 kg/m². **Methods:** In this prospective, single-center cohort study, 95 patients scheduled for bariatric surgery were included (liver disease no other than NAFLD, BMI > 50 kg/m²). Liver biopsies were performed during surgery. Liver fibrosis was histologically determined according to Kleiner. AST-to-platelet ratio index (APRI), Fibrosis-4 score (FIB-4), NAFLD fibrosis score (NFS) and BMI, AST/ALT-ratio and diabetes score (BARD) with standard and optimized thresholds, determined by maximum Youden-Index, were calculated. Accuracy, sensitivity, specificity, negative predictive value (NPV) and positive predictive value (PPV) were calculated for each NIT. Multiple regression analysis of clinical variables were used to identify predictive factors in our cohort. **Results:** Commonly used NITs showed weak prediction of liver fibrosis in our cohort, with area under the receiver operating characteristic curve (AUROC) of .70. ANOVA analyses identified five variables (presence of dyslipidemia, presence of diabetes, serum levels of ALT, AST and creatinine) significantly differing among stage of fibrosis. This resulted through multiple regression in the BMI50+-Fibrosis score (BMI50+) with an AUROC of .79. Sensitivity was 0.4 for APRI, 0.49 for FIB-4, 0.73 for NFS, 0.64 for BARD and 0.74 for BMI50+. Specificity was 0.93 for APRI, 0.71 for FIB-4, 0.57 for NFS, 0.43 for BARD and 0.79 for BMI50+. Accuracy in predicting fibrosis for established NITs ranged between 48 - 71%. Our score had the best accuracy (75% correctly classified patients) and best NPV for prediction of any degree of fibrosis. **Conclusion:** Performance of established NITs is weak in patients with a BMI over 50 kg/m². The BMI50+-Fibrosis score is a useful tool for this setting. A prospective evaluation of our score should be done in further studies.

2018-A | CELL FREE MESSENGER RNA PROFILES INDICATIVE OF SHARED PATHOLOGY BETWEEN NON-ALCOHOLIC FATTY LIVER DISEASE AND ALZHEIMER'S DISEASE

Naga P. Chalasani[1], Shusuke Toden[2], Rhys De Sota[2] and John J Sninsky[2], (1)Indiana University School of Medicine, (2)Molecular Stethoscope

Background: Emerging evidence indicates that non-alcoholic fatty liver disease (NAFLD) is associated with increased rates of dementia and poor cognitive performance. Cell-free RNA carriers in blood are expected to be involved in intercellular communication and provide signals of disrupted cellular homeostasis. We reported development of cell-free messenger RNA sequencing (cf-mRNA RNA-Seq) machine learning assays for NAFLD and Alzheimer's Disease (AD). Here we interrogated genes and pathways that are dysregulated in common for NAFLD and AD cell-free secretome. **Methods:** Cf-mRNA RNA-Seq was performed on 441 serum and plasma samples from NAFLD (176 NAFLD vs 23 healthy controls) and AD (126 AD vs 116 non cognitively impaired (NCI)) studies. Tissue-specific cf-mRNA content was evaluated using GTEx. Independent differential expression analysis was performed using DE-Seq2 and pathway analysis (GO, Reactome and KEGG) was conducted using differentially expressed genes in the studies. We evaluated genes that are dysregulated in both AD and NAFLD and validated these cf-mRNA genes in a tissue sequencing dataset. **Results:** Differentially expressed genes in cf-mRNA between NAFLD and healthy controls (2498 genes) as well as between AD and NCI (2591 genes) were identified. 296 genes were commonly dysregulated in both AD and NAFLD (198 up- and 98-downregulated). Pathway analysis revealed that Rho GTPase signaling pathway was the most dysregulated pathway for genes that are dysregulated in both diseases. Key dysregulated genes in AD in this pathway for cf-mRNA include RHOA, RAC1, ROCK1 and ROCK2. We confirmed dysregulation of a subset of Rho GTPase genes from a prior study of brain tissue. Furthermore, plasma cf-mRNA APOE expression was inversely correlated with plasma cf-mRNA RHOA expression. Finally, we identified dysregulation of other therapeutically targetable gene pathways for NAFLD and AD, such as GLP-1. **Conclusion:** Insight into

common dysregulated genes and pathways in the extracellular compartment of disparate diseases potentially can inform the repurposing of pharmacotherapies. We identified cf-mRNA genes that are dysregulated in both AD and NAFLD, in particular, Rho GTPase signaling genes. Rho GTPase signaling pathway is currently being targeted by pharmacotherapies such as statins for both NAFLD/NASH and AD. Besides the pharmacotherapies already being considered for these two diseases, our study may provide insight into other pathways that merit consideration.

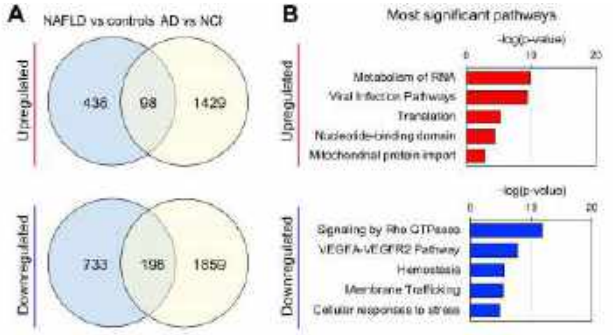

Figure 1: Identification of cf-mRNA dysregulated genes between NAFLD and AD. A) Overlap of genes between NAFLD vs controls, AD vs NCI (Upregulated genes (top), Downregulated genes (bottom). B) Most significant pathways for genes that are upregulated in both NAFLD and AD (top) and downregulated in NAFLD and AD (bottom).

2019-A | CHARACTERIZATION OF EXTRACELLULAR VESICLES PROTEOME FROM HUMAN HEPATOCYTES, NASH ORGANOIDS AND BLOOD FROM NASH PATIENTS IDENTIFIES NOVEL POTENTIAL BIOMARKERS

Ola Leszczynska[1], Benedikt Kaufmann[1], Christian Stoess[1], Hana Sung[1], Andrea D. Kim[1], Agustina Reca[1], Trevor Crafts[2], Bruce Wolfe[2] and Ariel E. Feldstein[1], (1) University of California, San Diego, (2)Oregon Health and Science University, Portland

Background: Nonalcoholic fatty liver disease (NAFLD) is currently one of the most common forms of chronic liver disease globally. The lack of effective treatments for NASH and the current requirement for an invasive liver biopsy for its diagnosis makes the discovery of reliable, noninvasive biomarkers urgently needed. In this study, we aimed to investigate the protein profile of extracellular vesicle (EV) release by primary human hepatocytes and human organoids and compared their profiles to those of circulating EVs from patients with the spectrum of NAFLD. **Methods:** EVs from the serum of healthy (n = 4) and NASH (n = 33; fibrosis stage: F0 = 7, F1 = 7, F2 = 6, F3 = 12) subjects, EVs supernatants from normal primary human hepatocytes (PHH), and human liver organoids (HLO) cultured in normal or NASH media were characterized. Quantification of EV populations was determined via NanoView® chip analysis using established EV protein markers including CD9, CD81, CD63, and the ASGPR1-hepatocyte-specific marker. Additional characterization of EVs was performed via Cryo-EM and Western blotting. The multiplex aptamer-based protein array SOMAscan® platform was performed to establish the EV proteome. The top 40 most differentially expressed proteins in early NASH versus healthy controls and late NASH vs healthy controls were clustered using unsupervised complete linkage clustering. **Results:** The number of EVs derived from NASH stimulated PHHs and HLOs increased compared to those from healthy cultures, and were quantified for hepatocyte marker ASGPR1 (PHH: Healthy 9.2×10^5 vs NASH 4.51×10^6 p **d** 0.001; HLO: Healthy 7.4×10^5 vs NASH 6.14×10^6 p **d** 0.0001) and tetraspanins markers CD9 (PHH: Healthy 1.71×10^8 vs NASH 1.76×10^8, p **d** 0.05), CD63 (PHH: Healthy 1.79×10^8 vs NASH 1.87×10^8; HLO: Healthy 7.7×10^7 vs NASH 1.45×10^8, p **d** 0.05), and CD81 (PHH: Healthy 1.9×10^8 vs NASH 1.95×10^8, p **d** 0.05; HLO: Healthy 3.2×10^8 vs NASH 4.1×10^8, p **d** 0.001). Cryo-EM confirmed the EV ultrastructure and showed no specific changes in EV morphological features present among study groups. The average size of circulating EV did not differ between NASH and healthy control samples. Differential protein expression datasets were analyzed between various groups as depicted in Table 1. **Conclusion:** In this report, we have characterized the EV proteome from supernatants of primary human hepatocytes, human liver organoids, and blood samples of patients with NASH allowing for the identification of novel cell-type specific and disease-related biomarkers.

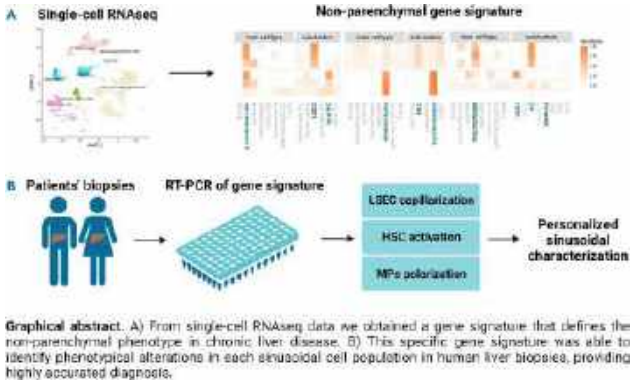
2020-A | CHARACTERIZATION OF RELEVANT HEPATIC SINUSOIDAL CELL POPULATIONS IN HUMAN CHRONIC LIVER DISEASE: FROM SINGLE-CELL DATA TO PERSONALIZED MEDICINE

Sergi Guixé-Muntet[1], Anabel Fernandez-Iglesias[1], David Sanfeliu-Redondo[1] and Jordi Gracia-Sancho[1,2], (1)Idibaps - Hospital Clínic Barcelona - Ciberehd, Barcelona, Spain, (2)Inselspital - University of Bern, Bern, Switzerland

Background: Transcriptomic data from hepatic tissue mainly represents the most abundant cell types in the liver and masks smaller cell subpopulations, such as non-parenchymal cells (liver sinusoidal endothelial cells, LSECs; hepatic stellate cells, HSC; and macrophages, MP), with high interest for the study of chronic liver diseases (CLD). Single-cell sequencing allows for finer analyses, but its implementation for routine patient care is nowadays unrealistic. The aim of this study was to propose an unbiased single-cell RNA seq-derived gene panel that could reliably define the state of the liver sinusoid in health and disease. **Methods:** We reanalyzed published data from liver sc-RNAseq and generated signature matrices with specific genes for each of the non-parenchymal cells populations. These matrices were used on our RNAseq data from human livers to estimate the changes in sinusoidal cells subpopulations (healthy vs activated / dedifferentiated populations) in CLD. Validations were performed with standard RT-PCR. **Results:** Gene deconvolution from decompensated cirrhotic livers (ethanol, $n = 12$) showed significant increments in capillarized LSECs ($FC = 5.7$), activated HSC ($FC = 1.8$), and fiber-associated MP ($FC = 4.9$) vs control tissues, which were validated in an external cohort of patients with NASH ($n = 39$, GSE139602). 6 genes per cell type (LSEC, HSC, MP) were chosen as the most specific (95% expression vs other hepatic cell types) and the differential expression of said genes was validated by RT-PCR in an internal cohort ($n = 19$ control, $n = 36$ cirrhosis, $p < 0.05$) and in an external cohort of 216 patients with NAFLD-NASH (GSE135251) with different METAVIR stages (control, NAFLD and NASH F0 to F4). Importantly, our panel was able to discriminate samples from early vs advanced CLD patients with an accuracy of 96% and 80%, respectively, and predicted endothelial capillarization ($r = 0.90$, $p < 0.001$), HSC activation ($r = 0.77$, $p < 0.001$) and macrophage polarization ($r = 0.79$, $p < 0.001$). **Conclusion:** This unbiassed gene panel, resulting from an advanced re-analysis of available data, can be easily assessed by accessible techniques (RT-PCR) and allows the characterization of sinusoidal cells phenotype in human liver tissue. This gene signature could be a useful tool for personalized clinical decision making, aiding in the diagnosis, assessment of drug response or in choosing the most relevant cell target for therapy for an individual patient.



Graphical abstract. A) From single-cell RNAseq data we obtained a gene signature that defines the non-parenchymal phenotype in chronic liver disease. B) This specific gene signature was able to identify phenotypical alterations in each sinusoidal cell population in human liver biopsies, providing highly accurated diagnosis.

Background: Skeletal muscle (SM) dystrophy and myosteatosis are emerging as hallmark manifestations of chronic liver disease (CLD). These alterations in body composition could have marked implications for functional status that would render these patients vulnerable to physiological stressors. The aim of this study was to characterize SM quantity, quality and function in patients with CLD. **Methods:** In this prospective cohort study, 21 patients with CLD (Age 57 ± 11; Female 76%: Black 14%) underwent an 8-minute full-body 3.0 T MRI to provide a comprehensive and quantitative SM composition analysis using AMRA® Researcher. SM quality was determined by isometric knee extensor strength assessed by dynamometry. A battery of physical function tests was performed to assess speed and agility, lower body functional strength and aerobic capacity. Frailty status was determined according to the Fried criteria. Participants also completed an assessment of mitochondrial oxidative capacity of the wrist flexor muscle group. Near infrared spectroscopy coupled with repeated, transient arterial occlusions were used to measure the recovery kinetics of oxygen consumption following a bout of hand grip exercise. The post-exercise metabolic recovery rate constant (T_c) was calculated and reported as an index of mitochondrial plasticity. **Results:** Patients with lower muscle mass had reduced knee extensor strength ($r = 0.50$, $p < 0.05$), worse functional agility ($r = 0.58$, $p < 0.01$) and impaired lower body functional strength ($r = 0.61$, $p < 0.01$). Patients with higher muscle fat infiltration (MFI) had reduced knee extensor strength ($r = -0.70$, $p < 0.01$), worse functional agility ($r = -0.64$, $p < 0.01$), impaired lower body functional strength ($r = -0.44$, $p < 0.01$) and lower aerobic capacity ($r = -0.74$, $p < 0.01$). Frail patients had significantly higher mean MFI (8.9 ± 1.2%) compared to pre-frail patients (6.4 ± 0.5%; $p < 0.05$). This cohort of patients with CLD had significantly diminished SM mitochondrial oxidative capacity (T_c: 75 ± 7 s) compared to healthy controls (52 ± 4 s; $p < 0.05$) indicating diminished SM mitochondrial function. **Conclusion:** These findings provide foundational data demonstrating the association between muscle composition (quantity and quality) and functional status in patients with CLD. Moreover, patients demonstrate worse SM mitochondrial plasticity compared to their healthy counterparts. These findings could facilitate the development of biologically relevant biomarkers, risk stratification and therapeutic options.

2022-A | CHKA AND MBOAT7 AS POTENTIAL TARGETS FOR MAFLD-HCC WITH EARLY STAGE OF FIBROSIS: REVEALED BY METABOLOMICS AND TRANSCRIPTOMIC ANALYSIS

Jihan Sun[1], Fatima Dahboul[1], Estelle Pujos-Guillot[2], Stéphanie Durand[2], Mélanie Petera[2], Delphine Centeno[2], Benoit Colsch[3], Zoulim Guillaume[4], Aicha Demidem[5] and Armando Abergel[6], (1)Université Clermont Auvergne, (2)Inrae-UNH, (3)CEA-Paris Saclay, (4)UNH-1019, (5)UNH, (6)CHU-Clermont Ferrand

Background: Metabolic dysfunction Associated Fatty Liver Disease (MAFLD) is increasingly recognized as a major health burden in developed countries. It can eventually progress to HCC and up to 25% of MAFLD-HCC arise in the absence of severe liver fibrosis, posing a challenge for early detection and treatment (De A et al., 2020, J clin Exp Hepatol). We previously reported the existence of 2 phenotypes of MAFLD-HCC by metabolomics analysis according to fibrosis level (F0F1 *vs.* F3F4) (Buchard et al., 2021, Metabolites, Buchard et al., 2021, AASLD Hepatology). The aim of our current study is to explore lipid pathways and identify potential biomarkers related to MAFLD-HCC. **Methods:** Fifty-six pairs (F0F1 = 28, F3F4 = 28) of human MAFLD-HCC (TT) and non-tumor tissues (NTT) and five healthy tissues were collected from CRB. Foie. A non-targeted metabolomics strategy was applied using LC-MS. Based on the results of LC-MS, qRT-PCR regarding sphingomyelin synthase 2 (SGMS2), sphingomyelin phosphodiesterase 1 (SMPD1), choline Kinase alpha (CHKA) and membrane-bound O-acyltransferase 7 (MBOAT7) was performed. **Results:** Firstly, LC-MS analysis shown that the comparison between the two groups of MAFLD-TT and MAFLD-NTT revealed the presence of two different lipids profiles according to the fibrosis severity (F0F1 *vs.* F3F4). Most of sphingolipids including ceramides (Cer) and sphingomyelins (SM), and glycerophospholipids, including phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylinositol (PI) were increased in MAFLD-HCC-F0F1 while they decreased in MAFLD-HCC-F3F4 (Fig. 1A). Secondly, the results of qRT-PCR indicated that the RNA expression of SGMS2, SMPD1 remain unchanged in MAFLD-TT compared with NTT, regardless of fibrosis level. In contrast, the RNA expression of CHKA and MBOAT7 were exclusively up-regulated in MAFLD-TT-F0F1 compared to NTT-F0F1 using healthy tissues as control (Fig. 1B). These results were in accordance with our metabolomics data that have shown that PC content were highly accumulated in

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

MAFLD-TT-F0F1. **Conclusion:** Metabolomics and transcriptomic analysis allow us to discriminate MAFLD-HCC according to fibrosis severity. Our findings identified that CHKA and MBOAT7 could be proposed as biomarkers to MAFLD-HCC patients without or with low level of fibrosis. In addition, the different expression of CHKA support the idea that choline could be used as a more efficient tracer of PET-scan in MAFLD-HCC patients.

2023-A | CIRCULATING HEPATIC EXOSOMAL miR122 AS A BIOMARKER OF NAFLD/NASH ACTIVITY

Susan D Rouster, Carrie Jennings and Kenneth E Sherman, University of Cincinnati

Background: NAFLD/NASH is an important contributor to liver-related morbidity and mortality. There is a need for new biomarkers to define disease activity and disease stage. Hepatic exosomes or extracellular vesicles are lipid products of cell membranes. Isolation and evaluation of circulating hepatic microRNAs such as miR122 enveloped by exosomes may provide non-invasive measures to better assess disease and effect of treatment interventions. **Methods:** Serum samples from an IRB approved biorepository at the University of Cincinnati were utilized for this analysis. Clinical data and samples were available for both participants with NAFLD/NASH (NA) and healthy controls (HC). Hepatic exosomal RNA was isolated from serum using the Qiagen (Germantown, MD) miRNeasy Serum Advanced kit, with RNA spike-ins to monitor RNA isolation quality. RNA was then subjected to reverse transcription using the miRCURY LNA RT kit, including additional synthetic spike-ins to monitor cDNA synthesis and presence of inhibition. The resulting cDNA template was then amplified by qPCR using the Qiagen miRCURY LNA SYBR Green kit and miRNA PCR assays for each target (spike-ins, reference miRNA (*C. eleg* miR39), and liver-specific miRNA 122). Relative expression was determined using the $2^{-\Delta\Delta CT}$ method compared to the reference miRNA and reported as fold change from the HC group. **Results:** The study set included 27 participants with NAFLD/NASH and 8 healthy controls. The mean age of NAFLD/NASH participants was 56 years and mean age of HC was 44 years. Most participants were white, non-Hispanic (94%) and female (69%). The NA subjects had a mean BMI of 35.2, and an ALT of 47.8 U/L. The mean NASH Fibrosis Score (NFS) was 0.30. The mean hepatic exosomal miR122 fold change among NA was 17.6 (range 0.02 to 198.97) compared to HC. (ANOVA $<$ 0.05, One-tailed test). A linear regression model was utilized to explore factors associated with miR122 from hepatic exosomes, and yielded an $R^2 = 0.62$. ALT and AST were highly associated with exosomal miR122. BMI, FIB4, race, age, and gender were not significant factors in the model. Subjects with F3 liver fibrosis had a 43.1-fold increase in exosomal miR122 while F4 cirrhotic patients had only a 3.78 increase over the index controls. **Conclusion:** Exosomal miR122 may represent NAFLD/NASH inflammatory activity which declines once cirrhosis is established. Further exploration of this biomarker in defining disease activity may help identify candidates for therapeutic interventions that target the active necroinflammatory process.

2024-A | CIRCULATING SHORT-CHAIN FATTY ACIDS AND SEVERITY OF THE NON-ALCOHOLIC FATTY LIVER DISEASE IN PATIENTS WITH TYPE 2 DIABETES MELLITUS

Chia-Yen Dai[1], Wei-Wen Hung[2], Hui-Ju Tsai[2,3], Wei-Chun Hung[3] and Yi-Chun Tsai[2,3], (1)Kaohsiung Medical University Hospital, Kaohsiung Medical University, (2) Kaohsiung Medical University Hospital, (3)Kaohsiung Medical University

Background: Non-alcoholic fatty liver disease (NAFLD) is a major global health concern. The increasing prevalence of NAFLD has been related to type 2 diabetes mellitus (T2D). The gut microbiota has frequently been linked to metabolic diseases such as NAFLD, diabetes, and obesity, and dysregulation of the intestinal microbiota (gut dysbiosis) can cause NAFLD. Short-chain fatty acids (SCFAs) are volatile fatty acids produced by intestinal bacteria to metabolize dietary fiber which involve glucose metabolism, insulin sensitivity, and lipogenesis through diverse pathways, thereby affecting the development of diabetes and obesity. The relationship between short-chain fatty acids (SCFAs) and NAFLD severity is ambiguous in T2D subjects. This study aimed to explore the association between SCFAs with the severity of NAFLD in T2D patients in Taiwan. **Methods:** We employed echography to examine the severity of hepatic steatosis. The serum levels of 9 SCFAs, namely formate, acetate, propionate, butyrate, isobutyrate, methylbutyrate, valerate, isovalerate and methylvalerate were measured using liquid chromatography mass spectrometry (LC-MS). Demographic data including the history of tobacco smoking, alcohol consumption and clinical data were collected through interviews and medical records at enrollment. **Results:** A total of 259 T2D patients (mean age: 61.4 ± 10.6 years; ranged from 25.4 to 88.1 years; 142 had no or mild NAFLD, and 117 had moderate to severe NAFLD) was enrolled in this cross-sectional study. The participants with moderate to severe NAFLD had lower levels of formate, isobutyrate and methylbutyrate than the those who without NAFLD or with mild NAFLD. Lower circulating levels of isobutyrate and methylbutyrate were associated with an increased severity of NAFLD. After adjusting for age, BMI **e** 27 kg/m2, T2D duration, Hb, GOT, GPT, log-formed TG, metformin usage, habit of smoking, alcohol drinking, history of hypertension, gout, and hyperlipidemia, the patients with low levels of circulating isobutyrate (odds ratio (OR): 0.17, 95% confidence index (CI): 0.03-0.86) and methylbutyrate (OR: 0.25, 95% CI: 0.08-0.76) levels had an increased risk of moderate to severe NAFLD. Negative correlations between circulating isobutyrate and methylbutyrate levels and the severity of NAFLD were found in men but not in women. In addition, a negative correlation between NAFLD severity with circulating isobutyrate and methylbutyrate levels was found independently of a glycated hemoglobin (HbA1C) level of 7.0%. **Conclusion:** Circulating levels of isobutyrate and methylbutyrate were significantly and negatively correlated with NAFLD severity in the enrolled T2D patients. SCFAs may be related to NAFLD severity in T2D patients.

2025-A | CLINICAL UTILITY OF LIVER AND SPLEEN ELASTOGRAPHY IN THE MANAGEMENT OF PATIENTS LIVING WITH LIVER DISEASE

Carmen Lara Romero[1], Maria Del Barrio[2], Maria Del Carmen Rico[1] and Manuel Romero-Gómez[3], (1) Hospital Universitario Virgen Del Rocio, (2)Hopsital Universitario Marqués De Valdecilla, (3)Ucm Digestive Diseases, Virgen Del Rocio University Hospital, Instituto De Biomedicina De Sevilla, Ciberehd, University of Seville, Sevilla, Spain

Background: Portal hypertension (PH) is responsible for the progression of liver diseases and the development of complications. In patients with liver elastography < 10 kPa, advanced liver disease is ruled out according to Baveno VII consensus. Aims: a) To analyze the prevalence of portal hypertension and porto-sinusoidal vascular disease (PSVD) in patients with liver disease; b) Identify non-invasive parameters of suspicion of PSVD and/or hidden PH; c) Assess the clinical impact of the presence of elevated spleen stiffness in the development of complications. **Methods:** Prospective cohort of 276 consecutive patients seen in a hepatology consultation who underwent liver and splenic transient elastography (Fibroscan 630, Echosens, France). Thresholds for advanced disease were spleen stiffness measurement (SSM) > 45 kPa and Liver stiffness measurements (LSM) > 10kPa. It was evaluated: hepatic, renal, metabolic function, concomitant treatment, ultrasound, endoscopy, liver

histology and portal hemodynamic. Statistical analysis: t-student, ANOVA, Chi-square, Spearman's coefficient, U-Mann-Whitney, Wilcoxon, logistic regression, and linear correlation. **Results:** SSM > 45kPa in 23 cases of 154 with LSM < 10kPa (14.9%) versus 56 of 122 with LSM > 10kPa (45.9%); p < 0.001). The predictive parameters of SSM > 45 kPa in patients with LSM < 10 kPa are collected in the table (platelets, INR, Child-Pugh and MELD3.0). In the multivariate analysis, the platelet count and MELD 3.0 were independently related to SSM > 45kPa and LSM < 10kPa. The rate of decompensation (hepatic encephalopathy, ascites, or variceal bleeding) was 1.5% in patients with LSM < 10 kPa and SSM < 45kPa (2/131), versus 13% (3/23) in patients with LSM < 10kPa and SSM > 45kPa, 15.4% (10/65) in patients with LSM > 10kPa and SSM < 45kPa and 44% (24/54) in patients with LSM > 10kPa and SSM > 45kPa; p < 0. 0001. **Conclusion:** The SSM can detect up to 15% of cases of occult PH/PSVD in patients with LSM < 10kPa and SSM > 45kPa. In patients with LSM < 10kPa, a decrease in platelet count or an increase in MELD 3.0 should lead to suspicion of PH. The presence of altered SSM is associated with an increased risk of liver events. The implementation of SSM will improve the management of patients with liver disease.

	Univariate analysis			Multivariate analysis	
Variable	SSM≤45kPa (n=129)	SSM>45kPa (n=23)	p	HR (IC95%)	p
Platelets	240±83	173±112	<0,001	0,982 (0,973-0,991)	p=0,008
INR	0,99±0,18	1,13±0,29	<0,073		
MELD 3.0	6,93±0,98	8,75±2,93	<0,055	1,335 (1,002-1,778)	p=0,048
Child-Pugh	5,0±0,0	5,75±1,36	<0,082

2026-A | COMBINED HEPATIC AND ADIPOSE TISSUE TRANSCRIPTOMICS HIGHLIGHTS CIRCULATING NASH BIOMARKERS

Marica Meroni[1], Emilia Rita De Caro[1], Federica Chiappori[2], Miriam Longo[3], Erika Paolini[4], Ettore Mosca[2], Ivan Merelli[2], Rosa Lombardi[5], Sara Badiali[1], Marco Maggioni[6], Alessandro Orro[2], Alessandra Mezzelani[2], Luca Valenti[7], Anna Ludovica Fracanzani[5] and Paola Dongiovanni[6], (1)Fondazione Irccs Cà Granda Ospedale Maggiore Policlinico Milano (ITALY), (2)National Research Council (ITB-CNR), 20054 Segrate, Italy, (3)Fondazione Italiana Fegato, (4) Fondazione Irccs Cà Granda Ospedale Maggiore Policlinico, Milan, Italy., Milano, MI, Italy, (5)Università Degli Studi Di Milano, (6)Fondazione Irccs Cà Granda Ospedale Maggiore Policlinico, (7)Department of Transfusion Medicine and Haematology, Fondazione Irccs Ca' Granda Ospedale Maggiore Policlinico

Background: Obesity represents the main contributor to nonalcoholic fatty liver disease (NAFLD) and adipose tissue is strongly interlaced with the liver in the disease pathogenesis and progression. Previous studies were restricted to investigate the hepatic transcriptome across the entire spectrum of NAFLD, whereas the transcriptomic changes which occur in visceral adipose tissue (VAT) in relation to liver damage have been poorly investigated. Therefore, we aimed to compare hepatic and VAT transcriptome in NAFLD patients with the purpose to identify shared gene pathways and biomarkers useful for the diagnosis of advanced liver damage. **Methods:** We performed high-throughput RNA-sequencing in 167 hepatic samples from and in a subset of 79 matched adipose tissues, isolated from obese individual's who underwent bariatric surgery. Patients were subdivided in normal liver, mild and severe NAFLD, according to histology and NAFLD activity score (NAS). Circulating cathepsin D (CTSD), a marker of autophagy-lysosomal pathway was assessed by ELISA in serum samples collected at the time of the biopsy. **Results:** We identified a specific transcriptomic signature that may discriminate patients with mild and severe NAFLD, including 424 deregulated genes in liver and 209 in VAT. According to pathway and network analyses, inflammation, ECM remodeling and mitochondrial dysfunction were upregulated whereas oxidative phosphorylation was downregulated in both tissues. We highlighted 13 genes commonly deregulated in both tissues and among them, CTSD showed the most robust diagnostic accuracy in discriminating mild and severe NAFLD. In 52 of 167 obese subjects and in a validation cohort of 432 histologically-characterized NAFLD patients, increased serum CTSD was associated with steatosis, inflammation, steatohepatitis (NASH), fibrosis and NAS > 5. The area under the curve (AUC) adjusted for transaminases to foresee severe NAFLD *versus* mild and normal liver was 0.78 and 0.87, respectively. **Conclusion:** CTSD may be a possible biomarker of severe NAFLD since its hepatic/adipose tissue expression as well as circulating levels correlated with liver damage thus allowing to discriminate advanced disease.

Serum cathepsin D (CTSD) as possible biomarker to detect severe NAFLD. CTSD expression is stratified according to the severity of NAFLD in both liver (**A**) and adipose tissue (**B**). Boxes span from 25° to 75° percentile, while whiskers indicate the 10° and 90° percentile. Normal liver (CTRL) is plotted in red, mild in green, while Severe NAFLD in blue. CTSD serum concentration was evaluated in n=432 patients (Liver Clinic cohort) (**C**). $p<0.05$ at one-way ANOVA. ROC curves describe the accuracy of circulating CTSD (pg/mL) in foreseeing severe NAFLD from mild NAFLD (SvM) (**D**), obtained considering CTSD alone, or in a generalized linear model with transaminases (ALT and AST).

Disclosures: The following people have nothing to disclose: Marica Meroni, Emilia Rita De Caro, Federica Chiappori, Miriam Longo, Erika Paolini, Ettore Mosca, Ivan Merelli, Rosa Lombardi, Sara Badiali, Marco Maggioni, Alessandro Orro, Alessandra Mezzelani, Luca Valenti, Anna Ludovica Fracanzani, Paola Dongiovanni

2027-A | COMPARATIVE EFFICACY OF FIBROSIS-4, LIVER STIFFNESS MEASUREMENT, AND FIBROSCAN-AST SCORE TO PREDICT MAJOR LIVER-RELATED OUTCOMES IN NON-ALCOHOLIC FATTY LIVER DISEASE: AN INTERNATIONAL MULTICENTER STUDY

Yu JUN Wong[1,2], Esteban Urias[3], Michael W Song[4], Tanvi Goyal[3], Wei Xuan Tay[5], Nicole Xinrong Han[5], Jing Hong Loo[5], Tian Yu Qiu[5], Majd Aboona[6], Claire Faulkner[6], Karn Wijarnpreecha[7], Yiong Huak Chan[8] and Vincent Chen[9], (1)Department of Gastroenterology & Hepatology, Changi General Hospital, (2)Duke-Nus Medical School, Singhealth, (3)University of Michigan, (4)University of Michigan, Ann Arbor, (5)Changi General Hospital, (6)University of Arizona College of Medicine, Phoenix, AZ, (7)University of Arizona College of Medicine Phoenix, Phoenix, AZ, (8)Yong Loo Lin School of Medicine, National University of Singapore, Singapore, (9)University of Michigan Medical Center

Background: Non-invasive tests (NITs) such as FIB-4, liver stiffness measurement (LSM) by vibration controlled transient elastography (VCTE), and FibroscanAST (FAST) are frequently used for risk stratification in non-alcoholic fatty liver disease. However, when NITs yield discordant results, it remains unclear as to how such discrepancies should be interpreted. Furthermore, data on the impact of FAST score on the longitudinal outcomes of NAFLD patients remained unclear. We aim to evaluate the comparative performance of FIB-4, LSM and FAST score to predict 3-year clinical outcomes in NAFLD patients. **Methods:** We included consecutive adult NAFLD patients with VCTE performed between 2015-2022 from USA and Singapore. NAFLD patients stratified based on baseline FIB-4, LSM and FAST score were followed-up until clinical outcomes such as major liver-related outcomes (MALO: defined as liver-related events or death), liver-related events, death and major adverse cardiac events (MACE). **Results:** A total of 1,837 NAFLD patients (63% with obesity and 39% with diabetes) with VCTE were followed-up for median 3.5 years. Overall incidence rate per 1000 person-years for MALO, death and MACE was 6.3, 4.9, and 1.8, respectively. FIB-4 stratified NAFLD patients into low-risk (<1.3), intermediate-risk (1.3-2.67) and high-risk (>2.67) in 58.8%, 31.7% and 9.5%, respectively. No MALO occurred with baseline FIB-4 <1.3, regardless of LSM and FAST score. In fact, 10% of low-risk NAFLD patients by FIB-4 were misclassified as "high-risk" by VCTE. Higher FIB-4 was associated with higher risk of MALOs within each LSM category. FIB-4 was more accurate to predict the occurrence of MALO than LSM (*tAUC at 3 y: FIB4: 0.90 vs 0.79, p = 0.023; 5 y: FIB4: 0.89 vs 0.80 p = 0.035*) or FAST score (*tAUC at 3 y: FIB4: 0.90 vs 0.78, p = 0.014; 5 y: FIB4: 0.89 vs 0.72 p < 0.001*). All 3 scores had limited ability to predict MACE (*tAUC: 0.58-0.68*). Using NITs to identify low-risk NAFLD patients to be discharged to primary care, sequential FIB4/LSM testing identified 77.5% of low-risk patients, but missed 11.8% of MALO. Combination of FIB4/LSM reduces the missed MALO to 0%, but substantially reduced the proportion of low-risk patients identified to 41.3%. FAST score identified similar number of low-risk patients to combine FIB-4/LSM but missed more (22.2%) of MALO. **Conclusion:** In this multicenter international study, FIB-4 has good negative predictive value to identify low-risk NAFLD patients to be monitored in primary care setting. LSM results in false positive in 10% of low-risk NAFLD (FIB-4 <1.3) in whom none developed MALO or LRE, suggesting that LSM is not always superior in the setting of discordant NIT result. In moderate/high-risk NAFLD patients, FIB-4 and LSM synergistically predicted the risk of MALO, even among "high-risk" patients by VCTE. Our findings support the sequential approach of FIB-4 followed by VCTE as recommended by current guidelines.

2028-A | COMPARISON OF MAST, FAST, AND FIB-4 AS NONINVASIVE PREDICTORS OF FIBROTIC-NASH AND NASH

Xiao die Wei[1], Jing Zhang[2], Shi Qi[3], Xinxin Wang[4], Qiqige WuYun[5] and Nengwei Zhang[5], (1)Department of Hepatology, Beijing Youan Hospital, Capital Medical University, (2)Beijing Youan Hospital, Capital Medical University, (3)Department of Radiology, Beijing Youan Hospital, Capital Medical University, (4)Department of Pathology, Beijing Youan Hospital, Capital Medical University, (5)Department of Surgery, Capital Medical University Affiliated Beijing Shijitan Hospital

Background: Non-alcoholic steatohepatitis (NASH) and fibrotic NASH are key events in the course of non-alcoholic fatty liver disease (NAFLD). Recently, two predictors based on images have been proposed as non-invasive tests (NITs) with perfect efficiency, such as magnetic resonance imaging [MRI]- AST(MAST) and FibroScan-AST (FAST score), although they were not verified widely. This study aimed to validate their diagnostic accuracy and compare to fibrosis-4 (Fib-4) for detecting NASH and fibrotic NASH. **Methods:** The study involved 108 patients with biopsy-proven NAFLD undergoing contemporaneous Magnetic Resonance Elastography (MRE), MRI proton density fat fraction (MRI-PDFF), and FibroScan. NASH was diagnosed according to Non-alcoholic steatohepatitis-Clinical Research Network-Histologic Scoring System. Fibrotic-NASH was defined as NASH with fibrosis **e** 2 stage. **Results:** Of the entire cohort, 55.6% (n = 60) were male, with a median age of 38 (interquartile range: 31-48) years. The proportions of NASH and Fibrotic-NASH were 64.8% and 25.9%, respectively. For Fibrotic NASH detection, MAST (AUC 0.810, 95%CI 0.719-0.900) were comparable to FAST (AUC 0.782, 95%CI 0.689-0.874, p = 0.347) and both better than of FIB-4(0.626, 95%CI 0.502-0.751, both p < 0.001). When used as the rule-in criteria, the positive predictive value (PPV) of MAST (63.6%) was higher than that of FAST (40.0%) and FIB-4(50.0%). When used as the rule-out criteria, the NPV of MAST, FAST and FIB-4 were 58.8%, 27.5% and 47.6%, respectively. For the diagnosis of NASH, AUCs (95% CI) of MAST, FAST, and FIB-4 were 0.803 (0.719-0.886), 0.799 (0.708-0.892), and 0.635 (0.526-0.745), respectively (p = 0.930,0.002). When used as the rule-in criteria, PPV of MAST, FAST and FIB-4 were 100.0%, 83.3% and 83.3%, respectively.When used as the rule-out criteria, the NPV of was MAST, FAST and FIB-4 were 91.2% , 66.7% and 81.0% , respectively. **Conclusion:** The MAST score was better than FAST and FIB-4 for identifying patients of Fibro-NASH and NASH.

Table 2. Predictive performances of diagnostic models for Fibro-NASH and NASH.
AUC, area under the receiver-operating characteristic curve; FAST, FibroScan-AST; MAST, MRI-AST; FIB-4, Fibrosis-4 index; p values by the Delong test indicates the difference of AUC between models.

	For Fibro-NASH		For NASH	
Models	AUC (95%CI)	P value	AUC (95%CI)	P value
MAST	0.810 (0.719-0.900)	Reference	0.803(0.719-0.886)	Reference
FAST	0.782 (0.689-0.874)	0.347	0.799(0.708-0.892)	0.930
FIB-4	0.626 (0.502-0.751)	<0.001	0.635 (0.526-0.745)	0.002

2029-A | COMPARISONS OF LIVER BIOPSY FIBROSIS STAGING WITH NAFLD ACTIVITY SCORE (NAS)

Kirstan Franklin[1], Joshua T. Ghansiam[1], Jasmine Tidwell[1], Gabrielle Bachtel[1], Austin Vaughn[1] and Guy W. Neff[2], (1)Covenant Metabolic Specialists, LLC, (2) Tampa General Medical Group, Bradenton, FL

Background: The global incidence of NAFLD and NASH is increasing. Determining the severity and depth of these disorders is confounded by an assortment of conflicts about non-invasive testing (NIT) techniques and tissue demands. The liver biopsy process provides fibrosis, inflammation, steatosis grade, and ballooning in the liver, all of which translate to the NAFLD Activity Score (NAS). Identifying non-histologic pathways is imperative with the vast number of forthcoming patients in need of therapy. This project aims to compare liver biopsies fibrosis staging with resulted NAS in order to

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

identify any correlations between the two sets of data. **Methods:** Data taken from our clinic over the previous 36 months was collected. Comparisons were done using subjects who had liver biopsies to see if fibrosis staging has any link to NAS. Data collected biopsy results to evaluate fibrosis and NAS values. **Results:** 86 patients had biopsies done and were chosen for analysis. Patients were categorized numerically according to their Fibrosis Staging, which varied from 0 to 4, and their NAS scores were compared. Though the data showed a favorable trend between liver fibrosis staging and computed NAS from stage 0 to 2, it was lost at stages 3 and 4. The broken trend might be due to the lack of patients with fibrosis stage 4 compared to the more abundant data for lower stages. **Conclusion:** The data examined and evaluated showed an optimal analysis to fibrosis staging and NAS up until stage 2, showing the presence of NAFLD and NASH. More research is needed to understand whether NAS characteristics are associated with particular indications based on fibrosis stage.

2030-A | CONNEXIN 32 EXPRESSION AND ALPHA-SYNUCLEIN ACCUMULATION IN BALLOONING CELLS OF NON-ALCOHOLIC STEATOHEPATITIS (NASH) AND OTHER INFLAMMATORY LIVER DISEASES

Koichi Tsuneyama, Tokushima University Graduate School and Mayuko Ichimura-Shimizu, Department of Pathology and Laboratory Medicine, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan

Background: Ballooning is a crucial pathological finding in the diagnosis of non-alcoholic steatohepatitis (NASH). However, it is often challenging to differentiate it from glycogen retention, hydropic degeneration, or fatty degeneration, making the diagnosis difficult. Cytokeratin 8/18 has been used to identify ballooning cells, but its effectiveness in detecting them accurately is limited. Therefore, there is a need for a marker that can precisely identify ballooning cells. Alpha-synuclein, a protein deposited in neurons in Parkinson's disease, has been found in various organs besides neurons. In our recent study (Kakimoto, et al., Pathol Res Pract 247 (2023) 154525), we reported that polyclonal antibodies against phosphorylated alpha-synuclein and ubiquitin selectively react with acidophilic aggregates in ballooning cells. The absence of a positive reaction with a monoclonal antibody against phosphorylated alpha-synuclein suggests that the acidophilic aggregates in ballooning cells may be denatured alpha-synuclein products degraded through the ubiquitin pathway. In this study, we compared the expression of connexin 32 and alpha-synuclein in the livers of patients with NASH and other inflammatory liver diseases. **Methods:** We utilized liver biopsy tissue samples from 20 patients with NASH, 10 patients with primary biliary cholangitis (PBC), and 10 patients with chronic hepatitis C. Immunohistochemical analysis was performed using polyclonal antibodies against phosphorylated alpha-synuclein and monoclonal antibodies against connexin 32. **Results:** Connexin 32 expression was uniformly observed on hepatocyte membranes in all PBC cases (10/10). However, in NASH, its expression was heterogeneous, showing attenuation or loss in 80% (16/20) of hepatocytes with fatty degeneration. Connexin 32 was strongly expressed in a portion of the hepatocyte membrane in many hepatocytes exhibiting ballooning. In chronic hepatitis C, 20% (2/10) of the cases showed heterogeneous expression of Connexin 32. The polyclonal alpha-synuclein antibody exhibited strong reactivity with eosinophilic aggregates in ballooning cells in NASH, but no positive reactions were observed in PBC or chronic hepatitis C. **Conclusion:** Although alpha-synuclein is physiologically taken up by hepatocytes through connexin 32, the expression of connexin 32 is heterogeneous in NASH, resulting in variations in alpha-synuclein uptake by hepatocytes from cell to cell. Abnormal accumulation of alpha-synuclein in neurons is known to contribute to Parkinson's disease and Lewy body dementia. Abnormal accumulation of alpha-synuclein in ballooning cells highlighted the importance of understanding the brain-liver association mediated by alpha-synuclein.

2031-A | COST-EFFECTIVENESS OF DIFFERENT MODALITIES OF DIAGNOSING AND MONITORING INCREASED BURDEN OF NON-ALCOHOLIC LIVER DISEASE (NAFLD)

Abdullah Mubarak, Caleb Keng, James Gray, Sai Priya Metla and Mahnoor Fatima, Liver Center of Texas

Background: Early diagnosis of non-alcoholic steatohepatitis (NASH) and adequate staging of liver fibrosis can help manage patients at risk for NAFLD. A biopsy remains the gold standard for diagnosing NAFLD, but it is invasive in nature and expensive. The new Liver MultiScan (LMS) is an MRI scan used to diagnose NAFLD and can measure fat content and inflammation. Cost-effectiveness in diagnosing liver disease has been a recent concern, sparking ideas about moving away from biopsies to more non-invasive tools to diagnose NAFLD. **Methods:** 30 patients diagnosed with similar stages of NASH and received an LMS and Fibroscan from January 2021 and December 2022 were included in the analysis. 11 of the patients received a biopsy prior to receiving imaging. The standard deviation (SD) of LMS and fibroscan measurements of fat content and liver fibrosis were respectively compared. Secondly, the spreads of biopsy and non-biopsy patient groups on LMS fat content and fibrosis measurements were compared. Data from Healthcare Bluebook and online sources was used in identifying the average costs of various tools for monitoring NAFLD to address concerns about cost-effectiveness. **Results:** There are significant differences in the variability of the measurement of fat content between LMS and Fibroscan imaging with LMS results showing a significantly lower SD. There are significant differences in the variability of the measurement of liver fibrosis between LMS and Fibroscan imaging with Fibroscan results showing a significantly lower SD. Figure 1 shows that the spreads of the biopsy and non-biopsy data sets are similar in measuring fat content. The similar distribution of data suggests that datasets have similar variability. Figure 2 shows that the spreads of the biopsy and non-biopsy data sets are similar in measuring liver fibrosis. The similar distribution of data suggests that datasets have similar variability. Figure 3 shows the approximate costs for monitoring NAFLD: liver biopsy, $4000; liver multi scan, $1182; liver fibroscan, $135; and FIB-4, $14 (no data reported with FIB-4 in our analysis). **Conclusion:** Based on the spreads of fat content and liver fibrosis when biopsy and non-biopsy patients were compared, we concluded that non-invasive monitoring is cost-effective and a liver biopsy may not be necessary in most cases if LMS can identify NASH and NAFLD in a reliable way. There is not enough evidence to suggest that liver biopsies are obsolete, but the findings are consistent with past literature on the potential benefits of using non-invasive tools to diagnose NAFLD.

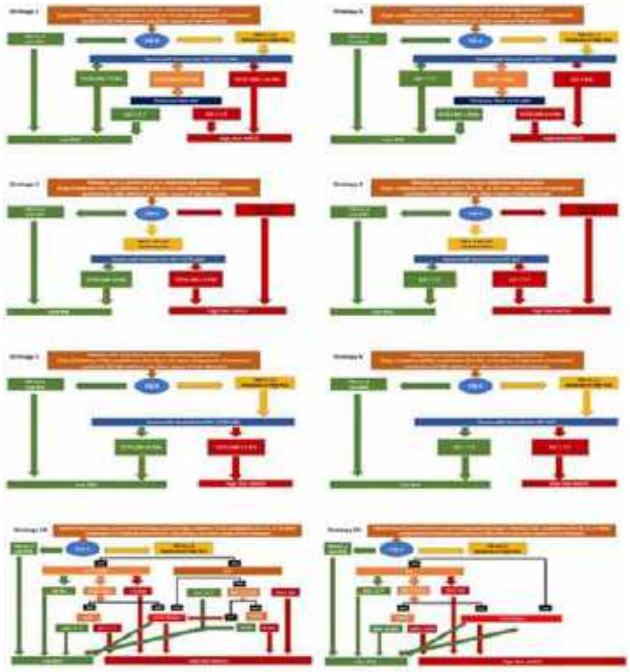
Background: American Association for the Study of Liver Diseases (AASLD), American Association of Clinical Endocrinologist (AACE), and European Association for the Study of the Liver (EASL) have established pathways to use non-invasive test (NITs) to identify high risk NAFLD. The cost-effectiveness of these pathways has not been established. Aim: To estimate the cost-effectiveness of different strategies to identify NAFLD with advanced fibrosis (AF) (**e** F3) using NITs. **Methods:** A cost-utility model for patients seen at primary care or endocrinology practices consists of a decision tree and Markov model. If patients had type 2 diabetes (T2D), prediabetes (Pre-D), or **e** 2 other components of metabolic syndrome (**e** 2-MS) without any other causes of liver diseases (viral hepatitis, alcoholic liver disease, excessive alcohol use), they entered a decision tree with 6 NIT screening strategies using first line and second line NIT testing. Markov model was used to simulate the natural history of NAFLD/NASH. Costs and health effects of 6 screening strategies were compared to no screening (Figure). The decision tree distributes patients between true and false positive and negative diagnoses based on the sensitivity and specificity of the diagnostic pathways. Prevalence of AF (12.20% in T2D, 4.87% Pre-D, and 4.91% **e** 2-MS) was obtained from the nationally representative sample of the U.S. population (National Health and Nutrition Examination, 2017-2020). The Markov model reflects the subsequent progression or regression across 10 health state and death in each year over 20-year time horizon. Direct medical costs were obtained from the Center for Medicare and Medicaid Services Fee Schedule 2023 and published data. Costs were reported in 2023 US dollars and a discount rate of 3.5%. Utility scores were based on EQ5D scores of patients with NAFLD and different disease stage. The results were a weighted average with weights equal to the distribution of T2D, Pre-D and **e** 2-MS (24.6%, 44.6%, and 30.8%). An additional scenario analysis was simulated considering the availability of VCTE and ELF tests at primary care, endocrinology and GI/Hepatology care in the U.S. **Results:** The decision tree that reported the lowest false positive diagnosis of AF was observed in strategy 1 (7.7%) versus strategy 2, 3, and 5 (11.7-12.7%), and strategy 4 and 6 (16.9-17.3%). In contrast, true positive (3.9-4.4%) and false negative (2.4-2.7%) were similar across the 6 strategies. The cost-utility model showed that all screening options were cost-effective as compared to no screening due to higher long-term cares cost of no screening arm (Table). Our findings remained robust in the additional scenario sensitivity analysis. **Conclusion:** In this economic evaluation, guidelines to identify high risk NAFLD appear to lead to net cost savings. While the results are specific to the U.S, the model can easily be adapted for other countries.



Table

	Projected Prevalence AF (%)	Average Diagnostic Pathway Costs	Average Staging Costs	Average Long-term Care Costs	Average Total cost	Average Total QALYs	Average Total Cost/Total QALY
No Screen	12.85%	$0.00	$818.67	$46,373.21	$46,881.31	9.417	$4,964.58
Strategy 1	12.48%	$268.22	$679.82	$45,151.68	$45,822.50	9.499	$4,843.14

2033-A | DETECTION OF NASH INDUCED METABOLIC ALTERATIONS FOR FUNCTIONAL NON-INVASIVE DIAGNOSTICS

Giuseppe Ferrandino, Federico Ricciardi, Antonio Murgia, Max Allsworth, Billy Boyle, Karina Joyce and Olga Gandelman, Owlstone Medical

Background: Diagnosis and staging of non-alcoholic steatohepatitis (NASH) relies on liver biopsy, an invasive procedure that can lead to complications. Furthermore, histopathology analysis of liver biopsy provides only information on anatomical alterations, lacking insights into the functional impact of the disease on hepatic metabolic capacity. These limitations hinder

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

the efficacy evaluation of experimental drugs for NASH treatment. By using a rat model, we explored pharmacokinetic alterations induced by NASH that can be exploited for functional, non-invasive diagnostic purposes. **Methods:** A total of 12 Wistar Han rats were fed a normal diet (ND) and 12 a choline deficient high fat diet (CDHFD). After 8 weeks, liver fibrosis was assessed by liver biopsy. After 10 weeks, rats were split in four groups of 3 ND, and 3 CDHFD and orally administered by gavage with emulsions containing 2-pentanone, 2-butanol, benzyl alcohol, or other compounds, all known to be metabolized in the liver by specific metabolic pathways. Blood samples were collected before, and at different timepoints after administration, and expected bioproducts were quantified by mass spectrometry. **Results:** Rats fed a CDHFD showed 3 times higher area of liver fibrosis compared to ND rats (Fig. 1A), and impaired body weight gain as expected. Before administration all the assessed compounds showed levels close to background. Benzoic acid, a metabolic product of benzyl alcohol, generated by the alcohol dehydrogenase (ADH) pathway, and further metabolized to hippuric acid, showed a spike in blood 5 minutes after benzyl alcohol administration, with levels of 2-folds higher in CDHFD rats, up to 4 hours (Fig. 1B). Similarly, 2,3-Butanediol and 3-hydroxy-2-butanone, metabolic products of 2-butanol generated by ADH/CYPs pathways, showed higher levels, up to 3-fold increase in CDHFD 8 and 12 hours after administration of 2-butanol (Fig. 1C-D). A similar alteration was observed for 2-3 pentanediol, a metabolic product of 2-pentanone. **Conclusion:** The results reported here show that metabolic alterations induced by NASH cause changes in blood concentration of hepatic xenobiotic products. These changes could be used for diagnostic purposes. The assessed compounds are generally recognized as safe (GRAS), can be administered in large doses to humans, and are detectable in breath. Therefore, this approach has a translational application for NASH detection using a breath test.

2034-A | DEVELOPMENT AND VALIDATION OF A NEW IMAGING BIOMARKER COMBINING DEMILI AND MRE TO IDENTIFY AT RISK NONALCOHOLIC STEATOHEPATITIS (AT-RISK NASH) PATIENTS

Isabel Fernandez-Lizaranzu[1], Rebeca Siguenza[2], Jiaxu Liang[1], Carmen Lara Romero[1], Sheila Gato[1], Rocio Montero-Vallejo[3], Maria Jesus Pareja[4], Rocio Aller[5], Javier Castell[6] and Manuel Romero-Gómez[7], (1) Instituto De Biomedicina De Sevilla, Ibis/Hospital Universitario Virgen Del Rocío/Csic/Universidad De Sevilla. Digestive Diseases Ucm and Ciberehd, (2) University Hospital Valladolid, (3)Instituto De Biomedicina De Sevilla, Ibis/Hospital Universitario Virgen Del Rocío, Huvr /Csic/Universidad De Sevilla Sevilla, Spain/Centro De Investigación Biomédica En Red (Ciberehd), Madrid, Spain, (4)Pathological Anatomy Service. Virgen Del Rocío University Hospital. Seville, Spain., (5)Digestive Diseases Department. Valladolid University Hospital. Department of Medicine. University of Valladolid, Valladolid, Spain, (6) Department of Diagnostic Radiology. Virgen Del Rocío University Hospital. Seville, Spain, (7)Ucm Digestive Diseases, Virgen Del Rocio University Hospital, Instituto De Biomedicina De Sevilla, Ciberehd, University of Seville, Sevilla, Spain

Background: Non-alcoholic steatohepatitis at risk (NASH with Fibrosis **e** 2) is a clinical priority, as these patients are at the highest risk of disease progression and will benefit most from pharmacologic treatment. In this study, we combined DeMILI 3.0 (Detection of metabolic liver injury method based on magnetic resonance imaging, MRI), that has shown promising accuracy in the identification of NASH, with Magnetic Resonance Elastography (MRE) to identify at-risk NASH patients and we compared it with available methods: FAST (FibroScan-aspartate aminotransferase scores), MAST (MRI-aspartate aminotransferase score) and MEFIB (MRE and FIB-4). **Methods:** Eighty-four patients recruited between 2020 and 2022 at 'Virgen del Rocio' University Hospital (Seville, Spain) were included as a prospective cohort. Main characteristics: 50% female, median age of 59 (±12) years, 32% (n = 27) patients were at-risk NASH. All patients underwent MRI, liver biopsy and laboratory testing. NASH and fibrosis were scored based on the SAF Histologic System. To identify at-risk NASH patients, a score was

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

developed using Logistic Regression. MRE and DeMILI were conducted using a 3.0T scanner without contrast medium and four sequences were performed: SSFSE-T2 (Single Shot Fast Spin Echo T2-weighted), FAST-STIR (Fast Short inversion Time Inversion Recovery) and DYNAMIC, and MRE-SE-EPI (spin-echo echo planar imaging based MRE). To compute our score, liver ROIs (Regions of Interest) where selected at the MRI, then computed to obtain a NASH score for DeMILI and measured to obtain the mean liver stiffness values for MRE. DeMILI-MRE score were also calculated in an external validation cohort (n = 29) at Valladolid Clinical University Hospital (Valladolid, Spain). The diagnostic accuracy was evaluated by AUROC (the area under the receiver operating characteristic curves) and compared to FAST, MAST and MEFIB score using DeLong method. **Results:** In the derivation cohort (n = 27), DeMILI-MRE score demonstrated a high performance and discrimination with the optimal cut-off: -0.97, AUROC = 0.80 (95%CI 0.70-0.88), with a sensitivity (SE) of 81% and a specificity (SP) of 72%. In the validation cohort (n = 29), the DeMILI-MRE score showed AUROC = 0.76 (95%CI 0.57-0.90), SE = 85% and SP = 69%. Based on diagnostic criteria, all scores were transformed into categorical variables, the AUROC of DeMILI-MRE index > -0.97 was 0.77 (95% CI: 0.66-0.85), which exhibited better discrimination of at-risk NASH than MEFIB positive (MRE > 3.3kPa and FIB-4 > 1.6): AUROC = 0.64 (95% CI: 0.53-0.75), FAST score (> 0.67): AUROC = 0.60 (95%CI 0.49-0.71), and MAST score (> 0.242): AUROC = 0.60 (95% CI :0.48-0.71). **Conclusion:** Initial results with limited cohorts show that DeMILI-MRE score showed a good diagnostic performance identifying non-invasively at-risk NASH patients with the optimal cut-off -0.97. It seems to outperform previous biomarker scores.

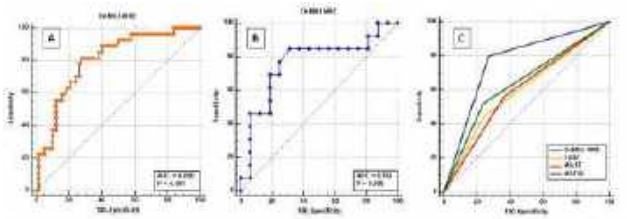

Figure: ROC curves of DeMILI-MRE score at (A) the derivation cohort (n=27), (B) the validation cohort (n=29), and (C) comparison of the diagnostic performance of different scores to identify at-risk NASH

2035-A | DEVELOPMENT OF A NON-INVASIVE DIAGNOSIS FOR FATTY LIVER IN CHILE: PRELIMINARY RESULTS

Maria Spencer Sandino[1,2], Franco Godoy[1,2], Claudio Vargas[3], Felipe Elorrieta[4], Laura Huidobro[2,5], Francisco Barrera[6] and Catterina Ferreccio[1,2], (1)Pontificia Universidad Católica De Chile, (2)Advance Center for Chronic Diseases, Accdis, (3)Hospital Posta Central, (4)Universidad De Santiago De Chile, (5)Universidad Católica Del Maule, (6)The University of Sydney

Background: Non-alcoholic fatty liver disease (NAFLD) is the most frequent chronic liver disease. NAFLD prevalence is estimated at 40% in Latin America and 47.5% in Chile in 2019. NAFLD causes 4,000 deaths in adults, representing 5% of total annual deaths, and Non-Alcoholic Steatohepatitis(NASH) is the primary cause of liver transplantation. NAFLD could be controlled if detected at earlier stages. Imaging techniques, biomarkers, and anthropometric measurements are the most commonly used diagnostic methods. However, imaging techniques are expensive and not accessible in poor areas in Latin America. This study aims to develop an algorithm that can identify the risk of NAFLD in a low-resource setting when no images are available. **Methods:** The study is nested in the MAUCO cohort, including 349 participants of the MAUCO+ lifestyle intervention aimed at preventing NAFLD and cardiovascular diseases, which included participants aged 45-60 years, with varying degrees of fatty liver; who were not taking medications that affect muscle mass or liver function, did not have severe disease or physical condition that could interfere the intervention. We analyzed the baseline data of all participants pre-intervention, including abdominal ultrasound (US), FibroScan, weight, height, waist circumference, AST, ALT, GGT, lipids, blood sugar, insulin, hemoglobin A1c, HOMA-IR, platelet count, and high-sensitivity C-reactive protein. We used ordinal logistic regression to predict the risk of fatty liver and its severity (0 = no risk, 1 = mild risk, and 2 = severe risk), with FibroScan as the gold standard. To evaluate the predictive performance, we validated our findings in five independent datasets using the k-fold cross-validation method in R. **Results:** Our model selected as predictors: sex, waist circumference, ALT, GGT, insulin, glycemia, and high-sensitivity C-reactive protein > 0.2 mg/dL. The algorithm predicts

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

the absence of fatty liver with a specificity of 84%; the sensitivity for mild and moderate or severe fatty liver was 62% and 60%, and its corresponding specificity was 56% and 81%; Youden´s accuracy was 18% for mild disease and 41% for moderate or severe fatty liver. **Conclusion:** Our algorithm was easy and feasible for screening fatty liver, that is suitable for implementing in virtual platforms, but its accuracy needs improvement. The following steps are to improve the sensitivity of the gold standard by adding the measurement of liver fibrosis and to improve the sensitivity of the algorithm, including percentage of body fat, and evaluate a new version in a sample of 1,000 participants, which will be available for the 2023 AASLD Conference.

2036-A | DEVELOPMENT OF A NOVEL CLINICAL SCREENING TOOL TO PREDICT LIVER FIBROSIS

Madeleine Haff[1], Na Wang[2], Emily Kate Sisson[2] and Michelle Long[1,3], (1)Boston Medical Center, Boston, MA, (2)Boston University, (3)Novo Nordisk

Background: Nonalcoholic fatty liver disease (NAFLD) is a major contributor to liver disease in the United States, and non-invasive tools such as vibration-controlled transient elastography (VCTE) estimate the risk of liver fibrosis and help guide patient care. Unfortunately VCTE is not readily available to all patients, as it requires specialized equipment and expertise. In our study, we developed a screening index that uses patient data that is readily available in the clinic to predict odds of significant fibrosis on VCTE. **Methods:** Logistic Least Absolute Shrinkage and Selection Operator (LASSO) regression was used to select clinical factors that best predict fibrosis (VCTE > 8 kPa) in 3013 participants in the Framingham Heart Study cohort. We excluded participants who had significant alcohol use, missing covariates, no VCTE, or unreliable or ineligible liver stiffness measurements. To evaluate predictive performance, we randomly split 70% as training data and 30% as test data for 100 times. We then used Delong's test based on area under the curve (AUC) to assess whether other additional clinically meaningful factors improved the predicted probability of the simple screening index, then used net reclassification index (NRI) to evaluate strength of model improvement. **Results:** In our cohort of 3013 participants, 54.8% were women and the mean age was 54.3 years (Standard Deviation (SD) 9.1). Mean Body Mass Index (BMI) was 28.4 kg/m^2 (SD 5.6), prevalence of diabetes was 8.2%, and the prevalence of suspected significant fibrosis (liver stiffness > 8.0 kPa) was 9.8%. In our analysis, among available patient characteristics, the most selective variables were BMI and having diabetes, along with systolic blood pressure (SBP), age, and sex. These characteristics formed our base model for predicting significant fibrosis, with AUC 0.7048. When alanine transaminase (ALT) or aspartate transaminase (AST) were added to the model, this significantly improved the predictive probability of the base model. This effect was strongest with AST, with AUC 0.7240 with p value 0.0044. The NRI indicated that 6.95% (95 CI 2.22-11.7%) of participants were correctly recategorized when AST was added to the model, with p value 0.0042. **Conclusion:** We developed a new screening index to predict significant liver fibrosis based on easily-measured patient demographic and biometric data (BMI, diabetes, SBP, age, sex, and AST). This tool may help identify patients at risk for complications of NAFLD, especially where VCTE is not available. Future studies are needed to validate this screening index and compare to existing indices.

2037-A | DIAGNOSTIC ACCURACY OF VCTE AND 2D-SWE IN BIOPSY-PROVEN NAFLD AND PERFORMANCE OF TWO-STEP APPROACHES TO PREDICT ADVANCED FIBROSIS

Madalina-Gabriela Taru[1,2], Dan-Corneliu Leucuta[2], Lidia Neamti[2], Anca Maniu[3], Vlad Taru[4], Bobe Petrushev[3], Ioana Rusu[3], Cristian Tefas[2,3], Petra Fischer[2], Andreea-Ioana Terec[5], Lucia Maria Procopciuc[2], Bogdan Procopet[2], Horia Stefanescu[3] and Monica Lupsor-Platon[2,3], (1)Department of Medical and Surgical Sciences, University of Bologna, 40126 Bologna, Italy, (2)Luliu Hatieganu University of Medicine and Pharmacy, 400012 Cluj-Napoca, Romania, (3) Octavian Fodor Regional Institute of Gastroenterology and Hepatology, 400162 Cluj-Napoca, Romania, (4) Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, (5)Niculae Stăncioiu Heart Institute, 400001, Cluj-Napoca, Romania

Background: Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) pose significant challenges to the healthcare system, and the

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

prediction of advanced fibrosis (**e** F3) is a crucial aspect in their management. **Methods:** In a retrospective study, we analyzed 149 consecutive patients with biopsy-proven NAFLD/NASH who underwent liver biopsy (LB) at our tertiary medical center between 2013 and 2021. Patients with concurrent HCC or other causes of liver disease were excluded. We assessed the diagnostic accuracy of VCTE (vibration controlled transient elastography using M or XL probes according to the equipment's recommendations, min. 10 valid measurements, reliable) and of 2D-SWE-SSI (two-dimensional shear wave elastography, Aixplorer, SuperSonic Imagine, min. 5 valid measurements, reliable) in detecting different stages of liver fibrosis. A subgroup of patients with baseline matched VCTE-2D-SWE-SSI were further included in comparative two-step algorithms (FIB4+VCTE vs. FIB4+2D-SWE-SSI) to assess the diagnostic performance and the need for LB in unclassified patients for the diagnosis of **e** F3. **Results:** Out of 149 patients, 2(1.3%) presented F0 on biopsy, 30(20.2%) F1, 42(28.2%) F2, 35(23.5%) F3, 40 (26.8%) F4 according to NASH CRN. The AUC for FIB4 (1.3) in detecting **e** F3 for all patients was 0.78 (95%CI). 119(95.7%) presented baseline reliable VCTE measurements, 73(93.2%) baseline reliable 2D-SWE-SSI measurements and 55(36.9%) matched VCTE-2D-SWE SSI. The AUCs for VCTE in detecting **e** F2, **e** F3 and F4 were 0.889, 0.928, and 0.939 with optimal cut-offs (Youden Index) of 8.8 kPa, 12.2 kPa, and 16.8 kPa. The AUCs for 2D-SWE in detecting **e** F2, **e** F3 and F4 were 0.873, 0.908, and 0.882 (95%CI), with optimal cut-offs (Youden Index) of 7.5 kPa, 9.4 kPa, and 12.5 kPa. For better Se and Sp, we considered rule-in and rule-out cut-offs for **e** F3 with both elastography techniques: for VCTE 8.8 kPa (Se/Sp = 93.85/74.07) and 11.8 kPa (Se/Sp = 81.54/94.44); for 2D-SWE-SSI 9.1 kPa (Se/Sp = 91.89/80.56) and 12 kPa (Se/Sp = 70.27/91.67). Using this thresholds and the 8 and 12 kPa cut-offs for VCTE, the need for LB for the patients in grey zone remained 3(5.45%) for FIB4+VCTE standard cut-offs, 2(3.63%) for FIB4+VCTE our cut-offs and 8 (14.5%) for FIB4+2D-SWE-SSI. No significant differences were observed among strategies (McNemar's exact test). **Conclusion:** Both FIB4+VCTE and FIB4 +2D-SWE exhibit potential as promising screening approaches for predicting **e** F3 in suspected NAFLD.

2038-A | DIGITAL PATHOLOGY QUANTITATIVE IMAGE ANALYSIS AND AI METHOD DETECTS THE TREATMENT EFFECT OF PEGBELFERMIN IN CIRRHOSIS PATIENTS WITH A PERFORMANCE THAT BENCHMARKS MANUAL HISTOLOGICAL ASSESSMENT

Li Chen[1], Anne Minnich[2], Edgar D. Charles[2], Zachary D. Goodman[3], Mathieu M. Petitjean[4] and Arun Sanyal[5], (1)Pharmanest, (2)Bristol Myers Squibb, (3)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (4)Pharmanest Inc, (5)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Manual histological evaluation of liver biopsy is the gold standard for fibrosis staging in Non-Alcoholic Steatohepatitis (NASH), but it is limited by its inter and intra-reader variability. Digital Pathology image analysis (FibroNest™) has the potential to overcome the current limitation of such standards. This exploratory post-hoc analysis compared FibroNest's continuous scores with NASH-CRN categorical stages in patients with NASH from the phase 2b FALCON2 study (NTC03486912). **Methods:** Eligible adults were 18-75 years of age (N = 145) with NASH diagnosed by histologic assessment of liver biopsy according to NASH CRN criteria and stage 4 fibrosis, defined as Cirrhosis. During the 48-week double-blind treatment period, patients received 10mg, 20mg, or 40mg pegbelfermin subcutaneous or placebo once weekly. Liver biopsies were obtained six months before or during screening and at week 48. Formalin-fixed, paraffin embedded sections of the liver biopsies were stained with Masson Trichrome and imaged at 40X. Quantitative image analysis was performed to extract single-fiber quantitative traits (qFTs, N = 315) from the fibrosis histological phenotype. A previously validated selection of principal qFTs were normalized and combined into a fibrosis severity score (Ph-FCS, 1 to 10). A prospective score (PT-Ph-FCS) was developed to normalize the Ph-FCS on non-steatotic parenchymal tissue. Each digital image was evaluated for quality along 20 dimensions (tissue processing, staining, scanning) to generate a Digital Biopsy Adequacy score (DBA). **Results:** Ph-FCS was able to classify F3 (n = 47) from F4 (n = 229) stages with a sensitivity (specificity) of 73.80% (74.47%) for a Ph-CFS = 3 cut off value (Fig. A). Groups sizes with paired biopsies were

22, 24, 20, 27 for the placebo,10mg, 20mg, 40mg groups following removal of images considered non-evaluable for FibroNest algorithms (i.e., DBA < 5). Responders were identified with a 1-unit reduction for the histological stage (Fig. B-C). Using an absolute reduction of 0.3 (4-fold higher than the analytical variability), the Ph-FCS resolved 15% to 20% (resp. 0% to 10%) more responders than NASH CRN (resp. Ishak) categorical stages which is consistent with an increased detection threshold (Fig. B). A 25% relative reduction of Ph-FCS (corresponding to an absolute change of 0.75 to 2 for 3 < Ph-FCS < 8) detected fewer responders than when using NASH-CRN or Ishrak (Fig. C). There was no difference between the Ph-FCS and the PT-Ph-FCS which is attributed to the lack of antisteatotic effect of the treatment in this study, as reported elsewhere. **Conclusion:** Quantitative digital pathology image analysis and AI generates continuous scores for fibrosis that enhance conventional histological staging and resolve the continuum of cirrhosis. The definition of meaningful change criteria using this continuous scoring remains to be improved.

2039-A | DISCOVERY OF A 12-GENE SIGNATURE UNVEILS NEW CANDIDATE BIOMARKERS FOR NON-ALCOHOLIC FATTY LIVER DISEASE PROGRESSION

Maria Jimenez Ramos, Timothy James Kendall, Lucia Bandiera, Filippo Menolascina and Jonathan A Fallowfield, University of Edinburgh

Background: Non-alcoholic fatty liver disease (NAFLD) represents a global healthcare challenge, with an estimated prevalence of 32.4% worldwide and death rates predicted to increase in the coming years. To date, there are no qualified non-invasive biomarkers. We interrogated the human NAFLD RNA-sequencing (RNA-seq) database from SteatoSITE (https://steatosite.com/) to identify gene expression patterns across the NAFLD spectrum and link them to decompensation and mortality outcomes. **Methods:** We used bulk RNA-seq data generated from n = 579 NAFLD samples and n = 34 normal liver controls. Samples had been defined histologically as isolated steatosis or fibrosis stages F0/F1, F2, F3 and F4. Differentially expressed genes were subjected to Gene Set Enrichment Analysis (GSEA) to identify enriched biological processes/pathways. The common genes were uploaded to the STRING database in Cytoscape with a confidence score **e** 0.4. The most significant module was isolated from the major protein-protein interaction (PPI) network via the Molecular Complex Detection (MCODE) plugin. Gene Ontology (GO) annotations were determined for these hub genes. Through Kaplan-Meier analysis, we evaluated the link between the hub genes and both all-cause mortality and decompensation events. **Results:** GSEA of the dysregulated genes (274 in isolated steatosis, 232 in F0/F1, 477 in F2, 1113 in F3 and 2669 in F4) identified enriched pathways linked to extracellular matrix, cytokine-cytokine receptor interaction and metabolic pathways. 79 genes, shared among all NAFLD stages, were used to generate a PPI network. From these, MCODE identified one module comprising 12 hub genes (Figure) with significant network connectivity; some implicated in NAFLD pathobiology or liver fibrogenesis. These genes were linked to two key GO terms: p38 MAPK cascade and integrated stress response signalling. Network members were also significantly associated with risk of clinical outcomes, such as all-cause mortality (FOSB, EGR1, CEBPD, ZFP36, JUNB) and decompensation events (FOS, EGR1, NR4A1, JUNB). **Conclusion:** We used integrated bioinformatics analysis to identify a 12-gene signature associated with progression of NAFLD. Some of these genes exhibit significant correlations with all-cause mortality and decompensation events and may thus represent potential biomarker candidates or tractable therapeutic targets for NAFLD. External validation is required to confirm and further establish the significance of our observations.

2040-A | DISCOVERY OF AN EARLY DIAGNOSTIC BIOMARKER OF NONALCOHOLIC STEATOHEPATITIS (NASH)

Tanya Nguyen and Carla Nieser, Sapient

Background: Nonalcoholic steatohepatitis (NASH) is a complex, multifactorial disease. Our understanding of the pathophysiology that underlies progression from NAFLD to NASH is still incomplete, limiting development of mechanism-based therapies to treat NASH and slow disease progression. Herein we describe the discovery of a small molecule biomarker revealing potential drug targets, and that provides an early diagnostic for NASH by predicting disease development more than 10 years in advance. **Methods:** We applied next-generation high-throughput liquid chromatography-mass spectrometry (LC-MS) based methods for non-targeted metabolomics analysis to broadly measure > 45,000 small molecule biomarkers across samples derived from more than 10,000 individual's in multiple independent studies around the world. Biocomputational analysis identified a number of molecules that are highly increased in individual's who go on to develop

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

clinically apparent liver disease, and are increased with NASH score in an independent NASH registry study. These molecules were examined in a preclinical model distinguishing NASH from NAFLD to validate the mechanistic connection of the molecules with NASH. The validated biomarker was further investigated using Sapient's Human Biology Database, comprised of data from more than 100,000 biosamples across a large, diverse population. A genome-wide association study (GWAS) was performed to determine the genetic loci associated with the circulating level of the biomarker in humans. Mendelian randomization was further performed to evaluate the causal relationship between the biomarker and liver damage as indicated by alanine transaminase (ALT). **Results:** Through this large-scale population-level analysis with independent datasets, a single molecule was found to be robustly elevated with disease severity in patients with biopsy-proven NASH and was prioritized as a key diagnostic biomarker for subsequent validation in preclinical and human studies. Translation of the biomarker to a preclinical model found the molecule to be highly conserved, with animals that went on to develop NASH having a marked elevation in the biomarker even prior to pathologic evidence of liver inflammation. Biological validation in Sapient's Human Biology Database found this biomarker to be elevated > 10 years prior to formal diagnosis of NASH . The biomarker is causal to liver damage measured by ALT. It is stable over time and geographic location, but changes dynamically in obese patients after bariatric surgery with improvement in NASH. **Conclusion:** This biomarker has been validated in tens of thousands of individual's from around the world and found to represent a robust, non-invasive early diagnostic biomarker for NASH. Equally important, the biomarker may be causal to NASH and reveal new pathways that drive the development of liver disease that may represent new biological targets for NASH therapeutics. Disclosures: The following people have nothing to disclose: Tanya Nguyen, Carla Nieser

2041-A | ECONOMIC IMPACT OF NON-INVASIVE TESTS FOR THE IDENTIFICATION OF PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD)

Donald B Chalfin[1], Maria X Sanmartin[2,3], Pina C Sanelli[2,3], Artem T Boltyenkov[1] and David Eric Bernstein[4], (1)Siemens Healthcare Diagnostics, Inc., (2)Northwell Health, Forest Hills, NY, (3)Donald and Barbara Zucker School of Medicine, (4)New York University

Background: Noninvasive tests (NITs) may facilitate detection of advanced fibrosis (AF) in nonalcoholic fatty liver disease (NAFLD) in the primary care setting (PCP) and may enable more efficient identification of afflicted patients. We developed a health economic model to evaluate the comparative effectiveness of diagnostic strategies employing currently available NITs. **Methods:** We developed a decision analytic model to assess the cost-effectiveness of diagnostic strategies to detect AF comparing the following 8 strategies: 1) FIB-4 only, 2) Enhanced Liver Fibrosis (ELF) only, 3) Transient Elastography (TE), 4) FIB-4 followed by ELF for indeterminant FIB-4 (FIB4/ELF), 5) FIB-4 followed by TE for indeterminant FIB-4 (FIB4/TE), 6) ELF followed by TE for indeterminant ELF (ELF/TE), 7) TE followed by ELF for indeterminant TE (TE/ELF), and 8) FIB-4 followed by ELF for indeterminant FIB-4 (FIB4/ELF). The downstream consequences following NITs were modeled according to AASLD 2023 guidelines. We employed a Markov state transition model to depict disease progression and long-term outcomes for a lifetime horizon. The primary outcomes were quality adjusted life years (QALYs) and cost in 2022 USD. **Results:** The results of the base-case scenario revealed that ELF/TE had the highest benefits (19.52 QALYs) and the lowest expected cost ($708,793) per patient. The FIB-4/TE, TE/ELF, & FIB4/ELF strategies yielded lower expected effectiveness (19.5; 19.5; 19.5 QALYs, respectively) and higher expected costs ($710,332, $710,846, $710,898, respectively) than ELF/TE. ELF, TE, and FIB-4 also yielded lower QALYs (19.49; 19.49; 19.48, respectively) at a higher cost per patient (711,374; 711,727; 712,274, respectively) compared with ELF/TE. Thus, the ELF/TE strategy had superior clinical outcomes and cost savings, thereby representing the dominant strategy. When the sensitivity of ELF was independently varied from 0 to 100%, ELF/TE was the most cost-effective strategy when ELF sensitivity exceeded 71.5%. In a probabilistic sensitivity analysis, the ELF/TE strategy remained cost-effective for all iterations when the willingness-to-pay threshold was varied from $0 to $200,000 USD. **Conclusion:** This study reveals that the ELF/TE strategy is the most cost-effective option to identify AF in NAFLD. Adoption of a cost-effective NIT strategy may facilitate effective use of scarce health-care resources along with efficient AF detection for patients who present to PCPs.

Results of the Base-Case Scenario for All Strategies

Strategy	Cost	QALYs	ICER	Dominated
ELF/TE	708,793	19.52	Reference	No
FIB 4/TE	710,332	19.5	Negative	Yes
TE/ELF	710,846	19.5	Negative	Yes
FIB 4/ELF	710,898	19.5	Negative	Yes
ELF	711,374	19.49	Negative	Yes
TE	711,727	19.49	Negative	Yes
FIB 4	712,274	19.48	Negative	Yes

2042-A | EICOSANOID LIPIDOMICS IMPROVES CARDIOVASCULAR RISK PREDICTION IN A PROSPECTIVE COHORT WITH BIOPSY-PROVEN NONALCOHOLIC FATTY LIVER DISEASE: A PILOT ANALYSIS

Robert M Wilechansky, Alessandra Grossman, Oluwafemi Balogun, Kathleen E. Corey and Tracey G. Simon, Massachusetts General Hospital

Background: Eicosanoid lipid species have been associated with cardiovascular disease (CVD) and may be useful biomarkers to identify patients with metabolic syndrome at risk for incident CVD. Given the overlap between metabolic syndrome and non-alcoholic fatty liver disease (NAFLD), it is possible that eicosanoids may also predict CVD events in patients with NAFLD, though this has not yet been elucidated. **Methods:** Targeted lipidomics analysis of 35 eicosanoid lipids was performed in a prospective cohort with biopsy-proven NAFLD and no CVD at baseline (n = 157). Principal component analysis identified a subset of ten lipids that explained most of the variation in the data. Multivariable (MV)-adjusted Cox proportional hazards regression identified lipids associated with incident CVD events (myocardial infarction, heart failure, stroke, peripheral vascular disease, arrhythmia) after adjusting for aspirin use and the ACC/AHA 10-year ASCVD risk score. Hazard ratios reflect a 1-standard deviation change in lipid concentration; false discovery rate (FDR) < 0.2 defined significance. To test the utility of clinical factors and eicosanoids for predicting incident CVD, we used a series of variable selection methods to construct MV models combining the ACC/AHA ASCVD risk score (base model) with clinical factors and eicosanoids. Models were optimized by 15-fold cross-validation and compared to the base model by C-index, net reclassification improvement (NRI), and integrated discrimination improvement (IDI). **Results:** The cohort consisted of 52% women with a median follow-up of 9.4 years. After MV adjustment, two eicosanoid lipids were associated with incident CVD: 9-HETE (aHR 0.29, 95% CI 0.09-0.95, FDR = 0.15) and 11-HETE (aHR 5.38, 95% CI 1.1-26.3, FDR 0.15). There was a borderline association with 14-HDoHE (aHR 1.77, 95%CI 0.91-3.45, FDR 0.22). The base model for predicting incident CVD yielded a C-index of 0.71. The LASSO-Cox method had the highest C-index of 0.74 and included liver fibrosis severity, aspirin use, 11-HETE, and 14-HDoHE with the base model. The LASSO-Cox model resulted in NRI 0.39 (95% CI 0.22-0.59) and IDI 0.13 (95% CI 0.065-0.24), both $p < 0.0001$ compared to the base model. **Conclusion:** Targeted lipidomics identified eicosanoids associated with incident CVD risk in a prospective cohort of patients with biopsy-proven NAFLD. Eicosanoid lipidomics may be a valuable tool in combination with liver-specific factors for improving CVD risk prediction in NAFLD.

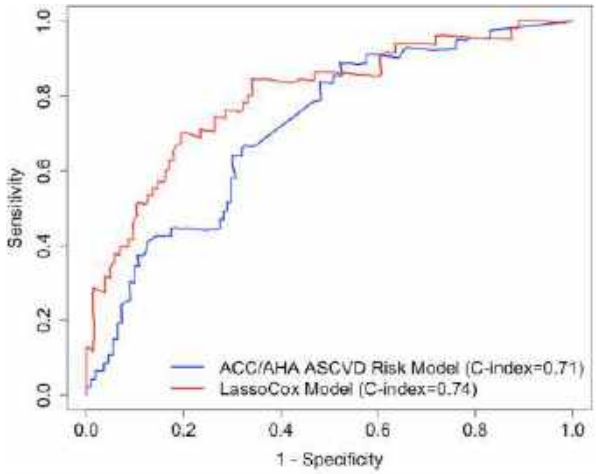

Figure 1: Receiver operating characteristic curves illustrating discriminatory ability of the base model (ACC/AHA ASCVD 10-year risk score) compared to the LASSO-Cox model (ASCVD Risk, fibrosis stage, aspirin use, 11-HETE, 14-HDoHE) in terms of 10-year risk prediction of cardiovascular events. ACC: American College of Cardiology; AHA: American Heart Association; ASCVD: atherosclerotic cardiovascular disease; LASSO: least absolute shrinkage and selection operator.

2043-A | EVALUATING THE UTILITY OF NON-INVASIVE TESTS AS CONTINUOUS MEASURES OF HEPATIC FIBROSIS IN NAFLD

EN Ying Tan[1], Xiang Xuan Eunice Tan[1], Daniel Q Huang[1], Jonathan Lee[1], Margaret Li Peng Teng[1], Nur Halisah Jumat[1], Dean Tai[2], Elaine Lay Khim Chng[2], Yock Young Dan[1] and Mark Dhinesh Muthiah[1], (1) National University Health System (NUHS), (2) Histoindex Pte Ltd, Singapore, Singapore, Singapore

Background: Fibrosis in NASH is the only histological finding that correlates with liver related outcomes, and its improvement is a key outcome measure in assessing therapeutic trials in the disease. Fibrosis on histology is scored according to the Kleiner-Brunt system or the Steatosis-Activity-Fibrosis (SAF) system. However, these scoring systems are limited by their categorical nature, with challenges differentiating patients at the junction between stages. NIT's developed based on these "categorical bins" are only tested for categorical

Symbols: ƒ, Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

outcomes (eg. Advanced fibrosis). We aimed to correlate common NIT's with a validated novel continuous histological fibrosis score (qFibrosis), to determine the performance of the NIT's as continuous variables. **Methods:** Patients with biopsy-proven NAFLD were enrolled from National University Health System, Singapore. Patients with any other causes for their liver disease were excluded. Their biopsy specimens underwent an artificial intelligence-based quantitative evaluation for fibrosis (qFIBS by HistoIndex®, Singapore). Fibrosis-4 index (FIB-4), AST to Platelet Ratio Index (APRI), NAFLD Fibrosis Score (NFS), as well as vibration-controlled transient elastography (VCTE), AGILE 3+ and FibroScan-AST (FAST) score were measured. The relationship between histological scoring for fibrosis and qFib, as well as the relationship between NITs and qFib was evaluated by simple linear regression analysis. **Results:** 248 multi-ethnic Asian patients with biopsy-proven NAFLD were recruited to undergo qFIBS and non-invasive tests from 2014 to 2021. qFibrosis and histological score for fibrosis had a linear relationship with an R^2 of 0.39 ($p < 0.001$). qFibrosis was significantly correlated with all evaluated NITs (all p-values < 0.001), with respective R^2 values of 0.12, 0.12, 0.14, 0.44, 0.27 and 0.18 for FIB-4, APRI, NFS, VCTE, AGILE 3+ and FAST. On scatterplots, confidence intervals for the regression lines appear narrow in the qFibrosis range of 1-3. **Conclusion:** qFibrosis correlates well with pathologist-reported fibrosis scores. NITs may have a role as continuous measures of fibrosis in NAFLD, which may be used as more sensitive indicators of fibrosis progression or regression, or to evaluate response to therapy. Given the narrow confidence intervals at low to intermediate levels of fibrosis, NITs may perform well in such settings, where early intervention has greatest yield. However, serum NITs are limited in assessing stage differences due to their narrow dynamic range. VCTE is moderately correlated and with the highest dynamic range, and may potentially be the most useful NIT for evaluating degree of fibrosis as a continuous variable.

2044-A | EVALUATION OF DIAGNOSTIC PERFORMANCE OF B-MODE ULTRASOUND USING ULTRASOUND-GUIDED ATTENUATION PARAMETER FOR LIVER STEATOSIS ASSESSMENT IN PATIENTS WITH CHRONIC LIVER DISEASE

Yuichi Yoshida, Ayako Urabe and Masafumi Naito, Suita Municipal Hospital

Background: B-mode ultrasound (B-USD) is commonly used for diagnosing fatty liver but has limitations in terms of sensitivity. Ultrasound-guided attenuation parameter (UGAP) is a novel ultrasound-based attenuation imaging method for non-invasive quantification of liver fat content. Recent study using a large cohort of patients with chronic liver disease (CLD) showed that the value of UGAP has excellent diagnostic accuracy for liver steatosis assessment according to the value of MRI-PDFF as a reference (*Clin Gastroenterol Hepatol. 2022*). Based on this background, current study was aimed to evaluate the diagnostic performance of B-USD using UGAP for liver steatosis assessment in patients with CLD. **Methods:** We retrospectively enrolled 379 patients with CLD (HCV/HBV/NAFLD/ALD/PBC. AIH/others: 90/99/63/40/31/56) who underwent both B-USD and UGAP. The diagnostic performance of B-USD for liver steatosis assessment, including bright liver (BL), deep attenuation (DA), hepatorenal echo contrast (HRC), and vessel blurring (VB), was independently examined by two experienced observers using UGAP as a reference value. **Results:** Interobserver agreement of two observers using the kappa statistic was analyzed, yielding the following values for BL, DA, HRC, and VB: 0.767, 0.604, 0.788, and 0.506, respectively. These values indicate that the agreement between the observers ranged from moderate to good. According to previous report, the cut-off value of UGAP for the diagnosis of grade 1, grade 2, and grade3 liver steatosis was defined as 0.650, 0.710, and 0.770 dB/cm/MHz, respectively. These cut-off values divided patients into several groups: 177 cases classified as grade 1 or higher (referred to as G1), 103 cases classified as grade 2 or higher (referred to as G2), and 50 cases classified as grade 3 or higher (referred to as G3). The diagnostic performance of four B-USD

parameters was then assessed according to the value of UGPA as reference for G1, G2, and G3 of fatty liver using diagnostic accuracy, sensitivity, and specificity. The diagnostic accuracy of four parameters for G1 was as follows: 0.718 for BL, 0.662 for DA, 0.715 for HRC, and 0.623 for VB. The sensitivity of four parameters for G1 was as follows: 0.463 for BL, 0.282 for DA, 0.452 for HRC, and 0.198 for VB. The specificity of four parameters for G1 was as follows: 0.941 for BL, 0.995 for DA, 0.946 for HRC, and 0.995 for VB. These data suggest that B-USD has moderate diagnostic accuracy with high specificity and low sensitivity for G1. Specifically, the sensitivity of DA and VB remained low in G2 or G3:0.456 for DA and 0.320 for VB in G2, and 0.780 for DA and 0.540 for VB in G3. **Conclusion:** Our study showed that B-USD exhibits high specificity but low sensitivity in detecting mild steatosis. The data further suggest that UGAP could be an effective and objective tool to improve the sensitivity of B-USD.

2045-A | FIBROSCAN-AST (FAST) SCORE IS DIRECTLY RELATED TO PATIENT-REPORTED OUTCOMES, INCLUDING FATIGUE IN PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE: A GRAPHICAL MODEL ANALYSIS

Ryuki Hashida[1], Takumi Kawaguchi[2], Dan Nakano[1], Tsubasa Tsutsumi[1], Tomoya Sano[1], Keisuke Amano[1], Machiko Kawaguchi[1], Hiroshi Tajima[1], Hiroo Matsuse[1], Lynn Gerber[3], Zobair M. Younossi[4] and Koji Hiraoka[1], (1)Kurume University, (2)Kurume University School of Medicine, (3)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (4) Inova Health System

Background: Patients with non-alcoholic fatty liver disease (NAFLD) frequently report fatigue. While this is a patient reported outcome (PROs), it is associated with various factors including pathological findings such as hepatic inflammation and fibrosis. FibroScan-AST (FAST) score is a useful non-invasive tool to identify non-alcoholic steatohepatitis (NASH) patients with significant disease activity and fibrosis. We aimed to investigate the independent factors associated with PROs including fatigue for patients with NAFLD and their FAST scores. **Methods:** We enrolled 116 patients with NAFLD (age 57 [41-67], female/male 44/72). PROs were assessed by the Chronic Liver Disease Questionnaire (CLDQ)-NAFLD/NASH, which consist of 6 domains including fatigue. We defined each of domain scores < 6 were classified into the Impairment group. According to the total and fatigue domain scores of CLDQ-NAFLD/NASH, patients were classified by each domain, impaired PROs/non-impaired PRO ($n = 74/42$) and impaired fatigue/no fatigue ($n = 96/20$) groups. A cut-off value of 0.67 in the FAST score was used to categorize a high (significant disease activity) or low FAST score. Independent factors associated with impaired PROs and fatigue were analyzed using logistic regression analysis, decision tree analysis and graphical model. **Results:** Total CLDQ-NAFLD: In logistic regression analysis, the high FAST score was only identified as a negative independent factor for impaired total CLDQ-NAFLD (OR 5.9, 95% CI 1.11-31.20, $p = 0.034$). Age, gender, body mass index, estimated glomerular filtration rate, hemoglobin, and hemoglobin A1c (HbA1c) were not independent factors for the impairment of Total CLDQ-NAFLD. Decision-tree analysis showed that the FAST score was the initial classifier for the impaired total CLDQ-NAFLD. The impairment of total CLDQ-NAFLD was observed in 94.1 % and 56.5% of patients with a high FAST and a low FAST score, respectively. The graphical model revealed that FAST score, BMI, and age directly interact with impaired total CLDQ-NAFLD. Fatigue: Age and BMI were selected as factors for impairment fatigue in the logistic regression analysis. However, there was no significant factor for impairment fatigue. The high FAST score was the initial classifier for fatigue in decision-tree analysis. Fatigue was observed in 100%and 78.3% of patients with a high FAST and a low FAST score, respectively. The graphical model revealed that FAST score, BMI, eGFR, and age directly interact with fatigue. **Conclusion:** We found that the FAST score directly interacted with total CLDQ-NAFLD and the domain of fatigue. The FAST score may useful tool to assess impaired CLDQ-NAFLD.

2046-A | FIBROTIC NASH INDEX (FNI) IN DIABETICS WITH NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD)

Pegah Golabi[1,2,3], James M. Estep[1,2,3], Sean Felix[1,2,3], Maria Stepanova[4], Soroor Owrangi[2], Brian P. Lam[1,2,3], Maria João Meneses[5], Andrei Racila[1,2,3], Laurent Castera[6], Maria Paula Macedo[5] and Zobair M. Younossi[1,2,3], (1)Center for Liver Disease, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, VA, (2)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (3)Inova Medicine, Inova Health System, Falls Church, VA, (4)Center for Outcomes Research in Liver Diseases, Washington, DC, (5)iNOVA4Health, NOVA Medical School|Faculdade De Ciências Médicas, NMS|FCM, Universidade NOVA De Lisboa; Lisboa, Portugal, (6)Department of Hepatology, Beaujon Hospital, AP-HP, Université Paris Cité, Inserm UMR1149, Clichy, France.

Background: Non-invasive tests (NITs) for identification of fibrosis in NAFLD patients are increasingly used in clinical practice. Performance of these NITs could be affected by presence of type 2 diabetes (T2D). Our aim was to assess performance of FNI score in NAFLD patients with T2D. **Methods:** Clinical and laboratory data for a cohort of patients with NAFLD and T2D were used to calculate FNI scores using their HDL, AST, and HbA1c values [low-risk (**d** 0.10) and high-risk (**e** 0.33)]. Patients' liver biopsy readings, liver stiffness measurements (LSM) by transient elastography, ELF and FIB-4 scores were available. **Results:** There were 531 NAFLD patients with T2D and FNI included: 55 ± 12 years old, 43% male, mean BMI 36.8 ± 9.1, 81% hyperlipidemia, 79% hypertension, mean ELF 9.48 ± 1.10, mean FIB-4 1.43 ± 0.91. Of all patients, 18% had low-risk FNI and 49% high-risk FNI scores. Patients with higher FNI scores had more hyperlipidemia (70% in low-risk vs. 84% in high-risk, $p = 0.0123$). There was significant correlation of FNI with ELF and FIB-4 (Spearman's rho = +0.23 and +0.36, respectively, $p < 0.0001$) and with LSM (rho = +0.31, $p < 0.0001$). In patients with liver biopsy (n = 236), there was significant association of FNI scores with histologic fibrosis: FNI (mean ± SD) = 0.26 ± 0.23 in F0-F1 (40% of the sample), 0.38 ± 0.29 in F2 (19%), and 0.52 ± 0.30 in F3-F4 (41%) (Figure). There was also significant association with elevated and high LSM: mean FNI 0.41 ± 0.29 in patients with LSM < 9 kPa vs. 0.50 ± 0.32 in LSM 9 to < 12 kPa vs. 0.56 ± 0.28 in LSM **e** 12 kPa ($p = 0.019$). The predictive performance of FNI for identification of advanced fibrosis (F3-F4) was as follows: area under the ROC curve (AUC) 0.71 (0.65-0.78); for the low-risk cutoff of 0.10, sensitivity (95% CI) 91.7% (84.2-96.3%), specificity 28.6% (21.3-36.8%), PPV 46.8% (43.8-49.8%), NPV 83.3% (71.0-91.1%); for the high-risk cutoff of 0.33, sensitivity 64.58% (54.2 - 74.1%), specificity 64.3% (55.8-72.2%), PPV 55.4% (48.7-61.8%), NPV 72.6% (66.3 - 78.1%). For comparison, ELF had AUC = 0.81 (0.74-0.89), and FIB-4 AUC = 0.83 (0.78-0.88) in the same sample of patients with NAFLD and T2D. **Conclusion:** The FNI score is associated with histologic fibrosis and its NIT surrogates such as ELF, TE and FIB-4 in NAFLD patients with type 2 diabetes.

Naruyasu Kakita[3], Hirokazu Takahashi[4], Hidenori Toyoda[5], Goki Suda[6], Tomohide Tatsumi[1] and Tetsuo Takehara[2], (1)Osaka University, Graduate School of Medicine, (2)Osaka University Graduate School of Medicine, (3)Kaizuka City Hospital, (4)Saga University, (5)Ogaki Municipal Hospital, (6)Hokkaido University Hospital

Background: The incidence rate of liver cancer in NAFLD patients is low, and there is a growing need for biomarkers that can effectively narrow down the high-risk patients of liver cancer development. In this study, we investigated whether serum GDF15, which we recently reported as a risk marker for liver cancer development in patients with chronic hepatitis C, is useful as a predictive marker of NAFLD-associated liver cancer. **Methods:** GDF15 levels were measured by ELISA using stocked sera. We investigated the relationship between serum GDF15 levels and hepatocarcinogenesis in 519 biopsy-proven NAFLD patients without a history of liver cancer (biopsy cohort). We also validated using another institutional cohort of 221 patients with clinically diagnosed NAFLD with or without biopsy (validation cohort). **Results:** In biopsy cohort, the median age was 61 years old, and the median observation period was 62 months. The median Fib-4 index was 1.82, 55% were NASH, and 26% had advanced fibrosis(F3-4). Serum GDF15 level was significantly higher in the NASH group than in the NAFL group, and significantly higher in the advanced fibrosis group. The median GDF15 level was 1.22 ng/ml, and total 22 patients developed liver cancer. Multivariate analysis using the Cox proportional hazards model identified Fib-4 (HR:1.68(1.43-1.96)) and GDF15 (HR:1.61(1.36-1.86)) as factors contributing to liver carcinogenesis. Using the Cut off value of serum GDF15 level of 1.75, based on the Youden index, cumulative liver cancer incidence was significantly higher in the high GDF15 group (154 patients), with 5-year liver cancer incidence rates of 9.7% and 0% in the high and low GDF15 groups, respectively. Even among 140 patients with Fib-4 > 2.67, cumulative liver cancer incidence was significantly higher in the high GDF15 group, with 5-year liver cancer incidence rates of 17.0% and 0% in the high and low GDF15 groups, respectively. Furthermore, the GDF15 high group had a significantly higher incidence of decompensated liver events, liver disease-related death, and overall mortality. In the validation cohort, the median observation period was 43 months, and 74 patients were classified in the high GDF15 group (> 1.75 ng/ml). Total 10 patients developed liver cancer. Cumulative liver cancer incidence was significantly higher in the high GDF15 group, with 5-year liver cancer incidence rates of 17.1% and 0.9% in the high and low GDF15 groups, respectively. Among 54 patients with Fib-4 > 2.67, the 5-year incidence of liver cancer in the GDF15 high group was 24.2%, whereas no one from the low GDF15 group developed liver cancer. The incidence rates of decompensated liver events, liver-related deaths, and overall mortality were significantly more frequent in GDF15 high group. **Conclusion:** In NAFLD patients, high serum GDF15 is a risk factor for liver cancer development.

2048-A | GENETIC ALGORITHMS REVEAL POTENTIAL TO STRATIFY NAFLD HETEROGENEITY

Ibon Martínez-Arranz[1], Cristina Alonso[1], Rebeca Mayo[1], Ruben Gil-Redondo[2], Itziar Mincholé[1], Alejandro Montilla[1], Óscar Millet[2], Mazen Noureddin[3], Shelly C. Lu[4], Nicholas Davidson[5] and José M Mato[2,6], (1)OWL Metabolomics, Derio, Spain, (2)CIC Biogune, Basque Research and Technology Alliance (BRTA), Derio, Spain, (3)Houston Research Institute, Houston, TX, (4)Cedars-Sinai Medical Center, Los Angeles, CA, (5)Washington University Medical School, Departments of Medicine and Molecular Biology and Pharmacology, Saint Louis, MO, (6)National Institute for the Study of Liver and Gastrointestinal Diseases (CIBERehd, Instituto de Salud Carlos III), Madrid, Spain

Background: Non-alcoholic fatty liver disease (NAFLD) affects individual's worldwide. Identification of subtypes within NAFLD is crucial for personalized treatment. **Methods:** Here we employed genetic algorithms to subclassify a cohort of 849 patients previously classified into metabotypes of impaired VLDL secretion (A, n = 541) or increased VLDL secretion (C, n = 308)[1]. We aligned these patient metabotypes with two mouse models, Mat1a-KO and Ldlr-KO. **Results:** Using

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

genetic algorithms, we successfully subclassified 112 of 541 patients (20.7%) as subtype A-M and 54 of 308 patients (17.5%) as subtype C-L. Notably, the patients stratified as A-M and C-L displayed lipid profiles resembling those observed in the Mat1a-KO and Ldlr-KO mouse models, respectively. Additionally, these stratified patients exhibited distinct lipoprotein profiles. Our findings suggest that utilization of genetic algorithms holds potential in identifying distinct metabotypes with NAFLD. Patients classified as A-M exhibit lower LDL levels than patients classified as C-L, especially in LDL-4, LDL-5 and LDL-6 subfractions. Apo-B: (LDL-4 p = 4.36E-04; LDL-5 p = 9.25E-04; LDL-6 p = 4.99E-02) Phospholipids: (LDL-4 p = 4.35E-04; LDL- 5 p = 9.27E-04; LDL-6 p = 9.97E-03) Particle Numbers: (LDL-4 p = 4.36E-04; LDL-5 p = 4.27E-05; LDL-6 p = 4.99E-02). The same effect was found in HDL subfractions. Apo-A1: (HDL-3 p = 4.27E-02; HDL-4 p = 9.86E-03) Phospholipids: (HDL-3 p = 5.42E-03; HDL-4 p = 7.73E-03). **Conclusion:** Our study demonstrates that the implementation of genetic algorithms enables the subclassification of NAFLD patients into distinct metabotypes associated with relevant mouse models. The characterization of patient subtypes based on genetic profiles and lipidomic patterns provides valuable insights for tailoring personalized treatment strategies. This approach has the potential to identify NAFLD patients who are more likely to respond favorably to pharmacological interventions validated through the use of specific targets. Further investigations are warranted to validate these findings and explore the clinical implications for improved management of NAFLD patients. [1]: Martínez-Arranz I, Bruzzone C, Noureddin M, et al. Metabolic subtypes of patients with NAFLD exhibit distinctive cardiovascular risk profiles. *Hepatology*. 2022;76(4):1121-1134. doi:10.1002/hep.32427

2049-A | GLYCEMIC CONTROL IMPACTS FIB-4 PERFORMANCE TO PREDICT ADVANCED FIBROSIS AND IS INDEPENDENTLY ASSOCIATED WITH THE PRESENCE OF HEPATOCYTE BALLOONING: COMBINED DATA FROM MULTIPLE THERAPEUTIC TRIALS INCLUDING MORE THAN 6,000 PATIENTS (IN COLLABORATION WITH NAIL-NIT CONSORTIUM)

Stephen A Harrison[1], Julie Dubourg[2], Sophie Jeannin[2], Naim Alkhouri[3], Mazen Noureddin[4] and Jörn M. Schattenberg[5], (1)Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom, (2) Summit Clinical Research, San Antonio, TX, (3)Arizona Liver Health, Phoenix, AZ, (4)Houston Research Institute, Houston, TX, (5)I. Department of Medicine, University Medical Centre Mainz, Johannes Gutenberg University, Mainz, Germany, Mainz, Germany

Background: Fib-4 was developed as a non-invasive biomarker to predict advanced fibrosis in other liver disease and was consequently adopted in non-alcoholic fatty liver disease (NAFLD) / nonalcoholic steatohepatitis (NASH) by international guidelines. Fib-4 is recommended as a biomarker to stratify NASH patients according to their risk of advanced disease. We aimed to assess the accuracy of Fib-4 and the impact of glycemic control on its performance in the clinical trial setting. **Methods:** We combined screening data from 7 NASH non-cirrhotic phase 2 trials. Advanced fibrosis was defined as fibrosis stages 3 or 4. Descriptive analysis, univariate and multivariate logistic regression and prediction of probabilities were performed. **Results:** Out of 6,558 patients, 2,123 with centrally read liver biopsy, Fib-4 and glycated hemoglobin (HbA1c) measurements were included. According to the American Association for the Study of Liver Diseases (AASLD) 2023 guidelines, the proportions of patients in the low-risk group (Fib-4 < 1.3), intermediate-risk group (Fib-4 1.3 – 2.66), and high-risk group (Fib-4 **e** 2.67) were 59%, 37%, and 4%, respectively. In the low-risk group, 20% of patients had advanced fibrosis (17% in HbA1c **e** 6.5% versus 28 % in HbA1c $< 6.5\%$). In the intermediate-risk group, 47% of patients had advanced fibrosis (56% in HbA1c **e** 6.5% versus 41% in HbA1c $< 6.5\%$). In the high-risk group, 63% of patients had advanced fibrosis (67% in HbA1c **e** 6.5% versus 58% in HbA1c $< 6.5\%$). For each Fib-4 value, the probability of advanced fibrosis was increased in patients with HbA1c **e** 6.5% compared to those with HbA1c $< 6.5\%$ (Figure). In univariate analysis, both Fib-4 and HbA1c were associated with the presence of ballooning with increased Fib-4 and HbA1c values corresponding to higher probability of ballooning. After adjustment on age, gender, ethnicity, AST and Fib-4, HbA1c remained significantly associated with the presence of ballooning. For every 1% increase in HbA1c, the adjusted odds of hepatocyte ballooning increased by 1.6 (95% confidence interval: 1.4 – 1.8). **Conclusion:** Glycemic control as assessed by HbA1c is an independent predictor of hepatocyte ballooning and impacts the thresholds of Fib-4 to predict advanced fibrosis. The integration of glycemic control parameters within the Fib-4 score would increase its ability to predict advanced fibrosis in the NASH population.

f 2050-A | HEAD-TO-HEAD COMPARISON OF FAST, MAST, MEFIB AND cT1 IN IDENTIFYING AT-RISK NASH PATIENTS IN A LOW-PREVALENCE POPULATION

Mazen Noureddin[1], Naim Alkhouri[2], Cassandra Chaldaureille[3], Julie Foucquier[3], Veronique Miette[3], Laurent Sandrin[3], Celine Fournier[3] and Stephen A Harrison[4], (1)Houston Liver Institute, Houston, TX, (2) Arizona Liver Health, Phoenix, AZ, (3)Echosens, (4) Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom

Background: The recently published AASLD practice guidance on the management of NAFLD patients recommend 4 non-invasive tests and associated cut-off values to rule-in and rule-out presence of "at-risk NASH": FAST, MAST, MEFIB (MRE + FIB-4) and cT1. The aim of this study was to compare the performances of these NITs using liver biopsy (LB) as the reference in a population with low prevalence of at-risk NASH patients. **Methods:** Patients referred for a routine colon cancer screening with no prior history of liver disease or alcohol abuse underwent a LB if LSM by VCTE **e** 7kPa, MRE **e** 3kPa, MRI-PDFF **e** 5% or cT1 **e** 780ms. LB were assessed by two expert pathologists in a double-blind manner with consensus, using the NASH CRN scoring system. At-risk NASH was defined by NAS **e** 4 with at least 1 in steatosis, ballooning, lobular inflammation and fibrosis stage F **e** 2. Diagnostic performances of NITs were assessed using Receiver Operating Curve (ROC). **Results:** 170 patients (40.6% females; mean ± SD age 55.9 ± 6.0 y; mean ± SD BMI 33.1 ± 4.9 kg/m²) were included in this analysis. At-risk NASH was diagnosed in 11.8% of patients. Area under ROC (AUC) of MAST, FAST, MEFIB and cT1 were 0.91 [0.85;0.98], 0.86 [0.78;0.94], 0.52 [0.48;0.57], 0.77 [0.67;0.87], respectively. FAST outperformed cT1 in terms of AUC ($p = 0.045$), specificity for patients in the rule-out zone and positive predictive value (PPV) for patients with a score above the rule-in cut-off. MAST outperforms FAST, MEFIB and cT1 in terms of AUC ($p = 0.031$, $p < 1.10^{-4}$ and $p = 0.003$, respectively). The sensitivity of MAST and MEFIB at rule-out and rule-in cutoffs were numerically lower than FAST but had higher specificity. Moreover, the rate of at-risk NASH patients with a score above the high cut-off was higher for FAST compared to MAST and MEFIB. The percentage of well-classified patients was significantly higher for FAST compared to cT1 ($p = 0.015$). However, percentage of patients in the indeterminate zone was significantly lower for MAST than FAST, MEFIB and cT1 ($p < 1.10^{-4}$ in all cases) (Table). **Conclusion:** MAST and FAST have demonstrated superior performance in the identification of at-risk NASH patients. However, factors such as cost, and their correlation with histological changes and liver-related outcomes over time should be carefully considered when determining the optimal tests. Furthermore, the potential benefits of sequential testing warrant further investigation to establish their efficacy and reliability.

2051-A | IDENTIFICATION OF NAFLD SUBTYPES BASED ON TRANSCRIPTOME ANALYSIS: IMPLICATIONS FOR TARGETED THERAPIES

Hyo Young Lee[1], Hyunwoo Oh[1], Eileen Yoon[2], Huiyul Park[3], Sang Bong Ahn[4], Joo Hyun Sohn[2] and Dae Won Jun[2], (1)Uijeongbu Eulji Medical Center, (2)Hanyang University College of Medicine, (3)Hanyang University, (4)Eulji Medical Center

Background: Non-alcoholic fatty liver disease (NAFLD) is a complex condition with significant heterogeneity. The development of effective NAFLD drugs requires a deeper understanding of the disease's pathophysiology and identification of the appropriate target population based on specific mechanisms of action. This study aimed to propose NAFLD subtypes based on transcriptome analysis, enabling a more targeted approach to treatment selection. **Methods:** Liver tissue transcriptome data from 120 NAFLD patients were analyzed, and an additional validation cohort of 200 patients' transcriptome data from public databases was utilized. Non-negative matrix factorization (NMF) clustering was applied to classify the patients into optimized groups, and distinctive gene signatures representing each subgroup were extracted. **Results:** Three distinct patient groups were identified according to transcriptome analysis in training cohort (n = 120). Group 1 comprised individual's without underlying conditions such as hypertension and diabetes, displaying minimal liver fibrosis. Histologically, most cases were characterized by NAFLD without steatohepatitis or significant fibrosis, with upregulated expression of genes related to de novo hepatic fat synthesis. Group 2 consisted of patients with NAFLD and steatohepatitis, exhibiting advanced fibrosis and increased expression of genes associated with immune response and inflammation. Group 3 predominantly included NASH patients with diabetes and hypertension, as well as the highest fibrosis stage. This group exhibited activation of genes related to reactive oxygen species and fibrosis. Pathway analysis revealed specific upregulated and downregulated pathways in each group, serving as potential biomarker pathways for the three NAFLD subtypes. These findings were further validated in the independent public data cohort of 200 patients. **Conclusion:** Transcriptome analysis enabled the classification of NAFLD patients into three distinct subtypes, characterized by distinct gene expression patterns and specific pathway activation or suppression.

Área De Enfermedades Raras (CIBERER), (6)Department of Medicine, Dermatology and Toxicology, Universidad De Valladolid, Valladolid, Spain, (7)Radiology Unit, Hospital Clínico Universitario De Valladolid. 47003 Valladolid, Spain

Background: Significant fibrosis is a clinically relevant endpoint that can be inferred by using a Transient Elastography (TE) cut-off of 8 KPa. This value, however, has low specificity and can lead to a large number of unnecessary referrals to specialized units. Objective: To find serological biomarkers able to improve the specificity of this cut-off to detect significant fibrosis (F2+) in patients with NAFLD and other liver diseases. **Methods:** Potential candidates were identified through the analysis of gene expression of liver biopsies coming from 1) NAFLD patients with or without histologically diagnosed significant fibrosis obtained by microarray [Identification cohort, 3 cohorts, F0-F1 (139) *vs*. F2-F4 (47)] and RNA-seq [Validation cohort, 4 cohorts, F0-F1 (234) *vs*. F2-F4 (197)] and 2) Patients with viral hepatitis induced by HBV [F0-F1 (63) *vs*. F2-F4 (61)] or HCV [F0-F1 (15) *vs*. F2-F4 (28)]. Differences in expression levels were filtered by FDR (**d** 0.05) and through a series of public datasets to retain exclusively secreted proteins able to reach the bloodstream. Common candidates were ranked according to p-value in each dataset and average ranking was used to select the final candidates. Circulating levels of selected candidates were independently validated in serum samples of NAFLD biopsy-proven patients (N = 42) by Enzyme-linked immunosorbent assay (ELISA). **Results:** Gene expression analyses identified 3 potential circulating biomarkers associated to significant fibrosis independent of aetiology (named as FICE1, 2 and 4 for Fibrosis Inducible Circulating Element) and one showing a strong significant association to fibrosis exclusively in NAFLD and CHB (FICE3) (Figure 1a). Preliminary ELISA analysis in NAFLD patients [F0-F1 (23) *vs*. F2-F4 (19)] indicates a significant association to F2+ of circulating levels of biomarkers FICE3 and FICE4 and suggests that circulating FICE2 might also be associated to significant fibrosis (Figure 1b). FICE4 was able to retain a strong association to significant fibrosis in a subanalysis in which only patients with a TE **e** 8 KPa were included [F0-F1 (16) *vs*. F2-F4 (19)] (figure 1c). FICE4 at a cut-off of 40ng/µl combined with TE **e** 8 KPa was able to retain a high ability to rule in significant fibrosis [94.7% (18/19)] compared to TE alone [100% (19/19)] and largely increased the ability to rule out patients without significant fibrosis [70% (16/23) vs 30% (7/23)] (Figure 1d). **Conclusion:** Our analysis has identified at least one circulating biomarker that might be useful to improve the ability of TE **e** 8 KPa to rule in and out the presence of significant fibrosis in patients with NAFLD. Validation in a larger number of samples and additional cohorts in which the leading cause of liver disease is caused by other aetiologies are currently ongoing.

2053-A | IDENTIFICATION OF NOVEL HUB GENES THAT MAY PREDICT THE RISK OF LIVER FIBROSIS PROGRESSING TO HEPATOCELLULAR CARCINOMA IN NON-ALCOHOLIC FATTY LIVER DISEASE

Baiyi Liu[1], Xiaoxiao Wang[1], Rui Jin[2], Zilong Wang[1], Yuyun Song[1], Xiaohe Li[1], Feng Liu[1] and Huiying Rao[1], (1)Peking University People's Hospital, Peking University Hepatology Institute, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Diseases, Beijing International Cooperation Base for Science and Technology on NAFLD Diagnosis, (2)Peking University People's Hospital

Background: Nonalcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease worldwide and has been increasingly recognized as a contributing factor of hepatocellular carcinoma(HCC), in which liver fibrosis is a crucial stage. At present, the exact pathogenesis of liver fibrosis-related HCC in NAFLD has not been fully elucidated. In this study, we analyze the key genes related to liver fibrosis and HCC in NAFLD, aiming to predict the risk of liver fibrosis progressing to HCC in NAFLD. **Methods:** NAFLD fibrosis and NAFLD-related HCC datasets were selected for identifying differentially expressed genes (DEGs). The common genes of DEGs were taken out for GO and KEGG enrichment analysis, and protein-protein interaction(PPI) network were integrated to explore the potential function of the DEGs and hub genes. According to the hub genes, Lasso Cox regression analyses were performed to determine a gene model that was optimal for risk prediction of the progression of fibrosis to HCC in NAFLD. In order to evaluate the performance of the gene model , two data sets were analyzed, one for NAFLD fibrosis and NAFLD-HCC and the other for NAFLD fibrosis and NASH-HCC. Receiver operating characteristic curves (ROC) were used to evaluate model performance in these two HCC datasets. The enrichment analysis and tumor immune infiltration associated with high and low risk group were performed. **Results:** 559 DEGs in NAFLD fibrosis and 2164 DEGs in NAFLD HCC were identified. A total of 88 common DEGs were found. GO and KEGG enrichment analysis suggested that common DEGs were strongly associated with response to reactive oxygen spices, positive regulation of stress-activated MAPK cascade and apoptotic signaling pathway, IL-17 signaling pathway. Seven genes, including TIPM1, COL1A1, CXCL9, FOS, VWF, CD79A, VCAN, were identified as hub genes by the PPI network and then were used to construct a gene model. By the calculation of the gene model, the area under the receiver operating characteristic curves (AUCs) for risk prediction were 0.893 in the NAFLD-HCC dataset and 0.751 in the NASH-HCC dataset. Also, overall survival in the high-risk group was significantly shorter than that in the low-risk group in TCGA dataset. Gene set enrichment analysis(GSEA) indicated that the PPAR signaling pathway, insulin signaling pathway, fatty acid metabolism were significant up regulation in the high-risk group and negative regulation of intrinsic apoptotic signaling pathway was significant up regulation in the low-risk group. The positive correlation between CXCL9 and Macrophage M1 and negative correlation between VCAN and Macrophage M2 was strongly high in the high-risk group. **Conclusion:** The 7 hub genes may predict the risk of liver fibrosis developing into HCC in NAFLD and may mediate the potential molecular mechanism of NAFLD developing into HCC, which is hopeful to be biomarkers for predicting progression, diagnosis and treatment of diseases.

2054-A | IDENTIFYING NOVEL HEPATOCELLULAR CARCINOMA ONCOGENES IN NASH AND NAFLD PUBLIC DATA SETS

Mazen Almasry, University of Wisconsin Hospital and Clinics, Jihad Aljabban, University of North Carolina and

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Maryam Panahiazar, University of California San Francisco

Background: Non-alcoholic fatty liver disease (NAFLD) is one of the leading causes of liver disease worldwide, with an estimated prevalence of 32.4%, which is set only to increase. 20-30% of NAFLD cases will progress to non-alcoholic steatohepatitis (NASH) and, ultimately, to cirrhosis and hepatocellular carcinoma (HCC). HCC may even arise outside the background of cirrhosis in 20% of cases. NAFLD is a growing cause of HCC, which remains a cancer with poor outcomes. Oncogenic changes may be present in earlier stages of NAFLD before cirrhosis. Identifying these changes may help risk stratify patients. **Methods:** We employed the Search Tag Analyze Resource for the GEO platform to search the National Center for Biotechnology Information (NCBI) Gene Expression Omnibus (GEO) to tag NAFLD and NASH samples. We conducted two separate meta-analyses of data from 62 NAFLD liver biopsies with 83 healthy liver biopsies and 187 NASH liver biopsies with 154 liver biopsies. Samples were taken from series GSE48452, GSE59045, GSE89632, GSE66676, and GSE107321 for the NAFLD meta-analysis and series GSE17470, GSE37031, GSE48452, GSE63067, GSE89632, and GSE83452. Novel HCC genes identified from recent, high-impact papers were compiled and compared to our dataset to characterize undescribed oncogenic changes in NAFLD. **Results:** We have found upregulation of several recently described oncogenes in HCC in our NAFLD and NASH datasets. These genes hold roles in cell division, metabolism, cellular signaling, and inflammation. Upregulated oncogenes included centrin 2 (CETN2, NASH $p = 0.0113$, NAFLD $p = 5.41$ E-8), acyl-CoA thioesterase 12 (ACOT12, NASH $p = 0.00174$, NAFLD $p = 0.00661$), annexin A4 (ANXA4, NASH $p = 0.0401$), tripartite motif containing 32 (TRIM32, NAFLD $p = 2.21$E-5), and the matrix metalloproteinases MMP6 (NASH $p = 2.86$E-4). **Conclusion:** As global cases of NAFLD expand, so will the consequences of the disease. One of the most morbid outcomes is HCC. Understanding of HCC is burgeoning, and novel oncogenes not previously or well-described in NAFLD may explain increased HCC risk in both the presence or absence of cirrhosis. Oncogenes illustrated in our dataset may serve to risk stratify NAFLD patients and motivate aggressive and earlier intervention.

2055-A | IFN-GAMMA IN THE BLOOD OF NAFL PATIENTS PREDICTS FATTY LIVER DETERIORATION

Ha Neul Kim[1], Hei-Gwon Choi[1], Soon Ok Kim[1] and Eun Hyuk Soo[2], (1)Chungnam National University, (2) Chungnam National University Hospital

Background: Non-alcoholic fatty liver (NAFL) is a liver disease in which fat accumulates more than 5% and is divided into Mild, Moderate, and Severe according to the severity of the fatty liver. There are no blood biomarkers that can identify the severity of fatty liver. NAFL progresses to Non-alcoholic steatohepatitis (NASH) by pro-inflammatory cytokines. It has been reported that interferon-gamma (IFN-γ) may play an important role in the progression of NASH. Therefore, IFN-γ expression was confirmed in the blood of patients according to the severity of fatty liver. **Methods:** The severity of fatty liver in NAFL patients was identified using magnetic resonance imaging (MRI) and Ultrasound (US) (IRB approval number: 2020–06-083). Peripheral blood mononuclear cells (PBMC) were isolated and analyzed using flow cytometry. The expression of IFN-γ was confirmed in the patient's blood and serum, and correlation with NAFLD scores was confirmed. In addition, the patient was followed up to confirm the change in IFN-γ. **Results:** In patients who underwent MRI-PDFF, CD8 T cell expression was increased in severe patients PBMC compared to normal PBMC. $CD45^{+}IFN\text{-}\gamma^{+}$ NK cells increased according to the severity of fatty liver in patients who underwent ultrasound. In fibrosis progression by calculation of NFS, IFN-γ expression was increased. Patients were separated using NFS, in the intermediate group, NK cells, and $CD45^{+}$ IFN-γ cells were increased compared to the F0-F2 group PBMC. $CD45^{+}$IFN-γ cells in NAFLD patients who followed every three months had a positive correlation with GGT. Serum IFN-γ was expressed low in patients with reduced BMI and correlated with NFS. Conversely, the serum IFN-γ expression of patients with increased BMI showed an increased pattern. BMI and serum IFN-γ levels of the patients followed up showed similar patterns. **Conclusion:** In conclusion, the expression of IFN-γ in the blood can be used as a practical serum biomarker to measure the severity of NAFL.

2056-A | IL-18 AND IL-18BP AS NON-INVASIVE BIOMARKERS OF NASH IN A BARIATRIC PATIENT COHORT

Christian Stoess[1], Janset Onyuru[1], Trevor Crafts[2], Ola Leszczynska[1], Alexander Wree[3], Daniel Hartmann[4], Helmut Friess[4], Bruce Wolfe[2], Andrea Stroud[2], Hal Hoffman[1] and Ariel E. Feldstein[1], (1)University of California, San Diego, (2)Oregon Health and Science University, Portland, (3)Charité, Berlin, (4)Technical University of Munich, Munich

Background: Non-alcoholic fatty liver disease (NAFLD) is a prevalent condition in individual's with obesity. A critical stage in the progression of the disease is the transition from hepatic steatosis to non-alcoholic steatohepatitis (NASH). Liver biopsy is currently the gold standard for diagnosing NASH. Non-invasive biomarkers are needed to identify high-risk patients. Interleukin-18 (IL-18) is released during pyroptosis, a lytic cell death known to be involved in the development of NASH. Here, we investigated the role of IL-18 and its antagonist IL-18 binding protein (IL-18BP) as potential non-invasive biomarkers for NASH. **Methods:** A total of 179 serum samples were collected at the preoperative time point. All patients included in the study underwent liver biopsy either by needle sampling or wedge resection during bariatric surgery. Serum samples were measured using the human IL18 Bpa DuoSet ELISA (DY119, R&D Systems) and the human total IL-18 DuoSet ELISA (DY318-05, R&D Systems) according to the manufacturer's instructions. Histologic evaluation was performed by a pathologist according to the NASH Clinical Research Network classification system. **Results:** Serum IL-18 and IL-18BP levels were significantly higher in patients with a NAS score **e** 4 than in subjects with a NAS score < 4 ($p < 0.05$ and $p < 0.001$). Serum IL-18BP alone showed a diagnostic accuracy for NASH with an AUROC of 0.64 (95%CI 0.54-0.74, $p < 0.05$) and 0.68 for a NAS score **e** 4 (95%CI 0.59-0.76, $p < 0.0001$). Serum IL-18 detected a NAS score **e** 4 with an AUROC of 0.63 (95%CI 0.53-0.72, $p = 0.012$). To better understand the association of serum of IL-18 and IL18-BP levels with the different histological components of NASH, we examined correlations with fibrosis, steatosis, inflammation, and ballooning. We observed significantly elevated serum IL18-BP levels in patients with advanced stages of fibrosis compared to patients without fibrosis. Grouping of patients with fibrosis stage 0-1 vs. 2-3 resulted in significant discrimination of these two groups ($p < 0.01$). IL-18 and IL-18BP levels were both increased in specimens with advanced lobular inflammation. The association of serum IL-18BP with known markers of NASH progression, including AST, ALT, BMI, and triglycerides was tested. Serum IL-18BP levels showed a moderate correlation with the plasma AST level ($r = 0.41$, $p < 0.0001$) and ALT ($r = 0.36$, $p < 0.0001$). Meanwhile, serum IL-18BP levels exhibited a weak correlation with triglycerides ($r = 0.25$, $p < 0.0001$). Binary logistic regression revealed that IL-18BP independently predicted NASH ($p = 0.016$) and a NAS score **e** 4 ($p < 0.001$) in our patient cohort whereas IL-18 predicted a NAS score **e** 4 ($p = 0.011$). **Conclusion:** IL-18 and IL-18BP are associated with pathological parameters of NASH and can predict a high NAS score in patients with obesity. Both, IL-18 and IL-18BP can potentially serve as biomarkers for NASH.

2057-A | IMPACT OF TIME-VARYING ANALYSIS OF LIVER ENZYMES AND BASELINE FACTORS ON THE DEVELOPMENT OF SIGNIFICANT FIBROSIS IN NAFLD: A SINGAPORE RETROSPECTIVE COHORT STUDY

Ian Yang Liew[1], Hwee Pin Phua[2], Wei-Yen Lim[2], Angela Li Ping Chow[2], Xiu Ying Loo[1], Keivin Wei Wen Sim[1], Eng Sing Lee[3,4] and Kuo Chao Yew[5], (1)Ministry of Health (MOH) Holdings Pte Ltd, Singapore, (2) Department of Preventive and Population Health, Tan Tock Seng Hospital, (3)Clinical Research Unit, National Healthcare Group Polyclinics, (4)Lee Kong Chian School of Medicine, Nanyang Technological University, (5)Department of Gastroenterology and Hepatology, Tan Tock Seng Hospital

Background: Non-alcoholic fatty liver disease (NAFLD) progression to advanced fibrosis is associated with liver complications and mortality{Ye, 2020 #4340}. While liver transaminases are not a perfect screening tool, their use in screening remains relevant, especially for the primary care physician. **Methods:** We conducted a retrospective cohort study to investigate how differences in baseline patient characteristics and changes in liver transaminases can help predict advanced fibrosis in a multi-ethnic Asian population at a tertiary centre. Eligible patients that fulfilled the inclusion and exclusion criteria with a complete set of data were followed up from January 1, 2007 to October 31, 2017. This generated a final cohort comprising 490 patients for alanine aminotransferase (ALT), 417 for aspartate aminotransferase (AST), and 417 for the AST/ALT ratio

groups. Hazard ratios and 95% confidence intervals were estimated for ALT, AST, and AST/ALT ratio as factors of significant fibrosis(> F3 on *fibroscan*, FIB-4 > 1.3) using separate multivariable Cox regression models and treating these as time-varying covariates. **Results:** The median length of follow up for all patients (n = 2170) was 52.6 months (23.0, 81.1). Patients who developed fibrosis (n = 434; 20.0%) exhibited lower baseline ALT, AST and albumin levels, but had higher NAFLD fibrosis score, FIB-4 score, AST/ALT ratio and platelet count (Table 1a). Cox regression analysis showed that ALT and AST were significant predictors (Table 1b) of fibrosis. Specifically, when keeping gender, age, Charlson Comorbidity Index(CCI), presence of metabolic syndrome, baseline AST (log) and platelet count (log) constant, a 10% increase in ALT is associated with 6.3% (95% CI: 2.9% - 9.9%) increase in hazard, while a 10% increase in the AST value is associated with 10.8% (95% CI: 6.9% - 14.9%) increase. Female gender, age and CCI at baseline were also statistically significant risk factors associated with fibrosis. Analysis of the data was limited by missing laboratory data amongst patients due to the retrospective nature of the study. **Conclusion:** This study highlights the importance of assessing changes in liver transaminase levels over time in identifying NAFLD patients at risk of developing fibrosis. Further prospective studies would be necessary to verify the use of these measurements in the prediction of fibrosis in NAFLD patients.

2058-A | IMPROVING PRIMARY CARE PROVIDER AWARENESS AND USE OF FIB-4 RISK-STRATIFICATION FOR NONALCOHOLIC STEATOHEPATITIS (NASH)

Max Lloyd Goldman[1], Rena K. Fox[2], Danielle Brandman[3], Delia Falliers[4], Kendall B Islam[2] and Janet N Chu[2], (1)Kaiser Permanente Northern California, (2) University of California, San Francisco, (3)Weill Cornell Medical College, New York, NY, (4)University of California, Los Angeles

Background: AASLD guidance recommends primary care providers (PCPs) perform fibrosis-4 index (FIB-4) risk assessment to determine the need for specialty management of patients at-risk for NASH. However, few PCPs are aware of or use FIB-4. We implemented AASLD's FIB-4 risk-stratification algorithm and evaluated PCP knowledge and use of FIB-4 pre- and post-intervention. **Methods:** At a large, diverse health system, we conducted a three-part study: 1) a pre-intervention PCP survey to ascertain nonalcoholic fatty liver disease (NAFLD) knowledge and practice patterns, 2) an intervention implementing a FIB-4 risk-stratification referral algorithm in primary care, and 3) a post-intervention PCP survey. During the 18-month intervention, PCPs received an electronic medical record (EMR) notification for each of their patients with diabetes and either a low-risk (< 1.3) or a high-risk (> 2.67) FIB-4, including recommendations for patients at low-risk to be managed in primary care and those at high-risk to be referred to hepatology. One year later, a post-intervention survey measured the change in FIB-4 knowledge and use of FIB-4 in managing patients at-risk of NASH. Pre- and post-survey responses were compared using two-sample z-tests for proportions. **Results:** The 88/115 pre- and 69/119 post-intervention survey respondents included PCPs delivering care to 26,602 patients. Among post-survey PCPs, 64% received messages for low- and 54% for high-FIB-4 patients during the intervention. Comparing post- to pre-survey responses, PCP knowledge of fibrosis as a predictor of cirrhosis improved (86% vs. 76%, p = 0.02), knowledge of FIB-4 components increased (46% vs. 25%, p = 0.003), and more PCPs reported now applying FIB-4 for patients with elevated LFTs (59% vs. 16%, p < 0.001). Finally, 46% reported that their likelihood of managing NAFLD patients with low FIB-4 in primary care and/or appropriately referring patients with high FIB-4 to hepatology increased. **Conclusion:** Implementing a FIB-4 risk-stratification algorithm in primary care substantially impacted PCPs' management of NAFLD patients one year later. PCPs demonstrated significantly improved awareness of FIB-4, and most importantly, continued to incorporate FIB-4 risk-stratification into their specialty-

referral decision-making, resulting in appropriate referral of high-risk patients to hepatology, while continuing PCP management of low-risk patients. This study provides evidence that PCPs introduced to FIB-4-based risk stratification adopt the strategy, resulting in improved practice patterns.

2059-A | INCREASED CARDIOVASCULAR AND KIDNEY DISEASE RISK IN PATIENTS WITH ADVANCED FIBROSIS DUE TO NONALCOHOLIC STEATOHEPATITIS

Kathleen E. Corey[1], Jun Xu[2], Sharlene Lim[2], Kaiyi Zhu[2], Vladislav A Malkov[2], Jason Melehani[2], Lisa Boyette[2], Timothy R. Watkins[2] and Andrew N. Billin[2], (1)Massachusetts General Hospital, Somerville, MA, (2) Gilead Sciences, Inc.

Background: NNASH is associated with increased risks of CVD and CKD. Liver fibrosis stage is an independent predictor of liver-related outcomes in patients with NASH, but the associations of hepatic fibrosis with CVD and kidney disease risk are unclear. Our study aimed to characterize CVD and kidney disease risk in patients with NASH using the SomaSignal® platform. **Methods:** In a phase 2b study (NCT03449446), a subset of participants (pts) with noncirrhotic (F2/F3) or compensated cirrhotic NASH (F4) with paired plasma and liver biopsy samples at baseline were included (N = 175). Liver biopsy fibrosis stage was determined using the NASH CRN system. Risk for future liver events was categorized by baseline ELF scores (low **d** 9.8, high **e** 11.3). SomaSignal® tests (SomaLogic® Colorado) for primary CVD risk (R1123, including MI, stroke, TIA, hospitalization for HF or CV death) and 4-yr kidney disease risk (R1138, probability of progressive chronic renal insufficiency, including 50% decline in eGFR, initiating dialysis or becoming a candidate for kidney transplantation) were performed on baseline plasma samples. The probability of CVD or kidney disease progression was compared between pts by fibrosis stage and ELF risk categories. The fraction of the study population in risk categories for each test was determined. **Results:** At baseline, 16% of noncirrhotic and 21% of cirrhotic pts were characterized by SomaSignal® tests as high risk for primary CVD. By ELF categories, 11% and 33% of pts at low and high risk for liver events, respectively, were characterized as high risk for primary CVD, suggesting that higher risk of liver events may be associated with greater primary CVD risk. 35% of noncirrhotic and 50% of cirrhotic pts were characterized as being at moderate/high 4-yr kidney disease risk. By ELF categories, 29% and 73% of participants at low and high risk for liver events were characterized as being at high 4-yr kidney disease risk, despite the median eGFR being similar between these two groups. **Conclusion:** SomaSignal® results of CVD and kidney disease progression risk suggest that severity of liver fibrosis (by histology or ELF) is associated with an increasing risk for these comorbidities. Individual's with eGFR < 60 mL/min were excluded from the study and yet many participants had 4-yr kidney disease risk scores indicating high risk. Conventional measures of kidney disease risk may underrecognize the risk for progression of CKD. The utility of these tests should be evaluated in larger studies.

2060-A | INCREASED LIVER DISEASE ACTIVITY IN PEOPLE WITH PSORIATIC DISEASE AFTER CONTROLLING FOR OBESITY, IDENTIFIED BY QUANTITATIVE MAGNETIC RESONANCE IMAGING

Charlie Diamond[1], Lija James[2], Elizabeth Shumbayawonda[1], Hussein Al-Mossawi[2], Helena Thomaides-Brears[1], Rajarshi Banerjee[1] and Laura Coates[2], (1)Perspectum Ltd., (2)University of Oxford

Background: Psoriatic arthritis and psoriasis (PsA, Ps) are chronic inflammatory conditions of the joints and skin, respectively. Treating with methotrexate (MTX) is associated with hepatotoxicity and liver damage. As risk of psoriatic disease is associated with obesity, this population is also at high risk of fatty liver disease. Magnetic resonance imaging (MRI) provides a non-invasive assessment of liver characteristics, including steatosis and disease activity. Here, we evaluated liver health in participants with PsA and Ps compared to age, sex, and BMI-matched non-psoriatic controls (NCs), using quantitative MRI. **Methods:** Data from 19 participants were collected from an ongoing, prospective study recruiting participants with PsA and Ps on new anti-rheumatic treatments (COLIPSO REC: 20/LO/0616). Retrospective data from 49 NCs (COVERSCAN study, NCT04369807 and UK Biobank application 9914) matched for age, sex, and BMI were included. MRI-derived measures of liver fat (%) and disease activity (cT1) were compared, and prevalence of liver damage from clinical thresholds was assessed with Fisher's exact tests. Wilcoxon rank sum tests were used for continuous variables. Multivariate linear regression estimated the effects of variables influencing cT1. **Results:** In this cohort of middle-aged, overweight people with mild PsA or Ps but no diabetes (age 46 y [IQR: 38 – 59]; 53% male; BMI of 28kg/m^2 [IQR: 25 – 31]; 6 years disease duration [IQR: 3 – 13]; 32% on Methotrexate) liver disease activity (cT1 ³800ms) was more prevalent than the matched NCs (32% vs. 6.1%; p-value: 0.011). Severe liver disease (cT1 ³875ms) was frequent (21% vs. 0% in NCs; p-value: 0.005). The significant increase in liver disease activity in the PsA and Ps patients was equivalent to > 2 NAFLD Activity Score (NAS) points (101ms difference in cT1), after controlling for differences in BMI (figure 1). Non-alcoholic steatohepatitis (NASH), defined as cT1 ³800ms and liver fat ³5%, was more prevalent in the PsA/Ps group (26% vs. 4.1%; p-value: 0.016). Liver health did not differ between patients on MTX from those on other anti-rheumatic treatments (p = 0.34). **Conclusion:** Individual's suffering with PsA/Ps have a significantly higher prevalence of liver disease compared to matched controls, even at higher BMI. The increased liver disease activity in PsA/Ps patients may result from underlying chronic inflammation.

2061-A | INTEGRATION OF THE ENHANCED LIVER FIBROSIS (ELF) TEST FOR ADVANCED FIBROSIS AND CIRRHOSIS DETECTION IN A REAL-WORLD CLINICAL ENVIRONMENT

Jessica C. Rachman[1], Mina M. Al-Hamadani[1,2], Amberly Komatz[1], Shweta Chakraborty[1], Czarina Mae Morley[1], Ashley M. Goff[1], Jessica N. Wilson[1], Nancy J. Todd[1], Jessica J. Taggart[1], Ryan M. Taylor[1], Nizar T. Talaat[1], Steven A. Weinman[1] and Winston Dunn[1], (1) University of Kansas Medical Center, (2)Medstar Washington Hospital Center / Georgetown University

Background: Nonalcoholic fatty liver disease (NAFLD) affects approximately 26% of the US population, of which 2% develop nonalcoholic steatohepatitis (NASH) with advanced fibrosis or cirrhosis. The study explores the potential of integrating Enhanced Liver Fibrosis (ELF) testing with Vibration-Controlled Transient Elastography (VCTE) in a real-world clinical environment to improve identification of high-risk cases. **Methods:** 359 patients undergoing hepatology evaluation for NAFLD were randomized into the intervention group ($n = 179$) or the control group ($n = 180$). In this design, participants in the intervention group received the ELF test, while participants in the control group did not. The ELF test result was made accessible to the hepatologist before a liver biopsy decision. The primary outcome measured was the rate of advanced fibrosis (**e** F3) diagnoses, determined through either liver biopsy or clinical tool. The secondary outcome was the liver biopsy rate. Diagnosis rates were compared using logistic regression. **Results:** The control group had a mean FIB-4 of 1.50 (SD = 1.40) with 31.3% having type II diabetes. 108 (60.3%) underwent Fibroscan and 37 (20.7%) underwent liver biopsies, with 8 patients (4.5%) showing **e** F3 fibrosis. The intervention group had a mean FIB-4 of 1.49 (SD = 1.17) and a higher type II diabetes incidence of 39.4%. Here, 111 (61.7%) underwent Fibroscan and 40 (22.2%) underwent liver biopsies. No difference in the biopsy rate was observed in the two groups ($p = 0.6283$). However, a higher number of patients in the intervention group (20 patients, 11.1%) compared to the control group (9 patients, 5.0%) had **e** F3 fibrosis (OR 2.672, 95% CI 1.185 – 6.605, $p = 0.0231$). **Conclusion:** This study demonstrates that the integration of ELF testing in a real-world clinical setting, which already includes VCTE, can increase the detection of advanced fibrosis and cirrhosis in NAFLD patients without increasing liver biopsy rates. Importantly, this strategy can enhance patient care by minimizing invasive procedures while maximizing diagnostic capability.

2062-A | KEY GENE VALIDATION IN HEPATIC FIBROSIS AND HEPATOCELLULAR CARCINOMA IN AFRICAN AMERICANS WITH NAFLD

Tanmoy Mondal[1], Coleman I. Smith[2], Christopher A Loffredo[3], Ruth Quartey[1], Charles D. Howell[4], Brent E. Korba[3], Kwabi-Addo Bernard[1], Gail Nunlee-Bland[1], Leanna Rucker[2], Gemeyel Moses[1], Marika Clark[1], Sharleine Cotin[1], Jheannelle Johnson[1], Miranda Newheart[1], Faith Bentley[1], Tia Pope[1], Nacorria Lightsey[1], Triniti Davis[1], Oluwaseyi Oyebola[1], Karma A Matthews[1], Jasneet Sahota[1] and Somiranjan Ghosh[1], (1)Howard University, Washington, DC, (2)Georgetown University Hospital, (3)Georgetown University, (4) Howard University Hospital, Washington, DC

Background: Growing prevalence of Non-Alcoholic Fatty Liver Disease (NAFLD) is alarming in the USA and has increased to 47.8% of the population. African Americans (AA) with NAFLD have a high risk of progression to fibrosis (28.5%) but this group has been chronically understudied. We identified the key Hepatic Fibrosis and Hepatocellular Carcinoma pathways through global gene expression. In this pilot study, we compare and validate the previously identified signature genes using TaqMan Low-Density Array (TLDA) in the pathogenesis of Hepatic Fibrosis and Hepatocellular Carcinoma from the blood of AA with NAFLD. **Methods:** AA NAFLD research participants (n = 19; mean age: 46.6 ± 8.2) were recruited from the Georgetown University Liver Transplantation Unit, Washington DC, along with healthy AA controls (n = 12; mean age: 35.9 ± 11.1) from the same region. Their sociodemographic, lifestyle exposures, and medical background information were recorded. TaqMan® Array (FAST Plate) for TaqMan® Array Human Liver Cancer 96-well plate, fast (Applied Biosystems, Catalog #4413255, Santa Clara, CA, USA) over the ABI QuantStudio 5 Real-Time PCR System was used to run the QRT-PCRs, coupled with Ingenuity Pathway Analysis (IPA®) validate and visualize the major pathways. **Results:** We identified 13 key genes (e.g., *ADAM17, AKT1, CFLAR, E2F1, EP300, HMBS, RUNX3, SFRP2, STAT3, TCF4, TGFβ1, ITGB1* and *TP53*) that were validated by TLDA method. *TGFβ1 (*responsible for liver cell growth and division), *E2F1 (*cell proliferation) and *HMBS* (catalyzes synthesis of hydroxymethylbilane synthase) were significantly up and downregulated, respectively. IPA analysis revealed *Hepatic Fibrosis Signaling* as the top canonical pathway with its corresponding bio-functions; viz., Hepatocellular

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Carcinoma development, which was further validated by IPA match analysis. **Conclusion:** This pilot study offers an opportunity to gain insight into NAFLD disease dynamics in AA that may help in developing molecular classifiers to identify the disease risks using non-invasive peripheral blood. However, further multiethnic validation using large sample size as well as comparisons of blood and liver biopsies is necessary to strengthen our findings.

2063-A | LIPIDOME CHANGES ASSOCIATED WITH A DIET-INDUCED REDUCTION IN HEPATIC FAT AMONG ADOLESCENT BOYS: AN UNTARGETED AND TARGETED LIPIDOMICS ANALYSIS

Helaina E. Huneault[1], Catherine C. Cohen[2], Xueyun Liu[3], Chih-Yu Chen[3], Zachery R. Jarrell[4], Kristal M. Maner-Smith[3], Eric A Ortlund[3] and Miriam B. Vos[5], (1) Nutrition & Health Sciences Doctoral Program, Laney Graduate School, Emory University, Atlanta, GA, USA, (2)Section of Nutrition, Department of Pediatrics, School of Medicine, University of Colorado Anschutz Medical Campus, Aurora, CO, USA, (3)Department of Biochemistry, Emory School of Medicine, Emory University, Atlanta, GA, USA, (4)Division of Pulmonary, Allergy and Critical Care Medicine, Emory University, Atlanta, GA, USA, (5)Division of Gastroenterology, Hepatology, and Nutrition, Department of Pediatrics and Nutrition and Health Sciences Graduate Program, Emory University

Background: Lipid dysregulation is central to non-alcoholic fatty liver disease (NAFLD) onset and progression. However, little is known about lipid partitioning changes that occur with improvement in NAFLD. Using metabolomics, we recently showed that a low-free sugar diet (LFSD) treatment in adolescents with NAFLD was associated with metabolome changes that may indicate improved oxidative stress, inflammation, and lipid metabolism. To further explore these findings, we employed untargeted and targeted lipidomics to examine systemic lipid adaptations associated with the LFSD treatment and improvement of hepatic steatosis in study participants. **Methods:** Fasting plasma samples from 40 adolescent boys (11-16 yrs.) with NAFLD were collected at baseline and after eight weeks following randomization to a low-free sugar diet (LFSD) intervention ($n = 20$; goal: $< 3\%$ total energy intake) or usual diet ($n = 20$). Plasma samples were extracted and analyzed by liquid chromatography with tandem mass spectrometry (LC-MS/MS). Data analysis was performed using Thermo LipidSearch, Skyline, and R Studio version 4.2.3. **Results:** Using LC-MS/MS, a total of 11 lipid classes were measured, and paired t-test analysis revealed that the intervention group had significantly lower levels of cholesterol esters, triacylglycerides (TAGs), diacylglycerides (DAG), lysophosphatidylcholine (LPC), and phosphatidylcholine (PC) species after the diet treatment ($p < 0.05$). Additionally, we identified 274 lipid features with high confidence based on m/z, retention time, and fragmentation. Among these features, 29 were differentially expressed in the intervention group after the eight-week LFSD (adjusted $p < 0.05$). TAGs containing 48-50 carbons and one double bond were significantly decreased. Interestingly, total TAGs were positively correlated with total cholesterol and negatively correlated with alanine aminotransferase (ALT) and aspartate aminotransferase (AST) ($p < 0.05$). Oxylipins analysis revealed a significant decrease in the abundance of 8-isoprostane and 14,15-dihydroxy-5Z,8Z,11Z-eicosatrienoic acid (DiHET) after the LFSD intervention. **Conclusion:** We identified novel lipidome changes associated with a LFSD-induced reduction in hepatic steatosis, primarily reflecting changes in lipid species circulating in human plasma. Future studies are needed to elucidate the mechanism of these findings and whether the abundance of these lipids can be used as biomarkers indicative of NAFLD regression.

2064-A | LIVER BIOPSY VERSUS NON-INVASIVE TESTS (NITS) WITH LABORATORY AND DEMOGRAPHIC ANALYSIS ACROSS ALL FIBROSIS STAGES IN 460 US PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE (NAFLD)

Keerthi Thallapureddy[1], David Twitchell[1], Kristen Ott[1], Lisa Pedicone[2], Jonathan Gelfond[1], Nagasri Shankar[1], Martin Goros[1], Anna Liles[2], Chioma Owo[1], Fatma Ozguc[1], Fatima Ochoa Nunez[2], Nina Kumar[1], Iqra Kazi[1], Harry Nguyen[1], Eric Lawitz[1,2], Eugenia Tsai[1,2], Fabian Rodas[1,2], Carmen E. Landaverde[1,2] and Fred

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Poordad[1,2], (1)UT Health San Antonio, (2)Texas Liver Institute

Background: Liver biopsy remains the "gold" standard in quantifying steatosis and fibrosis in NAFLD. While NITs are often used in clinical practice, it remains unclear which modality is best to use, how they compare to each other and how various patient variables may impact degree of fibrosis. **Methods:** The dataset includes 460 patients seen in South Texas from 2017-2022. All patients had a liver biopsy, 457 had FIB-4 score, 455 had NAFLD Fibrosis Score (NFS) and 237 had FibroScan. Patient demographics, baseline characteristics, labs, biopsy, and NIT results were analyzed based on degree of fibrosis defined by liver biopsy (F0 vs F1/F2 vs F3/F4). Kruskal-Wallis rank sum test, Pearson's Chi-squared test or Fisher's exact test was used to calculate p-value. Wilcoxon rank sum test was used to compare tissue sample length vs specialist performing the biopsy (Radiology or Hepatology). Association between BMI and degree of steatosis was estimated with Spearman's rank correlation test ($\alpha = 0.05$). **Results:** Median age was 51, 66.4% were female, and 73.3% were Hispanic/Latino White. Patients in the F3/F4 subgroup were significantly older and had the highest proportion of diabetes (69.3%; $p < 0.001$) and/or hypertension (71.5%; $p = 0.008$) (Table 1). There were differences in AST ($p < 0.001$), GGT ($p = 0.005$), ALP ($p = 0.041$) and Tbili ($p = 0.005$) across all fibrosis stages with highest values in the F3/F4 group. AST/ALT ratio increased as the stage of fibrosis increased ($p < 0.001$). Median BMI was 35 kg/m^2 and there was no association with levels of fibrosis ($p = 0.2$). Spearman's rank correlation revealed no association between BMI and steatosis ($p = 0.076$). FibroScan, FIB-4 and NFS showed statistically significant associations to liver biopsy staging ($p < 0.001$) (Table 1). Further analyses of predictors and steatosis quantification will be presented. The median biopsy sample length was 2.2 cm (0.6-3.2 cm) with 12 portal tracts; samples were statistically shorter when performed by Radiology (1.6 cm) vs Hepatology (2.2 cm) ($p < 0.001$). **Conclusion:** The analyses demonstrate that in NAFLD patients, age, diabetes, and hypertension were statistically associated with fibrosis. Interestingly, BMI did not correlate with degree of steatosis or advanced fibrosis suggesting that weight loss alone may not be adequate as a therapy for all NAFLD/NASH patients. Accurate biopsy interpretation relies on adequate tissue samples. Radiology-acquired samples were smaller which increases risk for sampling errors. NITs can be reliable tools as they generally correlate with liver biopsy fibrosis staging. Multivariate analyses comparing NITs to liver biopsy for staging and steatosis grade in this large cohort of NAFLD patients will be presented.

f 2065-A | LIVER HISTOLOGY OVERESTIMATES STEATOSIS IN PRESENCE OF ADVANCED FIBROSIS: COMBINED DATA FROM MULTIPLE THERAPEUTIC TRIALS INCLUDING MORE THAN 6,000 PATIENTS (IN COLLABORATION WITH NAIL-NIT CONSORTIUM)

Mazen Noureddin[1], Julie Dubourg[2], Sophie Jeannin[2], Naim Alkhouri[3], Jörn M. Schattenberg[4] and Stephen A Harrison[5], (1)Houston Research Institute, Houston, TX, (2)Summit Clinical Research, San Antonio, TX, (3) Arizona Liver Health, Phoenix, AZ, (4)I. Department of Medicine, University Medical Centre Mainz, Johannes Gutenberg University, Mainz, Germany, Mainz, Germany, (5)Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom

Background: Liver fat content (LFC) as measured by magnetic resonance imaging-proton density fraction (MRI-PDFF) is a validated and commonly used

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

endpoint in nonalcoholic steatohepatitis (NASH) clinical trials. We aimed to describe the agreement between steatosis grade as defined by the NASH-CRN histologic scoring system and MRI-PDFF. **Methods:** We combined screening data from 7 NASH non-cirrhotic phase 2 trials. The previously validated thresholds were used to determine steatosis grades according to MRI-PDFF: grade 0 (LFC < 6.4%), grade 1 (LFC: 6.4-17.4%), grade 2 (LFC: 17.4-22.1%), and grade 3 (LFC **e** 22.1%). Descriptive analyses were performed to describe the agreements between the 2 methods (histology versus imaging). **Results:** Out of the 6,558 patients, 1,286 with both MRI-PDFF and centrally read liver biopsy assessments were included. The mean age was 54.1 years (SD: 11.3). The majority of patients were female (61%), non-Hispanics (57%) and 41% had a glycated hemoglobin (HbA1c) **e** 6.5%. 48% of the patients met the criteria of "at-risk NASH" (NASH + NAS **e** 4 + Fibrosis Stages 2 or 3). The median NAS was 4 and the median steatosis grade was 2. The mean LFC was 18% (SD: 7.4). Agreement between histology and imaging steatosis grades was met in 52.8% of the cases whereas the histology grade was underestimated in 12.4% and overestimated in 34.8% of the cases compared to imaging grades (table). Among the "overestimated" group, 62% of patients met the "at-risk NASH" criteria according to histology. After reclassification of histology results based on imaging values, only 46% of the patients would have been considered "at-risk NASH". The main differences between the "overestimated" and "agreement" groups were: fibrosis severity ($p < 0.001$; 51.6% of F2-F3 in the "agreement" group compared to 68% in the "overestimated" group) and presence of ballooning ($p < 0.001$; 63.3% in the "agreement" group versus 76.4% in the "overestimated" group). **Conclusion:** The likelihood of steatosis grade overestimation by liver histology is higher in patients with more advanced fibrosis and presence of ballooning. This overestimation might have an important impact on baseline assessment of patients within NASH clinical trials. Further analyses are warranted to gain a better understanding.

2066-A | LIVER STIFFNESS MEASUREMENTS WITH A NEW POINT-OF-CARE DEVICE, HEPATOSCOPE, USING TWO-DIMENSIONAL TRANSIENT ELASTOGRAPHY SHOWED GOOD CORRELATION TO OTHER NON-INVASIVE TESTS

Victor De Ledinghen[1], Dan Cohen-Dutartre[2], Adrien Besson[3], Francoise Manon[4], Joelle Abiven[4], Anne-Laure De Araujo[4], Rhizlane Houmadi[4], Julie Dupuy[4], Juliette Foucher[4], Joel Gay[3] and Claude Cohen-Bacrie[3], (1)University Hospital Bordeaux, (2)Inria, (3)E-Scopics, (4)CHU Bordeaux, Bordeaux, France

Background: Non-invasive tests (NITs) are recommended for the risk stratification of patients at risk of non-alcoholic steatohepatitis (NASH). Liver stiffness measurement (LSM) by ultrasound-based transient elastography (TE) is one of them, and Fibroscan® (FS) provides a 1D-measurement of shear wave speed (VCTE™) in hepatology practice. Large-scale screening of NAFLD-NASH could benefit from an available and affordable tool in primary care that would provide point-of-care reproducible and reliable LSM. We assessed the correlation between LSM obtained with TE using 2D-measurements of shear wave speed (2DTE) on a new ultrasound imaging point-of-care device, Hepatoscope™, and other NITs. **Methods:** 96 adult patients referred to routine hepatology consultation for chronic liver diseases were enrolled in this prospective single center study (NCT04782050). The following NITs for liver fibrosis were collected: LSM with VCTE, LSM with Aixplorer® ShearWave Elastography (SWE), FIB-4, APRI and NAFLD Fibrosis Score (NFS). LSM values as previously defined using 2DTE were collected with Hepatoscope within a region of interest positioned in the image. Data were analyzed with R to determine the correlation coefficient (r^2) between Hepatoscope LSM and other non-invasive tests. Patients of 70 years of age or older were excluded from correlation analyses with FIB-4. **Results:** All NITs used for liver fibrosis assessment were positively correlated with each other. LSM with VCTE, SWE and 2DTE were strongly correlated: $r^2 = 0.79$ (VCTE vs SWE), $r^2 = 0.75$ (VCTE vs 2DTE), and $r^2 = 0.80$ (2DTE vs SWE). Correlations between blood tests were weaker: $r^2 = 0.49$ (FIB-4 vs NFS), $r^2 = 0.31$ (FIB-4 vs APRI), and $r^2 = 0.10$ (APRI vs NFS).
2DTE correlated significantly better ($p < 0.001$) with APRI ($r^2 = 0.64$) than VCTE ($r^2 = 0.27$) and SWE ($r^2 = 0.33$). FIB-4 correlated moderately with 2DTE and SWE ($r^2 = 0.19$), and better than with VCTE ($r^2 = 0.12$; $p = 0.05$). NFS correlated weakly with 2DTE ($r^2 = 0.08$), and significantly better with VCTE ($r^2 = 0.16$) and SWE ($r^2 = 0.21$) ($p < 0.01$). **Conclusion:** LSM performed with the new point-of-care ultrasound imaging device Hepatoscope and 2DTE strongly correlated with other ultrasound-based LSM techniques (VCTE and SWE). Correlations between LSM by any technique and blood tests were found to be weak to good. These results suggest that Hepatoscope 2DTE may be used at the bedside in lieu of other LSM techniques for large scale screening purposes. Future comparative studies against liver biopsy are needed to validate existing LSM cutoffs for the triage of patients at risk of fibrotic NASH. Figure 1.

f 2067-A | LIVER STIFFNESS PROGRESSION IN BIOPSY-PROVEN NONALCOHOLIC FATTY LIVER DISEASE AMONG PEOPLE WITH DIABETES VERSUS PEOPLE WITHOUT DIABETES: A MULTICENTER STUDY

Daniel Q Huang, University of California San Diego, Laura Wilson, Johns Hopkins School of Public Health, Maral Amangurbanova, University of California, San Diego, Cynthia A. Behling, Pacific Rim Pathology, David E Kleiner, Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Kris V. Kowdley, Washington State University, Srinivasan Dasarathy, Cleveland Clinic Foundation, Norah Terrault, University of Southern California, Anna Mae Diehl, Duke University, Naga P. Chalasani, Indiana University School of Medicine, Brent A. Tetri, St Louis University, Saint Louis, MO, Arun Sanyal, Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA, James Tonascia, Johns Hopkins University and Rohit Loomba, University of California, San Diego, San Diego, CA

Background: There are limited data regarding whether liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE) progresses faster in people with type 2 diabetes mellitus (T2DM) versus those without T2DM in biopsy-proven nonalcoholic fatty liver disease (NAFLD). Therefore, we aimed to examine the time-to-progression of LSM between participants with versus without T2DM who had available paired VCTEs in a large, multicenter, multiethnic cohort study within the NASH CRN. **Methods:** This study included adult participants with biopsy-proven NAFLD who had VCTEs at least one year apart, recruited at eight sites across the United States as part of the NIDDK-sponsored NASH CRN. The Cox proportional hazards model was used to evaluate the hazards ratio (HR) for LSM progression and regression, defined by an upward or downward change, respectively, in the Baveno VII LSM categories for compensated advanced chronic liver disease (< 10 kPa, 10-14.9 kPa, 15.0-19.9 kPa, 20.0-24.9 kPa, **e** 25.0 kPa), compared between T2DM versus non-T2DM at baseline. **Results:** This study included 1,340 adult participants with NAFLD (62% female) with more than one VCTE. The mean (±SD) age and body mass index were 51.9 (±12.0) years and 33.9 (±6.6) kg/m^2, respectively. The median (IQR) time between VCTEs was 4.1(2.5-6.5) years. Participants with T2DM (n = 732) had a significantly higher cumulative incidence of LSM progression at 4-years (13% versus 11%), 6-years (25% versus 18%) and 8-years (52% versus 44%) compared to participants without T2DM (n = 608), $P = 0.008$ (Figure 1). Using multivariable Cox proportional hazards model adjusted for age, sex, BMI, and Hispanic ethnicity, the presence of T2DM was associated with statistically and clinically significant faster LSM progression (adjusted HR 1.31, 95% CI 1.00 – 1.71, $P = 0.046$). The association between T2DM and LSM progression remained consistent in sensitivity analyses for the presence of cirrhosis ($P = 0.03$). There was no significant difference in the time to regression between T2DM versus non-T2DM ($P = 0.78$). **Conclusion:** Utilizing serial VCTE data from a multicenter study of participants with biopsy-proven NAFLD and prospectively collected data, we demonstrate that participants with T2DM have a significantly faster time to LSM progression. These data may have important implications for clinical practice and clinical trial design.

2068-A | LIVER TISSUE PROTEOMICS-BASED PLASMA BIOMARKER FOR NASH

Achuthan Sourianarayanane, Medical College of Wisconsin and Brett Phineey, UC Davis

Background: Diagnosing patients with nonalcoholic steatohepatitis (NASH) among those with nonalcoholic fatty liver disease (NAFLD) is challenging. Liver biopsy and MRI are useful in this regard; however, the former is invasive, while the latter is costly and not readily available. Many plasma-based noninvasive tests have been proposed but have not been effective. This study evaluates the effectiveness of plasma biomarkers based on their correlation with liver tissue proteomics. **Methods:** We included 65 subjects diagnosed with NAFLD (17 without NASH, 38 with NASH but without advanced fibrosis, and 10 with advanced fibrosis) in this study. A portion of liver tissue was flash frozen at the time of liver biopsy and stored at -80°C along with their plasma. Following lipid fraction extraction, the liver tissue was sonicated and digested with trypsin at 37°C. Mass spectrometric analysis was performed for untargeted proteomics of liver tissue and plasma. We used the following parameters to increase the specificity and decrease the number of analytes discovered: q-value < 0.05, log fold change > 2 for liver tissue analysis, and a lesser cut-off of p-value < 0.5 and log fold change > 1 for plasma analysis to detect an adequate number of plasma proteins. **Results:** Among the patients, 20 plasma proteins were found to be up or downregulated between subjects with and without NASH. Plasma proteins were able to differentiate NASH subjects with an area under the receiver operating curve (AUROC) between 0.63 and 0.67 (Figure 1a) by different modeling methods. Among the liver tissue proteins, 66 were up or downregulated between those with and without NASH. None of the 20 plasma proteins of significance were found to be significantly up or downregulated in liver tissue. Of the 20 plasma proteins that were significantly up-or downregulated, only 16 were represented among 3,346 proteins detected by liver tissue proteomic analysis. A biomarker analysis using 16 of the plasma proteins also represented in liver tissue was able to differentiate patients with NASH from those without NASH with an AUROC of 0.827 (Figure 1b). In a model using ten proteins found significant in the liver tissue as a biomarker, patients with NASH were differentiated from those without NASH with an AUROC of 0.955. **Conclusion:** Proteomic analysis of plasma does not correlate with the liver tissue counterpart among subjects with NAFLD. The accuracy of biomarkers based on plasma proteins increases by corroborating proteins of significance with liver tissue analysis. Proteins found to differentiate NASH from NAFLD based on liver tissue analysis and are also represented in plasma would be an ideal noninvasive test to detect NASH.

Background: Nonalcoholic Fatty Liver Disease (NAFLD) prevalence poses a significant challenge, with fibrosis stage acting as a crucial prognostic indicator. Advanced fibrosis/cirrhosis (F3-4) cases often face swift disease progression. Non-Invasive Tests (NITs) for hepatologist referral or biopsy have limited accuracy. We propose a machine learning (ML) model offering a probabilistic prediction adaptable for both community and referral centers, where prevalence varies from 3.7 – 50%. Preliminary two-center data from the multi-center consortium inform this model. **Methods:** We collected retrospective data on patients diagnosed with NAFLD, Nonalcoholic Steatohepatitis (NASH), or cryptogenic cirrhosis; patients with other liver diseases were excluded. The primary outcome was advanced fibrosis (F3) or cirrhosis (F4). Data was divided into derivation (training) and validation (testing) cohorts. We employed Random Forest for ML, considering other models such as ElasticNet and Grant Boosting Machines. **Results:** The study incorporated 986 patients, with 269 having advanced fibrosis or cirrhosis. The mean FIB-4 was 1.76 (SD 1.52). The proposed ALADDIN score presented a 1 - Out-of-Bag (OOB) error rate of 78.3%, suggesting a strong fit to the training data. In the validation cohort, ALADDIN score demonstrated an AUC of 0.794 (95% CI 0.750 – 0.837), surpassing FIB-4 0.747 (0.697 – 0.798), p = 0.0039. With a 65% probability threshold, ALADDIN showed a PPV and NPV of 79%, against FIB-4's 65% PPV and 80% NPV at a 2.66 threshold. The Net Reclassification Improvement (NRI) of 0.379 and Integrated Discrimination Improvement (IDI) of 0.068 accentuate ALADDIN Score's enhanced reclassification and discrimination capacities over FIB-4. Figure 1 displayed ROC comparison of ALADDIN and FIB-4, and the top 20 variables. **Conclusion:** Preliminary data underscores the ALADDIN score's potential in outperforming the conventional FIB-4 score in a tertiary referral center setting. Patients with an ALADDIN score > 65% might require liver biopsy, 15% - 65% may need additional noninvasive testing, and < 15% can be monitored in primary care. The ALADDIN score facilitates tailor-made care based on specific cirrhosis probability. With further data, the model can be calibrated for community settings. This is the first ML model with an online calculator for public use, enabling personalized care. The model is accessible at https://globalalchep.shinyapps.io/ALADDIN/.

2070-A | MACHINE LEARNING-ASSISTED FIBROSIS STAGING IN H&E-STAINED TISSUE IS COMPARABLE TO STAGING WITH MASSON'S TRICHROME IN NON-ALCOHOLIC STEATOHEPATITIS

Yibo Zhang, Jun Zhang, Michael Griffin, Tan Nguyen, Filip Kos, Adam Stanford-Moore, Robert Egger, Yi Liu, Lara P. Murray, Julia A. Varao, James A. Allay, Chinmay R. Surve, Brea Johnson, Morgan Sweeney, Dana Lau-Corona, Michael G. Drage, Murray Resnick, Janani Iyer and Justin Lee, Pathai, Inc.

Background: In NASH clinical trials, fibrosis is staged via histologic examination of stained liver biopsies. However, stain quality is often highly variable, leading to inter-pathologist variability in staging. Here, we develop a machine learning (ML) method to infer the presence of fibrosis in hematoxylin and eosin (HE)-stained NASH biopsies, and test whether ML-based fibrosis augmentation in HE can be used for accurate NASH Clinical Research Network (CRN) fibrosis staging. **Methods:** Three expert NASH pathologists each

staged fibrosis from Masson's Trichrome (MT)-stained WSIs (1A) in 50 cases of histologically-confirmed NASH. Separately, ML models were trained to detect fibrosis in HE-stained WSIs using inferred Quantitative Multimodal Anisotropy Imaging (iQMAI; previously described). iQMAI was deployed on 50 independent HE WSIs (1B), corresponding to the 50 NASH cases evaluated previously using MT. Three expert NASH pathologists were each asked to: (i) stage fibrosis in these 50 HE WSIs with iQMAI overlays (iQMAI+HE; 1C), and (ii) gauge feasibility of staging from iQMAI+HE. Median consensus fibrosis stage was computed for each WSI, and linearly-weighted Cohen's Kappa was computed to compare staging performed in iQMAI+HE versus MT WSIs. **Results:** Pathologist consensus was established on MT and iQMAI+HE for 49/50 cases and 50/50 cases, respectively. WSIs covered a representative distribution of fibrosis stages (1D). Overall concordance between fibrosis staging from iQMAI+HE versus MT was 0.75 (95% CI 0.63–0.85; 1D). Stage-level agreement between iQMAI+HE and MT was greatest for stages F4 and F3, while for lower stages iQMAI+HE staging exhibited a bias towards more sensitive fibrosis detection (1D, 1E). Pathologists reported that staging fibrosis in iQMAI+HE was easier than, similar to, and more difficult than MT in 4%, 78%, 0% of cases, respectively (three-way discordance rate = 18%). **Conclusion:** Here, we show that pathologists can stage fibrosis in HE-stained NASH biopsies when provided with ML-derived iQMAI fibrosis augmentation. Currently, HE sections are used to evaluate NAFLD Activity Score component features only – the ability to additionally stage fibrosis from HE without requiring direct scanning of physical slides or adjacent MT sections could reduce study timelines, associated costs, and the impact of MT stain variability on inter-rater agreement. Future work should assess whether iQMAI may be more sensitive to patterns of early-stage fibrosis than MT, and whether this may improve screening and detection of drug effect in clinical trials.

Figure 1. (A) Example MT WSI staged by three pathologists. (B) Paired HE WSI corresponding to MT WSI in A. (C) iQMAI+HE overlay corresponding to HE WSI in B was staged by three pathologists. (D) Confusion matrix showing concordance between iQMAI+HE and MT reads. (E) Stage-level concordance between MT and iQMAI+HE scoring.

2071-A | MENOPAUSE MAY BE A GREATER RISK FACTOR FOR NONALCOHOLIC FATTY LIVER DISEASE IN LEAN WOMEN THAN OBESE WOMEN

Madeleine Chang[1], Ju Dong Yang[2], Elizabeth W. Brombosz[3], Tamneet Basra[3], Sudha Kodali[3], David W. Victor III[3], Naim Alkhouri[4] and Mazen Noureddin[5], (1) Arnold O. Beckman High School, (2)Cedars-Sinai Medical Center, Los Angeles, CA, (3)Houston Methodist Hospital, Houston, TX, (4)Arizona Liver Health, Phoenix, AZ, (5)Houston Liver Institute, Houston, TX

Background: Murine studies have shown that endogenous estrogen may be protective against nonalcoholic fatty liver disease (NAFLD). Epidemiologic studies suggest that postmenopausal (post-M) women are more likely to develop NAFLD and advanced liver fibrosis. In this study, we aimed to compare the severity and prevalence of NAFLD and liver stiffness in premenopausal (pre-M) and post-M women of different weight classes. **Methods:** Using the National Health and Nutrition Examination Surveys (NHANES) dataset from 2017-2020, we excluded all men, women < 18 years, women with excessive alcohol use (**e** 7 drinks per week), and women with viral hepatitis to arrive at a sample size of 3059 subjects. Out of these, only 1284 women (41.97%) had FibroScan® data and were included in this study. NAFLD was defined as a controlled attenuation parameter (CAP) score **e** 274 dB/m. Based on the BMI, the subjects were categorized into lean (BMI < 25 kg/m^2), overweight (BMI 25-29.9 kg/m^2), class I (BMI 30-34.9 kg/m^2), class II (BMI 35-39.9 kg/m^2), and class III obesity (BMI **e** 40 kg/m^2). Menopausal state was

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

determined via a subject's response to the NHANES questionnaire. Average CAP score (aCAP) and liver stiffness measurement (LSM) were obtained via FibroScan®. **Results:** 740 women were pre-M and 544 women were post-M. The prevalence of NAFLD was 30.27% for the pre-M women, which is lower than the 45.77% for the post-M women. The aCAP for pre-M women was 244.59 dB/m vs 269.14 dB/m for post-M women ($p < 0.05$). Lean, overweight, and class I obese pre-M women had lower aCAP than post-M women ($p < 0.05$). Notably, the differences in aCAP are more pronounced the leaner the subjects are. This indicates that leaner women (BMI < 35) are more likely to develop worsening hepatic steatosis after menopause than obese women (BMI **e** 35). For women with NAFLD, only lean post-M women had higher steatosis compared to lean pre-M women, with aCAP of 305.13 dB/m vs 286.77 dB/m ($p < 0.05$), respectively. This highlights the influence of menopause on lean women with NAFLD. In terms of liver stiffness, only the overweight and class II post-M women had higher average LSMs than pre-M women in the respective weight classes ($p < 0.05$). **Conclusion:** Our data suggests that menopause, and by implication estrogen, may play a more crucial role in the development of steatosis in women with a lower BMI than those with a higher BMI.

2072-A | MODFIB: A SIMPLE IMPROVEMENT OVER FIB-4 TO OPTIMIZE REFERRAL OF NAFLD PATIENTS FROM PRIMARY CARE TO SPECIALTY CARE

Nehna Abdul Majeed, Clinical Research Section, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Allison Carroll, Northwestern University Feinberg School of Medicine, Harish Gopalakrishna, Clinical Research Section, Gaithesberg, MD and Yaron Rotman, National Institute of Diabetes and Digestive and Kidney Diseases, Nih

Background: Among patients with nonalcoholic fatty liver disease (NAFLD), only those with significant fibrosis require referral to specialty care. Since NAFLD is extremely common, proper selection is crucial to detect all those in need while not overloading hepatologists. AASLD guidelines recommend using FIB-4 in primary care and referring those with FIB-4 > 1.3 for vibration controlled transient elastography (VCTE) as second line. However, the initial FIB-4 cut-off has limited accuracy. We aimed to use readily-available clinical parameters to improve the accuracy of FIB-4 to determine referral of people with NAFLD from primary care to hepatology. **Methods:** Cross-sectional study utilizing National Health and Nutrition Examination Survey (NHANES) 2017-2020 data. We included all adults with complete anthropometric, laboratory, and VCTE data. The analysis was limited to subjects with NAFLD, defined as controlled attenuation parameter > 263dB/m. Subjects were randomly split 80:20 to derivation (n = 2292) and validation

(n = 573) cohorts. The primary outcome was TE > = 8 kPa. Ethnicity, systolic blood pressure, body-mass index (BMI), total cholesterol, HbA1c, and FIB-4 were chosen *a priori* as potential predictors and tested using univariate and multivariate logistic regression. A predictive model was established using the regression coefficients, compared to FIB-4 in the derivation cohort, and cut-offs validated in the validation cohort. **Results:** In the derivation cohort, 381 (17%) of people with NAFLD had TE > = 8 kPa, suggestive of significant fibrosis. Of the tested clinical variables, BMI, HbA1c and FIB-4 were significantly associated with TE > = 8kPa on univariate and multivariate regression ($p < 0.0001$) and were used to derive the modified fibrosis score (ModFIB). ModFIB had higher area under receiver operating curve (AUROC) compared to FIB-4 (0.77 vs. 0.59, $p < 0.0001$) (Fig 1). Using the FIB-4 1.3 cut-off would have resulted in referral of 595 (26%) subjects to VCTE, with specificity of 76% but sensitivity of only 36%. For the same sensitivity, ModFIB would have 93% specificity with only 279 subjects needing referral. For the same number of referred subjects as FIB-4 (n = 595), ModFIB has sensitivity and specificity of 61% and 81%, respectively. The latter cutoff was examined in the validation cohort and had sensitivity and specificity of 68% and 92%, respectively. **Conclusion:** Fib-4 has reasonable specificity but poor sensitivity, with 64% of people with significant fibrosis missed. We provide a simple, non-invasive modification based on clinical parameters, that performs significantly better than FIB-4. The employment of ModFIB in primary care setting can markedly improve the selection of patients for VCTE and subsequent hepatology referral.

2073-A | MORPHOMETRIC AUTOMATED DIGITAL PATHOLOGY ANALYSIS REVEALS DIFFERENTIAL EFFECTS OF LANIFIBRANOR AND SEMAGLUTIDE IN THE BIOPSY-CONFIRMED GAN DIO-NASH MOUSE MODEL

Cindy Serdjebi[1], Florine Chandes[1], Bastien Lepoivre[1], Susanne E. Pors[2] and Michael Feigh[3], (1)Biocellvia, (2) Gubra a/S, Copenhagen, Denmark, (3)Gubra Aps

Background: Non-alcoholic steatohepatitis (NASH) predisposes to development of advanced fibrosis/cirrhosis. Currently, many clinical trials are ongoing to obtain either significant resolution of NASH without worsening of fibrosis or improvement of fibrosis without worsening of NASH. Semaglutide (glucagon-like-receptor (GLP)-1 agonist) and lanifibranor (pan-peroxisome proliferator activated receptor agonist) are currently in late-stage clinical testing. The present study aimed at investigating the effects of these two monotherapies in the Amylin NASH (GAN) diet-induced obese (DIO) and biopsy-confirmed mouse model with advanced fibrosis using morphometric digital pathology. **Methods:** GAN-DIO-NASH mice were treated with either vehicle, lanifibranor or semaglutide, and lean chow-fed animals served as control group. The pre- and post-treatment liver biopsies were stained with picrosirius red (PSR) and hematoxylin and eosin (H&E) and scanned at the magnification of X20. Histopathological NAFLD Activity Score (NAS) and fibrosis stage were evaluated by Gubra Histopathological Objective Scoring Technique (GHOST) AI-deep learning-based image analysis. In parallel, MorphoQuant, a fully automated and deterministic artificial intelligence to assess steatosis, fibrosis and collagen fiber dimensions (length and width). Effects of treatments were compared. **Results:** MorphoQuant analysis of pre-treatment biopsies showed no difference across the three GAN-DIO-NASH groups. Interestingly, a spontaneous regression of steatosis (-40.01%) and fibrosis (-11.68%) was observed in vehicle-treated animals. Using GHOST, semaglutide and lanifibranor promoted **e** 2-point significant improvement in NAS but none significantly improved fibrosis stage, albeit lanifibranor reduced levels of perisinusoidal and periportal fibrosis. MorphoQuant evidenced reduction of steatosis for semaglutide and lanifibranor (-63.93 and -78.26%, respectively). Fibrosis was greatly impacted by lanifibranor (-31.13%) whereas semaglutide showed a fibrosis reduction similar to vehicle-treated animals (-10.19%). Collagen fiber length was shortened for lanifibranor and semaglutide. Surprisingly, the width of collagen fiber tended to increase for semaglutide while no change was seen for lanifibranor. **Conclusion:** The GAN DIO-NASH mouse is highly applicable for profiling novel drug therapies targeting

NASH with advanced fibrosis. Notably, morphometric AI-digital pathology showed superior anti-steatotic action for lanifibranor, compared to semaglutide. In addition, anti-fbrotic effect of lanifibranor, but not semaglutide, was demonstrated, in alignment with the Phase 2 clinical trial data. Importantly, evaluation of collagen fibers dimensions allows to provide a better understanding of drug effect on fibrosis regression.

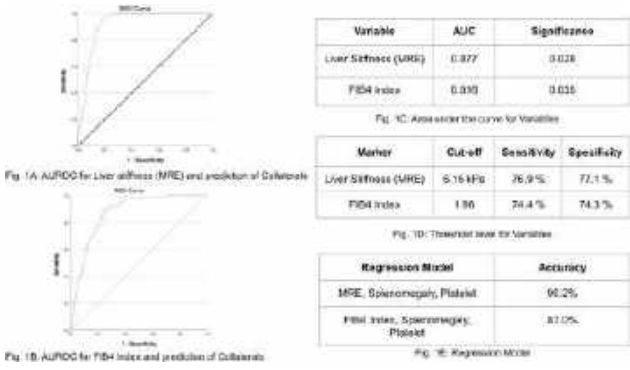
2074-A | MR ELASTOGRAPHY CAN RELIABLY PREDICT PORTO-SYSTEMIC COLLATERALS IN NON ALCOHOLIC FATTY LIVER DISEASE

Ameet Mandot[1], Tanvi Chipkar[1], Hiteshi Dhami- Shah[1], Gautham Pranesh[2], Rashmi Badhe[1] and Samir Ramnik Shah[1], (1)Global Hospitals, Mumbai, (2)Mitopower LLC

Background: MR Elastography(MRE) is a non-invasive gold-standard for evaluating liver fibrosis in Non-alcoholic Fatty Liver Disease (NAFLD). The sensitivity & specificity of other non-invasive studies like Fibro-Scan to detect clinically significant portal hypertension (CSPH) have traditionally been low due to technical factors related to obesity. Porto-systemic collaterals (PsC) signify presence of CSPH which is known to be associated with the risk of complications such as variceal hemorrhage, GI bleed, overt encephalopathy. The study aimed to establish a threshold level of liver stiffness(LS) using MRE for detection of PsC which would indicate CSPH in NAFLD. Additionally, the study explored combined use of FIB4 index & splenomegaly as indicators of PsC, offering potential applicability in community settings for NAFLD. **Methods:** A retrospective analysis was conducted on subjects with NAFLD who underwent MRE between January 2015 & December 2022. T2 weighted images were obtained during sequencing to assess spleen size & PsC. The spearman rank correlation test was used to determine the correlation between LS, FIB4 index & PsC. ROC analysis was performed to determine the threshold levels of MRE for predicting the presence of PsC. **Results:** A total of 392 subjects (Males:257; Females:135) with a mean age of 47 years ± 13 years & a median LS score of 2.7 kPa ± 2.8 kPa were included in the retrospective analysis. Of the 392 subjects, 104 subjects had advanced fibrosis (LS **e** 5 kPa). The correlation coefficient of PsC was significant with MRE ($r = 0.543$, $p < 0.001$) & FIB4 index ($r = 0.478$, $p < 0.001$). The MRE threshold level of 6.15 kPa correlated with the presence of PsC, with a sensitivity of 76.9% & specificity of 77.1%, ($AUC = 0.877$). A regression model incorporating MRE, splenomegaly & platelet count showed an accuracy of 90.2% for predicting CSPH in the form of PsC, while a regression model including FIB4 index, splenomegaly & platelets demonstrated an accuracy of 87% predicting PsC. **Conclusion:** MR Elastography is a reliable non-invasive method for predicting the presence of PsC & hence CSPH in patients with NAFLD. The MRE threshold level of 6.15 kPa serves as a robust indicator. Additionally, FIB4 alone & a regression model combining FIB4 index, splenomegaly & platelet count shows similar accuracy and can be beneficial in community settings where MRI may not be available.



Variable	AUC	Significance
Liver Stiffness (LSRE)	0.877	0.028
FIB4 Index	0.830	0.035

Marker	Cut-off	Sensitivity	Specificity
Liver Stiffness (LSRE)	6.15 kPa	76.9 %	77.1 %
FIB4 Index	1.86	74.4 %	74.3 %

Regression Model	Accuracy
MRE, Splenomegaly, Platelet	90.2%
FIB4 Index, Splenomegaly, Platelet	87.0%

2075-A | MULTIPARAMETRIC MAGNETIC RESONANCE IMAGING IMPROVES DETECTION OF PATIENTS WITH HIGH RISK NAFLD: REAL WORLD EXPERIENCE IN NAFLD CARE

Tatiana Hage[1], Meaghan Phipps[2], Lauren Nicolosi[2], Andrea Dennis[3], Mazen Noureddin[4] and Julia J. Wattacheril[5], (1)Cedars-Sinai Medical Center, Los Angeles, CA, (2)Columbia University Medical Center, New York, NY, (3)Perspectum Ltd, (4)Houston Liver Institute, Houston, TX, (5)Columbia University, New York, NY

Background: Early identification of patients with nonalcoholic fatty liver disease (NAFLD) at risk for advanced fibrosis (AF) is important in preventing disease progression to cirrhosis and decompensated liver disease. Non-invasive tests (NITs) including multi-parametric magnetic resonance (mpMR) imaging have emerged as clinically useful tools to stratify patients and identify those at risk for NASH and AF. Despite advancements in NITs, current clinical guidelines recommend using the Fibrosis-4 (FIB-4) score as the primary tool for risk stratification. We aimed to evaluate 1) the application of recent AASLD 2023 practice guidance recommendations for patients with suspected or established NAFLD and 2) the potential benefits of utilization of mpMR to improve detection of patients with NAFLD and AF. **Methods:** A prospective observational study was conducted on patients with NAFLD who received mpMR between 1/2019 and 12/2021 as part of standard clinical care. Patient demographics, medical comorbidities, and laboratory data were collected. We then applied the 2023 AASLD clinical practice guidance algorithm for patients with suspected or established NAFLD based on initial FIB-4 to our cohort. We compared this risk stratification with mpMR results, for which a cT1 value cutoff **e** 800ms was considered an indicator of high risk for NASH or fibrosis. **Results:** Of 103 patients with NAFLD diagnosed by hepatologists at two large, academic medical centers, 64% (66/103) had a FIB-4 < 1.3. Of these patients at low risk for NASH or AF by initial stratification, 57 patients had cT1 data available; 58% (33/57) had cT1 **e** 800ms on mpMR. Compared with patients with cT1 < 800ms on mpMR, there were trends for those with cT1 **e** 800ms to be younger (55 v. 50, $p = 0.22$), more likely to be women ($p < 0.01$), have higher BMI (32 v. 30, $p = 0.75$), and more likely to have diabetes (27% v. 17%, $p = 0.52$). Despite higher rates of dyslipidemia among patients with cT1 < 800ms (63% v. 52%, $p = 0.84$), fewer patients were on treatment for dyslipidemia in this group compared with those with cT1 **e** 800ms (40% v. 76%). cT1 was positively correlated with ALT ($r = 0.26$), AST ($r = 0.26$), liver fat from PDFF ($r = 0.72$), and fasting glucose levels ($r = 0.23$). **Conclusion:** In this real-world application of mpMR to aid in risk stratification of patients with NAFLD, *over half* of patients stratified as low risk by FIB-4 < 1.3 had cT1 **e** 800ms on mpMR, suggestive of increased risk for developing NASH or AF. Incorporation of mpMR earlier in the algorithm for patients with suspected or established NAFLD may improve our detection of those with advanced disease and allow for earlier intervention to prevent disease progression and complications.

Table 1: Characteristics of patients with FIB-4≤1.3 stratified by cT1 values on mpMR

	cT1<800ms (n=24) 	cT1 ≥800ms (n=33) 	p-value
FIB-4	0.94	0.84	0.18
Age (IQR)	55 (39-86)	50 (21-75)	0.22
BMI (IQR)	30 (26-47)	32 (24-44)	0.41
ALT > 40 (%)	6 (25)	16 (52)	0.09
Type 2 diabetes (%)	4 (17)	9 (38)	0.52
Hgb A1c (%) (IQR)	5.6 (4.8-8.5)	5.9 (5.2-11)	0.07
Triglycerides	161 (50-529)	174.5 (103-357)	0.49
LDL (IQR)	108 (28-182)	116.5 (52-163)	0.77
MRE (kPA)	2.37 (1.5-8)	2.1 (1.6-3)	0.11
PDFF (%) (IQR)	8.6 (0.6-16)	19.5 (2.2-29.5)	<0.01

ALT (alanine aminotransferase), BMI (body mass index), LDL (low density lipoprotein), MRE (magnetic resonance elastography), PDFF (proton density fat fraction). Example of cT1 images of a participant with cT1 626ms (green) and 850ms (orange).

2076-A | NAFLD IS ASSOCIATED WITH HIGH RISK LIPIDOMIC AND METABOLOMIC PROFILE IN VIRALLY SUPPRESSED PERSONS WITH HIV

Kung-Hung Lin[1], Eduardo Vilar[1], Kathleen E. Corey[2], Margery Connelly[3], Samir K. Gupta[1], Jordan E. Lake[4], Naga P. Chalasani[1] and Samer Gawrieh[5], (1)Indiana University School of Medicine, (2)Massachusetts General Hospital, Somerville, MA, (3)University of Florida, (4)University of Texas - Houston, (5)Indiana University School of Medicine, Indianapolis, IN

Background: NAFLD affects nearly half of the US adult persons with HIV (PWH). Metabolic dysregulation in NAFLD is associated with atherogenic dyslipidemia and production of circulating metabolites that enhance systemic inflammation and risk of cardiovascular disease, diabetes, and mortality. We investigated whether NAFLD in PWH is associated with changes in lipidomic and metabolomic parameters linked to cardiometabolic outcomes (CMO), and whether NAFLD severity influenced these changes. **Methods:** Consenting, adult PWH without alcohol abuse or chronic liver disease underwent vibration-controlled transient elastography for controlled attenuation parameter (CAP) and liver stiffness measurement (LSM). Lipidomic and metabolomic profiling on fasting serum samples was performed with NMR spectroscopy. Hepatic steatosis was defined by CAP **e** 263 dB/m. LSM **e** 8 kPa indicated clinically significant fibrosis (CSF). Logistic regression models assessed associations between NAFLD, CSF and lipidomic and metabolic parameters. **Results:** 192 participants were included: 70% cisgender male, 96% on suppressive (HIV-1 RNA < 50 copies/

mL) antiretroviral therapy (ART) and median age 51 (IQR 38-58) years, BMI 29 (IQR 26-33) kg/m^2, and CD4$^+$ T cell count 700 (IQR 510-951) /mm^3. Prevalence of NAFLD and CSF were 58% and 12%, respectively. Compared to PWH without NAFLD (No-NAFLD), PWH with NAFLD (NAFLD) had high cardiometabolic risk factors including higher total triglyceride, VLDL-C, branched-chain amino acids, GlycA, trimethylamine N-oxide levels, Lipoprotein-Insulin Resistance and Diabetes Risk Index scores, and lower HDL-C levels (Table). Alterations in these indices worsened from No-NAFLD to NAFLD without CSF to NAFLD with CSF (Table), while CD4$^+$ T cell count, HIV-1 RNA and ART classes were similar across the 3 groups. In a multivariable regression model adjusting for age, sex, race/ethnicity, BMI, and diabetes, NAFLD was independently associated with all these alterations, except for GlycA. **Conclusion:** In virally suppressed PWH, NAFLD is independently associated with altered lipidomic and metabolomic profiles that portend higher risk for CMO. This profile worsens further with increasing severity of NAFLD. To reduce risk for CMO, PWH and NAFLD, and especially those with CSF, should be screened for and offered interventions to address these lipid-metabolic changes.

2077-A | NAFLD PREVALENCE AND PREDICTORS IN PATIENTS WITH T2D IN PRIMARY CARE – INTERIM RESULTS FROM THE EPSONIP STUDY

Wile Balkhed[1], Patrik Nasr[2], Mikael Fredrik Forsgren[3], Martin Bergram[4], Olof Dahlqvist Leinhard[3], Nils Dahlström[4], Carl-Johan Carlhäll[4], Peter Lundberg[4], Karin Rådholm[4], Fredrik Iredahl[4], Stergios Kechagias[2] and Mattias Ekstedt[2], (1)Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden, Solna, Sweden, (2)Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden, (3)Amra Medical, (4) Linköping University

Background: The number of people with NAFLD has increased in parallel with the obesity epidemic. Type 2 diabetes (T2D) is associated with progressive NAFLD. Therefore, many guidelines recommend screening for NAFLD in T2D patients. Most NAFLD studies have been conducted in specialist care, not necessarily representative for primary care. Therefore, we aimed to investigate the prevalence of NAFLD and advanced fibrosis in primary care patients with T2D utilizing magnetic resonance (MR) imaging and transient elastography (TE). In this study, we present interim results from the EPSONIP study (NCT03864510). **Methods:** Patients with T2D, without previous liver disease, were prospectively included from primary care. Study participants underwent laboratory investigation, TE with controlled attenuation parameter (CAP) and MR imaging with liver proton density fat fraction (PDFF). **Results:** Two-hundred and eighty-seven participants have been included with available PDFF data for 191 patients to date. Out of these, 108 (57%) had a PDFF **e** 5 % and were classified as NAFLD. The mean PDFF in participants with NAFLD was 13.1 ± 6.7%. There was no difference in sex (35% and 34% were women in the NAFLD and non-NAFLD groups, respectively), age

(63.8 ± 8.0 and 64.1 ± 7.2 y), nor in diabetes- or lipid lowering treatment between groups (Figure 1). However, participants with NAFLD had a greater mean BMI (30.7 ± 3.9 *vs.* 27.1 ± 3.5 kg/m^2, $p = < 0.001$), waist circumference (108.5 ± 9.8 *vs.* 98.7 ± 10.2 cm, $p = < 0.001$), and HbA1c (52.8 ± 11.1 *vs.* 49.5 ± 9.5 mmol/mol, $p = 0.049$) compared to those without NAFLD. TE > 8kPa was observed more frequently in NAFLD patients (19.6% *vs* 1.2%, $p = < 0.001$) while there was no difference for > 12kPa, 1.9% and 2.5% in NAFLD and non-NAFLD groups respectively, $p = 0.778$. CAP was higher in participants with NAFLD, with an AUROC of 0.866 for detecting PDFF **e** 5%. Applying a sensitivity of > 90% for the presence of PDFF **e** 5%, a cut-off for CAP of 248 dB/m had a specificity of 66%. Regression analysis of factors to predict NAFLD found BMI, elevated CAP (> 248 dB/m), and elevation of ALT, HbA1c and GT predictive of NAFLD, and this relationship was confirmed when adjusting for age, sex, and BMI. However, in analysis adjusting for all the factors together, only BMI and elevated CAP were independent predictors of NAFLD, where higher BMI increased likelihood of NAFLD by 15% for every kg/m^2, while elevated CAP was associated with an 11.2 times increased risk of NAFLD. **Conclusion:** In this cohort of highly phenotyped primary care patients with T2D, more than half had NAFLD (57%), of whom 21% had suspected advanced fibrosis. Patients with NAFLD had higher BMI, waist circumference and HbA1c, however the only independent predictors of NAFLD were elevated CAP and BMI.

2078-A | NASH

Nadege T. Gunn[1], Stephen A Harrison[2], Guy W. Neff[3], Abigail Flyer[4], Alexander Liberman[5] and Leigh MacConell[5], (1)Impact Research Institute, (2)Pinnacle Clinical Research Center, San Antonio, TX, (3)Tampa General Medical Group, (4)Pacific Northwest Statistical Consulting, (5)Hightide Therapeutics

Background: HTD1801 is a new molecular entity which has been shown to significantly reduce liver fat content (LFC) and corrected T1 (cT1) as determined by MRI in an 18-week, placebo-controlled Phase 2 study in patients with nonalcoholic steatohepatitis (NASH) and type 2 diabetes (T2DM) (NCT03656744). Achieving response criteria by LFC or cT1 have both been associated with improvements in liver histology (**e** 2-point improvement in the NAFLD activity score). The purpose of this post-hoc analysis was to assess the characteristics and on-treatment changes in patients who achieved an MRI response. **Methods:** One hundred patients were randomized and treated with HTD1801 1000 mg BID (n = 34), HTD1801 500 mg BID (n = 33), or placebo (n = 33) for 18 weeks. MRI data was collected prospectively for evaluation of the primary endpoint (LFC), and cT1 was evaluated after the completion of the study for patients who had been randomized to HTD1801 1000 mg BID or placebo. MRI response was defined as achieving either **e** 30% LFC reduction or **e** 80 ms cT1 reduction. As cT1 was not assessed in the 500 mg BID group, this analysis focuses on patients randomized to HTD1801 1000 mg BID and placebo. **Results:** MRI response criteria was achieved by 2-fold more patients treated with HTD1801 compared to placebo (52% vs 24%). 22% of all patients randomized to HTD1801 vs 12% randomized to placebo achieved both the LFC and cT1 criteria. At baseline, LFC was balanced between MRI responders and non-responders, but cT1 was elevated in MRI responders. For patients who had been randomized to HTD1801, the baseline biochemical characteristics of MRI responders were indicative of more severe disease compared to MRI non-responders (Table 1). In contrast, patients who had been randomized to placebo and were MRI responders had less severe disease by biochemistry. Within the subgroup of MRI

responders, patients who had been randomized to HTD1801 had substantial improvements in ALT, FIB-4, FPG, HbA1c, LDL-C and weight. Furthermore, within the non-responders, modest improvements in ALT, FPG, HbA1c, LDL-C and weight were observed with HTD1801 compared to no change observed in placebo randomized patients. **Conclusion:** Twice as many patients achieved MRI response criteria with HTD1801 compared to placebo. Furthermore, improvements were observed with HTD1801 in liver biochemistry and key cardiometabolic parameters in both responders and non-responders. HTD1801 continues to be evaluated in a biopsy-based Phase 2b study (NCT05623189).

2079-A | NASH CIRRHOSIS: DISTINCT PHENOTYPICAL DIFFERENCES, MORE SYSTEMIC INFLAMMATION, AND MORE FRAIL THAN VIRAL-RELATED CIRRHOSIS

Yu JUN Wong[1,2], Heng Yi Tan[3], Siew Yoon Yap[4], Geraldine Lim[4], Seok Hwee Khoo[4], Jessica Tan[1], Rahul Kumar[1,2], Joan Khoo[5], Rosario Helen Barbara[6] and Paul Edward Hutchinson[3], (1)Department of Gastroenterology & Hepatology, Changi General Hospital, (2)Duke-Nus Medical School, Singhealth, (3) Flow Cytometry Laboratory, Life Sciences Institute, National University of Singapore, (4)Clinical Trial Research Unit, Changi General Hospital, (5) Department of Endocrinology, Changi General Hospital, (6)Department of Geriatric Medicine, Changi General Hospital

Background: NASH is replacing viral hepatitis as the fastest-growing etiology of liver cirrhosis globally with limited therapeutic options. The phenotypic, immunological and functional comparison between NASH and viral-related cirrhosis were limited. We aim to compare the phenotypical, immunological and functional differences between NASH and viral-related cirrhosis patients. **Methods:** This single-centre prospective cohort study recruited stable cirrhosis patients from May 2022 to January 2023. Baseline laboratory tests, liver stiffness measurement (LSM) and gender-specific functional tastings (handgrip, sit-to-stand (STS) and gait speed) were performed on the same day. Serum cytokines were measured using BioLegend LegendPlex Assay. Clinically significant portal hypertension (CSPH) was defined as either the presence of varices, collaterals, ascites, hepatic encephalopathy, or HVPG ≥ 10mmHg. Controlled etiology was defined as normal ALT (< 35Iu/ml), with either virological suppression (< 20Iu/ml) in HBV, SVR12 in HCV, or non-obese (BMI < 30kg/M^2) in NASH cirrhosis. Patients with signs of infection or immunosuppressants were excluded. **Results:** A total of 47 stable cirrhosis patients (NASH: 46.8%, Viral: 53.2% (HBV: 40.4%, HCV: 12.8%) were analyzed. Most patients had compensated cirrhosis (95.8% Child-Pugh Class A, 75% ALBI grade 1). The median (IQR) age was 63 years-old (56-71), BMI was 27.1kg/m^2 (23.7-30.2). Metabolic risk factors were prevalent: 89.4% had at least 1 metabolic risk factor, and 70.2% fulfilled metabolic syndrome. At baseline, the median (IQR) white blood cell (WBC) was 6.4 (5.0-7.5), neutrophil/leukocyte ratio (NLR) was 1.8 (1.5-2.8), and ALT was 30 (22-46). Compared to viral-related cirrhosis, NASH cirrhosis patients were more likely to be female gender (*64% vs 38%, p = 0.02*), with diabetes (*77% vs 44%, p = 0.036*), hypertension (*91% vs 56%, p = 0.01*), and dyslipidemia (*96% vs 60%, p = 0.0005*). NASH cirrhosis was less likely to have controlled underlying etiology (*27% vs 64%, p = 0.019*). Both NASH and viral-related cirrhosis patients were comparable in CTP-score, ALBI score, baseline liver stiffness measurement, and the prevalence of CSPH. However, NASH cirrhosis had a significantly higher level of inflammatory cytokines than viral-related cirrhosis: TNF-α (*6.9 vs 0, p = 0.029*), IL-8 (*28.6 vs 3.9, p = 0.002*), IL-12p70 (*9.1 vs 3.9, p = 0.029*), and IL-17A (*1.9 vs 0, p = 0.029*). NASH cirrhosis patients also more likely to have a weaker handgrip (*59.1% vs 28.0%, p = 0.042*), prolonged STS (*64% vs 44%, p = 0.244*), and reduced gait speed (*43% vs 20%, p = 0.117*). **Conclusion:** NASH cirrhosis patients had distinct phenotypic differences compared to viral-related cirrhosis. NASH cirrhosis had more systemic inflammation, were frailer, and yet were less likely to have controlled etiology than viral-related cirrhosis. Our findings highlight the unmet therapeutic need in NASH cirrhosis patients.

2080-A | NASH RESOLUTION INDEX: DEVELOPMENT AND EXTERNAL VALIDATION OF A NON-INVASIVE SCORE TO PREDICT HISTOLOGIC RESOLUTION OF NASH

Rohit Loomba[1], Maral Amangurbanova[2], Egbert Madamba[2], Harris Siddiqi[2], Claude B. Sirlin[2], Ricki Bettencourt[2], Lisa M. Richards[2] and Daniel Q Huang[3], (1)University of California, San Diego, San Diego, CA, (2)University of California, San Diego, (3)National University Health System (NUHS)

Background: The resolution of nonalcoholic steatohepatitis (NASH) is an accepted regulatory endpoint for subpart H approval of therapies developed for NASH stage 2 or 3 fibrosis but requires an invasive liver biopsy procedure for its assessment. There is a major unmet need to non-invasively determine the resolution of NASH in a precise and reproducible manner. Emerging data suggest that dynamic changes in non-invasive tests (NITs), such as changes in alanine aminotransferase (ALT) and magnetic resonance imaging proton-density-fat-fraction (MRI-PDFF) may help to predict NASH resolution, but a combination of NITs may be more accurate than either alone. We developed a novel non-invasive score, the NASH Resolution Index, to predict the histologic resolution of NASH. **Methods:** This study included 95 well-characterized patients (67% women) with biopsy-confirmed NASH who underwent paired contemporaneous MRI-PDFF and liver biopsy at two-time points as the derivation cohort. The primary objective was to determine a non-invasive score, comprising of a change in ALT, a change in MRI-PDFF, and a third clinical variable, to predict NASH resolution with no worsening of fibrosis. The score was then externally validated in a distinct cohort of 164 participants with biopsy confirmed NASH and a second liver biopsy after 24 weeks. **Results:** The median (IQR) age and BMI were 55 (22-75) years and 32.0 (21.0-47.0) kg/m^2, respectively, in the derivation cohort. The most predictive model (NASH Resolution Index) combined a change in MRI-PDFF, a change in ALT, and baseline AST, which was selected based on the highest area under the receiver operating curve (AUROC), and the lowest Akaike information criterion and Bayesian information criterion. The NASH Resolution index had an AUROC of 0.78 for predicting NASH resolution in the derivation cohort and calibrated well. The score calibrated well, performed robustly in an external validation cohort (AUROC 0.81), and outperformed MRI-PDFF (decline of **e** 30%) and ALT response (decline of **e** 17 U/L) (Figure 1), (all $P < 0.001$). **Conclusion:** The NASH Resolution index may be a useful score to non-invasively predict NASH resolution.

Figure 1: NASH Resolution Index versus ALT response (decline of 17 U/L or higher) and MRI-PDFF response (decline of 30% or higher) for predicting NASH resolution in the external validation cohort

2082-A | NIS2-MICE, AN ADAPTATION OF THE CLINICAL NIS2 +" DIAGNOSTIC TEST FOR THE DETECTION OF NAS e 4 & F e 2 IN GAN DIET-INDUCED OBESE AND BIOPSY-CONFIRMED MOUSE MODEL OF NASH WITH ADVANCED FIBROSIS

Yacine Hajji[1], Elodie Delecroix[1], Jérémy Magnanensi[1], Zouher Majd[1], Audrey Levy[1], Malte Hasle Nielsen[2], Susanne E. Pors[2], Christian Rosenquist[3] and Michael Feigh[4], (1)Genfit S.a., Loos, France, (2)Gubra a/S, Copenhagen, Denmark, (3)Novo Nordisk, Soborg, Denmark, (4)Gubra Aps

Background: The Gubra-Amylin NASH (GAN) diet-induced obese (DIO) and biopsy-confirmed mouse model of NASH with progression to advanced fibrosis (stage F3) represents a validated translational model used in preclinical research and drug discovery. NIS2 +™ is a clinical blood-based dual biomarker (miR34-a, YKL-40) test that has been recently developed and validated for the detection of at-risk NASH (NAS **e** 4 & F **e** 2) in humans. We here aimed to develop NIS2-Mice, an adapted mouse version of the NIS2+™ test and assessed its performance in the GAN DIO-NASH mouse model. **Methods:** Disease progression was profiled in C57BL6/J mice fed the GAN diet (40% fat, 22% fructose, 2% cholesterol) for 12-72 weeks ($n = 15$ per timepoint). Chow-fed mice ($n = 10$) served as healthy lean controls. Blood samples were collected for measuring miR34-a and YKL-40 and compared to automated deep-learning-based histopathological scoring of non-alcoholic fatty liver disease activity score (NAS) and fibrosis stage. A logistic regression was trained using the data obtained in the present study, fitting for the binomial NAS **e** 4 & F **e** 2 condition. Training diagnosis performance of NIS2-Mice test validity and its composite markers were assessed (AUC, sensitivity, specificity, Positive and Negative Predicted Values [PPV, NPV]). **Results:** After **e** 48 weeks on GAN diet, all mice demonstrated histologically-confirmed NAS **e** 4 & F **e** 2. The mean of NIS2-Mice constantly increased with disease severity, from 0.14 in lean controls to 0.91 at week 72 in GAN DIO-NASH mice. When compared with a paired-Delong test, NIS2-Mice test attained a significantly larger AUC compared with miR34-a (0.897 vs 0.853, $p = 0.033$) and YKL-40 (0.897 vs 0.635, $p < 0.0001$) alone, confirming the added-value of dual biomarker assessment over single biomarker use. Using a derived Youden cutoff (0.5492), the diagnostic performance of NIS2-Mice reached a sensitivity of 90%, a specificity of 78%, a PPV of 86% and an NPV of 84%. **Conclusion:** As observed in human patients for the clinical blood-based dual biomarker test NIS2+™, the adapted NIS2-

Mice test accurately and non-invasively detects histologically-confirmed NAS **e** 4 & F **e** 2 in the GAN DIO-NASH mouse model, further supporting clinical translatability and utility of the model in preclinical drug discovery for NASH. Furthermore, the NIS2-Mice test introduces an approach directly related to animal reduction and refinement in regulatory 3Rs preclinical testing and animal experimentation.

2083-A | NONINVASIVE DIAGNOSIS OF NONALCOHOLIC FATTY LIVER DISEASE BY ULTRASOUND-DERIVED FAT FRACTION: A MULTICENTER STUDY

Yi Dong[1], Yunlin Huang[1], Jia Li[2], Danlei Song[2], Rong Shan[3], Hao Wang[3], Jiaojian Lv[4], Siqin Long[4], Chuan Liu[2], Wenping Wang[5] and Xiaolong Qi[6], (1)Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, (2)Zhongda Hospital, Medical School, Southeast University, (3)Shandong Public Health Clinical Center, (4)Lishui People's Hospital, (5) Zhongshan Hospital, Fudan University, (6)Zhongda Hospital, Medical School, Nanjing, Jiangsu, China.

Background: To prospectively assess the role of ultrasound-derived fat fraction (UDFF) in the detection of hepatic steatosis using magnetic resonance imaging-derived proton density fat fraction (MRI-derived PDFF) as the reference standard. **Methods:** From January 2023 to April 2023, participants with or suspected of having nonalcoholic fatty liver disease (NAFLD) were prospectively recruited by multi-center. All participants underwent UDFF and MRI-derived PDFF measurements on the same day. Detailed medical history records were gathered. An MRI-derived PDFF cutoff of 5 % was used for the definition of NAFLD. The correlation between UDFF (%) and MRI-derived PDFF (%) was calculated using the Spearman correlation coefficient. The area under the receiver operating characteristic curve (AUC) was calculated to assess the accuracy of UDFF in the diagnosis of hepatic steatosis. **Results:** A total of 132 participants were included: 50.0 % (66/132) were male, median age was 41.0 years (interquartile ranges [IQR]: 32.3 - 54.0); 20.5 % (27/132) and 55.3 % (73/132) were categorized as over-weight (body mass index [BMI]: 23–25 kg/m^2) and obese (BMI > 25 kg/m^2), respectively; 60.6 % (80/132) of participants had NAFLD, 28.8 % (38/132) had dyslipidemia, 22.7 % (30/132) had type 2 diabetes mellitus, and 16.7 % (22/132) had hypertension. The UDFF had significant correlations with BMI (**Á**= 0.595, $P < 0.001$), triglycerides (**Á**= 0.506, $P < 0.001$), gamma-glutamyl transferase (**Á**= 0.452, $P < 0.001$), alanine aminotransferase (**Á**= 0.428, $P < 0.001$), aspartate aminotransferase (**Á**= 0.276, $P = 0.001$), high-density lipoprotein cholesterol (**Á**= - 0.221, $P = 0.011$), and total cholesterol (**Á**= 0.213, $P = 0.014$). The median UDFF and MRI-derived PDFF were 9.1 % (IQR: 4.4, 15.3) and 7.7 % (IQR: 3.4, 12.9), respectively. The Spearman correlation coefficient was 0.784 ($P < 0.001$) for UDFF versus MRI-derived PDFF. Using MRI-derived PDFF **e** 5 % as a reference, UDFF had good accuracy for the diagnosis of NAFLD (AUC of 0.914 [95 % confidence intervals [CI]: 0.863, 0.965]), with a sensitivity of 87.5 % (95 % CI: 0.785, 0.931) and a specificity of 84.6 % (95 % CI: 0.725, 0.920). The interobserver agreement and intraobserver agreement of UDFF measurement were excellent (correlation coefficients 0.904-0.969, $P < 0.001$). **Conclusion:** The UDFF was useful for assessing NAFLD when using MRI-derived PDFF as the reference standard.

f 2084-A | NOVEL ARTIFICIAL INTELLIGENCE-ASSISTED DIGITAL PATHOLOGY QUANTITATIVE IMAGE ANALYSIS PREDICTS THE OCCURRENCE OF LIVER-RELATED CLINICAL EVENTS IN THE MULTICENTRIC, EUROPEAN, HEPATIC OUTCOMES AND SURVIVAL FATTY LIVER REGISTRY (HOTSURFR) STUDY

Li Chen, Pharmanest, Louis Petitjean, Pharmanest, Princeton, NJ, United States, Javier Ampuero, Instituto De Biomedicina De Sevilla, Ibis/Hospital Universitario Virgen Del Rocío, Huvr /Csic/Universidad De Sevilla Sevilla, Spain/Centro De Investigación Biomédica En Red (Ciberehd), Madrid, Spain, Jérôme Boursier, Service Hépato-Gastroentérologie Et Oncologie Digestive, Centre Hospitalier Universitaire, Angers, France; & Laboratoire Hifih, Sfr Icat 4208, Université D'angers, Angers, France, Stergios Kechagias, Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden, Salvatore Petta, Sezione Di Gastroenterologia, Dipartimento Promozione Della Salute, Materno-Infantile, Di Medicina Interna e Specialistica Di Eccellenza "G. D'alessandro", Università Di Palermo, Palermo, Italy, Hannes Hagström, Unit of Hepatology, Department of Upper GI Diseases, Karolinska University Hospital, Stockholm, Sweden, Jörn M. Schattenberg, I. Department of Medicine, University Medical Centre Mainz, Johannes Gutenberg University, Mainz, Germany, Mainz, Germany, Frederic Charlotte, Sorbonne Université, Ican Institute, Hôpital Pitié-Salpêtrière, Leila Kara, Ican, Pierre Bedossa, Newcastle University, Mathieu M. Petitjean, Pharmanest Inc and Vlad Ratziu, Sorbonne Université, Assistance Publique-Hôpitaux De Paris, Hôpital Pitié Salpêtrière, Institute of Cardiometabolism and Nutrition (ICAN)

Background: Artificial intelligence-assisted digital pathology provides an automated, operator independent, sensitive and quantitative assessment of histological changes with the ability to identify patterns of fibrosis progression or regression. We previously showed that quantitative traits of collagen fiber parameters can be used to build a fibrosis score that is correlated with the semiquantitative histological NASH CRN stages. However, the value of the fibrosis severity continuous score for the prediction of clinical outcomes is unknown. Here, we aimed to determine if the same score established from baseline liver biopsies is correlated with incident liver-related events (LRE) in a large, multicentric, European cohort with long-term follow-up. **Methods:** 404 patients from 6 European centers with liver biopsy performed before 2011 for suspected NAFLD and clinical follow-up, were retrospectively analyzed. LRE were defined as occurrence of cirrhosis, cirrhosis decompensation events or hepatocellular carcinoma. Formalin-fixed, paraffin-embedded biopsies where stained with collagen stains (Masson Trichrome or Picro Sirius Red) and digitized at 40X. Histology was read centrally (NASH CRN classification). High resolution quantitative image analysis was used to generate a quantitative fibrosis severity score, Ph-FCS, previously optimized to model progression of fibrosis severity. **Results:** Mean age was 53.7 yrs, 58% were males, mean BMI 31.2 kg/m², 37% had diabetes and 60% arterial hypertension. The proportion of histological fibrosis stages were: stage 0: 53%, stage 1: 19%, stage 2: 8%, stage 3: 13% and stage 4: 7%. Median follow-up was 11.4 yrs (IQR 4.7). 63 pts (15.6%) had at least one LRE. Mean (median, sd) Ph-FCS was 5.19 (3.91, 3.74) in pts with LRE vs 2.60 (2.00, 2.22) in pts without LRE ($p < 0.001$) (Figure). At a cut-off value of 3, Ph-FCS had a sensitivity of 0.67 and specificity of 0.75 for the prediction of LRE. When the cut-off value was changed by +/-5% the sensitivity and specificity varied within a -0.048 to +0.028 range. A Ph-FCS score < 2 ruled-out (sensitivity 0.89) while a Ph-FCS score > 3.2 ruled-in (specificity 0.77) the occurrence of LRE. The risk of first LRE occurrence could be stratified using the baseline Ph-FCS score (Figure). **Conclusion:** Quantitative image analysis by digital pathology performed on stained liver slides provides continuous scores (Ph-FCS) that correlates with NASH CRN fibrosis stages and can predict the occurrence of liver-related events. Further validation for clinical outcomes on additional cases is ongoing with the objective to provide better histological surrogates for therapeutic trials.

2085-A | NOVEL MATRICELLULAR SERUM MARKERS PREDICT LIVER FIBROSIS AND FIBROGENESIS IN PATIENTS WITH NAFLD UNDERGOING BARIATRIC SURGERY

Rambabu Surabattula[1], Pierre Bel Lassen[2,3], Sudharani Myneni[1], Judith Aron-Wisnewsky[2,3], Laurent Genser[3], Jean-Daniel Zucker[2], Karine Clément[2,3] and Detlef Schuppan[1,4], (1)University Medical Center Mainz, (2) Sorbonne Université, (3)Pitié-Salpêtrière Hospital, (4) Harvard Medical School

Background: Obesity is a risk factor for NAFLD and the prevalence of NAFLD in patients eligible for bariatric surgery (BS) can reach 75% to 100%. BS provides successful weight loss and metabolic normalization, and leads to liver histological improvement in some but not all patients. We established and assessed novel serum markers of fibrogenesis in follow-up of a well-defined cohort of patients with obesity and NAFLD undergoing bariatric surgery. **Methods:** Sandwich ELISAs measuring the matricellular fibrosis marker thrombospondin-2 (TSP2) and the metabolism/inflammation/fibrosis-related markers insulin-like growth factor binding protein-7 (IGFBP7), CD163 and a disintegrin and metalloprotease thrombospondin like-9 (ADAMTS9) were established using combinations of recombinant proteins, commercial and self-produced monoclonal and polyclonal antibodies. Sensitivity and specificity were optimized, with intra- and Inter assay variations for serum or plasma below 10% and 15%, resp. 132 severely obese patients with matched liver biopsies were included. 54 patients showed intermediate to advanced fibrosis (stage F2-4) and 74 fibrosis stage F0-1. The evolution of the serum fibrosis markers post-bariatric surgery was analyzed from a subset of 51 subjects with follow-up at 3 & 12 months after BS. **Results:** Patients with F2-4 fibrosis displayed significantly higher baseline levels of the three markers vs patients with fibrosis F0-1 at baseline for TSP2 (88.6 vs 53.9), IGFBP7 (208.8 vs 128), ADAMTS9 (83.3 vs 47.4; ng/ml). These differences were more pronounced comparing fibrosis F3-4 with F0-2. The AUROC values to distinguish fibrosis F2-4 or F3-4 from F0-1 or F0-2 were 0.74 and 0.84 for TSP2, 0.84 and 0.78 for IGFBP7, and 0.72 and 0.70 for ADAMTS9. The AUROC value to distinguish fibrosis F2-4 and F3-4 from F0-1 and F0-2 was significantly increased for the combination of TSP2, IGFBP7 & CD163, reaching the range of a perfect test in view of biopsy sampling error. Levels of TSP2 significantly decreased 3 months after BS in patients with baseline F2-4 fibrosis, supporting its prominent role in liver fibrogenesis, and of IGFBP7, CD163 and ADAMTS9 in fibrogenic inflammation. **Conclusion:** We identified and validated 4 novel noncollagen serum markers of liver fibrogenesis and metabolic inflammation in a unique cohort of patients undergoing BS. The markers TSP2 and IGFBP7 showed the currently highest predictive value for predicting F2-4 fibrosis and response to BS.

(NAFLD) which can develop into liver fibrosis. Historically, liver biopsy has been used to assess fibrosis but noninvasive tests have now been developed that can be used to assess fibrosis risk. We assessed whether online education could improve gastroenterologists' understanding of the role of noninvasive tests for liver fibrosis and improve their confidence and competence in using these tests in clinical practice. **Methods:** Gastroenterologists participated in 2 online activities: a video lecture and a round table discussion with synchronized slides. For each activity, responses to 3 multiple-choice, knowledge or competence questions and 1 self-efficacy, 5-point Likert scale confidence question were analyzed. Educational effect was assessed using a repeated-pair design, pre-/post-assessment. A paired samples t-test was conducted for significance testing on overall average number of correct responses and for confidence rating. A series of McNemar's tests were conducted at the question level (5% significance level, $P < 0.05$). Activity 1 launched 1 Dec. 2022, data collection 6th Feb. 2023. Activity 2 launched 20th Jan. 2023, data collection 16th Mar. 2023. **Results:** Activity 1 (n = 393 gastroenterologists)

- Significant improvement in knowledge of serum biomarkers used in the FIB-4 test (50% correct responses at baseline, 63% post-activity; $P < 0.001$) and the ELF test (25% correct responses at baseline, 51% post-activity; $P < 0.001$)
- 48% gained confidence in their ability to use risk stratification scores to assess liver fibrosis

Activity 2 (n = 304 gastroenterologists)

- Significant improvement in knowledge of the advantages of the FIB-4 score (53% correct responses at baseline, 64% post-activity; $P < 0.001$) and of fibrosis and its link to liver-related mortality (79% correct responses at baseline, 84% post-activity; $P < 0.01$)
- Significant improvement in competence in selecting the AACE-recommended fibrosis biomarker panel to use in a paient case (44% correct responses at baseline, 65% post-activity; $P < 0.001$)
- 42% gained confidence in their ability to use noninvasive tests to assess the risk of liver fibrosis

Conclusion: These online video activities significantly improved gastroenterologists' knowledge, competence and confidence in the use of noninvasive tests to assess the risk of liver fibrosis.

2087-A | OPTIMIZING SURVEILLANCE FREQUENCY USING TRANSIENT ELASTOGRAPHY IN LOW-RISK NONALCOHOLIC FATTY LIVER DISEASE

Harish Gopalakrishna, Clinical Research Section, Gaithesberg, MD, Gayatri Nair, Medstar Georgetown University Hospital, Roham Salman Roghani, Eisenhower Health, Natarajan Ravendhran, Johns Hopkins School of Medicine and Yaron Rotman, National Institute of Diabetes and Digestive and Kidney Diseases, Nih

Background: Most individual's with nonalcoholic fatty liver disease (NAFLD) lack significant fibrosis and are considered "low risk". The optimal frequency of monitoring these individual's for progression is uncertain and guidance is based on expert opinion. We aimed to develop a prediction model to determine which low risk subjects can safely avoid re-screening with vibration controlled transient elastography (VCTE) within one year. **Methods:** We included two independent prospective cohorts (derivation and validation) of unselected subjects with NAFLD. All subjects had baseline liver stiffness measurement (LSM) using VCTE which was repeated after 6-12 months irrespective of baseline. Subjects with LSM < 8 kPa at baseline were defined as low risk. The primary endpoint was LSM **e** 8 kPa at follow up, suggesting possible progression. Models to predict the likelihood of possible progression were constructed using univariate and multivariate binary logistic regression. A sequential-testing algorithm was developed on the derivation cohort using the best performing model, maximizing negative predictive value (NPV) and accuracy, and its performance was tested on the independent validation cohort. **Results:** Out of 206 subjects in the derivation cohort, 96 were low risk. 24 (25%) low-risk subjects had a repeat LSM **e** 8 kPa after a median of 10 months. Potential progressors had higher baseline LSM (7 vs 5.6 kPa, $p < 0.01$), higher follow-up BMI ($p = 0.02$) and ALT ($p = 0.04$). A multivariate model combining baseline LSM ($p < 0.01$) and change in ALT from baseline to follow up visit ($p = 0.02$) performed best in identifying progressors with area under the ROC curve of 0.84 (95% CI: 0.74-0.94). Using this combination, a two-step decision algorithm was developed (figure). Baseline LSM thresholds determine which subjects require a follow-up VCTE in a year, while in subjects with intermediate baseline LSM, only those with ALT increase > 6 U/L require re-screening. This algorithm had a NPV of 92%, specificity of 78%, and accuracy of 78% in the derivation cohort. In the independent validation cohort ($n = 64$), it showed NPV of 91%, specificity of 72%, and accuracy of 71%. Applying the algorithm to both cohorts, would have decreased the number of repeat VCTE tests within 1 year by 75% with only 25% of possible progressors misclassified. **Conclusion:** For people with low-risk NAFLD based on baseline VCTE, a simple algorithm which can be applied in primary care setting can be used to avoid the need for a repeat VCTE in a year. Validation of the algorithm for longer monitoring intervals is ongoing.

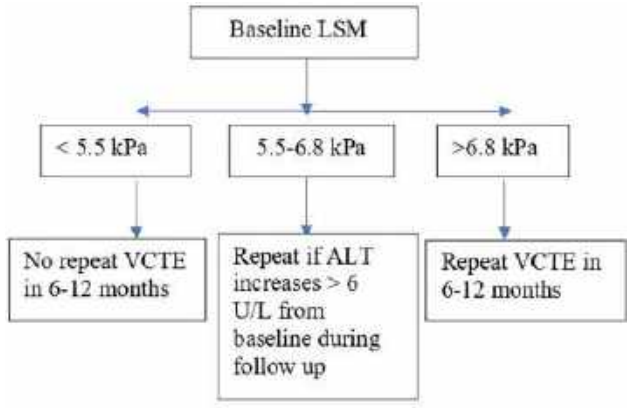

Figure: Step-wise decision algorithm

2088-A | PATIENTS WITH NASH CIRRHOSIS HAVE SIMILAR MUSCLE COMPOSITION TO NON-NASH PATIENTS ASSESSED BY NOVEL MRI-BASED MUSCLE ASSESSMENT TECHNOLOGY

Omar Jamil[1], Nirmal Desai[2], Jonathan Taylor[1], Carla Harmath[1] and Michael R. Charlton[1], (1)University of Chicago, (2)Loyola University

Background: While frailty and sarcopenia are well recognized markers of mortality and transplant outcomes, the current methods of assessment have limitations and may underestimate sarcopenia in patients with infiltrative muscle fat. MRI the gold standard for body composition analysis. An MRI-based technology to assess muscle health and body composition (AMRA® Profiler 4 MAsS Scan by AMRA Medical) uses a rapid neck-to-knee MRI protocol and automated image analysis technique to measure both muscle fat infiltration and free muscle fat volume and distinguishes between muscle and fat. Comparing muscle composition in patients with cirrhosis secondary to NASH to patients with cirrhosis from other etiologies using MRI has not been reported. **Methods:** A prospective cohort study is being conducted at the University of Chicago and began enrolling patients in August, 2022. Patients with cirrhosis underwent MAsS scan with analysis of muscle fat, muscle volume, subcutaneous fat, visceral fat and liver fat content. The protocol generates age and sex matched muscle fat index and muscle volume index. These indices are combined to create a composite score used to determine muscle composition using both muscle volume and fat infiltration. Patients were divided into two groups, those with cirrhosis secondary to NASH, and those with cirrhosis secondary to other etiologies (Non-NASH). STATA 18 was used for all statistical analyses. **Results:** MAsS Scan has been performed in 47 patients with cirrhosis. 27 patients had cirrhosis secondary to NASH (57%), 8 ETOH (17%), 8 viral (17%), 1 cholestatic (2%) and 3 other (6%). Age (62 and 63.2) and gender (48% female and 40% female) were similar between groups, while the NASH group had significantly more Hispanic (19% to 0%) and White (70% to 30%) patients while the Non-NASH group had more non-Hispanic and Black (55% to 4%) patients. The average BMI of the NASH group (31.2) was statistically higher ($p < 0.05$) than the Non-NASH group (26.9), while the MELD scores were similar (11.1 and 11.5). While the NASH patients had significantly ($p < 0.05$) more visceral fat (5.3L to 3.5L) and liver fat (6.5% to 3.2%), both groups had the same levels of fat infiltrating the thigh muscle (7.9% and 7.9%) and muscle volume (9.5L and 9.5L). As seen in Figure 1, when compared to age and sex matched controls, the muscle fat index and muscle volume index of NASH and Non-NASH patients are similar. The number of patients with adverse muscle composition, or sarcopenia, was 7 (15%) in the total cohort, without a significant difference between the two groups (11% of NASH patients and 20% of Non-NASH). **Conclusion:** Patients with NASH cirrhosis were found to have more visceral fat and liver fat. Visceral fat is correlated with an increased risk of cardiovascular disease. NASH and Non-NASH patients with cirrhosis were found to have similar levels of infiltrative fat and muscle volume as measured by a novel MRI protocol.

Research; Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom, San Antonio, TX, (3)I. Department of Medicine, University Medical Centre Mainz, Germany, (4)Genfit S.a., Loos, France, (5) Université De Lille, Inserm, CHU Lille, Institut Pasteur De Lille, Lille, France, (6)Newcastle Nihr Biomedical Research Centre, Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, UK, (7) Sorbonne Université, Institute for Cardiometabolism and Nutrition, Hôpital Pitié-Salpêtrière, Paris, France, (8)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Non-alcoholic steatohepatitis (NASH) is a progressive form of non-alcoholic fatty liver disease (NAFLD), the leading cause of chronic liver disease. While obesity is a major risk factor, NAFLD can affect people in all BMI categories. Timely diagnosis of at-risk NASH (NAS **e** 4 and F **e** 2), a condition associated with higher risk of liver-related/all-cause mortality, is critical. We compared the performance of NIS2+™, an optimization of the blood-based NIS4® technology for the detection of at-risk NASH, with well-established non-invasive tests (NITs), but designed for fibrosis evaluation, in different BMI-based groups. **Methods:** Among screened patients of the RESOLVE-IT Phase 3 trial (NCT02704403), those with NIS2+™, APRI, ELF™, NFS and FIB4 scores available, and with less than 90 days between liver biopsy and serum samples collection, were selected, resulting in a cohort of N = 2084 patients. This cohort was split in 5 BMI-based groups (lean [n = 84], overweight [n = 514], with obesity Class 1 [n = 727], Class 2 [n = 470] and Class 3 [n = 289]) based on the WHO criteria and according to ethnicity-specific cut-offs. NIS2+™ performance in detecting at-risk NASH in each BMI group was compared to other NITs using AUROC and associated paired Delong tests. Clinical performances (sensitivity, specificity, PPV, NPV) of NIS2+™ in each group using fixed cutoffs for ruling-out/in at-risk NASH were derived. **Results:** The prevalence of at-risk NASH increased with increasing BMI (33.3 to 50.2%, p = 0.0058), driven by a significant increase in NAS scores (3.13 to 4.37, p < 0.0001). ALT and FIB-4, surrogate markers for disease activity and fibrosis respectively, achieved moderate AUROCs for the detection of at-risk NASH (ALT: 0.665-0.755; FIB-4: 0.618-0.688), while NFS yielded the lowest performances in all groups (0.554-0.623). NIS2+™ had the highest accuracy and significantly outperformed all other NITs across the different subpopulations, with AUROCs ranging from 0.784-0.851. NIS2+™ sensitivity when ruling-out and specificity when ruling-in at-risk NASH ranged 0.71-0.96. NIS2+™ sensitivity when ruling-in and specificity when ruling-out at-risk NASH ranged 0.54-0.75. **Conclusion:** Across BMI categories, NIS2+™ significantly achieved the highest performances for the detection of at-risk NASH, returning consistent clinical performances when being used with fixed cutoffs for ruling-out/in at-risk NASH and could thus represent a promising tool to detect at-risk NASH in people at any BMI, including lean people.

2090-A | PNPLA3, MBOAT7 AND TM6SF2 MODIFY MITOCHONDRIAL DYNAMICS IN NAFLD PATIENTS: DISSECTING THE ROLE OF CELL-FREE CIRCULATING mtDNA AND COPY NUMBER

Miriam Longo[1], Erika Paolini[2,3], Marica Meroni[1], Michela Ripolone[4], Laura Napoli[5], Marco Maggioni[1], Anna Ludovica Fracanzani[3,6] and Paola Dongiovanni[1], (1)Fondazione Irccs Cà Granda Ospedale Maggiore Policlinico, (2)Fondazione Irccs Cà Granda Ospedale Maggiore Policlinico, Milan, Italy., Milano, MI, Italy, (3) Università Degli Studi Di Milano, (4)Fondazione Irccs Ca' Granda Ospedale Maggiore Policlinico, (5) 3Fondazione Irccs Ca' Granda Ospedale Maggiore Policlinico, (6)SC Medicina Ad Indirizzo Metabolico, Fondazione Irccs Cà Granda Ospedale Maggiore Policlinico, Milan, Italy

Background: Mitochondrial (mt) dysfunction is a hallmark of progressive NAFLD. MtDNA copy number (mtDNA-CN) and cell-free circulating mtDNA (ccf-mtDNA), which reflect mt-mass and mt-dysfunction, respectively, are gaining attention for NAFLD non-invasive assessment. We demonstrated that PNPLA3, MBOAT7 and TM6SF2 deficiency in HepG2 cells increased mt-mass, mtDNA-CN and ccf-mtDNA. Aims: To assess the genetic contribution on mt-dynamics, mtDNA-CN and ccf-mtDNA in 1) primary mouse hepatocytes silenced for PNPLA3/MBOAT7/TM6SF2 genes; 2) Discovery (n = 28) and Validation (n = 773) cohorts, including biopsied NAFLD patients, stratified according to number of risk variants (NRV = 3). **Methods:** Mt-morphology was assessed by TEM. mtDNA-CN was measured in the entire Validation cohort (n = 773), while ccf-mtDNA in a subgroup (n = 300) with available serum samples. mtDNA-CN and mt-related genes were evaluated in liver biopsies. **Results:** Primary mouse hepatocytes challenged with fat overload or PNPLA3/TM6SF2/MBOAT7 co-silencing lowered mt-fusion paralleled by higher mt-fission and ccf-mtDNA release, suggesting that lipid accumulation and genetics may independently unbalance mt-dynamics. In the Discovery cohort, NRV = 3 patients showed the highest mtDNA-CN compared to those with 1-2 or no variants. At TEM, NRV = 3 carriers increased mt-mass and presented an elevated pattern of mt-morphological alterations (swollen shapes, double membranes rupture). In the Validation cohort, mtDNA-CN associated with the NAFLD histological spectrum and NRV = 3 at multivariate analyses, supporting that both NAFLD severity and genetics may modulate mt-dynamics. In liver biopsies, mtDNA-CN was higher in NRV = 3 patients together with reduction of mt-fusion and activation of mt-fission, resembling what observed in hepatocytes. Ccf-mtDNA was augmented in NRV = 3 patients with low-moderate/severe NAFLD, thereby sustaining that this effect was amenable to the 3 at-risk polymorphisms. By stratifying the Validation cohort according to the clinical phenotype, we found that circulating mtDNA-CN progressively increased from steatosis to HCC and ROC curves showed that it significantly discriminated HCC cases ($p < 0.0001$; AUC: 0.86), resulting a good candidate for NAFLD monitoring. Serum ccf-mtDNA increased in HCC patients and it foretold HCC onset ($p < 0.0001$; AUC: 0.91). **Conclusion:** mtDNA-CN and ccf-mtDNA may have pathological and predictive significance in NAFLD patients at high-risk, especially in those genetically-predisposed.

2091-A | PROPOSAL OF A NOVEL SEROLOGICAL ALGORITHM COMBINING A FIBROSIS INDEX BASED ON FOUR AND SERUM MAC-2 BINDING PROTEIN GLYCOSYLATION ISOMER FOR ADVANCED FIBROSIS IN NON-ALCOHOLIC FATTY LIVER DISEASE

Yeowool Kang[1], Yang Hyun Baek[2], Sang Yi Moon[2], Dae Won Jun[3], Se Young Jang[4], Ki Tae Yoon[5], Young Youn Cho[6] and Hoon Gil Jo[7], (1)Dong-a University, (2) Dong-a University College of Medicine, (3)Hanyang University College of Medicine, (4)School of Medicine, Kyungpook National University, (5)Pusan National University Hospital, Busan, Republic of Korea, (6) Chung-Ang University Hospital, (7)Wonkwang University College of Medicine and Hospital

Background: Noninvasive testing methods have become increasingly critical in the diagnosis of liver fibrosis in chronic liver diseases. Herein, we compared the diagnostic performance of serum Mac-2 binding protein glycosylation isomer (M2BPGi) and other serological panels for fibrosis in patients with non-alcoholic fatty liver disease (NAFLD) and proposed an improved two-step diagnostic algorithm for advanced fibrosis in NAFLD. **Methods:** From March 2015 to September 2022, we enrolled 231 patients diagnosed with NAFLD at Dong-A University Hospital and Kyungpook National University Hospital who underwent liver biopsy in this retrospective study. Liver fibrosis stage was assessed according to the system devised by the

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

nonalcoholic steatohepatitis (NASH) clinical research network (CRN) scoring system. F3-F4 was defined as an advanced fibrosis. As a non-invasive method for assessing liver fibrosis, serum M2BPGi, fibrosis index based on four factors (FIB-4), aspartate aminotransferase-to-platelet ratio index (APRI), and non-alcoholic fatty liver disease fibrosis score (NFS) were evaluated. The accuracy of non-invasive markers in the diagnosis of liver fibrosis was calculated using area under the receiver–operator curve (AUROC) analysis. Statistical significance was considered at P-value < 0.05. **Results:** The average age of enrolled patients was 45.7 years. There were 124 (53.7%) males. Associated metabolic diseases were obesity (body mass index **e** 25 kg/m2) (n = 195, 84.4%) and diabetes (n = 75, 32.5%). The confirmed fibrosis grade in liver biopsy was F0 in 61 (26.4%) patients, F1 in 70 (30.3%), F2 in 41 (17.8%), F3 in 41 (17.8%), and F4 in 18 (7.8%). The areas under the receiver operating characteristic curves of serum M2BPGi, FIB-4, APRI, and NFS for advanced fibrosis (**e** F3) were 0.823, 0.858, 0.779, and 0.827, respectively. To reduce the performance of unnecessary liver biopsy, we propose a two-step algorithm using FIB-4 as an initial diagnostic tool and serum M2BPGi (**e** 0.6) as an additional diagnostic method for patients classified as intermediate (23%). Using the proposed algorithm, the sensitivity, specificity, accuracy, positive predictive value (PPV), and negative predictive value (NPV) were 0.812, 0.814, 0.814, 0.600, and 0.927, respectively (Fig. 1). **Conclusion:** Serum M2BPGi is a simple and effective test for advanced fibrosis in patients with NAFLD. Application of the two-step algorithm based on FIB-4 and M2BPGi proposed here can improve diagnostic performance and reduce unnecessary tests, making diagnosis easily accessible, especially in primary medical centers

2092-A | QUANTITATIVE ULTRASOUND FOR LIVER STEATOSIS ASSESSMENT WITH A NEW POINT-OF-CARE DEVICE, HEPATOSCOPE, IS REPRODUCIBLE AND SHOWED GOOD CORRELATION TO OTHER NON-INVASIVE TESTS

Victor De Ledinghen[1], Dan Cohen-Dutartre[2], Baptiste Hériard-Dubreuil[3], Adrien Besson[3], Francoise Manon[4], Joelle Abiven[4], Anne-Laure De Araujo[4], Rhizlane Houmadi[4], Julie Dupuy[4], Juliette Foucher[4], Joel Gay[3] and Claude Cohen-Bacrie[3], (1)Centre D'investigation De La Fibrose Hépatique, Bordeaux University Hospital, Pessac, France; Inserm U1053, Bordeaux University, Bordeaux, France., (2)Inria, (3)E-Scopics, (4)CHU Bordeaux, Bordeaux, France

Background: Qualitative liver ultrasound (US) is the first line non-invasive modality to screen for steatosis. Quantitative imaging-derived parameters such as US attenuation (UA), backscatter coefficient (BSC) and speed of sound (SOS) are known to be related to steatosis and have been proposed to improve the qualitative assessment. We evaluated the repeatability (intra-operator) and reproducibility (inter-operator) of UA, BSC and SOS measurements performed by expert and novice operators with the Hepatoscope™, a new ultraportable point-of-care US device. We also assessed their correlation with other available routine non-invasive tests: Fatty Liver Index (FLI), Fibroscan Controlled Attenuation Parameter (CAP™), and Aixplorer® UA and SOS. **Methods:** 96 adult patients referred to routine hepatology consultation for chronic liver diseases were enrolled in this prospective single center study (NCT04782050). UA, BSC and SOS measurements were computed from prospective acquisitions of raw US data with Hepatoscope. Operators were blinded to any median value for each series of acquisitions. UA, BSC and SOS measurements were estimated using the median of an incremented number of consecutive valid values. Data were analyzed with R to determine repeatability and reproducibility intraclass correlation coefficients (ICC), and the r^2 correlation between non-invasive tests. **Results:** BSC and UA measurements were highly repeatable, regardless of the number of values used to compute a measurement: ICC **e** 0.87. Reproducibility of BSC and UA measurements obtained from 3 valid values were 0.86 and 0.84, respectively. Repeatability by experts and novices were similar: 0.91 (95%CI [0.86-0.94]) and 0.87 (95%CI [0.81-0.91]) for BSC, respectively; 0.89 (95%CI [0.85-0.93]) and 0.87 (95%CI [0.81-0.91]) for UA, respectively. Using 3 values to compute SOS measurements, their overall repeatability and reproducibility were moderate: 0.71 and 0.65, respectively.

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

As shown in Table 1, UA, SOS and BSC correlated moderately with CAP; BSC showed the highest correlations with CAP (0.67; 95%CI [0.51-0.79]) and UA (0.88; 95%CI [0.80-0.93]). US parameters correlated weakly with FLI. **Conclusion:** Three values of liver steatosis-related US parameters with the Hepatoscope were sufficient to ensure moderate to excellent repeatability and reproducibility. These measurements correlated well with Fibroscan CAP. Hepatoscope may be used at the bedside to assess liver steatosis efficiently, although future studies against liver biopsy and MRI PDFF should confirm its performance for the triage of patients at risk of NAFLD-NASH. Table 1. Correlation coefficients (r^2) between ultrasound parameters related to steatosis and FLI.

	CAP	SSI ATT	UA	SSI SOS	SOS	BSC	FLI
CAP		0.27	0.49	0.27	0.33	0.67	0.20
SSI ATT			0.27	0.07	0.06	0.44	0.09
UA				0.10	0.17	0.88	0.15
SSI SOS					0.44	0.28	0.16
SOS						0.32	0.24
BSC							0.25

2093-A | RECOMMENDED CLINICAL CARE PATHWAYS (CCPS) WITH FIB-4 UNDERESTIMATES THE PREVALENCE OF ADVANCED FIBROSIS (AF) COMPARED TO SEQUENTIAL CCP WITH LIVERFAST GP+ (GP+) AND LIVER STIFFNESS MEASUREMENT (LSM) BY FIBROSCAN.

Naim Alkhouri, Arizona Liver Health, Phoenix, AZ, Ronald Quiambao, Fibronostics US Inc, USA and Mona Munteanu, Fibronostics

Background: CCPs have been developed to assist clinicians, including primary care medicine, in diagnosing NAFLD with AF based on noninvasive sequential testing with FIB-4 followed by liver stiffness measurement (LSM) by Fibroscan. (*Kanwal, Gastroenterology 2021; Rinella, Hepatology 2023*). Liverfast GP+ is a noninvasive blood-based AI-algorithm combining common biochemistry with anthropometrics that outperforms FIB-4 and has no limitations related to age or diabetes. (*deLédinghen, JHepatol 2023-A)* We recently validated GP+ that achieved 100% histological confirmation when concordant for AF with LSM. *(Alkhouri,JHepatol 2023-A).* The study aims to perform a comparative assessments of the prevalence of AF using recommended CCP (sequential FIB4 and LSM) and using newly released triage tool, GP +, downstream of LSM, on the 2017-March 2020 Pre-pandemic NHANES cohort. **Methods:** We performed a retrospective analysis of data collected from 15,560 US subjects from the nationally representative sample of NHANES 2017-March 2020 pre-pandemic cohort. Subjects were assigned to one of the four GP+ diagnostic categories; GP+ 4th category defines the presumed AF. Cut-offs of 2.68 and 1.3 have been used for FIB4 to assign AF and the indeterminate zone (IZ), respectively. All subjects aged 18 years or more without missing data for GP+, FIB-4 and LSM with IQR/median LSM < 30% have been included. Clinically significant fibrosis was assigned as per LSM **e** 8.0KPa. The prevalence and the agreement to identify AF have been estimated using recommend CCP and newly released GP+ in sequential combination with LSM. **Results:** A total of 7441 subjects have been included [mean(se) age 49(0.2) years, BMI 29.6(0.1)kg/m2, ALT 22(0.2)U/L, AST 22(0.2)U/L, diabetes 14%, LSM 5.8(0.06)kPa, CAP 263(1)dB/m]. 227 (3.1%) subjects had FIB4 > 2.67 and, among them, 86 (1.2%) have been presumed AF with LSM; among them, 57/86 have been presumed AF with GP+. In 1765 (23.7%) subjects FIB-4 ranged 1.30-2.67 (indeterminate); among them, 226 (3.0%) had presumed AF with LSM and 85/226 have been presumed AF with GP+. When GP+ have been used instead of FIB4, 520 (7.0%) subjects have been identified with AF and 183 (2.5%) have been confirmed with LSM. Among 1041 subjects whose doctor told them they had diabetes, 52 (5.0%) had FIB4 > 2.67 and 28 (2.7%) had AF confirmed with LSM; 381 (36.6%) had FIB4 indeterminate and, among them, 94 had AF confirmed with LSM. 199 (19.1%) had GP+ presumed AF and, among them, 93 (8.9%) have been confirmed with LSM. **Conclusion:** Using the strength of concordance between GP+ and LSM, the prevalence of presumed AF in the NHANES pre-pandemic cohort was estimated as being twice higher than if presumed with FIB4 (2.5% vs. 1.2%, respectively). Among patients with diabetes, the prevalence of presumed AF was 8.9%. GP+ can be used as a triage tool, confirmed with LSM, to better identify subjects to be addressed to hepatologists.

2094-A | REDUCING SCREEN FAILURE RATES FOR NASH CLINICAL TRIALS USING BALLOONING AND FIBROSIS ASSESSMENT WITH SECOND HARMONIC GENERATION/TWO-PHOTON EXCITATION MICROSCOPY AND ARTIFICIAL INTELLIGENCE ANALYSIS: RESULTS FROM THE TANDEM TRIAL

Kutbuddin Akbary[1], Ya-Yun Ren[1], Dean Tai[2], Naim Alkhouri[3], Dominique Brees[4] and Jossy Kochuparampil[4], (1)Histoindex Pte Ltd, (2)Histoindex Pte Ltd, Singapore, (3)Arizona Liver Health, Phoenix, AZ, (4)Novartis Pharma AG

Background: Liver biopsy evaluation in non-alcoholic steatohepatitis clinical research network classification (NASH-CRN) by pathologists' interpretation are used in clinical trials for inclusion criteria and treatment endpoints. Alternative methods maybe more sensitive and offer quantitative evaluation of liver histology. We describe second harmonic generation/two-photon excitation (SHG/TPE) microscopy with artificial intelligence (AI) analyses of liver biopsies for quantitative assessment of fibrosis and ballooning and its potential in reducing screening failure rates in NASH drug trials. **Methods:** Biopsy from 138 patients diagnosed with non-alcoholic fatty liver disease (NAFLD) excluded due to histologic criteria in a NASH phase 2 trial (NCT03517540), were evaluated for liver fibrosis and ballooning using SHG/TPE microscopy, providing measurements on a continuous scale (qFibrosis [qF] and qBallooning [qB]). Continuous values were changed to categorical scores (qF0–qF4/qB0-qB3) using previously established cut-offs. Patients excluded from the trial due to ballooning score (B0) or fibrosis score (F0, F1, F4) were evaluated. Comparative analysis was done to determine number of patients who failed screening, evaluated by central pathologist and SHG/TPE microscopy. **Results:** Based on central pathologist's readings, 56 patients were excluded for B = 0 score. Additionally, 64 patients who had B > 0 score were excluded due to fibrosis stage being either F0, F1 or F4 (F-screen) (Figure 1). Based on SHG/TPE microscopy and AI analysis, 45 patients with qB = 0 could potentially excluded from the trial. Additionally, 65 patients could be potentially excluded from the trial as their qF stage would be either qF0, qF1 or qF4 (qF-screen) (Figure 1). The difference between patients with B = 0 (n = 56) and qB = 0 (n = 45) is n = 11, with qB identifying more patients with non-zero ballooning grade compared to central pathologist. Using qB scores (qB = 0), it would have been possible to identify 11 patients that could have been included in the trial, if they had undergone a quantitative assessment of their ballooning grade using SHG/TPE. In other words, screen failure rate with B = 0 was 40.6% (56/138) whereas screen failure rate using qB = 0 was reduced to 32.6% (45/138) of patients. Exclusion of patients by central pathologist fibrosis stage and qF was almost identical (n = 64 and n = 65 respectively). **Conclusion:** Incorporating SHG/TPE with AI analyses for assessment along with central pathologist evaluations may be an effective means of improving screening failure rates in NASH trials, especially in assessing ballooning. This study suggests screen failure rates are high in pathologists assessments as they may underestimate grade of ballooning when compared to SHG/TPE imaging. Further research is needed to study clinical significance of such changes and identify appropriate parameters for assessing patient selection for clinical trials.

Figure 1. Comparison of Central pathologist and SHG/TPEF based fibrosis and ballooning scores in screen failure patients.

2095-A | RELEVANCE OF BODY COMPOSITION ASSESSMENT METHODS IN LEAN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE

Claudineia Almeida Almeida de Souza, Federal University of Bahia, Helma P Cotrim, Ufba; Federal University of Bahia- Brazil; Medicine School and Raquel Rocha; Luiza Vieira Valóis; Naiade Silveira; Urânia Oliveira; Rafael Peixoto; Carla Daltro

Background: The characteristics of NAFLD in lean patients (LEAN-P) have not been fully established. These patients have a predominance of visceral obesity or lipodystrophy, and the body mass index (BMI) may not be sufficiently to define LEAN-P with NAFLD. AIM: to assess the body composition of LEAN-P with NAFLD using anthropometric methods other than BMI. **Methods:** A cross-sectional study involved NAFLD patients, **e** 18 years old. NAFLD criteria: presence of steatosis by ultrasound; consumption **d** 140g of ethanol/week; absence of other liver diseases. The presence of liver fibrosis was assessed by FIB4 score. To evaluate body composition were used waist circumference (WC), neck circumference (NC), and tetrapolar bioimpedance (TBP). The sample was divided into two groups: LEAN-P (BMI < 24.9 kg/m²) and non-lean (BMI > 25 kg/m²). **Results:** Out of the 71 patients with NAFLD, 8.5% were classified as LEAN-P. Among these 83.3% had mild/moderate steatosis, 16.7% diabetes, 33.3% arterial hypertension. Fibrosis wasn't observed by FIB4 score. These characteristics were similar in non-lean. Excess fat mass was less common in lean patients (16.7% vs 90.5% $p < 0.001$), indicating a more balanced body composition in LEAN-P. Depletion of lean mass was less frequent in the LEAN-P compared to non-lean (16.7% vs 73.4%, $p = 0.010$). **Conclusion:** LEAN-P with NAFLD presented a more balanced body composition compared to non-lean. They also demonstrated a more favorable distribution of visceral obesity and low-fat mass. These results emphasize the relevance of considering body composition beyond BMI alone in the assessment of NAFLD in LEAN-P, leading to improve evaluation and clinic management of these cases.

2096-A | RELIABILITY OF LIVER ULTRASONOGRAPHY IN THE ASSESSMENT OF STEATOSIS IN THE CONTEXT OF PREGNANCY

Theresa Worthington[1], Tatyana Kushner[2], Pamela Argiriadi[1], Deborah Feldman[1], Sonam Rosberger[1], Marcia Lange[1], Keith Sigel[1], Rhoda Sperling[1] and Scott L. Friedman[1], (1)Icahn School of Medicine at Mount Sinai, (2)Icahn School of Medicine at Mount Sinai, New York, NY

Background: Non-alcoholic fatty liver disease (NAFLD) currently affects around 15% of women of child-bearing age in the United States, and this number is expected to increase in the coming decade. Liver sonography is the initial diagnostic test for NAFLD with prior data showing intra-observer kappa of 0.4-0.6 and inter-observer kappa of 0.2. Given the rise of NAFLD in the pregnancy population and increased use of ultrasound for diagnosis, we sought to evaluate reliability of ultrasound assessment in pregnant individual's. **Methods:** As part of the prospective Fatty Liver in Pregnancy (FLIP) study, pregnant adults with a BMI **e** 25 and no significant history of alcohol use were eligible for the

study. Consented individual's underwent a liver ultrasound at the time of their routine obstetrics anatomy scan at 18-26 weeks gestation. Three obstetric sonography technicians were trained to perform liver sonography by a diagnostic radiologist with expertise in abdominal imaging. One of three ultrasound units with a 2- to 5 MHz convex transducer was used to capture images of the maternal liver. To assess inter-rater reliability, images were de-identified and sent to two additional radiologists blindly for review, who were asked to grade the images as "no steatosis", "grade 1, 2, or 3 steatosis", or "non-diagnostic due to poor image quality." To assess intra-rater reliability, the images were later sent to the radiologists for a second blind review. A survey was conducted to delineate reasons for sub-optimal agreeability. **Results:** Liver ultrasound images were reviewed from 100 patients recruited to participate in the FLIP study from October 2022 to May 2023. The median age of the cohort was 29 (IQR: 24-32) with a median BMI of 30.5 (IQR: 24.9-34.6). A majority (53%) of the cohort identified as being Hispanic or Latino, and 36% identified as Black or African American. Based on our primary reviewer, 60% had no steatosis, 15% had stage 1, 5% had stage 2, 0% had stage 3, and 20% were non-diagnostic. Agreeability between our primary reviewer and reviewer B was 47% ($\kappa = 0.35$). Agreeability between our primary reviewer and reviewer C was 39% ($\kappa = 0.19$). Amongst all 3 reviewers, agreeability was 23% ($\kappa = 0.15$). Intra-rater agreement was 57% for our primary reviewer, 70% for reviewer B, and 52% for reviewer C. **Conclusion:** Inter-rater reliability is fair in the context of pregnancy, which is in line with prior data in non-pregnant settings. To improve inter- and intra-rater reliability, obstetric ultrasound technicians should receive frequent reinforcement training to ensure adequate image quality. Implementation of a scoring system that accounts for image quality issues in the context of pregnancy in addition to disease state would also be beneficial.

Overall Agreement: Primary Reviewer and Reviewer B	Overall Agreement: Primary Reviewer and Reviewer C	Overall Agreement Among Primary Reviewer, Reviewer B, Reviewer C
47% κ =.35	39% κ = .19	23% κ = .15
Intra-rater Agreement: Primary Reviewer	**Intra-rater Agreement: Reviewer B**	**Intra-rater Agreement: Reviewer C**

2097-A | REPEATABILITY OF VELACUR MEASUREMENTS USING SAME-DAY DIFFERENT-SCANNERS MEASUREMENTS

Stephen A Harrison[1], Caitlin Marie Schneider[2], Kathryn Jean Lucas[3], Tarek Hassanein[4] and Madhavi Rudraraju[1], (1)Pinnacle Clinical Research Center, San Antonio, TX, (2)Sonic Incytes Medical Corp, (3) Diabetes & Endocrinology Consultants, PC, (4) Southern California Research Center

Background: As non-invasive biomarkers become more integrated into the standard of care for diagnosis and monitoring of patients with chronic liver disease, it is important to understand their reproducibility. Here we report the results of the 'same-day, different-scanner' measurements for Velacur elasticity and attenuation in volunteers and patients. **Methods:** Several individual's were trained to perform Velacur exams on the same volunteer on the same day. Velacur exams were collected at 4 different sites across the United States. Exams were performed on both healthy volunteers and patients. Each exam with a particular scanner was made up of 3 to 5 measurements of elasticity and attenuation. The median value of these measurements was used as the result of the exam for analysis. The primary objective was to estimate the Standard Error of Measurement for both elasticity and attenuation, on the same subject, on the same day, with multiple scanners. The Standard Error of Measurement is an absolute measure of reliability of a test score and represents the error attributable to the scanner. **Results:** A total of 14 scanners at four sites in the US participated in this study. 24 volunteers were scanned, with an average of 2.9 scans per volunteer, ranging from 2 to 7. Of these volunteers, nine were patients with various degrees of non-alcoholic fatty liver disease and 15 were volunteers with no history of liver disease. The elasticity scores for all subjects ranged from 3.8 to 16.5 kPa with a mean of 6.1 kPa, and the attenuation measurements ranged from 115 to 376 dB/m, with a mean of 254 dB/m. The Standard Error of Measurement for Elasticity was 0.71 kPa and the Standard Error of Measurement for attenuation was 28 dB/m. **Conclusion:** The Standard Error of Measurement between users is a representation of the difference one might expect if different

scanners at the same clinic were to measure the same patient. This represents a 12.5% difference in elasticity measurements and a 11.7% difference in attenuation measurements. This is consistent with reported values from other modalities such as MRE. As all the scanners in the study were new to Velacur, these results are expected to improve as scanners gain experience. These results may help inform future use and understanding of Velacur-based assessments.

2098-A | RISK STRATIFICATION MODEL WITH A HIGH SENSITIVITY IN IDENTIFYING "AT-RISK" FIBROTIC NASH IN A SCREENING STUDY

Dong Tang[1], Hanyu LI[1,2], JUN Yang[3] and Kehui Nie[4], (1)Hangzhou Normal University Affiliated Hospital, (2) Hangzhou Normal University, (3)Taimei Medical Technology Co.,Ltd, (4)Taimei Technology

Background: Liver stiffness measurement (LSM) ≥ 8kPa detected on FibroScan is highly indicative of at-risk fibrosis. However, many community or non-tertiary medical centers do not have LSM examinations due to lack of the devices. we developed a non-invasively accessible method using serological biomarkers to identify or screen those at-risk fibrotic NASH subjects so that they may be further stratified with FibroScan at tertiary medical centers after initial screening. **Methods:** Patients and laboratory data from 2015 to 2021 were retrospectively reviewed, and divided into "low-risk" and "at-risk" groups using LSM ≥ 8kPa as a cut-off for fibrotic NASH. Major serological biomarkers were collected along with subsequent FibroScan reports, and patients confirmed later with NAS < 4 were excluded. The variables with $p < 0.2$ in univariate analysis were then selected for risk stratification modeling using logistic regression. A risk score was developed in the training data set (70% of all data) and validated in the test set (30% of all data). The area under the curve (AUC), sensitivity and specificity were assessed as model performance indicators and then compared to other serological scores (FIB-4 and Aspartate aminotransferase-to-Platelet Ratio Index). **Results:** A total of 73 subjects were included (low-risk: n = 30 vs at-risk: n = 43). The mean age was 39.2 ± 14.5 years and 45.1 ± 14.3 years in the low-risk and at-risk group, respectively. Among them 25% were female, 23% had type 2 diabetes, and 26% had hypertension. Univariate analysis showed that sex ($p = 0.025$), platelets (PLT) ($p = 0.085$), aspartate aminotransferase(AST) ($p = 0.045$), AST/ALT ratio ($p = 0.038$), and creatinine ($p = 0.014$) were associated with at-risk NASH. The risk stratification model integrated these selected variables and used stepwise regression with akaike information criterion (AIC), and then formulated in logistic scores. AST was an independent predictor of at-risk fibrotic NASH ($p < 0.05$), while AST/ALT ratio and creatinine showed a marginal significance ($p = 0.06$ and 0.054, respectively). The AUC, sensitivity, and specificity were 0.71, 0.92 and 0.5 in the test data, respectively. Delong's test showed no significant difference between our model and FIB-4 (AUC = 0.78), and APRI score (AUC = 0.67) in the test set (Figure 1). **Conclusion:** Our risk stratification model integrated easily accessible clinical information and laboratory indicators, and was sensitive in detecting at-risk fibrotic NASH when LSM is unavailable in a screening setting.

2099-A | SCREENING FOR HEPATIC FIBROSIS IN PRIMARY CARE BY FIB-4 SCORE, AUTOMATICALLY CALCULATED, FOLLOWED IN SECOND LINE BY THE ELF (ENHANCED LIVER FIBROSIS) TEST: WHAT ARE THE BEST FIB-4 THRESHOLDS

Denis Ouzan, Rhecca; Institut Arnault Tzanck, Guillaume Penaranda, Hopital Europeen, Malik Jlaiel, Bioesterel BIO Group and Jeremie Corneille, Bioesterel Biogroup

Background: Screening for liver fibrosis in the general population is a public health issue. We have shown in a previous study that FIB-4, can detect liver fibrosis in general practice and identify a possible cause of liver disease (1). The optimal FIB-4 threshold that allows this screening remains to be specified. FIB-4 thresholds usually used are: low risk if < 1.30, intermediate risk between 1.3 and 2.67, and high risk if ≥ 2.67. Only one study has proposed an age-dependent FIB-4 threshold: FIB-4 ≥ 1.3 for subjects younger than 65 years and ≥ 2 for those older than 65 years (2). The objective of our work was to explore different FIB-4 thresholds and in particular the threshold of 2 for all patients (which is much simpler and independent of age), by performing a second-line ELF (Enhanced Liver Fibrosis) score, after screening for liver fibrosis by FIB-4 in general practice **Methods:** The FIB-4 score was performed prospectively from March to September 2022 in all consecutive patients seen by 15 general practitioners , outside the emergency. When the FIB-4 was ≥ 1.3, it was defined

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

as positive, and a confirmatory ELF test was systematically performed. The positive FIB-4 test was confirmed when the second line ELF test was **e** 9.8 . **Results:** Among the 3427 patients seen in general practice, 869 (25%) had a positive FIB4 score,784 (22.5%) at intermediate (FIB-4:1.3-2.67) and 85 (2.5 %) at high risk of fibrosis (FIB-4 > 2.67). Among the 869 FIB-4 positive patients, 509 (59%) were confirmed by the ELF test. 35% of them were older than 65 years. Confirmation was significantly more frequent in subjects over 65 years of age compared to those under 65 years of age: 84 % vs 16 %, p < 0.0001 and in those with a FIB-4 in the high-risk zone, compared to the intermediate zone: 80% versus 56%, p < 0.0001. For an age-dependent FIB-4 threshold (> 1.3 (< 65 yrs.) /> 2 (> 65 yrs.) which concerned 55% of the FIB-4 positive subjects (n = 481), 56% were confirmed by the ELF test (n = 271). For the FIB-4 threshold of 2, regardless of age which concerned 33% of the FIB-4 positive subjects (n = 284), 74% of the FIB-4 **e** 2 subjects were confirmed by ELF testing versus 51% of those with a FIB-4 score < 2 (RR 1.88 (95% CI 1.52-2.32) p < 0 .001). The percentage of FIB-4 subjects in the intermediate fibrosis risk decreases from 22.5 % for a FIB-4 between 1.3 and 2.67, to 12 % for a FIB-4 between 1.3/2 and 2.67, and to 6 % for a FIB-4 between 2 and 2.67. **Conclusion:** ELF testing performed in the second line had significantly more confirmed advanced fibrosis in subjects with FIB-4 **e** 2. A threshold of 2 retains a high percentage of confirmation while reducing the size of the intermediate risk zone for fibrosis and may allow more effective screening for liver fibrosis in primary care. f 2100-A | SEQUENTIAL USE OF FIB-4 AND NIS2+" FOR AN ACCURATE DETECTION OF NON-CIRRHOTIC AT-RISK NASH PATIENTS FOR ENROLLMENT IN NASH CLINICAL TRIALS

Vlad Ratziu[1], Stephen A Harrison[2], Yacine Hajji[3], Jérémy Magnanensi[3], Stephanie Petit[3], Zouher Majd[3], Morgane Dehornois[3], Christian Rosenquist[4], Dean W Hum[3], Bart Staels[5], Quentin M. Anstee[6] and Arun Sanyal[7], (1)Sorbonne Université, Institute for Cardiometabolism and Nutrition, Hôpital Pitié-Salpêtrière, Paris, France, (2)Summit Clinical Research; Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom, San Antonio, TX, (3)Genfit S.a., Loos, France, (4)Novo Nordisk, Soborg, Denmark, (5)Université De Lille, Inserm, CHU Lille, Institut Pasteur De Lille, Lille, France, (6)Newcastle Nihr Biomedical Research Centre, Newcastle upon Tyne Hospitals NHS Foundation Trust, Newcastle upon Tyne, UK, (7)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: In clinical trials recruiting non-cirrhotic patients with at-risk NASH (NAS **e** 4; F **e** 2), many cirrhotic (F4) or non at-risk NASH patients are excluded after undergoing liver biopsy (LB), an invasive and costly procedure. While FIB-4 is a widely used test for fibrosis evaluation, NIS2+™, an optimization of the blood-based NIS4® technology, is designed to robustly identify at-risk NASH and highlighted efficient screening performances for patient referral to LB. We assessed the performance of a sequential use of FIB-4 (for ruling-out F4 patients) followed by NIS2+™ (for ruling-in at-risk NASH) to optimize the screening of NASH trials. **Methods:** Among > 5000 patients that were screened in the RESOLVE-IT Phase 3 trial (NCT02704403), those with non-historical LB, NIS2+™ and FIB-4 available, and **d** 90 days between LB and serum sample collection were selected, resulting in a cohort of 1929 patients. This cohort was used to compare the screening performance of the RESOLVE-IT trial vs a retrospectively simulated strategy involving FIB-4 followed by NIS2+™. The number of patients needed to screen (NNS), the LB failure rate (LBFR), the screening cost, and the number of F4 referred to LB were estimated for FIB-4 cutoff values of 2.0-3.0, and 0-0.8 for NIS2+™. Performances were estimated for the inclusion of 1000 patients. **Results:** Using the RESOLVE-IT screening process, the LBFR was 60%, with 3220 screenings to include 1000 patients, of which 128 F4 referred to LB and a cost estimated to $15M. An optimal pair of cutoff values (FIB-4 < 2.48, NIS2+™ **e** 0.53) was derived, to minimize the number of F4 patients wrongly referred to LB while achieving a

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

LBFR < 40%, a NNS < 4830 (< 50% increase) and a cost decrease. Using these cutoffs, the sequential use of FIB-4 and NIS2+™ would have reduced the LBFR to 39%, the number of F4 patients referred to LB to 89 (-30%) and the overall cost by $1.1M (-7.3%) with a manageable NNS of 4792. Using NIS2+™ high cutoff (**e** 0.68) following FIB-4 with a cutoff of 2.48 would have further reduced the LBFR (< 31%) and the number of F4 patients referred to LB (81; -37%) but with an increased NNS (6252) and overall cost (+$0.2M; +1%). **Conclusion:** In clinical trials screening for non-cirrhotic at-risk NASH, ruling-out F4 with FIB-4 followed by ruling-in at-risk NASH patients with NIS2+™ has the potential to significantly improve the recruitment process by reducing the LBFR, the number of F4 patients referred to LB and screening cost with a manageable NNS.

Background: The Agile scores – based on liver stiffness measurement (LSM) by VCTE, platelets, transaminases, diabetes, sex and age – were developed to refine the diagnosis of advanced liver fibrosis in NAFLD. Dynamic change of the scores over time and the corresponding clinical significance are currently unclear. We aimed to determine the prognostic implications of one-off and repeated Agile score assessments. **Methods:** This retrospective cohort study included data of patients with NAFLD who underwent VCTE examination at 16 centers in the Americas, Europe and Asia. The Agile scores were compared with LSM alone, FAST score and 6 other simple fibrosis scores. The primary outcome was liver-related events (LREs), defined as hepatocellular carcinoma or hepatic decompensation (ascites, variceal hemorrhage, hepatic encephalopathy or hepatorenal syndrome). **Results:** 16,603 patients with VCTE examination were included (age 55 ± 14, 57.8% male, median LSM 6.0 [IQR 4.7-8.5] kPa). At a median follow-up of 51.7 months, 316 (1.9%) patients developed LREs. Both Agile 3+ and Agile 4 scores classified fewer patients in the gray zone than LSM and most fibrosis scores and achieved the highest discriminatory power in predicting LREs (area under receiver-operating characteristic curve 0.87-0.90 at 3 and 5 years, compared with 0.78 for FAST and 0.86 for LSM). Among patients with Agile 3+ score < 0.451, 0.451-0.678, and **e** 0.679, the incidence of LRE was 0.7, 3.3, and 24.9 per 1,000 person-years, respectively ($P < 0.001$). 10,921 patients had repeated VCTE at a median interval of 15 months and were included in the serial analysis. 81.9% and 92.1% of patients had stable Agile 3+ and Agile 4 scores (same risk categories at both assessments) (Figure). The incidence of LRE was 0.6 and 30.1 per 1,000 person-years in patients with persistently low and high Agile 3+ scores, respectively, while patients with changing risk categories between two visits had moderate risk. A similar trend was observed for the Agile 4 score, though it missed more LREs in the low-risk group. **Conclusion:** The Agile scores classify fewer patients into the gray zone than other noninvasive tests and have high stability on repeated testing. This translates into superior performance in predicting LREs.

2102-A | SERUM CK18f IS AN INDICATOR OF LIVER INFLAMMATION, BALLOONING, AND PREDICTS INDICATION AND RESPONSE TO TREATMENT IN PATIENTS WITH NONALCOHOLIC STEATOTIC LIVER DISEASE

Miwa Kawanaka[1], Hirokazu Takahashi[2,3], Michihiro Iwaki[4], Ken Nishinio[5], Wenli Zhao[2], Masato Yoneda[4], Kenichi Tanaka[2], Hideki Fujii[6], Yoshihiro Kamada[7], Yoshio Sumida[8], Hirofumi Kawamoto[5], Atsushi Nakajima[4] and JSG-NAFLD, (1)Kawasaki Medical Center, Kawasaki Medical School, Okayama, Japan, (2) Saga University, (3)Division of Metabolism and Endocrinology, Faculty of Medicine, (4)Yokohama City University Graduate School of Medicine, (5)Kawasaki Medical Center, Kawasaki Medical School, (6)Osaka Metropolitan University, (7)Osaka University Graduate School of Medicine, (8)Aichi Medical University

Background: Although various noninvasive diagnostic methods to predict liver fibrosis in nonalcoholic steatotic liver disease (NASLD) have been developed, no such markers have available to predict inflammation, ballooning, and other nonalcoholic steatohepatitis (NASH) changes. Furthermore, there are few reports comparing changes in histology and changes in CK18f after repeated liver biopsies. The aim of this study was to investigate whether the apoptosis marker, serum cytokeratin 18 fragment (CK18f), can help predict the response to treatment in NASLD. In addition, serum CK18f and liver fibrosis markers were evaluated as biomarkers for predicting the NAFLD activity score (NAS) **e** 4 and stage **e** 2, crucial criteria for NASH clinical trials by the Food and Drug Administration (FDA). **Methods:** A total of 565 patients with NASLD (mean age 58 (18–85) years, male/female: 269/296; stages: 0/1/2/3/4 :49/141/142/198/35) and undergoing liver biopsy were enrolled. We investigated the relationship between serum CK18f and liver histology, ALT, AST, Γ-GTP, FIB-4 Index, and type IV collagen 7S. The liver fibrosis markers and CK18f were used to diagnose

cases with stage ≥ 2 and NAS ≥ 4. Additionally, repeated liver biopsies of 110 patients with NASLD (mean observation period of 4 (0.5–21) years) were compared based on serum CK18f levels and hepatic histological changes (stage, grade, steatosis, and NAS). **Results:** The levels of serum CK18f were associated with serum ALT and AST, as well as liver inflammation, ballooning, and NAS. Of the 419 patients with FIB-4 index < 2.6, 206 (67.3%) demonstrated CK18f ≥ 260 and possible NAS ≥ 4, therefore, recommended for treatment. Conversely, 67% of cases with FIB-4 index < 2.6 and CK18f < 260 and 83% of cases with type IV collagen 7S < 5 and CK18f < 260 were diagnosed with stage < 2 and NAS < 4, excluding FDA criteria was possible.In the 110 repeated liver biopsy cases, inflammation, ballooning, and NASH changes were strongly correlated with CK18f changes. The Δ value of CK18f significantly decreased from 3.3 ± 2.8 to 1.4 ± 1.0 ($P < 0.0001$) in patients with 'no worsening fibrosis' and 'improved NAS', while significantly decreased from 3.1 ± 3.3 to 2.0 ± 1.6 ($P < 0.05$) in patients with 'improving fibrosis' and 'no worsening NAS'. **Conclusion:** CK18f levels are positively correlated with liver inflammation, ballooning, and NAS, reflecting changes in these factors and can predict NASLD progression and improvement. Moreover, CK18f is a useful non-invasive diagnostic marker for FDA criteria recommending treatment and can effectively replace liver biopsy.

2103-A | SERUM GALECTIN-3 IN PORTAL HYPERTENSION DUE TO NONALCOHOLIC STEATOHEPATITIS (NASH)

Pol Boudes, Ezra Lowe, Michael Inkmann and Steven Schoenfeld, Galectin Therapeutics

Background: Galectin-3 is a major driver of tissue inflammation and fibrosis. It is mainly produced by activated liver macrophages[1] and secreted in the extracellular matrix where it polymerizes to interact with macromolecules and cells to form a lattice structure called the galectin-3 fibrosome. Most galectin-3 is either intra-cellular or in the extra-cellular matrix and it is of interest to understand if serum measurement reflects its intra-tissular content. We use data from two clinical trials, one in non-cirrhotic NASH patients with liver fibrosis and one in cirrhotic NASH patients with portal hypertension (PH) to evaluate serum galectin-3 at different stages of the disease. **Methods:** The first study enrolled 31 NASH patients with Brunt F3 fibrosis (NCT01899859), the second study enrolled 162 NASH patients with Brunt F4 cirrhosis, with portal hypertension hemodynamically determined by a hepatic venous pressure gradient (HVPG) > 6 mm Hg but no decompensation (NCT02462967). Serum galectin-3 was measured at baseline with a commercial assay. Descriptive statistics, mean, standard deviation (SD), and ranges were provided and compared between F3 and F4 populations. For clinical relevance, serum galectin-3 was correlated with HVPG. **Results:** Serum galectin-3 appears normally distributed in both population and means (SD) were similar between F3 and F4 populations (Table), indicating that levels do not increase while disease progresses. In patients with PH, serum galectin-3 was not correlated with the measurement of HVPG ($R^2 = 0.0105$). **Conclusion:** Serum galectin-3 might not be a useful biomarker of disease activity in NASH, particularly in compensated cirrhosis with portal hypertension. As in the oncology setting, intra-tissular galectin-3 might be a more relevant biomarker of disease activity and a predictor of response to galectin-3 inhibitor treatment[2].

2104-A | SKIN AUTOFLUORESCENCE IS ASSOCIATED WITH FIB-4, FORNS AND FATTY LIVER INDEX – THE MAASTRICHT STUDY

Leen Heyens[1,2,3], Hanna Kenjic[2], Pieter Dagnelie[2], Casper Schalkwijk[2], Coen Stehouwer[2], Steven Meex[2], Jeroen Kooman[2], Otto Bekers[2], Marleen Van Greevenbroek[2], Hans Savelberg[2], Bastiaan De Galan[2], Annemarie Koster[2], Martinus Van Dongen[2], Simone Eussen[2] and Ger H. Koek[2], (1)Hasselt University, (2) Maastricht University, (3)Ziekenhuis Oost-Limburg

Background: Non-Alcoholic Fatty Liver Disease (NAFLD) is the most frequent cause of chronic liver disease in the Western world. In people with type 2 diabetes mellitus (T2DM), NAFLD is reaching epidemic proportions. Among T2DM patients and in normoglycemic individual's with NAFLD, higher levels of advanced glycation endproducts (AGEs) were seen. AGEs can be measured via skin autofluorescence (SAF). As SAF can be easily and non-invasively measured with an AGE reader, it could be a new way to assess the risk for steatosis and fibrosis in T2DM patients. We aimed to examine the association between SAF and liver steatosis and fibrosis, using non-invasive tests in the well-characterized cohort, The Maastricht Study. **Methods:** Data from The Maastricht Study, a prospectively designed, population-based observational cohort study, were used. Participants were excluded when they had alcohol overconsumption and missing data. Multivariable linear regression analysis was used to investigate the association of SAF with the standardized fibrosis-4 index (FIB-4), the Forns index (FI), and the fatty liver index (FLI). Regression models were adjusted for the following key potential confounders; age, sex, and educational status. Other potential confounders additionally adjusted for were: blood pressure, total-HDL cholesterol ratio, smoking status, history of cardiovascular disease, waist circumference, treatment for hypertension, lipid disorders, and glucose lowering medication. For FIB4, age was left out of the model, for FI, this was age and total-HDL cholesterol ratio, and for the FLI this was waist circumference, as these variables are part of the non-invasive score calculations. An interaction analysis was performed to assess the influence of sex. AGEs were assessed with the AGE Reader (DiagnOptics Technologies BV, Groningen, the Netherlands), which uses the characteristic fluorescent properties of certain AGEs to quantify their accumulation in the skin as SAF. **Results:** Of the 3451 participants, 1955 (56.6%) were used for analysis, of whom 598 (30.6%) had T2DM, 264 (13.5%) prediabetes, and 1069 (54.7%) a normal glucose metabolism (NGM). Median age and BMI were 63 (±12) yr and 29.6 (±6.6) kg/m² for T2DM, 62 (±11) yr and 27.3 (±5.4) kg/m² for prediabetes and 58 (±13) yr and 25.3 (±4.4) kg/m² for NGM, respectively. After full adjustment, it was seen that SAF was associated with a higher FLI (Stβ 0.083 [0.036;0.129]), a higher FI (Stβ, 0.106[0.069;0.143]), and FIB-4 (Stβ, 0.087 [0.037;0.137]). Male gender significantly influenced the SAF and FIB4 association (Stβ, 0.125 [0.061;0.189]). **Conclusion:** This observational cohort study showed a positive link between the non-invasive scores FLI, FIB-4 and FI, and SAF. Suggesting that SAF could be a potential non-invasive biomarker to detect liver steatosis and fibrosis among people with T2DM in a non-invasive way. Further research is warranted to confirm these results.

University of Mainz, Mainz, Germany, (4)Nordic Bioscience a/S, Denmark, (5)Nordic Bioscience a/S, (6) Histoindex Pte Ltd, Singapore, (7)Histoindex Pte Ltd, (8)Nordic Bioscience A/S, (9)Metabolic Liver Research Program, Department of Medicine, University Hospital Mainz, Mainz, Germany

Background: In NAFLD hepatic fibrosis develops slowly over time. The NASH CRN scoring system uses a 5-tier semi-crude system to stage hepatic fibrosis. Little is known about the correlation of non-invasive tests in relation to the spatial distribution of collagen in the liver. **Methods:** In this retrospective analysis liver biopsies of 132 patients with NAFLD were explored. Second harmonic imaging was used to quantitate hepatic fibrosis by qFibrosis. qFibrosis is a composite index combining collagen strings (#StrNumber), length of collagen strings (StrLength) in the central vein (CV), portal tract (PT) and zone 2. Pro-C3 (ELISA), a type III collagen formation marker of fibrosis was measured and correlated to the spatial distribution of collagen. **Results:** The mean age of the cohort was 54 years [43-60], 52.7% male and a mean BMI of 32.2 [28.7-37.0]. Comorbidities included type 2 diabetes (41.2%), arterial hypertension (72.5%), hypertriglyceridemia (32.8%) and obesity (BMI > 30; 54.2%). Standard laboratory included ALT (U/l) 73.0 [50.0-115.7] and AST 50 [38-67]. The histological fibrosis stages were distributed, according to Kleiner, as follows F0 (3.1%), F1a-c (27.5%), F2 (35.1%), F3 (23.7%) and F4 (10.7%). The median (Q1, Q3) qFibrosis value was 1.70 (1.39, 2.38) with a range from 0.48 – 7.77. The median (Q1, Q2) PRO-C3 (ng/mL) was 11.5 (9.4-16.2) with a range from 6.1 – 57.7. The Spearman correlation between PRO-C3 and qFibrosis was high ($\rho = 0.56$, 95% CI [0.43, 0.67]). This was not seen for AST ($\rho = 0.27$, 95 % CI [0.10, 0.43]), nor for ALT ($\rho = -0.080$, 95% CI [-0.25, 0.10]). When exploring the absolute amount of collagen across all regions (% SHG) the correlation with PRO-C3 was $\rho = 0.33$, 95% CI [0.16, 0.48]. The spatial distribution of collagen correlated with PRO-C3 only in the portal tract (StrAreaPT $\rho = 0.3$, 95% CI [0.13, 0.46]; StrLengthPT $\rho = 0.35$, 95% CI [0.18, 0.50]), but not zone 2 (StrAreaZ2 $\rho = -0.02$, 95% CI [-0.20, 0.16]; StrLengthZ2 $\rho = -0.15$, 95% CI [-0.32, 0.03]) or the central vein area (StrAreaCV $\rho = -0.07$, 95% CI [-0.25, 0.11]; StrLengthCV $\rho = -0.11$, 95% CI [-0.28, 0.07]). This correlation was not seen for either AST or ALT (all $\rho < 0.2$). **Conclusion:** The current analysis highlights that the correlation of non-invasive collagen biomarkers with hepatic collagen is dependent on the spatial distribution of collagen. While the NASH-CRN system stresses changes of collagen in the peri-portal region, the current finding highlight that in the design of blood-based biomarkers such as ProC3 spatial fibrosis distribution is relevant.

(1)Division of Hepatology, Department of Medicine II, Leipzig University Medical Center, Leipzig, Germany, (2)Clinic for Internal Medicine, Community Hospital Delitzsch, Delitzsch, Germany, (3)University Hospital of Leipzig

Background: Non-alcoholic fatty liver disease (NAFLD) may progress to liver cirrhosis and hepatocellular carcinoma (HCC). Biomarkers to identify patients at risk for progression who potentially benefit from a closer surveillance are lacking. Serum levels of soluble triggering receptor expressed on myeloid cells 2 (TREM2), a decoy receptor with pro-inflammatory effects on monocyte activation in the liver, was recently proposed as biomarker in NAFLD to identify patients with florid hepatic inflammation and, therefore, risk of disease progression (J Hepatol 2022;77:1373 and Hepatology 2023;77:558). We report TREM2 serum levels in patients with NAFLD, NAFLD cirrhosis and healthy controls. **Methods:** Soluble TREM2 serum levels were determined by a soluble TREM2 ELISA (Abcam). Laboratory parameters, patient characteristics, and vibration controlled transient elastography results were recorded. NAFLD patients were genotyped for rs738409 in PNPLA3, rs58542926 in TM6SF2, rs641738C > T in MBOAT7, rs1260326 in GCKR, and rs72613567 in HSD17B13 to calculate the polygenic risk score for HCC risk stratification in NAFLD (J Hepatol 2021;74:775). **Results:** Soluble TREM2 serum levels were higher in 146 NAFLD patients (age 55 ± 12 y, 54% female, 51% with cirrhosis) compared to 50 healthy controls (age 54 ± 2 y, 50% female) (48.8 ± 26.6 ng/mL vs. 27.2 ± 10.7 ng/mL, $p = 5.35x10^{-9}$). Patients with NAFLD cirrhosis had higher soluble TREM2 serum levels than non-cirrhotic NAFLD patients (52.4 ± 25.3 ng/mL vs. 44.9 ± 27.5 mg/mL, $p = 0.032$). Soluble TREM2 serum levels correlated with serum aspartate transaminase ($p = 4.79x10^{-5}$), alanine transaminase ($p = 0.001$), total bilirubin ($p = 0.008$), body mass index ($p = 0.019$), FibroScan-AST (FAST) score ($p = 3.23x10^{-8}$), and controlled attenuation parameter ($p = 0.002$) as non-invasive marker for liver steatosis, but not with liver stiffness measurements. High TREM2 serum levels were associated with a high polygenic risk score for HCC ($p = 0.001$). **Conclusion:** NAFLD patients with high soluble TREM2 serum levels might be at increased risk of disease progression, and potentially benefit from a closer surveillance. 2107-A | THE ALCOHOLIC LIVER DISEASE/NONALCOHOLIC FATTY LIVER DISEASE INDEX (ANI) IN CLASSIFICATION OF PATIENTS WITH METABOLIC DYSFUNCTION ASSOCIATED FATTY LIVER DISEASE (MAFLD)

Akash Roy[1], Usha Goenka[1], Surabhi Jajodia[1], Awanish Tewari[1], Nipun Verma[2] and Mahesh Goenka[1], (1)Apollo Hospitals, Kolkata, (2)Post Graduate Institute of Medical Education and Research, Chandigarh, India

Background: Metabolic dysfunction associated fatty liver disease (MAFLD) does not preclude alcohol consumption (AC) as a prerequisite for diagnosis. AC to a variable extent is not uncommon in patients with MAFLD. The Alcoholic Liver Disease (ALD)/Non-alcoholic Fatty Liver Disease Index (ANI) has been proposed as a differentiating tool, with an ANI score < 0 incrementally favouring non-alcoholic fatty liver disease (NAFLD). **Methods:** Consecutive patients with evidence of fatty liver (defined by MRI-PDFF > 6.5%) who met the definition of MAFLD were included. Patients with alcoholic hepatitis, established cirrhosis, hepatocellular carcinoma, endstage renal disease, advanced heart failure, contraindications to undergo MR imaging and pregnancy were excluded. AC was classified as moderate or significant according to standard definitions.ANI was calculated with an available online calculator. **Results:** 159 patients satisfied the inclusion criteria (22.1% females, mean age 46.59 ± 11.5, mean body mass index 28.1 ± 3.81) with 11.9%, 79.8%, 42,1% being overweight, obese and diabetic respectively. Alcohol consumption was reported in 66 (41.5%) of the patients [32 (20.1%) moderate, 34(21.3%) significant]. ANI scores were significantly different between no alcohol -3.5(-4.80 to -2.72)], any alcohol -1.27(-1.66 to -0.35), moderate alcohol -2.09(-2.68 to-1.15) and significant alcohol -0.02 (-1.3 to 1.5) consumers ($p < 0.05$ for all). The area under curve for ANI for any alcohol use, moderate alcohol use and significant alcohol use were 0.77, 95%CI, 0.705-0.84, cut-off -2.5), 0.61 (95%CI 0.53-0.68, cut-off -3.5) 0.82(95%CI 0.75-0.87, cut-off -1.56). ANI misclassified 8(5.1%) lifetime abstainers as probable ALD and 17 (10.6%) significant alcohol consumers as probable NAFLD. Gamma-glutamyl transpeptidase showed a weak co-relation with ANI [$r = 0.28$(95% CI 0.13-0.42, $p = 0.03$). **Conclusion:** ANI scores differ across the spectrum of AC in MAFLD and identified significant AC

in MAFLD. Different cut-offs instead of dichotomous splitting may better aid sub-stratification of AC in MAFLD.

2108-A | THE APPLICATION OF LIPIDOMIC ANALYSIS ON NONALCOHOLIC FATTY LIVER DISEASE IN MORBIDLY OBESE PATIENTS

Yin-Ru Hsieh[1], Hua-Chien Wu[2], Weu Wang[3], Ching-Wen Chang[4], I-Wei Chang[5], Chi-Long Chen[5], Chun-Chao Chang[6], Wei-Yu Kao[6] and Shih-Yi Huang[1], (1) School of Nutrition and Health Sciences, Taipei Medical University, Taipei, Taiwan, (2)Department of Internal Medicine, School of Medicine, College of Medicine, Taipei Medical University, Taipei, Taiwan, (3)Division of Digestive Surgery, Department of Surgery, Taipei Medical University Hospital, Taipei, Taiwan, (4) Graduate Institute of Metabolism and Obesity Sciences, Taipei Medical University, Taipei, Taiwan, (5) Department of Pathology, School of Medicine, College of Medicine, Taipei Medical University, Taipei, Taiwan, (6)Division of Gastroenterology and Hepatology, Department of Internal Medicine, Taipei Medical University Hospital, Taipei, Taiwan

Background: Nonalcoholic fatty liver disease (NAFLD) is a spectrum of liver disease including simple hepatic steatosis (NAFL) and nonalcoholic steatohepatitis (NASH) with or without fibrosis or cirrhosis. Approximately 25% global population has NAFLD. This study aims to use untargeted lipidomic analysis to investigate lipidomic profile features in liver and serum among with patients with NASH with mild fibrosis, NASH with significant liver fibrosis and healthy individual's. **Methods:** Lipidomics analysis was performed using ultra-high-performance liquid chromatography–tandem mass spectrometry on serum and liver samples from a prospective cohort study involving morbidly obese patients who underwent sleeve gastrectomy at Taipei Medical University Hospital between September 2016 and December 2020. Ultrasonography (US) and transient elastography (E score) were performed before surgery. Wedge liver biopsy was performed during surgery and significant liver fibrosis was defined as a fibrosis score > 2. Based on these criteria, We selected 10 patients without NAFLD, 20 patients with NASH in fibrosis stage 0-1 and 20 patients with NASH in fibrosis stage 2-4. **Results:** From the data of lipidome, significant changes were observed in sixty-eight lipid species in the liver and ninety lipid species in the serum. Lipids classification includes glycerolipids (GL), glycerophospholipids (GP), sphingolipids (SP), and sterol lipids (ST) that were identified and quantified with false discovery rate (FDR)-adjusted significant P values less than 0.05. Fourteen overlapping lipid species were found in the liver and serum. The heatmap shows that the relative abundance of lipid species in the liver and serum does not follow the same trend as the severity of liver fibrosis. The correlations of the lipid species in serum with clinical, metabolic features and with NAFLD parameters are presented. DG 32:0, TG 56:4, LPC 6:0, PC 40:8, PE 34:2, PE O-38:4, PE O-40:4,and CL 76:1 are positively correlated with the specific clinical characteristics; on the contrary, MG 18:1, DG 44:8, PA 28:3;O2, LPC 20:1 are negatively correlated with the specific clinical characteristics. Multiple predictive models were developed based on the top 3 high-variable importance plots-score metabolites and dimorphic data for detecting NASH with significant liver fibrosis detection. The AUROC (0.904, P = 0.005) was highest with the features of mixed lipid biomarkers and non-invasive serum markers (Figure 1). **Conclusion:** The concentrations of particular lipid species were associated with severity of fibrosis of the liver in NASH. Higher PE O-38:4, PE 34:2, and CL 76:1 in serum were associated with higher risk of significant liver fibrosis. The AUROC was highest with mixed lipid biomarkers and non-invasive serum markers.

Features	C statistic 95%CI	P value
Non-invasive serum markers (APRI, NAFLD-FS, FIB-4 score)	0.835 (0.525 - 1)	0.013
Imaging techniques (E score, US fibrosis score, splenic arterial pulsatility index)	0.841 (0.537 - 0.988)	0.016
Mixed lipid biomarkers and non-invasive serum markers	0.974 (0.775 - 1)	0.001
Mixed lipid biomarkers and imaging techniques	0.963 (0.743 - 1)	0.001

2109-A | THE DIAGNOSTIC ABILITY FOR THE DEGREE OF LIVER FIBROSIS USING FIB-3 INDEX, FIB-4 INDEX AND TRANSIENT ELASTOGRAPHY

Takashi Nishimura[1], Toshifumi Tada[2], Yukihisa Yuri[1], Ryota Nakano[1], Tomoyuki Takashima[1], Nobuhiro Aizawa[1], Naoto Ikeda[1], Shinya Fukunishi[1], Hideyuki Shiomi[1], Hirayuiki Enomoto[1], Seiichi HIrota[1], Hirohisa Yano[3] and Hiroko Iijima[4], (1)Hyogo Medical University, (2)Japanese Red Cross Himeji Hospital, (3)Kurume University School of Medicine, (4)Hyogo Medical University, Nishinomiya, Japan

Background: Fib-4 index and transient elastography (TE) is widely used as the non-invasive methods for diagnosing the degree of liver fibrosis in chronic liver disease. Otherwise, Fib-4 index can be influenced by age. Recently, new non-invasive biomarker based on AST, ALT and platelet without age, namely Fib-3 index, has been developed in NAFLD/NASH patients. The aim of this study was to compare the diagnostic ability for the degree of liver fibrosis among Fib-3 index, Fib-4 index and TE **Methods:** The 687 chronic viral hepatitis patients with 330 males(48%), 225 HBV(32.8%) from March 2021 to January 2022 were included in this study. The median age was 67 years old and the number of F0/F1/F2/F3/F4 were 32/ 280/ 138/ 163/ 74, respectively. IQR/median more than 0.3 in the liver stiffness values using TE were excluded. The histological liver fibrosis stage estimated by METAVIRE score was as reference standard. **Results:** Fib-3 index, Fib-4 index and TE increased significantly with the progression of F stage($p < 0.001$). AUROC and cut off values for advanced fibrosis(F3 **d**) were 0.757/ 2.916 in Fib-3 index, 0.772/ 1.944 in Fib-4 index, 0.861/ 7.8(kPa) in TE. AUROC and cut off values for liver cirrhosis were 0.806/ 3.072 in Fib-3 index, 0.804/ 3.919 in Fib-4 index and 0.936/10.1(kPa). The correlation coefficients(r) was 0.907 between Fib-3 index and Fib-4 index, 0.616 between Fib-3 index and TE, 0.590 between Fib-4 index and TE. Moreover, the sensitivity(Se)/ specificity(Sp)/ accuracy(AC) for advanced fibrosis(F3 **d**) using the aforementioned cut off value between the patients with more than 65 age and less than 65 age were examined. In patients with more than 65 age, Se/Sp/AC were 71.9/ 59.4/ 65.5 in Fib-3 index, 90.1/26.6/57.4 in Fib-4 index, 76.9/ 74.2/ 75.5 in TE. In patients with less than 65 age, Se/Sp/AC were 57.8/ 84.1/ 77.2 in Fib-3 index, 65.6/ 79.5/75.8 in Fib-4 index, 70.7/ 87.0/ 82.6 in TE. Se/Sp/AC in Fib-4 index between the twe groups were the largest difference. **Conclusion:** Fib-3 index was a useful non-invasive liver fibrosis diagnostic marker in patient with viral hepatitis.

2110-A | THE DIAGNOSTIC ACCURACY OF NON-INVASIVE TESTS OF FIBROSIS IN PATIENTS WITH METABOLIC ASSOCIATED FATTY LIVER DISEASE. A COMPARATIVE STUDY BETWEEN LIVER BIOPSY AND NON-INVASIVE SCORES OR FIBROSCAN.

Annalisa Cespiati[1,2], Rosa Lombardi[1,2], Daniel Smith[1,2], Cristina Bertelli[1], Felice Cinque[3] and Anna Ludovica Fracanzani[2], (1)SC Medicina Ad Indirizzo Metabolico, Fondazione Irccs Cà Granda Ospedale Maggiore Policlinico, Milan, Italy, (2)Università Degli Studi Di Milano, (3)Mcgill University Health Centre

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) is characterized by liver steatosis and at least one metabolic comorbidity. Due to limitations of liver biopsy, non-invasive tests of fibrosis (NITs) (FIB4 and NFS) and liver stiffness measurement (LSM) by Fibroscan are used to diagnose fibrosis. Aims 1) to evaluate the diagnostic accuracy of NITs and LSM in MAFLD 2) to evaluate their performance specifically in diabetic and obese subjects 3) to identify new thresholds for scores NITs and LSM in MAFLD. **Methods:** We enrolled 164 biopsy-proven MAFLD (mean age 56 ± 12 ys, 62% males) in Milan. Clinical, laboratory and Fibroscan data were collected within 6 months from biopsy. FIB-4 < 1.3, NFS < -1.455 and LSM < 8 kPa ruled out advanced fibrosis ($\geq$F3), FIB-4 > 3.25, NFS > 0.675 and LSM **e** 8 kPa suggested advanced fibrosis. **Results:** Prevalence of fibrosis > F3 was 24% at histology. FIB4 and NFS ruled out advanced fibrosis in 49% and 44% of cases, diagnosed it in 7% and 8% and had indeterminate values in 43% and 49% of cases, respectively. LSM **e** 8 kPa in 62% of subjects. All NITs showed a lower accuracy for both identification (AUROCs FIB-4 0.62; NFS 0.57; LSM 0.72) and exclusion (AUROCs FIB-4 0.65; NFS 0.68; LSM 0.72) of advanced fibrosis at biopsy compared to those for non-alcoholic fatty liver disease (NAFLD). The 59% of the cohort was obese, 47% diabetic. For ruling-in advanced fibrosis, FIB-4 and LSM performed worst in diabetic vs non-diabetic (AUROCs FIB-4 0.58 vs 0.69 $p < 0.001$; LSM 0.66 vs 0.71 $p < 0.001$) and in obese vs

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

non-obese MAFLD (AUROCs FIB-4 0.59 vs 0.65 $p < 0.001$; LSM 0.68 vs 0.75 $p < 0.001$). NFS accuracy did not significantly differ between diabetic and non-diabetic (AUROCs 0.58 vs 0.50 $p = 0.06$), whereas it seemed to perform better in obese vs non-obese (AUROCs 0.58 vs 0.55 $p = 0.01$). For the exclusion of fibrosis, all NITs performed worst in diabetic vs non-diabetic (AUROCs FIB-4 0.59 vs 0.67 $p = 0.001$; NFS 0.58 vs 0.63 $p = 0.003$; LSM 0.68 vs 0.69 $p = 0.06$) and in obese vs non-obese (AUROCs FIB-4 0.66 vs 0.69 $p = 0.002$; NFS 0.65 vs 0.70 $p = 0.003$; LSM 0.68 vs 0.74 $p < 0.001$). The Youden indexes of current cut-offs for FIB4 and NFS were < 0.5 for both ruling in and ruling out advanced fibrosis, whereas new thresholds as FIB-4 > 1.63/NFS > -1.09 and FIB-4 < 1.22/NFS < -1.23 had the best Youden indexes. As for Fibroscan, LSM > 10.4 kPa seemed to better identify MAFLD patients with advanced fibrosis, whereas a cut-off of 8.4 kPa to exclude it. **Conclusion:** In MAFLD, both FIB4 and NFS and Fibroscan performed worse compared to NAFLD, with the latter having the higher accuracy. The presence of diabetes and obesity impairs the performance of score and LSM. In MAFLD lower cut-off of both FIB-4 and NFS are warranted, whereas no change seems to be needed for LSM. Nevertheless, more accurate NITs should be developed specifically for MAFLD.

2111-A | THE NEXT GENERATION HEPQUANT TESTS MEASURE REDUCTION IN RISK FOR CLINICAL EVENTS IN COMPENSATED NASH CIRRHOSIS SUBJECTS TREATED WITH RESMETIROM

Michael P. McRae[1], Steve M. Helmke[2], Rebecca A. Taub[3] and Gregory T Everson[2], (1)Custom DX Solutions LLC, (2)Hepquant, (3)Madrigal Pharmaceuticals

Background: HepQuant SHUNT test (V1.1) quantifies liver function and physiology from the portal and systemic clearances of stable isotopes of carbon-13-labeled cholate (13C-CA) intravenously (IV) and deuterium-labeled cholate (d4-CA) orally. Simplified versions of the Test (V2.0 and LDT 1.0), which require fewer blood samples and shorter testing time, have been proposed for clinical applications. The objective of this study was to determine whether these NEXT GENERATION (NGEN) HepQuant Tests, using Risk ACE as endpoint, could detect treatment effects in MAESTRO-NAFLD-1 (NCT04197479), an open label, single arm study of resmetirom, a thyroid hormone receptor-β agonist being studied for the treatment of NASH (Harrison et al., Lancet 2019, 394:2012-24). **Methods:** Thirty-four subjects with compensated NASH cirrhosis (eligibility required at least 3 metabolic risk factors, and NASH cirrhosis diagnosed on liver biopsy or according to accepted criteria) underwent baseline testing and subsequent retesting at 28 and 48 weeks. For each test, IV 13C-CA and oral d4-CA were administered. Blood was sampled at 0, 5, 20, 45, 60, and 90 minutes for serum cholate concentrations. Using a compartmental model (McRae et al., 2023), V2.0 was calculated from IV and oral data; LDT 1.0 from only oral data; both at 20 and 60 minutes. Previously, a Poisson model (Risk ACE) was developed to estimate an individual's annual clinical event rate based on 220 subjects with 52 clinical events from the HALT-C trial. Risk ACE was calculated for each subject from the baseline and week 48 disease severity index (DSI). Risk ACE results between methods were compared. **Results:** For LDT 1.0, Risk ACE decreased with resmetirom treatment in 21 of 23 subjects, with significant decrease in the mean (−0.0182 clinical events per person-year, $p = 0.0407$). At 48 weeks, Risk ACE decreased in 19 of 23 subjects (−0.0355, $p = 0.1222$) (Figure 1). V1.1 and V2.0 also showed similar reductions in Risk ACE at 28 weeks (V1.1: −0.0194, $p = 0.1028$; V2.0: −0.0170, $p = 0.1145$) and 48 weeks (V1.1: −0.0257, $p = 0.1389$; V2.0: −0.0325, $p = 0.1605$). **Conclusion:** This study demonstrated that NGEN Tests measured a reduction in estimated clinical event rate after 28 weeks of resmetirom. These results show potential for these Tests and Risk ACE to provide a sensitive and interpretable metric of risk for All Clinical Events in monitoring patients. Further evaluation and clinical validation of NGEN Tests and Risk ACE is warranted.

2112-A | THE PREDICTIVE SCORE FOR SCREENING METABOLIC ASSOCIATED FATTY LIVER DISEASE WITH SIGNIFICANT FIBROSIS IN THE PRIMARY CARE SETTING: A MULTICENTER STUDY★

Kessarin Thanapirom[1,2,3], Kanokwan Sonsiri[1], Panarat Thaimai[1], Sirinporn Suksawatamnuay[1,2,3], Piyawat Komolmit[1,2,3] and Sombat Treeprasertsuk[4], (1)Division of Gastroenterology, Faculty of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Bangkok, Thailand, (2)Center of Excellence in Liver Fibrosis and Cirrhosis, Chulalongkorn University, Bangkok, Thailand., (3) Excellence Center in Liver Diseases, King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand, (4)Chulalongkorn University, Bangkok, Thailand

Background: Identification of patients with metabolic associated fatty liver disease (MAFLD) at high risk for significant fibrosis (SF) in resource-limited settings remains challenging due to the inaccessibility of liver biopsy or liver elastography. This study aimed to develop prediction models using clinical factors (CF) with or without simple laboratory tests to detect MAFLD with SF in primary care centers. Futhermore, we investigated the correlation between serum Mac-2 binding protein glycosylation isomer (M2BPGi), a novel liver fibrosis biomarker, and transient elastography (TE), as well as its role in the setting of unavailability of TE. **Methods:** We prospectively enrolled individual's without chronic Hepatitis B, C virus or excessive alcohol consumption from 6 primary hospitals in Thailand during 2021-2022. SF and liver steatosis were defined by TE using Fibroscan as cutoff **e** 7 kilopascal and controlled attenuated parameter (CAP) **e** 248 dB/m, respectively. Multivariate logistic regression was performed to develop models that predict MAFLD and SF using TE as the reference standard. A weight score was assigned for each predictor and the optimal cut-off of each model was determined. Excessive weight circumference (EWC) was defined as **e** 90 cm in male and **e** 80 cm in female. **Results:** In total, 613 of the 702 subjects were enrolled with a mean age of 54.9 ± 11.5 years. Of these, 29.4% (n = 180) were diagnosed with MAFLD and SF. Multivariate analysis found diabetes mellitus (DM), body mass index (BMI), EWC, ALT, AST to Platelet ratio index (APRI) and Fibrosis-4 (FIB-4) were potential predictors for detecting MAFLD with SF. Four predictive models were developed and assigned scores (Table 1). All models had a good ability to identify MAFLD with SF with an AUROC of 0.68 for CF, 0.75 for CF+ALT, 0.74 for CF+APRI and 0.74 for CF+FIB-4 ($p < 0.001$). The cutoff of CF **e** 2 demonstrated a 91.3% negative predictive value (NPV), 80.7% sensitivity, 48.2% specificity and the AUROC of 0.65 (95%CI: 0.60-0.69), indicating it was suitable to use for ruling-out MAFLD with SF patients in primary care settings. While employing the CF+ALT **e** 2.5 points had 75.6% sensitivity, 61.7% specificity and AUROC of 0.69 (95%CI: 0.64-0.74), which might be the most practical model for referral decisions. The levels of M2BPGi had a moderate positive correlation ($r = 0.67$, $p < 0.001$) with TE and related to the severity of liver fibrosis. Using M2BPGi **e** 0.87 cutoff index (Jang SY et al. Ann Lab Med 2021) to define SF, CF + ALT **e** 2.5 points had 42.5% sensitivity, 80.3% NPV and an AUROC of 0.58 (95%CI: 0.51-0.65, $p = 0.03$). **Conclusion:** In resource-limited setting, three simple clinical factors, including DM, EWC and BMI **e** 25 kg/m^2 could be used for ruling out MAFLD with SF. Moreover, combining serum ALT with these clinical factors may guide in the decision on referral to specialists for further investigation. If unavailable of TE, serum-based fibrosis marker e.g., M2BPGi might be used to evaluate SF.

Table 1 Predictors and assigned score for MAFLD and significant fibrosis.

Factor	Assigned score			
	Model 1 (Clinical factors: CF)	Model 2 (CF + ALT)	Model 3 (CF + APRI)	Model 4 (CF + FIB-4)
DM	1	1	1	1
BMI ≥ 25 kg/m^2	1	1	1	1
Excessive weight circumference	1	1	1	1
ALT ≥ 35 U/L	-	1.5	-	-
APRI ≥ 0.5	-	-	1.5	-
FIB-4 ≥ 1.45	-	-	-	1
Point	0-3	0-4.4	0-4.5	0-4

2113-A | THE SILENT THREAT: NONINVASIVE ASSESSMENT AND PREDICTORS OF ADVANCED FIBROSIS IN PATIENTS WITH TYPE 2 DIABETES AND NONALCOHOLIC FATTY LIVER DISEASE (NAFLD) IN A REAL-LIFE SETTING

Mona H. Ismail, King Fahd Hospital of the University, Alkhobar, Saudi Arabia.

Background: Nonalcoholic fatty liver disease (NAFLD) and type 2 diabetes are common metabolic disorders whose prevalence rates are expected to rise worldwide

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

due to aging and increasing obesity. Compared to the general population (around 25%), 50% to 70% of people with diabetes have NAFLD, and the severity of NAFLD (including fibrosis) tends to worsen with the presence of diabetes. Recent guidelines recommend screening for NAFLD and case findings of advanced disease with fibrosis in patients with type-2 diabetes. Therefore, we aimed to determine the role of non-invasive fibrosis tests in diagnosing advanced fibrosis in patients with type 2 diabetes and NAFLD in a real-life setting to facilitate their early identification and management. **Methods:** In this prospective cohort study, we recruited patients with type 2 diabetes attending the diabetes clinic at a tertiary university hospital and unaware of having NAFLD. Patients with secondary causes of hepatic steatosis were excluded. Clinical and demographical data collected were age, sex, nationality, body mass index, complete blood count, fasting blood sugar, hemoglobin A1c (HbA1c) level, liver enzymes, renal function, prothrombin time (PT), presence of comorbidities, dyslipidemia, and medications used. To estimate the prevalence of advanced fibrosis, we performed liver stiffness measurement (LSM) by transient elastography (Fibroscan, Echosens, France), and the NAFLD fibrosis score (NFS) and fibrosis-4 (FIB-4) index were calculated. Moreover, AST, ALT, and platelet counts were measured within one month of the Fibroscan evaluation. We used logistic regression to identify predictors of advanced fibrosis. **Results:** A total of 304 patients were included, and advanced fibrosis was seen in 56 (18.4%) patients with type 2 diabetes. The mean age was 53.0 $\pm$ 12.7 years; the majority were females (54.6%), Saudi nationals (86.5%), obese (65.5%), and with HbA1C **e** 7 (59.3%). The mean LSM was 8.4 $\pm$ 10.1 kPa, FIB-4 was 1.0 $\pm$ 0.9, and NFS was -0.6 $\pm$ 1.4. On multivariate analysis, the use of insulin, obesity, low platelets, low albumin, high transaminases, elevated HbA1c, and prolonged prothrombin time were frequently associated with advanced fibrosis. Obesity, the use of insulin, elevated ALT and GGT, and prolonged PT were independent predictors of advanced fibrosis. **Conclusion:** This study highlights the high prevalence of advanced fibrosis in patients with type 2 diabetes and NAFLD and identifies obesity, the use of insulin, elevated liver enzymes, and prolonged PT as significant risk factors. The use of noninvasive fibrosis tests such as LSM, FIB-4, and NFS can aid in the early identification and management of advanced fibrosis in these patients. Early detection and management of these conditions are crucial to prevent progression to cirrhosis and its sequala. Further research is needed to explore effective interventions for this high-risk population.
Disclosures: The following people have nothing to disclose: Mona H. Ismail

2114-A | THE UTILITY OF SEQUENTIAL SAFE SCORE AND FIBROSCAN IN PREDICTING CLINICALLY SIGNIFICANT FIBROSIS IN ASIAN NAFLD PATIENTS.

Pimsiri Sripongpun[1,2], Sombat Treeprasertsuk[3], Phunchai Charatcharoenwitthaya[4], Apichat Kaewdech[5], Naichaya Chamroonkul[5], Wah Kheong Chan[6], Cheng Han Ng[7], Mark Dhinesh Muthiah[8], Yock Young Dan[8] and W. Ray Kim[2], (1)Prince of Songkla University, Hat Yai, Thailand, (2)Stanford University School of Medicine, (3)Chulalongkorn University, Bangkok, Thailand, (4)Siriraj Hospital, Mahidol University, (5)Prince of Songkla University, (6)University of Malaya, (7)Yong Loo Lin School of Medicine, National University of Singapore, (8)National University Health System (NUHS)

Background: Clinically significant fibrosis (fibrosis stage 2 or higher, SF) has been proven to be associated with an increased risk of both liver-related and overall mortality in patients with NAFLD. However, the currently available algorithms of noninvasive tests mainly focus on the detection of the later stage of fibrosis (F3-4). We aimed to validate the recently proposed score (Steatosis-Associated Fibrosis Estimator, SAFE) in comparison with FIB-4, NFS and vibration controlled transient elastography (VCTE) and determine the diagnostic accuracy of the 2-step approach for the detection of F $\geq$ 2 in Asian NAFLD patients. **Methods:** The data of biopsy-proven NAFLD patients from 6 centers in 3 Southeast Asian countries (Thailand, Malaysia, and Singapore) were collected (N = 889). Liver biopsy was used as the reference standard, liver fibrosis stage was graded using NASH CRN criteria. We included only patients with available liver stiffness data measured by VCTE. Those with incomplete data on variables used to calculate SAFE, FIB-4, and NFS were excluded, as well as those with AST or ALT > 200 IU/L. The performance of SAFE, FIB-4, NFS, and VTCE in the diagnosis of SF were evaluated using areas under the receiver operating characteristics curve (AUROC). The sequential combination approach was also assessed. **Results:** A total of 383 patients were eligible for the analysis, SF was presented in 115 patients (30%). The mean SAFE, FIB-4, NFS scores and liver stiffness were significantly different between those with and without SF. Among blood-based biomarkers, SAFE score yielded the highest AUROC of 0.773, followed by FIB-4 (AUROC 0.759, p = 0.39), and significantly better than NFS (AUROC 0.729, p = 0.024). While VCTE showed the non-significantly higher AUROC of 0.785 (p = 0.68 vs SAFE). At the given low cutoff of < 0, SAFE yielded 92.17%

sensitivity and NPV of 89.9%. To maximize the ability of ruling out patients with no/mild fibrosis, the sequential combination of SAFE (< 0; > 100) followed by VCTE (< 7; > 11 kPa) showed a promising result in excluding patients with SF as shown in the figure. The proportion of patients having false negative results using this 2-step approach is only 3.4%. **Conclusion:** SAFE consistently showed the highest AUROC among blood-based noninvasive biomarkers in the diagnosis of SF in NAFLD patients and demonstrated the comparable AUROC with that of VCTE with a sensitivity > 90% in the detection of SF. In primary care setting, SAFE might be a useful screening tool, and sequential SAFE followed by VCTE is effective in identifying patients who can be managed safely with primary care doctors.

2115-A | TYPE VII COLLAGEN DEGRADATION IDENTIFIES EARLY FIBROSIS, STEATOSIS AND DISEASE ACTIVITY IN NAFLD

Andressa de Zawadzki[1], Diana Lemming[2], Peder Frederiksen[1], Morten Karsdal[3] and Jörn M. Schattenberg[4], (1)Nordic Bioscience a/S, (2)Nordic Bioscience, (3)Nordic Bioscience a/S, Denmark, (4)I. Department of Medicine, University Medical Centre Mainz, Johannes Gutenberg University, Mainz, Germany, Mainz, Germany

Background: Collagen turnover is a key feature in the progression of nonalcoholic fatty liver disease (NAFLD). The assessment of collagens can help to better understand the pathogenesis of NAFLD and to develop non-invasive tools for early diagnostic of disease. Type VII collagen is the main component of anchoring fibrils which connects the basement membrane to the interstitial matrix providing structural support to fibril forming collagens in the ECM. The anchoring fibrils differ significantly from the fibrillar collagens, type I, III and V, although they share the collagen domain structure. The role of type VII collagen in the pathogenesis of NAFLD and other liver diseases remains unestablished. The current study investigated type VII collagen turnover in health and NAFLD using the C7M neoepitope reflecting type VII collagen degradation. **Methods:** Serum concentrations of C7M and other non-invasive biomarkers associated with ECM remodeling including PRO-C3 (type III collagen formation), PRO-C4 (type IV collagen formation), were measured in 140 biopsy confirmed NAFLD patients and compared to 160 healthy individual's. **Results:** In the NAFLD group at the baseline, most participants were men (53%), 40% had type II diabetes, the mean age was 51 years and the distribution between fibrosis stages F0/F1/F2/F3/F4 was 3%/26%/36%/23%/11%. NAFLD patients exhibited significantly higher serum C7M levels in comparison to healthy individual's ($p = 1.5\times10^{-12}$). Serum concentrations of C7M were able to differentiate healthy individual's from NAFLD patients even in early disease stages (F0-F1; $p = 6.2\times10^{-12}$), hepatocyte ballooning (stage 0; $p = 0.04$), lobular inflammation (stage 0; $p = 9.8\times10^{-7}$), steatosis (stage 1; $p = 3.1\times10^{-12}$) and disease activity (NAS = 2; $p = 5.9\times10^{-5}$). PRO-C3 levels were able to discriminate different stages of fibrosis in NAFLD, however, did not distinguish early disease stages from healthy controls. The combination of C7M and PRO-C3 improved the distinguishing capability in NAFLD subgroups describing different stages of the disease (fibrosis; steatosis; ballooning; NAS) when compared to the isolated biomarkers. C7M was significantly different among individual's with healthy BMI, overweight and obese individual's. **Conclusion:** Type VII collagen degradation may provide an early indication of metabolic stress associated with enhanced activity of matrix metalloproteinases causing tissue remodeling driving tissue changes during the early stages of NAFLD.

2116-A | ULTRASOUND-DERIVED FAT FRACTION (UDFF) AND AUTO-POINT SHEAR WAVE (AUTO-PSWE) ON THE DEEP ABDOMINAL TRANSDUCER (DAX) FOR LIVER FAT QUANTIFICATION AND LIVER FIBROSIS ASSESSMENT - A PROSPECTIVE BIOPSY-CONTROLLED STUDY

Georg Semmler[1], Larissa Nixdorf[2], Lukas Hartl[1], Michael Schwarz[3], Lorenz Balcar[1], Mathias Jachs[3], Paula Richwien[2], Magdalena Mairinger[2], Daniel M Felsenreich[4], Benedikt Simbrunner[5], Julia Jedamzik[2], Lisa Gensthaler[4], Felix B Langer[4], Mattias Mandorfer[5], Thomas Reiberger[6], Gerhard Prager[2] and David Josef Maria Bauer[3], (1)Division of Gastroenterology and Hepatology, Department of Medicine III, Medical University of Vienna, Vienna, Austria, (2)Department of General Surgery, Division of Visceral Surgery, Medical University of Vienna, Vienna, Austria, (3)Medical University of Vienna, (4)Medical Univesity of Vienna, (5) Division of Gastroenterology and Hepatology, Department of Internal Medicine III, Medical University of Vienna, (6)Cemm Research Center for Molecular Medicine of the Austrian Academy of Sciences

Background: Ultrasound-derived fat fraction (UDFF) and auto-point shear wave (Auto-pSWE), have emerged as novel techniques for liver steatosis and fibrosis quantification. However, their diagnostic accuracy and cutoffs for steatosis and fibrosis staging have not been evaluated, yet. **Methods:** A prospective study, using liver biopsy as the gold standard, was conducted on obese participants with suspected or diagnosed non-alcoholic fatty liver disease (NAFLD) who were evaluated for bariatric surgery. Employing the Siemens Sequoia ultrasound VA30 system with the Deep Abdominal ultrasound transducer (DAX), the Auto-pSWE function triggers 15 pSWE measurements within a user-determined sectored region of interest. Participants underwent 5 Virtual Touch UDFF and Auto-pSWE measurements using the DAX, and 10 vibration-controlled transient elastography (VCTE) and CAP (CAP) measurements using the appropriate M- or XL-probe on the Fibroscan. VCTE was considered reliable when VCTE was **d** 7.1kPa or IQR/Median **d** 30%. The rule-in and rule-out cutoffs were chosen for approximately 90% specificity and sensitivity. **Results:** The study recruited 77 participants, 51 (66.2%) of which were female, with 61 (79.2%) biopsy-confirmed NAFLD. Participants' median age was 44 (IQR: 17.0) years, with a median BMI of 42.9 (IQR: 10.9) kg/m^2. Reliable VCTE was obtained in 65 (84.4%) participants. 61 (79.2%) displayed any steatosis (**e** S1), with 40 (51.9%) presenting at least moderate steatosis (**e** S2) on liver biopsy. UDFF detected any steatosis (**e** S1) with an ROC = 0.76 (rule-in cutoff: UDFF **e** 22% and rule-out cutoff: UDFF < 7%). For moderate steatosis (**e** S2), the ROC was 0.82 (rule-in cutoff: UDFF **e** 24% and rule-out cutoff: UDFF < 13%). While the UDFF and CAP ROC for diagnosing different grades of steatosis differed numerically, the differences were not statistically significant. 18 (23.4%) participants showed **e** F2, and only 5 (6.5%) showed **e** F3 on liver biopsy. Auto-pSWE diagnosed significant fibrosis (**e** F2) with an accuracy of ROC = 0.68 (rule-in cutoff: **e** 5.0kPa and rule-out cutoff < 2.4kPa). DeLong test revealed no significant difference in ROCs of reliable VCTE and Auto-pSWE for diagnosing significant fibrosis. **Conclusion:** UDFF and Auto-pSWE on the DAX probe are accurate non-invasive methods to rapidly assess steatosis and fibrosis in obese individual's. Hepatic steatosis (**e** S1) can be excluded with UDFF < 7% and confirmed with UDFF **e** 22%. Advanced liver fibrosis (**e** F2) can be confirmed with Auto-pSWE **e** 5.0kPa and excluded with Auto-pSWE < 2.4kPa.

2117-A | UNDER-IDENTIFICATION OF PATIENTS WITH METABOLIC RISK FACTORS AT HIGH RISK OF NON-ALCOHOLIC FATTY LIVER DISEASE CIRRHOSIS IN THE PRIMARY CARE CLINICS: A SINGLE CENTER RETROSPECTIVE STUDY

Oluwanifemi Balogun[1], Blanche Echikunwoke[1], Prutha Shah[1], Abiodun Idowu[1], Isaac Ogunmola[2], Smarajita Ghosh[1], Jessica Genkil[1], Mikaela Nikkola Jara-Tantoco[1], Nandakumar Mohan[1], Matthew Behme[1], Kevin B Lo[2] and Maria Lagarde Mussa[3], (1)Albert Einstein Medical Center, Philadelphia, PA, (2)Albert Einstein Medical Center, (3)Einstein Medical Center

Background: The incidence of NASH cirrhosis is on the rise mostly fueled by increasing prevalence of metabolic risk factors/obesity. The current AASLD guideline recommends the screening of high-risk patients for NASH cirrhosis. The well-validated and cost-effective non-invasive tests (NITs) such as the FIB-4 and NFS are useful in stratifying patients in the primary care setting and ensuring early identification of patients at high risk of NASH Cirrhosis. This study explores the utility of NITs and tests the hypothesis – that patients with metabolic risk factors in primary care clinics at risk of NASH cirrhosis are under-identified. **Methods:** This is a single center contemporary retrospective analysis of outpatients who have been seen at the primary care clinic at our institution from October 2021 to January 2022. Patients included had to be aged 35-65 years which is the age range for the scoring criteria for NAFLD in addition to diabetes mellitus or impaired glucose tolerance, or 2 or more other identified metabolic risk factors such as obesity or overweight, hypertension, PCOS and dyslipidemia. Primary outcome is proportion of patients screened at risk for NASH cirrhosis using NITs. **Results:** After screening and excluding 39% of patients with no lab data and not fulfilling inclusion criteria, a final number of 471 patients were analyzed. Majority of patients were African American (64%), mean age was 53.7 ± 8.1 and 55% were females. About two-thirds (313) have diabetes mellitus or impaired fasting glucose, while a significant number had hypertension (84%) and dyslipidemia (83%). More than half (68%) were classified as obese with a mean BMI of 33.4 ± 9.0 for the whole sample. Using the FIB-4 score to assess risk, 15% (72) were within intermediate risk while only 2% (11) were labeled as high risk. Meanwhile, using NFS score, 58% (272) and 10% (45) of patients were labeled intermediate and

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

high risk respectively. Using the NFS, among those at high risk of NASH cirrhosis, 96% of them had 3 metabolic risk factors, there was statistically significant association between number of metabolic risk factors and risk by NFS score $p < 0.001$. Results obtained using FIB-4 also showed a high proportion of patients in the intermediate and high-risk category having 3 metabolic risk factors or DM, but the association was not statistically significant. Only 28% (131) of all patients had some form of imaging, and among these patients, 39% (51) had findings of steatosis. There were more FIB-4 intermediate risk scores among those with steatosis on imaging 29% vs 16% in those without steatosis, but this did not reach statistical significance $p = 0.07$. **Conclusion:** There is a significant proportion of patients with multiple metabolic risk factors who present to a general medicine practice who are at risk for NASH fibrosis, who are not appropriately recognized. The use of yearly routine work-up and validated non-invasive scores may improve recognition of these patients.

2118-A | URINARY METABOLITE BIOMARKERS CHANGES IN OBESITY-INDUCED NAFLD AND OBESITY-INDUCED NAFLD PLUS XX.

Helena Yong[1], Ka Lung Andrew Chan[2], Gerald Larrouy-Maumus[3], Joseph Okor[1], Michael Munday[1], Andrew Rennie Hall[4], Alberto Quaglia[4] and Jude A. Oben[2,5], (1) University College London, (2)King's College University, (3)Imperial College University, (4)Royal Free Hospital, (5)Guy's and St Thomas' Hospital

Background: Obesity-induced Non-alcoholic fatty liver disease (NAFLD) is the leading causes of chronic liver disease, affecting 25% globally. It starts as hepatic steatosis, progresses to steatohepatitis, fibrosis, cirrhosis and possible hepatocellular cancer. NAFLD is often associated with obesity plus insulin resistance or type 2 diabetes. Liver function blood tests and non-invasive radiological imaging are clinically used to detect NAFLD. Whilst, liver biopsy remains the "gold standard" for detection and staging, the procedure is invasive and can be unreliable especially in obese patients.[1-3] There is a need for specific, non-invasive biomarkers for the detection and staging of NAFLD. Our aim was to assay urine metabolite changes in mice with obesity-induced NAFLD and obesity-induced NAFLD plus agent XX. **Methods:** C57BL/6 mice ($n = 78$) were fed a diet comprising high fat(54%), high cholesterol(1.4%) with high sucrose(55%) and fructose(45%) in drinking water, to simulate the diet typically consumed by obese patients with NAFLD. The urine of mice fed the obesogenic diet(OD) and OD plus XX (OD-XX), with their parallel controls fed normal chow (NC) for ~40 weeks, were assayed with metabolomic techniques. These techniques were Fourier-transform infrared(FT-IR), ^{1}HNuclear magnetic resonance(NMR), 2D ^{1}H–^{1}H total correlation heteronuclear single quantum coherence(TOCSY) and electrospray liquid chromatography-mass spectrometry(ESI-LC-MS/MS) with multivariate analysis. Body, liver, liver/body weights, liver biochemistry and liver histology were evaluated. **Results:** Sera AST(IU/L) were elevated in OD and OD-XX cohorts compared to NC and decreased in OD-XX group vs OD (367.00 ± 46 vs 544.00 ± 22 vs 335.70 ± 35.05; NC vs OD vs OD-XX; $p < 0.01$). Sera ALT(IU/L) levels were also increased in OD and OD-XX cohorts and reduced in OD-Tx group vs OD (101.70 ± 15.79 vs 401.40 ± 10.57 vs 319.40 ± 43.79, NC vs OD vs OD-XX; $p < 0.01$). The NASH clinical research network scores increased for OD and OD-XX livers vs NC (1.0 ± 0.2 vs 5.10 ± 0.28 vs 5.92 ± 0.28; NC vs OD and NC vs OD-XX, $p < 0.04$; OD vs OD-XX - not significant). Principal component analysis score (PCA) plot (Fig.1) urine NMR spectra displayed differences between OD and OD-Tx groups, indicating that XX induced metabolite changes. **Conclusion:** We have identified specific urinary metabolites with ^{1}HNMR, 2D ^{1}H–^{1}H TOCSY and ESI-LC-MS/MS. The results demonstrate that metabolomic approaches may be useful in detecting novel biomarkers in human NAFLD.

2119-A | USE OF AGILE 3+ AS A SCREENING TOOL SUCCESSFULLY TARGETS NON-ALCOHOLIC STEATOHEPATITIS (NASH) SUBJECTS WITH IMPAIRED HEPATIC FUNCTION AND PORTAL-SYSTEMIC SHUNTING EVALUATED BY HEPQUANT SHUNT TEST: LESSONS LEARNED FROM THE HEPION ALTITUDE-NASH (e F3) TRIAL

Stephen A Harrison[1], Patrick Mayo[2], Todd Hobbs[2], Caroline Zhao[2], Carlos Canizares[2], Robert Foster[2] and Gregory T Everson[3], (1)Summit Clinical Research; Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom, San Antonio, TX, (2)Hepion Pharmaceuticals Inc., (3)Hepquant

Background: The progression of hepatic fibrosis in NASH has been linked to increased mortality and morbidity. Rencofilstat, a non-immunosuppressive pan-cyclophilin inhibitor, has demonstrated pleotropic effects well-suited for the treatment of NASH with advanced fibrosis. In this Phase 2 study, subjects were identified using the AGILE 3+ screening criteria, a predictor of **e** F3 fibrosis, and had baseline liver function and portal-systemic shunting measured by the HepQuant SHUNT test. The SHUNT test's Disease Severity Index (DSI) of 18.3 and systemically shunted portal flow (SHUNT%) of 27% have been linked to transition from F3 to compensated cirrhosis, portal hypertension, varices, and risk for adverse clinical outcomes. The baseline characteristics from the ALTITUDE-NASH trial are reported herein. **Methods:** In this multi-center, open-label study, 70 F3 NASH subjects with AGILE 3+ score > 0.53 were enrolled in a screening period of 2.4 months and randomized to receive rencofilstat once daily at 75, 150, or 225 mg for 120 days. Hepatic function was assessed using the SHUNT test, in which ^{13}C-cholate was administered intravenously and d4-cholate was taken orally, with blood sampled to determine cholate clearances. SHUNT% and DSI were calculated from the clearances and compared to other baseline tests. Additional objectives were to evaluate safety, tolerability, and PK. **Results:** Baseline mean (± SD) measurements were:

- Agile 3+ score 0.73 (0.15)
- FibroScan® kPa 15.0 (7.5)
- AST 27.2 (2.4)
- ALT 29.7 (2.7)
- ELF 9.6 (0.2)
- Fib-4 1.1 (0.1)
- Pro-C3 38.4 (2.4) ng/mL

Nearly half of subjects with baseline AGILE 3+ score **e** 0.53 had significant hepatic functional impairment as assessed by HepQuant Shunt DSI > 18.3, including a quarter with both significant functional impairment and increased portal-systemic shunting (SHUNT% > 27%) (Figure 1). This group demonstrated mean Pro-C3 levels of 38.4 (20.0) ng/mL with ELF scores of 9.7 (0.93). Average age was 60 years with an average BMI of 38; 51% were female and 71% with diabetes. Demographics were similar across the 3 treatment groups. **Conclusion:** Use of AGILE 3+ as a screening tool for identifying subjects was successful in allowing a timely recruitment of F3 NASH subjects. In addition, the sequential use of AGILE 3+ coupled with the HepQuant SHUNT test may identify subjects at high risk for clinical complications from an otherwise well-compensated advanced NASH population.

2120-A | USE OF MULTI-PARAMETRIC MEASURES TO DIFFERENTIATE AND BETTER ASSESS FIBROSIS PATTERNS BETWEEN BASELINE AND END-OF-TREATMENT (EOT) PATIENTS IN NASH CLINICAL TRIALS: RESULTS FROM THE FALCON-1 AND 2 CLINICAL TRIALS

Kutbuddin Akbary[1], Dean Tai[2], Ya-Yun Ren[1], Anne Minnich[3] and Edgar D. Charles[3], (1)Histoindex Pte Ltd, (2)Histoindex Pte Ltd, Singapore, (3)Bristol Myers Squibb

Background: Clinical trials for NASH conducted recently target specific pathological pathways in development of fibrosis, steatosis, inflammation. Effects on steatosis and inflammation impact fibrosis indirectly, compared to drugs that targets fibrosis directly. In the past, quantitative fibrosis assessment was done as a single measure, either biomarkers like ProC3, or histology-based measurements like collagen proportionate area (CPA). Performances of these tests showed significant differences in drug trials, between baseline and EOT (End-Of-Treatment) respectively. This study investigates the possibility to overcome this limitation using multi-parametric measurements like Somalogic (a biomarker) and qFibrosis (AI histology). **Methods:** Biopsy slides were obtained from FALCON-1 (NCT03486899) and FALCON-2 (NCT03486912) clinical trials. SHG/TPE (Single Harmonic Generation/Two-Photon Excitation) microscopy and AI (Artificial-Intelligence) analysis were used to estimate NASH-CRN based fibrosis parameters as continuous variables for 301 biopsy slide pairs. Biomarker data used are serum AST and ALT; additional biomarkers like ProC3, PC3X, ELF, Somalogic; SHG/TPE digital pathology measures like qFibrosis continuous values, qFibrosis stages, % SHG-CPA (percentage area of SHG). Biomarker data in Falcon-1 was at 24 weeks and Falcon-2 at 48 weeks. These data were correlated with histopathological assessment by pathologists using NASH-CRN fibrosis staging (used as a benchmark). Statistical analysis was

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

done using Spearman correlation (r-values for each pair). **Results:** Correlation results of data against NASH-CRN staging scores is summarised in Figure 1. Overall, amongst biomarkers, Somalogic showed best correlation (r = 0.61) with NASH-CRN, followed by PC3X (r = 0.52). Among SHG/TPE data, %SHG-CPA showed best correlation (r = 0.53) followed by qFibrosis values (r = 0.42). Comparing differences in these correlation values between baseline and EOT data, there is hardly any difference for single parameter measures like PC3X (r = 0.54 to r = 0.5) and %SHG-CPA (r = 0.54 to r = 0.53). But for multi-parameter measures like Somalogic (r = 0.54 to r = 0.66) and qFibrosis values (r = 0.51 to r = 0.32), differences between baseline and EOT appear more marked. **Conclusion:** With promising drugs for NASH in the pipeline, it is essential to identify biomarkers to better assess fibrosis changes post-treatment. Drug effects on SHG parameters suggest fibrosis regression and progression patterns differ qualitatively, and can be taken into consideration in evaluating biomarkers. Multi-parametric components within biomarkers take into consideration changes between baseline and EOT patients, to better assess heterogeneity of fibrosis progression and regression. Furthermore, we can evaluate the parameter level correlation between SHG/TPE imaging and multi-parametric biomarkers to better understand fibrosis regressions.

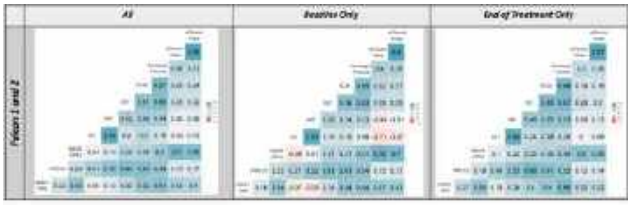

Figure 1: Correlation of various NIT measures and SHG/TPE based digital pathology measurements bench marking with NASH-CRN staging results on fibrosis assessment. On the left, all patients were included in the assessment, and on the right, patients from baseline and end-of-treatment are assessed separately.

2121-A | USE OF NIS4 IN PRIMARY CARE AND ENDOCRINOLOGY CLINICS IDENTIFIES PEOPLE WITH TYPE 2 DIABETES AT A HIGHER RISK OF SEVERE NONALCOHOLIC STEATOHEPATITIS

Srilaxmi Kalavalapalli[1], Eddison GodinezLeiva[1], Romina Lomonaco[1], Stephen Marangi[1], Enrique ValdezSaenz[1], Andrea Ortiz Rocha[1], Yasmine Mohseni[1], Margery Connelly[1], Toni Prezant[2], Kelly Chun[2], Maria Lupi[1], Juan Munoz Pena,[1], Juan Perdomo Rodriguez[1], Jeffrey Budd[1], Anu Sharma[1], Diana Barb[1] and Kenneth Cusi[1], (1)University of Florida, (2)Labcorp

Background: The noninvasive diagnosis of non-alcoholic steatohepatitis (NASH) remains challenging. Liver biopsy still remains the gold standard to diagnose NASH but it is usually not feasible. The novel diagnostic biomarker NIS4 is a blood-based test that measures four independent NASH-associated biomarkers (A1c, miR-34a-5p, A2M and YKL-40) and produces a score. The aim of this study was to assess the prevalence of high-risk NASH (NASH with significant fibrosis [**e** F2]) as estimated by NIS4 or elastography in a university-based outpatient clinic setting. **Methods:** To this end, we recruited from primary care and endocrine clinics a total 600 participants attending routine clinic appointments (age: 56 ± 11 y; BMI: 31.4 ± 6.6 kg/m^2; T2DM: 40%; obese without T2DM [OB]: 30%), unaware of having NAFLD. Participants were screened by: a) Transient elastography (Fibroscan®) for steatosis (CAP **e** 274 dB/m) and for fibrosis (LSM **e** 7.0 kPa); and b) NIS4 for high-risk NASH (defined as a NIS4 **e** 0.63; low-risk: < 0.36). **Results:** Among patients with T2DM or OB, 70% had steatosis compared to 29% without obesity or T2DM (CON) ($p < 0.01$), while fibrosis (LSM **e** 7.0 kPa) was present in 17% of patients with T2DM and 8% in those with OB (CON = 1%; $p < 0.01$). High-risk NASH by NIS4 occurred frequently among patients with T2DM, whether they had (30%) or not (20%) obesity, but less frequent in OB (6%) and was rare in those without T2DM or obesity (1%). NIS-4 correlated with steatosis (CAP) ($r = 0.39$; $p < 0.001$) and fibrosis (LSM) ($r = 0.35$; $p < 0.001$). The strongest correlation was for patients having LSM **e** 8.0 kPa (**e** F2; $r = 0.49$, $p < 0.01$; $r = 0.42$-45 for **e** F3-4, $p < 0.05$). Patients with high-risk NASH (NIS4 **e** 0.63) compared to those with low-risk NASH (NIS4 < 0.36) more often had fibrosis (26% vs 4%), AST **e** 30 IU/L (40% vs. 8%) and ALT **e** 30 IU/L (38% vs. 13%), hepatic- and adipose tissue-insulin resistance (HOMA-IR: 63% vs. 29% and adipo-IR: 72% vs 56%, respectively; all $p < 0.01$). NIS4 correlated with having metabolic syndrome ($r = 0.41$; $p < 0.01$) and high-risk NASH was more common in people from endocrinology vs. primary care clinics (28% vs. 10%; $p < 0.05$). **Conclusion:** Presence of NASH with clinically significant fibrosis is common in T2DM, and increases significantly (> 50%) if obesity is present. An elevated NIS4 can help identify people with more severe NASH and an unfavorable cardiometabolic profile in need of intensive multidisciplinary care.

2122-A | USE OF NONINVASIVE FIBROSIS CALCULATORS IN AN URBAN DIABETES CENTER SUGGESTS LARGE BURDEN OF UNDETECTED ADVANCED LIVER DISEASE

Valeria Martinez Lebron[1], Seta Degann[1], Ahmed Ebeid[2], Cyrus Adams-Mardi[3], Andrea Fry[4], Ameer Abutaleb[5], Diala El-Maouche[6], Zahid Masood Vahora[5], Stephen Gray[5] and Lynt B. Johnson[5], (1)Department of Medicine, George Washington University Hospital, Washington, DC, (2)Alexandria University Faculty of Medicine, Alexandria, Egypt, (3)The George Washington University School of Medicine and Health Sciences, (4)George Washington University Medical Faculty Associates, (5)Department of Surgery, George Washington University Medical Faculty Associates, (6) Department of Endocrinology, George Washington University Medical Faculty Associates

Background: Nonalcoholic fatty liver disease (NAFLD) is prevalent in up to 60% of patients with type 2 diabetes mellitus (T2DM). T2DM accelerates the risk of hepatic fibrosis and hepatocellular carcinoma in patients with NAFLD. Our goal in this study was to identify patients with suspected NAFLD and hepatic fibrosis in a large T2DM clinic by using noninvasive fibrosis scoring systems. **Methods:** We conducted a retrospective study of patients with T2DM seen by an endocrinologist at the Medical Faculty Associates (MFA) Diabetes Center in Washington, DC, from November 1, 2021, until November 1, 2022. We included all subjects who were over 18 years old with a hemoglobin A1c (HbA1c) of 6.5 or higher. Patients with a history of significant alcohol consumption, decompensated cirrhosis, previous bariatric surgery, or prior chronic liver disease were excluded from the study. We identified patients at risk for hepatic fibrosis by using the Fibrosis-4 (FIB-4) Index, NAFLD Fibrosis Score (NFS) and AST to Platelet Ratio Index (APRI) when lab values were available. **Results:** A total of 1,411 were evaluated for T2DM by an endocrinology provider during the one-year period. 336 patients met one or more of the exclusion criteria, leaving a total of 1075 patients included in the analysis. The majority were African American (n = 582, 54%), 261 were Caucasian (24.3%), and 85 were Hispanic (7.9%). Most patients were females (n = 675, 62.7%). The mean HbA1c was 8.1 ± 2.3. 643 patients (59.8%) were insulin dependent. Based on FIB-4 scores, we found that 21 (2%) patients had a score of > 3.25 associated with advanced fibrosis and 205 (19%) patients with scores of 1.45-3.25 had moderate fibrosis. Using the NFS calculator, there were 280 (26%) patients with values of > 0.675 consistent with F3-F4 disease. 247 (23%) had F0-F2 fibrosis. The rest of the cohort (n = 469, 44%) had indeterminate fibrosis scores. 79 patients had missing data (7%). A total of 6 (< 1%) patients met criteria for advanced fibrosis by APRI scoring. **Conclusion:** In our urban Diabetes Center, utilizing the NFS calculator may detect many patients with an advanced liver disease. Further research is needed to correlate these findings with transient elastography and other imaging evidence of fatty liver disease.

Arcare Center for Clinical Research - Jonesboro, (6) Premier Health Research, LLC, (7)Digestive Health Research of Southern California, LLC, (8)Birmingham Digestive Health Research, LLC, (9)GI Associates Research, LLC

Background: Transient elastography (TE) is a non-invasive procedure for identifying patients with suspected NAFLD, NASH, or Cirrhosis. However, existing screening methods like the FIB-4 index have limited utility in identifying which patients should undergo this procedure. Although FIB-4 can identify patients with advanced fibrosis, it lacks precision in detecting mild or moderate fibrosis and neglects common NAFLD and NASH risk factors like BMI and Type 2 Diabetes. Our aim was to utilize machine learning to better predict abnormal TE results. **Methods:** A cohort of 4062 patients who underwent TE was selected from the 2017-2020 NHANES dataset (78%, n = 3206) and combined with patients from primary care and specialty practices (22%, n = 856). Those with viral hepatitis, HIV, or excessive alcohol use were excluded. Patients were divided into control (LSM < 7.5 and CAP < 260, n = 1579) and treatment (LSM > = 7.5 and CAP > = 260, n = 534) groups. These groups were then combined into training (80%, n = 1690) and test sets (20%, n = 423) using a stratified shuffle split. Using XGBoost, multiple models were trained with seven features - Age, Sex, BMI, AST, ALT, Platelet Count (PLT), and Hemoglobin A1c (HbA1c) - expanding upon those used by FIB-4. Models were validated using Stratified K-Fold Cross Validation and performance was evaluated across several metrics, with F1 Score used to select the final model. For FIB-4, a cutoff of 1.45 was used to differentiate between control and treatment groups. **Results:** The final model demonstrated robust performance, surpassing FIB-4 across all metrics. PPV was 0.72 ± 0.05, NPV was 0.93 ± 0.02, Sensitivity was 0.79 ± 0.08, Specificity was 0.90 ± 0.03, F1 Score was 0.75 ± 0.05, AUROC was 0.92 ± 0.02, and Matthew's Correlation Coefficient (MCC) was 0.67 ± 0.07. Feature importance was also assessed using the gain metric with BMI (0.26 ± 0.02) and HbA1c (0.21 ± 0.03) ranking as top features. Conversely, FIB-4 scored significantly lower, with PPV = 0.28, NPV = 0.76, Sensitivity = 0.27, Specificity = 0.76, F1 = 0.27, AUROC = 0.56, and MCC = 0.03. **Conclusion:** The final model, expanding on FIB-4 features by including NAFLD and NASH risk factors, offers robust performance in identifying patients suitable for TE. These results validate the use of machine learning as a viable option for identifying at-risk patients in electronic health record systems, improving patient detection, and accelerating recruitment for NAFLD and NASH studies.

2124-A | VALIDATION OF A CLINICAL CARE PATHWAY TO RISK STRATIFY PATIENTS WITH NAFLD AND COMPARING FIB4 SCORING WITH OTHER NON-INVASIVE TESTING

Ria Ghose Kundu[1], Pooja Rangan[2], Claire Faulkner[3], Majd Aboona[3], Dylan Grade[1], Rahul Sharma[1], Vir Dolasa-Sahani[1], Naina Shaik[1], Rayna Shaik[1], Rida Nadeem[1], Karn Wijarnpreecha[2] and Naim Alkhouri[1], (1) Arizona Liver Health, Phoenix, AZ, (2)University of Arizona College of Medicine Phoenix, Phoenix, AZ, (3) University of Arizona College of Medicine, Phoenix, AZ

Background: FIB4 index was originally developed to diagnose advanced fibrosis, it has been incorporated recently into algorithms by the AGA,AACE,AASLD as the initial screening test to identify patients with at-risk

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

NASH that need referral to specialty clinics.FIB4 < 1.3 are low risk and will remain in primary care setting.This approach is reasonable in low-prevalence populations, the impact of using this approach in specialty clinic is not well-understood.This study was to assess the performance of low FIB4 in specialty clinic. We aim to determine validity of FIB4 index in identifying at risk NASH population and compare FIB4 index against other non invasive tests–FAST score, AGILE3 and AGILE 4 scores. **Methods:** Patients with biopsy-proven NAFLD and Fibroscan/ laboratory tests sufficient to calculate the FIB4 and other Fibroscan-based scores were included in this analysis. The histologic assessment was done based on the NASH CRN criteria and at-risk NASH was defined as NAS > / = 4 and fibrosis stage 2-4. The FAST score was calculated based on Fibroscan measured liver stiffness (LSM) and controlled attenuation parameter (CAP) + AST as a non-invasive test to diagnose at-risk NASH. The AGILE3+ was calculated based on LSM, AST, ALT, platelet count, diabetes, age and gender as a non-invasive test for advanced fibrosis.We conducted a single center retrospective cohort study on NAFLD patients in a tertiary care clinic in Phoenix, AZ. Patients with significant or advanced fibrosis on liver biopsy examination and fibroscans were included in the study. FAST score, AGILE 3+ score AGILE 4 score are all designed to identify advance fibrosis /cirrhosis in suspected NAFLD patients. Baseline characteristics, laboratory test, NITs, and at-risk NASH were compared across FIB-4 categories (low, intermediate, high). **Results:** A total of 589 NAFLD patients were included in this study. The mean age was 65 in high FIB4 group and 52 in the low FIB4 group. Female population were 73.11% and 64.84% respectively in low FIB4 and high FIB4 group. The prevalence of at-risk NASH is 45.05% in high FIB4 group and 18.82% in low FIB4 group. 46% of the population had FIB4 < 1.3 and would have stayed within primary care without being further evaluated. In patients with FIB < 1.3, 23.8% of patients had a FAST score in the rule-in zone **e** 0.67 indicating the possibility of having at-risk NASH. Furthermore, on liver biopsy, 18.8% of patients had histology confirmed at risk NASH. Moreover, 17.8% of patients had AGILE3+ in the rule-in zone for advanced fibrosis (**e** 0.67). **Conclusion:** Approximately 20% of patients with NAFLD and low FIB4 index who are seen in specialty care may have at-risk NASH and 17% may have advanced fibrosis. These results validate the recommendation by AASLD that sequential testing starting by FIB4 index should only be used in low-prevalence populations by PCPs and not in high-prevalence populations seen in specialty clinics.

2125-A | VALIDATION OF A PLASMA SCREENING PANEL FOR PEDIATRIC NONALCOHOLIC FATTY LIVER DISEASE USING METABOLOMICS

Helaina E. Huneault[1], Alasdair E. Gent[2], Catherine C. Cohen[3], Zhulin He[4], Zachery R. Jarrell[5], Rishikesan Kamaleswaran[2] and Miriam B. Vos[6], (1)Nutrition & Health Sciences Doctoral Program, Laney Graduate School, Emory University, Atlanta, GA, USA, (2) Department of Biomedical Informatics, Emory University School of Medicine, Atlanta, GA, USA, (3) Section of Nutrition, Department of Pediatrics, School of Medicine, University of Colorado Anschutz Medical Campus, Aurora, CO, USA, (4)Pediatric Biostatistics Core, Department of Pediatrics, School of Medicine, Emory University, Atlanta, GA, USA, (5)Division of Pulmonary, Allergy and Critical Care Medicine, Emory University, Atlanta, GA, USA, (6)Division of Gastroenterology, Hepatology, and Nutrition, Department of Pediatrics and Nutrition and Health Sciences Graduate Program, Emory University

Background: Nonalcoholic fatty liver disease (NAFLD), the most common liver disease in children, is a leading cause of liver-related morbidity and mortality. Histological evaluation of liver biopsy remains the gold standard for diagnosis, although more efficient screening methods are needed. We previously developed a novel NAFLD screening panel in youth using machine learning applied to high-resolution metabolomics (HRM) and clinical phenotype data. Our objective was to validate this panel in a separate cohort. **Methods:** Clinical data were collected from a combined cross-sectional sample of children from three previously conducted studies. HRM was performed on fasting plasma samples. NAFLD was assessed by magnetic resonance imaging proton density fat fraction (MRI-PDFF), magnetic resonance spectroscopy (MRS), or evaluation of liver biopsy. Given available data, we used a modified version of our previous panel, which included waist circumference (WC), fasting insulin, glucose, and triglycerides. Metabolite features included three amino acids, two phospholipids, and dihydrothymine. To validate the panel, our data was split into training (67%) and test (33%) sets. Due to recruitment restrictions, oversampling was used to balance the training set. Support vector machine and random forest classifiers were tested. Model-specific hyperparameters were selected from a grid search (5-fold cross-validation) with an area under the receiver operating characteristic (AUROC) used for scoring. **Results:** A total of 161 patients with stored frozen samples were analyzed (75% male; 12.8 ± 2.6 years of age; BMI 31.0 ± 7.0 kg/m^2; 81% with NAFLD, 58% Hispanic race/ethnicity). Fasting insulin, triglycerides, HOMA-IR, total cholesterol, ALT, AST, and WC were significantly higher in children with NAFLD than non-NAFLD controls (all $p < 0.05$). Previously, our screening panel detected NAFLD with an AUROC of 0.94, sensitivity of 73%, and specificity of 97%, using a random forest classification model. Our present random forest model achieved an AUROC of 0.94, 95% sensitivity, and 80% specificity for detecting NAFLD in the test set (Figure 1). **Conclusion:** We were able to validate a modified version of our previous screening panel of metabolites and clinical phenotype variables for detecting pediatric NAFLD. Therefore, this panel has promising potential for use as a screening tool for NAFLD in youth. Further investigation to understand the biological significance of the included metabolic features is warranted.

Figure 1. ROC curve produced from the random forest classifier.

Keyur Patel[1,2], (1)University Health Network, (2) University of Toronto, (3)Mcgill University Health Centre, (4)University of Minnesota, (5)Department of Medicine, McGill University Health Centre, Westmount, QC, Canada, (6)Mcgill University

Background: Non-invasive methods to detect advanced fibrosis (F3-4) and cirrhosis (F4) are increasingly utilized to risk-stratify patients with non-alcoholic fatty liver disease (NAFLD). These include simple serum-based tests such as FIB-4 score. The recent AASLD guidance suggests use of 'rule-in' and 'rule-out' cut-offs, FIB4 **e** 3.48 and < 1.67, respectively, to detect F4. 'Rule-in' cut-off was based on a recent individual patient meta-analysis with 90% specificity for detection of cirrhosis. Our aim was to validate and assess performance of FIB-4 cut-offs in our cohort of patients with biopsy-proven NAFLD from two Canadian tertiary care centres. **Methods:** Patients were **e** 18 years at time of study onset, with biopsy-proven NAFLD, with biopsy completed between 2010 – 2021 at one of two tertiary care centres (University Health Network, Toronto, ON; McGill University Health Centre, Montreal, QC), with available FIB-4 scores from within ± 6 months of biopsy. Alternate causes of liver disease were excluded based on clinical review. were applied. Diagnostic test performance for FIB4 < 1.67 and **e** 3.48 to predict F4 was assessed using area under the receiver operating curve (AUROC). **Results:** 390 patients were included with mean age 48.7 ± 12.9 years, 54.6% were male, and 30.8% had diabetes. Prevalence of F4 was 22% (n = 87), with 21% F3 (n = 83), and 56.4% (n = 220) F0-2. Overall mean FIB-4 score was 1.81 ± 1.75, and 3.24 ± 2.16 for F4. FIB-4 had AUROC 0.79 at proposed thresholds, with 32% indeterminate or misclassified (Table 1) . Of patients with F4, 57.8% (n = 50) had a FIB-4 score < 3.48, and 23.0% (n = 20) had a FIB-4 score < 1.67. **Conclusion:** In our cohort of biopsy-proven NAFLD patients, FIB-4 with cut-offs **e** 3.48 and < 1.67 to 'rule in' and 'rule out' F4, respectively, performed with high specificity but limited sensitivity. However, nearly 60% of patients with cirrhosis would have been missed using an upper FIB-4 cut-off of 3.48. As such, the proposed FIB-4 thresholds for F4 are not yet optimized for use in tertiary clinical practice.

Table 1

F4 Prevalence 22%	AUROC (95% CI)	Sensitivity	Specificity	PPV	NPV	+LR	-LR	Indeterminates (n)	Misclassified (n)
FIB-4 <1.67 and ≥ 3.48	0.790 (0.740 – 0.834)	64.9%	93.1%	68.5%	92.0%	9.39	0.38	22.3% (87/390)	9.5% (37/390) False positives – n = 17 False negatives – n = 20

AUROC – area under the receiver operating curve; PPV – positive predictive value; NPV – negative predictive value; +LR – positive likelihood ratio; -LR – negative likelihood ratio; indeterminates – patients with FIB-4 ≥ 1.67 and < 3.48.

2127-A | VALIDATION OF LIVERFAST-GP+ (GP+) AS A NON-INVASIVE TEST FOR RISK STRATIFICATION FOR PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD): SINGLE-CENTRE STUDY USING LIVER BIOPSY AS REFERENCE STANDARD★

Yong Wen Leow[1], Lee Lee Lai[1], Nik Raihan Nik Mustapha[2], Sanjiv Mahadeva[1], Ronald Quiambao[3], Mona Munteanu[3] and Wah Kheong Chan[1], (1) University of Malaya, (2)Hospital Sultanah Bahiyah, (3) Fibronostics US Inc, USA

Background: LIVERFASt-GP+ (GP+) is an AI-based non-invasive test, devised to screen for and provide risk stratification for non-alcoholic fatty liver disease (NAFLD), by using simple blood biomarkers and anthropometric measurements. A study has found it to be superior to Fibrosis-4 score (FIB4), with no grey zone and no drawbacks related to age. Previous studies on GP+ have been carried out in US-based population and there are few validation studies elsewhere. We aimed to validate GP+ in our local population and to explore its role in combination with other non-invasive tests. **Methods:** We performed a retrospective analysis of data from NAFLD patients who underwent a liver biopsy at the University of Malaya Medical Centre in two previous studies. In addition, patients with diabetes who underwent transient elastography in a separate study and had controlled attenuation parameter < 248 dB/m and liver stiffness measurement (LSM) < 5 kPa were considered as not having steatosis and fibrosis. Patients were assigned to one of the four GP+ diagnostic categories, which included "No steatosis and fibrosis", "Steatosis only, no fibrosis", "Mild or moderate fibrosis, any steatosis", and "Advanced fibrosis, any steatosis", based on a proprietary algorithm. **Results:** The data for 350 patients were analyzed (median age 55 y, 45% male, advanced fibrosis 22%).

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

The Cohen's weighted kappa value for the agreement between GP+ diagnostic category and histological diagnosis was 0.179 (95% confidence interval 0.126 - 0.233; p-value = < 0.001), indicating a poor agreement. The sensitivity, specificity, positive predictive value, negative predictive value, misclassification rate and indeterminate results from assessments using GP+ alone, GP+ in combination with LSM, FIB4 alone and FIB4 in combination with LSM to diagnose advanced fibrosis are shown in Table 1. GP+ had a higher negative predictive value for advanced fibrosis compared with FIB4 and a lower misclassification rate when used as a two-step approach in combination with LSM for the diagnosis of advanced fibrosis compared to FIB4 in combination with LSM. **Conclusion:** GP+ may have a role in identifying NAFLD patients who require further evaluation with LSM and in risk stratification when used as a two-step approach in combination with LSM.

Table 3. The misclassification rate, indeterminate results, sensitivity, specificity, positive predictive value and negative predictive value using different approaches to identify patients with advanced fibrosis.

	GP+ alone	FIB4 alone	FIB4 alone without indeterminate group	Combination of GP+ and LSM	Combination of FIB4 and LSM
Misclassification, % (n/N)	42 (147/350)	14 (37/272)	22 (78/348)	8 (25/249)	11 (37/325)
Indeterminate results, % (n/N)	0 (0/350)	22 (76/348)	0 (0/348)	14 (48/347)	6 (20/345)
Sensitivity, % (n/N)	99 (61/61)	9 (3/33)	56 (38/68)	60 (25/42)	38 (20/53)
Specificity, % (n/N)	50 (142/282)	97 (232/239)	83 (232/280)	97 (249/257)	99 (268/272)
Positive predictive value, % (n/N)	30 (61/201)	30 (3/10)	44 (38/86)	76 (25/33)	83 (20/24)
Negative predictive value, % (n/N)	95 (142/149)	89 (232/262)	89 (232/262)	94 (249/266)	89 (268/301)

For the "FIB4 alone without indeterminate group" analysis, ≥1.3 and ≥2.0 were considered as diagnostic of advanced liver fibrosis for patients <65 years old and for patients ≥65 years old, respectively. For the "FIB4 alone" analysis, 1.3 – 2.67 and 2.0 – 2.67 was considered as indeterminate for patients <65 years old and for patients ≥65 years old, respectively; >2.67 was considered diagnostic of advanced liver fibrosis. For the "Combination of GP+ and LSM" analysis, patients with GP+ "Advanced fibrosis, any steatosis" result underwent LSM. For the "Combination of FIB4 and LSM" analysis, patients with indeterminate FIB4 result underwent LSM.

FIB4, Fibrosis-4 score; LSM, liver stiffness measurement.*

2128-A | VALIDATION OF NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD) OUTCOME SCORE (NOS) TO PREDICT LIVER-RELATED EVENTS IN NAFLD: AN INTERNATIONAL MULTICENTER STUDY

Wei Xuan Tay[1], Yiong Huak Chan[2], Majd Aboona[3], Michael W Song[4], Claire Faulkner[3], Nicole Xinrong Han[5], Jessica Cristiu[6], Karn Wijarnpreecha[7], Vincent Chen[8] and Yu JUN Wong[1], (1)Department of Gastroenterology & Hepatology, Changi General Hospital, Singapore, (2)Yong Loo Lin School of Medicine, National University of Singapore, Singapore, (3)University of Arizona College of Medicine, Phoenix, AZ, (4)University of Michigan, Ann Arbor, (5)Changi General Hospital, (6)University of Michigan, Ann Arbor, Michigan, USA, (7)University of Arizona College of Medicine Phoenix, Phoenix, AZ, (8)University of Michigan Medical Center

Background: Current AASLD and AGA guidelines recommend the sequential use of FIB-4 and liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE) to risk stratify Non-alcoholic fatty liver disease (NAFLD) patients, but availability of VCTE may limits the scalability of this approach. The NAFLD Outcome score (NOS), derived from six routine parameters (albumin, platelet, age, bilirubin, diabetes and INR) was introduced to identify at-risk NAFLD patients requiring surveillance for liver-related events (LRE). However, the comparative performance between NOS and liver-stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE), with or without FIB-4, as recommended by current guidelines, remained unclear. Aim: To compare NOS against LSM, with or without FIB-4 to predict the occurrence of the first LRE or major adverse cardiac events (MACE). **Methods:** We conducted an international multicenter retrospective cohort study including consecutive NAFLD patients who underwent VCTE from three centers in USA and Singapore. We exclude patients with prior LRE or MACE, concomitant liver disease, significant alcohol intake, unreliable LSM, missing value for NOS and those with follow-up less than 6 months. LRE was defined as liver decompensation, hepatocellular carcinoma and liver transplantation. MACE was defined as composite endpoints of either myocardial infarction, coronary revascularization, heart failure requiring hospitalization or stroke. **Results:** A total of 747 NAFLD patients with a diverse ethnic background were included (57.3% Asian, 13.5% Hispanic, 20.1% White, 3.5% black). The mean (±standard deviation) age was 55 (±14), 50% was male, 58% were obese, 49% were diabetic. Median FIB-4 was 1.1, median LSM was 6.7kPa, with 18% having advanced fibrosis and 21.6% having cirrhosis. Over a median follow-up of 34.5 months, the cumulative incidence of LRE and MACE was 6.2 (95%CI: 3.6-12.8) and 10.7 (95%CI: 10.6-10.9) per 1,000 person-years, respectively. While NOS had a comparable accuracy to predict LRE at 5 years than VCTE and FIB-4 (tAUC 0.93 vs 0.82 vs 0.92), NOS is more accurate than FIB-4 to predict MACE at 5-years (tAUC: 0.79 vs 0.62, DeLong's test: p = 0.003). To identify low-risk NAFLD patients who can be discharge to primary care, sequential FIB-4 and LSM identify more "low-risk NAFLD patients" at the expense of missing 18.2% of LRE than Fib-4 alone (0%)

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(Table 1). NOS at a revised cut-off (NOS < -2.3) identify more "low-risk" NAFLD patients than sequential testing of FIB-4/LSM (82.3% vs 76.6%) without missing more LRE (18.2% vs 18.2%). Both FIB-4, LSM and NOS has suboptimal performance to predict MACE in this cohort. **Conclusion:** The revised NOS cut-off (NOS < -2.3) may provide an alternative for population-based NAFLD risk-stratification, independent of VCTE. Validated tools in addition to fibrosis markers are needed to stratify MACE risk in NAFLD patients.

Table 1: Diagnostic performance of NOS, FIB-4 and LSM to predict the occurrence of liver-related events in NAFLD patients

Non-invasive tests (NITs)	Cut-off of NITs	Low-risk NAFLD	Missed LRE	Missed MACE
FIB-4 alone	FIB4 <1.3	440/747 (58.9%)	0/11 (0%)	9/18 (50%)
Sequential FIB-4 and NOS	FIB-4 < 1.3, then NOS < -1.3	771/747 (95.2%)	8/11 (72.7%)	15/18 (83.3%)
Sequential FIB-4 and LSM	FIB-4 < 1.3, then LSM < 8 kPa	572/747 (76.6%)	2/11 (18.2%)	11/18 (61.1%)
NOS	NOS <-1.3	708/747 (94.8%)	8/11 (72.7%)	14/18 (77.8%)
NOS	NOS <-2.3	615/747 (82.3%)	2/11 (18.2%)	10/18 (55.6%)

2129-A | VALIDATION OF THE HISTOINDEX AI DIGITAL PATHOLOGY PLATFORM AS AN AIDING TOOL TO INCREASE PATHOLOGIST CONCORDANCE ON FIBROSIS STAGING IN NASH

Desiree Abdurrachim[1], Serene Lek[2], Yongqi Zhou[1], Chun Kit Wong[1], Charlene Zhi Lin Ong[1], Ashmita Saigal[3], Radha Krishnan[4], Geoffrey Walford[5], Elaine Lay Khim Chng[6], Dean Tai[6], Gideon Ho[6], Annaswamy Raji[7], Thomas Forest[8], Richard Baumgartner[9], Saswata Talukdar[3], Chih-Liang Chin[3], Samuel S. Engel[7], Asad Abu Bakar Ali[1], David E Kleiner[10] and Arun Sanyal[11], (1)Cardiometabolic Diseases, MSD, Singapore, (2) Clinnovate Health UK Ltd, UK, (3)Cardiometabolic Diseases, Merck & Co., Inc., South San Francisco, CA, (4)Global Clinical Development, MSD (UK) Limited, London, UK, (5)Translational Medicine, Merck & Co., Inc., Boston, MA, USA, (6)Histoindex Pte Ltd, Singapore, (7)Global Clinical Development, Merck & Co., Inc., Rahway, NJ, USA, (8)Non-Drug Safety, Merck & Co., Inc., West Point, PA, USA, (9)Biostatistics and Research Decision Sciences, Merck & Co., Inc., Rahway, NJ, USA, (10)Laboratory of Pathology, National Cancer Institute, Bethesda, MD, (11) Department of Internal Medicine, Virginia Commonwealth University, Richmond, VA

Background: Intra- and inter-observer variability in histological staging of fibrosis in NASH clinical trials lead to suboptimal selection of patients and confound assessment of fibrosis response. Aim: To prospectively evaluate the utility of the HistoIndex artificial intelligence (AI) digital pathology tool to improve the reliability of fibrosis staging in NASH. **Methods:** Histology slides from two trials (NCT #03517540, #03912532) including 80 baseline/screening biopsies and 40 paired baseline and end-of-treatment biopsies were used. Four expert hepato-pathologists, masked to each other, read a total of 120 biopsy sections twice each, masked to study source, with and without the AI aiding tool respectively, in random order reading 30 biopsies each week. Following a washout period of 4 weeks, the process was repeated again. The AI aiding tool consisted of unstained second harmonic generation/two photon excitation fluorescence (SHG/TPEF) images and the AI quantitative fibrosis (qF) values. Pathologist median scores were considered the reference standard. Inter-observer kappa was computed. The impact of harmonization on need for adjudication using the current FDA-recommended approach to histological assessment was also determined. Significance was set at $P < 0.05$. **Results:** The fibrosis stage distribution (based on pathologist median without AI) is F0: 6, F1: 12, F2: 48, F3: 27, F4: 25. Compared to conventional reads, AI-assisted reads improved inter-observer kappa, with the greatest impact shown for F0-F2 population (figure). In clinical trials, this kappa improvement would have reduced the number of cases requiring adjudication by a third reader by 30%. The rates of concordance between 4 pathologists for inclusion of NASH with F2-F3 increased from 45% to 74% with AI; concordance on exclusion of other stage combinations increased from 38% to 55%. This was associated with decreased variance around the median reads. For masked assessment of treatment response, AI increased concordant assessment of fibrosis response from 49% to 61%. Overall, at least 3 out of 4 pathologists considered SHG/TPEF image useful in 83% cases and qF values useful in 55% cases; this was greatest for F1-F2. **Conclusion:** SHG/TPEF-based HistoIndex

AI tool enhances pathologist confidence and inter-rater reliability for assessment of fibrosis stage in NASH. They validate the utility of SHG/AI as an aid for pathologist assessment of fibrosis. These data support the use of SHG/AI to enhance the efficiency of clinical trials and reliability of fibrosis readouts of response from trials.

D'alessandro", Università Di Palermo, Palermo, Italy

Background: International regulatory agencies recommend testing drug therapy for patients with compensated nonalcoholic fatty liver disease (NAFLD)-related cirrhosis or with noncirrhotic fibrotic nonalcoholic steatohepatitis (NASH) because they are at risk of developing liver-related events (LRE). We aimed to compare the risk of LRE in NAFLD patients stratified for F2-F4 fibrosis and NASH. The secondary aim was to compare the accuracy of histologically defined fibrotic NASH with liver stiffness measurement (LSM) and AGILE 3+ score for prediction of LRE. **Methods:** 1938 consecutive patients with biopsy-proven NAFLD (Kleiner scoring system) were enrolled. Fibrotic NASH was defined as NASH with F2-F4 fibrosis. LSM was measured by transient elastography (FibroScan device). LRE were recorded during follow-up. Cox multivariate models were used to assess the association between fibrotic NASH or F2-F4 fibrosis without NASH, of LSM (**e** 8 or **e** 10 Kpa) and of AGILE 3+ with LRE. The diagnostic performance for the prediction of LRE was assessed using the area under the receiver operating characteristic (AUROC) curves. **Results:** The observed 5-year actuarial rate of LRE was 0.4%, 0.2%, 5.1% and 6.6% in patients with F0-F1 fibrosis without NASH, F0-F1 fibrosis with NASH, F2-F4 fibrosis without NASH, and fibrotic NASH, respectively. At multivariate Cox regression analysis using F0-F1 fibrosis without NASH as reference, both F2-F4 fibrosis without NASH (adjusted hazard ratio [aHR] 9.96, 95% C.I. 3.35 - 29.62, $p < 0.001$) and fibrotic NASH (aHR 10.14, 95% C.I. 3.51 - 29.25, $p < 0.001$) were associated with LRE occurrence. In the 1074 patients with available LSM, LSM **e** 10 KPa (aHR 6.31, 95% C.I. 2.46 - 16.2, $p < 0.001$) or AGILE 3+ > 0.67 (aHR 27.45, 95% C.I. 5.72 – 131.74, $p < 0.001$) independently predicted the development of LRE and had similarly acceptable 5-year AUROC to fibrotic NASH and F2-F4 fibrosis (0.772, 0.818, 0.739, and 0.780, respectively). **Conclusion:** The risk of developing LRE is similar in patients with fibrotic NASH and with F2-F4 fibrosis without NASH. The use of LSM **e** 10 KPa or AGILE 3+ > 0.67 could be an accurate option to identify NAFLD patients worthy to be included in clinical trials testing new pharmacological agents.

2131-A | A CROSS-SECTIONAL ONLINE SURVEY TO UNDERSTAND EXISTING NAFLD/NASH CURRICULUM GAPS IN US PRIMARY CARE PROVIDER AND SPECIALTY TRAINING PROGRAMS

Alina M. Allen, Department of Gastroenterology and Hepatology, Mayo Clinic, Rochester MN, USA, Michael R. Charlton, University of Chicago, Anthony Hoovler, Novo Nordisk Inc., Amy Articolo, Novo Nordisk Inc., Moorestown, NJ, Travis Fisher, Novo Nordisk Inc, Douglas T. Dieterich, Icahn School of Medicine at Mount Sinai, New York, NY, Stephen A Harrison, Pinnacle Clinical Research Center, San Antonio, TX and Mazen Noureddin, Houston Research Institute, Houston, TX

Background: NAFLD affects approximately 30% of the US population and up to 25% of patients with NAFLD progress to NASH. Unrecognized and unaddressed, NASH can lead to significant hepatic and extrahepatic – especially cardiovascular – morbidity and mortality. Inclusion of NAFLD in the Graduate Medical Education curricula is critical to ensure proficiency in the identification and care of patients with NAFLD. This study aimed to identify gaps, uncover barriers to implementation and opportunities to improve NAFLD education in current US training programs for specialists and primary care providers (PCPs), who care for most patients with NAFLD. **Methods:** A nationwide, cross-sectional, quantitative online survey of residency / fellowship program leaders in hepatology, gastroenterology, endocrinology and primary care (internal medicine and family practice) and of NP/PA program leaders was conducted from 2/2023-5/2023. An IRB exemption was issued. **Results:** 181 respondents completed the survey; 93 (51%) represented PCP programs, 40 (22%) represented specialist programs and 48 (27%) represented NP/PA programs. NAFLD was included in the core curriculum of 97% of all programs and NASH was included in 92%, mostly via seminars, lectures or conferences; however, NASH education during inpatient rotations was included in 72%. The inclusion of NASH education was considered to be very appropriate (85%) and very important (73%) by majority of specialist programs, followed by PCP programs (72%, 56%) and NP/PA programs (63%, 50%). PCP curricula directors believe their trainees are more responsible than specialists for identifying and screening patients at risk for NASH. Among NASH core competencies, most PCP, specialty and NP/PA programs were likely to include education on risk factors/comorbidities, long-term complications, NASH clinical characteristics, NASH screening and diagnosis, and lifestyle management, but less likely to include education on pharmacologic intervention, clinical trials, and genetic risk. Of 18 NASH diagnostic test options surveyed within a program's core curriculum, only eight were included by at least 50% of programs (Fig. 1). FIB-4, a cornerstone screening tool, was covered in only a third of primary care programs but was covered in more than three quarters of specialty-based programs. The main barriers to integrating NASH education were lack of space in the curriculum, access to expert faculty and available treatments. Only 29% of respondents expressed plans to expand their NASH curricula. **Conclusion:** Despite inclusion in most PCP and specialist program curricula, results from this survey suggest significant gaps in NASH education, particularly in screening and diagnostic tools. However, directed training program enhancements may serve to elevate provider proficiency in the care of patients with NASH.

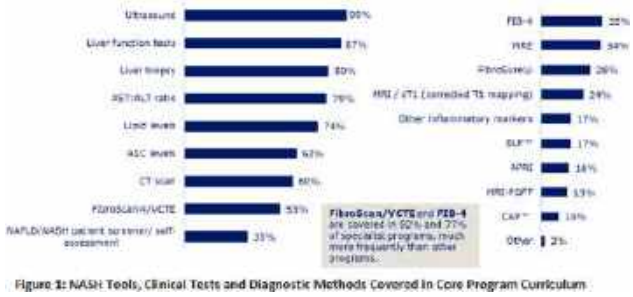

Figure 1: NASH Tools, Clinical Tests and Diagnostic Methods Covered in Core Program Curriculum

Angers, France; & Laboratoire Hifih, Sfr Icat 4208, Université D'angers, Angers, France

Background: EASL and AASLD both recommend screening of liver fibrosis in at-risk individual's. However, the criteria defining "at-risk individual's" are not clearly established. The aim of this study was to define the picture of the patient at risk of elevated liver stiffness who needs evaluation with non-invasive tests for liver fibrosis. **Methods:** Four cohorts of patients from tertiary care (included in diabetology, pneumology and cardiology) or primary care were included in the derivation set. Two cohorts from the general population (Rotterdam and France) were included in the validation set. All patients were older than 40 and had a LS measurement (LSM) with FibroScan. The primary endpoint was the presence of LSM > 8 kPa. **Results:** In the derivation cohort (1,483 patients): median age was 60 years, 68.6% were male, median BMI was 29.1 kg/m^2 (IQR 26.0-32.0), 32.8% had type 2 diabetes mellitus (T2DM), 60.1% were on antihypertensive therapy, 41.0% used lipid-lowering drugs. Median alcohol consumption was 20 g/week. Median LSM was 5.9 (IQR: 4.5-8.1) kPa, 25.7% of patients had a LSM > 8 kPa. In multivariate analysis adjusted for age and sex, three risk factors were significantly associated with LSM > 8 kPa: T2DM, BMI > 30 kg/m^2 and alcohol consumption more than WHO thresholds ($p < 0.001$). The rate of LSM > 8 kPa increased with the number of risk factors, from 10% (no risk factor) to 65% (3 risk factors; Figure 1A). In the validation cohorts from France and the Netherlands (Rotterdam study) respectively, 1,190 and 4,377 patients were included. Median age was 57 and 67 years, median BMI was 26.3 (IQR 23.5-28.7) and 26.8 (IQR 24.4-29.4) kg/m^2, and 7.6 and 8.2% had T2DM. Median LSM was 5.3 (IQR 4.4-6.5) and 4.8 (IQR 3.9-6.0) kPa; 7.7 and 6.0% of individual's had a LSM > 8 kPa. In the French cohort, the rate of LSM > 8 kPa increased, from 5.5% in patients without risk factors to 28.6% in case of 2 risk factors (no patient had 3 risk factors; Figure 1A). In the Dutch (Rotterdam) cohort, 4.2% without risk factors had LSM > 8 kPa and this rate reached to 33.3% in case of 3 risk factors (figure 1A). **Conclusion:** We propose that the definition of being at-risk for liver fibrosis in those individual's older than 40 years should be based on three clinical conditions: presence of T2DM, BMI > 30 kg/m^2 and alcohol consumption more than WHO thresholds. In case of one risk factor, a simple screening test should be prescribed. In case of 2 or 3 risk factors, the liver should be evaluated more carefully (Figure 1B).

2133-A | A RAPID RISE IN THE GLOBAL PREVALENCE OF NONALCOHOLIC FATTY LIVER DISEASE (NAFLD) AND NON-ALCOHOLIC STEATOHEPATITIS (NASH) AMONG PATIENTS WITH TYPE 2 DIABETES (T2D)

Zobair M. Younossi[1,2,3,4], Pegah Golabi[1,2,3,4], Jillian K. Price[1,2,3], Soroor Owrangi[1], Nagashree Gundu-Rao[5], Romona Satchi[5] and James M. Paik[1,2,3,4], (1)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (2)Center for Liver Disease, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, VA, (3)Inova Medicine, Inova Health System, Falls Church, VA, (4)The Global Nash Council, Washington, DC, (5)Division of Endocrinology, Inova Health System, Falls Church, VA

Background: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease and closely associated with type 2 diabetes. (T2D). Our aim was to estimate the global prevalence of NAFLD, non-alcoholic steatohepatitis (NASH), and advanced fibrosis among patients with T2D. **Methods:** We systematically searched PubMed and Ovid MEDLINE for terms including NAFLD, NASH, and T2D and collected data from the (1990-2019) survey year (last published December 2022) according to PRISMA. Two reviewers independently assessed study eligibility, extracted data, and assessed studies for bias. The meta-analysis was conducted using a random-effects model. Assessment of bias risk used the Joanna Briggs Institute. **Results:** The search identified 3134 studies from 33 countries. Of these, data were extracted from 122 eligible studies that included 2,224,144 patients with T2D to determine the prevalence of NAFLD. Another 12 studies with 2,733 T2D patients with liver biopsy data were eligible for determination of the prevalence of NASH, significant fibrosis (SF, **e** F2) and advanced fibrosis (AF, **e** F3). Across the entire study period (1990-2021), the global pooled prevalence of NAFLD (based on transient elastography CAP) among patients with T2D was 62.25% (47.12-77.38%). In patients with T2D, the global NAFLD prevalence has increased by +50.09% [45.52% (25.01-67.57) in 1990-2004 to 68.32% (63.20-73.04)] in 2016-2021 ($p = 0.008$). The highest NAFLD prevalence among T2D patients was observed in Eastern Europe ($n = 11$ studies, 78.95%, 73.90-83.25%), followed by Middle East ($n = 15$, 69.83%, 60.67-77.86%), Western Europe ($n = 19$, 68.52%, 63.75-72.92%), USA & Australia ($n = 14$, 63.82%, 50.75-75.12%), South Asia ($n = 24$, 62.61%, 55.09-69.58%), East Asia ($n = 17$, 60.89%, 56.26-65.33%), Asia Pacific ($n = 10$, 51.56%, 38.83-64.08), Latin America ($n = 6$, 51.35, 38.83-64.08%), and Africa ($n = 6$, 43.05%, 20.82-68.49%). Among NAFLD patients withT2D who had available liver biopsy, the global pooled prevalence of NASH, significant fibrosis (**e** F2) and advanced fibrosis (**e** F3) were 59.69% (44.35-73.34%), 46.30% (29.35-64.16%), and 25.38% (15.95-37.87%), respectively. **Conclusion:** The prevalence of NAFLD among T2D is very high and growing. The majority of NAFLD patients with T2D have NASH with a significant proportion having Advanced Fibrosis. Patients with NAFLD and T2D should be prioritized for risk stratification using recently developed algorithms.

2134-A | AASLD/AGA NAFLD PRACTICE GUIDANCE FOR SCREENING DIABETICS: FACTORS ASSOCIATED WITH ADVANCED FIBROSIS, IMPLICATIONS FOR CARE DELIVERY, AND COST-REDUCTION USING AGE-ADJUSTED FIB-4 CUT-OFFS

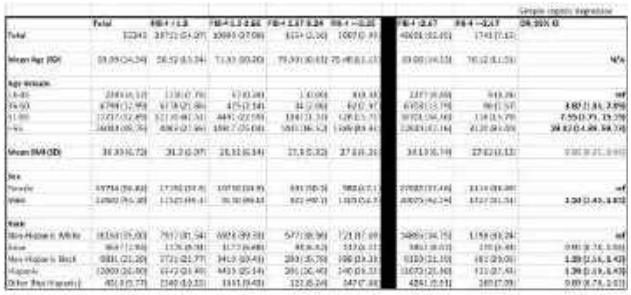
Rohit R Nathani[1], Anna Mageras[2], Carolina Villarroel[3], Silpa Yarra[3], Nina Priven[1], Heather Viola[1], Stephanie Wang[1], Theresa Mack[1], Martin Arron[1], Fernando Carnavali[1], Xiaotao Zhang[2] and Meena B. Bansal[2], (1)Mount Sinai Morningside and West Hospital, (2)Icahn School of Medicine at Mount Sinai, (3)Mount Sinai Beth Israel Hospital

Background: Patients with NAFLD and advanced fibrosis have the highest risk of liver-related mortality. AASLD/AGA recommends a sequential algorithm of FIB-4 score followed by VCTE to identify diabetic patients with advanced fibrosis requiring hepatology evaluation. This study aimed to characterize a diverse urban DM population, calculate FIB-4 scores, identify factors associated with FIB-4 **e** 2.67, and determine cost implications of algorithm adherence. **Methods:** Using the Mount Sinai Health System's DM registry, we identified patients aged 18+ who received primary care in 2022. Labs to calculate FIB-4 scores and baseline demographic and referral data were extracted from the EMR. FIB-4 scores were stratified as low (< 1.30), indeterminate (1.3-2.66), high risk for advanced fibrosis (2.67-3.24), and cirrhosis (**e** 3.25). Chi square and Anova tests were used to compare demographics and BMI across FIB4 groups. Logistic regression was used

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

to determine factors associated with FIB4 **e** 2.67. Total referral costs for VCTE/hepatology were calculated using insurance-specific rates (cohort: 49% Medicare, 36% commercial, 15% Medicaid), and sub-analyses were conducted to evaluate different age-specific cut-offs. **Results:** Among 57,151 adult diabetic patients, FIB-4 scores could be calculated for 91.6% (n = 52,342). Table 1 presents the distribution of age, BMI, sex, and racial/ethnic categories across FIB-4 categories. Male (1.53, 95% CI: 1.43, 1.65), Hispanic (1.30; 95% CI: 1.19, 1.43), and non-Hispanic Black (1.29, 95% CI: 1.16, 1.42) patients had increased odds of FIB4 **e** 2.67 compared to women and non-Hispanic white patients, respectively. BMI was inversely associated with FIB-4 **e** 2.67 (0.95, 95% CI: 0.95, 0.96). Only a small percentage of patients with FIB-4 1.3-2.66 (4%) were referred to VCTE or hepatology, while 14% with FIB-4 **e** 2.67 were referred to hepatology. Adjusting the indeterminate zone cut-off for patients over 65 to FIB-4 **e** 2 reduced the number of patients in the indeterminate zone from 57% to 17%, leading to potential cost savings of approximately $2 million. For patients aged 18-35, using a lower cut-off of FIB-4 **e** 1 increased potential costs by $24K as more patients would require further evaluation. **Conclusion:** FIB-4 scores can be easily calculated for most diabetic patients based on routinely ordered labs. Male sex, Hispanic and Black race/ethnicity were significantly associated with higher FIB-4 scores. The low referral rates to hepatology suggest a lack of awareness regarding FIB-4 use for risk stratification and adherence to AASLD/AGA guidance. Age-adjusted cut-offs can help reduce costs and unnecessary referrals. Implementing an EMR-based FIB-4 calculator, provider usage and patient outcome reports, and robust educational programs may improve adherence to the AASLD/AGA guidance pathway. The efficacy of these interventions is currently under evaluation.



Projected Costs for VCTE/Hepatology referrals by FIB-4 groups

2135-A | ADHERENCE TO DIETARY APPROACHES TO STOP HYPERTENSION DIET AND NON-ALCOHOLIC FATTY LIVER DISEASE IN A NATIONALLY REPRESENTATIVE SAMPLE OF U.S. CHILDREN AND YOUTH

Vanessa Garcia-Larsen[1], Hani Tamim[2], Kirstie Ducharme-Smith[1], Faisal M Sanai[3] and Saleh A Alqahtani[4,5], (1)Johns Hopkins University, (2)Alfaisal University, (3)King Abdulaziz Medical City-Jeddah, (4) Johns Hopkins University School of Medicine, (5)King Faisal Specialist Hospital and Research Center

Background: Non-alcoholic fatty liver disease (NAFLD) has become increasingly prevalent among children and youth. Lifestyle-related factors, including diet, modulate the risk of NAFLD, but evidence on the role of diet quality in NAFLD in young people is scant. We aimed to investigate the association of adherence to the Dietary Approaches to Stop Hypertension (DASH) diet and NAFLD amongst U.S. youth. **Methods:** Children and youth aged 12-29 years of age participating in the National Health and Nutrition Examination Survey (NHANES) cycles between 2005-2016 were included in this study. NAFLD was assessed using the improved U.S. fatty liver index (iFLI) for the multiethnic U.S. population, which predicts the presence of NAFLD based on age, ethnicity, waist circumference, gamma-glutamyltransferase activity, fasting insulin, and fasting glucose. Diet quality was assessed using the DASH diet score (higher scores = better adherence). Survey-weighted logistic regression models were used to investigate the association of DASH score (quartiles) and NAFLD (iFLI **e** 30 used in this study), adjusting for age, sex, race/ethnicity, body mass index (BMI), total energy intake, household income, education, and NHANES cycle. **Results:** A total of 5,586 participants (mean age 19.1 ± 5.1 y) with complete data were

included; 15.1% of all subjects, including 12.3% of children (< 18 y of age), and 17.9% of those aged 18+ had an iFLI **e** 30. The mean DASH pattern score of subjects was 22.3 (SD ±5.0), indicative of 46% adherence to the DASH-style diet pattern. Compared with those with lowest adherence (quartile 1), those with highest adherence (quartile 4) to the DASH pattern had lower odds of having NAFLD (adjusted odds ratio 0.68; 95% confidence interval 0.48, 0.95). **Conclusion:** Amongst U.S. children and youth, adherence to the DASH diet was negatively associated with NAFLD, independently of other important risk factors, including BMI. Improving diet quality in this age group may contribute to preventing NAFLD.

2136-A | AGE HAS INDEPENDENT POSITIVE AND NEGATIVE ASSOCIATIONS WITH ADVANCED FIBROSIS AND STEATOSIS: COMBINED DATA FROM MULTIPLE THERAPEUTIC TRIALS INCLUDING MORE THAN 6,000 PATIENTS (IN COLLABORATION WITH NAIL-NIT CONSORTIUM)

Stephen A Harrison[1], Julie Dubourg[2], Sophie Jeannin[2], Naim Alkhouri[3], Jörn M. Schattenberg[4] and Mazen Noureddin[5], (1)Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom, (2) Summit Clinical Research, San Antonio, TX, (3)Arizona Liver Health, Phoenix, AZ, (4)I. Department of Medicine, University Medical Centre Mainz, Johannes Gutenberg University, Mainz, Germany, Mainz, Germany, (5) Houston Research Institute, Houston, TX

Background: Age has been previously identified as an independent risk factor for fibrosis severity in non-alcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH). We aimed to assess the relationship between age and NAFLD/NASH components. **Methods:** We combined screening data from 7 NASH non-cirrhotic phase 2 trials. We performed univariate and multivariate logistic regression analyses to predict advanced fibrosis (as defined by fibrosis stages F3-F4) and to predict higher grades of steatosis (as defined by steatosis grades 2 or 3). **Results:** Out of 6,558 patients, 2,271 with centrally assessed liver biopsies were included in this analysis. The mean age was 54.2 years (y) (SD: 11.7). The presence of advanced fibrosis increased with age ranging from 12.5% in age < 25y, to 22.8% in age 25-45y, to 33.4% in age 45-65y and to 39.9% in age > 65y. Inversely, the presence of grade 3 steatosis decreased with age ranging from 40% in age < 25y, to 32.3% in age 25-45y, to 23.2% in age 45-65y and to 16.2% in age > 65y. In multivariate analysis, after adjustment on gender, ethnicity, AST, glycated hemoglobin (HbA1c) and liver stiffness measurement (as measured by FibroScan®), age remained significantly associated with the severity of fibrosis ($p < 0.001$, Figure). After adjustment on gender, ethnicity, ALT, HbA1c and controlled attenuation parameter (as measured by FibroScan®), age remained negatively associated with the severity of steatosis ($p = 0.001$, Figure). **Conclusion:** This analysis provides compelling evidence supporting the natural course of NAFLD as a disease with slow progression. As individual's age, we observed a decrease in steatosis accompanied by a worsening of fibrosis. These findings underscore the dynamic nature of NAFLD and highlight the importance of longitudinal studies to better understand its trajectory over time.

2137-A | AMONG PEOPLE WITH HIV, NON-HISPANIC BLACKS HAVE A SIGNIFICANTLY LOWER PREVALENCE OF NAFLD AND CLINICALLY SIGNIFICANT FIBROSIS

Eduardo Vilar-Gomez II[1], Samer Gawrieh[1], Jordan E. Lake[2], Tinsay A. Woreta[3], Montreca Releford[1], Mark S. Sulkowski[4], Rohit Loomba[5], Jennifer C. Price[6], Kathleen E. Corey[7], Susanna Naggie[8], Sonya Heath[9], Laura Wilson[10], Richard K. Sterling[11] and Naga P. Chalasani[1], (1)Indiana University School of Medicine, (2)University of Texas - Houston, (3)Johns Hopkins Medicine, Baltimore, MD, (4)Johns Hopkins Medicine, (5)University of California, San Diego, San Diego, CA, (6)University of California, San Francisco, (7)Harvard University, (8)Duke Clinical Research Institute, Durham, NC, (9)University of Alabama at Birmingham, (10)Johns Hopkins School of Public Health, (11)Virginia Commonwealth University Health System

Background: Racioethnic differences in the prevalence of NAFLD and clinically significant fibrosis (CSF) have been previously reported but this has been adequately investigated in people with HIV (PWH). We estimated racioethnic differences in the prevalence of NAFLD and CSF among PWH. **Methods:** This cross-sectional

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

analysis includes PWH ≥ 20 years prospectively enrolled in two US multicenter studies from March 2018 to April 2023 who underwent VCTE examinations (Fibroscan®). NAFLD was defined by CAP ≥ 263 dB/m in the absence of excessive alcohol intake, steatogenic medications, and other causes of liver disease. CSF was defined as LSM ≥ 8 kPa. Self-reported racioethnic groups included non-Hispanic White (NHW), non-Hispanic Black (NHB), and Hispanic. Associations between racioethnic groups and the risk of NAFLD and CSF were examined via multivariable logistic regression models. **Results:** The study sample included 873 adults (mean age, 52 y; 72% men; 253 [29%] NHW, 409 [47%] NHB, and 211 [24%] Hispanic. NAFLD and CSF were present in 465 (53%) and 131 (15%) individual's, respectively. The prevalence of NAFLD was 60% for NHW, 43% for NHB, and 64% for Hispanics (overall $P < 0.01$). The prevalence of CSF was 22% for NHW, 11% for NHB, and 13% for Hispanic (overall $P < 0.01$). As compared with NHW, upon controlling for relevant co-variates (Table), NHB had lower risk of both NAFLD (Adj. OR: 0.37, 95% CI: 0.23-0.58) and CFS (Adj. OR: 0.44, 95% CI: 0.26-0.75). There was no difference in the risk of NAFLD and CSF between NHW and Hispanic ethnicity in the controlled analysis (Table). There was no association with antiretroviral therapy, CD4 cell counts, or HIV viral load (data not shown). In addition to race, age, body mass index (BMI), waist circumference, type 2 diabetes (T2D), ALT, and triglyceride levels were independently associated with the risk of NAFLD (Table). Age, BMI, waist circumference, T2D, hypertension, ALT, AST, and platelet count were independently associated with the risk of CSF (Table). **Conclusion:** Non-Hispanic Black race is associated with lower prevalence of NAFLD and clinically significant fibrosis, in comparison to NHW and Hispanic ethnicity in a large cohort of PWH. Hispanic ethnicity is not associated with a higher prevalence of CSF than NHW in this cohort. HIV related factors did not influence NAFLD prevalence. Social drivers of health and genetic factors may underlie these differences and require further study.

Results based on logistic multivariable analysis.

	NAFLD (CAP≥263 dB/m)		CSF (LSM≥8 kPa)	
Variable	OR (95% CI)	P value	OR (95% CI)	P value
Age	1.03 (1.009-1.05)	<0.01	1.03 (1.006-1.05)	0.01

2138-A | ASSESSING NAFLD AWARENESS AND EDUCATIONAL NEEDS IN PATIENTS WITH TYPE 2 DIABETES

Alexander Kusnik, Hassan Liaqat, Javeria Nasir, Roshan Subedi, Rutwik Pradeep Sharma, Andrew Jung, Nicole Hunter, Rafia Zafar, Ari Chodos, Richard Alweis and Krishnakumar Rajamani, Rochester Regional Health

Background: Inadequate awareness of non-alcoholic fatty liver disease (NAFLD) is assumed among individual's with type 2 diabetes mellitus (T2DM), necessitating a better understanding of their existing awareness levels and educational requirements. This understanding is crucial for developing effective interventions and programs aimed at early detection and management of NAFLD. **Methods:** This prospective study utilized a 36-item survey administered through tablet computers in an endocrinologist's office, using the REDCap platform. A total of 179 patients participated in the study, providing information about their education, marital status, income, awareness of liver disease, knowledge of diabetes complications, and educational needs regarding NAFLD. These responses were also correlated with relevant blood work and medical imaging suggesting liver disease. **Results:** Out of 179 respondents, 59.00% were female (106) and 40.80% were male (73). The mean age for females was 61 years, and for males, it was 63 years. The majority identified as White (86.00%), followed by African-American (10.10%), Hispanic (2.20%), and Asian (1.7%). In terms of marital status, 59.9% were married, 19.8% were single, 10.70% were divorced, and 9% were widowed. Regarding educational status, the majority of patients were high school graduates (30.7%) or had completed professional/vocational/technical training (23.5%). Approximately 30% had a bachelor's degree or higher. The mean body mass index (BMI) was 61 for females and 62.6 for males. Respondents' income distribution: Less than $30,000 - 23.60%, $30,000-$50,000 - 24.10%, $50,000-$100,000 - 33.90%, $100,000 or above - approximately 18%.The mean duration of T2DM was 15.95 years for males and 22.58 years for females. More than 92% of respondents reported either having no preexisting liver disease or being uncertain about their own liver disease. Awareness of NAFLD was limited, with 72.9% having only slight awareness or being completely unaware. Summarizing the degree of agreement based on a 7-point Likert scale, the preferred learning methods regarding NAFLD were doctor-led education (93.2%), access to pamphlets in the doctor's office (82.4%), and educational videos during wait times (81.5%). Patients agreed that there is a need for more information about NAFLD from healthcare personnel (88.2%) and increased availability of NAFLD resources on the internet, television, or social media (81.3%). **Conclusion:** Our study reveals an interest among patients with T2DM to learn about NAFLD. The data collected in the endocrinology outpatient setting indicates that patients favor doctor-led education, pamphlets, and videos as their preferred learning methods for NAFLD, particularly during wait times. Supplying educational materials like pamphlets and videos on NAFLD could boost awareness in this high-risk population and potentially facilitate doctor-led education.

2139-A | ASSESSMENT OF NAFLD AWARENESS AND DIAGNOSTIC TOOL UTILIZATION AMONG INTERNAL MEDICINE RESIDENTS IN THE UNITED STATES

Alexander Kusnik[1], Richard Alweis[1], Andrew Brown[2], Ari Chodos[1], Seshavadhani Kumar[3] and Krishnakumar Rajamani[1], (1)Rochester Regional Health, (2)University of Rochester, (3)Rochester Institute of Technology

Background: NAFLD, often linked to obesity and metabolic syndrome, is commonly underdiagnosed,

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and the level of NAFLD knowledge among Internal Medicine Residents is largely unexplored. Considering their crucial role in patient care across diverse settings, it is imperative to identify and address knowledge gaps to improve patient outcomes. **Methods:** To assess NAFLD knowledge among Internal Medicine residents, an anonymous Research Electronic Data Capture (REDCap) survey was distributed via professional email addresses to residents from six community and university hospitals. The survey included questions adapted from the NASH Needs Assessment Survey, allowing for comparisons with existing data from gastroenterologists, endocrinologists, and Primary Care Physicians (PCPs). Additionally, the survey inquired about the utilization of recommended diagnostic tools, such as the FIB-4 score and elastography, to accurately diagnose NAFLD. **Results:** The study involved 86 Internal Medicine residents, whose responses regarding NAFLD prevalence and definitions are depicted in Figure 1. Comparing these findings with data from the NASH Needs Assessment Survey, including gastroenterologists, endocrinologists, and PCPs, strong evidence (p-value 0.001, at a significance level of 5%) suggests that the proportion of residents aware of the definition of non-alcoholic fatty liver (NAFL) is at least 9% smaller than that of Gastroenterologists/Hepatologists (G/H). Moreover, a statistically significant difference (p-value **H** 0) in awareness levels emerges among residents concerning the prevalence of NAFLD between men and women compared to primary care physicians. The upper bound of the 95% confidence interval is -0.096, indicating that the proportion of residents aware of the extent of NAFLD prevalence between men and women is at least 9.6% smaller than that of primary care physicians and at least 20% smaller than that of gastroenterologists. Despite the relative awareness of NAFLD, 75% of surveyed Internal Medicine residents reported not screening for NAFLD/NASH in clinical practice. Additionally, most respondents (88% and 82%) indicated that they had never or rarely utilized the recommended FIB-4 screening tool or liver stiffness measurement, respectively. Nearly all residents (98%) expressed the need for increased attention to NAFLD and its complications during their residency training. **Conclusion:** This study compares NAFLD awareness levels between Internal Medicine residents and other healthcare professionals. Despite some level of awareness, a notable proportion of surveyed residents exhibited limited familiarity with diagnostic tools and expressed a need for additional education on NAFLD/NASH during their residency training. This highlights the importance of implementing structural interventions within Internal Medicine residency programs to enhance NAFLD diagnostic strategies.

2140-A | ASSOCIATION BETWEEN BARIATRIC SURGERY AND MACROVASCULAR DISEASE AND MORTALITY OUTCOMES IN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE, TYPE 2 DIABETES, AND OBESITY

Arunkumar Krishnan, Atrium Health Levine Cancer Institute, Tinsay A. Woreta, Johns Hopkins Medicine, Baltimore, MD, Dipatsree Mukherjee, Apex Institute of Medical Sciences, William R. Hutson, West Virginia University School of Medicine and Saleh A Alqahtani, Johns Hopkins University School of Medicine; King Faisal Specialist Hospital and Research Center

Background: The prevalence of non-alcoholic fatty liver disease (NAFLD), one of the most common liver diseases, is rising. Patients with NAFLD have relevant metabolic comorbidities, including obesity and Type 2 Diabetes Mellitus (T2DM). Cardiovascular disease (CVD) is one of the major causes of death in this patient population. The role of bariatric surgery (BS) in reducing macrovascular complications, especially in patients with NAFLD, type 2 diabetes mellitus (T2DM), and obesity, has not been well characterized. We aimed to determine the association between BS and the development of major adverse cardiovascular events (MACE) among patients with NAFLD, T2DM, and obesity at a population level. **Methods:** This large population-based, retrospective cohort study was conducted using the TriNetX dataset. All adult patients (> 18 y) diagnosed with NAFLD and who had previous

ischemic heart disease or heart failure (HF) were identified after excluding other chronic liver disease etiologies. We performed a 1:1 propensity score matching (PSM) for demographics, body mass index (BMI), and comorbid conditions to similar controls as patients without a surgical history. BS procedures included Roux-en-Y gastric bypass and sleeve gastrectomy. The primary outcomes were the incidence of macrovascular diseases defined as the composite indicator of the first occurrence of HF, MACE, or cerebrovascular disease. The secondary outcome was the incidence of all-cause mortality. We conducted sensitivity analyses to assess the robustness of our findings. The hazard ratio (HR) was calculated to compare the association of the BS with the outcomes. **Results:** Of the 53204 eligible adults, 2463 patients underwent BS, and 50741 patients did not undergo BS; following PSM, both cohorts are well matched with 2449 patients. Among the BS cohort, most participants were female, younger, white, and had a smoking history. BS patients had a higher mean BMI than the non-BS cohort. In the adjusted analysis (Table 1), the risks of MACE (HR, 0.37), HF (HR, 0.65), and a composite cerebrovascular disease (HR, 0.43) were significantly lower for BS than for non-BS patients. BS was also associated with a lower incidence of the secondary outcome all-cause mortality (HR, 0.40) and a composite outcome of major CVD. These outcomes were consistent at follow-up duration of 1, 3, 5, and 7 years. The results of the sensitivity analysis were consistent, and all statistically significant associations remained unchanged. **Conclusion:** Compared with nonsurgical care, bariatric surgery had a significantly lower risk of macrovascular complications and all-cause mortality in patients with NAFLD, T2DM, and obesity.

Table 1: Outcomes of surgical and nonsurgical patients with nonalcoholic fatty liver disease, obesity, and type 2 diabetes mellitus

Outcomes	BS (n=2449)	Non-BS (n=2449)	Hazard Ratio (95% CI)
	Patients with events, N	Patients with events, N	
Primary outcome (cardiovascular diseases)			
MACE[†]	59	151	0.37(0.27-0.50)
HF	108	160	0.65(0.51-0.83)
Composite cerebrovascular disease*	54	118	0.43(0.31-0.60)
Secondary outcome			
Mortality	22	52	0.40(0.24-0.67)

Abbreviations: BS, bariatric surgery; IHD, ischemic heart disease; HF, heart failure; MI, myocardial infarction
[†]A composite endpoint of MACE was defined occurrence of myocardial infarction (ST-segment elevation myocardial infarction and Non-ST-elevation myocardial infarction), unstable angina, and ischemic heart disease
*A composite endpoint of cerebrovascular disease was defined as the occurrence of stroke, carotid stenosis, transient ischemic attack, and carotid interventions or surgeries)

2141-A | ASSOCIATION BETWEEN NON-ALCOHOLIC FATTY LIVER DISEASE AND CORONARY ARTERY DISEASE OUTCOMES: A SYSTEMATIC REVIEW AND META-ANALYSIS

Hazem Abosheaishaa[1], Islam Mohamed[2], Muhammad Ghallab[1], Ahmed Alzamzamy[3], Natalie Balassiano[1], Jawad Khan[1], Moataz Yousry Soliman[4], Moaz Elshair[5], Mai Hussein[6], Md Ripon Ahammed[1], Muhammad Almas Baig[1], Amr Ali[7], Mohammed Abdelwahed[7], Ahmed Omran[8] and Mahmoud Nassar[1], (1)Icahn School of Medicine at Mount Sinai, (2)University of Missouri- Kansas City, (3)Department of Gastroenterology and Hepatology, Maadi Armed Forces Medical Complex, Military Medical Academy, Cairo, Egypt, (4)Faculty of Medicine, Al-Azhar University, (5) Faculty of Medicine , Al-Azhar University, (6)Clinical Research Administration/ Ministry of Health and Population, Egypt, (7)Department of Pathology, Donald and Barbara Zucker School of Medicine at Hofstra/ Northwell, Uniondale, New York., (8)Trmc/Rwjbh , Rutgers Njms

Background: To evaluate the association between non-alcoholic fatty liver disease (NAFLD) and cardiovascular outcomes, including angina, coronary artery disease (CAD), coronary artery calcification (CAC), myocardial infarction (MI), and calcified coronary plaques. **Methods:** A comprehensive search of databases, including PubMed, EMBASE, and Cochrane Library, was conducted up to January 2023. Studies were included investigating the relationship between NAFLD and cardiovascular outcomes in adult populations. Exclusion criteria were studies on animals, pediatric populations, and those not published in English. The risk of bias in the included studies was assessed using the Cochrane Collaboration's tool for randomized controlled trials and the Newcastle-Ottawa Scale for observational studies. Pooled odds ratios (ORs) and 95% confidence intervals (CIs) were calculated using random-effects models. **Results:** The meta-analysis included 32 studies with a total of 5610990 participants. Significant associations were found between NAFLD and increased risks of angina (RR: 1.45, 95% CI: 1.17, 1.79), CAD (RR: 1.21, 95% CI: 1.07, 1.38), and CAC > 0 (RR: 1.39, 95% CI: 1.15, 1.69). Additionally, a significant association was observed between NAFLD and calcified coronary plaques (RR: 1.55, 95% CI: 1.05, 2.27). However, no significant association was found between NAFLD and CAC > 100 (RR: 1.16, 95% CI: 0.97, 1.38) or MI (RR:

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

1.70, 95% CI: 0.16, 18.32). **Conclusion:** The meta-analysis demonstrated a significant association between NAFLD and cardiovascular outcomes independent of conventional CVD risk factors. These findings emphasize the importance of prevention, early detection, and proper management of NAFLD. PROSPERO reference number: CRD42023394727.

2142-A | ASSOCIATION BETWEEN SARCOPENIA AND CORONARY ATHEROSCLEROSIS IN PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE

Yeonjung Ha, Young Eun Chon, Joo Ho Lee and Kwan Sik Lee, CHA Bundang Medical Center, CHA University

Background: The aim of this study was to examine the impact of sarcopenia on coronary atherosclerosis in patients with metabolic dysfunction-associated fatty liver disease (MAFLD). **Methods:** This retrospective study included 1,872 patients who were diagnosed with MAFLD between 2012 and 2016 at health check-ups and underwent coronary calcium scan or computed tomography angiography during follow-up. The primary outcome was the incidence of coronary atherosclerosis (calcium score > 100 or stenosis degree > 50%). Sarcopenia was defined if the sarcopenia index was < 0.789 in men and < 0.512 in women, respectively, on bioelectrical impedance analysis. Multivariate Cox proportional hazards regression was performed to assess associations between sarcopenia and outcomes. Propensity score matching was used to control baseline differences in cardiovascular risk or fibrosis burden. **Results:** Overall, 1,723 (92.0%) and 149 (8.0%) patients were non-sarcopenic and sarcopenic, respectively. Compared to the non-sarcopenic group, the sarcopenic group was older (56.9 vs. 46.8 y), had a higher body mass index, and more frequently had comorbidities such as hypertension or diabetes (Ps < 0.05). The incidence of coronary atherosclerosis was significantly higher in the sarcopenic group than in the non-sarcopenic group ($P < 0.001$) during a median follow-up of 67.3 months. Multivariable analysis demonstrated an independent association between sarcopenia and coronary atherosclerosis (hazard ratio, 1.73; 95% confidence interval, 1.28–2.34; $P < 0.001$). The results were confirmed in the propensity score stratification analysis. **Conclusion:** Sarcopenia was an independent predictor of coronary atherosclerosis after adjusting for baseline cardiovascular risk and fibrosis burden.

Background: Non-alcoholic fatty liver disease (NAFLD) is the most common chronic liver disease in pediatrics. NAFLD ranges in severity from isolated hepatic steatosis (nonalcoholic fatty liver [NAFL]) to non-alcoholic steatohepatitis (NASH) wherein hepatocellular inflammation, and/or fibrosis coexist with steatosis. Circulating microRNA (miRNA) levels are known to change in NAFLD but the extent to which microRNAs serve as predictive biomarkers of NAFLD remains unknown. This study aimed to investigate the relationship between plasma miRNA levels with histological features of NAFLD among adolescents from the multicenter perspective Teen-Longitudinal Assessment of Bariatric Surgery (Teen-LABS) study. **Methods:** This nested case-cohort study included 81 adolescents diagnosed with NAFLD at the time of surgery and 54 controls. 843 plasma miRNA were profiled using the established HTG EdgeSeq platform. Intra-operative core liver biopsies were collected from cases and controls and liver tissues were analyzed by histology using validated criteria. We examined associations of miRNA and disease status using multivariate logistic regression after adjusting for age, sex, race, BMI, parental income and geographic clinical site of surgery. Ingenuity Pathways Analysis (IPA) was used to identify putative biological functions of NAFLD-associated miRNA ($p < 0.05$). **Results:** There were 15 significantly upregulated and 23 significantly downregulated plasma miRNA in NAFLD cases compared to controls ($p < 0.05$). Additionally, 17 miRNA were associated with 4 or more NASH-related stages, including NASH, NASH with fibrosis, lobular inflammation, ballooning or higher steatosis grade. Notably, miR-6741-5p was significantly up-regulated in all NASH related stages ($p < 0.05$). Moreover, miR-193b-5p and miR-122-5p were upregulated in NASH and NASH with fibrosis, lobular inflammation and higher steatosis grade ($p < 0.05$). Pathway analysis showed that 12 miRNA, including miR-100-5p, miR-122-5p, miR-143-3p, miR-146-5p, miR-182-5p, miR-193a-3p, miR-199a-5p, miR-22-3p, miR-221-3p, miR-2355-5p, miR-34a-5p and miR-378-3p were involved in hepatotoxicity (e.g., fibrosis, cirrhosis and hepatocellular carcinoma). **Conclusion:** Findings demonstrated that multiple, specific plasma miRNA were associated with advanced pediatric NAFLD. Larger studies with more heterogeneity of NAFLD phenotypes are needed to determine the ability of miRNA to accurately predict NAFLD stages in pediatrics.

2144-A | AWARENESS AND KNOWLEDGE OF NON-ALCOHOLIC FATTY LIVER DISEASE AMONG NURSES IN BEIJING, CHINA

Wei Zhang, Peking University People's Hospital, Peking University Hepatology Institute and Danli Ma, Peking University People's Hospital, Hepatology Department

Background: Prevalence of non-alcoholic fatty liver disease (NAFLD) is increasing in China; however, awareness and knowledge of NAFLD is lacking among the Chinese public. We have conducted a survey on adult patients in Beijing in our previous studies and found less than 50% participants had awareness of NAFLD. **Methods:** We conducted a survey on nurses in the Peking University People's Hospital in Beijing, China. Subjects provided demographic and medical history data. NAFLD-related knowledge and diet and physical activity patterns were assessed. **Results:** 518 participants (5.2% with a diagnosis of NAFLD and 9.5% with a family history of NAFLD) completed the surveys.

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Response rate was 98.9% (518/524). Median age was 32, 7.7% (40/518) were men, 65% participants had some college education, 72.8% were lean (normal BMI) but 39.2% were truncal obesity, 9.7% with a diagnosis of dyslipidemia, 44.4% had a history of high blood pressure, and 53.3% had at least twice night shifts in every week. More than 60% reported minimal physical activity and often eating dessert. 53.2% had awareness of NAFLD and about 90% reported that they had some knowledge of NAFLD. Median baseline knowledge score (of a total of 25) was 17 and detailed description was showed in Figure 1. Multivariate logistic regression analyses found higher knowledge score (>17) was associated with higher BMI and family history of NAFLD or diabetes. **Conclusion:** Nurses in Beijing had not enough knowledge about NAFLD, and most were not physically active. Programs to increase public awareness of NAFLD and promote physical activity are critical to curb this growing epidemic.

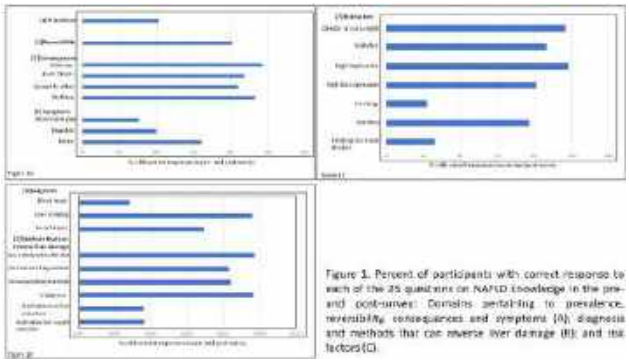

Figure 1. Percent of participants with correct response to each of the 25 questions on NAFLD knowledge in the pre- and post-survey. Domains pertaining to prevalence, reversibility, consequences and symptoms (A); diagnosis and methods that can reverse liver damage (B); and risk factors (C).

f 2145-A | BARIATRIC SURGERY AND CARDIOVASCULAR OUTCOMES IN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE, OBESITY, AND CARDIOVASCULAR DISEASE: A POPULATION-BASED RETROSPECTIVE COHORT STUDY★

Arunkumar Krishnan, Atrium Health Levine Cancer Institute, Dipatsree Mukherjee, Apex Institute of Medical Sciences, William R. Hutson, West Virginia University School of Medicine, Tinsay A. Woreta, Johns Hopkins Medicine, Baltimore, MD and Saleh A Alqahtani, Johns Hopkins University School of Medicine; King Faisal Specialist Hospital and Research Center

Background: The role of bariatric surgery (BS) in reducing major adverse cardiovascular events (MACE), especially in patients with nonalcoholic fatty liver disease (NAFLD) with preexisting cardiovascular disease (CVD), has not been well characterized. We aimed to determine the association between BS and the development of MACE among patients with NAFLD, CVD, and obesity at a population level. **Methods:** This large population-based, retrospective cohort study was conducted using the TriNetX dataset. All adult patients (>18 y) diagnosed with NAFLD, who had previous ischemic heart disease or heart failure, were identified after excluding other chronic liver disease etiologies. We performed a 1:1 propensity score matching (PSM) for demographics, body mass index (BMI), and comorbid conditions to similar controls as patients without a surgical history. The primary outcome was the incidence of extended MACE, a composite endpoint of coronary artery interventions, and composite cerebrovascular events. Secondary outcomes included a 2-component composite outcome of major CVD and all-cause mortality. We conducted sensitivity analyses to assess the robustness of our findings. The hazard ratio (HR) was calculated to compare the association of the BS with the outcomes. **Results:** A total of 91946 patients were identified. Among these, 2827 patients had a history of BS, and 88119 did not, with a median follow-up time of 4.9 years. After PSM, BS and nonsurgical (NS) groups (3822 each) were well matched. Among the BS cohort, most participants were female, younger, white, and had a smoking history. BS patients had a higher mean BMI than the NS cohort. In the unadjusted cause-specific models, the BS cohort had a significantly reduced risk of major CVD compared with the NS group. In the adjusted analysis (Table 1), the risks of MACE (HR, 0.60), composite cerebrovascular diseases (HR, 0.67), and a composite outcome of coronary artery interventions or and surgeries (HR, 0.59) were significantly lower for BS than NS patients. BS was also associated with a lower incidence of the secondary outcome all-cause mortality (HR, 0.63) and a composite outcome of major CVD (HR, 0.82). These outcomes were consistent at follow-up duration of 1, 3, 5, and 7 years. The sensitivity analysis results were consistent, and all statistically significant associations remained unchanged. **Conclusion:** Compared with NS care, BS was associated with a significantly lower risk of MACE and all-cause mortality in patients with NAFLD, obesity, and CVD.

Table 1 : Outcomes of surgical and nonsurgical patients with nonalcoholic fatty liver disease, obesity, and cardiovascular disease.

Outcomes	Patients with outcome		Hazard Ratio (95% CI)

M. and a. Migliavacca" Center for Liver Disease, Department of Pathophysiology and Transplantation, University of Milan, (4)Foundation Irccs Ca' Granda Ospedale Maggiore Policlinico, Division of Gastroenterology and Hepatology, (5)Department of Transfusion Medicine and Haematology, Fondazione Irccs Ca' Granda Ospedale Maggiore Policlinico, (6)Section of Gastroenterology and Hepatology, Dipartimento Di Promozione Della Salute, Materno Infantile, Medicina Interna e Specialistica Di Eccellenza (PROMISE), (7)Sezione Di Gastroenterologia, Dipartimento Promozione Della Salute, Materno-Infantile, Di Medicina Interna e Specialistica Di Eccellenza "G. D'alessandro", Università Di Palermo, Palermo, Italy, (8)Department of Medical and Surgical Sciences, University of Bologna, (9)Irccs Aoubo - Bologna, (10)Liver Disease and Transplant Unit, Polytechnic University of Marche, (11) University of Turin

Background: Non-alcoholic fatty liver disease (NAFLD) is closely associated with type 2 diabetes mellitus (T2DM). Both these conditions are associated with an increased risk of cardiovascular disease (CVD), but the relation between the long-term risk of CVD and the severity of liver fibrosis in diabetic NAFLD patients is partially unknown. In a cohort of diabetic patients consecutively referred by Diabetes Units, we aimed to assess a) the prevalence of NAFLD and the prevalence of advanced liver fibrosis, and b) to explore the association between the risk of CVD and liver fibrosis in patients with T2DM. **Methods:** From April 2021 to April 2023, a total of 675 consecutive patients with T2DM attending 6 different diabetes referral centers were prospectively enrolled. Liver stiffness (LS) was assessed by vibration controlled transient elastography (VCTE) and liver steatosis by controlled attenuation parameter (CAP). Liver steatosis was defined according to CAP values **e** 275 dB/m. A VTCE cut-off **e** 8.0 kPa was used to identify patients at risk of advanced liver fibrosis. Framingham risk score (FRS) was used to estimate the 10-year CVD risk; FRS **e** 21.6% for male and 21.5% for female identified patients at high CVD risk. **Results:** Overall 576 out of 675 patients underwent VCTE + CAP. Patients' median age was 59 (53–64) years and 334 (58.0%) of them were males; 51.3% of patients were obese (BMI **e** 30 kg/m^2) and 66.1% had arterial hypertension. Elevated liver enzymes (ALT and/or AST and/or γGT) were found in 21.6% of patients. Liver steatosis by CAP was detected in 338 (58.7%) patients, among them 77 (22.8%) had a LS **e** 8 kPa. Data for the estimation of FRS were available in 289/338 (85.5%) patients; 131/289 (45.3%) showed high CVD risk. The distribution of high CVD varied significantly according to LS (**e** 8 kPa, 56.1% vs. < 8 kPa, 42.2%; p = 0.047). At multivariate analysis corrected for BMI and transaminases, high CVD risk resulted significantly and independently associated to advanced liver fibrosis (OR = 1.87, 95%CI 1.14–3.07; p = 0.013). **Conclusion:** In patients with T2DM and NAFLD, the prevalence of advanced liver fibrosis by VTCE is approximately 23%. In these patients, the association between CVD risk and advanced liver fibrosis supports a careful integrated multidisciplinary follow-up. *This research was supported by Gilead Sciences, Inc (study ID: IN-IT-989-5790).*

2147-A | CHANGES IN LIVER STIFFNESS AND CONTROLLED ATTENUATION PARAMETERS OF TRANSIENT ELASTOGRAPHY ACCORDING TO WEIGHT CHANGE IN NON-ALCOHOLIC FATTY LIVER PATIENTS

Seong Kyun Na, Inje University Sanggye Paik Hospital

Background: It is not clear how much controlled attenuation parameter (CAP) and liver stiffness (LS) of transient elastography (TE) decrease with weight loss. We investigated whether there were significant chnages in CAP and LS according to the degree of weight loss in patients with nonalcoholic fatty liver disease (NAFLD). **Methods:** From 2017 to 2022, the patients with NAFLD at Jeju National University Hospital in Korea who had TE tests more than once while losing body weight were analyzed. CAP and LS were compared between the time of the first test and the time of the weight was most lost during the follow-up. **Results:** A total of 410 patients were analyzed retrospectively and 74.6% of patients lost body weight during the follow-up period. The mean BMI was 28.71 ± 4.21 kg, and the average number of TE tests per patient was 2.90 ± 1.04, and up to 6 were performed. The interval between the first TE and follow-up TE tests was 597.9 ± 338.9 days. Patients who lost weight were divided into 5 groups according to the degree of weight loss (WL), and all groups showed significant CAP change (-25.62 in the 0 to 3% WL group, -21.52 in the 3 to 5% WL group, -41.92 in the 5 to 7% WL group, -32.79 in the 7 to 10% WL group, -74.16 in the more than 10% WL group, all p-values < 0.05). The mean LS change by group was +0.75 in the 0 to 3% WL group, -0.30 in the 3 to 5% WL group, +0.40 in the 5 to 7% WL group, -0.40 in the 7 to 10% WL group, –1.31 in the more than 10% WL group, and was significant only in the more than 10% WL group ($p = 0.002$). There was a significant correlation between WL and CAP in the 3 to 5% WL group (Pearson's $r = 0.300$, $p = 0.006$) and in the 5 to 7% WL group (Pearson's $r = 0.330$, $p = 0.025$), and a significant correlation between WL and LS in the more than 10% WL group (Pearson's $r = 0.413$, $p = 0.010$). **Conclusion:** In patients with NAFLD, there was a significant correlation between weight loss and CAP. LS decreases significantly when weight loss is greater than 10% of baseline body weight.

2148-A | CHARACTERISTICS AND ASSOCIATION OF OBESITY WITH NASH IN THE MANAGEMENT OF LIVER FIBROSIS

Dong Tang[1], Hanyu LI[1,2], JUN Yang[3] and Kehui Nie[4], (1)Hangzhou Normal University Affiliated Hospital, (2) Hangzhou Normal University, (3)Taimei Medical Technology Co.,Ltd, (4)Taimei Technology

Background: Targeted management of NASH population with high-risk metabolic comorbidity is crucial for early interventions. This study investigated the relation of characteristics of obese patients with NASH fibrosis. Major laboratory indicators, imaging biomarkers and pathological results were reviewed and analyzed. **Methods:** This was a secondary analysis from the NASH study in 2015-2021 at our institution. All patients were histologically confirmed with NASH fibrosis and those with concomitant or preexisting severe liver diseases were excluded. Patients with a BMI ≥ 25 kg/m^2 were sub-grouped as obese NASH and the rest were non-obese NASH. Liver fibrosis stages of F2-F4 defined substantial fibrosis. Demographics, serological variables, MRI biomarker, elastography stiffness and fibrosis stages between obese and non-obese NASH group were compared. Confounding factors were adjusted, and risk analyses of statistically significant

variables were done using logistic regression. The primary outcome was the liver fibrosis. We also analyzed contribution of type 2 diabetes mellitus (T2DM) to NASH fibrosis in obese and non-obese subjects. **Results:** The study included 73 biopsy-confirmed NASH patients. Obese NASH patients had a significantly higher proportion of substantial fibrosis (40.8%) than non-obese NASH (16.7%, p = 0.039). Among the obese patients (n = 49), three had a fibrosis grade of F4, while no F4 patients were seen in the non-obese NASH. High density lipoprotein (HDL, p = 0.027), bilirubin (p = 0.042), controlled attenuation parameter (CAP, p = 0.002), and liver stiffness measurement (LSM, p = 0.046) were significantly different between obese and non-obese group. Moreover, obese patients had a significantly higher risk of substantial fibrosis (OR, 3.448; 95% CI, 1.023-11.625; p = 0.039) than non-obese group. After adjustment of sex, age, HDL, and bilirubin, obesity was an independent risk factor of substantial fibrosis (adjusted OR, 4.53; 95%CI, 1.084-18.937; p = 0.038). There was no significant difference in the proportion of patients with T2DM between obese (22.4%) and non-obese (25%) NASH, and no interaction between T2DM and obesity on the substantial fibrosis. **Conclusion:** Obesity added greater risk to liver fibrosis in the NASH patients. Serum indicators and imaging biomarkers were significantly different between obese and non-obese NASH group. Cross-interaction of T2DM with obesity on fibrosis needs to be investigated in a larger sample size.

Table 1. Characteristics of obese and non-obese patients and substantial fibrosis.

	All patients(n=73)	Obesity(n=49)	Non-obesity(n=24)	p-value

2149-A | CHARACTERIZING THE MANAGEMENT OF PATIENTS WITH NASH (WITH VERSUS WITHOUT CIRRHOSIS) IN REAL-WORLD CLINICAL PRACTICE: RARE ASSESSMENT BY HEPATOLOGISTS AND LOW FREQUENCY OF IMAGING

Christina Qian[1], Michael R. Charlton[2], Shelagh M Szabo[1], Rosie Sun[1], Hannah Rochon[1] and Jesse Fishman[3], (1)Broadstreet Heor, (2)University of Chicago, (3)Madrigal Pharmaceuticals

Background: Nonalcoholic steatohepatitis (NASH) affects 3-6% of US adults. Guidelines recommend patients with NASH undergo regular assessment and follow-up by specialists, specifically gastroenterologists/hepatologists to ensure adequate care and monitor for complications. However, intervals for follow-up vary depending on disease severity. Patients with cirrhosis should be assessed annually whereas those without every 2-3 years. While there is increased use of noninvasive tests (NITs), liver biopsy remains the gold standard for grading/staging NASH. This analysis aimed to characterize the management of patients with NASH (with vs without cirrhosis) in real-world clinical practice. **Methods:** Optum's de-identified Clinformatics® Data Mart Database (01Oct2015-31Dec2022) was used for this analysis. Adults with **e** 1 inpatient claim for NASH (ICD-10-CM K75.81) as the primary or secondary diagnosis or **e** 2 outpatient claims for NASH were included. Patients with other causes of liver disease, HIV, or exposure to heavy metals were excluded. Baseline cirrhosis status was classified by **e** 1 code for cirrhosis, decompensated cirrhosis, liver transplant, or hepatic cell carcinoma (HCC) in the 6 months before or 1 month after first NASH diagnosis. Patients were followed until death, loss of follow-up, or study end. Demographics, comorbidities, specialist visits, and imaging procedures were estimated for patients with vs without cirrhosis. Statistical analyses were performed within the Optum de-identified data workspace using Jupyter Notebook. **Results:** While almost all patients had **e** 1 specialist visit, only 67.3% with and 50.6% without cirrhosis visited a gastroenterologist and < 1% visited a hepatologist (Table). Average annual visits were less than half among patients without cirrhosis. Liver biopsy was rarely performed, even among patients with cirrhosis. Among imaging NITs, the most frequently used were abdominal ultrasound and CT. **Conclusion:** The results of this analysis suggest patients with NASH are not seen by a gastroenterologist and < 1% are seen by a hepatologist, even when diagnosed with cirrhosis. Liver biopsy is rarely performed, reflecting increased reliance on NITs. While additional stratification by comorbidities and disease severity may help better elucidate clinical

practice in the real world, the low frequency of abdominal imaging among patients with cirrhosis implies screening/surveillance for HCC only occur at ~50% the recommended frequency. Our results suggest clinical practice is only partially aligned with clinical guidelines.

Table 1. Patient characteristics and healthcare resource utilization in NASH patients with versus without cirrhosis

	With cirrhosis (n=9,157)		Without cirrhosis (n=19,419)	
Baseline characteristics				
Age, mean (SD) years	67.1 (10.8)		59.8 (13.4)

Background: Combination of FIB4 and liver stiffness measured by vibration controlled transient elastography (LSM-VCTE) is supported by cross sectional studies of diagnostic accuracy. Here we aim to study the prognostic value of FIB-4 followed by LSM-VCTE. **Methods:** This was an individual participant data meta-analysis of people with NAFLD and baseline biopsy, LSM-VCTE, and FIB-4 measured within 6 months. The outcome was a composite endpoint of all-cause mortality, cirrhosis decompensation (ascites, variceal haemorrhage, hepatic encephalopathy), hepatocellular carcinoma, liver transplantation or progression to model of end stage liver disease score **e** 15. Study-specific cumulative hazard functions and derived aggregated survival curves were built for: G1 (FIB-4 < 1.3), G2 (1.3 **d** FIB-4 < 2.67; LSM-VCTE < 10 kPa), G3 (1.3 **d** FIB-4 < 2.67; 10kPa **d** LSM-VCTE < 20 kPa), G4 (1.3 **d** FIB-4 < 2.67; LSM-VCTE **e** 20kPa) and G5 (FIB-4 **e** 2.67). G3 was further stratified according to fibrosis (F0-2, F3, F4), and LSM-VCTE one (15 kPa) or two cut-offs (13.5 kPa, 17 kPa). G5 was similarly subclassified according to fibrosis and LSM-VCTE. Unreliable LSM-VCTE (LSM **e** 7.1 kPa and IQR/median > 0.3) readings were excluded. **Results:** Data from 2383 (51% males, median age 54 (IQR 19) years, 42% with type II diabetes mellitus) were available, after exclusion of unreliable LSM-VCTE. Median follow-up was 56 months and the primary outcome was reached in 5.3% (n = 127). There were significant differences in the prognostic information carried by all groups (study-stratified log-rank tests; $p < 0.0001$; Fig. 1a). Within G3, patients with cirrhosis (G3_F4) showed the poorest prognosis, and similar survival probabilities were seen between patients in G3_F0-2 and G3_F3 ($p = 0.02$; Fig. 1b). LSM-VCTE did not further separate G3 (Fig. 1c-d). Within G5, LSM-VCTE ($p < 0.001$, Fig. 1e), and histology ($p = 0.004$, Fig. 1f) provided further prognostic granularity. **Conclusion:** Sequential application of FIB-4 and LSM-VCTE classifies patients into 5 groups with differing risk of future adverse events, further supporting the continued use of this approach in clinical practice. In those with FIB4 **e** 2.67, LSM-VCTE and biopsy can provide further prognostic granularity. Biopsy can also separate out risk subgroups in those with 1.3 **d** FIB4 < 2.67. Our analysis is limited by relatively small numbers in groups G3 and G5. Repeated NIT measurements over time or other approaches may provide additional prognostic insight but these were beyond the remit of our study.

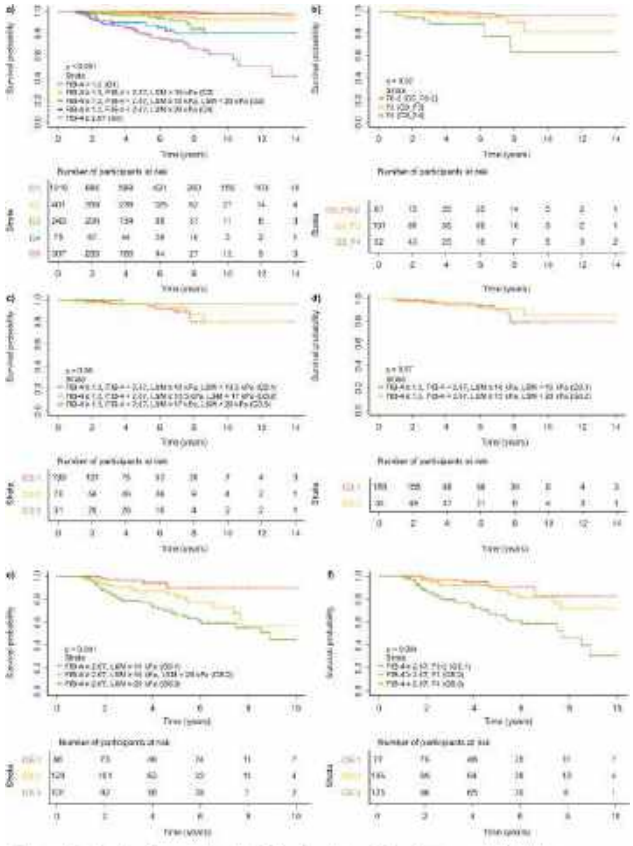

Figure 1 Estimates of survival probabilities for (a) participant groups stratified by sequential test cut-offs (FIB-4 followed by LSM-VCTE, (b) participants from group G3 stratified by histologically assessed fibrosis; (c) G3 participants further stratified by LSM-VCTE with two cut-off: 13.5 and 17 kPa, and (d) a single cut-off: 15 kPa. P-values were calculated using stratified log-rank tests.

2151-A | COMPARISON OF CHARACTERISTICS AND OUTCOMES IN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE WHO DID OR DIDN'T RECEIVE LIVER BIOPSY

Xinrong Zhang[1], Leslie Yeeman Kam[1], Scott D. Barnett[1], Linda Henry[1], Ramsey Cheung[1,2] and Mindie H. Nguyen[1], (1)Stanford University Medical Center, Palo Alto, CA, (2)Veterans Affairs Palo Alto Health Care System

Background: Liver fibrosis is an independent predictor for liver-related outcomes and mortality in nonalcoholic fatty liver disease (NAFLD). Although liver biopsy remains the reference standard to assess liver fibrosis, few patients undergo liver biopsy except in the setting of clinical trials. Thus, biopsy patients likely represent a highly selected group in clinical practice. However, data examining the outcomes of NAFLD patients who underwent liver biopsy versus those who did not are sparse. Therefore, this study aimed to compare clinical characteristics and outcomes in real-world adult NAFLD patients with and without liver biopsy using a large nation-wide insurance database in United States (US). **Methods:** We conducted a retrospective cohort study of adult patients with diagnosed NAFLD using the Truven Health MarketScan Research Database between January 2007 and December 2021. Patients were categorized into two groups: those with or without liver biopsy at any time during follow-up. We used Kaplan Meier methods to estimate the rates of developing hepatocellular carcinoma (HCC), cirrhosis and hepatic decompensation in NAFLD patients with or without liver biopsy after propensity score (PS) matching and factors associated with such outcomes. **Results:** We identified a total of 586,720 eligible NAFLD patients: 35,600 with biopsy and 551,120 without biopsy. There were significant differences in several baseline characteristics such as age, comorbidities, percent of patients with baseline cirrhosis and HCC. After 1:5 PS matching on age, sex, comorbidities, use of metformin and statins, a total of 35,600 NAFLD patients with liver biopsy and 178,000 matched NAFLD patients without liver biopsy who had similar distribution in age, sex, comorbidities and use of metabolic drugs were included in our study analysis. Compared to non-biopsy patients, matched biopsy patients had higher crude incidence per 1,000 person-years for HCC (1.15 vs. 0.08), cirrhosis (64.53 vs. 23.22) and hepatic decompensation (22.36 vs. 14.93), respectively (all $P < 0.001$; Table). In multivariable analysis, patients with liver biopsy had more than 14 times higher risk of developing HCC, close to 3 times higher risk of cirrhosis, and 51% higher risk of hepatic decompensation. In subgroup analysis, the association remained consistent and significant for all 3 outcomes when stratified by age (18-49, 50-59 and **e** 60 y), sex, diabetes, hypertension, hyperlipidemia and obesity (body mass index **e** 30 kg/m^2 vs. non-obese). **Conclusion:** In this large nation-wide cohort from US, discrepancies in clinical characteristics and liver-related outcomes exist between patients with and without liver biopsy. Patients with liver biopsy had a significantly higher risk of developing HCC, cirrhosis and hepatic decompensation than those without, and may represent a highly selected group of patients whose data may not be representative of the general population of NAFLD patients.

Table. Incidence rate and hazard ratio for HCC, cirrhosis, or hepatic decompensation in NAFLD patients with or without liver biopsy after PS matching

	Liver biopsy status	Person-years	No. of events	Crude incidence per 1,000 person-years	Adjusted HR (95% CI)*	P-value
HCC						
	Without	721,991	58	0.08	ref	
	With	142,457	164	1.15	14.42 (10.68-19.46)	<0.001
Cirrhosis						
	Without	684,296	15,892	23.22	ref	
	With	124,063	8,006	64.53	2.82 (2.74-2.90)	<0.001
Hepatic decompensation						
	Without	697,654	10,417	14.93	ref	
	With	136,473	3,051	22.36	1.51 (1.45-1.57)	<0.001

* Analysis was by Cox proportional hazard model. Adjusted for age, sex, diabetes, hypertension, hyperlipidemia, obesity (body mass index ≥30kg/m^2), use of metformin and statins. The endpoint of hepatic decompensation was recorded among overall NAFLD patients after PS matching.

HCC, hepatocellular carcinoma; CI, confidence interval; HR, hazard ratio; NAFLD, nonalcoholic fatty liver disease; PS, propensity score

composite endpoint of all-cause mortality, decompensation of cirrhosis (ascites, variceal haemorrhage, hepatic encephalopathy), hepatocellular cancer, liver transplantation or progression to model of end stage liver disease score **e** 15. Study-specific cumulative hazard functions, derived aggregated survival curves, and study-stratified Cox regression models were built for the following groups: fibrosis stage F0-2, F3, F4 for histology; LSM < 10 kPa, 10 kPa **d** LSM < 20 kPa, and LSM **e** 20 kPa; Agile 3 + < 0.451 , 0.451 **d** Agile3+ < 0.679 , Agile3+ **e** 0.679 ; Agile 4 < 0.251 , 0.251 **d** Agile 4 < 0.565, Agile 4 **e** 0.565 ; FAST < 0.35 , 0.35 **d** FAST < 0.67, FAST **e** 0.67. **Results:** Data from 2518 patients were available and 2383 (51% males, median age 54 (IQR 19) years, 42% with type II diabetes mellitus) were included in the analysis, after exclusion of participants with unreliable LSM-VCTE. The primary outcome was reached in 5.3% (n = 127) after a median follow-up of 56 months. There were significant differences in the prognostic information carried by all trichotomised index tests (p < 0.0001; Figure 1). On Cox regression, fibrosis stage F3 (HR 3.8), and F4 (HR 16.8), 10 kPa **d** LSM < 20 kPa (HR 3.7), LSM **e** 20 kPa (HR 12.2), 0.451 **d** Agile3+ < 0.679 (HR 2.2), Agile3+ **e** 0.679 (HR 12.4), 0.251 **d** Agile4 < 0.565 (HR 4.4), Agile 4 **e** 0.565 (HR 12.8), 0.35 **d** FAST < 0.67 (HR 3.0) and FAST **e** 0.67 (HR 8.0) were independent predictors of outcomes after adjusting for confounders. **Conclusion:** LSM-VCTE based composite scores, like histologically assessed fibrosis are independent predictors of outcome in NAFLD after correcting for potential confounding factors.

2153-A | CONCURRENT HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN PATIENTS WITH METABOLIC DYSFUNCTION ASSOCIATED FATTY LIVER DISEASE IS ASSOCIATED WITH SIGNIFICANTLY GREATER RISKS OF CIRRHOSIS AND HEPATOCELLULAR CARCINOMA

Robert J. Wong[1], Zeyuan Yang[1], Aaron Yeoh[2], Albert Do[3], Aijaz Ahmed[4] and Ramsey Cheung[5], (1)VA Palo Alto Healthcare System, (2)Stanford University - School of Medicine, (3)Yale University, New Haven, CT, (4) Stanford University School of Medicine, (5)Stanford University Medical Center, Palo Alto, CA

Background: Metabolic dysfunction associated fatty liver disease (MAFLD) is highly prevalent among U.S. adults, and particularly among U.S. Veterans. While human immunodeficiency virus (HIV) infection increases the risk of hepatic steatosis, it is not clear if concurrent HIV among patients with MAFLD is associated with increased risk of liver disease progression.

We aim to evaluate the association between HIV infection status and risk of incident cirrhosis, hepatocellular carcinoma (HCC), and hepatic decompensation among a national cohort of adult Veterans with MAFLD. **Methods:** Adults with MAFLD with and without concurrent HIV infection were identified using the national Veterans Affairs database from 1/1/2010 to 12/31/2017 with follow-up through 12/31/2022. Among patients without cirrhosis or HCC at baseline, the overall incidence of cirrhosis, HCC, and hepatic decompensation (ascites, hepatic encephalopathy, variceal bleeding, or hepatorenal syndrome) per 1000 person-years was evaluated using Nelson-Aalen methods for estimating cumulative hazards rates. Comparisons of incidence rates between MAFLD patients with vs. without concurrent HIV were performed using log-rank testing and the z-statistic. **Results:** Among 1,243,766 Veterans with MAFLD, 1,686 had concurrent HIV and 1,242,080 did not have concurrent HIV. Compared to MAFLD patients without HIV, those with concurrent HIV were more likely to be African American (48.5% vs. 19.4%, $p < 0.01$), were younger (55.6 vs. 61.9 y, $p < 0.01$), and had lower proportion with hypertension (56.1% vs. 58.4%, $p < 0.05$), diabetes (38.1% vs. 44.0%, $p < 0.01$), and dyslipidemia (62.5% vs. 67.9%, $p < 0.01$). Compared to MAFLD patients without HIV, those with concurrent HIV were significantly more likely to develop cirrhosis (13.0% vs. 6.1%, $p < 0.01$), HCC (2.9% vs. 1.2%, $p < 0.01$), and hepatic decompensation (12.4% vs. 7.2%, $p < 0.01$) on follow-up. On cumulative hazards assessment, the incidence of cirrhosis, HCC, and hepatic decompensation was 10.52 vs. 5.29 per 1000 person-years ($p < 0.01$), 2.70 vs. 1.27 per 1000 person-years ($p < 0.01$), and 12.72 vs. 7.31 per 1000 person-years ($p < 0.01$) among MAFLD patients with vs. without concurrent HIV, respectively. **Conclusion:** Among a national cohort of U.S. Veterans with MAFLD, patients with concurrent HIV had significantly greater risks of cirrhosis, HCC, and hepatic decompensation. Better understanding the drivers of this increased risk of liver disease progression associated with HIV infection in patients with MAFLD will help guide closer monitoring and targeted interventions improve long-term management and outcomes among this group of patients.

2154-A | COST-EFFECTIVENESS OF MULTIPARAMETRIC MAGNETIC RESONANCE IMAGING COMPARED TO LIVER BIOPSY FOR THE DETECTION OF NON-ALCOHOLIC STEATOHEPATITIS AMONG PATIENTS WITH TYPE 2 DIABETES TREATED WITH SEMAGLUTIDE

Mohsen Rezaeihemami[1], Anneli Andersson[1], Prashant K. Pandya[2], Marika French[3], Kenneth Cusi[4] and Helena. Thomaides-Brears[1], (1)Perspectum Ltd, (2) Perspectum Inc, (3)Perspectum, (4)Division of Endocrinology, Diabetes and Metabolism, University of Florida, Gainesville, FL, USA

Background: Semaglutide is recommended for treating patients with type 2 diabetes (T2D) and non-alcoholic steatohepatitis (NASH) in American Association of Clinical Endocrinology guidelines. Multiparametric magnetic resonance imaging (mpMRI) is a non-invasive, quantitative alternative to biopsy for assessment of liver characteristics, including steatosis and disease activity. We aimed to evaluate the life-time cost-effectiveness of prescribing semaglutide in US people with T2D based on 1)diagnosis of NASH by liver mpMRI or biopsy and 2) suspicion of NASH only. **Methods:** We developed a multi-state Markov model for NAFLD progression in T2D comparing mpMRI to liver biopsy for the diagnosis of NASH (figure 1A). We considered 3 effects for semaglutide: slowing fibrosis progression, the regression of fibrosis and reducing mortality from cardiovascular and liver related causes. NAFLD stage and history, transition probabilities, costs, and quality of life scores were defined from literature. Relative risk of fibrosis progression/regression following semaglutide

(costing $9500 over 52 weeks) was calculated from published NN9931-4296 study data. We assumed a hypothetical cohort of 1000 people with T2D aged 50 years suspected of having NASH in the US following initial triage by FIB4 and transient elastography (TE) who could be referred for semaglutide treatment. The outcomes were costs (in US dollars, year 2021 values) and quality adjusted life-years (QALYs), discounted at 3% annually over a lifetime horizon. **Results:** In this hypothetical cohort of 1000 T2D patients with suspected NASH, identifying patients for treatment with semaglutide using mpMRI would avoid 215 unnecessary biopsies in comparison to the biopsy-based diagnosis and 112 unnecessary treatments compared to the treat-all strategy. MpMRI results in direct cost savings of $3250 per patient compared with biopsy, and a gain of 0.162 QALYs over the patient lifetime (figure 1B). Using mpMRI also results in direct cost savings of $1787 per patient compared with treating all 1000 patients with semaglutide, and a gain of 0.018 QALYs over the patient lifetime. These findings were robust across deterministic and probabilistic sensitivity analyses. **Conclusion:** The implementation of mpMRI for detection of NASH among patients with T2D ahead of semaglutide prescription can lead to cost savings and improved lifelong patient quality of life. Such improvements would be seen if implemented instead of diagnosis by biopsy and instead of prescribing semaglutide to all patients without further confirmation of NASH beyond triage with FIB4 and TE.

2155-A | CROSS-SECTIONAL STUDY IN GENERAL POPULATION FOR THE PREVALENCE OF NONALCOHOLIC FATTY LIVER DISEASE, DISTRIBUTION OF FIBROSIS STAGE USING VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY, AND DETERMINING THE BEST CUT OFF VALUE OF FIB-4 INDEX

Yuji Ogawa[1], Wataru Tomeno[2], Michihiro Iwaki[3], Takashi Kobayashi[3], Asako Nogami[4], Takaomi Kessoku[3], Kazuo Notsumata[5], Hirotoshi Fujikawa[6], Kento Imajo[7], Masaru Baba[8], Miwa Kawanaka[9], Hideyuki Hyogo[10,11], Taku Hakamada[7], Takashi Honda[12], Miwa Tatsuta[13], Takato Ueno[14], Shigeru Mikami[15], Yasushi Imamura[16], Ken Furuya[8], Noriaki Manabe[9], Tomoari Kamada[9], Masato Yoneda[17], Takumi Kawaguchi[18], Satoru Saito[3] and Atsushi Nakajima[17], (1) National Hospital Organization Yokohama Medical Center, (2)International University of Health and Welfare Atami Hospital, (3)Yokohama City University Graduate School of Medicine, (4)Yokohama City University Graduate School of Medicine, Yokohama Kanazawa Ward, Japan, (5)Fukui-Ken Saiseikai Hospital, (6)Jcho Yokohama Central Hospital, (7)Shin-Yurigaoka General Hospital, (8)Japan Community Health Care Organization Hokkaido Hospital, (9)Kawasaki Medical School, (10)Life Care Clinic Hiroshima, (11)JA Hiroshima General Hospital, (12)Nagoya University Graduate School of Medicine, (13)Kkr Takamatsu Hospital, (14)Asakura Medical Association Hospital, (15)Kikkoman General Hospital, (16)Kagoshima Kouseiren Hospital, (17)Yokohama City University, (18) Kurume University School of Medicine

Background: Increase the prevalence of obesity, diabetes, and metabolic syndrome continues to grow the prevalence of nonalcoholic fatty liver disease (NAFLD). Non-invasive tests, such as Fibrosis-4 index (FIB-4), liver stiffness measurement (LSM), and serum markers are useful for identifying patients with advanced fibrosis. Since the prevalence of advanced fibrosis is different between in general population and in specialist clinics in tertiary centers, a general population-based study is important for the efforts to understand this epidemic and to mitigate the disease burden. We aimed to investigate the prevalence of NAFLD, the

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

distribution of fibrosis stage, and determining the best cut off value of FIB-4 index in general population. **Methods:** A cross-sectional study was conducted among 6540 subjects who received health check-up exams from 2018 to 2021 in 12 centers in Japan. All subjects were performed ultrasonography and the all subjects with fatty liver were performed vibration-controlled transient elastography (VCTE) with M probe. Reliable LSM was defined as LSM < 7 kPa or LSM ≧ 7.1 kPa with interquartile range (IQR) < 30% in subjects with BMI < 30. **Results:** Mean age of the study subjects was 54.0 ± 61.0 years (range 47-61 y). The overall prevalence of NAFLD was 32.4%. Patients in each stage of liver fibrosis using VCTE were 89.6% (fibrosis stage 0), 7.6% (fibrosis stage 1), 1.5% (fibrosis stage 2), 0.8% (fibrosis stage 3), 0.5% (fibrosis stage 4). FIB-4 showed significantly steady stepwise increase in each stage of liver fibrosis. For the diagnosis of advanced fibrosis (fibrosis stage 3 or 4), we used FIB-4 index ≧ 1.3, ≧ 1.3+2.0 (≧ 1.3 for age < 65 and ≧ 2.0 for age ≧ 65). and ≧ 1.45. The sensitivity, specificity, negative predictive value (NPV), and positive predictive value (PPV) of FIB-4 ≧ 1.3/ ≧ 1.3+2.0/ ≧ 1.45 was 78.2/73.9%/78.2%, 75.5/82.6/ 84.0%, 99.6/99.5/99.6%, and 3.9/5.2/5.9%, respectively. When FIB-4 Index ≧ 1.3/ ≧ 1.3+2.0/ ≧ 1.45 was used as an indicator for referral of advanced fibrosis to a hepatology clinic, the referral rate was 25.1/18.0/ 16.7%, respectively. **Conclusion:** A selection bias may exist in hepatology clinics in tertiary centers, then we conducted this general population-based (unbiased population-based) prospective study. As it is impossible to perform liver biopsy in the general population, we performed VCTE for all NAFLD patients and investigated the distribution of fibrosis stage. Our study showed that the accurate prevalence of NAFLD and the distribution of liver fibrosis stage using VCTE. FIB-4 showed high NPV but low PPV. The FIB-4 Index cut-off value of 1.45 suggested the possibility of reduction in the number of patients requiring hepatology assessment compared to FIB-4 ≧ 1.3 or ≧ 1.3+2.0. UMIN Clinical Trials Registry No. UMIN000035188

2156-A | DAIRY PRODUCTS INTAKE AND THE PREVALENCE, INCIDENCE, AND RECOVERY OF NON-ALCOHOLIC FATTY LIVER DISEASE IN EASTERN CHINESE POPULATION

Yurou Xu[1], Youyi Wang[1], Qi Zhao[1], Bo Chen[1], Na Wang[1], Tiejun Zhang[1], Yonggen Jiang[2], Yilin Wu[2], Na He[1], Genming Zhao[1] and Xing Liu[1], (1)The Key Laboratory of Public Health Safety of Ministry of Education, Department of Epidemiology, School of Public Health, Fudan University, Shanghai 200032, China, (2)Songjiang District Center for Disease Control and Prevention, Shanghai 201600, China

Background: Non-alcoholic fatty liver disease (NAFLD) is a growing public health concern. Modifiable factors such as diet and lifestyles are of research interest in preventing or reversing the disease. To date, the relationship between dairy products and NAFLD remains unclear. **Methods:** Based on the Shanghai Suburban Adult Cohort and Biobank study (SSACB), participants aged from 20 to 74 in Songjiang district were enrolled from 2016 to 2017, and a random sample was followed up from 2019 to 2020. Dietary intake and demographic characteristics were collected by questionnaire and physical examination at baseline. NAFLD was defined as having fatty liver diagnosed by ultrasonography in non-excessive alcohol drinkers (<30g/day for males and <20g/day for females). Multivariate logistic regression models were used to analyze the association between baseline prevalence and intake of dairy products, and Cox hazard proportion regression models were used to analyze the association between incidence and recovery with dairy products in the follow-up population. Stratified analysis and sensitivity analysis was also conducted in this study. **Results:** A total of 34040 participants were included in the baseline analyses. After adjusted for age, gender, BMI, education, smoking, alcohol intake, physical activity level and total energy intake, logistic regression model showed that higher dairy product intake was negatively correlated with the prevalence of NAFLD in Songjiang baseline population ($OR_{>2\sim7 \text{ vs } 0 \text{ servings/week}}=0.90$, 95% CI: 0.84-0.97 and $OR_{>7 \text{ vs } 0 \text{ servings/week}}=0.90$, 95% CI: 0.84-0.98). Out of 12,305 patients in the random sample, 9640 were eligible for inclusion criteria. Among those 5583 participants without NAFLD at baseline, 1306 developed NAFLD after a median follow-up time of 3.0 years. The incidence of NAFLD was also inversely associated with dairy intake ($HR_{>7 \text{ vs } 0 \text{ servings/week}}=0.81$, 95% CI: 0.69-0.96). Among those 4057 participants with NAFLD at baseline, 1091 recovered after a 3-year follow-up. The recovery was positively associated with total dairy intake of >0-2 servings/week (HR = 1.45, 95%CI: 1.20-1.65), while the association of higher intake with reversal was not significant ($HR_{>7 \text{ vs } 0 \text{ servings/week}}=0.87$, 95%CI: 0.72-1.04). **Conclusion:** In this study, we found that higher dairy product intake was associated with lower prevalence and incidence of NAFLD. Moderate intake was protective to NAFLD, whereas there was a trend towards poorer NAFLD reversal among those with higher intake.

Background: Nonalchoholic fatty liver disease (NAFLD) and its severe form, nonalcoholic steatohepatitis (NASH), are associated with obesity, type 2 diabetes, and metabolic syndrome. NASH prevalence is estimated at 6% globally and up to 14% in middle-aged Americans, with a higher prevalence in Hispanics. There are significant disparities in clinical trial enrollment in the U.S. for most diseases, with Hispanic patients being significantly underrepresented, raising concerns about generalizing drug efficacy to this

population. Our study aims to assess the representation of sex, age, and ethnicity in relation to disease severity across multiple US NASH clinical trials. **Methods:** We combined screening data from 8 NAFLD/NASH non-cirrhotic phase 2 trials. Descriptive analyses were performed. **Results:** We identified 6,623 patients with available demographic data; 57.4% were females and 49.3% self-identified as Hispanic. The mean age of the entire cohort was 54.3 years (SD 11.8). The distribution of patients across different age groups screened into the studies is illustrated in the figure. Among the 2,217 patients who underwent a liver biopsy, 63% of females were diagnosed with NASH, compared to 55% of males ($p < 0.001$). Furthermore, NASH with significant fibrosis (Fibrosis stage 2, 3, or 4) was observed in 51% of females and 42% of males ($p < 0.001$). In terms of ethnicity, 57% of Hispanics were diagnosed with NASH, while the proportion was slightly higher at 62% for non-Hispanics ($p = 0.039$). Similarly, the percentage of non-Hispanics with significant fibrosis (49%) was slightly higher than that of Hispanics (44%) ($p = 0.011$). **Conclusion:** Clinical trials focusing on NASH predominantly recruit middle-aged adults, with a noticeable underrepresentation of young adults and more importantly, elderly patients, who tend to present with more severe forms of the condition. Contrary to prior assumptions, our study findings indicate that Hispanics are adequately represented in NASH clinical trials conducted in the United States. This could be attributed to the presence of a broader network of trial sites in regions with significant Hispanic populations.

2158-A | DEVELOPMENT AND VALIDATION OF A RISK SCORE FOR FIBROSIS STAGE 2 OR HIGHER: A REAL-NAFLD STUDY OF 1902 REAL-WORLD PATIENTS WITH BIOPSY

Vy H. Nguyen[1,2], Takanori Ito[3], Hansen Dang[4], Pei-Chien Tsai[5], Miwa Kawanaka[6], Masanori Atsukawa[7], Taeang Arai[7], Korenobu Hayama[8], Ming-Lun Yeh[9], Mayumi Maeda[2], Scott D. Barnett[10], Wan Long Chuang[11], Chung-Feng Huang[5], Chia-Yen Dai[9], Jee-Fu Huang[12], Ramsey Cheung[10], Ming-Lung Yu[5], Shinichi Aishima[13], Hidenori Toyoda[14] and Mindie H. Nguyen[10], (1)Harvard Medical School, (2)Stanford University Medical Center, (3)Nagoya University Graduate School of Medicine, (4)Stanford University, (5)Hepatobiliary Section, Department of Internal Medicine, and Hepatitis Center, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, (6)Kawasaki Medical School, (7) Nippon Medical School Hospital, (8)Nippon Medical School, (9)Kaohsiung Medical University, (10)Stanford University Medical Center, Palo Alto, CA, (11) Kaohsiung Medical University Hospital, Kaohsiung Medical University, (12)Hepatobiliary Section, Department of Internal Medicine, and Hepatitis Center, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, Kaohsiung, Taiwan, (13)Saga University, (14) Ogaki Municipal Hospital

Background: Patients with nonalcoholic fatty liver disease (NAFLD) who develop fibrosis stage 2 or higher are at increased risk of both liver-related and non-liver-related morbidity and mortality. We aimed to develop and validate a simple-to-use and accurate fibrosis risk score using readily available clinical information from real-world patients with NAFLD. **Methods:** This study included 1902 patients with NAFLD with liver biopsy recruited in the REAL-NAFLD registry, an observational chart review registry at 5 centers (1 United States, 1 Taiwan, and 3 Japan). We randomly divided the patients into a training (N = 1268) and validation (N = 634) cohort on a 2:1 ratio. We used logistic regression with stepwise selection to identify statistically significant variables to assemble a modified fibrosis-4 index (mFIB-4) score. **Results:** The mFIB-4 score includes the original FIB-4 index, Asian race, and diabetes. This 12-point risk score yielded an area under receiver operating characteristic curves (AUC) of 0.67, 0.76, and 0.83 in distinguishing **e** F1, **e** F2, and **e** F3, respectively, in the validation cohort. Compared to the FIB-4 index, the mFIB-4 performs better at distinguishing **e** F1 and **e** F2 in the validation cohort (0.67 vs. 0.56, $p < 0.0001$, and 0.76 vs. 0.70, $p < 0.0001$, respectively). There was no significant difference between mFIB-4 and FIB-4 at distinguishing **e** F3 (0.82 vs. 0.81, $p = 0.11$, respectively). Using Youden's index and optimizing the sensitivity and specificity at each score, the mFIB-4 score was further categorized as follows: 1-8 low risk and 9-12 high risk. Patients in the high-risk categories are associated with nearly a 10% probability of having **e** F2, nearly 5 times higher than those in the low-risk group (Figure). Similarly, the probability of having **e** F3 is about 1% in the low-risk group but close to 6% in the high-risk group. **Conclusion:** The mFIB-4 score provides two distinct risk categories with no indeterminate group to stratify the risk of developing significant fibrosis in patients with NAFLD. Additional validation analyses are needed to validate the use of mFIB-4 in other subgroups to identify patients at increased risk of developing fibrosis.

2159-A | DIABETICS ON INSULIN THERAPY HAVE SIGNIFICANTLY HIGHER ATHEROSCLEROTIC CARDIOVASCULAR DISEASE (ASCVD) BURDEN AND PROBNP CAN DISCRIMINATE ASCVD WITH HIGH SPECIFICITY IN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE

Puneet Puri[1,2], Gowthami Kanagalingam[1,2], Bryan Badal[1,2], Joyce Xiyuan Badal[3], Benjamin Blake[4], Joelle Lemmons[1], Zenaida Malpaya[1], April Morris[1], Maribeth Capuno[1], Ashley Long[1], HoChong Gilles[1], Joseph Spataro[1,2], Jennifer Miller[1,2], Jasmohan S. Bajaj[1,2], Brian C. Davis[1,2], M. Rehan Khan[1], Ion Jovin[1] and Michael Fuchs[1,2], (1)Mcguire Richmond VA Medical Center, (2)Virginia Commonwealth University, (3) University of Toledo College, (4)Weill Cornell Medical College

Background: Cardiovascular (CV) morbidity and mortality is high in patients with nonalcoholic fatty liver disease (NAFLD). Diabetics are at high risk of CV disease (CVD). We aimed to examine this CVD burden and impact of insulin vs. non-insulin therapies in patients with NAFLD which is not well described. **Methods:** NAFLD patients were prospectively evaluated for presence of cardiovascular disease (CVD). The diagnosis of NAFLD was established either on imaging (Vibration Controlled Transient Elastography [VCTE] and MRI Proton Density Fat Fraction [PDFF]) or liver histology. A 10-year FRS was calculated and those with intermediate ($>10\%$) and high ($>20\%$) risk were offered CT heart to assess for coronary artery calcium (CAC) score. A CAC score of 0 is considered optimal, while CAC score of 1-99 is low risk, 100-399 is intermediate risk and 400 or greater is high risk atherosclerotic burden. Fasting blood samples for traditional CVD risks were also performed. Statistical analysis were performed using JMP. **Results:** Total of 201 Veterans (84% male) with mean ($\pm$SD) age of 56.6 $\pm$ 10 years were studie. Histologic evaluation was available on 128 with 17.5% at-risk NASH (F2 fibrosis or higher). 21/201 (10.5%) had pre-existing coronary artery disease (CAD) at time of presentation. Almost 100% of those were on aspirin and statin therapy. 27 (13.4%) had no diabetes, 59 (29.3%) had prediabetes, 115 (57.2%) had diabetes. Statin use was seen in 135 (67.5%) and 98 (48.8%) were taking aspirin and 81 (40.3%) were on both aspirin and statin. A CAC score **e** 1 indicated CAD and was seen in 60% (73/121 coronary CT scans). Diabetics compared to non-diabetics had ~3 fold higher median Framingham heart risk (FHR) score (13, IQR 8-25) vs. (35, IQR 19-49; $p<0.0001$). Notably, no significant differences were noted between diabetics, non-diabetics and prediabetics for CAC scores. Among diabetic patients insulin also had a higher Framingham risk score compared to non-insulin therapy (28, IQR 18-45) vs. (45, IQR 35-56), $p=0.001$. CAC score (231, IQR 12-1572 vs 6.5, IQR 0-403, $p=0.009$). Based on CAC score those on insulin therapy had higher risk of coronary artery disease (OR 4.5; 1.2-17.3). FHR score was two folds higher in those with either statin or aspirin use (33, IQR 19-46 vs. 17.2, IQR 11-27 $p<0.0001$. However, Framingham risk score was 2.5 fold higher in statin and ASA users compared to non-users (35% vs 14%, $p<0.0001$). Those that had evidence of coronary artery disease based on CAC score 23% were not on statins. Amongst those who had severe CAD (CAC score >100) about 20% were not on statins. Pro-BNP had an area under the curve of 0.77 with CI 0.64-0.87, $p<0.0001$ with YODEN index of 0.48. Specificity 92% for cutoff >49). **Conclusion:** NAFLD patients with diabetes on insulin have high risk of CAD and pro-BNP can discriminate CAD with high specificity

2160-A | DIAGNOSIS IS DELAYED: PERICOMPLICATION DIAGNOSIS OF NONALCOHOLIC FATTY LIVER DISEASE

Richie Manikat[1], Sally Tran[1], Leslie Yeeman Kam[1], Deepti Dronamraju[2], Ramsey C. Cheung[3] and Mindie H. Nguyen[1], (1)Stanford University Medical Center, Palo Alto, CA, (2)Stanford University Medical Center, (3)Veterans Affairs Palo Alto Health Care System

Background: Nonalcoholic fatty liver disease (NAFLD) is a condition in which screening guidelines remain controversial as the characteristics that predispose to the development of complications remain unclear. An earlier diagnosis of NAFLD may allow adequate time for intervention and help prevent complications such as hepatocellular carcinoma (HCC), cirrhosis, or advanced liver disease requiring a liver transplant. Our aim was to determine the proportion of patients with a delayed diagnosis of NAFLD, defined as patients diagnosed with NAFLD within 6 months or after a complication like HCC, cirrhosis or liver transplant. **Methods:** This is a retrospective analysis of patients within the Truven MarketScan database (1/2007-12/2021), a claims database for more than 250 million U.S. people with private insurance. All adults **e** 18 years who had a diagnosis of NAFLD, a liver complication (defined as HCC, cirrhosis or liver transplant), and had at least 12 months of insurance coverage prior to the first liver complication were included. **Results:** The study population included 143,310 patients with a diagnosis of NAFLD and at least one associated liver complication. The mean age was 56.3 ± 14.0 years and 53% were female. Two-thirds of the patients (95,843, 66.8%, $p < 0.001$) were diagnosed with NAFLD less than six months before or even after the development of a liver complication (Figure). Patients with a pericomplication diagnosis of NAFLD were more likely to be older (57.6 ± 14.5 vs. 53.8 ± 12.5), have cardiovascular disease (13.7% vs. 5.5%), hypertension (72.2% vs. 68.4%), diabetes (45.7% vs. 43.2%), chronic kidney disease (16.7% vs. 7.1%), obesity (36.2% vs. 31.1%), tobacco use (18.7% vs. 12.6%) and illicit drug use (2.3% vs. 1.4%), all $P < 0.001$. The mean Charlson Comorbidity Index (CCI) was significantly greater in this group compared to patients that were diagnosed earlier (mean 3.0 ± 3.0 vs 1.9 ± 2.3, $p < 0.0001$). On multivariable logistic regression adjusted for age, sex, and CCI, a first visit with a medical provider specializing in gastroenterology (OR 0.32, 95% CI 0.31-0.32, $p < 0.001$), cardiology, endocrinology, or nephrology (OR 0.44, 95% CI 0.43-0.45, $p < 0.001$) more than 1 year prior to a complication was associated with a significantly lower odds of delayed diagnosis of NAFLD. **Conclusion:** Diagnosis of NAFLD in real-world patients is severely delayed, with 2 in 3 patients diagnosed either after or within 6 months from a liver complication. Patients followed longitudinally by medical providers in gastroenterology and other metabolic specialties for one year or greater had a lower risk of an early complication. Early diagnosis and continued follow-up of NAFLD does delay the risk of developing the devastating complications of this condition.

2161-A | DIET QUALITY, LIVER STEATOSIS, AND FIBROSIS IN U.S. YOUTH

Vanessa Garcia-Larsen[1], Hani Tamim[2], Noara Alhusseini[2], Saad A Alghamdi[3], Mohammad Shagrani[3], Faisal Abaalkhail[4], Waleed K Al-Hamoudi[4], Faisal M Sanai[5] and Saleh A Alqahtani[1,3], (1)Johns Hopkins University, (2)Alfaisal University, (3)King Faisal Specialist Hospital and Research Center, (4)King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia, (5)King Abdulaziz Medical City-Jeddah

Background: Nonalcoholic fatty liver disease (NAFLD) is the fastest-growing lifestyle-related non-communicable disease in the world. Current evidence suggests metabolic disruptions associated with obesity and type II diabetes mellitus (T2DM) as main drivers of the disease in adults. Childhood diet and NAFLD have been less examined. We aimed to investigate the association between diet quality and objectively measured NAFLD in adolescents and youth from a population-based study. **Methods:** As part of the U.S. National Health and Nutrition Examination Survey (NHANES) Program, we analyzed data in individual's aged **e** 12 < 21 years old participating in the 2017-2018 cycle, with valid FibroScan® measurements. Liver steatosis (NAFLD; controlled attenuation parameter [CAP] score of **e** 248 dB/m) and advanced fibrosis (liver stiffness measurement of **e** 9.4 kPa [F3-F4]) were measured through vibration-controlled transient elastography with CAP. Two diet quality indices widely used in the U.S. population were derived, namely the Dietary Approaches to Stop Hypertension (DASH; 8 = lowest adherence, 40 = highest adherence) and the Alternative Healthy Eating Index (AHEI; 0 = low adherence, 110 = highest adherence). The associations between diet quality indices (per standard deviation [SD] increase in score) and NAFLD-related outcomes were examined with survey-weighted logistic regressions adjusting for potential confounders. **Results:** Among 972 youth aged 15.7 ± 2.4 (male 51.0%) with complete data, the prevalence of liver steatosis was 28.3%, while 3.2% had advanced fibrosis. The mean DASH score was 21.8 (SD ± 4.7), indicative of 43.0% adherence to the DASH-style diet pattern, and the mean AHEI score was 53.7 (SD ± 7.9). A per-SD increase in DASH score was associated with lower odds of having liver steatosis (odds ratio [OR] 0.78.9; 95% confidence interval [95% CI] 0.65, 0.95; p-value 0.016), but not with advanced fibrosis (OR 1.44; 95% CI 0.79, 2.61). AHEI score was associated with lower odds of both outcomes, but these did not reach statistical significance. **Conclusion:** The high prevalence of NAFLD observed in youth represents a major public health challenge. A greater adherence to a DASH pattern was associated with liver steatosis but not fibrosis. Highlighting the importance of diet quality to prevent NAFLD and to promote higher adherence to a DASH pattern in adolescents may support public health strategies for its prevention.
Disclosures: The following people have nothing to disclose: Vanessa Garcia-Larsen, Hani Tamim, Noara Alhusseini, Saad A Alghamdi, Mohammad Shagrani, Faisal Abaalkhail, Waleed K Al-Hamoudi, Faisal M Sanai, Saleh A Alqahtani

2162-A | DIETARY AND CALORIC INTAKE IN PATIENTS WITH NAFLD COMPARED TO THE GENERAL US POPULATION: INSIGHTS FROM THE NHANES STUDY

Giovanni A. Roldan[1], Sebastian Niezen[2], Jiada Zhan[3], Ju Dong Yang[4], Walid S. Ayoub[4], Alexander Kuo[4] and Hirsh Trivedi[4], (1)Columbia University, New York, NY, (2)University of Pittsburgh Medical Center, (3)Emory University, (4)Cedars-Sinai Medical Center, Los Angeles, CA

Background: Non-alcoholic fatty liver disease (NAFLD) is a complex, multisystemic condition associated with poor dietary habits, particularly high fat and high fructose intake, which develops in genetically predisposed individual's. The management of NAFLD typically involves reducing caloric intake and improving dietary quality. This study aims to examine the dietary composition and caloric intake of patients with NAFLD and compare them to patients without NAFLD. **Methods:** We conducted an analysis of data from the National Health and Nutrition Examination Survey (NHANES) spanning the years 2017 to 2020 to assess populations with and without NAFLD. NHANES encompasses self-reported demographic, socioeconomic, health, and dietary information. One in-person dietary recall was used. NAFLD was defined as having a controlled attenuation parameter (CAP) score equal or higher than 285 dB/m on vibration-controlled Transient Elastography (VCTE), with no other potential etiologies for liver steatosis. The NHANES study population consisted of 15,560 participants, with 3,598 individual's categorized as either NAFLD or non-NAFLD. **Results:** Among the included participants, 1,336 met the criteria for NAFLD, while 2,262 did not. Analysis of 24-hour recall data revealed no statistically significant difference

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

in total caloric intake between the two groups (2200 kcal in NAFLD vs. 2160 kcal in non-NAFLD; p = 0.06). The macronutrient composition of the diets in both groups was generally similar, except for a higher intake of total saturated fatty acids observed in the NAFLD population (29.6 gm vs. 28.3 gm; p = 0.04). **Conclusion:** Patients with NAFLD exhibited comparable total caloric intake and macronutrient dietary composition, as reported in 24-hour recall data, compared to patients without NAFLD. However, there was a higher intake of total saturated fatty acids among individual's with NAFLD. These findings suggest that additional factors, including genetic polymorphisms, may play a larger role in the development of NAFLD compared to dietary composition alone.

	Non-NAFLD		NAFLD		
Dietary component[1]	gm	kcal (%)	gm	kcal (%)	p-value
Carbohydrate	245 ± 128	980 (45.38)	251 ± 124	1004 (45.64)	0.12

2163-A | DIFFERENCES BETWEEN BIOPSY-PROVEN NASH PATIENTS WITH AND WITHOUT DIABETES MELLITUS

Hansen Dang[1,2], Vy H. Nguyen[3,4], Pei-Chien Tsai[5], Takanori Ito[6], Miwa Kawanaka[7], Masanori Atsukawa[8], Taeang Arai[9], Korenobu Hayama[10], Ming-Lun Yeh[11], Mayumi Maeda[4], Wan Long Chuang[12], Chung-Feng Huang[5], Chia-Yen Dai[5], Jee-Fu Huang[13], Ramsey Cheung[14], Shinichi Aishima[15], Hidenori Toyoda[16], Ming-Lung Yu[17] and Mindie H. Nguyen[14], (1)Stanford University, (2)University of Iowa, Carver College of Medicine, (3)Harvard Medical School, (4)Stanford University Medical Center, (5)Hepatobiliary Section, Department of Internal Medicine, and Hepatitis Center, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, (6)Nagoya University Graduate School of Medicine, (7)Kawasaki Medical School, (8)Nippon Medical School Hospital, Tokyo, Japan, (9)Nippon Medical School Hospital, (10)Nippon Medical School, (11)Kaohsiung Medical University, (12)Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University, (13)Kaohsiung Medical University Hospital, (14)Stanford University Medical Center, Palo Alto, CA, (15)Saga University, (16)Ogaki Municipal Hospital, (17) Kaohsiung Chang Gung Memorial Hospital,

Background: Diabetes mellitus is strongly associated with the development of NAFLD and NASH. However, studies characterizing the effects of diabetes on the severity of NASH remain sparse. To address this, we aimed to examine the characteristics of patients with and without diabetes in a multinational cohort of biopsy-confirmed NASH patients. **Methods:** Data were obtained from REAL-NAFLD registry which includes 1902 patients with NAFLD with liver biopsy at five medical centers, one in the U.S. and four in Asia (Japan and Taiwan). Patients with biopsy-confirmed NASH were eligible for the study and were divided into those with diabetes (n = 407) and those without diabetes (n = 636). Logistic regression was performed to estimate odds ratios associated with worse fibrosis stage on pathology and NAS score **e** 5. **Results:** Analyses of baseline characteristics between the two groups revealed significant differences in demographics, comorbidities, and liver function. NASH patients with diabetes were older (55.34 vs 48.32, $p < 0.001$) and more likely to have hypertension (67.74% vs 40.63%, $p < 0.001$), hyperlipidemia (66.09% vs 45.42%, $p < 0.001$), and cirrhosis (31.96% vs 21.96%, $p < 0.001$) compared to those without diabetes. Additionally, they had lower ALT levels (68 U/L vs 75 U/L),

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

higher FIB-4 index (1.85 vs 1.48), and were more likely to have advanced liver fibrosis on pathology (all $p < 0.05$). On multivariable logistic regression, adjusting for age, sex, ethnicity, BMI, diabetes, platelets, albumin, we found that diabetes was independently associated with increased odds of having liver fibrosis stage **e** F2 on biopsy (aOR = 1.92, 95% CI: 1.49-2.47, $p < 0.001$). When assessing for advanced fibrosis and higher (**e** F3), diabetes was again found to have a significant association (aOR = 2.10, 95% CI: 1.57-2.82, $p < 0.001$). Additionally, in a different multivariable logistic model, diabetes was found to be independently associated with a NAS score **e** 5 (aOR = 1.36, 95% CI: 1.06-1.75, $p < 0.001$). **Conclusion:** In our multinational study of biopsy-proven NASH patients, diabetes mellitus was found to be significantly associated with higher odds of worse fibrosis stage on biopsy and NAS score at the time of NASH diagnosis. More surveillance and interventions are needed for NASH patients with diabetes, as worse fibrosis stage increases the risk of cirrhosis and liver-related mortality.

Table 1. Baseline characteristics of biopsy confirmed NASH patients with and without diabetes mellitus

Characteristics	No diabetes mellitus (n=822)	Diabetes mellitus (n=468)	*P*-value
Age	48.32 ± 15.90	55.34 ± 12.84	**<0.001**
Male (%)	391 (47.57)	213 (45.51)	0.477

2164-A | DIFFERENCES IN BODY COMPOSITION OF MAFLD PATIENTS ACCORDING TO BODY MASS INDEX AND METABOLIC PROFILE

Eva Juárez-Hernández[1], Iván López-Méndez[1], Karen D Bernal-Contreras[1,2], Alain Velázquez-Alemán[1], Andrea Maldonado-Rojas[1], Graciela Elia Castro-Narro[1], Martha Helena Ramos-Ostos[1] and Misael Uribe[1], (1)Medica Sur Clinic & Foundation, (2)Universidad Anáhuac México

Background: Body composition (BC) has been linked to liver steatosis; however, there are not evidence about alterations in BC in MAFLD patients, therefore, the aim of this study is to describe differences in BC, in these patients **Methods:** It is a cross sectional study with patients whom attended at check-up unit. Liver steatosis was evaluated by controlled attenuation parameter (CAP) and patients were classified according to definition of MAFLD for overweight/obese and lean patients. Patients were classified according to body mass index (BMI), in five groups: G1: < 25kg/m²-non-MAFLD; G2: < 25 kg/m²-MAFLD; G3: 25-30 kg/m²-MAFLD; G4: > 30 kg/m²-MAFLD and metabolically healthy (< 3 metabolic abnormalities) (MH) and G5: > 30 kg/m²-MAFLD and metabolically unhealthy (MU). BC was assessed by bioelectrical impedance (RJL Quantum IV) obtaining measurements of resistance; reactance; phase angle; percentages of fat; total body water (TBW%); intracellular and extracellular water (ICW% and ECW%) and skeletal muscle mass (SMM%). Differences in BC was analyzed by Kruskall-Wallis test. Continuous data showed as median and interquartile range. **Results:** A total of 140 patients were included (G1 n = 30; G2 n = 24; G3 n = 30; G4 n = 26; G5 n = 30). 56.4% (n = 79) were male with median of age of 49 [41-55] years. Overweight/obese MAFLD patients showed significant lower resistance and reactance levels (p **d** 0.05). Fat % was higher in MAFLD obesity groups (G4: 41[24-45] %; G5: 40.4 [36.5-43.2] %) than G1 (31[26.9-34.5]) (p **d** 0.001); according to vectorial analysis, chaquexia was observed in 18.4% (n = 7) of patients in G4 and 15.8%

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(n = 6) in G5 patients. Fat% was also higher in patients of G5 (MU) than G2 (34.3[29.8-40.4], p = 0.02) and G3 (35[31.1-38.3], p = 0.01) patients. Obese MAFLD patients showed lower %TBW, ICW% and ECW% (p **d** 0.001). (Figure). According to SMM%, it was lower in MU obese MAFLD patients (29.1[26.3-31.1]) compared to healthy controls (33.4[29.3-36.8], p = 0.006) and overweight MAFLD patients (32[29.7-34.4], p = 0.02). Phase angle did not show significant differences. **Conclusion:** Overweight/obese MAFLD patients shows BC abnormalities in comparison with healthy controls and lean MAFLD patients. BC parameters of resistance, reactance, body water and skeletal muscle mass are significant lower in obese patients, metabolically healthy and unhealthy. These changes could be explained for the sarcopenia and fat-muscle interchange and no necessary for the presence of metabolic abnormalities.

2165-A | DIFFERENCES IN INCIDENCE OF ADVERSE CLINICAL EVENTS AMONG NAFLD PARTICIPANTS WITH LIVER BIOPSY PROVEN NAFLD STRATIFIED BY NASH: A SYSTEMATIC REVIEW AND META-ANALYSIS

David M Le[1], Thomas Baez[1], Michael H Le[2], Hansen Dang[3], Vy H. Nguyen[4], KeeSeok Lee[3], Takanori Ito[5], Yuankai Wu[4], Yee Hui Yeo[6], Fanpu Ji[7], Ramsey Cheung[8] and Mindie H. Nguyen[8], (1)Burrell College of Osteopathic Medicine, (2)Larner College of Medicine at the University of Vermont, San Jose, CA, (3)Stanford University, (4)Stanford University Medical Center, (5) Nagoya University Graduate School of Medicine, Japan, (6)Cedars-Sinai Medical Center, Culver City, CA, (7)The Second Affiliated Hospital of Xi'an Jiaotong University, (8)Stanford University Medical Center, Palo Alto, CA

Background: Nonalcoholic fatty liver disease (NAFLD) exists as a spectrum, with nonalcoholic steatohepatitis (NASH) representing the more severe subtype of NAFLD. Both NAFLD and NASH are associated with increased risks of morbidity and mortality. We aimed to determine and compare the incidence rates of adverse clinical events associated with biopsy confirmed NAFLD and NASH. **Methods:** We performed a systematic review and meta-analysis of cohort studies of adults with NAFLD at baseline using 3 databases (Cochrane library, EMBASE, PubMed) to evaluate the pooled incidence of adverse clinical events associated with biopsy-confirmed NAFLD and NASH. Random-effects models were used to estimate the pooled incidence of adverse clinical events. **Results:** A total of 13 studies of biopsy confirmed NAFLD patients (n = 14570) and 16 studies of biopsy confirmed NASH patients (n = 9297) were identified and included in meta-analysis. Median study year for NAFLD was 2004 with median follow-up of 3612.5 person-years. Median study year for NASH was 2004 with median follow-up of 1722 person-years. All analyses showed significant heterogeneity (I^2 **e** 50%) and no asymmetry on funnel plot or significance on egger's test (p > 0.05). Data are reported as incidence rate per 1000 person-years. No significant differences in incidence were observed for all-cause (10.3 vs 23.5), cardiovascular-related (6.2 vs 6.1), and non-liver cancer related mortality (5.2 vs. 7.0) between those with NAFLD and NASH. Those with NASH had higher incidence of liver-related mortality compared to NAFLD (10.2 vs 1.4), however this did not reach statistical significance. Additionally, there were no significant differences in the development of non-liver cancer between NAFLD and NASH (10.8 vs 13.8). Compared to patients with NAFLD alone, significantly higher incidence of liver-related events was observed among patients with NASH (4.2 vs 34.2). Incidence for hepatocellular carcinoma was significantly higher among NASH patients (0.8 vs 14.8), however no significant differences were noted for fibrosis progression (62.8 vs 115.7), cirrhosis (5.7 vs 10.8), and decompensation (2.4 vs 4.6). No patients with NAFLD received a liver transplant, with 57/273 NASH patients undergoing liver transplant. Additionally, no significant differences were observed in the incidence rate per 1000 person-years of diabetes (18.4 vs 22.7), dyslipidemia (43.5 vs 39.4), and cardiovascular disease (22.9 vs 16.2) between those with NAFLD and NASH (figure). **Conclusion:** Compared to those with NAFLD alone, those with NASH had significantly higher incidence of liver-related events and hepatocellular carcinoma with a trend for higher incidence of liver-related mortality, though this did not achieve statistical significance. Identification and early intervention for patients with

2166-A | DISEASE PROGRESSION IN TAIWANESE NON-ALCOHOLIC STEATOHEPATITIS PATIENTS: SUBGROUP ANALYSIS OF THE PLACEBO PATIENTS IN A DOUBLE-BLIND RANDOMIZED TRIAL

Ming-Lun Yeh[1,2], Jee-Fu Huang[3], Chung-Feng Huang[4], Chia-Yen Dai[4], Ming-Lung Yu[5] and Wan Long Chuang[6], (1)Kaohsiung Medical University, Kaohsiung, Taiwan, (2)Kaohsiung Medical University, (3)Kaohsiung Medical University Hospital, (4)Hepatobiliary Section, Department of Internal Medicine, and Hepatitis Center, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, (5)Kaohsiung Chang Gung Memorial Hospital, (6)Hepatobiliary Division, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung Medical University

Background: Disease progression remains elusive in Asian non-alcoholic steatohepatitis (NASH) patients. We aimed to investigate the paired histopathological features of the Taiwanese NASH patients randomized into placebo group in a double-blind randomized trial. **Methods:** All the placebo group patients received a 6-month strict multi-disciplinary program of lifestyle modifications led by physician, dietician, and nursing staff. The histopathological and clinical features obtained from paired biopsies 24 weeks apart were assessed. The endpoints were normalization of transaminase levels, metabolic parameters, decrease of NAFLD Activity Score (NAS) **e** 1, and fibrosis stage decrease **e** 1 stage. We also aimed to elucidate the predictors associated with disease progression. **Results:** A total of 37 biopsy-proven NASH patients were enrolled. The normalization of transaminase level increased from 0% to 13.5%. There were also significantly increased proportions of patients with normal total cholesterol, triglyceride, and hemoglobin A1c levels. Fifteen (40.5%) patients had increased NAS **e** 1, whereas 10 (27.0%) patients had NAS regression, respectively. Twelve (32.4%) patients had increased fibrosis **e** 1 stage. Only 2 (5.4%) patients had fibrosis regression. A high fasting plasma glucose (FPG) level was associated with NAS progression. Older age, higher transaminase and FPG levels were factors associated with fibrosis progression. There were 7 (18.9%) patients achieving body weight reduction > 3%, and 4 (57.1%) of them had NAS regression. No significant effect of weight reduction in the progression of fibrosis was observed. **Conclusion:** Taiwanese NASH patients had a significant disease progression with a short-term lifestyle modification program. A more precise or intensive program may be needed for disease control. **Background:** Disease progression remains elusive in Asian non-alcoholic steatohepatitis (NASH) patients. We aimed to investigate the paired histopathological features of the Taiwanese NASH patients randomized into placebo group in a double-blind randomized trial. **Methods:** All the placebo group patients received a 6-month strict multi-disciplinary program of lifestyle modifications led by physician, dietician, and nursing staff. The histopathological and clinical features obtained from paired biopsies 24 weeks apart were assessed. The endpoints were normalization of transaminase levels, metabolic parameters, decrease of NAFLD Activity Score (NAS) **e** 1, and fibrosis stage decrease **e** 1 stage. We also aimed to elucidate the predictors associated with disease progression. **Results:** A total of 37 biopsy-proven NASH patients were enrolled. The normalization of transaminase level increased from 0% to 13.5%. There were also significantly increased proportions of patients with normal total cholesterol, triglyceride, and hemoglobin

A1c levels. Fifteen (40.5%) patients had increased NAS **e** 1, whereas 10 (27.0%) patients had NAS regression, respectively. Twelve (32.4%) patients had increased fibrosis **e** 1 stage. Only 2 (5.4%) patients had fibrosis regression. A high fasting plasma glucose (FPG) level was associated with NAS progression. Older age, higher transaminase and FPG levels were factors associated with fibrosis progression. There were 7 (18.9%) patients achieving body weight reduction > 3%, and 4 (57.1%) of them had NAS regression. No significant effect of weight reduction in the progression of fibrosis was observed. **Conclusion:** Taiwanese NASH patients had a significant disease progression with a short-term lifestyle modification program. A more precise or intensive program may be needed for disease control.

2167-A | DISPARITIES AND DISCORDANCE IN PROBLEM LIST DOCUMENTATION OF FATTY LIVER DISEASE AMONG PATIENTS WITH RADIOGRAPHIC FINDINGS OF HEPATIC STEATOSIS IN OUTPATIENT SETTINGS

Ashley Spann, Dario Giuse and Manhal Izzy, Vanderbilt University Medical Center

Background: The prevalence of nonalcoholic fatty liver disease (NAFLD) is rapidly rising in the United States. Despite this, patients and providers are often unaware of the disease. Natural language processing (NLP) has previously been shown to accurately detect hepatic steatosis. By leveraging an electronic health record (EHR) embedded natural language processing (NLP) tool applied to radiology reports, we aimed to assess the concordance between NLP and existing chart documentation in identifying patients with NAFLD. **Methods:** This retrospective, single, large academic center study included patients who were seen in either outpatient office or telemedicine visits by gastroenterology/hepatology, primary care, or endocrinology providers during a 1-year period (1/1/2021 – 12/31/2021). Liver transplant recipients and those patients without an internally interpreted abdominal imaging study within the 3 years prior to their visit were excluded. An EHR-embedded NLP tool that maps unstructured contextual data within the electronic health record to Unified Medical Language System (UMLS) concept codes was applied to abdominal radiology reports obtained within the 3 years prior to the office visit. Multivariable logistic regression was used to assess for associations of NLP concordance with problem list documentation. **Results:** A total of 28,829 patients meeting inclusion criteria were seen in telemedicine or in office encounters during the observation period with available historical abdominal imaging. The NLP tool detected hepatic steatosis on imaging within the prior 3 years for 8,177 patients (28.4% of total patient population), however only 1,999 patients (24.4% of those positive for HS by NLP) had concordant problem list documentation of fatty liver disease at the time of their office visit. Among NLP-positive patients, patients had significantly greater odds of having concomitant problem list documentation of NAFLD if Hispanic, seen by a gastroenterology provider or had documented components of metabolic syndrome (Figure). Black patients, women, older patients and those seen in endocrinology clinics had significantly lower odds of having documentation of a NAFLD diagnosis (Figure). **Conclusion:** This study highlights that less than 1/4th of patients with HS on imaging as detected by NLP have discrete documentation of HS or NAFLD within their medical records. Additionally, black patients, women and those seen by endocrinology providers were less likely to have documented diagnoses of NAFLD within their medical records even in the presence of hepatic steatosis on imaging. Natural language processing techniques offer a solution to detect patients with hepatic steatosis on imaging from radiology reports and can augment accurate and equitable capture of these patients to potentially facilitate EHR-embedded decision support tools to provide directed care for these patients.

Multivariable Logistic Regression Model for Likelihood of NAFLD Diagnosis Among Patients with Hepatic Steatosis on Imaging Detected by Natural Language Processing

Variable	Odds Ratio	95% CI	p-value
Age at Visit	0.99	0.98 – 0.99	< 0.001
BMI at Visit	1.02	1.01 – 1.03	< 0.001
Female Gender	0.89	0.80 – 1.00	0.047

2168-A | DOES STEATOSIS PREDICT OUTCOMES IN LIVER DISEASE? TRANSIENT ELASTOGRAPHY CAP SCORE IS ASSOCIATED WITH CIRRHOSIS, DECOMPENSATION, HCC AND DEATH AMONG U.S. VETERANS WITH LIVER DISEASE

Nicole J. Kim[1], Philip Vutien[1], Joleen A Borgerding[2], Lauren A. Beste[1,3] and George Ioannou[1,2], (1) University of Washington, (2)Veterans Affairs Puget Sound Healthcare System, (3)VA Puget Sound Healthcare System

Background: Liver steatosis is common in patients with chronic liver disease (CLD), but whether the degree and etiology of steatosis predicts disease progression or mortality remains unknown. **Methods:** We identified 13,008 U.S. Veterans with CLD and at least one FibroScan® done after 1/1/2015. We excluded patients with decompensation (ascites, variceal bleed, or hepatic encephalopathy) or hepatocellular carcinoma (HCC) prior to FibroScan® date. We categorized liver steatosis by FibroScan® Controlled Attenuated Parameter (CAP) scores, as stage 0 (< 274 dB/m), 1 (274-289), 2 (290-301), and 3 (**e** 302). We assessed for development of cirrhosis, decompensation, HCC, and death until 1/1/2022. Multivariable Cox-proportional hazards regression (adjusting for age, sex, race/ethnicity, BMI, diabetes, history of alcohol use disorder, CLD etiology, and FibroScan® liver stiffness score) was used to assess for associations between CAP scores (by stage and stage **e** 1 vs. 0) and these outcomes, overall and by CLD etiology. **Results:** The cohort was 95% male, 52% White, 32% Black, 7.3% Hispanic, and 2.9% Asian, with a median age of 65.4 years (IQR 10.6). Fifty-seven percent (n = 7,433) had cirrhosis and CLD etiologies included active hepatitis C (HCV; 28%), cured HCV (21%), non-alcoholic fatty liver disease (NAFLD; 28%), alcohol-associated liver disease (ALD; 13%), and chronic hepatitis B (10%). Of the cohort, 46%, 8.1%, 5.7%, and 40% of patients had a CAP score of stage 0, 1, 2, and 3, respectively. On overall multivariable analysis, CAP score stage **e** 1 (vs. 0) was associated with an increased risk of cirrhosis (adjusted HR [aHR] 1.18 [95% CI: 1.01-1.37]), and a decreased risk of decompensation (aHR 0.77 [0.63-0.93]), HCC (aHR 0.80 [0.65-0.99]) and death (aHR 0.66 [0.59-0.75]). CAP score stage 3 (vs. 0) was associated with an increased risk of cirrhosis in active HCV (aHR 1.37 [1.07-1.75]) and NAFLD (aHR 1.37 [1.01-1.85]), decreased risk of decompensation in active HCV (aHR 0.58 [0.37-0.89]) and NAFLD (aHR 0.54 [0.36-0.79]), and decreased risk of death in cured HCV (aHR 0.64 [0.47-0.88]), ALD (aHR 0.45 [0.32-0.63]), and NAFLD (aHR 0.47 [0.36-0.62]). There was no association between CAP score and risk of HCC by CLD etiology. **Conclusion:** In patients with CLD who had a FibroScan®, CAP score **e** 274 dB/m is associated with an increased risk of cirrhosis and decreased risk of decompensation, HCC, and death. The associations between CAP score and liver disease outcomes vary by CLD etiology.

2169-A | ELEVATED PREVALENCE OF UNDIAGNOSED ADVANCED LIVER DISEASE IN A HISPANIC COMMUNITY

Isela De La Cerda, Miryoung Lee, Joseph B. McCormick and Susan P. Fisher-Hoch, Uthealth Houston School of Public Health Brownsville Campus

Background: Assessment and prevention of non-alcoholic fatty liver disease (NAFLD) is absent at the community level. Noninvasive scoring algorithms (NSAs) incorporating hepatic biomarkers with FibroScan imaging identify stages of advanced liver disease (ALD). FibroScan® is a non-invasive measure of hepatic fibrosis measured in kiloPascals (kPa) and liver fat by the Controlled Attenuation Parameter (CAP). The FibroScan-AST score (FAST) identifies nonalcoholic steatohepatitis (NASH) the inflammatory subtype of NAFLD, Agile3+ identifies advanced liver fibrosis and Agile4 cirrhosis. We used these 3 NSAs to estimate the community-level prevalence of ALD in a large Hispanic

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

cohort on the US/Mexico border where the population has elevated rates of cirrhosis and hepatocellular carcinoma. Since this cohort has high rates of metabolic syndrome, we assessed the association of this with ALD. **Methods:** This cross-sectional study included participants with a FibroScan between 2015-2023 from the Cameron County Hispanic Cohort (CCHC). The CCHC is an extensively phenotyped, randomly recruited community cohort. We identified NAFLD in those with > 5% hepatic steatosis (CAP > 233) and no history of alcohol abuse or hepatitis. Established cut offs for the NSAs are: FAST **e** 0.67 for NASH, Agile3+ **e** 0.68 for advanced fibrosis, and Agile4 **e** 0.57 for cirrhosis. We grouped NASH, advanced fibrosis, or cirrhosis into ALD, and metabolic syndrome as defined by the American Heart Association. We conducted bivariate analysis to compare those with ALD and those without. We conducted logistic regressions to estimate the prevalence odds ratio of metabolic syndrome and its components among those with ALD. **Results:** We detected NAFLD in 658 of 1,202 participants (55%). Using NSAs we then identified 43/658 (6.53%) with ALD. The prevalence odds ratio for presence of metabolic syndrome among the 43 was highly significant (POR: 2.06; 95% CI: 1.10 – 3.94). Further logistic regression models of the 5 components of metabolic syndrome showed that participants with hypertension had twice the odds (POR: 2.31; 95% CI: 1.18 – 4.51) of having ALD, and those with high fasting blood glucose levels 3 times (POR: 3.04; 95% CI: 1.53 – 6.33) compared to those who did not have signs of ALD. **Conclusion:** Liver disease NSAs are useful for screening of populations for ALD in the NAFLD spectrum. Using this approach, we were able to show high rates of undiagnosed but significant disease and identify those most at risk.

2170-A | EPIDEMIOLOGIC TRENDS IN COMORBIDITY BURDEN AND HEALTHCARE RESOURCE UTILIZATION IN NONALCOHOLIC STEATOHEPATITIS (NASH): A LONGITUDINAL STUDY

Umer Farooq[1], Zahid Tarar[2], Abdallah El Alayli[1], Chengu Niu[3], Ammad Javaid Chaudhary[4] and Kamran Qureshi[1], (1)Saint Louis University, (2)University of Missouri, (3)Rochester General Hospital, (4)Henry Ford Hospital

Background: Nonalcoholic steatohepatitis (NASH) is on the rise globally, including the United States (US), and is linked to comorbidities, including diabetes mellitus (DM), cardiovascular disease (CVD), and chronic kidney disease (CKD). This has significant implications for healthcare resources including hospitalizations and undermines the quality of life. Despite extensive effort there is no FDA-approved treatment for NASH available as yet. In view of rising burden, we performed a longitudinal analysis to investigate trends of NASH related to hospitalizations and the impact of comorbidities on in-hospital mortality and on associated resources utilization. **Methods:** We used the National Readmission Database (2016-2020) which includes discharges for patients with and without repeat hospital visits in a year and those who have died in the hospital. We employed International Classification of Diseases (ICD)-10 codes to identify adult NASH patients. The linear trend of NASH diagnosis, hospitalizations, comorbidities, and mortality was tested using the Mantel-Haenszel linear trend test. The variables adjusted for in the regression models while computing adjusted hospitalization and readmission rates were: gender, age, Charlson Comorbidity Index score, median household income for patients' zip codes, hospital location/ bedside, and teaching status. We used Stata, version 14.2, to perform analyses considering 2-sided $P < 0.05$ as statistically significant. **Results:** The analysis included 530,908 patients (mean age 62.15 y, females 61%). Incidence of NASH among hospitalized patients was noted to have increased from 27.82 to 43.44 per 10,000 patients from 2016 to 2020 ($P < 0.01$). Comorbidities such as CKD (29.09% to 31.95%, $P < 0.01$), liver cirrhosis (51.05% to 56.02%, $P < 0.01$) showed increasing trends (Figure. 1). All-cause inpatient mortality in NASH adults increased from 3.92% to 4.53% ($P < 0.01$), as well as palliative care utilization in this population (6.41% to 7.38%, P: 0.03). Liver transplantation rates did not significantly change (1.55% to 1.79%, P: 0.51). No decline was observed in 30 and 90-day readmission rates. Hepatic failure and cirrhosis (30.71%), infections (8.67%), NASH (5.84%), and non-variceal upper gastrointestinal bleeding (4.33%) were the leading causes of readmission. Mean hospitalization costs rose from $19,004 to $21,600 ($P < 0.01$). Notably, comorbidities of DM and hepatocellular carcinoma in NASH did not exhibit an increase over the study period. **Conclusion:** Rising trend in hospitalizations noted in adult NASH population is concerning. The parallel rise in comorbidity burden, resource utilization, and mortality in hospitalized NASH patients is seen in the recent years while readmission trends exhibited a lack of decline. National strategies for effective management are needed to decrease the economic burden of NASH on the healthcare system.

2171-A | EVALUATION OF PERFORMANCE CHARACTERISTICS OF NON-INVASIVE FIBROSIS SCORES AND MACHINE LEARNING MODELS IN PATIENTS WITH METABOLIC-ASSOCIATED FATTY LIVER DISEASE

Srikrishna Gurumurthy, Tesla STEM High School and Pankaj Rajvanshi, Swedish Medical Center

Background: Non-invasive fibrosis scores (NIFS) have excellent sensitivity (Sn) and negative predictive value (NPV) for evaluation of significant (SF) and advanced fibrosis (AF) in patients with non-alcoholic fatty liver disease (NAFLD). Machine learning models (MLM) have been shown to be superior to NIFS in patients with NAFLD. However, the performance characteristics of these tests have not been well defined in patients with type 2 diabetes mellitus (T2DM) and NAFLD (also called metabolic-associated fatty liver disease, MAFLD). We aimed to define the performance characteristics of NIFS and novel MLMs in patients with MAFLD. **Methods:** We analyzed data from the NIDDK NAFLD Adult database for 1073 patients with liver biopsy results available. Patients were divided into the NAFLD group (NAFLD +/- T2DM) & the MAFLD group (NAFLD with T2DM). We calculated FIB-4, APRI, BARD, and NAFLD Fibrosis scores (NFS) in all patients. We also created an MLM for each group of patients using an XGBoost model with 30 parameters. Cut-off values for SF ($\geq$F2) were FIB-4 > 1.3, APRI > 0.7, BARD score > 2, and NFS of > -1.455. AF ($\geq$F3) was assessed with FIB-4 > 2.67, APRI > 1, NFS > 0.675, and Cirrhosis (F4) with a FIB-4 > 3.48 or APRI > 1.5. Statistically significant values ($p < 0.05$) are annotated with an asterisk (*). **Results:** Among 1073 patients, 317 (29.5%) had T2DM, 298 (94%) of all patients had BMI > 27, 262 (82.6%) had a BMI > 30. Among NIFS, in the MAFLD group, FIB-4 had the best AUROC of 0.67*, specificity (Sp) (67.5%)*, and positive predictive value, PPV (47.9%)* for prediction of **e** F2. However, APRI at a cut-off value of > 0.7 had better Sn (79.9%)* and NPV (82.7%)*. The Sn of FIB-4 did not improve by decreasing the cutoff value to < 1.3 or < 1. For **e** F3, FIB-4 had the best AUROC (0.63)*, Sp (34.6%)*, PPV (58.8%)*, and NPV (78.3%)*. The Sn of FIB-4 was inferior to NFS (90.7% vs 92%) *. For patients with Cirrhosis, FIB-4 had better AUROC (0.64) *, Sp (36.9%)*, PPV (84.9%) *, & NPV (52.9%)*. APRI had superior Sn (95.5%* vs. 91.5%) than FIB-4. A comparison of performance characteristics of FIB-4 and MLM is shown in Table 1. MLM & FIB-4 perform similarly when predicting **e** F2. However, for > F3 and F4, MLM has better AUROC, Sp, and PPV, while FIB-4 has better Sn but similar NPV. In the NAFLD group, for **e** F2, FIB-4 had best AUROC and NPV, APRI > 0.7 had the best Sn (82.6%)* & BARD score had the highest Sp and PPV. For **e** F3, AUROC of NFS was better* than FIB-4 but Sn* of FIB-4 was superior to NFS. For F4, FIB-4 significantly* outperforms others in all parameters. **Conclusion:** Performance of current NIFS in MAFLD is variable. FIB-4 & MLMs have better AUROC than other NIFS. MLMs have better AUROC, Sp, and PPV compared to FIB-4, whereas FIB-4 has better Sn & NPV. An approach using FIB-4 with cutoff of > 1.3 followed by MLM prediction may be superior and cost-effective for screening at a population level in patients with T2DM. The efficacy of MLMs needs to be further studied and compared to other blood & imaging-based tests in patients with MAFLD.

Table 1. Comparison of FIB-4 and Machine Learning Models in patients with MAFLD

Fibrosis	Accuracy	AUROC	Sensitivity	Specificity	PPV	NPV
≥ F2						
FIB-4	0.70*	0.70	72.9%	68.7%	52.3%	85.1%

2172-A | EVOLVING TRENDS IN NAFLD/NASH PATIENT EXPERIENCES: COMPARATIVE ANALYSIS FROM "THE STATE OF NAFLD/NASH CARE IN AMERICA" 2022-2023 SURVEYS

Neeraj Mistry, Wayne Eskridge, Henry E Chang, Tiffany Mensah and Diana Evans, Fatty Liver Foundation

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: The aim of this study was to understand the evolving social and medical experiences of NAFLD/NASH patients in the United States through the comparison of findings from "The State of NAFLD/NASH Care in AmericaTM", an annual online patient survey, between 2022 and 2023. An understanding of the experiences of these patients is crucial in identifying needs and gaps in care that impact their health outcomes. Through an aggregated analysis, we aim to inform the development of effective interventions and policies addressing the unmet needs of this population. **Methods:** Survey items were developed with the patient community and FLF's Medical Advisory Group. The survey was available in English and Spanish and addressed four key domains of the patient experience: diagnosis and staging, medical management and physical impact, psychosocial and environmental impact, and current health. Social media, email, and partnerships with local community based organizations were used to distribute the survey. We conducted a comparative analysis of the 2022 and 2023 survey data. **Results:** Across both years, primary care physicians (PCPs) remain the most common entry point for NAFLD/NASH diagnosis. Consistent with the previous year, most respondents reported receiving none or not enough information at diagnosis. Compared to 2022, more respondents in 2023 reported visiting a specialist (hepatologist or gastroenterologist) within six months of diagnosis. Fewer received no referral to a specialist. There was an increase in respondents who felt they understood their condition somewhat or better than before after visiting a specialist. In 2023, we observed a shift in living arrangements, with fewer respondents living alone and a greater number residing with a spouse or long-term partner. Concurrently, respondents increasingly perceived their spouses or partners as crucial sources of support compared to 2022. The frequency of a psychologist or psychiatrist in respondents' care teams decreased from 2022 to 2023. Emotional health trends also shifted, with less reported depression and anger, yet an increase in feelings of fear and anxiety from 2022 to 2023. **Conclusion:** Targeted Continuing Medical Education (CME) for PCPs frequently in contact with NAFLD/NASH patients should be sustained at minimum and strengthened where resources allow. Resources on home-based care, care navigation, and other topics for spousal caretakers are needed given their prominent role within patients' lives. Implementing interventions to combat stigma, bolster mental health, and improve accessibility to mental health services is an urgent requirement for improving NAFLD/NASH patient care.

2173-A | EXAMINATION OF THE ROLE OF DIET QUALITY ON NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD) AMONG HISPANICS IN THE RIO GRANDE VALLEY: A CROSS-SECTIONAL STUDY

Maria Lisette Flores, Uthealth Science Center School of Public Health, Miryoung Lee, Uthealth Houston School of Public Health Brownsville Campus and Marcia C Otto, Uthealth Houston School of Public Health Houston Campus

Background: The prevalence of non-alcoholic fatty liver disease (NAFLD) has increased to epidemic proportions in the U.S. and disproportionately affects Hispanics. Literature suggested that diet quality and specific food items were associated with NAFLD. A dietary recall survey can help determine potential relationships between diet and NAFLD risk. In this cross-sectional study, we examined how overall diet quality and specific diet items were associated with NAFLD risk in Hispanics from the Cameron County Hispanic Cohort (CCHC), a population-based cohort in southernmost Texas. **Methods:** The study sample comprised 993 adults (Females 68%). Liver stiffness measurement (LSM) and steatosis using a controlled attenuation parameter (CAP) were obtained using FibroScan®. Interviews were conducted to obtain the demographics and medical history. To determine NAFLD risk, four outcomes were considered: LSMs (kPa), steatosis (CAP), significant fibrosis (LSM **e** 7.0 kPa), and steatosis status (CAP > 288 dB/m). Consumption frequency of twenty-eight food item groups was acquired through a 24-hr dietary recall survey. A modified dietary scoring system, Healthy Eating Index (HEI, range 0-55), was utilized to quantify overall diet quality. The independent relationships of food items with NAFLD outcomes were examined using multiple linear and logistic regression models. **Results:** Median (interquartile range) CAP and LSM scores were 286 (241-327) and 4.6(3.7-6.0). 49% of participants had steatosis, and 15% had significant fibrosis. The modified HEI's mean (SD) score was 6.2(3.3). Modified HEI seems negatively associated with fibrosis status (OR = 0.94, 95%CI: 0.89-0.99) in the age and gender-adjusted model, but the relationship was attenuated in the model adjusted for sociodemographic factors and comorbidity. Consumption of certain food groups was significantly related to increased NAFLD risk, including lower consumption of baked fish or wheat bread items. Compared to participants reporting no consumption of wheat bread items, including tortillas, participants who reported consuming them at least once had 0.5(95%CI 0.3-0.8) times the odds of having steatosis or 0.7(0.4-1.5) times the odds of having fibrosis. Similarly, participants with twice or more consumption had 0.9 (0.6-1.2) times the odds of steatosis or 0.6(0.4-1.0) times the odds of fibrosis. **Conclusion:** Our findings suggest that the consumption frequency of certain food items could potentially impact NAFLD risk in Hispanics.

2174-A | EXPERIENCES AND UNMET NEEDS IN NON-ALCOHOLIC STEATOHEPATITIS (NASH): INSIGHTS FROM PATIENTS AND PATIENT CAREGIVERS

Jeff McIntyre[1], Naim Alkhouri[2], Villum Wittrup-Jensen[3], Hans-Jacob Randskov[3], Emmanuel A. Tsochatzis[4], Teresa Casanovas[5], Ramy Younes[3] and Jörn M. Schattenberg[6], (1)Global Liver Institute, Washington, DC, USA, (2)Arizona Liver Health, Phoenix, AZ, (3) Boehringer Ingelheim International Gmbh, Ingelheim, Germany, (4)UCL Institute for Liver and Digestive Health, London, UK, (5)Asociación Catalana De Pacientes Hepáticos (ASSCAT), Barcelona, Spain, (6) Metabolic Liver Research Program, I. Department of Medicine, University Medical Centre Mainz, Germany

Background: Non-alcoholic steatohepatitis (NASH) is known to have a substantial impact on patients' health-related quality of life; however, a gap remains in quantifying patients' experiences and emotions throughout disease progression. This survey assessed primary experiences, emotions, and unmet needs of patients with NASH and caregivers of those with NASH. **Methods:** A 30-minute, web-based quantitative survey was conducted as part of a global research study; this was sent to patients with NASH and caregivers of those with NASH identified by quantitative fieldwork specialist organisations in the USA, UK, Canada, Germany, Japan and China. Respondents were aged 18–70 years, and they (or the person they cared for) had been diagnosed with NASH by a medical test, had a healthcare professional currently treating them and knew which stage of NASH they were originally diagnosed with and currently in. **Results:** 391 individual's were included in the final sample (n = 252 patients, n = 139 caregivers; 63%

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

male; mean age 43.0 y). Respondents often reported that nuanced symptoms (fatigue 47%, loss of appetite 42%, nausea 40%) prompted them to seek diagnosis. The most common form of diagnosis reported was CT scan (62%), elevated liver enzymes (50%) or liver biopsy (47%), with fibrosis assessments to monitor progression (55%). Most reported understanding the disease severity at diagnosis (97% reported diagnosis as moderately/very serious), but less than half fully understood their diagnosis. Almost all (99%) reported conducting their own research, but many were overwhelmed by the amount of information (66%). Respondents stated they were highly motivated to make lifestyle changes at diagnosis; 60% viewed such changes as highly challenging, but 68% felt very successful in implementing them (Figure). NASH substantially impacted respondents' lives in areas such as pain, weight perception, time with friends/family, and financial expenses of maintaining lifestyle changes (each ranked 'very impactful' by ~15%). Respondents were initially concerned and uncertain, but were more hopeful and confident after initial diagnosis. **Conclusion:** Patients received their NASH diagnosis via a variety of media, and a majority showed willingness to implement lifestyle changes. Patients feel overwhelmed by the available information when conducting research. The survey findings highlight the large unmet need for further disease education using clear, reliable information sources, and the need for improvements in disease management.

Figure. Patient views towards lifestyle changes by current stage of NASH

2175-A | FACTORS ASSOCIATED WITH ADVANCED LIVER FIBROSIS IN A POPULATION WITH TYPE 2 DIABETES: A 5-YEARS RETROSPECTIVE COHORT STUDY IN MEXICO CITY★

Zeltzin Soto Montes[1], Maria Juliana Corredor-Nassar[1], Froylan David Martinez-Sanchez[2], David Medina-Julio[1], Carolina Martinez-Perez[1], Gibran Gonzalez-Alvarez[1], Victor Manuel Paz-Zarza[1], Sandra Milena Feria-Agudelo[1], Alejandra Diaz-Jarquin[1], Omhariany Medina-Garza[1], Erika Karina Tenorio-Aguirre[2] and Jacqueline Cordova Gallardo[3], (1)Hospital General Manuel Gea Gonzalez, (2)Hospital General Manuel Gea González, (3)Hospital General Manuel Gea Gonz

Background: Metabolic-associated fatty liver disease (MAFLD) is a major cause of liver related morbidity and mortality worldwide. Identifying people at high risk of experiencing complications is important to prevent disease progression. Some patients have metabolic risk factors associated with MAFLD such as Type 2 Diabetes. However, current practice guidelines do not recommend systematic screening, due to uncertainties surrounding the prevalence of advanced fibrosis in patients with diabetes. **Methods:** Retrospective cohort study that included clinical and biochemical data of 1,035 patients with diagnosis of diabetes. We defined advanced liver fibrosis as fibrosis-4 index (FIB-4 index) more than 4. Logistic regression analysis was used to estimate the Odds Ratios for advanced liver fibrosis in patients with diabetes. **Results:** The mean age of the patients was 59 ± 14 years, 68.7% were women, the mean body mass index (BMI) was 28.5 ± 6.0 kg/m^2, median serum creatinine was 0.87 (0.71-1.03) mg/dL, median fasting glucose was 122 (99-161) mg/dL and mean hemoglobin A1c was 7.63 ± 2.09 %. Overall, 15.1% had advanced fibrosis and 54.9 % had hypertension. Likewise, the frequency of evolution of diabetes was 60.2% in 0-4 years, 16.1% in 5-9 years and 23.7% in > 10 years. Fasting glucose levels (OR = 1.005 [1.003-1.008]), hemoglobin A1c (OR = 0.869 [0.769-0.982]), and diabetes evolution > 10 years (OR = 2.051 [1.329-3.167]) were independently associated with advanced liver fibrosis. **Conclusion:** Although lower hemoglobin A1c was associated with lower odds, uncontrolled fasting glucose and disease duration were independently associated with advanced liver fibrosis. These data could partially support that implementing systematic screening for liver fibrosis in patients with diabetes could reduce the burden of liver fibrosis by MAFLD.

2176-A | FAST-TRACK ELASTOMETRY SERVICE FOR NONALCOHOLIC FATTY LIVER (NAFLD) PATIENTS

Mohamed Alsenbesy[1,2], Monika Rau[3], Johannes Weiss[3], Oliver Goetze[3] and Andreas Geier[4], (1)Arabian Gulf University (AGU), (2)South Valley University (SVU) Hospital, (3)Uniklinikum Wuerzburg, (4)Department of Hepatology, University of Würzburg, Würzburg, Germany

Background: Nonalcoholic fatty liver disease (NAFLD) is increasing globally with an estimated prevalence of approximately 25%. Nonalcoholic steatohepatitis as the progressive disease entity often leads to fibrosis and end-stage disease. The magnitude of NAFLD patients are not diagnosed and have no access to further clinical assessment. Diagnostic pathways for individual risk evaluation fitting with available resources are of utmost importance in real-world clinical practice. **Methods**: Retrospective analysis of 1346 anonymized outpa- tient datasets at Würzburg University Hospital, Germany. Transient elastography (TE) with controlled attenuation parameter and laboratory-based risk scores (NFS, FIB-4) were the main diagnostic workup tools for risk stratification **Results:** After preselection based on questionnaire information NAFLD still accounts for

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

one-fifth of patients in the liver outpatient service. More than 80% of NAFLD patients receive their first-time diagnosis in our unit. Laboratory-based risk scores and TE are valuable tools for second-step risk assessment as shown in our clinical data analysis. Moreover, 65% of NAFLD patients use inpatient services for at least 1 day. The policy to perform liver biopsy in high-risk patients above the recommended threshold of 9.6 kPa if any clinical doubt exists regarding the diagnosis of cirrhosis leads to a histological down staging in almost 80%. **Conclusion:** Questionnaire-based referral from primary care followed by broadly available fast-track TE and eventually liver biopsy for selected patients is the standard practice in our unit. This approach represents a feasible model to handle the large gap between availability and clinical need for TE facilities.

2177-A | FATTY ACID DESATURASE 2 rs174583 GENETIC VARIANT IS INVOLVED IN ADVANCED FIBROSIS IN FATTY LIVER DISEASE

Shunsuke Ikejima, Kazuyoshi Kon, Kumiko Arai, Akira Uchiyama, Hiroo Fukada, Kyoko Fukuhara, Reiko Yaginuma, Toshifumi Sato, Maki Morinaga, Masahiro Tada, Hisafumi Yamagata, Hironao Okubo and Kenichi Ikejima, Juntendo University School of Medicine

Background: Genetic factors are deeply involved in the pathological progression of nonalcoholic fatty liver disease (NAFLD) and alcohol-associated liver disease (ALD); however, details remain unclear. In recent years, it has been demonstrated that the progression of fatty liver disease is closely associated with the risk of cardiovascular diseases. Genetic variants of fatty acid desaturase (FADS) are associated with fatty acid metabolism, and several studies have reported that minor allele homozygotes of FADS2 gene rs174583 are associated with essential fatty acid composition, serum insulin levels and cardiovascular risk factors. In this study, therefore, we investigated the impact of FADS single nucleotide polymorphism (SNP) on progression of fatty liver disease. **Methods:** A total of 34 patients with biopsy-proven fatty liver disease (10 with ALD, 24 with NAFLD) were evaluated. A control group consisted of 26 patients with non-fatty liver disease other than primary biliary cholangitis. Genotypes were established using Taqman assays targeting PNPLA3 rs738409, FADS1 rs174556, and FADS2 rs174583. Allele frequencies in each group were evaluated by Chi-square test. Patients with fatty liver disease were classified to non-advanced fibrosis (fibrosis stage 0-2) and advanced fibrosis (stage 3-4). Multiple linear regression analysis was performed to determine independent risk factors. **Results:** The GG allele carrier of PNPLA3 was significantly frequent in 44% of the fatty liver group compared to 8% of the control group. The frequency of TT minor allele of FADS1 and FADS2 was 15% and 19% in the control group, and 18% and 38% in the fatty liver group, showing no significant difference between the groups. In contrast, the TT allele of FADS2 was significantly higher at 64% in advanced fibrosis group compared to 20% in non-advanced fibrosis in fatty liver disease. In a multivariate analysis including PNPLA3 GG allele, FADS1 TT allele, FADS2 TT allele, etiology, age, and sex, only the TT allele of FADS2 was an independent risk factor for advanced fibrosis ($P = 0.011$). **Conclusion:** These findings clearly demonstrated that the TT allele of FADS2 is associated with the development of advanced fibrosis, whereas the GG allele of PNPLA3 is closely related to the development of fatty liver disease. It is postulated that the TT allele of FADS2 rs174583 is a critical bridge between progression of fatty liver and increased cardiovascular events.

2178-A | FATTY LIVER ITSELF IN MAFLD DOES NOT INCREASE ALL-CAUSE MORTALITY IN INDIVIDUALS WITH METABOLIC DYSFUNCTION

Min-Sun Kwak[1], Hyunseok Kim[2], Z. Gordon Gordon Jiang[3], Mazen Noureddin[4] and Ju Dong Yang[2], (1)

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

Seoul National University Hospital Gangnam Center, (2) Cedars-Sinai Medical Center, Los Angeles, CA, (3)Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, (4)Houston Research Institute, Houston, TX

Background: A novel term, metabolic dysfunction-associated fatty liver disease (MAFLD), was proposed by a group of experts. However, it remains unclear whether hepatic steatosis *per se* in MAFLD contributes to an elevated risk of mortality in individual's with overweight/obesity, metabolic dysregulation, or type 2 diabetes mellitus (DM) (referred to as the metabolic dysfunction-association (MA) group), which are known significant risk factors for increased mortality. This study aimed to compare all-cause and cause-specific mortality between the 'MAFLD' group and the 'MA without fatty liver' group. **Methods:** A total of 10,052 participants from NHANES III were included. Fatty liver was diagnosed using ultrasound, and MAFLD was defined based on the criteria proposed by an international panel of experts. Mortality risks were compared between the 'MAFLD' group and the 'MA without fatty liver' group using the Cox proportional hazards model with complex survey design weights, adjusted for demographic and anthropometry factors (age, sex, race, body mass index and waist circumference), social history (education, marriage status, smoking and alcohol history and exercise) and comorbidity variables (hypertension, DM and hyperlipidemia). Linked mortality data, including all-cause, cancer, cardiovascular, and other causes-related mortality, were examined from 1988 through 2019. For liver-related mortality, data were evaluated from 1988 through 2006. **Results:** Over an average follow-up period of 23.0 years, the 'MAFLD' group did not exhibit a significant increase in all-cause mortality (adjusted hazard ratio [95% confidence interval], 1.07 [0.99-1.16], $P = 0.100$), cancer mortality (1.08 [0.86-1.36], $P = 0.508$), or cardiovascular mortality (0.89 [0.78-1.02], $P = 0.084$) compared to the 'MA without fatty liver' group. However, other causes-related mortality, which included liver-related mortality, was higher in the MAFLD group (1.36 [1.14-1.62], $P = 0.001$). This trend persisted in sensitivity analyses conducted on participants without viral hepatitis or heavy alcohol consumption. No significant effect modification was observed according to subgroups. Liver-related mortality, assessed over a 13.8-year follow-up period, showed a marginal increase in the 'MAFLD' group (2.49 [0.99-6.23], $P = 0.052$) compared to the 'MA without fatty liver' group. **Conclusion:** The 'MAFLD' group did not demonstrate an elevated risk of all-cause, cardiovascular, or cancer mortality when compared to the 'MA without fatty liver' group. However, there was a trend toward an increased risk of liver-related mortality in the MAFLD group.

2179-A | FIRST RESULTS OF THE EVOLUTION AND THE INFLUENCE OF STATIN TREATMENT ON NAFLD IN A PRIMARY CARE COHORT OVER A 2-YEAR PERIOD

Leen Heyens[1,2,3], Wouter Robaeys[2], Liesbet Vernijns[4], Anneleen Robaeys[5], Sven Francque[6] and Geert Robaeys[2], (1)Ziekenhuis Oost-Limburg, (2)Hasselt University, (3)Maastricht University, (4)Huisartsenbox, (5)Huisartsenpraktijk Termolen, (6)University of Antwerp, Edegem, Belgium

Background: Non-alcoholic fatty liver disease (NAFLD) has become the most frequent cause of chronic liver disease. Non-alcoholic fatty liver can evolve into non-alcoholic steatohepatitis, fibrosis, cirrhosis, and hepatocellular carcinoma. Data concerning the evolution of NAFLD in a primary care continuum remain scarce. As a therapeutic option, besides lifestyle changes, statins might influence the evolution of steatosis or fibrosis.

Therefore, we aimed to map the evolution of NAFLD and the influence of statin treatment in a primary care (PC) cohort assessed by liver stiffness (LSM) and controlled attenuation parameter (CAP™). **Methods:** In a prospective, multicentric cohort study in two large PC practices in Belgium between October 2020 and May 2023, a FibroScan® measurement (for assessment of steatosis by CAP™ and of LSM as a surrogate for fibrosis) and clinical examination (waist circumference (WC) and BMI) was performed at baseline and follow-up. Steatosis was defined as a CAP™ value > 215 dB/m. At the start, lifestyle advice was given. Recent laboratory data, medical background, and medication for both study visits were gathered from the electronic patient file. **Results:** Of the 67 study participants evaluated, 11 (16.4%) were excluded due to treatment with tamoxifen, not being sober, alcohol abuse, or IQR/MED > 30%. In total, 56 (83.6%) participants were included, of whom 21 (37.5%) were men, 55 (94.0%) were of Caucasian origin, and 40 (71.7%) had steatosis. The mean age, median BMI, and mean WC at baseline were 62 ± 10 years, 26.3 ± 6.0 kg/m², and 91.3 ± 12.2 cm, respectively. At follow-up, WC (91.7 ± 12.5 vs. 95.9 ± 11.2 cm; $p < 0.001$) and CAP™ (251.4 ± 62.8 vs. 261.2 ± 56.0 dB/m; $p = 0.005$) were significantly higher while BMI remained unchanged ($p = 0.098$). LSM and the serum level of triglycerides decreased significantly (5.2 ± 2.3 vs. 4.3 ± 1.5 kPa; $p = 0.021$ and 102 ± 62 vs. 87 ± 37 mg/dl; $p = 0.008$). No statistical differences were found for the liver enzymes AST, ALT, and GGT. Twenty of the 56 (64.3%) participants took statins and 2 (3.6%) fibrates. No statistical difference between baseline and follow-up was seen for CAP™ for statin users (246.5 ± 64.1 vs. 265.4 ± 58.1 dB/m; $p = 0.266$) and non-users (254.3 ± 62.9 vs. 258.7 ± 55.9 dB/m; $p = 0.691$). Non-statin users saw a significant decrease in LSM (5.5 ± 2.6 vs. 4.4 ± 1.3 kPa; $p < 0.001$) at follow-up, which was not seen with statin users (5.3 ± 2.0 vs. 4.3 ± 2.2 kPa; $p = 0.179$). **Conclusion:** Overall, we saw a decrease in fibrosis and triglycerides during the two-year follow-up time in a Caucasian PC cohort. No study participant developed decompensated liver disease. However, we did see an increase in steatosis accompanied by an increase in waist circumference, although lifestyle advice was given during the first visit. Moreover, statin use did not influence steatosis or fibrosis evolution, though future research is warranted to further investigate the influence of statin treatment on NAFLD.

2180-A | FOOD INSECURITY IS ASSOCIATED WITH LOWER NAFLD PREVALENCE BUT GREATER LIVER FIBROSIS IN PEOPLE WITH HIV

Ani Kardashian, University of Southern California, Los Angeles, CA, Audrey Lloyd, University of Alabama at Birmingham Heersink School of Medicine, Eduardo Vilar-Gomez II, Indiana University School of Medicine, Susanna Naggie, Duke Clinical Research Institute, Durham, NC, Mark S Sulkowski, Johns Hopkins University School of Medicine, Division of Infectious Diseases, Tinsay A. Woreta, Johns Hopkins Medicine, Baltimore, MD, Jordan E. Lake, University of Texas - Houston, Holly Crandall, Indiana University, Rohit Loomba, University of California, San Diego, San Diego, CA, Laura Wilson, Johns Hopkins School of Public Health, Richard K. Sterling, Virginia Commonwealth University Health System, Sonya Heath, University of Alabama at Birmingham, Naga P. Chalasani, Indiana University Medical Center, Indianapolis, IN and Jennifer C. Price, University of California, San Francisco

Background: Food insecurity, defined as the economic or social condition of limited or uncertain access to nutritionally adequate foods, is a growing public health problem in the US. In recent years, it has emerged as a risk factor for nonalcoholic fatty liver disease (NAFLD) and advanced liver fibrosis in the general population. However, little is known about the impact of food insecurity on liver disease in people with HIV (PWH). We aimed to examine associations between food insecurity and NAFLD and liver fibrosis prevalence in a diverse multicenter cohort of PWH. **Methods:** PWH aged 20 years on suppressive antiretroviral therapy, HIV RNA < 200 copies/mL, and without chronic viral hepatitis or other known cause of liver disease were screened for NAFLD and fibrosis by vibration controlled transient elastography at 8 US centers. NAFLD was defined as CAP **e** 263 decibels/m in the absence of self-reported heavy alcohol use and advanced fibrosis was defined as liver stiffness measurement (LSM) **e** 10 kPa. Food security was measured using the validated Six-Item Short Form US Household Food Security Survey Module, and participants were categorized as being food secure or food insecure. We used multivariable logistic regression to estimate odds ratios (OR) and 95% confidence intervals (CI) of NAFLD and advanced fibrosis by food security status. **Results:** Among 570 PWH, mean age was 54 years, 410 (72%) were male, 26% White, 49% Black, 21% Hispanic, 267 (47%) had BMI **e** 30 kg/m^2, and 171 (30%) were diabetic. NAFLD was present in 306 (54%) and advanced fibrosis in 45 (8%) of participants. Food

insecurity was present in 175 (31%) of the entire cohort, 84 (27%) of those with NAFLD, and 21 (47%) of those with advanced fibrosis. Among the entire cohort, participants who were food insecure were less likely to have type 2 diabetes (25% vs 32%) and undetectable HIV-1 RNA (76% vs 85%) compared to those who were food secure ($P < 0.05$ for all) but there were no differences in age, body mass index (BMI), or race and ethnicity. In a fully covariate-adjusted analysis, food insecurity was associated with a lower risk of NAFLD (OR = 0.51 [95% CI: 0.31-0.83], $P < 0.01$) (Table). By contrast, food insecurity was associated with a higher risk of advanced fibrosis among the entire cohort (OR = 2.32 [95% CI: 1.15-4.67], $P = 0.02$) after adjustment for age, sex, race and ethnicity, BMI, physical activity, and education level (Table). **Conclusion:** Food insecurity is highly prevalent among adult PWH and is associated with a lower risk of NAFLD but a greater risk of advanced fibrosis. Our findings suggest that food insecurity in PWH may contribute to hepatic fibrosis through mechanisms other than hepatic steatosis. Further studies are needed to confirm our observations and to better understand their mechanisms and implications.

Table. Multivariable logistic regression* of food security and the risk of NAFLD (CAP ≥263 decibels/m) and advanced fibrosis (LSM ≥10 kPa) in the entire cohort (N=570)

	NAFLD		Advanced fibrosis	
	OR (95% CI)	P value	OR (95% CI)	P value
Food insecure (reference: food secure)	**0.51 (0.31-0.83)**	**<0.01**	**2.32 (1.15-4.67)**	**0.02**
Male sex	1.52 (0.88-2.65)	0.13	2.42 (0.97-6.02)	0.06
Race

2181-A | GASTROINTESTINAL MALIGNANCIES IN HOSPITALIZED PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD): ANALYSIS OF THE NATIONAL INPATIENT SAMPLE (NIS)

Tamoor Afzaal, David Hudson, Mohammad Qasim Khan, Karim Mohammed Qumosani and Anouar Teriaky, Western University

Background: It is estimated 1.5 billion people worldwide have some element of chronic liver disease (CLD) or cirrhosis.[1] Non-alcoholic fatty liver disease (NAFLD) has become the most common cause of CLD, affecting up to 30% of the world population.[1,2] It is well known cirrhosis is the strongest risk factor for the development of hepatocellular carcinoma. However, several studies have shown the association of NAFLD and the development of extra hepatic malignancies, specifically an increased risk of gastrointestinal malignancies.[2-5] The aim of this study was to determine the incidence of gastrointestinal malignancies (esophagus, gastric, colorectal, pancreatic) for patients with NAFLD compared to controls without NAFLD using an adult inpatient population. **Methods:** Using a population based retrospective study design, we analysed data from the United States Nationwide Inpatient Sample (NIS) database for 2013. Using validated International Classification of Diseases, Ninth Revision (ICD-9) codes we identified inpatients 18 years or older with NAFLD and a diagnosis of a gastrointestinal malignancy (esophagus, gastric, colorectal, pancreatic). We then compared that cohort to adult inpatients without NAFLD. We adjusted for multiple confounders (age, payer type, location, hypertension, dyslipidemia, obesity, type 2 diabetes mellitus, chronic kidney disease, smoking, alcohol and cirrhosis) and performed a multivariable logistic regression analysis to evaluate the impact of NAFLD on gastrointestinal related malignancies. **Results:** Utilizing the NIS database we were able to identify 36,597,790 potential patients to include in the study. 235,035

patients had NAFLD and a gastrointestinal malignancy while 36,362,755 patients were in the control group. The average age of the NAFLD group was 54.91 and non-NAFLD was 57.37. The NAFLD group had 56.9% females while the non-NAFLD group had 59.1%. Majority of patients in both groups were white, 70.9% in the NAFLD group and 68.6% in the control group. Patients with NAFLD had a higher incidence of gastric cancer (odds ratio [OR]: 1.25, 95% confidence interval [CI]: 1.01-1.55), colon cancer (OR: 1.14, 95% CI: 1.05-1.25), and pancreatic cancer (OR: 1.51, 95% CI: 1.30-1.77). There was no significant difference between the two groups for rectal cancer (OR: 0.94, 95% CI: 0.78-1.12), esophageal cancer (OR: 0.91, 95% CI: 0.69-1.18) and hepatic cancer (OR: 1.11, 95% CI: 0.97-1.27). **Conclusion:** Using a large database, when compared to controls, patients with non-alcoholic fatty liver disease had an increased incidence of gastric, colonic and pancreatic malignancies but no difference in rectal, esophageal and hepatic malignancies.

2182-A | GLYCEMIC CONTROL TARGET ASSOCIATED WITH A LOWER RISK OF LIVER-RELATED AND CARDIOVASCULAR EVENTS IN NONALCOHOLIC FATTY LIVER DISEASE

Nobuharu Tamaki[1], Shunichi Wakabayashi[2], Takefumi Kimura[2], Yutaka Yasui[1], Kaoru Tsuchiya[1], Hiroyuki Nakanishi[1], Daniel Q Huang[3], Takeji Umemura[2], Masayuki Kurosaki[1] and Namiki Izumi[1], (1)Musashino Red Cross Hospital, (2)Shinshu University Hospital, Matsumoto, Japan, (3)National University Health System (NUHS)

Background: Optimizing glycemic control in diabetes mellitus may prevent liver-related events and major adverse cardiovascular events (MACE) in patients with nonalcoholic fatty liver disease (NAFLD). However, the hemoglobin A1c (HbA1c) threshold associated with a lower complication rate is unknown. In this nationwide population-based cohort study, we investigated the association between HbA1c levels and these complications. **Methods:** We investigated a nationwide large claim database from 2016 to 2021 and identified 633,295 patients with NAFLD with mean 4.2 years follow-up. HbA1c levels were measured annually with mean 4.26 times and the mean HbA1c value was used for analyses. The *primary endpoint* was the incidence of liver-related events and MACE, and the optimal HbA1c level associated with a lower incidence of complications was determined. **Results:** The 5-year incidence of liver-related events in patients with the mean HbA1c of < 6.0%, 6.0-6.9%, 7.0-7.9%, 8.0-8.9%, and **e** 9.0% were 0.04%, 0.07%, 0.17%, 0.16%, and 0.15%, respectively, and those of MACE were 0.38%, 0.73%, 1.0%, 1.3%, and 2.2%, respectively. Multivariable analyses demonstrated that adjusted hazard ratios (HR, 95% confidence interval [CI]) of HbA1c (per 1%) for liver-related events and MACE were 1.26 (1.12-1.42) and 1.36 (1.32-1.41), respectively. When compared to patients with < 6.0%, adjusted HRs (95% CI) in patient with HbA1c levels of 6.0-6.9%, 7.0-7.9%, 8.0-8.9%, and **e** 9.0% were 1.28 (0.9-1.7), 2.34 (1.7-3.5), 2.79 (1.6-5.0), and 3.52 (1.8-7.0) for liver-related events, and were 1.25 (1.1-1.4), 1.68 (1.5-1.9), 2.33 (1.9-2.8), and 4.11 (3.4-5.0) for MACE. The risk of liver-related events and MACE increased in a dose-dependent fashion with an increase in HbA1c. A HbA1c level of 7% was selected as the optimal threshold for predicting liver-related events and MACE. Adjusted HRs (95% CI) of HbA1c **e** 7.0% compared to < 7.0% for liver-related events and MACE were 2.40 (1.79-3.22) and 1.98 (1.78-2.19), respectively. **Conclusion:** HbA1c of 7% was the optimal threshold associated with a lower incidence of complications and be utilized as a target for glycemic control in patients with NAFLD.

2183-A | HEALTH CARE RESOURCE UTILIZATION AND COST BURDEN OF HIGH DISEASE SEVERITY IN US ADULTS WITH NONALCOHOLIC STEATOHEPATITIS: A RETROSPECTIVE COHORT STUDY

Michael R. Charlton[1], Ivy Tonnu-Mihara[2], Chia-Chen Teng[2], Ziqi Zhou[2], Feven Asefaha[3], Rakesh Luthra[4], Amy Articolo[4], Anthony Hoovler[4] and Chioma Uzoigwe[4], (1)University of Chicago, (2)Carelon Research, (3)Panalgo, (4)Novo Nordisk Inc.

Background: Nonalcoholic steatohepatitis (NASH) is the progressive, inflammatory form of non-alcoholic fatty liver disease. Recent professional society guidance recommends noninvasive initial screening for more severe disease with fibrosis-4 index (FIB-4) scores; thus, it is important to understand whether health care resource utilization (HCRU) varies with FIB-

Symbols: ᶠ , Poster of Distinction; ★, Foundation Award Recipient

4 score. This study aimed to assess and compare the economic and HCRU burdens of NASH in adults aged **e** 18 years, stratified by disease severity based on FIB-4. **Methods:** This observational, retrospective study utilized the Healthcare Integrated Research Database (HIRD®), which contains health care claims data for commercially insured and Medicare Advantage health plan members from 14 geographically diverse plans across the United States. Primary outcomes were all-cause, cardiovascular (CV)-related, and liver-related medical costs and HCRU associated with hospitalization stratified by FIB-4 score in patients with **e** 2 diagnoses of NASH during the patient identification period (October 1, 2016, to May 31, 2022). Generalized linear regression with negative binomial and gamma distribution models were used to compare HCRU and costs, respectively, by disease severity while controlling for confounders. **Results:** The cohort included a total of 5104 patients with NASH and was composed of 3162, 1343, and 599 patients with low, indeterminate, and high FIB-4 scores, respectively. After adjustment, the rate of all-cause HCRU was significantly higher in the high FIB-4 group when compared with the low FIB-4 group reference (rate ratio, 1.63; 95% CI, 1.32-2.02; $P < 0.001$). No significant differences in the rate of CV-related HCRU were observed; however, the CV-related cost ratio was 1.26 (95% CI, 1.11-1.45; $P < 0.01$) in the indeterminate group and 2.15 (95% CI, 1.77-2.62; $P < 0.001$) in the high FIB-4 group. Patients with indeterminate and high FIB-4 scores were 2.97 (95% CI 1.78-4.95) and 12.08 (95% CI 7.35-19.88) times more likely to utilize liver-related health care resources and 3.68 (95% CI 3.11-4.34) and 33.73 (95% CI 27.39-41.55) times more likely to incur liver-related costs, respectively ($P < 0.001$ for all). **Conclusion:** Compared with patients with NASH with low FIB-4 scores, those with indeterminate and high FIB-4 scores were more likely to utilize liver-related healthcare resources and incur higher CV- and liver-related costs after controlling for confounders.

HCRU and medical costs associated with hospitalization for patients with indeterminate and high FIB-4 scores vs patients with low FIB-4 scores. Incidence rate ratios (IRR) of HCRU and costs ratios after adjustment are shown. The low FIB-4 reference is represented by a vertical dashed line. Error bars represent the 95% CI values. Open circles represent indeterminate FIB-4 IRR and costs ratios, and filled circles represent high FIB-4 IRR and costs ratios.

2184-A | HIERARCHICAL CONTRIBUTION OF COMPONENTS OF METABOLIC SYNDROME TO THE PROGRESSION OF NONALCOHOLIC FATTY LIVER DISEASE

Phuc Le[1], Moosa Tatar[1], Michael Rothberg[1], Laura Wilson[2], Daniela Allende[1], Anna Mae Diehl[3], Rohit Loomba[4], Naga P. Chalasani[5], Brent Neuschwander-Tetri[6], Arun Sanyal[7], James Tonascia[2], Srinivasan Dasarathy[8] and NASH Clinical Research Network, (1) Cleveland Clinic, (2)Johns Hopkins School of Public Health, (3)Duke University, (4)University of California, San Diego, San Diego, CA, (5)Indiana University Medical Center, Indianapolis, IN, (6)Saint Louis University, (7)Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA, (8)Cleveland Clinic Foundation

Background: Metabolic syndrome (MetS) is characterized by the presence of three or more of the following five cardiometabolic risk factors: large waist, impaired fasting glucose/diabetes, low high-density lipoprotein, hypertriglyceridemia, and hypertension. Patients with MetS have greater risk of developing the more severe forms of nonalcoholic fatty liver disease (NAFLD), such as advanced fibrosis, nonalcoholic steatohepatitis (NASH), and hepatocellular carcinoma. In this study, we evaluated the effect of MetS and its components, as well as baseline histology, on the progression and regression of NAFLD. **Methods:** We conducted a multicenter prospective cohort study using the NASH Clinical

Symbols: f , Poster of Distinction; ★, Foundation Award Recipient

Research Network (NASH CRN)'s noninterventional registry (2002-2022). We included patients **e** 18 years with biopsy-proven NAFLD who had paired biopsies **e** 1 year apart and no missing data on MetS. Outcomes included histological progression or regression defined by NAFLD activity score (NAS), NASH or fibrosis using predefined criteria. Crude incidence rate (IR) was compared among groups with versus without MetS or individual components using Kaplan-Meier curves and the log-rank test. Cox proportional hazard models were used to estimate the effect of MetS on fibrosis progression/regression, adjusted for patient demographics and baseline histology. **Results:** Of the 452 patients followed for 4.3 (range: 1-15.6) years, mean age was 51 years, one-third were male, and 85% were White. At baseline, patients with MetS, large waist circumference or impaired glucose/diabetes had worse ballooning and fibrosis scores and were more likely to have definite NASH than those without, while patients with hypertension had a higher prevalence of advanced fibrosis (F **e** F2) than those without. MetS was not associated with any outcomes in either adjusted or unadjusted models. In adjusted model, impaired glucose/diabetes was associated with a higher risk for fibrosis progression (aHR = 1.61; 95% CI: 1.11-2.34) while hypertension was associated with a lower risk (aHR = 0.64; 95% CI: 0.43-0.96). No other components were associated with the outcomes. **Conclusion:** In this NASH CRN patient cohort, MetS was not a risk factor for fibrosis progression or regression, but impaired glucose/diabetes was associated with increased progression and hypertension with decreased progression. Further studies are needed to understand the mechanism underlying the impact of hypertension on fibrosis progression in NAFLD patients.

2185-A | HIGHER ULTRA-PROCESSED FOOD INTAKE WAS POSITIVELY ASSOCIATED WITH ODDS OF NAFLD IN BOTH US ADOLESCENTS AND ADULTS: A NATIONAL SURVEY

Longgang Zhao[1], Xinyuan Zhang[1], Euridice Martinez Steele[2], Chun-Han Lo[3], Fang Fang Zhang[4] and Xuehong Zhang[1,5], (1)Brigham and Women's Hospital, Harvard Medical School, (2)University of São Paulo, (3) University of Nevada, (4)Tufts University, (5)Harvard T.H. Chan School of Public Health

Background: The influence of consumption of ultra-processed foods (UPF) on non-alcoholic fatty liver diseases (NAFLD) remains poorly understood. Related evidence for adult NAFLD is limited and no study has yet evaluated adolescent NAFLD. **Methods:** We conducted a study among 806 adolescents and 2,734 adults who participated in the National Health and Nutrition Examination Survey (2017-2018). UPF intake was estimated using the dietary data collected by two 24-hour dietary recalls. NAFLD was defined by transient elastography. Logistic regression was used to estimate the multivariable odds ratio (OR) and 95% confidence intervals (CI) for associations between UPF consumption and NAFLD with survey weight adjustments. **Results:** The mean consumption of UPF was 812 grams/day for adolescents and 823 grams/day for adults. A total of 12.4% among adolescents and 35.6% of the participants among adults had NAFLD. Higher UPF intake was associated with higher odds of NAFLD in both adolescents ($OR_{\text{Quintile 5 vs Quartile 1}} = 2.34$, 95% CI = 1.01-5.41, $P_{trend} = 0.15$) and adults ($OR_{\text{Quintile 5 vs Quintile 1}} = 1.78$, 95% CI = 1.04-3.03, $P_{trend} = 0.002$). In adults, about 68% and 71% of the association between UPF intake and NAFLD was mediated by body mass index and waist circumference (all P values < 0.001), respectively. We also found higher UPF intake was positively associated with serum levels of albumin and C-reactive protein in adults. Results were similar for adolescents though not statistically significant. **Conclusion:** Higher UPF intake was associated with higher odds of having NAFLD among both adolescents and adults. These associations are largely mediated by elevated body fatness. Further prospective studies are needed to confirm our findings. If confirmed, reducing UPF intake might help prevent NAFLD in both adolescents and adults.

Salute, Materno-Infantile, Di Medicina Interna e Specialistica Di Eccellenza "G. D'alessandro", Università Di Palermo, Palermo, Italy, Hannes Hagström, Unit of Hepatology, Department of Upper GI Diseases, Karolinska University Hospital, Stockholm, Sweden, Jörn M. Schattenberg, Metabolic Liver Research Program, I. Department of Medicine, University Medical Center Mainz, Mainz, Germany, Lisa Belin, Assistance Publique Hôpitaux De Paris, Paris, France, Frederic Charlotte, Sorbonne Université, Ican Institute, Hôpital Pitié-Salpêtrière, Leila Kara, Ican and Pierre Bedossa, Newcastle University

Background: NASH trials assume that histological classifications predict hepatic events. We evaluated the diagnostic performance of the new European EPoS staging and SAF grading systems. **Methods:** Patients from 7 European centers biopsied for suspected NAFLD before 2011 and with long-term follow-up were scored by the NASHCRN and the EPoS 7 tier (1 minimal fibrosis, 2: portal/periportal fibrosis, 3:early bridging, 4: advanced bridging, 5 early cirrhosis, 6 advanced cirrhosis) staging systems by a central pathologist. Activity was scored by NAS and SAF grading. Hepatic morbimortality (HMM) was a composite of liver-related death, occurrence of cirrhosis, cirrhosis decompensation events. Overall mortality, primary liver cancer (PLC), cardiovascular events (CVE) and extra-hepatic malignancies (EHM) were recorded. Median follow-up was calculated by reverse Kaplan-Meier. Incidence rates were compared using log-rank test and univariate and multivariate Cox proportional hazard models were used to estimate hazard ratios (HR) for each outcome. **Results:** 711 patients were included: 63% males, mean age 52 yrs, BMI 30.1 kg/m², diabetes 36%, arterial hypertension 59%, dyslipidemia 54%, daily alcohol 0-5 g: 84%, 5-20/30 g: 13%, moderate (20/30-50 g): 3%, active smokers 19%. Prevalence of fibrosis stages was: NASH CRN, F0:45%, F1:24%, F2:11%, F3:14%, F4:6% and EPoS, F0:48%, F1:20%, F2:11.5%, F3:6.5%, F4:4%, F5:6%, F6:4%. Median follow-up was 11.12 yrs (0.1-20). 84 pts died (11.8%), 92 pts developed HMM (12.9%), 32 PLC (4.5%), 72 CVE (10.1%) and 80 EHM (11.3%). The 5 and 10 yr incidence of HMM was 4.8% (3.2-6.4) and 12.7% (10-15), and that of all-cause death 2.9%(1.6-4.1) and 9.3% (7-11.5). In multivariable analysis, age, diabetes, arterial hypertension and moderate alcohol consumption were associated with an increased risk of HMM. After adjustment for clinical variables and NAS, fibrosis stage was associated with HMM: HRs *vs stage 0 were,* for NASH CRN: F1: 3.06; F2: 11.04; F3: 21.1; F4: 21.2, for EPoS: F1: 2.3; F2: 8.3; F3: 19.8; F4: 18.1; F5+6: 21.7. Both staging systems had similar calibration and discrimination Harrell's C index (0.84). AUROCs for cumulative incidence of HMM at 5 yrs was 0.83 and at 10 yrs 0.86. Both were significantly associated with overall survival, PLC, CVE and EHM. SAF histological activity was associated with HMM starting grade 2 ($p < 0.001$). Steatohepatitis stage 2-4 (but not 0-1) by EPOS and cirrhosis (5-6 by EPOS) were significantly associated with HMM. Only cirrhosis was associated with CVE. Baseline FIB4 risk strata were significantly associated with HMM, overall survival, PLC, cardiovascular events but not EHM. **Conclusion:** This large multicentric cohort demonstrated the prognostic value of the EPoS classification. Fibrosis starting stage 1 (NASH CRN) or stage 2 (EPoS) and activity grade predicted hepatic events.

Background: Previous studies showed that fibrosis stage predicts all-cause and disease specific mortality in patients with NAFLD. Here we aim to study whether the presence non-alcoholic steatohepatitis (NASH) adds prognostic information to different fibrosis stage groups. **Methods:** We conducted an individual participant data meta-analysis of patients with NAFLD who had baseline biopsy. NASH was defined as NAFLD activity score **e** 4 with score of at least 1 for steatosis, lobular inflammation, and ballooning. The primary

outcome was a composite endpoint of all-cause mortality, cirrhosis decompensation (ascites, variceal haemorrhage, hepatic encephalopathy), hepatocellular carcinoma, liver transplantation or progression to a model of end stage liver disease score **e** 15. Study-specific cumulative hazard functions and derived aggregated survival curves were built for F0-1, F2-4 without and with NASH. We further stratified the histologically assessed fibrosis groupings to: F0-1, F2-3 without and with NASH, F4 without and with NASH. **Results:** Data from 29 studies and 2,518 participants with biopsy proven NAFLD were included in the analysis (45% females, median age 54 (IQR 19) years, 46% with type II diabetes mellitus) 48% with NASH. The primary outcome was reached in 5.8% (n = 145) after a median follow-up of 58 months. The presence of NASH did not add prognostic information to the group of patients with F2-4 fibrosis, but those with F2-4 fibrosis had worse outcomes that those with fibrosis F0-1 (study-stratified log-rank tests, $p < 0.001$; Figure 1a), however, similar probabilities of reaching the composite endpoint were observed within patient groups with F2-4 irrespective of the presence of NASH. When histologically assessed fibrosis was further stratified to F0-1, F2-3 and F4, the presence of NASH did not add prognostic information to those with F2-3 fibrosis, and seemed to have a protective effect on those with cirrhosis (Figure 1b). **Conclusion:** The presence of NASH remains important for diagnostic purposes, however does not appear to add prognostic information to fibrosis stage. In the context of cirrhosis, absence of NASH indicates more advanced disease with worse prognosis.

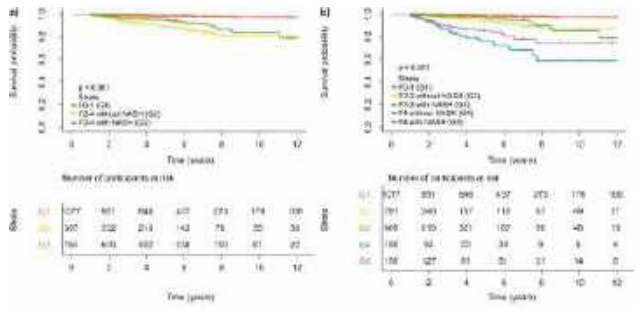

Figure 1 Estimates of survival probabilities for participant groups stratified by histologically assessed fibrosis: (a) F0-1 vs F2-4 with or without NASH and (b) F0-1 vs F2-3 with and without NASH vs F4 with and without NASH. P-values correspond to the outcome of the study-stratified log-rank test.

2188-A | HOSPITALIZATION OUTCOMES AND READMISSION RATES IN NASH CIRRHOSIS WITH TYPE II DIABETES MELLITUS: A POPULATION-BASED STUDY

Adnan Malik, Midwestern University, Waseem Amjad, Harvard University Medical School, Syed Hammad Rahman, Methodist Houston, Manpreet Bains, Saint Joseph Medical Center and Shailendra Singh, West Virginia University School of Medicine

Background: Non-Alcoholic Steatohepatitis (NASH) has a bidirectional relationship with diabetes mellitus. NASH-related cirrhosis is the one of the leading cause of liver transplantation. Our study aims to investigate hospital resource utilization in hospitalized patients with NASH cirrhosis and type 2 Diabetes Mellitus (DMII). **Methods:** We identified adult patients with NASH cirrhosis through the ICD-9 and ICD-10 CM diagnosis codes for the primary discharge diagnosis in the national readmission database (NRD) for 2010-2017. The inclusion criteria for index admissions include adult patients(age $>$ 18 y), non-elective admissions, NASH, and cirrhosis. We excluded the patients who were admitted in December or other causes of cirrhosis (Alcohol liver disease, Hepatitis B virus, Hepatitis C virus, Autoimmune Hepatitis, Hemochromatosis, Primary Biliary Cirrhosis, Primary Sclerosing Cholangitis, and Wilson's disease) and Type I Diabetes Mellitus. Outcomes of NASH cirrhosis in relationship with DMII was computed in a multivariate model adjusted for age, gender, comorbid conditions and hepatic decompensatory events. **Results:** 1,960,205 hospitalizations for NASH cirrhosis were identified from 2010 to 2017. Out of these, a total of 958,838 (48.9%) patients had a DMII, while 1,001,368 (51.08%) did not have DMII. Diabetes prevalence in the NASH cirrhotic population has been slowly trending up from 48% to 52% from 2010 to 2017. DMII were elder (66.1 $\pm$ 11.4 vs 63.6 $\pm$ 14.3, $p < 0.001$) and had more presentation of female (52.8% vs. 46.8%. $p < 0.001$) than non-diabetes. Prevalence of obesity, heart disease and chronic kidney disease was higher in DMII.DMII in NASH cirrhosis was

associated with lower 30-day readmission (Hazard Ratio (HR) 0.99 (Confidence Interval 0.98-0.99), $P < 0.001$) and in hospital mortality (Odds ratio [OR]: 0.62, 95% CI: (0.61 – 0.64), $p < 0.001$). The first three common causes of re-admission in the DMII group were Cirrhosis related complications, Sepsis, and Acute Kidney Injury (AKI).The length of hospital stay (β: -0.404 (-0.450 to -0.359), $p < 0.001$) for the DMII group was statistically significantly shorter. The median cost of hospitalization (β:33,797 (18,479 – 64,872)], $p < 0.001$) for the DMII group was significantly lower than the non-DMII group. **Conclusion:** DMII prevalence is increasing in NASH cirrhosis and these patients have high comorbidity index. These patients have a lower risk of 30-day readmission and lower mortality compared to patients without diabetes. The median cost of hospitalization and length of stay was also statistically significantly lower. The most common cause for readmission, second to cirrhosis-related complications was sepsis. Also, we think the clinical outcomes are better in the diabetic NASH cirrhotic population due to improved outpatient care and follow-ups.

Table 2: Primary outcomes and association with type 2 diabetes mellitus in NASH cirrhosis (Multivariate)

Outcomes	Effect estimate (OR, HR, b-Coefficient)	Comparison between T2DM and non-diabetics p-value
Inpatient Mortality (OR)	0.62 (0.61 – 0.64)	<0.001
Length of stay (Coeff)	-0.404 (-0.450 to -0.359)	<0.001
Length of stay in survivors (Coeff)	-0.420 (-0.464 to -0.376)	<0.001
Hospital charges in dollars(Coeff)	-0.4368 (-0.4991 to -0.3745)	<0.001
Hospital charges in survivors (Coeff)	-4080.5 (-4650 to -3511)	<0.001
30-day readmission (HR)	0.99 (0.98-0.99)	<0.001

2189-A | HYPERFERRITINEMIA PREDICTS NON-ALCOHOLIC FATTY LIVER DISEASE AND SIGNIFICANT FIBROSIS IN PATIENTS WITH TYPE 2 DIABETES

Maral Amangurbanova[1], Daniel Q Huang[1], Kaleb Tesfai[1], Ricki Bettencourt[1], Harris Siddiqi[1] and Rohit Loomba[2], (1)University of California, San Diego, (2) University of California, San Diego, San Diego, CA

Background: Elevated levels of serum ferritin, a marker of hepatic iron overload and inflammation, may be associated with non-alcoholic fatty liver disease (NAFLD) and insulin resistance. However, this relationship remains unclear in patients with type 2 diabetes mellitus (T2DM) and hyperferritinemia. Therefore, we aimed to determine the prevalence of NAFLD and significant hepatic fibrosis among patients with T2DM and hyperferritinemia. **Methods:** This is a cross-sectional analysis of a prospective cohort of 523 adults (64% female) aged 50–80 years old with T2DM and without a diagnosis of hemochromatosis. NAFLD and significant fibrosis were defined as magnetic resonance imaging-proton density fat fraction (MRI-PDFF) **e** 5% and magnetic resonance elastography (MRE) **e** 3.0 kPa, respectively. Hyperferritinemia was defined as serum ferritin **e** 200 µg/L in females or **e** 300 µg/L in males. The prevalence of NAFLD and significant fibrosis were compared between patients with and without hyperferritinemia. A logistic regression analysis was used to assess the association between serum ferritin and NAFLD. **Results:** The mean age and body mass index (BMI) were 64.1 (±8.1) years and 31.5 (±5.9) kg/m^{2,} respectively. The overall prevalence of hyperferritinemia was 20.5% (N = 107). Patients with hyperferritinemia were more likely to be younger, Asian, and have a longer duration of T2DM, compared to those without hyperferritinemia. Hyperferritinemia was associated with higher aspartate transaminase (AST), alanine aminotransferase (ALT), bilirubin, albumin, hemoglobin, and low-density lipoprotein cholesterol (LDL-C) levels.The median (IQR) MRI-R2* (60.90 [51.67, 72.01] s^{-1} Hz vs 46.22 [41.23, 51.41] s^{-1} Hz, $P < 0.001$), MRI-PDFF (11.23% [5.75, 18.32] vs 7.21% [3.33, 13.06], $P < 0.001$), MRE (2.48 [2.12, 3.31] kPa vs 2.32 [2.02, 2.83] kPa, $P = 0.043$) and vibration-controlled transient elastography (VCTE) (6.70 [4.70, 9.50] kPa vs 5.60 [4.40, 7.90], $P = 0.003$) were higher in participants with hyperferritinemia, compared to those without hyperferritinemia. The prevalence of NAFLD (78.5% vs 62.1%, $P = 0.001$) and significant fibrosis (35.5% vs 22.1%, $P = 0.002$) were higher in patients with hyperferritinemia compared to those without hyperferritinemia (Figure 1). Hyperferritinemia remained an independent predictor of NAFLD (OR 2.01, 95% CI 1.19-3.39, $P = 0.009$) and significant fibrosis (OR 2.33, CI 1.43-3.77, $P = 0.001$), even after adjustment for age, sex, obesity, and insulin use. **Conclusion:** The presence of hyperferritinemia is associated with a substantially higher risk of NAFLD and significant fibrosis. Hyperferritinemia may be a useful biomarker for NAFLD and significant fibrosis in people with T2DM.

2190-A | IMPACT OF ANTHROPOMETRIC PARAMETERS ON OUTCOMES IN ASIANS WITH METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE

Yeonjung Ha, Young Eun Chon, Joo Ho Lee and Kwan Sik Lee, CHA Bundang Medical Center, CHA University

Background: We examined the incidence and predictors of clinical outcomes in metabolic dysfunction-associated fatty liver disease (MAFLD), focusing on anthropometric parameters. **Methods:** Adult patients with MAFLD were identified in nationwide databases and a hospital cohort. Primary endpoints were atherosclerotic cardiovascular disease (ASCVD) and advanced fibrosis. Logistic and Cox regression analyses were used to analyze the association between anthropometric parameters and endpoints. **Results:** In total, 4,407 of 15,256 (28.9%) and 6,274 of 25,784 subjects (24.3%) had MAFLD in the nationwide database; of these, 403 (9.2%) and 437 (7.0%) subjects were of lean/normal weight, respectively. Compared to the overweight/obese group, the lean/normal weight group had a significantly lower muscle mass (15.0 kg vs. 18.9 kg) and hand grip strength (31.9 kg vs. 35.1 kg), and had a higher ASCVD risk (9.0% vs. 6.3% and 15.9% vs. 8.5%; Ps < 0.001). Sarcopenia (odds ratio [OR], 6.66; 95% confidence interval [CI], 1.79−24.80) and hand grip strength (OR, 0.92; 95% CI, 0.86−0.97; Ps = 0.005) were associated with the ASCVD risk in the lean/normal weight group. In a hospital cohort (n = 1,363), the ASCVD risk was significantly higher in the lean/normal weight group than in the overweight/obese group (median follow-up, 39.1 mo). Muscle mass was inversely correlated with the ASCVD risk (hazard ratio [HR], 0.72; 95% CI, 0.56−0.94); while visceral adiposity was associated advanced fibrosis (HR, 1.36; 95% CI, 1.10−1.69; Ps < 0.05). **Conclusion:** Muscle mass/strength was significantly associated with the ASCVD risk in patients with MAFLD. Visceral adiposity was an independent predictor of advanced fibrosis.

2191-A | IMPACT OF HELICOBACTER PYLORI ERADICATION ON CLINICAL AND LABORATORY PARAMETERS IN NON-ALCOHOLIC FATTY LIVER DISEASE: A SYSTEMATIC REVIEW AND META-ANALYSIS OF THE RANDOMIZED CONTROLLED TRIALS

Fouad Jaber[1], Saqr Alsakarneh[2], Azizullah Beran[3], Tala Alsharaeh[4], Abdelrahman Abdelshafi[5], Mohamed Jaber[6], Mohamed Ahmed[1], Yazan Abood[7], Kimberly Sanders[1], Adel Muhanna[2], Mir Mirzulqarnain[8], Mohammad Almeqdadi[9], Hassan Ghoz[1], Wendell K. Clarkston[2] and John H. Helzberg[10], (1)University of Missouri- Kansas City, (2)University of Missouri-Kansas City, (3)Indiana University School of Medicine, Department of Gastroenterology and Hepatology, Indianapolis, IN, (4)University of Jordan, Department of Medical Education - Faculty of Medicine, Amman, Jordan, (5)Department of Medical Education, Faculty of Medicine-Assiut University, Assiut, Egypt, (6) Department of Medical Education, Al-Azhar University-Faculty of Medicine, Gaza, Palestine, (7)Department of Internal Medicine, Rutgers New Jersey Medical School, Newark, NJ, USA., (8)University of Missouri Kansas City, Department of Gastroenterology and Hepatology, Kansas City, MO, (9)Tufts Medical Center, (10) University of Missouri Kansas City, Department of Gastroenterology and Hepatology - Saint Luke's Hospital, Department of Gastroenterology and Hepatology, Kansas City, MO

Background: Helicobacter pylori (HP) infection is associated with non-alcoholic fatty liver disease (NAFLD) and insulin resistance; however, the correlation between HP eradication and NAFLD remains controversial. This systematic review and meta-analysis examined the effect of HP treatment on clinical and laboratory parameters in NAFLD patients. **Methods:** We conducted a literature search of PubMed, Embase, Scopus, and Web of Science databases through October 2022 for randomized controlled trials (RCTs) examining the effect of HP treatment in NAFLD patients versus lifestyle changes alone. The primary outcome was the change in steatosis parameters. Secondary endpoints were changes in anthropometric parameters, inflammatory markers (TNF-a), and metabolic parameters (fasting blood glucose (FSG), homeostasis model assessment of insulin resistance (HOMA-IR), AST/ALT, and lipid profile). The random effects model was used to calculate the standardized mean difference (SMD) with associated 95% confidence intervals (CI) for our desired outcome. **Results:** Four RCTs met our inclusion

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

criteria. 453 patients were included (mean age 42.8 years, 58.5% males), with 228 (50.3%) in the HP eradication group and 225 (49.7%) in the lifestyle modification group. HP eradication had a significant effect on reducing liver steatosis and TNF-α levels compared to lifestyle modification alone (SMD: -0.9; 95% CI: -14.67, -3.82, I2 = 0% and SMD: -6.3; 95% CI: -9.04, -3.56, I2 = 0%, respectively) (Figure. 1). No significant effect between the two groups was noticed in regards to BMI (SMD: -0.21; 95% CI: -0.9, 0.49, I2 = 0%), ALT (SMD: -3.2; 95% CI: -8.36, 1.96, I2 = 11%) or AST levels (SMD: -0.96; 95% CI: -4.61, 2.69, I2 = 0%), HOMA-IR measurements (SMD: -0.21; 95% CI: -0.57, 0.14, I2 = 0%) as well as in serum FBG levels (SMD: -0, 06, 95% CI: -0.29, 0.16, I2 = 0%), or lipid profile (Table. 1). **Conclusion:** This meta-analysis revealed that HP eradication significantly reduced liver steatosis and inflammatory marker (TNF) levels in patients with NAFLD. However, HP eradication appears to have similar effects on NAFLD outcomes compared to lifestyle changes in other metabolic aspects such as liver enzymes, FSG, lipid profile, HOM-IR, and anthropometric measurements. The variability in interventions, confounding variables, and diagnostic limitations of the included studies emphasize the need for further studies to validate our results.

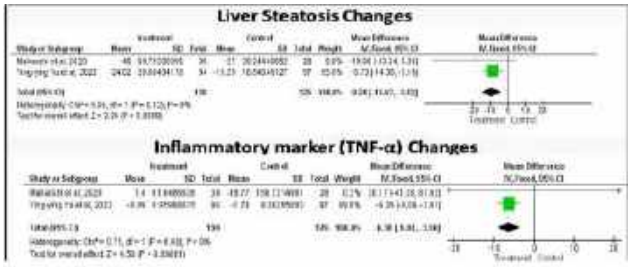

Figure 1: Forest plot of total change difference in (A) Controlled Attenuation parameter (CAP) measurement and (B) Tumor Necrosis Factor-α (TNF-α) between the intervention and control groups with their 95% confidence interval.

Outcome	RCTs, n	SMD (95% CI)	Heterogeneity I²	Heterogeneity P-value	Overall Effect (P-value)
Laboratory findings					
FBG Levels (mg/dL)	3	-0.06 (-0.29, 0.16)	0%	0.42	0.53 (0.6)

2192-A | IMPACT OF SEX AND DIABETES ON LONG-TERM OUTCOMES OF PATIENTS WITH NAFLD

Catherine Hand[1,2], Vy H. Nguyen[2,3], Leslie Yeeman Kam[4], Jung Eun Park[2], Richard Hx Le[2,5], Nicholas Ajit Rouillard[2], Ashley Fong[2], Surya Gudapati[2,6], Audrey Ha[2], Mayumi Maeda[2], Scott D. Barnett[4], Linda Henry[4], Ramsey Cheung[4,7] and Mindie H. Nguyen[2,4], (1)Long School of Medicine Uthscsa, (2)Stanford University Medical Center, (3)Harvard Medical School, (4)Stanford University Medical Center, Palo Alto, CA, (5)William Carey University College of Osteopathic Medicine, (6) Washington University, (7)Veterans Affairs Palo Alto Health Care System

Background: Nonalcoholic fatty liver disease (NAFLD) is one of the leading causes of cirrhosis and liver cancer in the United States (U.S). Male sex and diabetes mellitus (DM) are both known to associate with the risk of NAFLD. However, there are limited data on the impact of sex and DM on the long-term mortality outcomes of patients with NAFLD. As such, we aimed to characterize the mortality outcomes among NAFLD patients stratified by sex and DM. **Methods:** In this retrospective study, NAFLD were identified using liver imaging and/or histology at a U.S. medical center from 1995-2021. Patients with other concurrent liver diseases were excluded. We used Kaplan-Meier curves to evaluate mortality outcomes of patients with NAFLD stratified by sex and DM. We used Cox proportional hazard regression to evaluate the association between DM on mortality among DM and non-DM, and among subgroups of male and female patients. **Results:** Our study included 10,207 eligible NAFLD patients (43% male). Compared to females, males were younger (48.1 ± 15.2) with less comorbidities at baseline (obesity: 49.1% vs. 57.6%; DM: 24.9% vs. 32.1%; non-liver cancer:16.2% vs. 18.6%, all $P < 0.001$). Similar findings were observed in subgroup analysis of NAFLD patients without DM. However, in NAFLD patients with DM, we observed opposite findings with males more likely to have comorbidities at baseline. DM NAFLD males were also noted to have higher percentage of cirrhosis as

compared to females (35.0% vs. 29.9%, P = 0.004). Mortality rates (per 1000 person-years) were lower in males compared to females in the total cohort for all-cause (0.06 [0.04-0.07] vs. 0.07 [0.06-0.08], P = 0.18), liver-related (0.004 [0.002-0.008] vs. 0.01[0.01-0.02], P = 0.24), and non-liver related (0.05 [0.04-0.07] vs. 0.06 [0.05-0.07], P = 0.32) mortality, but these differences were not statistically significant (Figure 1A-C, left panels). In NAFLD patients without DM, males had a significantly lower incidence of all-cause mortality compared to females (0.04 [0.03-0.05] vs. 0.06 [0.04-0.03], P = 0.02) but not in analysis of cause-specific mortalities (Figure 1A-C, middle panels). Meanwhile, overall and cause-specific mortalities among DM NAFLD patients were similar between males and females (Figure 1A-C, right panels). In multivariable Cox's regression analysis adjusted for age, sex, ethnicity, BMI, FIB-4 index, baseline cirrhosis or HCC, and Charlson Comorbidity index, male sex was independently associated with lower mortality compared to females though this association did not reach conventional level of statistical significance (aHR 0.66 95%CI 0.42-1.02, P = 0.06). **Conclusion:** Non-DM male patients with NAFLD had lower mortality than female patients, while there was no significant difference in mortality between DM male and female patients. Further studies are needed to examine the interaction between sex and metabolic comorbidities to inform individualized therapies for patients with NAFLD.

Figure 1. Mortality Outcomes of NAFLD Patients by Sex

2193-A | IMPACT OF SEX AND TYPE 2 DIABETES MELLITUS ON QUALITY OF LIFE AMONG NON-ALCOHOLIC FATTY LIVER DISEASE PATIENTS: A LARGE CANADIAN COHORT STUDY

Elizabeth Baguley[1], Madelyn Knaub[1], Wendy Schaufert[2], Mark Gordon Swain[1] and Abdel-Aziz Shaheen[3], (1)University of Calgary, (2)Alberta Health Services, (3)Cumming School of Medicine, University of Calgary, Calgary, AB, Canada

Background: Non-alcoholic fatty liver disease (NAFLD) is a growing epidemic worldwide. A NAFLD diagnosis can significantly impact quality of life (QoL). We described QoL among NAFLD patients at risk of advanced liver fibrosis. We evaluated associations between sex and type 2 diabetes mellitus (T2DM) status on QoL domains. **Methods:** In this prospective study, the Patient-Reported Outcomes Measurement Instrument Survey (PROMIS-29), a 29-item validated survey with seven health domains (pain interference, depression, physical function, ability to participate in social roles/activities, fatigue, anxiety and sleep disturbance, and a single pain intensity item) was administered to patients identified in primary care through the Calgary NAFLD pathway with either an inconclusive or elevated (**e** 8kPa) shearwave elastography (n = 812) between March 2017 and March 2023. Patients completed the PROMIS-29 survey before assessments with transient elastography (Fibroscan®) and hepatologist discussion. PROMIS-29 scores were compared between our NAFLD cohort and a reference 2000 General US Census population. PROMIS-29 scores of our cohort were compared based on sex (female vs. male) and T2DM status (yes vs. no). A T2DM diagnosis was confirmed in patients with hemoglobin A1c **e** 6.5%, or a previous T2DM diagnosis and treatment with T2DM medications. **Results:** Participants had a median age of 58 yrs (IQR:48.3-66.0). Over half of the participants were female (57.4%), and 41.0% had T2DM. Compared to the reference population, our cohort scored worse in the physical function, sleep disturbance, anxiety, and pain interference domains ($p < 0.001$); however, our cohort showed a better score for participation in social roles and activities ($p = 0.001$). Females experienced worse ($p < 0.001$) QoL compared to men across all PROMIS-29 domains (Table 1). Participants with T2DM experienced greater issues with physical functioning ($p < 0.001$), more fatigue ($p = 0.004$), increased depression ($p = 0.044$), more sleep disturbances ($p < 0.001$), reduced ability to participate in social roles and activities

($p = 0.003$), higher pain interference ($p < 0.001$), and increased overall pain intensity ($p < 0.001$), when compared to participants without T2DM (Table 1). **Conclusion:** Among NAFLD patients identified in primary care at risk for significant liver fibrosis, females and patients with T2DM had reduced QoL. Further, NAFLD patients have reduced QoL across many health domains compared to the general population.

Table 1: Quality of life measures for entire NAFLD cohort, including comparisons between sex (female vs. male) and type 2 diabetes status

Quality of Life Measure	Entire NAFLD cohort (n=812)	Female (n=466)	Male (n=346)		Non-T2DM (n=469)	T2DM (n=333)

2194-A | IMPACT OF USE OF SODIUM-GLUCOSE COTRANSPORTER 2 INHIBITORS ON DEVELOPMENT OF LIVER-RELATED COMPLICATIONS IN PATIENTS WITH TYPE 2 DIABETES: A TERRITORY-WIDE COHORT STUDY

Guanlin Li[1,2,3], Yin Leung[4], Tsz-Fai Yam[1,2,3], Grace Lai-Hung C Wong[1,2,3], Vincent Wai-Sun Wong[1,2,3] and Terry Cheuk-Fung Yip[1,2,3], (1)Department of Medicine and Therapeutics, the Chinese University of Hong Kong, (2)Medical Data Analytics Centre (MDAC), the Chinese University of Hong Kong, (3)Institute of Digestive Disease, the Chinese University of Hong Kong, (4)Faculty of Medicine, the Chinese University of Hong Kong

Background: Emerging data show that sodium-glucose cotransporter 2 inhibitors (SGLT2i) can improve liver function and ameliorate hepatic steatosis in patients with type 2 diabetes (T2D). However, some studies reported conflicting results on the long-term effect of SGLT2i on liver-related complications. We aimed to study the impact of the use of SGLT2i on the development of liver-related complications in patients with T2D. **Methods:** Adult T2D patients in 2007-2021 were identified using a territory-wide electronic database in Hong Kong. T2D was defined by any use of non-insulin antidiabetic agents, continuous use of insulin for ≥ 28 days, hemoglobin A_{1c} ≥ 6.5%, fasting glucose ≥ 7mmol/L, and/or diagnosis codes. The primary outcome was liver-related events (LRE), which included hepatocellular carcinoma, ascites, variceal bleeding, hepatic encephalopathy, spontaneous bacterial peritonitis, hepatorenal syndrome, liver transplantation, and liver-related death. Patients with LRE before or within 6 months after T2D diagnosis, type 1 diabetes, or a history of cancer were excluded. A time-dependent cause-specific hazard model was used to examine the impact of the use of SGLT2i and other antidiabetic drugs over time and the risk of LRE, with non-liver-related death as a competing event. **Results:** Of 624,067 T2D patients (mean age 61.7 ± 13.2 y, 53.4% males), 2.3% had cirrhosis at T2D diagnosis; 6.8% and 0.5% had hepatitis B virus (HBV) and hepatitis C virus (HCV) infection respectively. At a median (25th-75th percentile) follow-up of 6.2 (3.0-9.9) years, 35,664 (5.7%) patients received SGLT2i and 9,026/624,067 (1.4%) patients developed LRE. In multivariable analysis, older age, male gender, presence of cirrhosis, HBV infection, and HCV infection were associated with a higher rate of LRE. The use of SGLT2i was not associated with a lower rate of developing LRE (adjusted cause-specific hazard ratio [aCSHR] 0.89, 95% confidence interval [CI] 0.76-1.05, p = 0.156). The use of statin (aCSHR 0.74 [95% CI 0.71-0.78]), metformin (0.90 [0.86-0.95]), and alpha-glucosidase inhibitors (0.67 [0.50-0.90]) were associated with a lower rate of developing LRE, while the use of insulin (3.15 [3.00-3.30]), sulfonylureas (1.26 [1.20-1.32]), and dipeptidyl peptidase 4 inhibitors (1.16 [1.08-1.25]) were associated with a higher rate of developing LRE. The use of SGLT2i was associated with a lower rate of non-liver-related death (aCSHR 0.76, 95% CI 0.70-0.82, p < 0.001) (Table). **Conclusion:** The use of statin, metformin, and alpha-glucosidase inhibitors but not SGLT2i was associated with reduced development of liver-related complications in a large territory-wide cohort of patients with T2D.

Table. Univariate and multivariable analysis by time-dependent cause-specific hazard model after imputation on factors associated with liver-related complications in patients with type 2 diabetes.

Parameters	Liver-related complications				Non-liver-related death

2195-A | IMPLEMENTATION OF MACHINE LEARNING ALGORITHMS FOR THE SCREENING OF ADVANCED LIVER FIBROSIS AMONG NON-ALCOHOLIC FATTY LIVER DISEASE PATIENTS: AN IN-DEPTH EXPLANATORY MODELING★

Shoham Dabbah[1,2], Itamar Mishani[3], Yana Davidov[2], Mariya Likhter[2], Monika-Inda Kaufmann[2] and Ziv Ben-Ari[1,2], (1)Tel Aviv University, (2)Sheba Medical Center, (3)Carnegie-Mellon University

Background: The increasing prevalence of non-alcoholic fatty liver disease (NAFLD) has created an urgent need to improve the screening for advanced liver fibrosis among NAFLD patients, with the goal of reducing its associated morbidity and mortality. Machine learning algorithms (MLAs) have the potential to predict advanced fibrosis in NAFLD patients, however it is essential to justify and speculate on the predictions made by these MLAs to ensure responsible and safe use by clinicians in the future. We aim to train and validate MLAs for predicting advanced fibrosis in NAFLD patients and to provide sound reasoning for these predictions. **Methods:** In this study we collected laboratory, demographic, and clinical features of NAFLD patients managed at a large, single-tertiary center between January 2013 and January 2022 (n = 618). MLAs were trained to identify advanced fibrosis, defined as **e** F3 based on liver biopsy (n = 123) or as **e** 9.3 kPa according to 2-dimensions shear wave elastography (n = 495), based on routine features documented within 6-month of fibrosis assessment. Area under ROC curves of MLAs were compared against NAFLD fibrosis score (NFS) and Fibrosis-4 index (FIB-4) on a test dataset collected independently during 2022 (n = 350). The sensitivity and specificity of NFS **e** -1.445 and FIB-4 **e** 1.3 on the test dataset were compared to that of each MLA's threshold which was tuned to achieve 95% sensitivity. Feature importance was derived using extreme gradient boosting (XGBoost) and partial dependence plots were used to assess the relationship with the probability of advanced fibrosis. Probabilities were calibrated to allow customized decisions in different clinical scenarios. **Results:** Artificial neural network, random forest and XGBoost algorithms outperformed both FIB-4 and NFS in advanced fibrosis prediction while logistic regression and support vector machine (SVM) outperformed only FIB-4 ($p < 0.05$ all). XGBoost's threshold achieved sensitivity equal to NFS **e** -1.445 (94% vs. 97%, $p = 0.3$) but higher compared to FIB-4 **e** 1.3 (94% vs. 83%,$p < 0.05$) with significantly higher specificity (76%) compared to both NFS (50%) and FIB-4 (58%) (both $p < 0.01$). The most important features for prediction were hemoglobin A1c (HbA1c), aspartate transaminase (AST), gamma-glutamyl transpeptidase (GGT), platelet count and age, while the least important were gender and serum triglycerides. Age showed interactions with AST and HbA1c, while HbA1c strongly interacted with AST and with GGT. **Conclusion:** This study demonstrated the potential of MLAs to improve the screening for advanced fibrosis among NAFLD patients. Utilizing interpretable MLAs, clinicians could gain a deeper understanding of the features contributing to the probability of advanced fibrosis and to tailor further liver fibrosis stage assessment to the patient's circumstances. Overall, our findings highlight the promise of MLAs in improving clinical decision-making for NAFLD patients.

2196-A | INCIDENCE OF ADVERSE CLINICAL EVENTS IN PERSONS WITH NAFLD: A SYSTEMATIC REVIEW AND META-ANALYSIS

David M Le[1], Thomas Baez[1], Michael H Le[2], Hansen Dang[3,4], Vy H. Nguyen[5], KeeSeok Lee[3], Takanori Ito[6], Yuankai Wu[5], Yee Hui Yeo[7], Fanpu Ji[8], Ramsey Cheung[9] and Mindie H. Nguyen[9], (1)Burrell College of Osteopathic Medicine, (2)Larner College of Medicine at the University of Vermont, San Jose, CA, (3)Stanford University, (4)University of Iowa, Carver College of Medicine, (5)Stanford University Medical Center, (6) Nagoya University Graduate School of Medicine, Japan, (7)Cedars-Sinai Medical Center, Culver City, CA, (8)The Second Affiliated Hospital of Xi'an Jiaotong University, (9)Stanford University Medical Center, Palo Alto, CA

Background: Nonalcoholic fatty liver disease (NAFLD) is associated with a multitude of adverse outcomes. We aimed to estimate the pooled incidence rate of adverse events associated with NAFLD. **Methods:** We performed a systematic review and meta-analysis of cohort studies of adults with NAFLD at baseline using 3 databases (Cochrane library, EMBASE, PubMed) to evaluate the pooled incidence of adverse events. Random-effects models were used to estimate the pooled incidence of adverse clinical events. **Results:** A total of 79 eligible studies (1,377,466 persons) were analyzed. Diagnostic modality included ultrasound (n = 31), biopsy (n = 29), ICD-code (n = 13), and other imaging (n = 6). 74% of studies were good quality with a median study year ranging from 1987 to 2017. Baseline characteristics (mean/proportion (95% confidence interval)) of NAFLD patients were as follows: mean age 51.5 years (50.0-52.9), BMI 28.9 kg/m^2 (28.0-29.8), fasting glucose 105.7 mg/dL (102.3-109.1), total cholesterol 205.3 mg/dL (200.6-210), triglycerides 162.3mg/dL (153.2-171.4), ALT 56.0 U/L (49.4-62.6), AST 40.7 U/L (36.4-44.9), diabetes 28.7% (24.5-33.0), hypertension 42.6% (37.5-47.9), dyslipidemia 42.4% (32.8-52.3), metabolic syndrome 41.7% (26.6-57.7), smoking 31.1% (26.9-35.4), fibrosis 54.5% (40.8-68.0), cirrhosis 22.0% (12.5-33.2), NASH 58.9% (47.2-70.0). All analyses revealed significant heterogeneity (all I^2 **e** 50%) with no asymmetry on funnel plot and no significant differences on egger's test for all outcomes ($p > 0.05$). Using a modified Newcastle-Ottawa scale, the majority (74%) of studies were of good quality with a median score of 8 out of total 9. Incidence rate per 1000 person-years varied by cause of death: all-cause mortality (14.6) cardiovascular related (4.53), non-liver cancer related (3.27), and liver-related mortality (3.10). Incidence rate per 1000 person-years for liver-related events was 24.3. Further subgroup analysis identified fibrosis progression (49.0), cirrhosis (10.9), liver transplant (12.0), and hepatocellular carcinoma (3.39). Incidence of cirrhotic decompensation was (12.1) with decompensation-specific events inclusive of ascites (6.7), varices (4.7), and hepatic encephalopathy (2.31). Incidence rate per 1000 person-years of metabolic events included metabolic syndrome (25.4), hypertension (25.8), hyperlipidemia/dyslipidemia (26.4), and diabetes mellitus (19.0). Overall incidence of cardiovascular events was 24.77, inclusive of coronary artery disease/congestive heart failure (40.1), myocardial infarction (7.1), and stroke (8.1). Other non-liver events included renal impairment (30.3), depression/anxiety (29.1), and non-liver cancer (10.5) (Figure). **Conclusion:** The estimated incidence rates for adverse events among those with NAFLD is high. Early identification and treatment are necessary to prevent disease progression and its associated morbidity and mortality.

2197-A | INCIDENCE OF NAFLD-RELATED HEPATOCELLULAR CARCINOMA WITH DETAILED STRATIFICATION BY RISK FACTORS: A NATIONWIDE UNITED STATES COHORT STUDY

Rongtao Lai[1], Scott D. Barnett[2], Leslie Yeeman Kam[2] and Mindie H. Nguyen[2], (1)Shanghai Ruijin Hospital, (2) Stanford University Medical Center, Palo Alto, CA

Background: Prior studies have suggested that patients with non-alcoholic fatty liver disease (NAFLD) are at higher risk for hepatocellular carcinoma (HCC) development regardless of cirrhosis status. HCC risk varies by several factors including sex, age, and the presence of cirrhosis and/or diabetes mellitus (DM). To date, data on HCC incidence stratified by a combination of relevant background risks are limited. Therefore, our goal was to estimate HCC incidence in a stratified manner using a large nationwide U.S. cohort of NAFLD patients. These granular data can help inform HCC surveillance strategies and to inform future economic modeling and public health planning studies. **Methods:** We performed a retrospective cohort study utilizing the Truven Health MarketScan® Databases (January 2007-December 2021) to identify patients with NAFLD as defined by ICD-9/10 codes. We excluded patients with other concurrent liver disease etiologies, HCC at baseline, and those with follow-up < 1 year. We used Kaplan-Meier methods to estimate HCC incidence and multivariable Cox's regression analysis to identify factors associated with HCC. HCC incidence estimates were stratified by sex, age, cirrhosis status, and the presence of DM. **Results:** We identified 741,816 NAFLD patients who met our study criteria. The cohort mean age was 51.5 ± 12.8 years, with 46% male, and 49% with cirrhosis. The HCC incidence (per 1000 person-years [PY]) was 0.72 overall (95% confidence interval [CI], 0.68-0.75), 0.95 (95%CI, 0.89-1.01) for male *vs* 0.52 (95%CI, 0.48-0.56) for female, 4.29 (95% CI, 4.06-4.51) for cirrhosis *vs* 0.14 (95%CI, 0.13-0.16) for non-cirrhosis, and 1.19 (95%CI, 1.12-1.26) for DM *vs* 0.41 (95%CI, 0.38-0.44) for non-DM. An age trend was evident, especially for the **e** 60 years group as compared to the younger group (2.72, 95%CI 2.55-2.88 *vs* 0.35, 95%CI, 0.33-0.38) (all $P = 0.0001$). As shown in heatmap Table, NAFLD incidence was as low as 0.04 for both males and females (95%CI, 0.01-0.07 males, 0.01-0.08 females) among patients younger than 40 years without cirrhosis or DM and as high as 19.06 (95%CI, 16.10-22.01) in males and 8.44 (95%CI, 6.78-10.10) in females among patients aged **e** 70 years with cirrhosis and diabetes. On multivariable analysis adjusted for age, sex, cirrhosis status, and DM, the strongest significant risk for HCC was cirrhosis (adjusted hazard ratio [aHR], 17.01), while there was almost 50% higher HCC risk with DM (aHR, 1.41) and with each yearly increase in age (aHR, 1.03) (all $P < 0.001$). **Conclusion:** In this large nationwide cohort of real-world NAFLD patients, we have utilized heat map to provide detailed, stratified HCC incidence rates across various combinations of risk factors. We identified subsets of the population with low to high HCC risk, thus providing essential information to inform HCC surveillance, prevention, public health efforts, and future modeling studies.

Table. Heat map of incidence rate per 1000 person-year of HCC in 741,816 patients with NAFLD using four background risks for stratified analysis

Gender	Comorbidity	Age	No cirrhosis	Cirrhosis
Male	No diabetes mellitus	<40	0.04	0.52
		40-49	0.07	0.82
		50-59	0.12	3.52
		60-69	0.33	9.04
		≥70	0.4	12.12
	Diabetes mellitus	<40	0.07	0.28
		40-49	0.09	1.94
		50-59	0.13	5.95
		60-69	0.72	17.15

2198-A | INCIDENCE, DISABILITY-ADJUSTED LIFE YEAR, AND MORTALITY OF NON-ALCOHOLIC STEATOHEPATITIS-RELATED LIVER CANCER IN SOUTHEAST ASIA AND WESTERN PACIFIC REGIONS FROM 2000 TO 2019

Aunchalee Jaroenlapnopparat, Mount Auburn Hospital/ Harvard Medical School, Pojsakorn Danpanichkul, Chiang Mai University, Natchaya Polpichai, Weiss Memorial Hospital, Panisara Fangsaard, Bassett Medical Center and Karn Wijarnpreecha, University of Arizona College of Medicine Phoenix, Phoenix, AZ

Background: The etiologies of liver cancer in Asia has shifted from viral to non-viral. Given varieties of socio-economic factors and advancement of healthcare in Asia, we aimed to study the epidemiology trend of non-alcoholic steatohepatitis (NASH)-related liver cancer in South East Asia (SEA) and West Pacific (WP) from 2000 to 2019. **Methods:** This study analyzed the incidence, disability-

adjusted life years (DALYs), and mortality for NASH-related liver cancer in the SEA and WP regions between 2000 and 2019 from the Global Burden Disease (GBD) Study 2019. Raw numbers of cases, age-standardized rate, and genders were extracted from the study. Joinpoint program was used to analyze the annual percentage change (APC). **Results:** Between 2000 and 2019, the incidence of NASH-related liver cancer had decreased in WP, with a greater decrease in females (APC -3.06 in females vs -2.4 in males). On the contrary, NASH-related liver cancer incidence had increased in SEA, with a greater increase in males than females (APC 0.84 in males vs 0.57 in females). Similarly to the decrease in incidence, mortality and DALYs due to NASH-related liver cancer had decreased in WP, especially in females. As the increased incidence of NASH-related liver cancer in SEA, mortality and DALYs had increased. In SEA, males had a higher increase in mortality, and DALYs than females. **Conclusion:** Over the past decade, the incidence, mortality, and DALYs of NASH-related liver cancer had decreased in WP but increased in SEA. This may reflect an improvement of prevention and management of NASH-related liver cancer in the WP region. Males in both regions had a higher burden of NASH-related liver cancer when compared to females. Further studies are warranted to elaborate underlying sexual disparity in the burden of NASH-related liver cancer.

2199-A | INCIDENTAL FINDING OF HEPATIC STEATOSIS ON ABDOMINAL ULTRASOUND: INCIDENCE AND MANAGEMENT

Chad Spencer[1], Alvin Green[1], Hajira Malik[1], Cesar Moreno[1], Michael Tran[1], Ian Tfirn[2] and Rajab Idriss[1], (1) University of South Alabama, (2)Independent Researcher

Background: Due to the high prevalence of obesity/metabolic syndrome, fatty liver disease is increasingly detected as an incidental finding on imaging and maybe dismissed without further evaluation. The goals of our study are 1) to determine the incidence of hepatic steatosis on outpatient ultrasounds obtained for non-liver related causes and 2) to assess if patients were referred for specialist care and fibrosis assessment. **Methods:** We conducted a retrospective study of all adult patients who underwent outpatient abdominal ultrasound for non-liver related reasons at our institution between January, 2018 - December, 2018. A total of 459 patients were included in the initial assessment; of these, 227 patients were excluded from the study for either of the following: known history of liver disease, heavy alcohol use and/or already seeing a gastroenterologist or hepatologist. The following data was collected: demographic information, medical comorbidities, body mass index (BMI), lab results, referral to gastroenterology/hepatology, and fibrosis assessment. Chi-square test and independent samples t-test was performed to evaluate for differences between patients based on the presence or absence of hepatic steatosis on ultrasound. Patients in the hepatic steatosis subgroup were further analyzed to determine if any factors predicted referral to gastroenterology/hepatology. **Results:** The cohort was predominantly female (78.45%), Caucasian (56%) with mean age of 42.3 years old. Of the 232 patients included in the study, 74 (31.9%) were found to have hepatic steatosis on ultrasound. Those with hepatic steatosis were more likely to have hypertension ($p = 0.024$), hyperlipidemia ($p = 0.021$), obese BMI (mean BMI 33.33 kg/m² vs. 28.32 kg/m²; $p = 0.001$), and elevated ALT (27.69 IU/L vs. 20.88 IU/L; $p = 0.027$). Of the 74 patients with hepatic steatosis on ultrasound, 29 (39.1%) were referred to a gastroenterologist or hepatologist, but only 14 underwent fibrosis assessment with elastography and/or liver biopsy. Patients with hepatic steatosis who were referred to gastroenterology/hepatology were more likely to be Caucasian (72.41% vs. 51.1%; $p = 0.163$), older (mean age 47 vs. 44.6; $p = 0.568$) and have elevated ALT (31 IU/L vs. 25.62 IU/L; $p = 0.228$). **Conclusion:** In this cohort of patients without known liver disease, many were incidentally found to have hepatic steatosis on ultrasound, with an incidence of 31.9%. Those with hepatic steatosis were

Symbols: ƒ , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

more likely to have hypertension, hyperlipidemia, obesity, and elevated ALT. Patients with higher ALT, older and Caucasian were more likely to be referred for further work up.

2200-A | INCREASED MORTALITY AND LIVER-RELATED COMPLICATIONS IN LEAN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE COMPARED TO NON-LEAN

Claire Faulkner[1], Majd Aboona[2], Pooja Rangan[2,3], Vincent Chen[4], Cheng Han Ng[5], Daniel Q Huang[6], Mark Dhinesh Muthiah[6], Donghee Kim[7], Moises Ilan Nevah Rubin[3,8], Ma Ai Thanda Han[3,8], Michael Fallon[3,8] and Karn Wijarnpreecha[3,8], (1)University of Arizona College of Medicine - Phoenix, Phoenix, AZ, (2)University of Arizona College of Medicine-Phoenix, Phoenix, AZ, (3) Banner University Medical Center, (4)University of Michigan Medical Center, (5)Yong Loo Lin School of Medicine, National University of Singapore, (6)National University Health System (NUHS), (7)Stanford University Medical Center, (8)University of Arizona College of Medicine Phoenix, Phoenix, AZ

Background: Nonalcoholic fatty liver disease (NAFLD) is a leading cause of chronic liver disease worldwide. About 20% of patients with NAFLD are not overweight or obese (lean NAFLD). The natural history and racial disparities of lean NAFLD versus non-lean NAFLD are not well understood. **Methods:** In this multi-state health system study, we included patients with NAFLD with follow-up duration of over 365 days at the Banner Health System between 2012 and 2022 based on ICD codes. We excluded those with underweight BMI, missing data on race, body mass index (BMI), or lab values, other etiologies of liver disease, baseline decompensated cirrhosis, baseline cancer diagnosis, or bariatric surgery. Primary outcomes were mortality and incident outcomes (cardiovascular disease, liver-related events (LRE), cirrhosis, cancer, and type 2 diabetes (DM)) amongst lean vs. non-lean subjects with NAFLD. **Results:** A total of 37,027 NAFLD subjects were included, 8.76% of which were classified as lean, 22.96% overweight, 29.29% obesity class I, and 38.99% obesity class II or III. Our cohort was predominantly female (60.76%) and White (63.83%). Median follow-up duration was 1,398 days. Compared to lean subjects, overweight (HR 0.48, 95% CI 0.38-0.61), obese class 1 (HR 0.48 95% CI 0.38-0.60), and obese class 2-3 (HR 0.55, 95% CI 0.44-0.70) individual's had significantly lower mortality, after adjusting for confounders. Furthermore, the incidence of LRE was also significantly lower in overweight (HR 0.59, 95% CI 0.45-0.78), obese class 1 (HR 0.58, 95% CI 0.45-0.76), and obese class 2-3 (HR 0.56, 95% CI 0.43-0.73) subjects. Among the lean NAFLD group, Native American/Alaska Native (NA/AN) subjects had a significantly higher incidence of LRE as compared to White subjects (HR 3.50, 95% CI 1.00-12.21). Within the non-lean group, Black and NA/AN subjects had significantly higher mortality, LRE, and DM compared to White subjects. **Conclusion:** This study highlights varied mortality and incident outcomes amongst lean and non-lean subjects with NAFLD, showing that lean NAFLD may portend a poorer prognosis with higher incidence of death and LRE, despite similar incidences of cirrhosis and CVD. We also found racial disparities in lean NAFLD, showing NA/AN individual's have a significantly higher incidence of LRE compared to White individual's. Further research is needed to elucidate the underlying disparities in NAFLD.

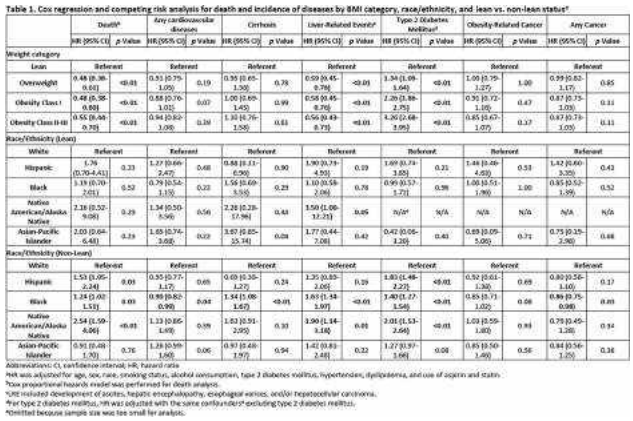

Table 1. Cox regression and competing risk analysis for death and incidence of diseases by BMI category, race/ethnicity, and lean vs. non-lean status†

	Death^a		Any cardiovascular diseases		Cirrhosis		Liver-Related Events^b		Type 2 Diabetes Mellitus^c		Obesity-Related Cancer		Any Cancer

2201-A | INCREASING INCIDENCE AND PREVALENCE OF HCC AND CIRRHOSIS IN PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE

Ronald Samuel[1], Basim Ali[1], Jennifer Kramer[2], Yumei Cao[2], George Cholankeril[1], Ruben Hernaez[3], Tzu-Hao (Howard) Lee[3], Hashem B. El-Serag[1] and Fasiha Kanwal[4], (1)Baylor College of Medicine, (2)Micheal E Debakey, (3)Baylor College of Medicine, Houston, TX, (4)Michael E. Debakey VA Medical Center

Background: Patients with nonalcoholic fatty liver disease (NAFLD) are at risk for developing costly and morbid complications, although the actual incidence and prevalence of these complications is unknown. We examined time trends in the incidence and prevalence of cirrhosis and hepatocellular carcinoma (HCC). **Methods:** We calculated the annual incidence and prevalence of cirrhosis and HCC in a national sample of Veterans identified as having NAFLD based on a previously validated algorithm between 2010 and , with follow up until 12/31/2022. We used ICD-9/10 codes to define cirrhosis and used a combination of Veterans Affairs (VA) Cancer Registry and manual review of patient charts to confirm HCC cases. We used direct standardization using the age distribution of 2010 as the standard to adjust the incidence and prevalence rates for aging of the cohort. We compared the incidence and prevalence in the first year *versus* the last year using a chi-square test. **Results:** In this cohort, the number of individual's with NAFLD increased from 17,413 in 2011 to 49,796 in 2022. The mean age of the yearly cohorts increased from 54.1 years in 2011 to 58.6 years in 2022. There was no significant change in gender distribution. The annual age-standardized incidence rates of cirrhosis increased over time from 1.5 per 1000 persons in 2011 to 2.4 per 1000 in 2022 (p-value < 0.0001). HCC age-standardized incidence rose from 0.08 per 1000 in 2011 to 0.3 per 1000 persons with NAFLD in 2022 ($p < 0.0001$. The prevalence of cirrhosis increased 5-fold from 3 per 1000 in 2011 to 15 per 1000 persons in 2022 ($p < 0.0001$). The prevalence of HCC rose by 3-fold from 0.2 to 0.8 per 1000 persons in 2022 ($p < 0.0001$). **Conclusion:** In a U.S. population with NAFLD, the annual incidence of HCC is low but rising over time. This increase is not explained by the ageing of the study cohort but could be related to progression of liver fibrosis over time. Both the incidence and prevalence of cirrhosis in patients with NAFLD increased over the last decade. Given the absence of targeted screening and effective treatments for NAFLD, the burden of NAFLD cirrhosis and HCC will continue to grow although it is unlikely to reach high proportions in the next decade.

2202-A | INCREASING INCIDENCE OF NON-ALCOHOLIC FATTY LIVER DISEASE IN OLDER ADULTS: A POPULATION-BASED TIME-TREND ANALYSIS USING THE GLOBAL BURDEN OF DISEASES STUDY 2019, 1990-2019

Saqr Alsakarneh[1], Saeed Abughazaleh[2], Fouad Jaber[1], Mohammad Aldiabat[3], Yassine Kilani[4], Mohamed Ahmed[5], Wael T Mohamed[1], Mohamad Khaled Almujarkesh[6], Nikki Duong[7], Mohammad Almeqdadi[8] and Hassan Ghoz[5], (1)University of Missouri-Kansas City, (2)Tufts University, (3)New York University, (4)Lincoln Medical Center, (5)University of Missouri- Kansas City, (6)Wayne State University, (7) Virginia Commonwealth University Health System, Oakland, CA, United States, (8)Lahey Clinic Medical Center

Background: Non-Alcoholic Fatty Liver Disease (NAFLD) incidence and prevalence rates have dramatically elevated; however, there are limited data about recent US age and gender-specific NAFLD incidence trends. The aim of this study is to conduct a time-trend analysis of age and gender-specific NAFLD incidence rates in the US using the Global Burden Diseases (GBD) 2019 database. **Methods:** Data was obtained from the GBD 2019 database, an International database that covers 100% of NAFLD diagnosed cases in the US. NAFLD incidence rates, age-adjusted to the standard US population, were calculated using SEER*Stat software (v.8.4.0.1, National Cancer Institute "NCI") and were stratified by gender, as reported in the database. Time-trends were estimated as annual percentage change (APC) and average APC (AAPC) using Joinpoint Regression

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

Software (v.4.9.0.1, NCI) utilizing Monte Carlo permutation analysis to generate the simplest trend. Pairwise comparison was conducted between gender-specific trends using the tests of parallelism and coincidence. Age-specific trends were also assessed in two age sub-groups: younger adults aged 15-49 years and older adults aged 50-74 years. A two-sided P-value cut-off of 0.05 was utilized for statistical significance. **Results:** In 2019, there were 4.1 million patients diagnosed with NAFLD in the US. Overall, incidences rates have been increasing significantly in older adults but not younger adults (AAPC = 2.2 vs 0.8, AAPC difference = 1.4, $P < 0.001$). Age-specific trends were not identical ($P < 0.001$) nor parallel ($P < 0.001$) suggesting that NAFLD incidence rates are different and increasing at a greater rate compared to younger adults. Similarly, female's incidence rates have been increasing significantly higher than males (AAPC = 1.2 vs 1.0) with an AAPC difference between females and males of 0.2 (= 0.027), suggesting that the disparity between NAFLD incidence trends between age-specific groups arises from women. **Conclusion:** Our results suggest that NAFLD incidence trends have been increasing in older adults while stable in younger adults over the last three decades. The greatest difference between older and younger adults seemed to be arising from older women. While this increase can be due to high obesity rates and sedentary lifestyle, it can also represent a true increase in incidence. Future studies are warranted to investigate risk factors associated with the increasing incidence in older adults, especially in older women.

Trend analysis of Non-Alcoholic Fatty Liver Disease Age-Standardized Incidence rate with Gender and Age Variations from 1990 to 2019

Incidence	Trends[a]			Gender/Age-specific AAPC difference (95% CI)[b]	Pairwise comparison P-values		
	Time period	APC (95% CI)	AAPC (95% CI)		Gender/Age-specific AAPC difference	Coincidence[c]	Parallelism[c]
Gender							
Male	1990-1995	2. 2 (2.0 to 2.4)	1.0 (0.8 to 1.1)	0.2	0.027	<0.001	<0.001
	1995-2000	-1.2 (-1.5 to -0.9)					
	2000-2007	0.2 (0.0 to 0.4)					
	2007-2014	1.0 (0.8 to 1.1)					
	2014-2017	4.5 (3.4 to 5.5)					
	2017-2019	0.6 (-0.4 to 1.6)					
Female	1990-1994	1.9 (1.6 to 2.1)	1.2 (1.0 to 1.3)				
	1994-2005	-0.3 (-0.4 to -0.2)					
	2005-2010	1.3 (1.0 to 1.6)					
	2010-2014	2.6 (2.2 to 3.1)					
	2014-2017	3.9 (3.0 to 4.8)					
	2017-2019	0.7 (-0.2 to 1.5)					
Age							
50-74 years	1990-1992	6.9 (5.3 to 8.5)	2.2 (2.0 to 2.4)	1.4	<0.001	<0.001	<0.001
	1992-1995	4.5 (3.0 to 6.1)					
	1995-2006	0.3 (0.2 to 0.4)					
	2006-2011	2.7 (2.2 to 3.2)					
	2011-2017	3.4 (3.0 to 3.7)					
	2017-2019	0.1 (-1.4 to 1.6)					
15-49 years	1990-1992	3.6 (2.8 to 4.3)	0.8 (0.7 to 1.0)				
	1992-1995	1.9 (1.2 to 2.7)					
	1995-2009	-0.5 (-0.5 to -0.4)					
	2009-2014	1.0 (0.8 to 1.3)					
	2014-2017	4.0 (3.2 to 4.7)					
	2017-2019	0.5 (-0.2 to 1.3)					

[a] Time-trends were computed using Joinpoint Regression Program (v4.9.0.1, NCI) with 5 maximum joinpoints allowed (5-line segments).
[b] Tests whether age/gender-specific trends were identical. A significant P-value indicates that the trends were not identical (i.e., they had different incidence rates and coincidence was rejected).
[c] Tests whether age/gender-specific trends were parallel. A significant P-value indicates that the trends were not parallel (i.e., parallelism was rejected).

2203-A | INCRETIN-BASED THERAPIES, AND SODIUM-GLUCOSE COTRANSPORTER-2 INHIBITORS AND RISK OF NEW-ONSET NONALCOHOLIC FATTY LIVER DISEASE AND HEPATOCELLULAR CARCINOMA AMONG PATIENTS WITH TYPE 2 DIABETES IN THE UNITED STATES: A NATIONWIDE REAL-WORLD LARGE POPULATION-BASED COHORT STUDY

Arunkumar Krishnan[1], Dipatsree Mukherjee[2], William R. Hutson[3], Shailendra Singh[3], Shyam Thakkar[3], Tinsay A. Woreta[4] and Saleh A Alqahtani[5,6], (1)Atrium Health Levine Cancer Institute, (2)Apex Institute of Medical Sciences, (3)West Virginia University School of Medicine, (4)Johns Hopkins Medicine, Baltimore, MD, (5)Johns Hopkins University School of Medicine, (6) King Faisal Specialist Hospital and Research Center

Background: Nonalcoholic fatty liver disease (NAFLD) is highly prevalent among patients with type 2 diabetes mellitus (T2DM). There has been a growing interest in the effects of second-line anti-diabetic drugs, such as glucagon-like peptide 1 receptor agonists (GLP-1 RA) and sodium–glucose cotransporter-2 inhibitors (SGLT-2i), on reducing hepatic fat content beyond their glucose-lowering effects. The association between these drugs and the risks of NAFLD and hepatocellular carcinoma (HCC) has not been explored in the US population. Thus, we aimed to determine whether GLP-1 RA and SGLT-2i are associated with a decreased risk of new onset of NAFLD and HCC compared with dipeptidyl peptidase-4 inhibitors (DPP-4i) among patients with T2DM. **Methods:** We conducted a population-based, retrospective cohort study with consecutive adult patients diagnosed with T2DM using TriNeTx dataset. Cohort entry was defined as the date of the first-ever prescription for one of the drugs of interest (GLP-1 RA or SGLT-2i, compared to DPP4i) during the study period. We used a lag of 6 months for all exposures to minimize protopathic bias. We performed a 1:1 propensity score matching (PSM) to reduce confounding effects. The primary outcomes were defined as the first incidence of NAFLD and HCC. We conducted a secondary and sensitivity analysis to assess the robustness of our findings. The outcomes were estimated using a Cox proportional hazards model

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

with hazard ratios (HR) and 95% confidence intervals (CI). **Results:** In this cohort, 425641 patients received GLP-1A treatment, 353887 patients received SGLT-2i, and 352098 patients received DPP-4i were included. After PSM matching (341015 patients), 1687 patients developed new-onset NAFLD after GLP1-RA, whereas 2087 patients after SGLT-2i (HR 0.19; 95% CI: 0.18-0.30) (Table 1). Similarly, the new incidence of HCC was also lower among new users of GLP1-RA (HR 0.51). SGLT2i (353051 patients after PSM), was also associated with lower risks of new-onset NAFLD (HR: 0.49) and HCC (HR: 0.25). The results from the secondary analysis by increasing lag exposure of drugs and in a sensitivity analysis by excluding the previous events remained consistent with the one generated in the primary analyses. **Conclusion:** New users of GLP1-RA and SGLT-2i were associated with lower risks of new-onset NAFLD and HCC compared with DPP4i, and both drugs seemed to be safe and efficacious in lowering the risk of new incidences of NAFLD and HCC in patients with T2DM.

Table 1: Outcomes between the new Users of GLP-1RA, SGLT2 compared to DPP-4i in patients with and type 2 diabetes

Event and Treatment Group	Patients with Event, N	Hazard Ratio (95% CI)
New-onset NAFLD		
Cohort 1:		
GLP1-RA (n=341015)	1681	0.19 (0.18 – 0.30)
DPP-4i (n=341015)	2087	
Cohort 2:		
SGLT-2i (n= 353051)	1003	0.49 (0.47 – 0.51)
DPP-4i (n= 353051)	1478	
Hepatocellular carcinoma		
Cohort 1:		
GLP1-RA (n=341015)	203	0.51 (0.43 – 0.60)
DPP-4i (n=341015)	397	
Cohort 2:		
SGLT-2i (n= 353051)	194	0.25 (0.20 – 0.31)
DPP-4i (n= 353051)	379	

Abbreviations: GLP-1RA, glucagon-like peptide 1 receptor agonists; SGLT-2, sodium–glucose cotransporter-2 inhibitors; DPP-4i, dipeptidyl peptidase-4 inhibitors.

2204-A | INDIVIDUALS WITH ADVANCED FIBROSIS HAVE WORSE FINE MOTOR PERFORMANCE

Ali A. Weinstein[1,2], Leyla De Avila[1], Jillian K. Price[1], Carey Escheik[1], Pegah Golabi[1], Lynn Gerber[1,3,4] and Zobair M. Younossi[1,3,4], (1)Betty and Guy Beatty Center for Integrated Research, Inova Health System, Falls Church, VA, (2)Department of Global and Community Health, College of Public Health, George Mason University, Fairfax, VA, (3)Center for Liver Disease, Department of Medicine, Inova Fairfax Medical Campus, Falls Church, VA, (4)Inova Medicine, Inova Health System, Falls Church, VA

Background: Non-alcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease worldwide. With the growing prevalence of NAFLD, there is an increased interest in the potential relationship between NAFLD and cognitive function. However, NAFLD is a broad term that comprises a wide range of liver pathologies, ranging from simple steatosis to non-alcoholic steatohepatitis. Therefore, fibrosis, a marker of severity, may be a better way to investigate this potential relationship. Fine motor performance (FMP) may serve as an early warning sign for cognitive deficits and issues with mental health. Our aim was to determine if there was a difference in FMP comparing those with advanced fibrosis to those without. **Methods:** Individual's aged 25-69 were enrolled in a cross-sectional study. Those with excess alcohol consumption or viral liver disease were excluded. Each participant performed the Grooved Pegboard Test (GPT), a well-established measure of FMP. The GPT is a manual dexterity test consisting of a pegboard with 25 slots where examinees are asked to match the groove of each peg with the groove of the board before they can be inserted. The NAFLD Fibrosis Score (NFS) was calculated for each individual. Those with scores higher than 0.676 were considered to have advanced fibrosis. **Results:** A total of 54 participants (54% advanced fibrosis, 44% female, age: 58.7 ± 8.4 years, body-mass index (BMI): 33.9 ± 6.0 kg/m^2) completed the assessments. GPT times were statistically significantly slower (see Figure) in those with advanced fibrosis (90.1 ± 19.3 seconds) compared to those without (75 ± 12.8 seconds; $p < 0.05$). Individual's with advanced fibrosis were statistically significantly older and had higher BMI's than those without ($p's < 0.05$). Statistically significant differences on GPT remained present after controlling for age and BMI ($p's < 0.05$). **Conclusion:** Presence of advanced fibrosis is associated with reduced FMP compared to the absence of advanced fibrosis. Since FMP may be an early warning sign for cognitive deficits, there is a need for prospective trials investigating potential explanatory mechanisms that can elucidate the relationship between liver fibrosis and FMP.

2205-A | INFLAMMATORY GENE EXPRESSIONS IN SUBCUTANEOUS AND VISCERAL ADIPOSE TISSUES AND LIVER HISTOLOGY IN PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE

Zhengyi Wang[1], Harsha Chandraratna[2], Jeremy Tan[3], Bastiaan De Boer[4], Jeffrey M Hamdorf[1], Gary P. Jeffrey[1], George Garas[1] and Leon A. Adams[5], (1)The University of Western Australia, (2)Murdoch Hospital, (3)Singapore General Hospital, (4)Pathwest, (5)University of Western Australia

Background: Non-alcoholic fatty liver disease (NAFLD) is a common metabolic disorder however the underlying pathogenic mechanisms remain unclear. One potential pathway is through the systemic inflammation regulated by adipose tissue which promotes hepatic steatosis and fibrosis in patients with obesity. This study aimed to investigate the association between immune/inflammatory gene expression in adipose tissue in patients with and without NASH/NAFLD. **Methods:** Clinical data, liver, subcutaneous and visceral adipose tissue samples (SAT; VAT) were prospectively collected from 75 adult patients aged 20 to 65 years during bariatric surgery. Patients were categorized as normal liver (n = 30), simple steatosis (n = 29), and non-alcoholic steatohepatitis (NASH; n = 16). mRNA expression was assessed by RT^2 profiler array with gene expression calculated as fold changes standardised to two housekeeping genes. **Results:** Macrophage markers *TREM2, CD68*, and *MSR1* had increased gene expression in NASH subjects compared to those with normal liver in both SAT and VAT (*TREM2* fold change SAT 2.8 ± 2.0 vs. 2.1 ± 2.9, $P = 0.002$; VAT 2.8 ± 1.8 vs. 1.5 ± 1.2; $P = 0.01$; *CD68* SAT 1.5 ± 0.5 vs. 1.2 ± 0.8; $P = 0.022$; *MSR1* SAT 1.7 ± 1.2 vs. $1.1 \pm .5$ $P = 0.022$). *NLRP3* expression increased in both simple steatosis and NASH compared to the normal liver group in VAT (simple steatosis 1.6 ± 1.4 vs.1.0 ± 0.3, $P = 0.003$; NASH 2.0 ± 2.0, $P = 0.001$). These genes were also more expressed in SAT compared to VAT in all three groups (all $P < 0.05$). In contrast, gene expression of inflammatory and immune modulating cytokines and chemokines (including *IL2, 6, 10, 18, 33* and *CXCL2, 8, 10)* were not different between groups. *TREM2* expression in both tissues were positively associated with serum ALT (SAT: r_s 0.384, $P = 0.001$; VAT 0.333, $P = 0.004$), glucose (SAT: 0.348, $P = 0.002$; VAT: 0.424, $P < 0.001$), insulin (SAT: 0.373, $P = 0.002$; VAT: 0.393, $P = 0.001$), and triglycerides (SAT: 0.303, $P = 0.009$; VAT: 0.339, $P = 0.003$) in the whole cohort. *MSR1* expression levels were also correlated with higher fasting glucose (SAT: 0.387, $P = 0.001$; VAT: 0.301, $P = 0.009$) and insulin (SAT: 0.416, $P < 0.001$; VAT: 0.414, $P < 0.001$) in both tissues whereas in SAT it was also correlated with increased ALT (0.390, $P = 0.001$) and AST (0.327, $P = 0.006$). **Conclusion:** Macrophage markers rather than inflammatory cytokines, are upregulated in adipose tissue in patients with NASH compared to those with normal liver histology, and correlate with markers of metabolic dysfunction.

2206-A | INTEGRATING FIB-4 SCORE INTO ANNUAL VISIT SCREENING FOR OPTIMAL NON-ALCOHOLIC FATTY LIVER DISEASE EVALUATION IN PATIENTS WITH TYPE 2 DIABETES MELLITUS AT A COMMUNITY INTERNAL MEDICINE RESIDENCY CLINIC

Adalberto Guzman[1], Evelyn Calderon Martinez[1], Wern Lynn Ng[1], Anas Atrash[1], Fernanda Ibarra[2] and Douglas M. Levin[3], (1)UPMC, (2)Woodhull Medical and Mental Health Center, (3)Ohio State University, Columbus, OH, United States

Background: Non-Alcoholic Fatty Liver Disease (NAFLD) is a prevalent condition in patients with type 2 diabetes mellitus (T2DM). Identifying patients at higher risk of advanced liver disease is crucial for appropriate management. This study aimed to assess the utility of integrating the FIB-4 score into annual visit screening for optimal NAFLD evaluation in patients with T2DM at a community clinic. **Methods:** A total of 133 patients with T2DM were enrolled in this study. During their annual visits, FIB-4 scores were calculated based on readily available clinical parameters, including age, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and platelet count. Patients with a FIB-4 score above 2.67 were referred to GI/Hepatology care for further evaluation. Patients with a FIB-4 score less than or equal to 1.3 were advised to continue regular follow-ups in 1 year. Patients with a FIB-4 score above 1.3 but less than 2.67 underwent a secondary risk assessment. **Results:** In our study, a total of 133 patients were enrolled to assess their liver fibrosis using the FIB-4 scoring system. Among these patients, 56 individual's (42%) exhibited a FIB-4 score above the threshold of 2.67, indicating a higher risk of liver disease progression. As a result, these patients were promptly referred to GI/Hepatology care for comprehensive evaluation and further management. Conversely, 44 patients (33%) demonstrated a FIB-4 score equal to or below 1.3, indicating a lower risk of advanced liver disease. For this group, it was recommended that they continue with regular follow-ups over the course of the next year to monitor any potential changes in their liver health. Interestingly, an additional 33 patients (25%) fell into an intermediate range of FIB-4 scores, above 1.3 but below 2.67. This range raises concern for potential underlying liver disease and warrants a more in-depth assessment to identify any secondary risk factors. As a result, these patients were identified for further investigation through a secondary risk assessment, ensuring a comprehensive evaluation of their liver health status. **Conclusion:** Integrating the FIB-4 score into annual visit screening in patients with T2DM at a community clinic showed promising results for optimizing NAFLD evaluation. A significant proportion of patients with T2DM had FIB-4 scores above 2.67, indicating a higher risk of advanced liver disease and necessitating further evaluation by Hepatology specialists. Patients with scores less than or equal to 1.3 were deemed at lower risk and advised to continue regular follow-ups. Patients with scores above 1.3 but less than 2.67 underwent a secondary risk assessment to guide appropriate management strategies. By accurately categorizing patients into different risk groups, healthcare professionalscan make informed decisions regarding appropriate referrals, follow-up plans, and additional risk assessments.

	Patients Enrolled	FIB-4 Score > 2.67	FIB-4 Score ≤ 1.3	FIB-4 Score > 1.3 and < 2.67
Count	133	56	44	33
Percentage	100%	42%	33%	25%

2207-A | INTERPLAY OF METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE AND VIRAL HEPATITIS ON LIVER DISEASE SEVERITY: A LARGE COMMUNITY-BASED STUDY IN A VIRAL ENDEMIC AREA

Chung-Feng Huang, Kaohsiung Medical University Hospital

Background: The features of metabolic dysfunction-associated fatty liver disease (MAFLD) and the interplays with viral hepatitis on liver disease severity in a community setting is elusive. **Methods:** We conducted a mass liver surveillance program in a hepatitis B virus (HBV) and hepatitis C virus (HCV) hyper-endemic area. The program aimed to identify MAFLD and non-MAFLD subjects with potentially advanced fibrosis, defined as one of the following: fibrosis-4 index (FIB-4) > 2.67, transient elastography > 8 kPa or NAFLD fibrosis score > 0.675. **Results:** A total of 5,378 subjects were consecutively enrolled in the current study. The prevalence of anti-HCV and HBsAg seropositivity were 19.3% and 9.7%, respectively. A total of 2,242 (41.7%) subjects had MAFLD, and 375 (7.0%) had advanced fibrosis. MAFLD subjects had a significantly higher proportion of advanced fibrosis

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

than non-MAFLD counterparts (8.7% vs. 5.7%, $P < 0.001$). The proportions of advanced fibrosis in subjects with non-HBV and non-HCV infection (NBNC), mono-HBV infection (mono-B) and mono-HCV infection (mono-C) were 2.8%, 5.7% and 23.4%, respectively. Factors associated with advanced fibrosis in the entire population included age > 65 years (odds ratio [OR]/95% confidence interval [CI]: 4.8/3.7-6.0, $P < 0.001$), male (OR/CI: 1.3/1.0-1.7, $P = 0.019$), anti-HCV seropositivity (OR/CI: 5.9/4.6-7.5, $P = 0.019$), MAFLD-lean metabolic dysregulation (MS) (OR/CI: 2.6/1.3-5.2, $P = 0.005$; compared to the non-MAFLD group) and MAFLD-diabetes (OR/CI: 1.5/1.1-2.1, $P = 0.008$; compared to the non-MAFLD group). MAFLD did not aggravate liver disease severity in HBV- or HCV-infected patients. However, among NBNC subjects, factors associated with advanced liver disease included age > 65 years (OR/CI: 10.6/7.1-15.8, $P < 0.001$), male (OR/CI: 1.3/1.0-1.6, $P = 0.041$), MAFLD-lean MS group (OR/CI: 9.1/2.4-34.6, $P = 0.001$; compared to non-MAFLD group) and MAFLD-DM group (OR/CI: 2.0/1.2-3.2, $P = 0.004$; compared to non-MAFLD group). **Conclusion:** MAFLD patients with diabetes and metabolic dysregulation had a higher risk of advanced liver disease in the community. The effect was enhanced only in nonviral hepatitis subjects.

2208-A | LIFESTYLE AND DIETARY BEHAVIORS OF PEOPLE WITH DIAGNOSED AND UNDIAGNOSED NON-ALCOHOLIC FATTY LIVER DISEASE - A NATIONALLY REPRESENTATIVE SAMPLE OF THE UNITED STATES

Madeline Novack[1], Wei-Ting Lin[2], Po-Hung (Victor) Chen[3], Chiung-kuei Huang[1], Hui-Yi Lin[4], Tung-Sung Tseng[4] and Peng-Sheng Ting[1], (1)Tulane University School of Medicine, New Orleans, LA, (2)Tulane University School of Public Health, (3)Johns Hopkins University School of Medicine, (4)Louisiana State University Health Sciences Center

Background: Non-alcoholic fatty liver disease (NAFLD) is one of the most common causes of liver disease in the United States, affecting an estimated 25% of adults. NAFLD is closely associated with metabolic syndrome and health behaviors. As such, reporting awareness of disease, and consequent lifestyle behavior changes, play an important role in NAFLD progression. In this study, we aim to compare the lifestyle and dietary behaviors of US adults with NAFLD who report being diagnosed with NAFLD to those who do not report diagnosis of NAFLD, to help clinicians identify high yield topics for behavioral counseling to reduce disease progression. **Methods:** National Health and Nutrition Examination Survey (NHANES) participants e 20 years-old with completed data including controlled attenuation parameter (CAP), liver stiffness measurement (LSM), alcohol intake, aspartate aminotransferase (AST), alanine aminotransferase (ALT) and body mass index from the 2017-2020 NHANES cycle were selected in this study. Undiagnosed NAFLD was defined as no self-reported liver disease, CAP > 302, and non or light alcohol drinkers (d 14 and d 7 standard drinks per week in men and women, respectively). Diagnosed NAFLD was based on self-report. Chi-square test and simple linear regression model were performed for categorical and continuous variables. All analyses were conducted under survey module with appropriate sampling weights. **Results:** Among US adults with NAFLD, 92.5% and 7.5% are undiagnosed NAFLD and diagnosed NAFLD, respectively. Participants with undiagnosed NAFLD were more likely to be non-Hispanic whites and college graduates or above (p's d 0.024). 84.4% of population with diagnosed NAFLD had low physical activity ($p = 0.019$), but other reported health behaviors were similar to those with undiagnosed NAFLD, such as any alcohol use, cigarette smoking, and daily caloric/sugar intake. Individual's with diagnosed NAFLD had higher AST and ALT (p's d 0.013). **Conclusion:** In this study, participants with diagnosed NAFLD were less physically active, but otherwise shared many similar habits to those with undiagnosed NAFLD. It appears the awareness of NAFLD alone did little to alter health behaviors. In addition, the relatively large proportion of participants who meet NAFLD by clinical criteria, but are not aware of NAFLD, supports the need for increased disease awareness. Our observation that there are more non-Hispanic Whites in the undiagnosed NAFLD group suggest there are disparities in the diagnosis of NAFLD that deserve further investigation.

2209-A | LIFESTYLE FACTORS AFFECTING NEW ONSET NONALCOHOLIC FATTY LIVER DISEASE

Yosuke Takahata[1], Atsushi Takahashi[2], Yukio Anzai[3], Naoto Abe[1], Tatsuro Sugaya[1], Masashi Fujita[1], Manabu Hayashi[1], Kazumichi Abe[4] and Hiromasa Ohira[1], (1) Department of Gastroenterology,Fukushima Medical University School of Medicine, (2)Fukuoka University, (3)Department of Gastroenterology,Watari Hospital, (4) Fukushima Medical University School of Medicine, Fukushima, Japan

Background: Evidence for the influence of lifestyle factors on nonalcoholic fatty liver disease (NAFLD) onset is limited because the association between lifestyle and NAFLD has been reported mostly based on cross-sectional studies. Our purpose was to elucidate which lifestyle factors are associate with NAFLD onset by a longitudinal study. **Methods:** This was a longitudinal study of 1,713 Japanese men and women who underwent multiple health checkups from June 2013 to the end of March 2018 at Watari Hospital in Fukushima, Japan, and they were not diagnosed with NAFLD at the first health checkup; the mean follow-up was 41 months. Baseline characteristics, including lifestyle factors, were compared among participants with and without NAFLD onset. We then conducted Cox regression analyses to identify the association between lifestyle factors and NAFLD onset. **Results:** Among 1,713 participants, 420 (24.5%) developed NAFLD. There were significant differences in body mass index, hepatobiliary enzymes, lipids, glucose, smoking and fast eating between participants with and without NAFLD onset. A multivariable logistic regression analysis adjusted for sex, age and lifestyle factors showed that fast eating (hazard ratio (HR): 1.51, 95% confidence interval (CI): 1.24-1.83, $p < 0.01$) and skipping breakfast (HR: 1.49, 95% CI: 1.05-2.10, $p = 0.03$) were risk factors for NAFLD onset. Moreover, fast walking was a preventive factor against NAFLD onset (HR: 0.78, 95% CI: 0.64-0.95, $p = 0.01$). **Conclusion:** These findings could help to identify and prevent future NAFLD onset.

2210-A | LIVER CHEMISTRIES TRENDS IN PREGNANT PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE

Zoe Finer[1], Christine R Lopez[2], Suzanne R. Sharpton[2], Rolanda Lister[2], Jennifer Thompson[2], Yue Gao[2], Christopher Lindsell[2] and Manhal Izzy[2], (1)Vanderbilt University School of Medicine, (2)Vanderbilt University Medical Center

Background: The pathophysiology of non-alcoholic fatty liver disease (NAFLD) is linked with insulin resistance and oxidative stress, both of which can be heightened in pregnancy. However, the effects of pregnancy on NAFLD are not well-defined. This study aimed to evaluate the possibility of worsening liver inflammation, as reflected by liver chemistries, during pregnancy in NAFLD patients. **Methods:** This is a retrospective study of all adult pregnant patients at a Tertiary North American Center between 2000-2021.

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Diagnostic codes and keywords from radiology reports identified patients with NAFLD prior to pregnancy compared to age-matched controls without liver disease. Patients without documented aspartate aminotransferase (AST), alanine aminotransferase (ALT), and platelet values within 2 years prior to conception were excluded. For pre-pregnancy AST/ALT values, the value closest to the date of pregnancy was used. For during-pregnancy AST/ALT values, the highest value during pregnancy was used. Multivariate linear regression was used for during pregnancy AST/ALT and logistic regression was used for categorical outcomes. **Results:** 285 patients were included with 117 NAFLD cases and 168 controls. Patients with NAFLD had significantly higher pre-pregnancy transaminases compared to controls. However, transaminases were comparable between the two groups during pregnancy, and so were the mean differences during pregnancy compared to pre-pregnancy (Table 1). In multivariate analysis, NAFLD ($p = 0.39$), pre-pregnancy AST ($p = 0.65$), and the interaction between NAFLD and pre-pregnancy AST ($p = 0.60$) were not associated with AST level during pregnancy. Furthermore, NAFLD ($p = 0.31$), pre-pregnancy ALT ($p = 0.70$), and the interaction between NAFLD and pre-pregnancy ALT ($p = 0.75$) were not associated with ALT level during pregnancy. In a subgroup analysis of patients with NAFLD, being at risk for advanced fibrosis (defined by having intermediate or high FIB4 or NAFLD and metabolic syndrome) was not associated with during pregnancy AST or ALT (AST $p = 0.71$, ALT $p = 0.50$). Of note, neither NAFLD ($p = 0.18$) nor its interaction with baseline transaminases predicated gestational diabetes ($p = 0.11$). **Conclusion:** Neither NAFLD nor its severity influenced the trends of transaminases during pregnancy. Changes in liver enzymes during pregnancy should not be attributed to NAFLD despite the pregnancy-related metabolic changes. Multi-center prospective studies are needed to validate our findings.

Table 1:

	NAFLD Subgroups			NAFLD vs. Control		
	At Risk (Mean, SD)	Not At Risk (Mean, SD)	P-value	NAFLD (Mean, SD)	Control (Mean, SD)	P- value
Pre-Pregnancy AST	48.0 (68.7)	26.0 (23.7)	0.127	30.7 (38.7)	22.1 (8.65)	0.02
Pre-Pregnancy ALT	45.3 (43.1)	32.1 (60.2)	0.221	34.9 (57.1)	19.3 (14.6)	0.005
During-Pregnancy AST	25.1 (7.07)	31.4 (61.2)	0.42	29.8 (52.9)	24.0 (9.50)	0.319
During-Pregnancy ALT	22.3 (14.5)	27.5 (41.9)	0.413	26.2 (36.8)	18.1 (9.32)	0.069
Difference between During-pregnancy and Pre-pregnancy AST	-13.0 (42.6)	7.00 (63.6)	0.102	1.87 (59.4)	3.03 (10.3)	0.86
Difference between During-pregnancy and Pre-pregnancy ALT	-18.3 (33.5)	-2.58 (68.6)	0.186	-6.66 (61.6)	0.509 (11.4)	0.322

2211-A | LIVER INDEXES AS A PREDICTOR OF ATRIAL FIBRILLATION AND STROKE IN TYPE 2 DIABETES MELLITUS: A POPULATION-BASED COHORT STUDY

Helen Huang, Royal College of Surgeons in Ireland, Oscar Hou In Chou, The University of Hong Kong, Jiandong Zhou, University of Oxford, Gary Tse, Tianjin Institute of Cardiology, Second Hospital of Tianjin Medical University; Kent and Medway Medical School, University of Kent and Canterbury Christ Church University; Hong Kong Metropolitan University and Cardiovascular Analytics Group (CVAG)

Background: The fibrosis-4 (FIB-4) index and the AST to platelet ratio index (APRI) were proposed to be non-invasive liver fibrosis indicator for screening and risk stratification of metabolic dysfunction associated fatty liver disease (MAFLD) amongst Type-2 diabetes mellitus (T2DM) patients. However, the predictive value of liver indexes on the development of atrial fibrillation and stroke in T2DM has not yet been addressed. **Methods:** The retrospective observational study in Hong Kong analyzed T2DM patients recruited from 1st January 2000 to 31st December 2003 and followed up until 31st December 2019. The primary outcome were new-onset atrial fibrillation (AF) and stroke, and mortlaity as secondary outcomes. We used univariate Cox proportional hazard models with Kaplan-Meier curves, as well as multivariate models adjusted demographics, past co-morbidities and medication. The optimal cut-offs were found with maximally selected rank statistics. **Results:** This cohort included 6,354 patient patients (male: 2,676, 41.0%; baseline age median: 67.16 [56.38 - 74.44] years; follow-up median: 16.67 [IQR: 10.63-18.05] years) with complete laboratory results. Univariate Cox regressions revealed significant associations of FIB-4 quartiles with all outcomes except for hemorrhagic stroke, while APRI quartiles were associated with all except for atrial fibrillation and transient ischemic stroke (Figure 1). Multivariable analyses identified quartile 3 for FIB-4 to be significantly associated with atrial fibrillation, ischemic and hemorrhagic stroke (all outcomes HR < 1.0, 95%CI: [< 1.0], $p < 0.05$). Quartile 3 for APRI were associated with ischemic stroke only (HR: 1.17, 95%CI: [1.02-1.37], $p = 0.02$). FIB-4 and APRI indexes at quartile 4 to be associated with an increased risk of all-cause mortality (FIB4 hazard ratio [HR]: 1.02, 95% confidence interval [CI]: [1.02 – 1.16], $p = 0.007$; APRI HR: 1.17, 95%

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

CI: [1.09 – 1.25], $p < 0.0001$). The results remained consistent in the sensitivity analysis. **Conclusion:** Liver fibrosis biomarkers FIB-4 and APRI predicted an increased risk of ischemic stroke and all-cause mortality amongst T2DM patients during a 16-year period, while FIB-4 independently predicted an increased risk in atrial fibrillation.

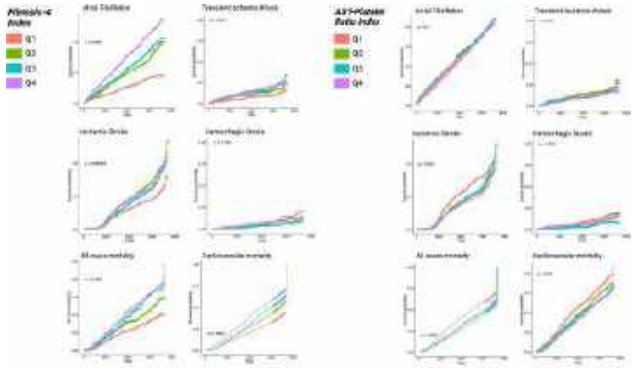

Figure 1. Univariate Kaplan Meier Curves demonstrated associations of quartiles with primary and secondary outcomes. Significance is achieved if the p-value is less than 0.05.

Background: Histologically assessed fibrosis in patients with non-alcoholic fatty liver disease (NAFLD) carries prognostic information. Here we aim to compare prognostic accuracy of histologically assessed fibrosis with liver stiffness measured by vibration-controlled transient elastography (LSM-VCTE), Agile 3+, Agile 4 and Fibroscan-AST (FAST) scores. **Methods:** This was an individual patient data meta-analysis of patients with NAFLD who had baseline biopsy, LSM-VCTE and blood parameters measured within 6 months. The primary outcome was a composite endpoint of all-cause mortality, decompensation of cirrhosis (ascites, variceal haemorrhage, hepatic encephalopathy), hepatocellular cancer, liver transplantation or progression to model of end stage liver disease score e 15. Prognostic accuracy for each non-invasive test (NIT) was compared to histology using time-dependent area under the curve (tAUC) analysis. Cumulative sensitivity and dynamic specificity are reported for a time horizon of 5 years for previously published thresholds for all index tests. **Results:** Data were available for 2,518 patients with biopsy proven NAFLD, of whom 135 (5.4%) were excluded due to unreliable LSM-VCTE values leaving 2383 in the final analysis (49% females, median age 54 (IQR 19) years, 42% with type II diabetes mellitus). The composite endpoint was seen in 5.3% (n = 127) after a median follow-up of 56 months. LSM based composite scores other than FAST showed a good and comparable tAUC to histology (Figure 1) and head-to-head pairwise comparison of LSM, Agile3 + and Agile4 against histology in all time frames show no statistically significant differences in predicting composite endpoints. For a time horizon of 5 years, the cumulative sensitivity (cSe) and dynamic specificity (dSp) were respectively 58% and 71%, and 44% and 90% for F3 and F4; 61% and 67%, and 36% and 91% for LSM-VCTE 10 kPa d LSM < 20 kPa, and LSM e 20 kP; 80% and 62%, and 71% and 73% for 0.451 d Agile3 + < 0.679, Agile3+ e 0.679; 55% and 83%, and 37% and 91% for 0.251 d Agile 4 < 0.565, Agile 4 e 0.565; and 91% and 37%, and 51% and 74% for 0.35 d FAST < 0.67, FAST e 0.67. **Conclusion:** Composite scores that include liver stiffness measurements (Agile 3 and Agile 4) have comparable prognostic accuracy to that of histologically assessed fibrosis and could be used for risk stratification in clinical practice. Assessing how change in composite scores over time impacts prognosis should be the focus of future studies.

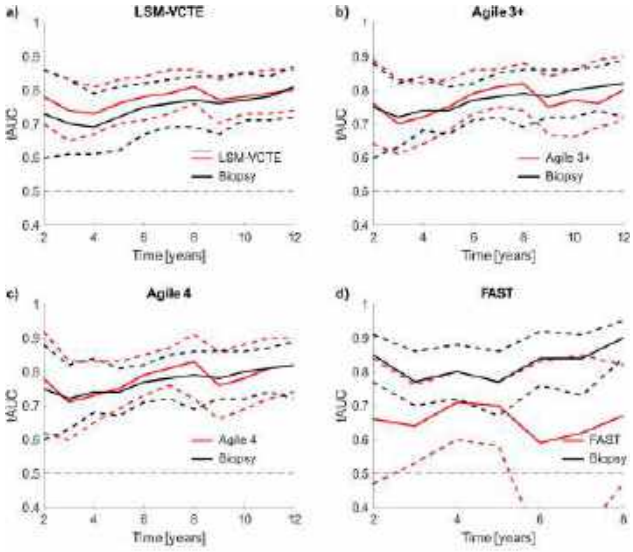

Figure 1 Time-dependent AUCs for LSM-VCTE (a), Agile 3+ (b), Agile 4 (c), and FAST (d) in head-to-head comparison with liver histology (in black). Dashed lines represent the 95% confidence intervals for all AUC estimates. Horizontal dashed lines represent an AUC of 0.5.

Background: There remains uncertainty about the natural history and prognosis of non-alcoholic fatty liver disease (NAFLD). We evaluated the transition between fibrosis stages in NAFLD patients with serial biopsies and related them to clinically relevant outcomes including hepatocellular carcinoma (HCC) and death. **Methods:** The study included patients enrolled in the European NAFLD Registry with e 2 biopsies taken > 240 days apart. Biopsies were scored by expert liver pathologists using the NASH CRN scoring system. Fibrosis progression rate was computed as the change in fibrosis stage over the time interval between the paired biopsies. The Kaplan-Meier method was employed to evaluate time to death and HCC diagnosis. The log-rank test was then used to compare the distributions. **Results:** We included 460 participants (59.3% male) that had undergone at least 2 liver biopsies of sufficient quality for evaluation. At baseline, age (mean ± SD) 51.9 ± 11.9; BMI 32.6 ± 5.3 kg/m^2. 51.5% had type 2 diabetes. 134 (29.1%) had NAFL and 326 (70.9%) NASH. The distribution of fibrosis stages was F0 67 (14.6%), F1 91 (19.8%), F2 129 (28.0%), F3 134 (29.1%), F4 39 (8.5%). The median interval between the paired biopsies was 4.75 years (range 0.7-23.8). Cases were followed for 0.7 to 29.8 years (mean/median of 8.3/6.3 yrs) from baseline and for up to 20 years from the second biopsy (mean/median of 3.6/1.8 yrs), providing > 3,819 person-years of follow-up for clinical outcomes. Fibrosis progressed in 138 patients (30%), mean interval 4.7 yrs/stage (ie 0.2 stages/yr); regressed in 128 (27.8%) patients, 2.4 yrs/stage (ie 0.4 stages/yr); and remained stable in 194 (42.2%) patients. Time to progress from F2 to F3: 6.7 ± 3.8 yrs, and from F3 to F4: 3.8 ± 2.0 yrs, suggesting fibrosis progression may accelerate as disease advances. Inter-stage change is summarised in Table 1. A total of 28 (6%) patients are known to have died at the time of the analysis. Seven (1.5% of cases, 25% of deaths) were liver-related. Ten (2.2%) patients had developed HCC during follow-up. Subsequent development of HCC was strongly associated with advanced fibrosis stages F3/4 at baseline (p-value < 0.0001). Survival probability was also lower in advanced fibrosis at baseline (p-value = 0.00049). **Conclusion:** Serial biopsy data from a European NAFLD cohort shows that 30% of patients exhibit fibrosis progression, whilst 27% exhibit regression over a mean interval of 4.8 years. Rates of change suggest that fibrogenesis progression may accelerate as disease becomes more advanced. As previously reported, cases with more advanced fibrosis exhibit worse survival. Further studies in larger cohorts with protocolised biopsies are warranted.

	Fibrosis stage (NASH CRN) at end of study

f 2214-A | LONG-TERM HEALTH CONSEQUENCES OF PEDIATRIC NONALCOHOLIC FATTY LIVER DISEASE

Jeffrey Schwimmer[1,2], Cynthia A. Behling[3], Sheila L Noon[1], Nhat Thai[1], Lauren F Chun[1], Rhys David[2], Nidhi P. Goyal[4], Warren L Shapiro[1,5], Andrew Wang[1], Elizabeth L. Yu[1] and Kimberly P Newton[1,2], (1)UC San Diego, (2)Rady Children's Hospital San Diego, (3) Pacific Rim Pathology, (4)University of California, San Diego, (5)Kaiser Permanente

Background: The incidence of nonalcoholic fatty liver disease (NAFLD) is on the rise in children, but the natural history and associated outcomes of this disease remain poorly understood. To fill this gap, we conducted a longitudinal cohort study investigating the

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

progression of NAFLD and its potential implications for health outcomes, including mortality and incident comorbidity. **Methods:** Our study included patients who were diagnosed with NAFLD as children between the ages of 2-18 years, from 2000 to 2017. We extracted data from electronic medical records, including laboratory tests, liver imaging, and liver histology reports. The diagnosis of NAFLD was based on imaging or liver biopsy showing hepatic steatosis in the absence of other causes of liver disease. Medical records were reviewed from the time of diagnosis of NAFLD to the most recent clinical encounter. Mortality was determined by examining the National Death Index. Surviving participants were invited to partake in a clinical research visit to evaluate their present health status and development of comorbid diagnoses. **Results:** We analyzed a cohort of 1605 children with NAFLD. The mean age at diagnosis was 12.7 ± 3.0 years, and 65.4% of participants were male. The mean duration of follow-up was 7.3 ± 4.2 years, accounting for a cumulative 11,717 person-years. Over this period, 3.8% (60/1605) of children with NAFLD died, with a mortality rate of 512 per 100,000 person-years (95% CI 394 - 655). The age and sex-adjusted standardized mortality ratio relative to the U.S. general population was 48.8 (95% CI 37.6-62.4). We found that older age at diagnosis (adjusted Hazard Ratio (aHR): 1.17, 95% CI: 1.04-1.31), male sex (aHR: 5.08, 95% CI: 1.85-13.91), and higher baseline gamma-glutamyl transferase (GGT) levels (aHR: 1.05, 95% CI: 1.02-1.08) were associated with increased mortality risk. Moreover, among those who died, 47% had liver-related mortality. At baseline, the prevalence of type 2 diabetes, hypertension, dyslipidemia, and obstructive sleep apnea were 4.9%, 8.5%, 21.8%, and 6.9%, respectively, with incidence rates of 879, 1878, 3949, and 1179 new cases per 100,000 person-years at risk. **Conclusion:** Our findings shed light on the natural history of pediatric NAFLD, revealing significant morbidity and mortality risks associated with the disease. The results underscore the need for increased awareness, early detection, and management of NAFLD in children to prevent the development of severe hepatic and extrahepatic comorbidities.

2215-A | MAFLD DIAGNOSTIC CRITERIA CAN EASILY IDENTIFY INDIVIDUALS WITH FATTY LIVER IN LEAN AND OVERWEIGHT INDIVIDUALS AMONG THE INDIAN POPULATION, EVEN WITHOUT HS-CRP

Anand V. Kulkarni[1], Sowmya T R[1], Pravalika Amike[1], Sathwika P[1], Hajera Fathima[2], Santhosh Cp Reddy[1], Shantan Venishetty[1], Manasa Alla[1], Mithun Sharma[3], Nageshwar D Reddy[1] and Padaki Nagaraja Rao[1], (1) Aig Hospitals, Hyderabad, India, (2)Joginpally B R Pharmacy College, (3)Asian Institute of Gastroenterology, Hyderabad, Telangana, India

Background: Metabolic (dysfunction)-associated fatty liver disease (MAFLD) criteria requires at least two metabolic risk abnormalities to be present in patients with lean individual's (Body mass index [BMI] < 25 kg/m^2 in Caucasians and < 23 kg/m^2 in Asians). These criteria also include high-sensitivity C-reactive protein (HS-CRP) and homeostatic model assessment for insulin resistance (HOMA-IR), which are not universally available. There is a paucity of data on the validity of this MAFLD criterion in the Indian population with a BMI < 25 kg/m^2, which we aimed to assess. **Methods:** Consecutive patients diagnosed with NAFLD based on ultrasonography and/or transient elastography attending the outpatient department over a period of 6 months were included prospectively. The primary objective was to assess the prevalence of non-obese NAFLD, and the secondary was to assess the proportion of patients satisfying at least two criteria of MAFLD among lean (Gr. A: BMI < 23 kg/m^2) and overweight individual's (Gr. B. BMI < 25 kg/m^2) for which data from previous studies were included from our centre. **Results:** Of the 301 patients diagnosed with NAFLD, 13.62% (41/301: 95%CI, 9.7-18.5%) were lean, and 17% (51/301; 95% CI, 12.6-22.3) were overweight individual's. Including data from other retrospective studies of non-obese patients, the total number of lean individual's was 95 (Gr. A), and overweight individual's were 63 (Gr. B). The mean age (44.6 vs. 43.9 y) and sex distribution (females: 18% vs. 19%) were similar among the two groups. The mean BMI was higher in Gr. B (23.91 ± 0.58 kg/m^2) than in Gr. A (21.58 ± 1.72 kg/

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

m^2; P < 0.001). Similarly, the mean waist circumference was higher in Gr. B (93.4 ± 4.5 cms) than in Gr. A (89.7 ± 6.72 cms; P < 0.001). The controlled attenuation parameter score (CAP) was lower in Gr. A (268 ± 45.24 dB/m) than Gr. B (295.37 ± 40.46 dB/m; P < 0.001). The liver stiffness measurement, FIB-4 and APRI score were similar among both groups. Similarly, the HDL, triglycerides, HbA1C and fasting blood sugar levels were similar among the two groups. None of the patients had HS-CRP reports available, and only 58 patients (40 among Gr. A and 18 among Gr. B) had HOMA-IR values. The proportion of patients satisfying at least two criteria of MAFLD was lower in Gr. A (87.4%) than in Gr. B (96.8%; P = 0.04) despite the absence of complete data. The proportion of patients satisfying three criteria (48.4% and 54%; P = 0.51), four criteria (21.1% vs. 23.8%; P = 0.7), five criteria (8.4% vs. 3.2%; P = 0.31) and six criteria (2.1% vs. 1.6%;P = 1) of MAFLD were similar among both groups. **Conclusion:** MAFLD diagnostic criteria can easily identify individual's with fatty liver in lean and overweight individual's among the Indian population, even without HS-CRP.

2216-A | MAFLD EXCLUDES LEAN FATTY LIVER DISEASE PATIENTS WITH SIMILAR METABOLIC PROFILES AND HEPATIC FIBROSIS COMPARED TO LEAN HEALTHY SUBJECTS

Ming Yang[1], Huixin Liu[2], Shunmin Guo[3], Pingqiu Shen[3], Ying Qiao[3], Wurong Chen[3], Yanqiu Gu[3], Rao Teng[3], Guiping Li[3], Jianzeng Qin[3], Xiaoran Yang[3], Zhi Qi[3], Yi Feng[3], Mengqi He[3], Zhe Liu[3], Wenyao He[3] and Lai Wei[1], (1)Hepatopancreatobiliary Center, Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, (2)Department of Clinical Epidemiology and Biostatistics, Peking University People's Hospital, (3)Meinian Onehealth Healthcare Holding Co., Ltd

Background: The prevalence and clinical characteristics data of lean metabolic dysfunction-associated fatty liver disease (MAFLD) are sparse. We aimed to investigate the clinical characteristics of lean MAFLD and the impact of new definition on the prevalence of fatty liver disease in the lean population. **Methods:** We consecutively enrolled 2,019 Chinese adults in 31 health check-up centers from 11 cities in 2022. A detailed questionnaire and the results of blood biochemical examinations and transient elastography were collected. **Results:** The prevalence of Lean MAFLD in the overall and MAFLD population was 3.3% (67 of 2,019) and 7.2% (67 of 925), respectively. Compared with non-lean MAFLD subjects, Lean MAFLD subjects were elder, more likely to be women, and to have lower proportion of metabolic syndrome, waist circumference, diastolic blood pressure, liver enzymes, HOMA-IR, AST-to-platelet ratio index, NAFLD fibrosis score, liver stiffness measurement, controlled attenuation parameter (CAP) but higher high-density lipoprotein cholesterol. The prevalence of MAFLD was lower than that of nonalcoholic fatty liver disease (NAFLD) in the lean population (9.25% vs. 16.30%, P < 0.05). Among 128 lean subjects with fatty liver, 59 fulfilled the diagnostic criteria for both lean MAFLD and lean NAFLD (lean MAFLD+NAFLD+), 59 lean MAFLD-NAFLD+, and 8 lean MAFLD+NAFLD-. The metabolic dysfunction and hepatic fibrosis in lean MAFLD-NAFLD+ subjects were comparable to those in lean healthy subjects. **Conclusion:** The new definition of MAFLD may reduce the prevalence of fatty liver disease in lean population but can exclude patients who have comparable metabolic profiles and hepatic fibrosis with lean healthy subjects.

Background: Nonalcoholic fatty liver disease (NAFLD) is a serious health problem due to its consequences. Clinical trials showed that GLP-1 receptor agonists (GLP-1RA) protect the heart in an array of patients with type 2 diabetes (T2D). However, the extent of these benefits in patients with NAFLD and T2D needs further investigation. Thus, we investigated the major adverse cardiovascular events (MACE) and mortality for patients with NAFLD and T2D taking GLP-1RA compared to other glucose-lowering drugs. **Methods:** This was a propensity score-matched, population-based cohort study with consecutive patients diagnosed with NAFLD and T2DM using the TriNeTx dataset. Cohort entry was defined as the date of the first-ever prescription for one of the drugs of interest (GLP-1 RA, sodium–glucose cotransporter-2 inhibitors [SGLT-2i] or other second/third-line drugs) during the study period. We used a lag of 6 months for all exposures to minimize protopathic bias. We performed a 1:1 propensity score matching (PSM) to reduce confounding effects. The primary outcomes were defined as the first incidence of new-onset heart failure (HF), composite MACE, and a composite of cerebrovascular disease, and the secondary outcome was mortality. We conducted a secondary analysis and sensitivity analysis to assess the robustness of our findings. The outcomes were estimated using a Cox proportional hazards model with hazard ratios (HR) and 95% confidence intervals (CI). **Results:** A total of 53249 new users of GLP-1RA were identified, and 39795 patients who received SGLT-2i were included in the control. For the secondary analysis, 2638687 were in second-or third line anti-diabetic treatment. The GLP-1RA group was non-inferior to the SGLT-2i group in terms of CV outcomes: the incidences of MACE (hazard ratio [HR], 1.06), HF (HR, 10.9), cerebrovascular diseases (HR, 0.99) were similar to SGLT-2i group (Table 1). Moreover, the mortality rates between the GLP-1RA were non-inferior to the SGLT-2i group (HR, 1.06). When compared to patients taking second-or third-line glucose-lowering drugs also, a significantly lower risk of MACE, HF, and mortality was observed (HRs 0.90). Sensitivity analysis showed a similar magnitude to the one generated in the primary and secondary analyses. **Conclusion:** In patients with NAFLD and T2D, initiators receiving GLP1-RA showed a significantly lower incidence of MACE and all-cause mortality rates. However, GLP1-RA was not inferior to SGLT-2i. These findings further suggest that GLP1-RA and SGLT-2i may provide additional protective effects against MACE.

Table 1. Cardiovascular outcomes between the Users of GLP-1RA vs. SGLT2 in patients with NAFLD and type 2 diabetes

Outcomes	GLP-1RA (N=38804), n	SGLT-2 (N=38804), n	HR (95% CI)
Primary outcome			
Heart failure	4572	4461	0.97 (0.93-1.01)
Cerebrovascular Diseases	3820	3611	0.99 (0.94-1.03)
MACE	2040	1979	0.95 (0.90-1.01)
Secondary outcome			
All-cause mortality	1248	1052	1.06 (0.97-1.15)

Abbreviations: GLP-1RA, glucagon-like peptide-1 receptor agonists; SGLT-2i, sodium–glucose cotransporter 2 inhibitor; MACE, major adverse cardiovascular events.
MACE as a composite endpoint was defined as the first occurrence of unstable angina, or myocardial infarction, and revascularization, including percutaneous coronary intervention or coronary artery bypass graft; a composite of cerebrovascular disease was defined as the first occurrence of stroke (ischemic or hemorrhagic stroke), cerebral infarction, transient ischemic attack, carotid intervention, or surgery.

2218-A | MANAGEMENT OF NONALCOHOLIC FATTY LIVER DISEASE IN A PRIMARY CARE SETTING

Julia R Gips[1], Lisa Yanek[1], Jiajun Wu[1], Tinsay A. Woreta[2], James P. Hamilton[2] and Jeanne M Clark[1], (1) Johns Hopkins University School of Medicine, (2)Johns Hopkins Medicine, Baltimore, MD

Background: The prevalence of nonalcoholic fatty liver disease (NAFLD) has grown exponentially in recent years. In many cases, primary care physicians (PCPs) are the first to suspect or diagnose NAFLD, often based on steatosis seen on abdominal imaging or elevated liver enzymes. While guidelines have been published detailing NAFLD management in the primary care setting, it is unclear what PCPs are doing in practice. **Methods:** For this retrospective cohort study, we used electronic health record (EHR) data from over 650,000 patients who had completed at least one PCP visit within a large Maryland medical network between July 2016 and March of 2023. Using ICD-10 codes, we extracted information including demographics, comorbidities, laboratory results, prescriptions, imaging orders, and referrals, on all patients who had a billed diagnosis of NAFLD or NASH during this time period. We then performed descriptive analyses within RStudio. **Results:** We identified 19,143 patients who had a diagnosis code of NAFLD (88.6%) and/or NASH (13.2%) at their PCP visit. Just over half (54.3%) were female, mean age was 55.2 years, and mean BMI was 31.1 kg/m^2. More than 50% of patients had hypertension and hyperlipidemia, and 35% had diabetes. Prior to diagnosis, 64% had an abdominal ultrasound, 41% an abdominal CT, and 12% an abdominal MRI. At the same visit as

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

the diagnosis, about 7% had ultrasound elastography ordered, 6% a liver biopsy, and less than 1% magnetic resonance elastography. During a mean follow-up time ranging from 0 to 7 years (mean 1.3 ± 1.8), patients had a mean of 11 visits (for any reason), during which 26% were identified as having fibrosis or cirrhosis. Only 19% overall were referred to a nutritionist and 11% had an appointment; 2.2% were referred to hepatology and 6% had an appointment. Less than 35% of patients had abdominal imaging ordered at any time after their first NAFLD visit. While nearly 80% of patients had overweight or obesity based on BMI, less than 15% were prescribed weight loss medication. **Conclusion:** Despite published recommendations on NAFLD management, PCPs are not following guidelines for risk stratification, referral to specialists, monitoring for fibrosis, or prescribing weight loss medication. As a result, care of patients with NAFLD, including a substantial minority with fibrosis or cirrhosis, may be suboptimal. Patients might benefit from targeted education of PCPs on the topic of NAFLD and improved support for its management in the primary care setting including better access to non-invasive fibrosis screening.

2219-A | MEASURES OF CARDIOMETABOLIC RISK AND ADVANCED FIBROSIS IN PRIMARY CARE PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE (NAFLD)

Andrew Schreiner, Medicine University of South Carolina

Background: Advanced fibrosis is the best predictor of future severe liver disease outcomes in patients with NAFLD. Though emerging evidence suggests significant roles for weight loss and diabetes avoidance may play roles in preventing advanced fibrosis, less is known about the relationship of other cardiometabolic risk factors with NAFLD progression to advanced fibrosis. In this study, we aimed to compare measures of cardiometabolic risk by progression to high-risk for advanced fibrosis in primary care patients with NAFLD. **Methods:** We performed a retrospective cohort study of primary care patients with NAFLD in a between 2012 and 2021. We evaluated patients with NAFLD and Fibrosis-4 Index (FIB-4) scores < 2.67 within 6 months of NAFLD ascertainment. Patients with preceding diagnoses of cirrhosis were excluded. Patients were followed from index FIB-4 until the outcome of a FIB-4 $\geq$ 2.67 or the end of the study period. Variables of interest were body mass index (BMI), systolic blood pressure (SBP), hemoglobin A1c (HgbA1c), triglycerides, low-density lipoprotein (LDL), thyroid stimulating hormone (TSH), estimated glomerular filtration rate (eGFR), and smoking status. Variables were treated as continuous variables and categorized by the threshold for primary care therapy intensification. Analyses were performed for the whole cohort and by the occurrence of a high-risk FIB-4 score. Chi square tests were used to compare categorical variables and two sample t-tests were used for continuous variables. **Results:** The cohort included 1,347 patients with a mean follow-up of 2.6 years (SD 2.5). Patients had a median of 9 (IQR 2-22) BMI and SBP values, 2 (IQR 1-4) HgbA1c values, and 4 (IQR 2-9) eGFR values. Of the cohort, 258 (19%) had a subsequent FIB-4 $\geq$ 2.67. A higher proportion of patients with a high-risk FIB-4 outcome had an eGFR < 59 ml/min (54% vs. 24%, $p < 0.001$), a TSH > 4.94 mIU/L (9% vs. 5%, $p = 0.043$), and were smokers (19% vs. 12%, $p = 0.005$), compared to patients without a FIB-4 > 2.67. A lower proportion of patients with FIB-4 $\geq$ 2.67 had a BMI $> 30 kg/m^2$ (61% vs. 70%, $p = 0.002$) compared to patients without a high-risk FIB-4. SBP, HgbA1c, and triglyceride values did not differ between patients by FIB-4 outcome. **Conclusion:** Nearly 1 in 5 primary care patients with NAFLD transitioned to a high-risk FIB-4 score during 2.6 years of follow-up, and reduced kidney function, thyroid dysfunction, and smoking were associated with a future high-risk for advanced fibrosis by FIB-4. Measures of cardiometabolic risk may offer primary care targets for NAFLD management to prevent future advanced fibrosis.

Table 1. Proportion of cohort patients with at least one uncontrolled cardiometabolic exposure and the patient-level mean exposure values during follow-up for the overall sample and by transition to high-risk FIB-4 outcome.

Categorical Measures				
		High-Risk FIB-4 (≥2.67)		
	Overall	Yes	No	p-value
Exposures, % (n)	n = 1,347	n = 258	n = 1,089

2220-A | MEDICATIONS FOR WEIGHT LOSS AND NASH: A NATIONAL SURVEY OF PROVIDER ATTITUDES, PRACTICES AND KNOWLEDGE

Gene Y. Im[1], Elizabeth Aby[2], Amon Asgharpour[3], Jonathan G. Stine[4], Jessica L. Mellinger[5] and Meena B. Bansal[1], (1)Icahn School of Medicine at Mount Sinai, (2) University of Minnesota, (3)Virginia Commonwealth University, (4)Pennsylvania State University, (5) University of Michigan Hospitals and Health Centers

Background: Weight loss is the cornerstone of treatment in nonalcoholic fatty liver disease (NAFLD), including nonalcoholic steatohepatitis (NASH). While there are currently nine FDA-approved medications for weight loss, they are often underutilized in patients with NAFLD/NASH. Our aim was to perform a national survey of provider attitudes, practices and knowledge regarding weight loss and medication use in patients with NAFLD. **Methods:** We conducted a national U.S. survey of hepatology and gastroenterology providers from 2/6/23 to 3/13/23. Surveys were sent to 747 providers with 304 complete responses (41%) from 44 states and the District of Columbia. Respondents were a diverse group (50% women, 55% White) of mostly early career (46% < 5 y out of training) hepatologists (74%) working in an academic medical center with a liver transplant program (86%). **Results:** A significant majority of providers (78%) see ≤ 5 patients with NAFLD per week, of whom < 25% are taking medications for weight loss or NASH. While nearly all (96%) respondents believed weight loss medications could benefit patients with NAFLD, 77% have never/rarely prescribed them due to low comfort (81%). Amongst prescribers, the glucagon-like peptide-1 receptor agonists (GLP-1RA) were preferred (66%) compared to < 5% each for other FDA-approved weight loss medications. (Figure 1) In contrast, 63% have prescribed medications for NASH in the past 12 months, most commonly vitamin E, GLP-1RA, and statins, with positive correlation to NASH patient volume ($p < 0.05$). (Figure 2) The top perceived barriers to prescribing weight loss medications were lack of training/unfamiliarity, cost, and side-effects. Dedicated obesity clinics were more common than for NASH (79% v 28%, $p < 0.05$). Most providers (87%) reported low formal obesity education during their training and nearly all (95%) agreed for its inclusion in GI/hepatology fellowship training. Only one-third of FDA-approved weight loss medications were correctly identified by > 50% of providers regardless of experience, demonstrating a knowledge gap. In contrast, 73% accurately recognized that there are no FDA-approved medications for NASH. Advanced practice providers, trainees and those with < 5 years of experience were more likely to incorrectly identify vitamin E, pioglitazone and semaglutide as FDA-approved medications for NASH ($p < 0.05$). **Conclusion:** This nationwide survey demonstrates that while off-label prescribing for NASH was common, there were low rates of weight loss medication prescribing due to low comfort from insufficient education despite strong beliefs that they can benefit patients with NAFLD.

2221-A | METABOLIC CONTROL WORSENS WITH INCREASING FIBROSIS STAGE IN PATIENTS WITH PRE-CIRRHOTIC NONALCOHOLIC STEATOHEPATITIS (NASH): COMBINED DATA FROM MULTIPLE THERAPEUTIC CLINICAL TRIALS INCLUDING MORE THAN 6,000 PATIENTS (WITH THE COLLABORATION OF NAIL-NIT CONSORTIUM)

Jörn M. Schattenberg[1], Julie Dubourg[2], Stephen A Harrison[3], Naim Alkhouri[4], Sophie Jeannin[2] and Mazen Noureddin[5], (1)University of Mainz, (2)Summit Clinical Research, San Antonio, TX, (3)Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom, (4)Arizona Liver Health, Phoenix, AZ, (5) Houston Research Institute, Houston, TX

Background: Metabolic comorbidities are well-established risk factors for nonalcoholic steatohepatitis (NASH) and liver fibrosis. Metabolic derangement has been hypothesized to independently contribute to the severity of NASH fibrosis stages. We aimed to describe patients' characteristics and liver histology across different group's metabolic comorbidities. **Methods:** We combined screening data from 7 non-cirrhotic therapeutic NASH trials. Patients were classified according to the 5-tier NASH CRN fibrosis stages (F0 to F4). Patients characteristics were described across fibrosis stages. **Results:** Out of the 6,558 patients, 2,271 with liver histology, clinical and laboratory data were included. The liver histology results and patients' characteristics in each group are shown in the Table. Across fibrosis stages, glycated hemoglobin (HbA1c) ($p < 0.001$) and fasting plasma glucose (FPG) ($p < 0.001$) increased from F1 to F3. Low density lipoprotein cholesterol (LDL) was lower in fibrosis stages F3-F4 compared to fibrosis stages F0 to F2. No trend was seen for other lipid parameters (high density lipoprotein HDL-cholesterol and triglycerides). In patients with cirrhosis, HbA1c and FPG were significantly lower. Uric Acid decreased consistently from F1 to F4. Waist and Hip circumferences increased from F1 to F3, but BMI was not significantly different between fibrosis stages. No effect was seen for CRP or Fibrinogen. Hispanic ethnicity tended to have earlier fibrosis stages compared to non-Hispanic populations. Similarly, males tended to have earlier fibrosis stages compared to females. **Conclusion:** Among the metabolic comorbidities, glycemic control worsens in patients with precirrhotic NASH with increasing fibrosis stages, while lipid panels and markers of inflammation are not different between fibrosis stages. Additional studies are needed to further confirm the independent association of HbA1c with NASH severity.

2222-A | METABOLIC DYSFUNCTION ASSOCIATED FATTY LIVER DISEASE AND ALCOHOL USE HAVE A SYNERGISTIC IMPACT ON SURVIVAL AMONG YOUNGER POPULATIONS

Jesse Pustjens[1], Laurens A. Van Kleef[1], Milan J. Sonneveld[2], Harry L. A. Janssen[3], Rob J. De Knegt[4] and Willem Pieter Brouwer[1], (1)Erasmus MC University Medical Center Rotterdam, (2)Erasmus University Medical Center, (3)Erasmus MC, University Medical Center Rotterdam, (4)Erasmus MC, University Medical Center

Background: It is currently unknown whether metabolic dysfunction associated fatty liver disease (MAFLD) with or without the use of alcohol equally impacts on survival across all ages. **Methods:** We studied the association between MAFLD, alcohol use, and the combination with all-cause mortality within the NHANES III cohort. Participants with missing values for classification of MAFLD, alcohol use and/or outcome were excluded. MAFLD was defined according to clinical practice guidelines. Alcohol use was defined as >10 gram or >20 gram daily for women and men, respectively. A total of 12.277 included participants were divided into equally sized age-groups: A) 20-29 ($n=3120$), B) 30-39 ($n=3034$), C) 40-59 ($n=3095$) and D) e 60 ($n=3028$) years. The association between MAFLD $\pm$ alcohol use with all-cause mortality was explored across the age groups through multivariable Cox regression analysis adjusted for sex, age, age^2, race, marital status, household income, and smoking. **Results:** Of 12.277 participants, 5.729 (47%) were male, MAFLD was detected in 3.816 (31%) and alcohol use in 1873 (13%). During a median follow-up of 23 years, 3.750 (31%) deaths occurred. Follow-up time was evenly distributed across age-groups, except for the oldest group. Combined presence of MAFLD and alcohol use showed an important synergistic detrimental effect in the younger population, which attenuated by increasing age category: for age-group A/B/C/D: adjusted Hazard Ratio (aHR) 2.34 (1.3-4.1), $p=0.003$, aHR 2.05 (1.3-3.2) $p=0.001$, aHR 1.35 (1.0-1.8) $p=0.049$ and aHR 1.24 (0.9-1.6) $p=0.053$, respectively (Table). In contrast to groups A/D, presence of MAFLD without alcohol was a significant factor impacting on survival for groups C/D (aHR 1.23 $p=0.015$ and aHR 1.22 $p<0.001$, respectively, Table). In groups C/D, alcohol use on top of MAFLD showed a clear additive effect. **Conclusion:** MAFLD and alcohol use show a synergistic detrimental effect on survival in younger populations, while this

synergistic effect attenuated into an additive effect with increasing age. These results further guide screening for at-risk liver disease in the younger, general population, and further support current practices advocating alcohol abstinence among patients with MAFLD.

2223-A | METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE AND ITS EFFECT ON CARDIOVASCULAR DISEASE RISK IN PATIENTS WITH HCV

Wesal Elgretli[1], Mohamed Shengir[1], Solomon Sasson[2], Luz Ramos Ballesteros[2], Philip Wong[3], Tianyan Chen[3], Marc Deschenes[2] and Giada Sebastiani[1,2], (1)Mcgill University, (2)Mcgill University Health Centre, (3) Department of Medicine, McGill University Health Centre, Montreal, QC, Canada

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) is a new definition of fatty liver disease that does not require the exclusion of secondary causes of hepatic steatosis (HS), such as viral hepatitis. The hepatitis C virus (HCV) is associated with HS and metabolic and cardiovascular dysregulation. Thus, the aim of our study was to determine the prevalence of MAFLD and significant liver fibrosis in HCV mono-infected patients and the frequency of cardiovascular disease (CVD) risk categories. **Methods:** This was a retrospective single-center study of HCV patients in the direct-acting antiviral era, in which HCV patients were evaluated for HS and liver fibrosis with liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) by transient elastography. MAFLD was diagnosed based on the presence of HS, defined as CAP 248 dB/m, plus one of the following metabolic conditions: overweight/obesity (BMI e 30 kg/m^2), type 2 diabetes, or evidence of metabolic dysregulation in lean individual's. According to these criteria, MAFLD was subclassified into three phenotypes.Significant liver fibrosis was defined as LSM e 8 kPa. Factors associated with MAFLD were identified via a multivariate logistic regression model. CVD risk was assessed using the 10-year atherosclerotic cardiovascular disease (ASCVD) risk estimator, and the prevalence of intermediate- and

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

high-risk categories were estimated since both are associated with more cardiovascular events. **Results:** We included 137 HCV mono-infected patients (mean age 59 years, 51% male, 27% with sustained virological response, SVR). The overall prevalence of MAFLD was 34%. Overweight/obesity was the predominant MAFLD phenotype, with a prevalence of 41%, followed by the diabetes phenotype at 31%. Significant liver fibrosis was more prevalent in those with MAFLD than in those without (see Figure, $p = 0.036$). The multivariate model adjusted for age, sex, infection with HCV genotype 3 revealed that those with SVR had an almost 90% lower risk of MAFLD than those without (adjusted odds ratio 0.11, 95% CI 0.02–0.65). Intermediate-high-risk ASCVD categories were more prevalent in the MAFLD group than in the no MAFLD group (see figure, 63 vs. 45%, $p = 0.047$). **Conclusion:** MAFLD is frequent among patients with hepatitis C. Nonetheless, achieving SVR significantly reduces its likelihood. MAFLD is associated with a higher prevalence of significant liver fibrosis and an intermediate-to-high CVD risk.

2224-A | METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE IS A SEXUAL DIMORPHIC DISEASE IN PEOPLE WITH HIV

Dana Kablawi[1], Thierry Fotsing Tadjo[1], Jovana Milic[2], Wesal Elgretli[3], Claudia Gioe[4], Bertrand Lebouché[1], Felice Cinque[1], Luz Ramos Ballesteros[1], Antonio Cascio[4], Giovanni Guaraldi[5], Giovanni Mazzola[6] and Giada Sebastiani[7], (1)Mcgill University Health Centre, (2) University of Modena and Reggio Emilia, Modena, Italy, (3)Mcgill University, Montreal, Canada, (4)University of Palermo, (5)Policlinico of Modena, Modena, Italy, (6) Sant'Elia Hospital, Caltanissetta, (7)Department of Medicine, McGill University Health Centre, Westmount, QC, Canada

Background: People with HIV (PWH) are at high risk for metabolic dysfunction-associated fatty liver disease (MAFLD). In the general population, sex differences exist in frequency and severity of MAFLD, with higher prevalence of MAFLD in men, but higher incidence of liver fibrosis in women. Less is known about sex differences in MAFLD and liver fibrosis in the setting of HIV infection. **Methods:** This was a multicenter cohort study of consecutive PWH who underwent screening for MAFLD and liver fibrosis by liver stiffness measurement (LSM) with associated controlled attenuation parameter (CAP). MAFLD was diagnosed as hepatic steatosis with a CAP $\geq$ 270 dB/m, plus any among type 2 diabetes, overweight (BMI > 25 Kg/m^2) or two other metabolic abnormalities. Significant liver fibrosis was diagnosed as LSM $\geq$ 8 kPa. Incidence of MAFLD and significant liver fibrosis was assessed through survival analysis. **Results:** 1359 PWH (25% females, 70% HIV mono-infected) were included. Prevalence of MAFLD at baseline was lower in women than men with HIV (17.7% vs. 24.3%, $p = 0.013$). Conversely, there was no difference in prevalence of liver fibrosis (10.7% vs. 13.4%) between women and men, but this was higher in women after menopause, at 28.5%. Women with MAFLD were more frequently of black ethnicity (48% vs. 14%, $p < 0.001$), had lower ALT (26.4 $\pm$20.4 vs. 33.4$\pm$22.5; $p = 0.035$), higher HDL cholesterol (1.46$\pm$0.57 vs. 1.11$\pm$0.33; $p < 0.001$), lower triglycerides (1.69$\pm$0.96 vs. 2.47$\pm$2.63; $p = 0.035$). 485 of these PWH

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

were followed for a median of 3.5 years. Incidence of MAFLD was similar between women and men with HIV. However, incidence of liver fibrosis was higher in women (7.0 per 100 person-years [PY] vs. 5.9 per 100 PY; p = 0.035) (Figure 1). Sex hormones analysis demonstrated higher FSH (41.5 vs 33.8 mIU/mL) and LH (21.4 vs 17.5 IU/L) in women with HIV and liver fibrosis than those without fibrosis. They were also more likely to have prior Tamoxifen exposure (3% vs 0.7%). On multivariable Cox regression, MAFLD (adjusted hazard ratio [aHR] 3.3, 95% CI 2.0-5.6) and female sex (aHR 2.2, 95% CI 1.3-3.5) were independent predictors of developing significant liver fibrosis. **Conclusion:** MAFLD presents with sex differences in PWH. Despite lower rates of MAFLD, women with HIV have higher incidence of significant liver fibrosis than men, especially after the age of 50 and after menopause. Future studies should target adequate consideration of sex differences in the clinical investigation of MAFLD to implement precision medicine for PWH.

2225-A | METABOLIC DYSFUNCTION–ASSOCIATED FATTY LIVER DISEASE IS ASSOCIATED WITH INCREASED RISK OF LIVER-RELATED COMPLICATIONS: A NATIONWIDE COHORT STUDY

Hyunjae Shin[1], Min Kyung Park[2], Hye-Sung Moon[3], Sung Won Chung[4], Yunmi Ko[2], Youngsu Park[2], Jeayeon Park[2], Moon Haeng Hur[1], Yun Bin Lee[1], Eun Ju Cho[2], Jeong-Hoon Lee[5], Su Jong Yu[2], Jung-Hwan Yoon[2] and Yoon Jun Kim[6], (1)Seoul National University Hospital, (2)Seoul National University College of Medicine, (3)Rexsoft, (4)Asan Medical Center, Seoul, Korea, Republic of (South), (5)Seoul National University College of Medicine, Seoul, South Korea, (6) Department of Internal Medicine and Liver Research Institute, Seoul National University College of Medicine, Seoul, South Korea

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD), a new definition encompassing the fatty liver disease associated with metabolic disorders, has been recently proposed. We aimed to analyze the long-term outcome of MAFLD, by focusing on liver-related outcomes. **Methods:** We conducted an analysis using data from the National Health Insurance Service of South Korea, which included 7,454,412 participants who took part in the 2009 health screening program. MAFLD was defined by an international expert consensus statement previously proposed. Based on this definition, participants were categorized into four groups: non-MAFLD, DM-MAFLD, overweight/obese-MAFLD, and lean-MAFLD. The primary outcome was the development of liver-related complications, including hepatocellular carcinoma, liver transplantation, decompensated liver cirrhosis, and liver-related mortal-

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

ity. We also examined cirrhosis and hepatocellular carcinoma risks in various MAFLD subgroups using the UK Biobank (UKB) dataset as a validation cohort. The UKB dataset included 466,162 individual's of Caucasian ethnicity. **Results:** Of the study subjects, 2,500,080 (33.5%) had MAFLD. During the median follow-up of 10.3 years, 20,843 patients (0.28%) developed liver-related complications. The MAFLD group had a higher overall risk of liver-related complications than the non-MAFLD group (adjusted cause-specific hazard ratio [aCHR] = 1.24; 95% confidence interval [CI] = 1.21–1.28; $P < 0.001$). The DM-MAFLD group showed a significantly higher risk of liver-related complications compared to the non-MAFLD group (aCHR = 1.82; 95% CI = 1.74–1.91; $P < 0.001$), followed by the lean-MAFLD group (aCHR = 1.22; 95% CI = 1.12–1.33; $P < 0.001$), and the overweight/obese-MAFLD group (aCHR = 1.13; 95% CI = 1.09–1.33; $P < 0.001$). Subgroup analysis and sensitivity analyses using Fine-Gray models and various definitions of MAFLD showed similar trends of the primary result of our study. In the UKB cohort, the DM-MAFLD group also had a higher risk of developing cirrhosis (aHR = 4.21; 95% CI = 3.43–5.16; $P < 0.001$) and hepatocellular carcinoma (aHR = 5.52; 95% CI = 3.40–8.95; $P < 0.001$) than the non-MAFLD group. **Conclusion:** Our study demonstrated a consistent association between MAFLD and the development of liver-related complications, in both our nationwide cohort analysis and among individual's of Caucasian ethnicity. Different subgroups of MAFLD had varying risks of complications, with the DM-MAFLD group showing the highest risk. Stratifying MAFLD patients based on specific criteria representing metabolic disorders may aid in identifying those at a higher risk of liver-related complications. This approach could prove beneficial for screening and surveillance, facilitating early intervention and improved management for patients at an increased risk of liver-related complications.

Sterling[10], Susanna Naggie[11], Rohit Loomba[12], Jennifer C. Price[13], Mary McLaughlin[14], Colleen Hadigan[14], Holly Crandall[2], Patricia Belt[15], Laura Wilson[15] and David E Kleiner[16], (1)Cleveland Clinic, (2)Indiana University, (3)Johns Hopkins University, (4)Pacific Rim Pathology, (5)Saint Louis University, (6)University of California San Francisco, (7)Duke University, (8)University of Washington, (9)Indiana University Medical Center, Indianapolis, IN, (10)Virginia Commonwealth University Health System, (11)Duke Clinical Research Institute, Durham, NC, (12)University of California, San Diego, San Diego, CA, (13)University of California, San Francisco, (14)National Institute of Allergy and Infectious Disease (NIAID), (15)Johns Hopkins School of Public Health, (16)Laboratory of Pathology, National Cancer Institute, Bethesda, MD

Background: People with HIV (PWH) are at risk for acute and chronic liver injury including alcohol and metabolic disorders. The morphologic spectrum of non-alcoholic fatty liver disease (NAFLD) and utility of NAFLD activity score (NAS) in predicting fibrosis in PWH remains unknown. In this study, we compared liver histological features of NAFLD in individual's with and without HIV. **Methods:** Two ongoing NIDDK funded observational studies had 123 liver biopsies from PWH with NAFLD (NAFLD-PWH) and 3244 liver biopsies from individual's with NAFLD without HIV. From these datasets, we selected 107 NAFLD-PWH biopsies with 107 age, sex, race/ethnicity, BMI and ALT matched controls (i.e. individual's with NAFLD without HIV). Case and control liver biopsies were centrally read using the NASH CRN histological scoring system. **Results:** NAFLD-PWH were comparable to the control group on age (49 vs 47 y), sex (79% male), race (White 65% vs 61% and African American 13%), ethnicity (Hispanic/Latino 26%), diagnosis of type 2 diabetes (24%), and mean BMI (31 kg/m^2). Compared to the control group, NAFLD-PWH had lower steatosis grade (grades 1 or 2 in 63% cases vs 47% controls, $p = 0.01$), lower inflammation grade (grades 1 or 2 in 70% cases vs 60% controls, $p = 0.03$), less hepatocyte ballooning (cases: 61% had none, 15% had many versus controls: 45% had none and 27% had many,

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

p = 0.03) and less portal inflammation (8% had more than mild versus 21% of controls). As a result, NAS was lower in NAFLD-PWH (3.17 ± 1.6 vs 3.97 ± 1.59 controls, p < 0.001). There was a trend towards lower steatohepatitis in NALFD -PWH (61%) vs controls (71%, p = 0.09). Conditional multiple logistic regression (Table 1) demonstrated that steatosis (p = 0.02), portal inflammation (p = 0.001) and ballooning (p = 0.01) are less associated with NAFLD-PWH than controls while fibrosis was more associated with NAFLD-PWH than controls (p = 0.03). **Conclusion:** The NAS and histologic drivers of fibrosis (e.g., inflammation and hepatocyte ballooning) are less pronounced in NAFLD-PWH and yet fibrosis stage was generally higher when compared to matched controls with NAFLD but no HIV. This may suggest HIV-specific factors beyond hepatic necroinflammation may contribute to fibrosis in NAFLD-PWH.

Table 1: Conditional logistic regression of NAFLD-PWH versus NAFLD in individuals without HIV on histologic features

	NAFLD-PWH vs. NAFLD in individuals without HIV		
	Odds ratio	95% CI	P
Steatosis grade (0-3)	0.66	(0.46, 0.95)	0.03
Portal chronic inflammation score (0-2)	0.34	(0.18, 0.65)	0.001
Ballooning score (0-2)	0.55	(0.34, 0.88)	0.01
Fibrosis stage (0-4)	1.42	(1.03, 1.97)	0.03

2227-A | NAFLD INCREASES THE RISK OF MACE AND REDUCES DISABILITY-FREE SURVIVAL IN OLDER AUSTRALIANS BUT IS NOT AMELIORATED BY ASPIRIN: DATA FROM THE ASPIRIN IN REDUCING EVENTS IN THE ELDERLY (ASPREE) RANDOMISED TRIAL

Daniel Clayton-Chubb[1,2,3], Stuart Keith Roberts[1], Cammie Tran[2], Ammar Majeed[1], Robyn L Woods[2], John Lubel[1], Alexander D. Hodge[3], Hans Schneider[1], John J McNeil[2] and William W. Kemp[1], (1)Alfred Health, (2)Monash University, (3)Eastern Health

Background: Non-alcoholic fatty liver disease (NAFLD) is a significant global health challenge. However, there are limited data on the impact of NAFLD on outcomes in older persons despite a projected doubling of the number of older persons by 2050. Additionally, while some studies suggest NAFLD may increase the risk of major adverse cardiovascular events (MACE) independently of other risk factors, aspirin as primary prevention has not been evaluated. We aimed to assess the impact of NAFLD on MACE and disability-free survival (survival without dementia or persistent physical disability) in community-dwelling older Australians and whether 100mg aspirin ameliorated those risks. **Methods:** We included participants from the ASPREE randomised-controlled trial that enrolled 16,703 community-dwelling Australians aged 70+ years without independence-limiting physical disability, dementia, or cardiovascular disease. Baseline anthropometry, biochemical, and questionnaire data were collected. NAFLD was defined as a Fatty Liver Index (FLI) e 60 in the absence of excess alcohol intake (>14 units/week in women, >21 units/week in men) or steatogenic medications. A FLI of <30 was used as a no-NAFLD comparator. **Results:** 5,967 participants were evaluated (2,970 [49.8%] no-NAFLD vs 2,997 [50.2%] NAFLD, age 75.0 $\pm$ 4.2, 58.9% women). The NAFLD cohort was younger (74.7 $\pm$ 3.9 vs 75.3 $\pm$ 4.4 years, $p<0.001$), heavier (BMI 32.0 $\pm$ 4.0 vs 23.9 $\pm$ 2.4 kg/m^2, $p<0.001$), and had increased rates of

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

metabolic comorbidities (including the metabolic syndrome [70.9% vs 12.5%, $p < 0.001$], diabetes [17.8% vs 4.5%, $p < 0.001$], hypertension [82.6% vs 69.6%, $p < 0.001$], and chronic kidney disease [30.3% vs 22.3%, $p < 0.001$]). When adjusting for age, gender, and baseline diabetes, NAFLD had an increased hazard of MACE (HR 1.39, $p = 0.01$) (Figure 1A) and reduced disability-free survival (HR 1.19, $p = 0.02$) (Figure 1B). When stratifying the NAFLD cohort by aspirin vs placebo (with no significant baseline differences between NAFLD-aspirin and NAFLD-placebo), there was no benefit of aspirin in reducing these risks in NAFLD subjects (Figure 1C-D) (both $p > 0.05$). **Conclusion:** Our data indicate that the presence of NAFLD is associated with an increased risk of MACE and reduced disability-free survival in older Australian adults, but this risk is not ameliorated by aspirin. This has implications for risk stratification and clinical relevance for the futility of aspirin as a primary prevention strategy in this population.

2228-A | NAFLD IS INDEPENDENTLY ASSOCIATED WITH LOWER SERUM TESTOSTERONE IN OLDER AUSTRALIAN MALES: DATA FROM THE ASPIRIN IN REDUCING EVENTS IN THE ELDERLY (ASPREE) RANDOMIZED TRIAL

Daniel Clayton-Chubb[1,2,3], Cammie Tran[3], Bu B Yeap[4], Robyn L Woods[3], William W. Kemp[1], John Lubel[1], Ammar Majeed[1], Hans Schneider[1], Alexander D. Hodge[2], John J McNeil[3] and Stuart Keith Roberts[1], (1) Alfred Health, (2)Eastern Health, (3)Monash University, (4)University of Western Australia

Background: Lower serum total testosterone (TT) concentrations are associated with increased risks of frailty, stroke, and all-cause mortality in older males, as well as poorer quality of life. Conversely, exogenous testosterone replacement in men with androgen deficiency due to pituitary or testicular disease improves body composition, bone density, and sexual function. Central adiposity is associated with both non-alcoholic fatty liver disease (NAFLD) and lower TT, raising the question of whether NAFLD and lower TT are directly or bidirectionally related. We aimed to assess the associations of lower TT with NAFLD and other health outcomes in a large cohort of community-dwelling older Australian males. **Methods:** We included participants from the ASPREE trial that enrolled 7524 male Australian participants aged e 70 years without independence-limiting physical disability, dementia, or cardiovascular disease. Anthropometry, biochemical, and questionnaire data were collected at baseline. NAFLD was defined as a Fatty Liver Index (FLI) e 60 without excess alcohol intake (> 21 units/week) or steatogenic medications. FLI of < 30 was used to define a no-NAFLD comparator group. Lower TT was defined as the lowest quartile of the ASPREE population (< 12.3 nmol/L) (Q1TT). We excluded those on hormonal modulators or a prostate cancer history. Associations were assessed using Poisson regression with robust variance. **Results:** 4713 participants (mean testosterone 16.6 ± 6.5 nmol/L, age 75.0 ± 4.2 y) were evaluated, with 2090 classified as NAFLD (1300, 62.2%) vs no-NAFLD (790, 37.8%). Comparing those with Q1TT to those without (TT 9.6 ± 2.3 vs 19.0 ± 5.6 nmol/L), those with Q1TT had higher rates of NAFLD (82.7% vs 54.7%, $p < 0.001$) and diabetes (20.8% vs 10.7%, $p < 0.001$), were heavier (BMI 29.4 ± 4.1 vs 27.4 ± 3.6 kg/m^2, $p < 0.001$), and were more likely to be pre-frail/frail (52.1% vs 36.3%, $p < 0.001$). The Q1TT group was slightly younger (74.8 ± 4.2 vs 75.1 ± 4.2 y, $p = 0.029$). Men with Q1TT were more likely to have NAFLD (Relative Risk [RR] 1.99, $p < 0.001$), diabetes (RR 1.38, $p = 0.002$), pre-frailty (RR 1.28, $p = 0.013$), and frailty (RR 1.62, $p = 0.007$) (Figure). BMI was weakly associated with Q1TT (RR 1.03, $p = 0.035$) but age was not ($p > 0.05$). **Conclusion:** In older Australian men, lower TT is associated with a greater risk of having NAFLD, diabetes, and frailty. Whether these associations are causal, and the scope for intervention to improve health of older men with NAFLD, merit further evaluation.

2229-A | NAFLD, BODY AND MUSCLE COMPOSITION PROFILE IN PATIENTS WITH T2D IN PRIMARY CARE – INTERIM RESULTS FROM THE EPSONIP STUDY

Wile Balkhed[1], Mikael Fredrik Forsgren[2], Patrik Nasr[3], Martin Bergram[3], Fredrik Iredahl[3], Karin Rådholm[3], Carl-Johan Carlhäll[3], Nils Dahlström[3], Peter Lundberg[3], Stergios Kechagias[4], Olof Dahlqvist Leinhard[2] and Mattias Ekstedt[4], (1)Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden, Solna, Sweden, (2)Amra Medical, (3) Linköping University, (4)Department of Health, Medicine and Caring Sciences, Linköping University, Linköping, Sweden

Background: Sarcopenia is common in patients with advanced liver disease but associations between sarcopenia and early-stage liver disease have not been established. Most NAFLD studies include selected patients from specialist care. We aimed to investigate the prevalence of NAFLD and sarcopenia as well as myosteatosis in primary care patients with type 2 diabetes (T2D) utilizing magnetic resonance imaging (MRI). **Methods:** Patients with T2D, without previous liver disease, were prospectively included from primary care. All participants underwent transient elastography (TE), neck-to-knee MRI, including liver proton density fat fraction (PDFF), quantification of visceral and abdominal subcutaneous adipose tissue (VAT and ASAT) and muscle composition (MC) assessment (thigh muscle fat infiltration [MFI] and fat-free muscle volume z-score [MVZ]) using AMRA® Researcher. MC phenotypes were defined as either only high MFI (myosteatosis), only low MVZ (low muscle volume), adverse MC ([AMC] *i.e.,* high MFI and low MVZ combined), or normal MC. **Results:** The first 151 participants with complete data were studied. Comparing participants with normal MC to those with only high MFI or only low MVZ, there was no difference in age (62 ± 7.9, 65 ± 6.4 and 65 ± 7.3 yrs respectively). There were 37%, 43% and 14% women respectively and women less frequently had only low MVZ compared to men, $p = 0.048$. Participants with only high MFI compared to only low MVZ had a greater mean BMI (30.3 ± 3.4 *vs* 26.8 ± 4.5 kg/m^2, $p = 0.002$), waist circumference (106.6 ± 7.6 *vs* 98.6 ± 10.6 cm,$p = 0.006$), higher VAT (6.83 ± 2.53 *vs* 5.08 ± 2.12 L, $p = 0.029$) and ASAT (8.78 ± 2.99 *vs* 7.20 ± 3.92 L, $p = 0.036$) (Figure 1). Comparing participants with AMC to all other participants, there was no sex difference (15% *vs* 34% women, $p = 0.083$). However, those with AMC were older (69.4 ± 4.3 *vs* 63.3 ± 7.5 yrs, $p = < 0.001$), had a greater waist circumference (111.1 ± 12.1 *vs* 103.6 ± 10.5 cm, $p = 0.004$), higher VAT (7.96 ± 2.37 *vs* 5.99 ± 2.44 L, $p = 0.002$), HbA1c (57.8 ± 12.1 *vs* 51.2 ± 10.5 mmol/mol, $p = 0.009$), as well as a higher frequency of FIB-4 > 1.35 (75% *vs* 52%, $p = 0.046$). TE > 8 kPa was observed in 11% of participants with no difference in MC phenotypes. Of participants, 90 (60%) had NAFLD (*i.e.,* PDFF e 5 %). There were no differences in prevalence of MC phenotypes between NAFLD and non-NAFLD participants ($p = 0.284$). In those with NAFLD, only high MFI, only low MVZ and AMC was observed in 18 (20%), 10 (11%) and 15 (17%), respectively. In non-NAFLD participants, only high MFI, only low MVZ and AMC was observed in 12 (13%), 12 (13%) and 5 (8%), respectively. **Conclusion:** In this cohort of primary care patients with T2D, AMC was more common with concurrent NAFLD, but there were overall no significant differences observed in MC between groups. Participants with low MVZ alone were leaner than those with high MFI alone, while participants with AMC were the most metabolically burdened. Patients with AMC had a higher frequency of elevated FIB-4.

Background: Previous studies have shown that the presence of non-alcoholic steatohepatitis (NASH) and fibrosis stage carry prognostic information in patients with NAFLD. Here we aimed to assess whether grading with the NAFLD activity score (NAS) had any additional prognostic value to fibrosis stage. **Methods:** We conducted an individual participant data meta-analysis of patients with NAFLD who had baseline biopsy. NASH is defined as NAFLD activity score e 4 with score of at least 1 for steatosis, lobular inflammation, and ballooning. The primary outcome was a composite endpoint of all-cause mortality, decompensation of cirrhosis (ascites, variceal haemorrhage, hepatic encephalopathy), hepatocellular carcinoma, liver transplantation or progression to a model of end stage liver disease score e 15. Study-specific cumulative hazard functions and derived aggregated survival curves were built for F0-1, F2-3 and F4. Within each grouping we further divided cases into those without NASH, and those with NASH and NAS < 6 or NAS e 6. Survival curves were compared using a study-stratified log-rank test. **Results:** Data from 29 studies and 2,518 patients with biopsy proven NAFLD were included in the analysis (45% females, median age 54 (IQR 19) years, 46% with type II diabetes mellitus) 48% participants had NASH. The primary outcome was reached in 5.8% (n = 145) after a median follow-up of 58 months. In patients without cirrhosis, the presence and severity of NASH did not have any impact on developing the composite end point during follow-up of NASH (p = 0.43 for F0-1, Figure 1a; p = 0.95 for F2-3, Figure 1b). In patients with cirrhosis the survival curves appeared to diverge, but the differences between NAS categories did not reach significance probably due to small numbers (p = 0.054, Figure 1c). **Conclusion:** The NAS score remains useful for the diagnosis of NASH but based on our data carries no prognostic information in non-cirrhotic NAFLD. In NAFLD cirrhosis, conclusions are limited by relatively small numbers.

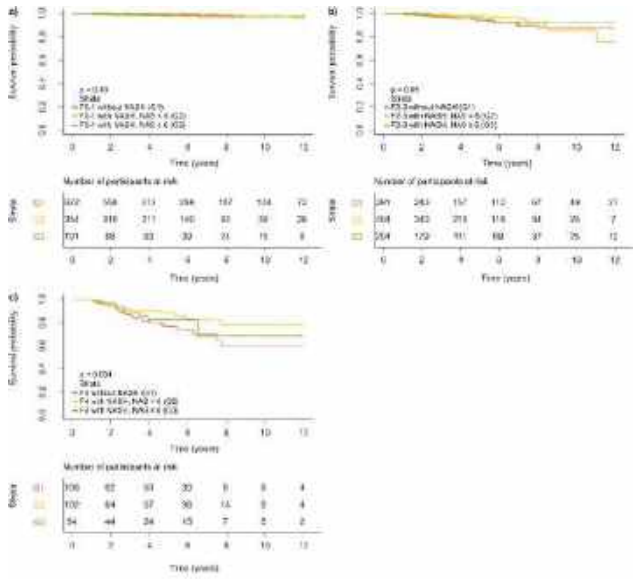

Figure 1 Estimates of survival probability in patients without NASH and with NASH stratified by their NAFLD activity score. P-value corresponds to the outcome of the study-stratified log-rank test.

2231-A | NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD) AND HEPATITIS B VIRUS (HBV) INTERPLAY: THEIR ROLE IN LIVER DISEASE DEVELOPMENT

Ploutarchos Pastras, Stavros Kanaloupitis, Ioanna Aggeletopoulou, Aspasia Antonopoulou, Efthymios Tsounis, Maria Kalafateli, Vasileios Issaris, Anna Boulouta, Konstantinos Papantoniou, Dimosthenis Drakopoulos, Evangelos Zazas, Eleni-Eirini-Konstantina Kottaridou, Georgia Diamantopoulou, Aggeliki Tsintoni, Konstantinos Thomopoulos and Christos Triantos, University Hospital of Patras

Background: Hepatitis B virus (HBV) infection is associated with lower risk of non-alcoholic fatty liver disease (NAFLD) in the absence of concurrent metabolic disorder. The aim of this retrospective case-control study is to evaluate the HBV infection impact on NAFLD patients, the clinical/laboratory characteristics of NAFLD-HBV patients and the NAFLD-HBV coexistence relation with the liver disease development. **Methods:** The medical charts of 575 NAFLD patients referred to outpatients' clinic due to abnormal liver biochemistry and/or presence of fatty liver were thoroughly reviewed. Fifty-seven patients were excluded because of other chronic liver diseases. Finally, 518 patients were included; 402 NAFLD and 116 NAFLD-HBV patients. Categorical data were compared using Pearson's chi-squared test or two-sided Fisher's exact test, when applicable. Mann-Whitney U test was used to compare differences between two independent groups. Binary logistic regression was performed to assess the risk factors associated with liver disease progression. **Results:** NAFLD-HBV patients had significantly lower levels of γ-GT ($p < 0.001$), and platelets ($p = 0.041$), and higher levels of ALP ($p = 0.023$) and INR ($p = 0.028$) compared to NAFLD patients. Moreover, a significantly lower percentage of NAFLD-HBV patients were overweight or obese compared to pure NAFLD patients ($p = 0.007$). Patients with NAFLD-HBV admitted to hospital more often than NAFLD patients ($p = 0.004$), but no difference was documented in mortality rates between the examined groups ($p = 0.999$). Multivariate analysis was used to explore the factors associated with liver disease development; HBV coexistence (aOR = 3.509, 95%CI: 1.201-10.254, $p = 0.022$), diabetes mellitus (aOR = 3.375, 95%CI: 1.176-9.683, $p = 0.024$), platelet count (aOR = 0.976, 95%CI: 0.965-0.987, $p < 0.001$) and total bilirubin (aOR = 1.785, 95% CI: 1.145-2.781, $p = 0.01$) were demonstrated as independent prognostic factors. **Conclusion:** NAFLD-HBV comorbidity was associated with reduced body weight, increased risk of hospital admissions and end-stage liver disease development. NAFLD-HBV coexistence constituted an independent risk factor for liver disease development. Active treatment for both disorders should be recommended.

Disclosure information not available at the time of publication: Ploutarchos Pastras, Stavros Kanaloupitis, Ioanna Aggeletopoulou, Aspasia Antonopoulou, Efthymios Tsounis, Maria Kalafateli, Vasileios Issaris, Anna Boulouta, Konstantinos Papantoniou, Dimosthenis Drakopoulos, Evangelos Zazas, Eleni-Eirini-Konstantina Kottaridou, Georgia Diamantopoulou, Aggeliki Tsintoni, Konstantinos Thomopoulos

2232-A | NONALCOHOLIC FATTY LIVER DISEASE (NAFLD): PREVALENCE, LIFESTYLE FACTORS, AND HEALTHCARE UTILIZATION AMONG HISPANIC AND NON-HISPANIC WHITE RESIDENTS IN US

Pankil Shah, Uthealth San Antonio, Mazen Noureddin, Houston Research Institute, Houston, TX, Naim Alkhouri, Arizona Liver Health, Phoenix, AZ and Naim et al.

Background: Nonalcoholic fatty liver disease (NAFLD) is a silent epidemic in U.S. with a disproportionately higher burden and worse outcomes in Hispanic population. Large-scale population-based analyses of association between *demographic, socioeconomic, and lifestyle factors* with NAFLD, stratified by Hispanic ethnicity, are lacking. **Methods:** This cross-sectional study used vibration controlled transient elastography (VCTE) data from the National Health and Nutrition Examination Survey (NHANES) 2017-2018 to examine the prevalence and disease severity of NAFLD in Hispanic and Non-Hispanic white (NHW) residents of U.S. Adjusted odds ratios and 95% confidence intervals for demographic, socioeconomic, comorbidity, and lifestyle factors associated with NAFLD were estimated from a multivariable logistic regression model. We also examined education, awareness, and healthcare utilization by Hispanic and NHW individual's with NAFLD. **Results:** A total of 2229 Hispanic and NHW participants met the inclusion criteria. The weighted analytic subset represented a population that was 79% for NHW and 21% for Hispanic, with a mean (standard error [se]) age of 48.9 (0.9) years and 51.9% women. The prevalence of NAFLD was significantly higher in Hispanic individual's (64.1% and 32.3%) compared to the NHW individual's (55.3% and 27.0%) based on the controlled attenuation parameter cutoff of 248 dB/m and 302 dB/m, respectively. After adjusting for other covariates, odds of NAFLD were significantly higher for Hispanic individual's compared to NHW (adjusted odds ratio [aOR]: 1.55, 95% CI: 1.15 – 2.10). Older age (aOR, 95% CI for every 10-year age interval: 1.30, 1.21 – 1.39), male sex (1.55, 1.14 - 2.11), less than college

education (1.54, 1.05 - 2.26), shorter duration of sleep per hour (1.12, 1.01 - 1.24), intake higher than estimated energy requirement per 100 kcals/day (1.02, 1.002 - 1.03), prediabetes (2.70, 1.77 - 4.13) and diabetes (6.31, 3.28 - 12.1) were significantly associated with NAFLD. Despite this high prevalence, only 5.1% of Hispanic and 2.5% of NHW patients with NAFLD reported being informed about having a fatty liver disease and majority patients reported having good or excellent health status. Half of the patients with NAFLD reported not having visited their healthcare provider in more than two years (Hispanic: 54.7% vs. NHW: 46,7%). **Conclusion:** A large proportion of U.S. adults have NAFLD, with significantly higher prevalence in Hispanic individual's than in NHW individual's. Individual and societal interventions to change an interconnected grid of modifiable factors (e.g., higher education, better work schedule, longer and better sleep, healthy diet, healthcare access, physician/patient ratio and communication, education/awareness campaigns and weight loss programs) are urgently needed to reduce the burden of NAFLD and its downstream consequences in U.S. residents, especially in vulnerable minority groups.

Table: Regression Analysis for Factors associated with NAFLD (based on CAP (> 248 dB/m)

Variables	Unadjusted OR	p-value	Adjusted OR**	p-value
Age (every 10 years)	1.29 (1.21 - 1.39)	< 0.001	1.19 (1.11 - 1.29)	0.001

2233-A | NONALCOHOLIC FATTY LIVER DISEASE IS ASSOCIATED WITH AN INCREASED RISK OF HEART BLOCK AND HEPATIC EVENTS

Marie-Lise Chrysostome[1], Sameer Prakash[2,3], Antonio J. J. Sanchez[2] and Patrick Ten Eyck[4], (1)Drexel University College of Medicine, Pittsburgh, PA, (2) University of Iowa Hospitals and Clinics, (3)Memorial Hermann, (4)University of Iowa

Background: Non-alcoholic fatty liver disease (NAFLD) has been associated with an increased risk of cardiovascular disease. Few studies have examined the association between NAFLD and the risk of cardiac conduction defects. We aimed to elucidate the relationship between heart block (HB) in NAFLD patients and development of hepatic decompensation events. **Methods:** We used the TriNetX platform to perform a retrospective cohort study of inpatient admissions at a large tertiary referral center, the University of Iowa Hospitals and Clinics, between January 2010 and December 2020. We identified patients with ICD-10 codes for NAFLD and at least one of the following: bradycardia, fascicular block, complete atrioventricular block, or other conduction disorder. Hepatic decompensation events were identified as ascites, hepatic encephalopathy, esophageal variceal bleeding, or hepatocellular carcinoma. We examined associated comorbidities including hypertension (HTN), diabetes mellitus (DM), coronary artery disease (CAD), and hyperlipidemia (HLD

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and the incidence of pacemaker placement. All diagnoses were summarized as counts and percentages. Two-way comparisons between measures were investigated by calculating odds ratio point and interval estimates along with p-values. **Results:** 834 patients with NAFLD were identified. 426 (51.08%) were male. 753 (90.29%) were white and 81 (9.72%) were not white. 78 (9.4%) patients also had a diagnosis of HB. 253 (30.34%) NAFLD patients experienced hepatic events. Table 1 shows subgroup characteristics of patients with/without HB 219 (29%) of the NAFLD patients without HB experienced hepatic events, while 34 (43.6%) of the NAFLD patients with HB experienced hepatic events (OR [95% CI], 1.89 [1.18-3.04]) ($p = 0.0095$). DM, HTN, and CAD were significantly associated with HB. Cirrhosis was significantly associated with HB (OR [95% CI],1.64 [1.02-2.63]) ($p = 0.0407$). **Conclusion**: To our knowledge, this is the first study to suggest that the presence of HB increases the odds of developing hepatic decompensation events in patients with NAFLD and cirrhosis. Our results are consistent with the fact that advanced NAFLD is strongly associated with cardiovascular complications, confirming a novel association with cardiac conduction defects which may increase the risk of disease progression and hepatic decompensation. Future studies are required to elucidate the biological mechanisms responsible for this association.

	Heart Block (N=78)		No Heart Block (N=756)					
Diagnosis	Count	%	Count	%	Odds Ratio	95% CI Lower	95% CI Upper	p-value

2234-A | NONALCOHOLIC FATTY LIVER DISEASE IS ASSOCIATED WITH MULTI-ORGAN COMORBIDITIES AND FIBROSIS PROGRESSION IN PATIENTS WITH INFLAMMATORY BOWEL DISEASE

Dana Kablawi[1], Solomon Sasson[1], Faisal Aljohani[1], Chiara Saroli Palumbo[2], Alain Bitton[1], Waqqas Afif[1], Peter Lakatos[1], Gary Wild[1], Talat Bessissow[1] and Giada Sebastiani[3], (1)Mcgill University Health Centre, (2)Yale University, New Haven, CT, (3)Department of Medicine, McGill University Health Centre, Westmount, QC, Canada

Background: Patients with inflammatory bowel disease (IBD) are at risk for nonalcoholic fatty liver disease (NAFLD) due to chronic inflammation, hepatotoxic drugs, alteration of gut microbiota. NAFLD carries higher risk of both liver fibrosis progression and extensive extra-hepatic involvement, including cardiovascular disease, extra-hepatic cancer, hypothyroidism, chronic kidney disease. Data on the association of NAFLD with liver fibrosis progression and its association with multi-organ disease are lacking in this population. **Methods:** We prospectively included consecutive IBD patients who underwent liver stiffness measurement (LSM) with associated controlled attenuation parameter (CAP) by Fibroscan as a part of a routine screening program at a single centre. NAFLD was diagnosed as any grade hepatic steatosis (HS) in absence of alcohol abuse and viral hepatitis co-infection. HS progression was defined as development of any grade HS ($CAP > 270$ dB/m), or transition to severe HS ($CAP > 330$ dB/m) for those with $CAP > 270$ but < 330 dB/m at baseline. Fibrosis progression was defined as development of significant liver fibrosis ($LSM \geq 8$ kPa), or transition to cirrhosis ($LSM \geq 13$ kPa) for those with $LSM > 8$ but < 13 kPa at baseline. We estimated incidence rates of HS and fibrosis progression by dividing the number of participants

developing the outcome by number of person-years (PY) of follow-up. Covariate adjustments for HS progression were evaluated by multivariable time-dependent Cox regression models. Predictors of extra-hepatic conditions were investigated by multivariable logistic regression analysis. **Results:** 430 patients were included (mean age 43 y, BMI 25 Kg/m^2, disease duration 14 years, c-reactive protein 5.2, ALT 22; females 45%, ulcerative colitis 31.8%, diabetes mellitus 4.7%). Patients with NAFLD had higher proportion of cardiovascular events (12% vs. 6%), chronic kidney disease (8% vs. 3%) and hypothyroidism (12% vs. 6%) compared to those without NAFLD. After adjusting for age, male sex, diabetes (aOR 3.53, 95% CI 1.68-7.42; p = 0.001) and Crohn's disease IBD subtype, NAFLD remained an independent predictor of extra-hepatic comorbidities (aOR 1.79, 95% CI 1.15–2.78; p = 0.01). Patients were followed for a mean of 26 months (standard deviation 16.4). The rate of HS progression was 16.2 per 100 PY (95% CI, 11.5-22.8), respectively. The rate of liver fibrosis progression was 6.12 per 100 PY (95% CI 3.48-10.44) (see Figure). In multivariable analysis and after adjusting for duration of IBD and BMI, ulcerative colitis was associated with faster progression of hepatic steatosis (adjusted hazard ratio 2.21, 95% CI 1.02-4.91). **Conclusion:** NAFLD is associated with extra-hepatic co-morbidities in patients with IBD and can progress to liver fibrosis and cirrhosis.

2235-A | NONALCOHOLIC STEATOHEPATITIS (NASH) REAL-WORLD EVIDENCE: ADVANCED APPROACHES TO ACHIEVE HIGH VALIDITY

Erin Murray, Mahder Teka, Paddu Vedam and Daniel Riskin, Verantos, Inc.

Background: Regulatory, market access, and prescribing decisions are increasingly based on insights from routine care, also known as real-world evidence (RWE). As RWE increasingly influences the standard of care, data quality has come under scrutiny. The data quality standard of accuracy, completeness, and traceability have been distilled to measurable values. To enable RWE in NASH, data quality must be understood in NASH. **Methods:** Accuracy was tested in two study arms for 19 pre-selected NASH-related concepts. The traditional RWE approach study arm was limited to structured data (open claims and electronic health record problem list). The advanced RWE approach study arm utilized structured data plus narrative data (primary care and specialist physician notes) processed using NASH-optimized technology, including natural language processing (NLP) and artificial intelligence (AI)-based inference. Data were extracted from 6087 encounters, each with paired structured and narrative data. A manual reference standard was created via chart abstraction with two annotators reviewing each record with a minimum required 80% inter-rater reliability measured as Cohen's kappa score. F1-score, a weighted average of recall (sensitivity) and precision (positive predictive value) was used to measure accuracy, with 80% considered the threshold for high reliability. A two-sided p-value of 0.05 and a Chi-squared test were used to compare the study arms. **Results:** The average recall, precision, and F1-score in the traditional study arm were 37.2%, 98.9%, and 54.1%, respectively. The average recall, precision, and F1-score in the advanced (NLP plus AI-based inference) study arm were 96.0%, 97.4%, and 96.7%, respectively. There was a 42.6% absolute increase and a 78.7% relative increase in F1-score between traditional and advanced approaches. A statistically significant difference between the two arms was indicated (p < 0.001) for all data elements where data were available. Cohen's kappa score indicated 88% inter-rater reliability, reflecting a highly credible reference standard. Applying AI-based inference following NLP improved concept extraction accuracy in situations where doctors used highly variable language. In particular, for liver fibrosis and alcohol use, F1-scores were 80.1% and 75.3% using NLP alone versus 94.7% and 91.2% using NLP plus inference. This represented an average relative increase of 19.7% by applying inference over NLP alone. **Conclusion:** Advanced data

and technology can enable high-validity RWE in NASH. Given substantial variability in data and technology, accuracy should be measured if the study protocol requires high-validity evidence. NLP alone may be insufficient technology to enable high accuracy, as seen in clinically important NASH concepts such as liver fibrosis and alcohol use.

Background: Accumulating evidence suggests that poly- and perfluoroalkyl substances (PFAS), a class of persistent organic pollutants, cause changes in hepatic lipid, amino acid, and glucose metabolism. Glucose homeostasis changes significantly during puberty, increasing the risk of developing metabolic syndromes. We performed a multi-layered study to determine the association of PFAS exposure with non-alcoholic fatty liver disease (NAFLD) in teenagers and to identify the molecular mechanisms whereby PFAS alters liver metabolism. **Methods:** Adolescents undergoing bariatric surgery were enrolled in the Teen-Longitudinal Assessment of Bariatric Surgery (Teen-LABS, 2007-2012). We measured plasma-PFAS by LC-MS/MS and plasma untargeted metabolomics by LC-HR/MS. Targeted proteomics was determined via Proximity Extension Assay technology (Olink®). Logistic regression controlling for confounders was used to investigate the association between PFAS and NAFLD. Metabolome and proteome datasets integration used latent unknown clustering integrating multi-omics data (LUCID) to identify multi-omic profiles of adolescents at higher risk of NAFLD. 3D InSight™ human liver spheroids (InSphero) were exposed to 20μM PFHpA for 7 days and analyzed by 10x genomics scRNAseq (kit 3' v3.1). **Results:** Among adolescents in the Teen-LABS study, we observed 68% higher odds of NAFLD per doubling of perfluoroheptanoic acid (PFHpA). We identified two distinct multi-omic risk profiles associated with high PFHpA exposure and higher odds of NAFLD. The first omic risk profile showed an association between high PFHpA levels and altered proteins, including low levels of C-C motif chemokine ligand 28 (CCL28), and high levels of several metabolic proteins, such as Carboxylesterase 1 and Aminoacylase 1. NAFLD was 6 times more likely in this PFHpA-protein risk profile. The second risk profile showed an association between high PFHpA and altered levels of amino acids and lipids metabolites. NASH was 4 times more likely in the PFHpA-metabolite risk profile, independent of the proteomic risk profile. In liver spheroids, PFHpA upregulated pathways involved in lipid and cholesterol metabolism, especially in hepatocytes, corroborating the second omic risk profile. **Conclusion:** This is the first study showing that high PFHpA exposure during childhood was associated with NAFLD. PFHpA primarily affected the lipid metabolism of hepatocytes in liver spheroids, supporting the omic risk profiles generated by metabolomics and proteomics dataset integration.

2237-A | POLYCYSTIC OVARIAN SYNDROME IS AN INDEPENDENT RISK ASSOCIATION FOR NAFLD AFTER CONTROLLING FOR METABOLIC AND GENETIC RISK FACTORS

Anya I. Mezina[1], Marijana Vujkovic[2,3], Carolin Victoria Schneider[4], Samiran Mukherjee[1,3], Joseph Park[2,5], Hersh Sagreiya[6], Walter R. Witschey[6], Kyong-Mi Chang[1,3], David E. Kaplan[1,3], Kirk J. Wangensteen[7] and Daniel J. Rader[5,8], (1)Division of Gastroenterology and Hepatology, Department of Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA, (2)Department of Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, (3)Corporal Michael J. Crescenz VA Medical Center, Philadelphia, PA, (4) University Hospital Rwth Aachen, (5)Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA, (6)Department of Radiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA, (7)Division of Gastroenterology and Hepatology, Department of Medicine, Mayo Clinic, Rochester, MN, (8)Division of Translational Medicine and Human Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA

Background: Polycystic ovarian syndrome (PCOS) affects up to 15% of reproductive-aged women. Non-alcoholic fatty liver disease (NAFLD) is frequently observed in women with PCOS, often attributed to comorbid insulin resistance, obesity, diabetes, and dyslipidemia. Susceptibility to NAFLD is influenced by genetic variants in *PNPLA3*, *TM6SF2*, and *HSD17B13*; however, the interactions between genetic and metabolic risk factors among women with PCOS are unclear. We sought to characterize the links between PCOS and NAFLD. **Methods:** We extracted clinical, laboratory, and whole exome sequencing data for European ancestry (EA) and African ancestry (AA) women from the Penn Medicine BioBank (PMBB v.2.2). PCOS was defined by ICD9/ICD10 codes, excluding disorders with similar clinical presentations. NAFLD was diagnosed as any of the following: 1) chronic elevation of alanine aminotransferase, 2) hepatic steatosis on CT imaging, or 3) ICD9/ICD10 codes for NAFLD, NASH, or cirrhosis. Subjects with liver diseases other than NAFLD were excluded. The association of PCOS with NAFLD and log-transformed median hepatic enzymes was tested using logistic and linear regression analyses. Meta-analysis of odds ratios was computed using the inverse variance method. Analyses were adjusted for allelic status at *PNPLA3*-p.I148M, *TM6SF2*-p.E167K, and *HSD17B13* (sum of variants in rs72613567, rs80182459 and rs62305723), in addition to age, age-squared, BMI, hypertension, DM2, dyslipidemia, and 10 principal components of genetic ancestry. **Results:** Among EA women, we identified 407 cases of PCOS (17.0% with NAFLD), and 11,630 non-PCOS cases (13.1% with NAFLD). There were 247 AA women with PCOS (13.8% with NAFLD) and 5,494 AA women without PCOS (13.1% with NAFLD). PCOS was associated with 1.68 higher odds of NAFLD (95% CI: 1.24, 2.28, $p = 0.0008$) among EA women; the association was not significant among AA women (OR 1.49, 95% CI: 0.98, 2.25). Meta-analysis of EA and AA cohorts found that PCOS was associated with 1.61 higher odds of NAFLD (95% CI: 1.26, 2.06, $p = 0.0001$). In both cohorts, PCOS was associated with increased AST (EA, $p = 0.01$; AA, $p = 0.001$) and more robustly associated with higher ALT levels (EA, $p = 0.0007$; AA, $p = 0.00001$). A synergistic interaction was observed between PCOS and p.I148M genotype among EA women only ($p = 0.03$ for AST, $p = 0.0005$ for ALT). Analyses were conducted in R (v.4.1.0). **Conclusion:** PCOS was associated with higher levels of AST and ALT among European and African ancestry women. Among European women, the impact of PCOS on hepatic enzymes was amplified by the presence of the *PNPLA3* p.I148M polymorphism. Trans-ancestral meta-analysis found that PCOS conferred 1.61 higher odds of NAFLD, after adjusting for common metabolic and genetic risk factors. This suggests that factors other than metabolic syndrome and genetic risk may predispose to NAFLD among women with PCOS.

2238-A | POST LIVER TRANSPLANT SURVIVAL AMONG HISPANIC AND NON-HISPANIC WHITE PATIENTS WITH NONALCOHOLIC STEATOHEPATITIS (NASH): AN ORGAN PROCUREMENT AND TRANSPLANTATION NETWORK (OPTN) ANALYSIS

Pankil Shah, Uthealth San Antonio, Mazen Noureddin, Houston Research Institute, Houston, TX and Naim Alkhouri, Arizona Liver Health, Phoenix, AZ

Background: End-stage liver disease (ESLD) is the last stage in the spectrum of nonalcoholic fatty liver disease (NAFLD)/NASH pathology, with liver transplant being the only definite treatment option. Compared to Non-Hispanic White patients, Hispanics have a higher prevalence of NAFLD/NASH and 30% higher mortality rates due to ESLD. We aimed to assess 5-year survival rate in patients receiving transplantation for NASH and examine disparity associated with Hispanic ethnicity. **Methods:** We assessed the survival in adult liver transplant recipients who had their transplant surgery between 2008 and 2018, using the limited dataset from OPTN. All-cause mortality was the primary outcome, re-transplantation was treated as a competing event, and ethnicity was the primary predictor using the Fine-Gray regression model. A bivariable model, a multivariable model with *a priori* clinical confounders, and a LASSO penalized feature selected model were built to examine racial/ethnic disparity in post-transplant survival. The confounding variables examined were age, sex, education, insurance, employment, citizenship, functional status, BMI, Model for End-stage liver disease (MELD), waitlist time, transplant type, region, comorbidity, hospitalization, life-supportive treatment, and Share-35 policy. **Results:** A total of 10,043 recipients, including 8445 (84%) Non-Hispanic White (NHW) and 1598 (16%) Hispanic, were identified and included. The overall probability of death was 20% in NHW and 18% in Hispanic patients at five years. The unadjusted subdistribution hazard ratio (SHR) (95% confidence interval [CI]) was 0.84 (0.72 – 0.98), adjusted SHR [CI] was 0.70 (0.60 – 0.83), and SHR [CI] of the penalized model was 0.71 (0.61 – 0.83) for Hispanic recipients compared to NHW recipients. Better survival for Hispanics was observed for one year, 10-year follow-up, after exclusion of non-US nationals, and stratification by pre- and post-Share-35 policy era. **Conclusion:** The better survival outcome was observed in Hispanic than NHW patients, which, despite clinical and socioeconomic risk profile being unfavorable in that group, perhaps points to cultural exposure or genetic traits of Hispanic patients that might drive such differences. With still a 5-year mortality rate of around 20%, there is a substantial need for continued research and advancement in the treatment and care of liver transplant recipients to prolong their survival.

Table 2: Subdistribution Hazard Ratio for 5-year mortality for Hispanic and Non-Hispanic white recipients

Model	SHR (95% CI)		
	1-year	5-year	10-year
Univariable/Unadjusted	0.78 (0.64 – 0.96)	**0.84 (0.72 – 0.98)**	0.80 (0.69 - 0.91)
Fully Adjusted using all a priori variables [a]	0.65 (0.53 – 0.81)	**0.70 (0.60 - 0.83)**	0.68 (0.58 – 0.80)
Adjusted for variables retained in LASSO Penalized Sub-distribution regression [b]	0.71 (0.57 – 0.88)	**0.71 (0.61 - 0.83)**	0.69 (0.60 – 0.80)

[a]Adjusted for *a priori* selected variables: age, sex, obesity, diabetes, encephalitis, ascites, dialysis, hospitalization, life-supportive treatment, MELD score at transplant, days on the transplant waitlist.
[b]LASSO penalized feature selection retained age, obesity, MELD score, hospitalization, life-supportive treatment, the distance of the transplant site to the procurement site, and the Share-35 era

Figure 1b. Cumulative Incidence Function, stratified by Ethnicity: A 5-year competing risk regression of the study population indicating the relative probability of death and re-transplantation following the first liver transplant in the Non-Hispanic White and Hispanic study population.

2239-A | PREDICTORS OF LIVER FIBROSIS AND ITS PROGRESSION IN THE GENERAL POPULATION

Kustaa Saarinen[1], Martti Farkkila[2], Antti Jula[3], Iris Erlund[3], Terhi Vihervaara[3], Annamari Lundqvist[3] and Fredrik Aberg[2], (1)Helsinki University Hospital, (2) University of Helsinki, (3)Finnish Institute for Health and Welfare

Background: Liver fibrosis stage is the key prognostic factor for liver-related outcomes in many liver diseases. There are only a few studies on the prevalence and progression of fibrosis and associated risk factors on the population level. The Enhanced Liver Fibrosis (ELF) test is a composite score based on three serum markers of matrix turnover. We evaluated factors associated with advanced fibrosis based on the ELF test and fibrosis progression over a 10-year follow-up. **Methods:** ELF was measured from frozen blood samples from the Health 2000 study, a population-based epidemiologic survey conducted in Finland in 2000-2001 (study baseline) and its follow-up study, Health 2011 (follow-up). Advanced fibrosis was defined as ELF e 9.8 and clinically significant fibrosis progression as an ELF-change > 0.6 over the follow-up. Chronic Liver Disease (CLivD) risk score, a recently published risk score for severe liver-related outcomes based on phenotypic data, clinical measurements and with ($CLivD_{lab}$) or without ($CLivD_{nonlab}$) laboratory test gamma-glutaminase was calculated at baseline (Åberg et al., J Hepatology 2022). **Results:** The baseline sample (Health 2000) comprised 6084 individual's, and the follow-up sample (Health 2011) 2937 individual's. Percentages of men in the baseline and follow-up samples were, respectively, 46% and 45%, mean age 52.7 and 48.5 years, mean BMI 26.9 kg/m2 and 26.5kg/m2, and prevalences of diabetes 10% and 6.2%. The age-adjusted prevalence of advanced fibrosis among men and women was 8.3% (95% CI 7.0 – 9.6) and 5.9% (95% CI 4.9-7.0), respectively. The most significant risk factors for advanced fibrosis in both sexes were obesity (BMI), abdominal obesity (waist circumference and waist-hip ratio), insulin resistance (HOMA-IR), and elevated transaminases ($p < 0.001$). Most individual's with advanced fibrosis had normal liver enzymes. The risk factors for a clinically significant fibrosis progression were obesity and especially abdominal obesity ($p < 0.05$) among women, and abdominal obesity and AST > 40 IU ($p < 0.05$) among men. The CLivD score was associated with a consistent elevation of ELF values at baseline (Figure 1). Also, the CLivD score predicted the magnitude of ELF increases over follow-up, independently of baseline ELF ($p < 0.001$). **Conclusion:** The majority of individual's with advanced fibrosis, estimated by the ELF test, present with normal liver enzymes. The CLivD score predicted both baseline ELF and its change over the follow-up.

2240-A | PREVALENCE AND PROGNOSIS OF PATIENTS WITH MAFLD-RELATED CIRRHOSIS AFTER ICU HOSPITALIZATION IN FRANCE: A MONOCENTRIC PROSPECTIVE STUDY

Guillaume Lherault[1], Philippe Sultanik[1], Vlad Ratziu[2], Raluca Pais[1], Sarah Mouri[1], Charlotte Bouzbib[3], Dominique Thabut Damais[4] and Rudler Marika[1], (1)Aphp, (2)Sorbonne Université, Institute for Cardiometabolism and Nutrition, Hôpital Pitié-Salpêtrière, Paris, France, (3) Hôpital Pitié-Salpêtrière, Aphp, Service D'hépato-Gastroentérologie, Unité De Soins Intensifs, (4) Groupement Hospitalier Aphp-Sorbonne Université, Hôpital De La Pitié-Salpêtrière, Paris, France

Background: Metabolic-associated fatty liver disease (MAFLD) has been recently defined. No data are available on decompensated MAFLD-related cirrhosis. We aimed to estimate the burden of MAFLD in patients (pts) with cirrhosis hospitalized in intensive care unit (ICU) for decompensation, and to compare prognosis of MAFLD-related cirrhosis to that of cirrhosis related to other cause, such as alcohol. **Methods:** All consecutive pts hospitalized in our ICU were prospectively included between Feb19 and Sept21. The diagnosis of MALFD was based on past exposure to diabetes or obesity/overweight, or on the combination of at least 2 minor metabolic risk factors metabolic abnormalities. We distinguished 3 groups of pts: MAFLD alone, alcohol-related cirrhosis (>30g/day), and mixed MAFLD (MAFLD and alcohol-related cirrhosis). One-year transplant-free survival (TFS), further decompensation (ascites, hepatic encephalopathy (HE), or acute variceal bleeding (AVB)), hepatocellular carcinoma (HCC), readmission, and liver transplantation (LT) were compared one year after hospitalization in ICU. **Results:** 410 pts were hospitalized in our ICU, and 335 pts were analyzed: 44 in the MAFLD, 188 in the alcohol, and 103 in the mixed MAFLD groups, respectively. Overall, the MALFD etiology (MALFD or mixed MAFLD) accounted for 147/335 (35.8%) pts. 38% of pts were admitted for AVB, 9.3% for HE, 24% for liver failure, 11% for sepsis, 8.1% for renal failure, 8.7% for TIPS placement, and 0.9 % for other causes, without any difference between the 3 groups. At baseline, pts in the MAFLD group were significantly older than pts in the alcohol and mixed groups (65 vs 57 and 60 years, respectively, $p<0.001$), had lower Child-Pugh (8 vs 11 vs 10, $p<0.001$) and MELD scores (16 vs 22 vs 20, $p<0.001$), and a more severe portal hypertension (large esophageal varices in 91 vs 71 and 76%, $p=0.03$). The one-year TFS was not statistically different in the MAFLD group: 56.8% in the MAFLD group vs 45.2% in the alcohol group and 49.5% in the mixed group ($p=0.2$). There was no difference regarding the development of further decompensation, HCC or readmission. Cardiovascular mortality was not higher in the MAFLD group and was responsible for less than 5% of mortality all groups. **Conclusion:** MAFLD, either alone or associated with alcohol, accounted for $>1/3$ of the causes of cirrhosis in our cohort. MAFLD-related cirrhosis is as severe as alcohol-related cirrhosis, and mortality is liver and not cardiovascular-driven. LT should be rapidly discussed in those pts because of older age and comorbidities.

2241-A | PREVALENCE OF HEPATIC STEATOSIS IN A MEXICAN THIRD LEVEL HOSPITAL AND RISK FACTORS FOR DEVELOPMENT OF CIRRHOSIS

José Alonso Ávila Rojo[1], Esmeralda Avila Rojo[1], David Aguirre-Villarreal[2], Ernesto Elizondo Zepeda[1] and Ignacio García Juárez[3], (1)Instituto Nacional De Ciencias Médicas y Nutrición Salvador Zubirán, (2) Instituto Nacional de Ciencias Medicas y Nutricion, (3) Instituto Nacional De Ciencias Medicas y Nutricion

Background: Non-alcoholic fatty liver disease (NAFLD) has become a growing concern worldwide, with hepatic steatosis being a key component of its pathogenesis. Understanding the prevalence of hepatic steatosis and identifying associated risk factors for hepatic fibrosis is crucial for early detection and intervention. Aim: to determine the prevalence of hepatic steatosis in asymptomatic patients admitted for suspected or diagnosis of atypical pneumonia. **Methods:** Clinical, laboratory, and imaging data were collected from electronic medical records. A total of 2353 patients were included and their demographic characteristics, prevalence of hepatic steatosis, and associated risk factors were analyzed. We used computerized tomography for the diagnosis of steatosis taking the Hounsfield units (<40 HU) as cutoff value evaluated on the III and VI hepatic lobes. **Results:** Out of the initial sample of 2353 patients, 17 were excluded, resulting in a final study population of 2336 patients. The average age of the participants was 56 years, ranging from 18 to 96. Of the total population, 871 (37%) were females and 1482 (63%) males. Among the study participants, a total of 931 (39.8%) patients were classified as overweight, while

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

1012 (43.3%) were classified as obese. In terms of specific conditions, 701 (29%) had diabetes mellitus and 796 (34.1%) met the diagnostic criteria for hepatic steatosis. Among the patients with hepatic steatosis, 245 (30.8%) also had diabetes mellitus. In terms of weight status, from the patients that were classified as overweight, 221 (23.7%) had hepatic steatosis, and from the patients that were classified as obese, 464 (45.8%) had hepatic steatosis. In terms of liver fibrosis scores, according to the APRI score, 151 patients met the criteria for fibrosis and 76 (50%) were classified as having significant fibrosis. Out of these 76 patients with significant fibrosis, 59 also had hepatic steatosis. The remaining 76 patients were diagnosed with advanced fibrosis and cirrhosis, of which 27 had coexisting steatosis. Using the FIB-4 index, 627 patients were identified as having fibrosis. Among them, 520 patients had fibrosis grades 2-3. Out of these 520 patients, 159 had concurrent hepatic steatosis. Additionally, 107 patients were classified as having advanced fibrosis, and 28 of them had steatosis. Furthermore, 164 patients had an FIB-4 index indicating advanced fibrosis and 40 had coexisting steatosis. According to the NAFLD fibrosis score, 225 patients were found to have advanced fibrosis, and 67 had hepatic steatosis. **Conclusion:** this study aimed to determine the prevalence and incidence of hepatic steatosis in asymptomatic patients. The findings revealed a significant burden of hepatic steatosis among the study population. Prioritizing the importance of early detection and intervention for hepatic steatosis, particularly in patients with associated risk factors such as diabetes, overweight, and obesity.

2242-A | PREVALENCE OF NAFLD AND ACCURACY OF NITS IN PATIENTS WITH POLYCYSTIC OVARY SYNDROME

Wouter Robaeys[1,2], Leen Heyens[1,2,3], Nathalie Dhont[2], Geert Verswijvel[2], Ger H. Koek[3,4], Geert Robaeys[1], Struyve Mathieu[2], Penders Joris[1,2] and Sven Francque[5,6,7], (1)Hasselt University, (2) Ziekenhuis Oost Limburg, (3)Maastricht University, (4) Maastricht University Medical Center, (5)University of Antwerp, Edegem, Belgium, (6)Translational Sciences in Inflammation and Immunology, Laboratory of Experimental Medicine and Paediatrics, Faculty of Medicine and Health Sciences, University of Antwerp, Antwerp, Belgium, (7)Department of Gastroenterology and Hepatology, Antwerp University Hospital, Antwerp, Belgium

Background: Patients with Polycystic Ovary Syndrome (PCOS) might be at increased risk for NAFLD. Only one study (PMID: 22837189) assessed the presence of NAFLD in adult PCOS using the gold standard for non-invasive detection of liver steatosis being MRI-PDFF. The results of previous studies regarding the prevalence of steatosis in PCOS measured by other tests (*e.g.,* controlled attenuation parameter CAP™, blood derived scores) were discordant, did not include the gold standard and studied multiple different patient groups.

The aim of the current prospective study is to investigate the prevalence of NAFLD in PCOS based on MRI and to assess the accuracy of CAP™ and non-invasive blood-derived tests in a well-defined patient population with and without PCOS. **Methods:** In this ongoing, prospective, monocentric, Belgian study NAFLD is detected in patients with PCOS diagnosed according to the Rotterdam consensus (2003) compared to apparently healthy women by means of hepatic MRI, CAP™ and blood based non-invasive tests (*a.o.*, Hepatic Steatosis Index (HSI)).

Using CAP™ NAFLD has been defined as CAP™ $>$ 215 dB/m while moderate to severe NAFLD has been defined as CAP™ $>$ 275 dB/m.

By means of hepatic MRI PDFF NAFLD has classically been defined as a value $>$ 5% but recently a threshold of 3.71% was proposed. **Results:** The demographics of the 42 PCOS patients and 29 healthy controls were: age 32 $\pm$ 5 vs. 35 $\pm$ 7 years (p = 0.046), BMI 26.9 [25.6-29.2] vs. 23.7

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

[23.5-27.0] kg/m^2 ($p > 0.05$), waist circumference 82 ± 80 cm vs. 77.4 ± 10.3 cm ($p > 0.05$), number of menstrual cycles 4.5 [4.3-6.6]] vs. 12.0 [10.3-12.1] ($p < 0.001$). Based on MRI NAFLD was detected using a threshold of 3.71% and of 5% in resp. 7 (21%) and 4 (10%) women with PCOS vs. 0 ($p = 0.02$) and 0 ($p = 0.09$) in controls.
Using CAP™ (cut-offs 215 dB/m and 275 dB/m) resp. 28 (67%) and 8 (19%) of the PCOS patients vs. 14 (48%) and 6 (21%) in controls were diagnosed with NAFLD ($p = 0.12$ and $p = 0.86$). HSI was increased in 16 (38%) patients with PCOS vs. 5 (17%) in controls ($p = 0.06$).
Diagnostic accuracy for NAFLD (MRI PDFF > 3.71%) was also high (AUC: resp. 0.89 and 0.93) (Figure 1). **Conclusion:** The MRI threshold significantly impacts on the observed prevalence of NAFLD in PCOS, with 5% substantially underestimating the prevalence, when studying this risk group. CAP™ and HSI have high accuracy to detect NAFLD as defined by MRI PDFF > 3.71%.
NAFLD is more prevalent in PCOS compared to controls. Further studies using a fully matched cohort and evaluating the reason for false positivity regarding CAP and HSI are in progress.

Figure 1: The accuracy of CAP™ and HSI compared to MRI-PDFF with a threshold of 3.71%

2243-A | PREVALENCE OF NONALCOHOLIC FATTY LIVER DISEASE AND FIBROSIS IN PATIENTS WITH PREDIABETES/ DIABETES BASED ON BODY MASS INDEX

Omar Alshuwaykh, California Pacific Medical Center, Aijaz Ahmed, Stanford University School of Medicine, George Cholankeril, Baylor College of Medicine and Donghee Kim, Stanford University Medical Center

Background: NAFLD is now the most common liver disease and may soon become the leading indication for liver transplantation **Methods:** We used data from the 2017-2018 NHANES. Excluding individual's with significant alcohol use and viral hepatitis, 4192 adult individual's had transient elastography. 893 individual's had diabetes and 1770 patients had prediabetes. We then categorized into three subgroups based on their BMI of normal (18.5-24.9 kg/m^2), overweight (25-29.9 kg/m^2), obesity (e 30 kg/m^2). Diabetes was defined as having hemoglobin A1c (A1c) e 6.5%, fasting blood glucose e 126 mg/dL, and/or treatment with oral hypoglycemic agent or insulin. Prediabetes was defined as fasting glucose of 100-125 mg/dL and A1c 5.7-6.4. CAP scores of e 263 dB/m were defined as NAFLD. A transient elastography e 8 kPa (e F2) and e 13.1 kPa (e F4) were defined as suspected fibrosis and cirrhosis **Results:** Population mean age was 49 years, 48% of the individual's were men. NAFLD prevalence was 81.2% (95% CI: 77.6-84.8) in patients with diabetes, and 55.9% (95% CI:52.9-59) in patients with prediabetes. Among patients with diabetes, prevalence of NAFLD was substantially higher in obesity (90.8%, 95% CI: 86.9-94.6), followed by overweight (73.1%, 95% CI: 64.7-81.5), and normal BMI (43.5%, 95% CI: 25.6-61.4). Among obese individual's, increasing obesity class was associated with increased NAFLD prevalence ($P < 0.001$). Prevalence of fibrosis (e F2) was highest among individual's with obesity (34.2%, 95% CI: 27.9-40.5). Likewise, prevalence of cirrhosis was highest (12.1%, 95% CI: 5.7-18.5) among individual's with diabetes. Among patients with pre-diabetes, prevalence of NAFLD was substantially higher in obesity (78.6%, 95% CI: 72.9-84.4), followed by overweight (49.7%, 95% CI: 43.7-55.7), and normal BMI (16.9%, 95% CI: 11.8-22.1). Among obese individual's, increasing obesity class was associated with increased prevalence of NAFLD ($P < 0.001$). Prevalence of fibrosis (e F2) was highest among individual's with obesity (17.9%, 95% CI: 12.8-22.9). Likewise, prevalence of cirrhosis was highest (7.3%, 95% CI: 4.7-9.9) among individual's with diabetes. Among obese individual's, increasing obesity class was linearly associated with increased prevalence of fibrosis and cirrhosis in those with diabetes and prediabetes ($P < 0.001$) **Conclusion:** Our findings highlight that patients with DM and obesity are more likely to have NAFLD and advanced fibrosis and should purse definitive diagnostic studies to receive the recommended interventions and follow up

2244-A | PREVALENCE OF NON-ALCOHOLIC FATTY LIVER DISEASE, HIGH-RISK NON-ALCOHOLIC STEATOHEPATITIS, AND LIVER FIBROSIS IN PATIENTS WITH OSTEOARTHRITIS

Markos Kalligeros[1], Athanasios Vassilopoulos[1], Stephanos Vassilopoulos[1], Jack R. Wands[2] and Kittichai Promrat[3], (1)Brown University, (2)Warren Alpert Medical School of Brown University, Providence, RI, (3)Brown University School of Medicine

Background: Non-alcoholic fatty liver disease (NAFLD) and osteoarthritis (OA) are two major health issues with an increasing global prevalence. This study sought to determine the prevalence of NAFLD, high-risk non-alcoholic steatohepatitis (NASH), and liver fibrosis among patients with OA. **Methods:** Utilizing data from the U.S. National Health and Nutrition Examination Survey (NHANES) 2017-2020 cycle, we calculated the age-adjusted prevalence of NAFLD (CAP e 285 dB/m), high-risk NASH (FAST score), and liver fibrosis (LSM) in OA patients. Sample weights were applied to ensure representative estimates. Independent risk factors for these conditions among OA patients were identified through multivariable logistic regression analysis. Adjusted odds ratios (aORs) and 95% confidence intervals (CIs) are presented. **Results:** Among the 871 patients with OA, the majority were aged 60 and above (66.5%), were female (64.2%), and of non-Hispanic white ethnicity (54.3%). The NAFLD was more prevalent in higher age groups, males, individual's with obesity (BMI e 30), diabetes, dyslipidemia, and metabolic syndrome, with all showing statistically significant differences (p-value < 0.05) (Figure 1a). The racial/ethnic distribution and presence of hypertension did not demonstrate a statistically significant difference between the NAFLD and non-NAFLD groups. The age-adjusted prevalence of NAFLD among U.S. adults with OA was estimated at 39.81% (95% CI: 29.55-51.04%). The prevalence of high-risk NASH, with FAST scores exceeding 0.35 and 0.67, was found to be 9.08% (95% CI: 3.63-20.95%) and 5.26% (95% CI: 1.35-18.39%), respectively. Furthermore, the age-adjusted prevalence of clinically significant fibrosis (LSM e 8 kPa) and advanced fibrosis (LSM e 13.1 kPa) was 12.71% (95% CI:5.76-25.73%) and 5.78% (95% CI: 20.48-15.27%), respectively (Figure 1b). Notably, OA patients with NAFLD demonstrated a higher likelihood of having diabetes (aOR 3.14; 95% CI: 1.33-7.41) and a BMI > 30 kg/m^2 (aOR 10.87; 95% CI: 2.81-42.13). **Conclusion:** Our findings suggest a higher prevalence of NAFLD, high-risk NASH, and liver fibrosis among OA patients compared to the general population, implicating obesity as a potential common denominator for these conditions. The coexistence of OA and NAFLD, particularly among patients with obesity, can pose substantial challenges to the implementation of lifestyle interventions due to physical limitations induced by OA. This predicament necessitates the need for clinicians to consider additional, tailored interventions that are feasible and effective for this patient group. Furthermore, an integrated approach for early screening and management of NAFLD in OA patients is crucial to mitigate potential adverse health outcomes. Future research should focus on alternative strategies that accommodate the physical constraints of this population, paving the way for comprehensive and effective patient care.

2245-A | PROJECTION OF THE CLINICAL BURDEN OF NAFLD IN US ADULTS FROM 2020-2050: A MODELING STUDY

Phuc Le[1], Moosa Tatar[1], Srinivasan Dasarathy[2], Naim Alkhouri[3], William Herman[4], Abhishek Deshpande[1], Glen Taksler[1], Wen Ye[5] and Michael Rothberg[1], (1) Cleveland Clinic, (2)Cleveland Clinic Foundation, (3) Arizona Liver Health, Phoenix, AZ, (4)University of Michigan Medical School, (5)University of Michigan

Background: Following the alarming rise in prevalence of obesity and diabetes, nonalcoholic fatty liver disease (NAFLD) is projected to become the leading indication for liver transplant (LT) in the United States in the next decade. A better understanding of the clinical burden associated with NAFLD will enable health systems to prepare to meet this imminent demand from patients. Our objective was to project the burden of NAFLD in US adults from 2020-2050 using a population-based natural history model. **Methods:** We developed an agent-based state transition model that consisted of two components, with a yearly cycle. The first component simulated the US population starting from the year 2000, incorporating new births and immigrants annually based on Census data. The second component tracked the natural history of NAFLD progression in adults, encompassing 14 distinct health states including no steatosis, simple steatosis, nonalcoholic steatohepatitis (NASH), fibrosis, cirrhosis, decompensated cirrhosis, hepatocellular carcinoma (HCC), LT, and liver-related or other causes of death. Model inputs were derived from the literature; unknown inputs were calibrated and validated against published estimates. **Results:** Validation of our model demonstrated a close match between predicted outcomes from 2000 to 2018 and published data on US population, trends in NAFLD prevalence, NASH proportion, incidence of HCC and LT, and overall survival rates among NAFLD patients. Our model predicts a steady increase in the prevalence of NAFLD among US adults from 27.8% in 2020 to 34.3% by 2050. Among NAFLD cases, the proportion of NASH is expected to increase from 20.0% to 21.8%. Prevalence should remain relatively stable for people aged 18-29 years but increase significantly for all other age groups. The proportion of NAFLD cases who develop cirrhosis is projected to increase from 1.9% in 2020 to 3.1% in 2050, and liver-related deaths should increase from 0.4% of all deaths to 1%. By 2050, NAFLD should cause 19,300 new cases of HCC and 4,200 new cases of LT per year, a substantial increase from 10,400 and 1,700 cases in 2020, respectively. **Conclusion:** Our model forecasts a substantial clinical burden of NAFLD over the next three decades. In the absence of effective treatments, health systems should plan for large increases in the number of HCC cases and the need for LT.

2246-A | PSD3 RS 71519934 LACKED SIGNIFICANT EFFECT ON THE RISK FOR HEPATIC STEATOSIS AND CLINICALLY SIGNIFICANT FIBROSIS IN US ADULTS

Kung-Hung Lin[1], Tae-Hwi Schwantes-An[2], Jingyi Tan[3], Samer Gawrieh[1], Niharika R. Samala[1], Jordan E. Lake[4], Kathleen E. Corey[5], Eduardo Vilar-Gomez II[1], Marco A Abreu[2], Xiuqing Guo[6], Tiebing Liang[1], Jerome I Rotter[7] and Naga P. Chalasani[1], (1)Division of Gastroenterology and Hepatology, Department of Medicine, Indiana University School of Medicine, Indianapolis, Indiana, USA, (2)Indiana University School of Medicine, (3)The Institute for Translational Genomics and Population Sciences, Department of Pediatrics, the Lundquist Institute for Biomedical Innovation at Harbor-UCLA Medical Center, Torrance, California, USA, (4)Division of Infectious Diseases, Department of Medicine, Indiana University School of Medicine, Indianapolis, Indiana, USA, (5)Division of Gastroenterology, Department of Medicine, Liver Center, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts, USA, (6) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, Indiana, USA, (7)The Lundquist Institute for Biomedical Innovation at Harbor-UCLA Medical Center

Background: Nonalcoholic fatty liver disease (NAFLD) has a strong heritable component. A recent study (PMID: 35102341) identified a multiple nucleotide variation (rs71519934, GT/AG) at the Pleckstrin and Sec7 domain-containing 3 (*PSD3*) gene which reduces susceptibility to the entire spectrum of NAFLD in individual's at risk. However, strengths of associations varied among different cohorts in that study. We examined the association between *PSD3* rs71519934 and the prevalence of hepatic steatosis and clinically significant fibrosis in two separate cohorts of US adults. **Methods:** *PSD3*-rs71519934 variant was genotyped using TaqMan SNP assay in patients from 2 cohorts, including 686 persons with NAFLD and 621 persons with HIV (PWH). Both cohorts had controlled attenuation parameter (CAP) and liver stiffness measurement (LSM) measured via vibration controlled transient elastography. Both CAP and LSM were tested as a continuous trait and as dichotomously categorized. NAFLD was defined as CAP e 263 dB/m in the absence of heavy alcohol consumption or other liver diseases. Clinically significant fibrosis was defined as LSM e 8 kPa. Associations between *PSD3* rs71519934 and CAP and LSM were examined separately in two cohorts. Linear and logistic regression analyses were adjusted for age, sex, and race/ethnicity. *PSD3* rs71519934 was additively coded for the minor (GT) allele. A meta-analysis was conducted by combining the results from the two cohorts. **Results:** Table 1 summarizes selected demographics, clinical characteristics, CAP and LSM values, and rs71519934 allele and genotype frequencies. For CAP, we did not observe statistically significant association between rs71519934 and either continuous or dichotomized CAP, in either PWH, NAFLD cohort, or meta-analysis. However, in the PWH cohort GT allele showed a trend for higher CAP value (increase of 9.1 dB/m per GT allele, $p = 0.07$). For LSM, either as a continuous or a categorical variable, there was no statistically significant association with rs71519934 in either PWH, NAFLD cohort, or meta-analysis. However, GT allele showed a trend for decreasing LSM measures (decrease of 0.33 kPa per GT allele, $p = 0.33$). **Conclusion:** The *PSD3* GT allele was not significantly associated with CAP and LSM in our study, but we observed a numerical trend towards lower liver stiffness but higher hepatic steatosis.

Table 1. Selected demographics, clinical characteristics, CAP and LSM values, and rs71519934 allele and genotype frequencies in the PWH, NAFLD cohort and in combination

Variable	PWH (N=621)	NAFLD (N=686)	Total (N=1,307)
Age in yrs, Mean (SD)	50.63 (11.66)	53.13 (25.48)	51.93 (20.18)

2247-C | RACIAL DISPARITIES IN PREVALENCE AND INCIDENCE OF CIRRHOSIS AND EXTRAHEPATIC MANIFESTATIONS IN NONALCOHOLIC FATTY LIVER DISEASE

Majd Bassam Aboona[1], Claire Faulkner[1], Pooja Rangan[2,3], Vincent Chen[4], Cheng Han Ng[5], Daniel Q Huang[6], Mark Dhinesh Muthiah[6], Donghee Kim[7], Moises Ilan Nevah Rubin[2,3], Ma Ai Thanda Han[2,3], Michael Fallon[2,3] and Karn Wijarnpreecha[2,3], (1) University of Arizona College of Medicine - Phoenix, Phoenix, AZ, (2)Banner University Medical Center, (3) University of Arizona College of Medicine Phoenix, Phoenix, AZ, (4)University of Michigan Medical Center, (5)Yong Loo Lin School of Medicine, National University of Singapore, (6)National University Health System (NUHS), (7)Stanford University Medical Center

Background: Nonalcoholic fatty liver disease (NAFLD) has increased in prevalence in recent years. Data on NAFLD in Native Americans are limited. We conducted a study to estimate the prevalence and incidence of NAFLD and its complications in an ethnically diverse population. **Methods:** We conducted a multi-state health system study on NAFLD patients seen at the Banner Health System, representing hospitals across Arizona, California, and Colorado, from 2012 to 2022 using ICD codes. We excluded patients with other causes of liver disease, underweight, baseline decompensated cirrhosis, baseline cancer diagnosis, prior bariatric surgery, or missing data on race, BMI, aspartate and alanine aminotransferase, and platelet. All patients were included in the prevalence cohort, and patients with a follow up of 365 days or greater were included in the incidence cohort. The primary outcomes are the prevalence and incidence of cirrhosis, cardiovascular disease (CVD), metabolic diseases, and chronic kidney disease (CKD) among ethnic groups. We performed a multivariate logistic regression analysis to determine the risk of diseases prevalence and competing risk analysis for diseases incidence among various ethnic groups with NAFLD and adjusted for multiple confounders (Table). Results: We included 51,452 NAFLD patients in the prevalence cohort and 37,027 in the incidence cohort. In both cohorts, 63-64% were White, 28% Hispanic, 3-4% African-American, 2% Native American, and 1% Asian/Pacific Islanders. Compared to White patients, Hispanic patients had a lower prevalence of CVD, and higher prevalence of cirrhosis, higher incidence of mortality, cirrhosis, and liver-related events (LREs). Furthermore, compared to white patients, Native Americans had a higher prevalence of cirrhosis and CKD, with a higher incidence of mortality, LREs, and type II DM. Blacks had a lower prevalence of peripheral artery disease, a higher prevalence of CKD, and a higher incidence of mortality and type II DM. **Conclusion:** In this large, ethnically-diverse cohort of patients with NAFLD, Native American, Hispanic, and Black patients had higher mortality compared to White patients. These same ethnicities had higher incidence of liver-related events and type II DM. Future studies are warranted to understand the underlying reasons for racial disparities in patients with NAFLD.

2248-C | REGIONAL AND SEX DIFFERENCES IN INCIDENCE OF ADVERSE CLINICAL EVENTS IN PERSONS WITH NAFLD: A SYSTEMATIC REVIEW AND META-ANALYSIS

Thomas Baez[1], David M Le[1], Michael H Le[2], Hansen Dang[3], Vy H. Nguyen[4], KeeSeok Lee[3], Takanori Ito[5], Yuankai Wu[4], Yee Hui Yeo[6], Fanpu Ji[7], Ramsey Cheung[8] and Mindie H. Nguyen[8], (1)Burrell College of Osteopathic Medicine, (2)Larner College of Medicine at the University of Vermont, (3)Stanford University, (4)Stanford University Medical Center, (5)Nagoya University Graduate School of Medicine, Japan, (6) Cedars-Sinai Medical Center, Culver City, CA, (7)The Second Affiliated Hospital of Xi'an Jiaotong University, (8)Stanford University Medical Center, Palo Alto, CA

Background: Nonalcoholic fatty liver disease (NAFLD) incidence and prevalence varies by region. We aimed to determine the regional incidence rates of adverse clinical events associated with NAFLD. **Methods:** We performed a systematic review and meta-analysis of cohort studies of adults with NAFLD at baseline using 3 databases (Cochrane library, EMBASE, PubMed) to evaluate the pooled incidence of adverse clinical events associated with NAFLD. Random-effects models were used to estimate the pooled incidence of adverse clinical events. **Results:** A total of 75 eligible studies (1,375,554 persons) were included. The included regions were North America (n = 16 studies, 563037 persons), Europe (n = 25, 498467 persons), and Western Pacific/Southeast Asia (WPSEA) (n = 34, 314050 persons). Median study year and person-years follow up are as follows: North America (2007, 5466 person-years), Europe (2007, 5400 person-years), WPSEA (2007, 5533 person-years). No asymmetry was observed on funnel plot analysis, with egger's test showing no significant differences for all outcomes ($p > 0.05$). All analyses showed significant heterogeneity (I^2 e 50%). Data are reported as incidence rate per 1000 person-years. All-cause, cardiovascular disease (CVD)-related, and non-liver cancer related mortality were lowest in WPSEA and highest in Europe. No significant differences were observed in liver-related mortality by region. Incidence rates of liver transplant were highest in North America and lowest in Europe. Hepatocellular carcinoma (HCC) had the highest incidence rate in WPSEA and lowest in North America. No significant differences were noted in the incidence rate of decompensated cirrhosis. Europe the lowest incidence of hypertension and type 2 diabetes, with North America having the highest incidence of hypertension and WPSEA having the highest incidence of type 2 diabetes. Overall incidence of cardiovascular events was highest in NA and lowest in WPSEA. Individual cardiovascular events (coronary artery disease/congestive heart failure, myocardial infarction, and stroke) showed no significant differences between regions along with renal impairment (table). No significant differences were observed in the incidence rate of adverse events when comparing males and females: all-cause mortality (12.5 vs 8.79, p = 0.62), liver-related events (48.4 vs 49.6, p = 0.96), decompensated cirrhosis (37.4 vs 32.8, p = 0.54), HCC (3.5 vs 11.1, p = 0.37), fibrosis progression (48.9 vs 52.1, p = 0.87), CVD (30.8 vs 30.8, p = 0.99), type 2 diabetes (23.5 vs 22.3, p = 0.81), and non-liver cancer (10.7 vs. 7.6, p = 0.41). **Conclusion:** Geographical variations in the incidence of adverse clinical events were observed among those with NAFLD. Additionally, no significant differences in adverse event were observed by sex. A multidisciplinary team should be considered in the management of NAFLD patients to treat and prevent the multitude of complications associated with NAFLD.

	Incidence rate per 1,000 person-years			
	Europe	North America	Western Pacific/ Southeast Asia	p-value

2249-C | RELATIONSHIP BETWEEN LIPOPROTEINS AND LIVER ENZYMES IN A PRIMARY CARE AND ENDOCRINOLOGY COHORT OF 246,252 PATIENTS

Mohammad S. Siddiqui, Virginia Commonwealth University, Michael Silver, Labcorp, Margery Connelly, University of Florida and Arun Sanyal, Division of Gastroenterology, Hepatology, and Nutrition, Virginia Commonwealth University, Richmond, VA

Background: Liver plays a central role in lipoprotein metabolism and is a key driver of atherogenesis. This relationship is best described in patients with non-alcoholic fatty liver disease (NAFLD) where cardiovascular disease is the leading cause of mortality. The published literature evaluating atherosclerosis in liver disease suffers from relatively small sample size and ascertainment bias, thus, limiting their interpretation on a larger scale such as primary care. Therefore, the aim of the current study was to better delineate the relationship between serum atherogenic risk and liver disease in a large primary care cohort. **Methods:** This retrospective study used anonymized Labcorp data of adult patients who had blood testing mostly in a primary care setting from Feb 2021 to Feb 2023. Atherogenic risk was quantified via NMR-based measurements of LDL, VLDL and HDL particle concentrations. To better understand the relationship between LDL-C based goals and atherogenic risk, the cohort was divided into LDL-C based targets (LDL < 70, 70-100, 100-130, and > 130 mg/dL). Liver disease was defined as elevated ALT (> 19 and > 31 IU/L in women and men, respectively). As cirrhosis and alcohol use can affect lipoprotein metabolism, a sensitivity analysis was performed where patients with ALT:AST < 1 were excluded. **Results:** A total of 246,252 patients met entry criteria (n = 80,848 with elevated ALT). Serum atherogenic lipoprotein concentrations (large VLDL, small LDL, and HDL particles) were significantly higher among patients with elevated ALT. Across the LDL-C thresholds, patients with elevated ALT had more atherogenic lipoproteins characterized by higher concentrations of pro-atherogenic small dense LDL and large VLDL particles and reduced levels of anti-atherogenic HDL particles (Figure 1; bar and line graphs represents % absolute values, respectively). A stepwise increase in the atherogenic profile was noted from lowest to highest LDL category, which were further exacerbated in patients with elevated ALT. In sensitivity analysis (excluding patients with ALT:AST < 1), the relationship between elevated ALT levels and higher concentrations of pro-atherogenic and lower concentrations of anti-atherogenic lipoproteins was re-demonstrated. **Conclusion:** In a large, community-based cohort, elevation in liver enzymes was closely associated with a more pro-atherogenic lipoprotein profile. These findings persisted in sensitivity analysis, suggesting these findings are likely related to underlying NAFLD.

2250-C | RELATIONSHIP OF BODY MASS INDEX TO INCIDENT MAJOR ADVERSE CARDIOVASCULAR EVENTS AND INCIDENT LIVER-RELATED OUTCOMES IN PATIENTS WITH BIOPSY-PROVEN NONALCOHOLIC FATTY LIVER DISEASE

Robert M Wilechansky[1], Prasanna K Challa[1], Marc S. Sherman[1], Jennifer E. Bevan[1], Raymond T. Chung[2] and Tracey G. Simon[1], (1)Massachusetts General Hospital, (2)Massachusetts General Hospital, Boston, MA

Background: NAFLD in nonobese individual's is increasingly recognized, and its outcomes are not well-defined. We sought to compare rates of incident major cardiovascular events (MACE) and liver-related outcomes in patients with biopsy-proven NAFLD of varying body mass index (BMI) in a hospital network-based cohort. **Methods:** We identified all adults with biopsy-confirmed NAFLD in the Mass General Brigham health network, between 1999 and 2021, using a validated natural language processing (NLP) algorithm. BMI was categorized into nonobese (BMI < 30), World Health Organization (WHO) class I obesity (BMI 30-34), and WHO class II/III obesity (BMI e 35). Outcomes were defined by ICD-9/ICD-10 codes and included incident MACE (composite hospitalization for myocardial infarction, heart failure, cerebrovascular disease, or peripheral vascular disease) and incident liver-related events (cirrhosis, hepatocellular carcinoma, or advanced liver disease). Cox proportional hazards models were used to estimate multivariable-adjusted hazard ratios (aHRs) and 95% confidence intervals (CI) for study outcomes, accounting for age, sex, diabetes, hypertension, aspirin use, statin use, liver fibrosis stage, and smoking status. **Results:** Among 1624 patients included in the study, 54% were female, with mean age 48 and mean BMI 31.5 kg/m^2; 53% had nonalcoholic steatohepatitis (NASH) on liver biopsy. Compared to the nonobese reference group, we observed significantly higher rates of incident MACE in patients with class 1 obesity (aHR 1.34, 95% CI 1.05-1.72), and in those with class II/III obesity (aHR 1.34, 95% CI 1.02-1.77). In subgroup analyses, the excess CVD risk associated with obesity was most pronounced in patients with NASH, compared to the nonobese reference group (class I obesity aHR 1.73, 95% CI 1.20-2.48; class II/III obesity aHR 1.59, 95% CI 1.08-2.34). In contrast, among patients without NASH, no significant differences in risk of MACE were found across BMI categories. There was no difference in rates of liver-related outcomes, including cirrhosis, hepatocellular carcinoma, and advanced liver disease according to BMI category. **Conclusion:** In a large cohort with biopsy-proven NAFLD, obesity was significantly associated with

increased incidence of MACE. This risk was particularly pronounced in patients with NASH and obesity. There was no difference in the risk of liver-related outcomes across BMI categories. Further confirmatory analyses may impact CVD prevention strategies in this patient population.

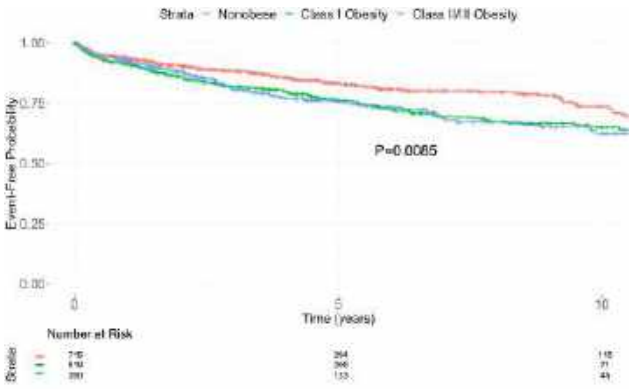

Figure 1: Kaplan-Meier estimator depicting CVD event-free probability in each BMI category over the duration of follow up in all participants. The overall log-rank test p-value is shown. CVD: cardiovascular disease; BMI: body mass index.

2251-C | RISK OF FATTY LIVER AND HEPATIC FIBROSIS ASSOCIATED WITH LONG-TERM USE OF TAMOXIFEN OR ANASTROZOLE MAY BE OVERESTIMATED IN PATIENTS WITH BREAST CANCER

Mateus Jorge Nardelli[1], Mísia Joyner De Sousa Dias Monteiro[1], Guilherme Grossi Lopes Cancado[1], Tereza Fontes Cal[2], Adriana Maria Lamego Rezende[1], Julia Cunha Vasconcelos[1], Carolina Martins Vieira[1], Paulo Henrique Costa Diniz[1], Juliana De Assis Silva Gomes Estanislau[1], Luciana Faria[1] and Claudia Alves Couto[3], (1)Universidade Federal De Minas Gerais, (2) Universidade Estadual De Campinas, (3)Universidade Federal De Minas Gerais, Belo Horizonte, Brazil

Background: Nonalcoholic fatty liver disease (NAFLD) is highly prevalent among women with breast cancer, particularly those who receive hormone therapy such as tamoxifen and anastrozole. While the survival rates of breast cancer patients have increased, the impact of endocrine therapy on the severity and progression of NAFLD in the long term remains unclear. This study aimed to assess the prevalence and severity of NAFLD in relation to adjuvant hormone therapy in patients with breast cancer, and to investigate the risk factors associated with its occurrence and progression. **Methods:** Cross-sectional study of women with breast cancer recruited from an oncology outpatient clinic. Abdominal ultrasound was used to detect liver steatosis, and transient elastography was used to evaluate hepatic fibrosis. Patients with metastatic disease were excluded. The patients were divided into three groups: no hormone therapy, those exposed to anastrozole, and those exposed to tamoxifen (current or interrupted). **Results:** A total of 233 patients with a mean age of 57 ± 10 years were enrolled, with a follow-up period ranging from 1 to 315 months (median 47, interquartile range [IQR] 79). Comorbidities included diabetes mellitus (22.8%), arterial hypertension (49.1%), dyslipidemia (25.3%), and obesity (44.2%). Of the patients, 71 (30.5%) did not receive hormone therapy, 20 (8.6%) were exposed to anastrozole for a median duration of 24 months (IQR 27), and 142 (60.9%) were exposed to tamoxifen for a median duration of 34 months (IQR 46). Liver steatosis was detected in 56.2% of the patients, with no significant differences between the three groups ($p = 0.340$). Liver stiffness was also similar between groups, with a median of 5.2 (IQR

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

2.2) kPa (p = 0.515), 9.9% of patients having liver stiffness e 8 Kpa (p = 0.372), and 5.0% of patients having a measurement e 12 Kpa (p = 0.338). Body mass index (BMI) and diabetes mellitus were independently associated with liver steatosis, while only BMI positively correlated with advanced fibrosis (liver stiffness e 8 kPa), even after adjustment for hormone therapy duration. **Conclusion:** More than half of the breast cancer patients had fatty liver disease, with around 10% having liver stiffness e 8 Kpa. Common metabolic risk factors, such as body mass index and diabetes mellitus, were independently associated with the occurrence and progression of NAFLD in breast cancer patients, regardless of hormone therapy exposure. The risk of NAFLD progression induced by tamoxifen and anastrozole seems to have been previously overestimated.

2252-C | SEATTLE MODEL: A NEW NON-INVASIVE SYSTEM BASED ON MACHINE LEARNING MODELS TO IDENTIFY ADVANCED FIBROSIS IN PATIENTS WITH MAFLD

Srikrishna Gurumurthy, Tesla STEM High School and Pankaj Rajvanshi, Swedish Medical Center

Background: Screening for advanced fibrosis (AF) in patients with non-alcoholic fatty liver disease (NAFLD) patients with type 2 diabetes mellitus (T2DM), also called metabolic-associated fatty liver disease (MAFLD), has been recommended. With the magnitude of the problem, resource constraints, costs, and complications of various tests; non-invasive tests that are inexpensive, easy to administer and have a high sensitivity (Sn) and positive predictive value (PPV) are needed. We have shown that machine learning models (MLMs) are superior to FIB-4 in the prediction of advanced liver fibrosis. Here, we report on a new model based on MLMs to predict advanced fibrosis in MAFLD. **Methods:** We analyzed data from the NIDDK NAFLD Adult database for 317 patients with NAFLD and T2DM (MAFLD) who had liver biopsy results available. We first created an MLM using an XGBoost model with 30 parameters. We then ran 5 random runs to identify the top 10 features, in rank of importance. We created our final model (called Seattle Model) using AST/ALT ratio, Platelet count, INR, and Waist Circumference. The performance of this model was internally validated in the dataset by splitting the data into training (20%) and validation (80%) datasets. The performance of Seattle Model was compared with FIB-4. **Results:** Among 317 patients in the NAFLD database, 298 (94%) had BMI > 27, 262 (82.6%) had a BMI > 30. Three features (AST/ALT ratio, Platelet Count, and INR) were consistent in 5 random runs of the initial model. The addition of waist circumference improved the performance of our model, and the final Seattle Model was created using these four parameters. It has an AUROC of 0.73, Sn 84.0%, specificity (Sp) 62.4%, PPV 71.4%, and a negative predictive value (NPV) of 78.1% for prediction of AF (e F3). For cirrhosis (F4), it has an AUROC of 0.783, Sn 91.4%, specificity (Sp) 79.3%, PPV 93.3%, and a negative predictive value of 47.9%. Comparison with FIB-4 is shown in Table 1. For AF (e F3), the Seattle Model was statistically superior ($p < 0.05$) to FIB-4 in AUROC, Sp and PPV. FIB-4 was statistically superior ($p < 0.05$) to the Seattle Model in Sn and NPV for F4 only. **Conclusion:** Seattle Model (a new MLM) is better than FIB-4 in prediction of advanced fibrosis and cirrhosis in patients with MAFLD. This new model for MAFLD needs further validation in larger datasets. Because of the excellent PPV of this model, further comparison of this model with imaging and blood tests may provide additional insights.

Table 1. Performance characteristics of Seattle Model compared to FIB-4 in the NIDDK NAFLD dataset.

Parameter	Seattle Model		FIB-4	
	≥F3	F4	≥F3	F4
Accuracy	0.74*	0.77	0.66	0.82
AUROC	0.73*	0.78*	0.64	0.70
Sensitivity	84%	77.4%	89%	91.4%*
Specificity	62.4%*	79.3%*	39.7%	49.6%
Positive Predictive Value	71.4%*	93.3%*	62.0%	87.2%
Negative Predictive Value	78.1%	48%	77%	61%*

2253-C | SIMULTANEOUS ASSESSMENT OF SKELETAL MUSCLE MASS AND HANDGRIP STRENGTH IDENTIFIES PATIENTS WITH NAFLD AT A HIGH-RISK OF ADVANCED LIVER FIBROSIS

David Sooik Kim[1], Pyo Hyeok Kwon[2], Jae Seung Lee[2], Hye Won Lee[2], Beom Kyung Kim[2], Jun Yong Park[2], Do Young Kim[2], Sang Hoon Ahn[2], Nikolaos T. Pyrsopoulos[1] and Seung Up Kim[2], (1)Rutgers University, New Jersey Medical School, Newark, NJ, (2)Yonsei University College of Medicine, Seoul, Republic of Korea

Background: Although sarcopenia is associated with multiple comorbidities, its diagnosis depends on

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

various diagnostic criteria with different diagnostic modalities. We investigated the association between appendicular skeletal muscle mass (ASM) measured by bioimpedance analysis (BIA) and handgrip strength (HGS) and identified the predictors of discordance between the two modalities in diagnosing sarcopenia. In addition, we investigated whether the combined use of the two diagnostic modalities identifies a high-risk subgroup among patients with nonalcoholic fatty liver disease (NAFLD). **Methods:** Between 2018 and 2023, 2,043 NAFLD patients with ASM by BIA and HGS were recruited. Sarcopenia was diagnosed when ASM/BMI < 0.882 in men and < 0.582 in women or by HGS < 28.9 kg in men and < 16.8 kg in women. Advanced liver fibrosis was defined as liver stiffness value by transient elastography greater than 9.6 kPa. **Results:** Among all patients, 794 (38.8%) and 200 (10.8%) patients had sarcopenia by BIA and HGS, respectively. ASM and HGS showed a positive correlation ($R = 0.79$, $P < 0.001$), that became more prominent when stratified by gender ($R = 0.96$) and by gender and age ($R = 0.98$) (all $P < 0.001$). In multivariate analysis, male gender (odds ratio [OR] = 1.3) and BMI (OR = 1.2) were the independent predictors of discordance between ASM and HGS in diagnosing sarcopenia ($P < 0.05$). Patients with sarcopenia both by BIA and HGS and those with sarcopenia by HGS only demonstrated a significantly higher probability of advanced liver fibrosis than that of patients without sarcopenia by both BIA and HGS (all $P < 0.001$). When adjusted for age, gender, HbA1c, platelet count, serum albumin, and total bilirubin, similar findings were observed (all $P < 0.05$). **Conclusion:** ASM by BIA and HGS showed a significant association and male gender and BMI were independently associated with the discordance between the two diagnostic modalities. In addition, the use of two diagnostic modalities was beneficial in identifying a high-risk population with advanced liver fibrosis among patients with NAFLD.

2254-C | SURGICAL MENOPAUSE IS ASSOCIATED WITH INCREASED PREVALENCE OF NONALCOHOLIC FATTY LIVER DISEASE: A SYSTEMATIC REVIEW AND META-ANALYSIS

Aunchalee Jaroenlapnopparat, Mount Auburn Hospital/Harvard Medical School, Ben Ponvilawan, University of Missouri-Kansas City School of Medicine, Pojsakorn Danpanichkul, Chiang Mai University, Jerapas Thongpiya, Texas Tech University Health Science Center and Suchapa Arayakarnkul, University of Minnesota

Background: Natural Menopause is associated with nonalcoholic fatty liver disease (NAFLD). However, data are inconsistent on whether surgical menopause is a risk of NAFLD. We aimed to collect all existing data to determine this association. **Methods:** Potentially eligible studies were identified from EMBASE, MEDLINE, and Web of Science databases from inception to April 2023 using a search strategy that was composed of the terms for "NAFLD" and "oophorectomy" or "surgical menopause". Eligible study must contain two groups of participants: one

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

group of postmenopausal women who underwent surgical menopause, and another group of premenopausal women. The study must report the association between surgical menopause and prevalent NAFLD. We extracted such data from each study and calculated pooled odds ratio (OR) by combining effect estimates of each study using a random-effects model. Funnel plot was used to assess for the presence of publication bias. **Results:** A total of 465 articles were identified. After two rounds of independent review by two investigators, 4 cross-sectional studies fulfilled the eligibility criteria. The meta-analysis of 4 studies revealed the significant association between surgical menopause (oophorectomy) and NAFLD with a pooled OR of 1.51 (95% CI, 1.31-1.74; $I^2 = 52\%$). The association remained significant in a sensitivity meta-analysis of 3 studies that reported the association with adjustment for age, BMI, diabetes status, and status of hormone use with a pooled OR of 1.39 (95% CI, 1.19-1.62; $I^2 = 0\%$). The funnel plot was fairly symmetric and was not suggestive of publication bias. **Conclusion:** The meta-analysis reveals that surgical menopause is associated with approximately 1.5 times higher odds of NAFLD. The association remains significant after adjusting for age, BMI, diabetes status, and status of hormone use.

2255-C | THE ASSOCIATION BETWEEN BASELINE ALCOHOL USE AND LONG-TERM RISK OF INCIDENT CIRRHOSIS AMONG A NATIONAL COHORT OF U.S. VETERANS WITH METABOLIC DYSFUNCTION ASSOCIATED FATTY LIVER DISEASE

Robert J. Wong[1,2], Zeyuan Yang[2], Ramsey Cheung[3], Ashwani K. Singal[4], Albert Do[5], Aijaz Ahmed[1] and Aaron Yeoh[6], (1)Stanford University School of Medicine, (2)VA Palo Alto Healthcare System, (3) Veterans Affairs Palo Alto Health Care System, (4) University of South Dakota, (5)Yale University, New Haven, CT, (6)Stanford University - School of Medicine

Background: Metabolic dysfunction associated fatty liver disease (MAFLD) is highly prevalent among U.S. adults, and particularly among U.S. Veterans, a population enriched in metabolic co-morbidities. The association between different levels of alcohol use and risk of disease progression among adults with fatty liver remains unclear, and data specifically in patients with MAFLD are lacking. We aim to evaluate the association between baseline levels of alcohol use and risk of incident cirrhosis among a national cohort of adult Veterans with MAFLD. **Methods:** Adults with MAFLD were identified using the national Veterans Affairs database from 1/1/2010 to 12/31/2022. Patients with cirrhosis or HCC at baseline or within 6 months after index date of MAFLD diagnosis were excluded. Baseline AUDIT-C scores were used to categorize patients into no alcohol (AUDIT-C = 0), low-risk alcohol (AUDIT-C = 1-2 for women and 1-3 for men), and high-risk alcohol (AUDIT-C > 3 for women and > 4 for men). Incidence of cirrhosis (per 100 person-years) was stratified by alcohol use categories and evaluated using Nelson-Aalen methods for estimating cumulative hazards rates. We applied competing risks methods that censored for death. Adjusted multivariate Cox proportional hazards models evaluated for predictors of cirrhosis. **Results:** Among 1,156,189 Veterans with MAFLD, 54.2% reported no alcohol use, 34.6% reported low-risk alcohol, and 11.2% high-risk alcohol. Compared to patients reporting no alcohol, high-risk alcohol users were younger (59.9y vs. 64.0y, $p < 0.01$), had lower proportion with diabetes mellitus (42.5% vs. 62.4%, $p < 0.01$), but had higher FIB-4 scores at baseline (proportion with FIB-4 > 2.67: 15.0% vs. 11.1%, $p < 0.01$). Compared to MAFLD patients with no alcohol use, the incidence of cirrhosis was significantly higher in patients with high-risk alcohol (0.76 vs. 0.53 per 100 person-years, $p < 0.01$), but significantly lower in patients with low-risk alcohol use (0.42 vs. 0.53 per 100 person-years, $p < 0.01$). On adjusted multivariate regression, compared to MAFLD patients with no alcohol use, those with high-risk alcohol use had significantly greater risk of cirrhosis (HR 1.27, 95% CI 1.23-1.32), whereas those with low-risk alcohol use had lower risk of cirrhosis (HR 0.89, 95% CI 0.86-0.91). **Conclusion:** Among a national cohort of U.S. veterans with MAFLD, high-risk alcohol use was associated with significantly higher risk of incident cirrhosis, whereas low-risk alcohol use as determined by AUDIT-C scores, was associated with lower risk of incident cirrhosis when compared to patients reporting no alcohol use.

2256-C | THE ASSOCIATION BETWEEN SUGAR-SWEETENED BEVERAGE CONSUMPTION AND NAFLD SEVERITY MEASUREMENTS

Sameer Khan[1], Laura Wilson[2], Patricia Belt[2], Jeanne M Clark[1], Jeffrey Schwimmer[3], David E Kleiner[4], Emily P. Sharkey[2], James Tonascia[2], Laura A. Miriel[2], Rohit Loomba[5] and Tinsay A. Woreta[6], (1)Johns Hopkins University School of Medicine, (2)Johns Hopkins School of Public Health, (3)UC San Diego, (4) Laboratory of Pathology, National Cancer Institute, Bethesda, MD, (5)University of California, San Diego, San Diego, CA, (6)Johns Hopkins Medicine, Baltimore, MD

Background: The consumption of sugar-sweetened beverages (SSBs) has been shown to be a risk factor for diabetes and obesity. Prior literature examining the association between SSB consumption and NAFLD is based on small, retrospective studies. In this study, we aim to assess the relationship between the intake of SSBs and NAFLD severity using a large, diverse population of adults with biopsy proven NAFLD in the U.S. **Methods:** We studied adult participants from the NASH CRN longitudinal cohort database who underwent vibration controlled elastography (FibroScan) within 6 months of liver biopsy and completed the Beverage Questionnaire (BEVQ-15) at study entry. The BEVQ-15 is a validated food frequency questionnaire that allows for calculation of total SSB calories (kcals). Baseline characteristics were compared across three categories of SSB consumption, none (0 kcal), minimum to moderate (1-164 kcals), and high (>164 kcals). NAFLD severity was assessed by liver biopsy and FibroScan. Multivariable regression analyses were performed to assess the relationship between the severity of fibrosis and steatosis with SSB consumption (log transformed due to non-normality), controlling for age, sex, race/ethnicity, smoking, alcohol use, hypertension, diabetes, and obesity. **Results:** The 935 participants (60% female, 78% Caucasian) had a mean age of 51 years, mean BMI was 34.8 kg/m^2; and 76% had obesity. 241 (26%) did not consume any calories through SSBs, 462 (49%) consumed 1 to 164 kcal, and 232 (25%) consumed more than 164 kcal. On liver histology, 326 patients (35%) had advanced fibrosis (stage 3 or 4). The mean LSM was 12.0 ($\pm$10.6) kPa. The mean CAP score was 326 ($\pm$52) dB/m. Greater SSB consumption was associated with higher BMI as demonstrated by a mean BMI of 34.2 ($\pm$6.5), 34.4 ($\pm$6.5), and 36.0 ($\pm$7.2) kg/m^2 for the none, minimum to moderate, and high SSB groups, respectively ($p=0.003$). There was also a significant positive association between greater SSB consumption and higher CAP scores, with median (IQR) scores of 329 (285-360), 330 (294-363), and 343 (311-370) dB/m ($p=0.006$) for each consecutive SSB group (Figure 1). Multivariable linear regression analysis demonstrated that greater SSB consumption was positively associated with CAP score ($p=0.02$). However, no significant association was found between SSB consumption and liver stiffness as measured by Fibroscan or liver fibrosis or steatosis severity based on liver histology data. **Conclusion:** This study provides evidence that adults with NAFLD who consume higher amounts of SSBs have higher BMI and CAP scores. SSB consumption did not correspond with higher grade steatosis on histology, which may reflect sampling variability of liver biopsy. Our findings underscore the importance of SSBs as a potential target for lifestyle modification in managing NAFLD. Further research is needed to elucidate the long-term impact of SSB consumption patterns on the trajectory of the disease.

2257-C | THE ASSOCIATION OF FOOD INSECURITY WITH HEPATIC STEATOSIS VARIES BY BMI AMONG WOMEN LIVING WITH AND WITHOUT HIV INFECTION

Ani Kardashian[1], Ilya Golovaty[2,3], Fan Xia[4], Yifei Ma[4], Sheri D. Weiser[4,5], Anjali Sharma[6], Howard Minkoff[7], Audrey L. French[8], Michael Plankey[9], Adaora A Adimora[10], Ighovwerha Ofotokun[11], Margaret Fischl[12], Deborah Konkle-Parker[13], Eric C. Seaberg[14], Phyllis C. Tien[4] and Jennifer C. Price[4], (1)University of Southern California, Los Angeles, CA, (2)University of Washington School of Medicine, (3)VA Puget Sound Health Care System, (4)University of California, San Francisco, (5)Center for AIDS Prevention Studies, University of California, San Francisco, (6)Albert Einstein College of Medicine, (7)State University of New York Downstate Health Sciences University, (8) CORE Center/Stroger Hospital of Cook County, (9) Georgetown University Hospital, (10)University of North Carolina at Chapel Hill, (11)Emory University School of Medicine, (12)University of Miami Miller School of Medicine, (13)University of Mississippi Medical Center, (14)Bloomberg School of Public Health, Johns Hopkins University

Background: Food insecurity, a key social determinant of health, is a risk factor for hepatic steatosis in the general population. In people living with HIV, food insecurity is associated with worse HIV-related morbidity and metabolic parameters, including obesity and diabetes. However, little is known about the impact of food insecurity on the risk of hepatic steatosis among women with (WWH) and at risk for HIV infection. **Methods:** We measured hepatic steatosis using controlled attenuated parameter (CAP) and food security status using the U.S. Household Food Security Survey Module in women without viral hepatitis. Women with high food security were considered to be food secure and women with marginal, low, or very low food security were considered to be food insecure. Hepatic steatosis was defined as CAP ≥ 248 decibels/m. We performed multivariable logistic regression to examine the association of food insecurity with hepatic steatosis, adjusting for age, sex, race and ethnicity, body mass index (BMI), alcohol use, insulin resistance, and HIV status. Given the potential influence of obesity on the relationship between food insecurity and hepatic steatosis, we also tested for interactions between BMI and food insecurity. **Results:** Among 1533 women (1115 WWH, 418 without HIV), mean age was 50 years, 14% were White, 76% Black, 14% Hispanic, 10% were heavy drinkers, mean BMI was 30 kg/m^2, and 20% reported food insecurity. Participants with food insecurity were more likely to be White (18% vs 14%), heavy drinkers (13% vs 9%), and have a lower BMI (mean 29 vs 31). Food insecurity was associated with lower odds of hepatic steatosis in multivariable analysis (OR: 0.60, CI: 0.2-1.0, $p = 0.05$). We identified a significant interaction between food insecurity and BMI (low food security*BMI $p = 0.02$; very low food security*BMI $p = 0.01$). For every 1-unit BMI increase, there was a 14% (95% CI: 12% to 16%, $p < 0.001$), 10% (95% CI: 6% to 15%, $p < 0.001$), 8% (95% CI: 0.3-16%, $p = 0.001$) and 5% (95% CI: -1% to 11%, $p = 0.10$) greater odds of hepatic steatosis in the high, marginal, low and very low food security groups, respectively. Interestingly, food insecurity was associated with greater hepatic steatosis in women with BMI < 25 kg/m^2 and lower hepatic steatosis in overweight/obese women with BMI ≥ 25 kg/m^2 (Figure). **Conclusion:** In a racially and ethnically diverse cohort

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

of women with and without HIV, women who reported food insecurity with BMI < 25 kg/m^2 had higher odds of hepatic steatosis while women with BMI e 25 kg/m^2 had lower odds of hepatic steatosis. Our findings suggest that food insecurity, in the presence of other factors that might lower BMI, such as chronic inflammatory processes, could worsen hepatic steatosis whereas food insecurity may attenuate the effect of higher BMI on hepatic steatosis. This study lays the groundwork for future efforts exploring potential mechanistic pathways.

2258-C | THE CASCADE OF NAFLD CARE IN THE VA: A WINDOW OF OPPORTUNITY

Sebastian Niezen[1], Heather M. Patton[2], Timothy R. Morgan[3], Jasmohan S. Bajaj[4], Dawn Scott[5], Vera Yakovchenko[6], Yiwen Yao[7], Lauren A. Beste[8,9] and Shari S. Rogal[6,10], (1)University of Pittsburgh Medical Center, (2)VA San Diego Healthcare System, (3)VA Long Beach Healthcare System, (4)Virginia Commonwealth University and Central Virginia Veterans Healthcare System, (5)Central Texas VA Healthcare System, (6)VA Pittsburgh Healthcare System, (7)VA Salt Lake City Healthcare System, (8)VA Puget Sound Healthcare System, (9)University of Washington, (10)University of Pittsburgh

Background: Non-alcohol-related fatty liver disease (NAFLD) affects over one-third of the U.S. population. Yet, it remains challenging to identify patients most at risk for disease progression. As pharmacotherapies emerge, it is critical to understand the cascade of NAFLD diagnosis and care to maximize the benefits of and access to these agents. The aims of this evaluation were to 1) develop a VA cascade of NAFLD care and 2) assess the current management of NAFLD in the VA. **Methods:** Using the Corporate Data Warehouse, we identified Veterans with labs or ICD-10 diagnosis codes for NAFLD risk factors (i.e., obesity, diabetes, prediabetes, or dyslipidemia) from 2019 to 2022. We collected demographic characteristics, comorbidities, Fibrosis 4 index score (FIB-4), diagnosis of NAFLD or cirrhosis, use of VA weight loss programs, GLP1-RA prescription, and GI/ hepatology visits and used regression models to identify the factors associated with diagnosis codes for NAFLD or cirrhosis diagnosis and GI/hepatology visits. **Results:** 4,230,277 Veterans had NAFLD risk factors, among whom 6% had FIB-4 > 2.67, 5% had a NAFLD diagnosis; and 2% had a cirrhosis diagnosis. The ratio of NAFLD: cirrhosis diagnoses was 3:1, suggesting a large undiagnosed population. Factors significantly associated with documented NAFLD diagnosis included higher FIB-4, younger age, female sex, elevated ALT, metabolic comorbidities, and alcohol use disorder. Within the cohort, 252,048 (6%) were engaged with a VA weight loss program, 104,120 (3%) received a GLP1-RA prescription, and 371,217 (9%) were seen in GI/ hepatology. Having a NAFLD diagnosis was associated with significantly increased use of VA weight loss programs (5.3% vs. 12.5%, $p < 0.001$) and GI/hepatology visits (7.6% vs. 31.5%, $p < 0.001$). **Conclusion:**

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Nearly half of Veterans in VA care have risk factors for NAFLD and 6% have a high FIB-4. However, few are diagnosed with NAFLD or cirrhosis, indicating opportunities to identify additional cases of NAFLD. NAFLD and cirrhosis diagnoses were associated with engagement with VA weight loss program and GI/hepatology engagement. These data suggest the need to efficiently diagnose and triage the large number of people with NAFLD risk factors to ensure appropriate care, particularly with the emergence of new pharmacotherapies.

Table 1. Patient characteristics at risk of NAFLD in VA

	Total number of Veterans at risk for NAFLD	FIB-4<1.3	FIB-4 1.3-2.67	FIB-4>2.67	GI/Hepatology visit	Elevated ALT	GLP1-RA Prescription
	N = 4,250,277	N=1,716,729	N=1,538,466	N=247,733	N = 371,217	N = 760,484	N = 104,120
Diabetes	1,946,846 (46.0%)	784,694 (45.7%)	703,772 (45.7%)	117,259 (47.3%)	179,462 (48.3%)	358,583 (47.2%)	103,055 (99.0%)
Obesity	2,002,969 (47.3%)	898,496 (53.1%)	677,127 (44.7%)	88,437 (36.3%)	206,222 (55.6%)	477,423 (62.8%)	67,962 (65.3%)
Hyperlipidemia	2,650,462 (62.9.6%)	1,059,304 (62.7%)	1,043,965 (68.9%)	151,363 (62.1%)	253,817 (68.4%)	484,206 (63.7%)	74,666 (71.7%)
NAFLD diagnosis	207,529 (4.9%)	69,590 (4.1%)	68,491 (4.5%)	17,557 (7.2%)	57,126 (15.4%)	104,826 (13.8%)	9,252 (8.9%)
Cirrhosis diagnosis	86,092 (2.0%)	9,118 (0.5%)	22,289 (1.5%)	27,598 (11.3%)	36,073 (9.7%)	28,837 (3.8%)	2,933 (2.8%)

Background: NAFLD can be associated with disease burden and stigma to patients and providers. Aims: To understand the disease burden and stigma related to NAFLD. **Methods:** Members of the Global NASH Council created two surveys (68-item patient and 41-items provider survey) about experiences and attitudes toward NAFLD and related terms. **Results:** The surveys were completed by 895 NAFLD patients (19 countries) and 629 providers (64% GI/hepatologists, 23 countries). Of all patients, 64% ever disclosed having NAFLD to family/friends; the main term used was "fatty liver" (82%) while "metabolic disease" or "MAFLD" were rarely used (never by 88%). 35% of patients reported experiencing stigma or discrimination (at least sometimes) due to obesity/overweight and only 12% due to their liver disease of NAFLD. From the Liver Disease Burden (LDB) survey (35 items, 7 domains; range 1-4, higher scores indicate greater burden), the total mean burden score was the highest in USA (1.97 ± 0.57) and lowest in Middle East and North Africa (MENA) region (1.74 ± 0.53). The Stigma domain score was also the highest in the USA (2.51 ± 0.71) and the lowest in MENA (1.84 ± 0.60). In multivariate analysis adjusted for country of enrollment, independent predictors of higher total LDB and Stigma scores were female sex, living outside urban areas, history of medical weight loss, having e 2 chronic comorbidities, and having severe fibrosis or cirrhosis ($p < 0.05$). Regarding how various diagnostic terms were perceived by patients, there were no substantial differences between "NAFLD", "fatty liver disease", "NASH", or "MAFLD" (Figure). In contrast, provider discomfort while taking care of patients with NAFLD was primarily related to the perceived patients' lack of willpower for lifestyle changes and taking care of their diabetes (43-48%). Furthermore, 40% of providers believed that the word "fatty" in the name of the disease was stigmatizing for patients (similar across regions and specialties) while 35% believed that the term "non-alcoholic" was stigmatizing (more commonly in the MENA region and among GI/hepatologists). Finally, 45% of providers (49% GI/hepatologists vs. 36% other specialties) believed that a name change may reduce the disease stigma. **Conclusion:** Drivers of stigma and disease burden varies between NAFLD patients, providers, and regions of the world. Female sex, non-urban living, comorbidities (cirrhosis, and medical weight loss) are predictors of greater disease burden and stigma scores in patients with NAFLD.

2260-C | THE PREVALENCE AND CLINICAL CHARACTERISTICS OF CHINESE ADULTS WITH METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE

Ming Yang[1], Huixin Liu[2], Shunmin Guo[3], Pingqiu Shen[3], Ying Qiao[3], Wurong Chen[3], Yanqiu Gu[3], Rao Teng[3], Guiping Li[3], Jianzeng Qin[3], Xiaoran Yang[3], Zhi Qi[3], Yi Feng[3], Mengqi He[3], Zhe Liu[3], Wenyao He[3] and Lai Wei[1], (1)Hepatopancreatobiliary Center, Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, (2)Department of Clinical Epidemiology and Biostatistics, Peking University People's Hospital, (3)Meinian Onehealth Healthcare Holding Co., Ltd

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) is a newly proposed diagnosis which is different from nonalcoholic fatty liver disease (NAFLD). We aimed to investigate the prevalence and clinical characteristics of Chinese adults with MAFLD. **Methods:** We consecutively enrolled 2,019 Chinese adults in 31 health check-up centers from 11 cities in 2022. A detailed questionnaire and the results of blood biochemical examinations and transient elastography were collected. **Results:** The prevalence of MAFLD and NAFLD among the health examination cohort was 45.8% (925 of 2019) and 42.6% (861 of 2019) ($P = 0.43$). The prevalence of MAFLD among subjects with BMI < 23, 23-24.9 and e 25 kg/m^2 was 9.25%, 43.95% and 77.88%, respectively. The corresponding prevalence of NAFLD was 16.30%, 39.53% and 66.47%, respectively. The proportions of subgroup 1 (overweight/obese), 2 (lean/normal weight with metabolic abnormalities), and 3 (diabetes) in the MAFLD subjects were 92.8%, 6.9%, and 13.4%, respectively. The mean age of MAFLD subjects was 45.8 years, and 65.9% subjects were male. 13.4%, 31.4%, and 41.3% of MAFLD subjects had diabetes mellitus, hypertension, and metabolic syndrome. Compared with NAFLD subjects, MAFLD subjects had higher

body mass index, waist circumference, liver enzymes, triglyceride, but similar AST-to-platelet ratio index, Fibrosis-4 index, NAFLD fibrosis score and liver stiffness measurement. **Conclusion:** MAFLD is highly prevalent in the general population. The definition of MAFLD may better reflect the pathogenesis related to metabolism but not improve the identification of patients at risk for fibrosis.

2261-C | THE ROLE OF HDL-CHOLESTEROL ON THE DEVELOPMENT OF LIVER FIBROSIS IN PATIENTS WITH NASLD

Hideki Fujii, Osaka Metropolitan University, Yoshihiro Kamada, Osaka University Graduate School of Medicine, Miwa Kawanaka, Kawasaki Medical School, Hirokazu Takahashi, Division of Metabolism and Endocrinology, Faculty of Medicine and Yoshio Sumida, Aichi Medical University

Background: The impact of HDL-cholesterol (HDL-C) on liver fibrosis in patients with nonalcoholic steatohepatitic liver disease (NASLD) remains unknown. We examined the role of HDL-C in patients with NASLD using data from a multicenter registry. **Methods:** This study was one of the sub-analyses of the CLIONE (Clinical Outcome Nonalcoholic Fatty Liver Disease) study. CLIONE study is a multicenter, registry-based, retrospective cohort study from fifteen hepatology centers in Japan. We identified 1,204 patients with biopsy-proven NASLD from for whom baseline HDL-C levels were recorded between 1994 and 2020. Liver biopsy specimens were digitized, pathologically diagnosed, and histologically scored using the NASH Clinical Research Network system. Stages 3 and 4 were defined as advanced fibrosis. **Results:** Clinical characteristics of the patients (N = 1,204) were as follows: median (interquartile range) age; 57 (45-66) years, male 520 (43%), BMI; 27.4 (24.9-30.8) kg/m^2, platelet count; 214 (176-262) $\times 10^9$/L, diabetes mellitus (DM); 441 (37%), presence of NASH; 792 (66%), and advanced fibrosis; 191 (16%). When a cutoff of 40 mg/dL of HDL-C is used, the low HDL-C group had significantly lower age [52.5 (38-64) vs. 58 (47-66), $P < 0.001$], higher proportion of males (60% vs. 38%, $P < 0.001$), higher percentage of DM (42% vs. 35%, $P = 0.037$), significantly lower albumin [4.3 (4.0-4.6) vs. 4.4 (4.1-4.6) mg/dL, $P < 0.001$] and platelet counts [209 (164-255) vs. 217 (179-264) $\times 10^9$/L, $P = 0.040$] than the high HDL-C group. Pathologically, the low HDL-C group had a significantly higher proportion of NASH (72% vs. 65%, $P = 0.027$) and a significantly higher proportion of advanced fibrosis (22% vs. 14%, $P = 0.004$) than the high HDL-C group. In a multivariate analysis using age, DM, presence of NASH, and gender as covariates, the low HDL-C group was significantly associated with advanced fibrosis [Odds ratio (95% confidence interval): 1.64 (1.14-2.37), $P = 0.008$]. **Conclusion:** Low HDL-C levels were an independent risk factor for advanced fibrosis in patients with biopsy-confirmed NASLD.

Variable (Reference)	HR (95%CI)	*P*-value
Age ≥65 years (<65 years)	1.71 (1.21–2.40)	**0.004**
Male (Female)	0.89 (0.63-1.26)	0.51
HDL-C<40 mg/dL (≥40 mg/L)	1.64 (1.14-2.37)	**0.008**
NASH (absence)	2.26 (1.52-3.36)	**<0.001**
DM (absence)	2.92 (2.11-4.03)	**<0.001**

Note: Significant results are highlighted in bold.

(1)Icahn School of Medicine at Mount Sinai, (2)Mount Sinai Institute for Liver Medicine, (3)Icahn School of Medicine at Mount Sinai (ISMMS), (4)Icahn School of Medicine at Mount Sinai, Englewood Cliffs, NJ, (5)Icahn School of Medicine at Mount Sinai, New York, NY

Background: The Mount Sinai NAFLD/NASH registry and biobank, launched in May 2022, is a longitudinal study aimed at identifying real-world factors related to fibrosis progression/non-progression and developing predictive algorithms for liver and cardiac clinical outcomes. Baseline profiles were characterized, and factors associated with advanced fibrosis stage identified. **Methods**: Patients who presented for standard of care visits for the management of NAFLD, and who had no evidence of other chronic liver diseases or excessive alcohol consumption were offered enrollment and consented. Baseline characteristics, including demographic information, lifestyle factors, fibrosis stage, comorbidities, metabolic profiles, and relevant laboratory values, were evaluated. Fibrosis stage was assessed using Fibroscan™ (F2: 8-10kPa; F3: 10-14kPa; F4: > 14kPa). Univariate ordinal logistic regression analyses were conducted to examine the association between baseline characteristics and the severity of fibrosis stage and simple logistic regression was performed to determine the association between baseline characteristics and advanced fibrosis stages (e F2 vs. F0/F1). **Results**: As of April 2023, 304 patients were included in the study. Mean age was 53.8 years (SD = 14.6) with 51% female. Racial/ethnic distribution consisted of Whites (24%), Black or African American (11%), and Asian (8%); 56% identified as Hispanic. 34% of patients were former or current smokers and 32% reported mild-moderate alcohol consumption. Almost 20% had cirrhosis, 40% had e F2 fibrosis, 61% were obese, and 42% had type 2 DM. In the ordinal logistic regression analysis, a statistically significant association ($p < 0.05$) was found between multiple variables and a higher odds of advanced fibrosis stage. These variables included age, BMI, obesity, FIB-4 score, SAFE score, GGT levels, MELD, TSH, IgA, and current medication use (Metformin, Aspirin, GLP-1, and PPI). Consistent associations were observed when comparing patients with e F2 fibrosis to F0/F1 (Table 1). **Conclusion**: In our diverse NAFLD registry, where 40% of patients had significant fibrosis, both expected predictors (e.g., high FIB-4) but also higher TSH, higher IgA, and PPI usage were associated with higher fibrosis stage. Data from this unique registry will enable real-world risk-stratification, sub-phenotyping, predictive modeling, and identification of patients who should be prioritized for emerging NASH therapeutics and HCC screening.

Table 1. Baseline characteristics of NASH registry and their association with fibrosis stage

2263-C | TWO YEARS OF WASTING WITH METABOLIC DISORDERS - INITIAL RESULTS ON MUSCLE COMPOSITION FROM THE LONGITUDINAL UK BIOBANK

Jennifer Linge[1,2], Mikael Fredrik Forsgren[1,2] and Olof Dahlqvist Leinhard[1,2], (1)Amra Medical AB, (2) Linköping University

Background: Adverse muscle composition (low muscle volume [MV] with high muscle fat infiltration [MFI]) assessed with magnetic resonance imaging (MRI) is common in general population (10%) and has been linked to poor functional performance, comorbidity, and all-cause mortality in non-alcoholic fatty liver disease (NAFLD), as well as increased hospitalization and all-cause mortality in general population. The aim of this study was to describe changes in muscle composition in different metabolic disorders in the longitudinal UK Biobank imaging study. **Methods:** 3761 participants were scanned twice approximately 2.2 years apart using a 6-minute MRI protocol. Images were analyzed for liver fat, fat-free MV and MFI of the thighs and spinal erectors using AMRA® Researcher, Linköping, Sweden. For each participant, a sex-, weight- and height invariant thigh MV z-score was calculated. Muscle composition changes were described in participants with NAFLD (without type 2 diabetes [T2D] and cardiovascular disease [CVD], AFLD (without T2D and CVD), T2D (without CVD), CVD (without T2D), comorbidity (T2D and CVD), and controls (without NAFLD, AFLD, T2D and CVD). Paired t-tests were used to test for significant changes within each group. Linear regressions adjusted for sex, baseline age and BMI, and weight change were used to test differences in change between controls and the other groups. **Results:** The cohort consisted of 51% females, with mean (SD) age 62.7 (7.3) years and BMI 26.2 (4.2) kg/m^2 at baseline. All groups were weight stable except AFLD and T2D that showed significant annualized weight loss (Table 1). All groups except the comorbidity group showed a significant decrease in hand grip strength, but none of the disease groups showed more rapid functional decline compared to the control group. Significant muscle wasting was observed for all groups (both reductions of MV and increases of MFI). Compared to the controls, NAFLD (without T2D and CVD) showed slower wasting (significantly less reduction of thigh MV z-score and increase in MFI), T2D showed larger loss of muscle volume (both thigh MV and MV z-score), while the comorbidity group showed larger increase of MFI (significantly so for anterior/posterior thigs). **Conclusion:** Significant changes in muscle composition (MV and MFI) can be observed across 2 years. Results indicate that individual's with metabolic disorders experience more rapid wasting and that different diseases may be associated with different wasting profiles.

2264-C | UNCOVERING THE GENETIC LINK: ASSOCIATION OF PNPLA3_rs738409 VARIANT WITH METABOLIC-ASSOCIATED FATTY LIVER DISEASE IN A SRI LANKAN POPULATION

Madunil Anuk Niriella[1], Anuradhani Kasturiratne[1], Dileepa Senajith Ediriweera[1], Shamila Thivanshi De Silva[1], Anuradha Supun Dassanayake[1], Arjuna Priyadrshin De Silva[1], Arunasalam Pathmeswaran[1], Ananda Rajitha Wickramasinghe[1], Norihiro Kato[2] and Hithanadura Janaka De Silva[1], (1)Faculty of Medicine, University of Kelaniya, Ragama, Sri Lanka, (2)National Center for Global Health and Medicine, Toyama, Shinjuku-Ku, Tokyo, Japan

Background: The PNPLA3_rs738409 variant has been identified globally as a potential genetic risk factor for non-alcoholic fatty liver disease (NAFLD). In the Ragama Health Study (RHS), a randomly selected population cohort of Sri Lankan adults, we have previously shown an association between the PNPLA3_rs738409 variant and NAFLD (OR = 1.25, 95% CI 1.08–1.44, P = 0.003) [1].

There is renewed interest in redefining fatty liver disease as metabolic-associated fatty liver disease (MAFLD). In this case-control study, we examined the association of the PNPLA3_rs738409 variant with MAFLD in the RHS population. **Methods:** The genotypes of the PNPLA3_rs738409 variant were determined using a polymerase chain reaction. In addition, the association of the PNPLA3_rs738409 variant with MAFLD vs controls was analysed using the Cochran–Armitage trend test. The genotype and allele frequencies of the PNPLA3_rs738409 variant were in Hardy-Weinberg equilibrium in MAFLD and control groups. **Results:** Genotype data of 3002 participants were analysed. There were 987 with MAFLD and 1212 controls. A significant association was observed for the PNPLA3 (rs738409) polymorphism with susceptibility to MAFLD (OR = 1.22, 95% CI 1.06–1.41, P = 0.006). Due to sample size limitation, there seems to be no significant differences in effect allele frequencies between NAFLD and MAFLD patients (OR = 0.98. 95% CI 0.85–1.14, P = 0.80). **Conclusion:** This study suggests that although the definitions of fatty liver disease (NAFLD and MAFLD) are phenotypically diverse, the genetic association with the PNPLA3_rs738409 variant and fatty liver seems consistent. **Reference**

2265-C | UNDERSTANDING THE INCREMENTAL COST OF NONALCOHOLIC STEATOHEPATITIS AND DIABETES USING ELECTRONIC HEALTH RECORDS AND CLOSED CLAIMS DATA

Jesse Fishman[1], Elliot B. Tapper[2], Stephen Dodge[1], Keith Miller[1], Dave Lewandowski[3], Alina Bogdanov[3] and Machaon Bonafede[3], (1)Madrigal Pharmaceuticals, (2)University of Michigan, (3)Veradigm

Background: Nonalcoholic steatohepatitis (NASH) and type 2 diabetes (T2D) are both linked to substantial healthcare casts. However, the incremental cost of each condition is not well understood. We, therefore, aim to quantify the incremental cost of NASH and T2D using real-world data. **Methods:** Patients with ≥ 2 diagnosis codes for NASH and/or ≥ 2 diagnosis codes for T2D were identified in electronic health records or claims between 1/1/2016 and 12/31/2021 in the Veradigm Integrated Dataset. Patients with viral hepatitis, alcohol-use disorder or alcoholic liver disease, type 1 diabetes, or gestational diabetes were excluded. Patients had to be ≥ 18 years old on the index date and have ≥ 24 months of continuous claims enrollment encompassing the index date (study period). The index date was the earliest diagnosis (after 1/1/2016) when the patient met all study criteria. Patients were stratified into 3 cohorts: NASH-only, T2D-only, and NASH+T2D. We calculated annualized costs from actual costs during the 24-month study period and then fit a generalized linear model, controlling for disease cohort, age, sex, and modified Charlson comorbidity index, to estimate the per year all-cause healthcare costs and incremental cost of adding T2D to a NASH diagnosis (or vice versa). Incremental costs were estimated by changing the disease indicator variable from NASH-only or T2D-only to NASH+T2D and observing the change in cost. **Results:** We identified 23,111 patients with NASH-only, 3,548,786 patients with T2D-only, and 30,339 patients with NASH+T2D. Mean (SD) age and percentage female was 52.1 (14.2) years and 57.4% for the NASH-only cohort, 62.0 (14.0) years and 56.4% for the T2D-only cohort, and 59.0 (12.2) years and 65.5% for the NASH+T2D cohort. First, we calculated adjudicated costs for all patients, and then, after excluding outliers (patients with costs in the top 1%) and selecting a random sample of 100,000 patients with T2D, the model-predicted mean cost per year was $7,668 for patients with NASH-only, $11,226 for patients with T2D-only, and $16,812 for patients with NASH +T2D. The incremental increase in cost per year of adding T2D to NASH was 63% (+$4,846) and the incremental increase in cost per year of adding NASH to T2D was 42% (+$4,692). **Conclusion:** Both NASH and T2D contribute to the high healthcare costs among patients with a dual diagnosis. Results from our analysis indicate that NASH comprises a higher portion of total healthcare costs among patients with NASH and T2D.

Table 1. All-Cause Healthcare Costs Per Year for Patients With Nonalcoholic Steatohepatitis (NASH) and/or Type 2 Diabetes (T2D)

Population	Mean Unadjusted Total Costs Incurred*	Mean Predicted Costs**	Mean Predicted Costs if cohort is now "NASH+T2D"	Incremental Costs of NASH+T2D or T2D+NASH
NASH-Only	$7,644	$7,668	$12,513	63%
T2D-Only	$11,515	$11,226	$15,917	42%
NASH+T2D	$16,120	$16,812	NA	NA

*Annualized costs incurred are calculated from actual paid medical claims during the study duration

**Predicted costs are modeled costs to estimate the comorbidity burden

2266-C | UNRAVELING THE PREVALENCE AND SUBGROUP PROPORTIONS OF LEAN NON-ALCOHOLIC FATTY LIVER DISEASE (NAFLD) IN THE UNITED STATES: A SYSTEMATIC REVIEW AND META-ANALYSIS

Anvesh Narimiti[1], Vinay Jahagirdar[2], Mithil Suresh Gowda[3], Moulika R Bandaru[3], Kaanthi Rama[4], Amrutha Jagaragallu[4] and Deepika Devuni[5], (1)Harvard School of Public Health, (2)University of Missouri Kansas City, (3)Saint Vincent Hospital, (4)Gandhi Medical College & Hospital, (5)UMass Chan Medical School

Background: Nonalcoholic fatty liver disease (NAFLD) is mainly seen in obese and/or individual's with type 2 diabetes mellitus. Lean NAFLD is defined as NAFLD in non-overweight individual's (BMI < 25 kg/m^2 or < 23 kg/m^2 in Asians). It is associated with higher cardiovascular, liver, and all-cause mortality compared to healthy individual's. Prevalence of lean NAFLD is as high as 19% in Asia. Several individual studies report the prevalence of lean NAFLD from various states in the United States (US). We aimed to look at the overall pooled prevalence of lean NAFLD in the US and pooled prevalence by sex and race, which has not yet been reported. **Methods:** Multiple databases, including MedLine and Embase, were searched from inception to April 2023. Outcomes of interest were pooled prevalence of lean NAFLD among NAFLD patients and among the general population, pooled proportion by sex and race, and pooled prevalence of comorbid conditions. Random effects model was employed. Freeman-Tukey double arcsine-transformed proportion was applied to stabilize variance. Sensitivity analysis was performed by omitting one study at a time. A cumulative meta-analysis in ascending chronological order of study year was also done to observe for changes in pooled prevalence over time. **Results:** Initial database search yielded 711 articles of which 11 were finally included. The cumulative study population was 68,931,874 patients. The pooled rates were as follows: prevalence of lean NAFLD among NAFLD patients 0.10 (0.08,0.12, $I^2 = 98.5\%$), prevalence among general population 0.01 (0.00,0.03, $I^2 = 99.9\%$). On subgroup analysis, pooled rates were as follows: Females 0.66 (0.56,0.75), Caucasians 0.69 (0.53,0.83), African Americans 0.03 (0.01,0.06), Hispanics 0.17 (0.05,0.35). Proportion of co-morbid conditions included diabetes 0.25 (0.11, 0.42), hypertension 0.22 (0.13,0.34) and hyperlipidemia 0.37 (0.12,0.66). Sensitivity analysis confirmed the robustness of our findings. Cumulative meta-analysis demonstrated a declining trend in lean NAFLD prevalence until the early 2000s followed by stabilization from 2016. No significant publication bias was detected, ensuring the reliability of our results. **Conclusion:** In the US the pooled prevalence of lean NAFLD among NAFLD patients is around 10% and among general population is around 1%. Prevalence of lean NAFLD among NAFLD patients appears to be lower in US than in the global population. Another noteworthy finding was the declining prevalence of lean NAFLD since the late 1980's, which may be due to the obesity pandemic contributing to increase in proportion of NAFLD individual's with obesity.

2267-C | UNRAVELLING THE LIVER-BRAIN CONNECTION: A TWO-SAMPLE MENDELIAN RANDOMIZATION STUDY INVESTIGATING THE CAUSAL RELATIONSHIP BETWEEN NAFLD AND CORTICAL STRUCTURE

Shitao Jiang, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College

Background: Non-alcoholic fatty liver disease (NAFLD) represents a growing public health concern due to its increasing prevalence, association with obesity and type 2 diabetes, and potential progression to advanced liver diseases. NAFLD has also been linked to cognitive decline and neuropsychiatric conditions, highlighting the possibility of a liver-brain axis. However, the causal relationship between NAFLD and cortical changes remains uncertain. This study aimed to explore the causal impact of NAFLD on cortical structures using a two-sample Mendelian randomization (MR) approach, providing crucial insights into the potential interaction between NAFLD and brain health. A better understanding of this relationship could have significant implications for preventing and treating cognitive deficits and neuropsychiatric disorders in patients with NAFLD. **Methods:** Summary data from genome-wide association studies (GWAS) for NAFLD were gathered from large-scale cohorts, ensuring a robust dataset for analysis. Surface area (SA) and cortical thickness (TH) measurements were derived from the Enhancing Neuro Imaging Genetics through Meta-Analysis (ENIGMA) Consortium magnetic resonance imaging (MRI) data of 33,992 participants. This extensive sample size increased the statistical power and generalizability of our findings.

The inverse-variance weighted (IVW) method served as the primary method for our analysis, while additional sensitivity analyses were conducted to detect potential heterogeneity and pleiotropy. These analyses included the MR Pleiotropy RESidual Sum and Outlier (MR-PRESSO), MR-Egger, and weighted median procedures, providing a comprehensive evaluation of the causal effect of NAFLD on cortical structures. **Results:** Our MR analysis revealed that NAFLD led to notable alterations in cortical structures, particularly in the pars orbitalis gyrus. This brain region plays a crucial role in cognitive functions, such as language processing and decision-making, which could be adversely affected by these structural changes. Specifically, genetically predicted NAFLD was linked to a decrease in TH ($\beta = -0.008$ mm, 95% CI: -0.013 mm to -0.004 mm, $P = 3.00 \times 10^{-4}$) within this region.

Importantly, no significant heterogeneity and pleiotropy were identified in our analysis. This finding strengthens the validity of our results and bolsters the argument for a causal relationship between NAFLD and cortical changes. **Conclusion:** The results of this two-sample MR study provide robust evidence for a liver-brain axis, as demonstrated by the causal association between NAFLD and changes in cortical structures. These findings emphasize the potential interaction between NAFLD and brain health, which could have far-reaching implications for preventing and treating cognitive deficits and neuropsychiatric conditions in patients with NAFLD.

2268-C | VALIDATION OF ALD/NAFLD INDEX TO DIAGNOSE AN ALCOHOL BASIS FOR STEATOHEPATITIS – MULTICENTER STUDY

Pongsakorn Tantigovit[1], Noppamate Preechathammawong[1], Mongkon Charoenpitakchai[1], Sombat Treeprasertsuk[2] and Sakkarin Chirapongsathorn[1], (1)Phramongkutklao Hospital and College of Medicine, (2)Chulalongkorn University, Bangkok, Thailand

Background: Distinguishing alcohol related liver disease (ALD) basis from a nonalcoholic fatty liver disease (NAFLD) basis for the clinical and histologic spectrum of steatohepatitic liver disease is difficult because of unreliability of alcohol consumption history. ALD/NAFLD Index (ANI) was create to diagnose ALD in patients with steatohepatitis. However, information regarding alcohol predictor is still lacking in outside North America populations. We aimed to validate a model to diagnose ALD in patients with steatohepatitis. **Methods:** A cross-sectional cohort study was performed at two tertiary care

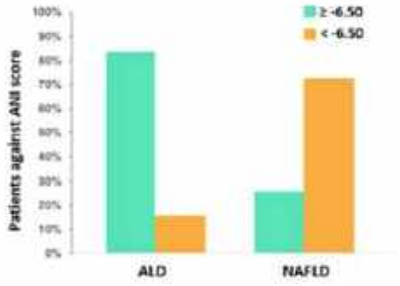
medical centers in Thailand, Phramongkutklao Hospital and King Chulalongkorn Memorial Hospital, to validate an ANI model using multivariable analysis and diagnostic accuracy of the test. This model was validated in 2 independent data sets comprising patients of varying severity of steatohepatitis spanning over 3 years. **Results:** Logistic regression identified mean corpuscular volume, aspartate aminotransferase (AST)/alanine aminotransferase (ALT) ratio, body mass index, and gender as the most important variables that separated patients with ALD from NAFLD. These variables were also used to validate in the ALD/NAFLD Index (ANI), with ANI of greater than -6.5 incrementally favoring ALD and ANI of less than -6.5 incrementally favoring a diagnosis of NAFLD, thus making ALD unlikely. ANI had a c-statistic of 0.879 in the validation sample. ANI performance characteristics were significantly better than several conventional and recently proposed biomarkers used to differentiate ALD from NAFLD, including the histopathologic feature, AST/ALT ratio, gamma-glutamyl transferase, and mean corpuscular volume of red cell. **Conclusion:** Regarding Asian patients, ANI accurately differentiates ALD from NAFLD in hospitalized, ambulatory, and pretransplantation patients and compares favorably with other traditional and proposed biomarkers.

Distribution of ANI score cut-off in ALD or NAFLD group corresponding ANI score



AUROC curve analysis in diagnosed Alcoholic liver disease

	ANI Cut-off	AUROC (95% CI)
ALD	-6.50	0.879 (0.794 – 0.964)

Diagnostic performance of ANI score (equal to -6.5)

	Sensitivity	Specificity	PPV	NPV	LR+	LR-	Accuracy
ANI	84 %	73.68 %	67.74 %	87.50 %	3.19	0.22	77.78 %

2269-C | VERY HIGH ELEVATION OF GAMMA-GLUTAMYL TRANSPEPTIDASE IN NASH CIRRHOSIS. A NEW PROGNOSIS FACTOR?

Pol Boudes, Galectin Therapeutics, Eric Lawitz, Texas Liver Institute, University of Texas Health San Antonio, San Antonio, TX, USA and Naga P. Chalasani, Indiana University Medical Center

Background: When monitoring patients with NASH, including NASH cirrhosis, an unexplained very high elevation of Gamma Glutamyl Transpeptidase VHGGT) is frequently encountered. Increased GGT has been linked to increased mortality in type 2 diabetes[1] and is associated with a worst prognosis in Primary Biliary Cholangitis[2]. We investigated patients with portal hypertension due to NASH cirrhosis to establish the frequency of VHGGT and whether this characteristic individualizes a clinically relevant subgroup of patients. **Methods:** The population consisted of 161 patients with NASH cirrhosis enrolled in a double-blind, placebo-controlled study of belapectin (NCT02462967). The mean age was 58.2 (8.4), 70% females. Cirrhosis was confirmed by liver histology (Ishak 5 or 6, Brunt F4) and the NAS score was reported. Portal hypertension was confirmed by a hepatic venous pressure gradient (HVPG) > 6 mm Hg. Liver stiffness was measured by Fibroscan. Patients had no current or recent history of alcohol consumption and no cirrhotic decompensation (varix bleeding, ascites, encephalopathy). Transaminases were < 10-fold the ULN, platelets e 60 000 / μL, and direct bilirubin < 2 mg/dL. There was no eligibility restriction on ALP and GGT. The definition of VHGGT was an elevation e 5-fold ULN (CTC Adverse Event grade 3 and above). **Results:** A VHGGT was present in 36/161 (22.4%) patients. Characteristics of interest between VHGGT and non-VHGGT patients are presented in the table. **Conclusion:** While patients with VHGGT may have some degree of cholestasis, the GGT increase is out of proportion with the increase in ALP and not associated with an increase in direct bilirubin. As a subgroup, VHGGT patients appears to be more cytolytic and have a higher degree of portal hypertension when compared to non-VHGGT patients. Further studies should establish the prognostic relevance of VHGGT. 1 Lee DY, et al. Sci Reports 2020;10:15375 2 Gerussi A, et al. Clin Gastroenterol Hepatol 2021;19:1688

2270-C | A RAT MODEL FOR METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE

Mutsumi Tsuchishima, Mikihiro Tsutsumi and Joseph George, Department of Hepatology, Kanazawa Medical University, Uchinada, Ishikawa 920-0293, Japan

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) is a major health problem worldwide. It is characterized by intense deposition of fat globules in the hepatic parenchyma and is accompanied with fibrosis that could potentially progress to liver cirrhosis and hepatocellular carcinoma (HCC). We developed a rat model to evaluate the molecular mechanisms associated with the pathogenesis of MAFLD and to screen appropriate modalities to prevent MAFLD. **Methods:** SHRSP5/Dmcr rats (spontaneously hypertensive rats / stroke prone) were fed a high-fat and cholesterol (HFC) diet for a period of 12 weeks and evaluated for the development of steatosis, steatohepatitis, fibrosis, and cirrhosis. The same set of control animals received normal diet. A group of animals were sacrificed at the end of the 4th, 6th, 8th, and 12th weeks from the beginning of the experiment. Blood and liver samples were collected for biochemical and histopathological evaluations. Immunohistochemical staining was performed for α-SMA, TNF-α, 4-hydroxy-2-nonenal (4-HNE), collagen type I, and type III. **Results:** Histopathology and trichrome staining demonstrated steatosis at 4th week, steatohepatitis with progressive fibrosis at 6th week, advanced fibrosis with bridging at 8th week, and cirrhosis *at* 12th week of HFC diet administration. Biochemical markers and immunohistochemical staining for α-SMA, TNF-α, 4-HNE, and collagens type I and type III demonstrated the progression of MAFLD from simple steatosis to liver cirrhosis. The animals that received normal diet did not show any biochemical or pathological alterations. **Conclusion:** The results of the current study demonstrated that HFC diet administration to SHRSP5/Dmcr rats is a good and reproducible animal model for MAFLD and is suitable to study the molecular mechanisms associated with the pathogenesis of MAFLD and to screen appropriate therapeutic modalities. *Email: georgej@kanazawa-med.ac.jp*

2271-C | ABHD5 OVEREXPRESSION PROTECTS PNPLA3-148M PRIMARY HUMAN HEPATOCYTES FROM STEATOSIS IN LIVER CHIMERIC MICE WITH NAFLD

Ype P de Jong[1], Mohammad Kabbani[2], Aditya Upadhyay[1], Chenhui Zou[1], Corrine Quirk[3], Maha Maaliki[2], Antonis Athanasiadis[4], Luis Chiriboga[5], Fulmer G Clifton[6] and Eleftherios Michailidis[4], (1)Weill Cornell Medicine, NY, (2)Mhh, (3)Rockefeller University, (4)Emory, (5)NYU, (6)Cleveland Clinic

Background: The methionine variant at position 148 of patatin-like phospholipase domain-containing protein 3 (PNPLA3-148M) is associated with advanced fatty liver disease. Previous studies have proposed a mechanism by which PNPLA3-148M sequesters alpha/beta-hydrolase domain containing 5 (ABHD5),

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

thereby impairing adipose triglyceride lipase (ATGL) activity on lipid droplets. Here we test the hypothesis that ABHD5 overexpression in primary human hepatocytes (PHH) with PNPLA3-148M can overcome sequestration and improve steatosis in liver chimeric mice with NAFLD. **Methods**: PHH from a homozygous PNPLA3-148M donor (PHH-148M) were lentivirally transduced with ABHD5 prior to transplantation into immunodeficient *Fah-/-* liver injury mice. To link the PNPLA3 genotype to steatosis, PNPLA3-148M and ABHD5 were co-transduced in PHH from a homozygous PNPLA3-148I donor (PHH-148I). After reaching peak liver humanization animals were challenged with a Western-style diet (WD, 60% kcal from lard, 23% sucrose, 0.03% cholesterol) and regular drinking water for four weeks. **Results**: PHH-148M developed more severe steatosis in response to WD than PHH-148I, which was confirmed in PNPLA3-148M transduced PHH-148I that, in addition, displayed widespread microvesicular steatosis. ABHD5 overexpression in PHH-148I did not affect steatosis. In contrast, ABHD5 overexpression in PHH-148M resulted in > 4-fold lower steatosis compared to control mice. While ABHD5 minimally improved steatosis in PNPLA3-148M transduced PHH-148I, it nearly completely resolved microvesicular steatosis. **Conclusion**: These findings support a model where sequestration of ABHD5 by PNPLA3-148M impairs triglyceride lipolysis by ATGL, leading to excess steatosis upon hypercaloric feeding. Overexpression liver chimeras with PHH-148I or PHH-148M grafts provide mechanistic insights on how PNPLA3 and ATGL maintain human lipid homeostasis under hypercaloric conditions.

2272-C | ACCELERATION OF AN ADVANCED NASH MODEL BY ACUTE AND TOXIC EFFECTS OF PHENOBARBITAL

Nico Kraus[1], Magnus Moeslein[1], Robert Schierwagen[1,2], Wenyi Gu[1,2], Maximilian Joseph Brol[1,2], Frank Erhard Uschner[1,2], Pierre-Emmanuel Rautou[3,4], Sophie Lotersztajn[5,6], Roger Flores-Costa[7], Joan Claria[7,8], Jonel Trebicka[1,2,8] and Sabine Klein[1,2], (1)University Hospital Frankfurt, (2)University Hospital Münster, (3)Hôpital Beaujon, (4)Université Paris-Cité, (5)Inserm, (6)Sorbonne Paris Cité, (7)Hospital Clínic-Idibaps, Barcelona, Spain, (8)European Foundation for the Study of Chronic Liver Failure

Background: Non-alcoholic steatohepatitis (NASH) is an increasing cause for liver cirrhosis globally. NASH-cirrhosis is responsible for liver related complications and no specific treatment is currently available. Animal models for the development of new therapeutic approaches are an unmet need. The aim of this study was to develop ananimal model of advanced NASH-cirrhosis in rats mimicking the human situation in a shorter period of time. **Methods:** Liver cirrhosis was induced by repetitive carbon tetrachloride (CCl_4) injections in combination with high fat and high-cholesterol western diet (WD). To boost liver injury animals received Phenobarbital in the drinking water using a short-term (ST) high (3d of 0.3g/L) or a long-term (LT) low dose (6 wks of 0.06g/L) treatment. **Results:** Rats developed advanced NASH-cirrhosis characterized by blood biochemistry, hepatic steatosis, inflammation and fibrosis. However, LT rats showed ascites as a definite sign of portal hypertension after around 6 weeks, whereas ST rats developed ascites after a median of 8 weeks. All rats showed increased portal pressure and concomitantly a decreased systemic arterial pressure compared to CCl_4 alone. Whereas all rat models develop NASH cirrhosis, only rats with LT treatment developed hepatocyte ballooning, which is a sign of parenchymal cell damage/death and also present in human NASH cirrhosis. **Conclusion:** The LT administration of low dose Phenobarbital in combination with CCl_4 intoxication and WD represents a novel rat model with accelerated development of advanced liver fibrosis mimicking all key characteristics of decompensated NASH-cirrhosis in humans.

2273-C | ACMSD INHIBITION REDUCES HEPATIC INFLAMMATION AND FIBROSIS IN A MURINE THERMONEUTRALITY MODEL OF NASH

Yasmine Liu[1], Masaki Kimura[2], Sandra Rodríguez-López[1], Angelique M.L. Scantlebery[3], Keno Strotjohann[1], Xiaoxu Li[1], Krisztian Homicsko[4], Archana Vijayakumar[5], Robert P. Myers[5], Maroun Bou-Sleiman[1], G. Mani Subramanian[5], Riekelt H Houtkooper[3], Takanori Takebe[2] and Johan Auwerx[1], (1)École Polytechnique Fédérale De Lausanne, (2) Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Amsterdam University Medical Center, Amsterdam, Netherlands, (4)Lausanne University Hospital, (5)Orsobio, Inc

Background: α-amino-β-carboxymuconate-ε-semialdehyde decarboxylase (ACMSD) is a branch point enzyme in the *de novo* NAD+ biosynthetic pathway in liver and kidney. TLC-065 is a potent ACMSD inhibitor that enhances fatty acid oxidation, and reduces *de novo* lipogenesis (DNL), lipotoxicity, and oxidative stress in murine hepatocytes and induced pluripotent stem cell (iPSC)-derived, steatotic human liver organoids (sHLO)[1]. Here, we evaluated therapeutic efficacy of TLC-065 in a murine model of NASH and assessed ACMSD expression in carriers of the glucokinase regulatory protein (GCKR) TT risk variant, which is characterized by increased DNL and NASH susceptibility[2]. **Methods:** C57BL/6J mice fed a western diet (WD) or chow were housed at thermoneutrality (TN; 30°C) for 23 weeks and treated with TLC-065 (25 mg/kg/day dosed in WD) from week 9-23. Hepatic fibrosis and inflammation were assessed histologically. *ACMSD* expression was assessed in HLO (+ oleic acid) derived from, and livers of, GCKR CC (ref) or TT carriers. **Results:** In the WD/TN mouse model, TLC-065 was well-tolerated over 14 weeks of dosing and led to pronounced NASH regression, evidenced by normalization of hepatic inflammation and fibrosis to levels observed in chow mice without affecting hepatic steatosis (Fig A). Decreased abundance of non-parenchymal cells including Kupffer cells and stellate cells were seen in liver transcriptome analysis (Fig B). *ACMSD* transcript levels were significantly higher in GCKR TT donor sHLO (Fig C) and with increasing NAS score in NASH subjects which was also associated with presence of the GCKR TT variant (Fig D). **Conclusion:** ACMSD inhibition reduced fibrosis and inflammation in a mouse TN model of NASH. Further, ACMSD expression was significantly increased in the presence of the GCKR TT risk variant which has increased NASH susceptibility providing an opportunity for precision medicine. In sum, these data support the development of novel ACMSD inhibitors to treat liver injury due to NASH and other etiologies. 2274-C | ADIPOSE TISSUE NAT10 IS ESSENTIAL FOR THE DEVELOPMENT OF NAFLD

Qianren Zhang[1], Rui Xue[1], Ren Tianyi[1] and Jiangao Fan[2], (1)Department of Gastroenterology, Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, (2)Department of Gastroenterology, Xinhua Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai 200092, China

Background: Adipose tissue dysfunction has been closely linked with nonalcoholic fatty liver disease (NAFLD), but the underlying mechanisms remain to be elucidated. N-4 cytidine acetylation (ac4C) is a novel epi-transcriptomic modification catalyzed by N-acetyltransferase 10 (NAT10). Our preliminary

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

experiment showed that 12-week HFD feeding induced significant upregulation of NAT10 in mouse epididymal fat. Here, we aimed to investigate the significance of adipose NAT10 in NAFLD development. **Methods:** Adipocyte-specific *Nat10*-knockout mice (*Nat10*^{AKO}) and wild-type littermates (*Nat10*$^{fl/fl}$) were fed with HFD (60% fat) for 16 weeks to induce NAFLD. After NAFLD modeling, all mice were euthanized for morphological, biochemical, histopathological and metabolic evaluations. Transcriptomic-wide mapping of ac4C modification was performed on mRNA samples isolated from primary epididymal adipocytes, with the aid of RNA-seq and acetylated RNA immunoprecipitation sequencing (acRIP-seq). **Results:** While being fed with HFD, *Nat10*^{AKO} mice gained much more weight than *Nat10*$^{fl/fl}$ mice and significant differences began to appear since week 3 of HFD feeding. After 16-week HFD feeding, glucose tolerance and insulin tolerance were improved in*Nat10*^{AKO} mice when compared with *Nat10*$^{fl/fl}$ mice. Due to metabolic chamber records, *Nat10*^{AKO} mice showed markedly higher oxygen consumption, carbon dioxide production, respiratory exchange ratio, heat production and movement than *Nat10*$^{fl/fl}$ mice. In addition, fasting *Nat10*^{AKO} mice had significantly lower levels of triglyceride, cholesterol, free fatty acids, insulin, glucose and leptin in serum when compared with fasting *Nat10*$^{fl/fl}$ mice. Masses of epididymal white adipose tissue, inguinal white adipose tissue, brown adipose tissue and liver were significantly smaller in *Nat10*^{AKO} mice than *Nat10*$^{fl/fl}$ mice. According to histological analyses, *Nat10*^{AKO} epididymal adipocytes were not only smaller in size than *Nat10*$^{fl/fl}$ epididymal adipocytes, but also infiltrated with fewer macrophages and neutrophils, which was in line with the downregulation of proinflammatory cytokines. Moreover, hepatic steatosis was remarkably reduced in *Nat10*^{AKO} mice than *Nat10*$^{fl/fl}$ mice. Combined analysis of RNA-seq and acRIP-seq demonstrated that *Nat10* deletion in adipocytes led to reduced ac4C abundance in cyclin A2 (*Ccna2*) and cyclin-dependent kinase 2 (*Cdk2*) mRNAs, which further decreased mRNA stability and transcriptional efficacy. Lower expressions of CCNA2 and CDK2 in *Nat10*^{AKO} adipocytes arrested cell cycle progression, thereby inhibiting adipogenesis. Besides, reduced ac4C modifications in *Pparg*, *Dgat1*, and *Srebp1c* mRNAs also contributed to *Nat10*^{AKO} phenotypes via hindering lipogenesis, adipocyte maturation and adipocyte proliferation. **Conclusion:** Elevated adipocyte NAT10 expression serves as an important pathogenic factor as well as a potential therapeutic target of NAFLD.

2275-C | AI MODELS TO PREDICT THE INFLUENCE OF NAFLD-ASSOCIATED RISK VARIANTS ON MOLECULAR PHENOTYPES

Henry Pratt, UMass Medical School and Daniel S. Pratt, Massachusetts General Hospital

Background: Genome-wide association studies (GWAS) have identified tens of risk loci for NAFLD, but the mechanism by which most of these variants confer risk is poorly-understood owing in large part to many of these variants lying outside of coding genes, and thus do not directly impact the structure and function of proteins. These non-coding risk variants may instead impact the expression of risk genes, but predicting which genes are impacted and in what biological contexts is challenging. **Methods:** We trained several AI models to predict the impact of sequence variants on regulatory element activity

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

in twenty different cell and tissue types with potential pathophysiological relevance to fatty liver disease, including hepatocytes, adipocytes, pancreatic endocrine cells, and various immune cells, as well as eight control cell types less likely to have involvement such as testicular cells and motor neurons. We then applied these models to sequence variants from two NAFLD GWAS encompassing 13,195 NAFLD patients and 1,143,407 healthy controls. We aimed to (1) identify cell and tissue types in which NAFLD variants are statistically more likely to regulate gene expression than expected by chance and (2) prioritize high-confidence candidate risk variants for future study. **Results:** Our models predicted effects on regulatory element activity for NAFLD-associated risk variants at 11 distinct genomic loci. Of these, 8 were predicted to be important by models trained in T cell lineages, including Th1 cells, Th2 cells, and Th17 cells, and 3 were predicted to be important by models trained on data from cells of the endocrine pancreas. This represented a significant enrichment for these cell types; we did not observe significant enrichment in other cell types tested. Of the 11 loci, 6 are predicted to influence activity of gene promoters and 5 are predicted to influence gene expression by modulating the activity of enhancers. NAFLD-associated risk alleles were equally likely to increase enhancer and promoter activity as to decrease it relative to protective alleles. **Conclusion:** We predict molecular phenotypes for 11 NAFLD-associated genomic loci. We link these loci both with predicted impacts on enhancers and promoters and with candidate cell types in which those impacts are most likely relevant. Our models support the hypotheses that both immune and endocrine pathways play roles in NAFLD pathophysiology and provide a targeted framework for further investigation of these loci.

2276-C | ALLO-LCA, A BILE ACID DERIVATIVE WITH DUAL ACTIVITY ON GPBAR1 AND RORΓT, ALLEVIATES NASH-INDUCED LIVER FIBROSIS

Michele Biagioli[1], Cristina Di Giorgio[1], Martina Bordoni[1], Silvia Marchianò[1], Carmen Massa[1], Rachele Bellini[1], Ginevra Urbani[1], Eleonora Distrutti[2], Angela Zampella[3] and Stefano Fiorucci[1], (1)University of Perugia, (2) Azienda Ospedaliera Di Perugia, (3)University of Naples, Federico II

Background: NAFLD is due to the pathological accumulation of lipids in hepatocytes. When lipid accumulation exceeds the protective mechanisms, hepatocytes become injured, process known as lipotoxicity, and release a number of inflammatory mediators that lead to recruitment and activation of ECM-forming cells with excessive deposition of a distorted ECM, leading to liver fibrosis. Liver fibrosis, is a late contributor to NASH pathogenesis. Upon liver injury, hepatocytes and non-parenchymal liver cells release pro-fibrogenetic mediators that binds to, and activate, HSCs. Bile acids (BAs) are amphipatic molecules synthesized in the liver. Beside their role in nutrient absorption, BAs are signaling molecules exerting a variety of regulatory function by activating a family of receptro called “bile acid activated receptors” (BARs). Recently identified derivatives of bile acids (called tertiary bile acids), have shown the ability to act simultaneously on GPBAR and also on RORγt on which some of them exert an inverse agonist activity. The action on RORγt makes these tertiary bile acids attractive therapeutic compounds with the ability to act on both the innate and adaptive immune systems. The aim of the study was to evaluate the effect the dual action on GPBAR1 and RORγt, by the administration of Allo-LCA, in preventing the development of NASH inflammation and fibrosis. **Methods:** In this study Allo-LCA will be used in rodent model of NASH, induced by the use of high fat diet (HFD) and intraperitoneal (i.p.) injections of carbon tetrachloride (CCl_4) (every 15 d, 200 µl/kg of body weight). Allo-LCA was administered at the dose of 10 mg/kg daily. The total duration of the experiment was 57 days. **Results:** Allo-LCA binds to GPBAR1 acting as an agonist with an EC50 of 2.7 µM and also acts as an inverse agonist of RORγt with an IC50 of 1.5 µM. The data demonstrated that Allo-LCA administration increased insulin sensitivity in mice exposed to HFD + CCl_4. Allo-LCA also reduced systolic and diastolic blood pressure compared to the experimental group treated with HFD + CCl_4 alone. Microscopic analysis of the liver by H&E and Sirius Red showed that the administration of HFD + CCl4 induced hepatic steatosis and severe fibrosis. Both processes were reversed by the administration of Allo-LCA. Furthermore, analysis of liver inflammation by qPCR showed that Allo-LCA decreased the expression of pro-inflammatory cytokines and markers of both macrophages and T lymphocytes indicating a decreased influx of immune cells in the liver. Moreover, the hepatic expression of Col1a1 and αSma were reduced by Allo-LCA indicating less HSC activation. **Conclusion:** Allo-LCA, with its potent dual action on GPBAR1 and RORγt, reduces liver inflammation induced by an HFD + CCl_4 increasing insulin sensitivity and reducing liver fibrosis, suggesting that this compound may represent a potent new treatment for NASH and related fibrosis.

2277-C | ALPHA-1 ANTITRYPSIN/PROTEINASE 3 IMBALANCE EXERTS PROTEOLYTIC REGULATION ON INTERLEUKIN-32 GAMMA TO PROMOTE NONALCOHOLIC STEATOHEPATITIS

JeongSu Park[1], Jin Lee[2], Feng Wang[1], Hwan Ma[1], Yong-Sun Lee[3], SangKyu Lee[4], Yoon Mee Yang[5], Hwan-Soo Yoo[1], Sang-Bae Han[1], Bumseok Kim[6], Jin Tae Hong[1] and Yoon-Seok Roh[1], (1)Chungbuk National University, (2)University of California, San Diego, (3) National Institute of Food and Drug Safety Evaluation, South Korea, (4)Kyungpook National University, (5) Kangwon National University, (6)Biosafety Research Institute and College of Veterinary Medicine, Jeonbuk National University, Iksan 54596, Korea.

Background: Excessive proteolytic activity is one of the key clinical aspects of nonalcoholic steatohepatitis (NASH). Alpha-1-antitrypsin (A1AT) has the main function of balancing the action of protease enzymes. However, the regulatory and downstream mechanism of A1AT in NASH remains unclear. **Methods:** Quintuple *Serpina1a–e* knockout (A1AT KO) mice, human IL-32γ transgenic (hIL-32γ Tg) mice, and hIL-32γ Tg/A1AT KO mice were fed with fast food diet (FFD). Liver tissues, hepatocytes, and Kupffer cells (KCs) were collected and analyzed by histology, RNAseq, secretome profiling, and cytokine array. **Results:** A1AT was found to be the most downregulated secreted protein in hepatocytes from FFD-fed mice by secretome profiling, and its expression was transcriptionally regulated by hepatocyte nuclear factor 4 alpha (HNF4A) with response to IL1β. In both humans and mice with NASH, the serum levels of A1AT were significantly decreased, whereas those of proteinase 3 (PR3), a pro-inflammatory serine protease, were increased. Consistently, the PR3/A1AT ratio was positively correlated with ALT and AST in human subjects. We approved similar trends in the correlation between IL1B, HNF4A, and SERPIINA1 expressions in patients with NASH using the RNAseq dataset. *In vivo* deletion of A1AT markedly increased expression of PR3, inducing more severe inflammatory responses and liver fibrosis. Pharmacological modulation of A1AT and PR3 alleviated the severity of NASH in mice. According to the PR3-bound cytokine array, IL-32γ was identified as a major target of PR3-mediated proteolytic cleavage. IL-32γ treatment decreased expression of pro-inflammatory cytokines in KCs. Consistently, in vivo overexpression of IL-32γ markedly alleviated FFD diet-induced hepatic inflammation, and liver fibrosis. Moreover, additional deletion of A1AT enhanced PR3 activity and dampened IL-32γ-mediated protective actions against NASH. Imbalance of A1AT and PR3 levels induced excessive degradation of IL-32γ in mice liver. The blockade of PR3-mediated IL-32γ cleavage by V104A mutation sustained its anti-inflammatory function in KCs. Furthermore, the cleaved IL-32γ (C-terminus) by PR3 induced profound inflammation, suggesting PR3 increases proteolytic processing of IL-32γ promoting liver inflammation and fibrosis. **Conclusion:** The hepatic A1AT maintains IL-32γ-mediated protective actions through inhibition of PR3-dependent proteolytic processing which could be a novel therapeutic strategy against NASH.

2278-C | ALTERED EphA2 SIGNALING IN NON-ALCOHOLIC FATTY LIVER DISEASE PROGRESSION

Brenna Pearson-Gallion[1], Alexandra Finney[1], Elizabeth Cockerham[1], Kelley Nunez[2], Chowdhury Abdullah[1], Eshika Tandon[1], Dhananjay Kumar[1], Richa Aishwarya[1], Matthew Scott[1], Cyrine Ben Dhaou[1], Kaylea Reeves[1], Paul Thevenot[3], Ari J. Cohen[4], James Traylor[1], Md Shenuarin Bhuiyan[1], Arif Yurdagul[1], Oren Rom[1] and Anthony W Orr[1], (1)Lsuhs-Shreveport, (2)Ochsner Health System, (3)Alton Ochsner Medical Foundation, (4)Ochsner Health System, New Orleans, LA

Background: Nonalcoholic fatty liver disease (NAFLD), the leading cause of chronic liver disease worldwide, results from diet-induced hepatic steatosis that can result in hepatocyte ballooning, inflammation and fibrosis driving nonalcoholic steatohepatitis (NASH). The Eph receptors, the largest family of receptor tyrosine kinases in the mammalian genome, affect inflammation and fibrosis in other model systems, and we have shown that EphA2 deletion reduces atherosclerosis despite increasing plasma cholesterol levels. While a GWAS study has linked EphA2 to NAFLD, the potential role of EphA2 in NAFLD has never been investigated. **Methods:** EphA2 expression and signaling was assessed in mice fed a high fat diet (HFD) for 8 and 24 weeks, in human liver samples from NASH patients, and in HuH7 cells treated with palmitic acid (FA), low density lipoprotein (LDL), and/or fructose. Global EphA2 KO mice were fed the FPC diet for 8 and 16 weeks followed by histological and molecular analyses. Primary hepatocytes and mitochondria were isolated from global EphA2 KO mice and used for Seahorse analysis. **Results:** Mice with early-stage nonalcoholic fatty liver disease (NAFLD) showed elevated EphA2 expression along with markers of EphA2 ligand-dependent signaling (EphA2 tyrosine phosphorylation). Consistently, HuH7 cells treated with FA, LDL, and/or fructose displayed a similar enhancement of EphA2 expression upon treatment. However, a mouse model of late-stage NASH exhibited reduced expression of the EphA2 ligand ephrinA1 and elevated markers of ligand-independent EphA2 signaling (Ser897 phosphorylation). Similarly, human liver samples from NASH patients show reduced ephrinA1 expression and elevated markers of EphA2 ligand independent signaling. Consistent with a role for EphA2 in NAFLD/NASH, global EphA2 KO mice show significantly lower indices of NAFLD following high fat diet feeding, including reduced hepatic steatosis and inflammation. RNA sequencing and Seahorse analysis illustrated enhanced metabolism in EphA2 KO mice. **Conclusion:** Taken together, our data demonstrate that EphA2 expression and signaling are altered during NAFLD/NASH pathogenesis and suggest that EphA2 inhibition may reduce NAFLD/NASH disease progression.

2279-C | ASTHMA AND OBESITY - SYNERGISTIC EFFECTS ON HEPATIC METABOLISM IN A MOUSE MODEL

Tim Westhoff[1], Holger Garn[2], Sarah Miethe[2], Verena Von Bülow[3], Martin Roderfeld[3] and Elke Roeb[3], (1) Justus-Liebig-University, (2)Philipps University, (3) Justus-Liebig-University, Giessen

Background: Obesity, as a component of the metabolic syndrome, is a widespread disease with steadily increasing case numbers in industrialized countries and serious health consequences such as non-alcoholic fatty liver disease (NAFLD). The prevalence of NAFLD is currently estimated at 26% worldwide. Asthma is the most common chronic respiratory disease, affecting approximately 350 million people worldwide. Asthma and obesity frequently co-occur and usually negatively influence the respective disease course. Recent epidemiological studies suggest a pathomechanistic link between obesity and asthma, but studies on mechanistic interactions at the cellular and molecular level are missing. **Methods:** The aim of our study was to analyze the comorbidity of NAFLD & asthma on molecular parameters of the hepatic metabolism in a mouse model. Therefore, four groups of C57BL/6 mice (n = 6 animals each) were fed either a high-fat diet (HFD) or normal diet (ND) until 20 weeks of age and additionally exposed to house dust mite extract (HDM) or PBS as a control in the last 4 weeks by repeated intranasal applications. Liver samples were analyzed by qRT-PCR and immunohistochemistry for biochemical markers with regard to glucose metabolism and inflammatory parameters. Differences between experimental groups were extracted by Kruskal-Wallis test (using SPSS29.0). **Results:** In all groups with HFD or HDM exposure, genes of glucose metabolism were differentially regulated as compared to healthy controls. In particular, expression of glycolysis associated enzymes such as phosphofructokinase 1 and aldolase was decreased in the HDM/HFD group. In addition, a decrease in succinyl-CoA synthetase was detected in liver tissue at both levels, mRNA (qRT-PCR) and protein (immunohistochemistry) expression. While

IL-10 as a parameter of hepatic anti-inflammatory immune mechanisms was increased in the HDM group, markers for Th1 immune responses were found to be downregulated in the HDM/HFD group. **Conclusion:** Our results demonstrate potentiated effects of asthma and obesity on parameters of the hepatic glucose metabolism and hepatic inflammation. Thereby, we verified a synergistic negative impact on liver function in succession with increased liver injury in the presence of both disease conditions.

2280-C | BILE SALT EFFLUX PUMP (BSEP) MEMBRANE-LOCALIZED ZONAL ABUNDANCE IN HUMAN LIVER TISSUE FROM PATIENTS WITH NONALCOHOLIC FATTY LIVER DISEASE (NAFLD)★

William A. Murphy[1], Anna Mae Diehl[2], Matthew S. Loop[3], Dong Fu[1], Cynthia D. Guy[2], Manal F. Abdelmalek[4], Georgia Sofia Karachaliou[5], Noora Sjöstedt[6], Sibylle Neuhoff[7], Paavo Honkakoski[8] and Kim L.R. Brouwer[1], (1)University of North Carolina at Chapel Hill, (2)Duke University, (3)Auburn University, (4)Mayo Clinic, Rochester, MN, (5)Duke University Medical Center, (6)University of Helsinki, (7)Certara UK Ltd., (8)University of Eastern Finland

Background: Zonal differences in NAFLD pathophysiology may be an important factor in disease progression and therapeutic response. Systemic and enterohepatic bile acids (BAs) are elevated in NAFLD and pericentral microcholestasis was reported in early nonalcoholic steatohepatitis (NASH). However, the mechanisms responsible for these changes are not well understood. BSEP, a canalicular membrane transporter, is the rate-determining step in hepatic BA secretion. BSEP has been implicated in cholestatic disease and is positively regulated by farnesoid X receptor, a pericentrally active NAFLD drug target. While no change in BSEP abundance in NAFLD was reported previously, quantitative estimates of membrane-localized BSEP are lacking, particularly across hepatic regions. To assess BSEP membrane-localized abundance ($BSEP_{MA}$) in NAFLD, we developed a machine learning image classification method to quantify BSEP canalicular membrane localization and tissue zonation using 3D liver biopsy images. **Methods:** Human liver biopsy sections were obtained from the Duke NAFLD Biorepository. Fibrosis stage and NAFLD-associated histologic features were assessed by board-certified pathologists to inform histologic-based diagnosis in accordance with current NASH Clinical Research Network criteria: Non-diseased liver (NDL; $n=10$), NAFL ($n=9$), NASH ($n=11$). Biopsies underwent immunofluorescence staining for BSEP, a canalicular membrane marker (CD-13), and nuclei (DAPI) followed by 40X confocal imaging (3 random areas were imaged per sample). To quantify membrane localization, hepatocellular BSEP fluorescence was segmented into 3D surfaces using the Imaris machine learning classifier and volumetric overlap (within 0.4 μm) with CD-13 was measured. To evaluate zonal abundance for each sample, BSEP fluorescence was quantified to reflect relative proportions across three equidistant hepatic zones between the portal tract and central vein (PT-to-CV axis). $BSEP_{MA}$ was obtained by adjusting zonal abundance measures for plasma membrane localization within a sample. A two-way repeated measures ANOVA was used for statistical analysis. **Results:** Relative periportal increases and pericentral decreases in $BSEP_{MA}$ were observed with NAFLD progression (Fig. 1A) and were associated with steatosis (Fig. 1B), lobular inflammation (Fig. 1C), and hepatocellular ballooning (Fig. 1D). Observed zonal differences in $BSEP_{MA}$ with fibrosis were inconclusive. **Conclusion:** Changes in periportal and pericentral $BSEP_{MA}$ occur with NAFLD progression. These findings provide novel insight into altered BA homeostasis in NAFLD. Increased periportal $BSEP_{MA}$ may protect from hepatotoxicity due to higher BA exposure in this region, while decreased pericentral $BSEP_{MA}$ may explain previous findings of microcholestasis. Thus, therapeutic approaches to increase pericentral $BSEP_{MA}$ could improve microcholestasis and pericentral NASH.

2281-C | BIOMARKERS TARGETING DIFFERENT EPITOPES OF THE SAME PROTEIN - TYPE III COLLAGEN - PROVIDE INFORMATION ABOUT BOTH FIBROGENESIS AND FIBROLYSIS IN PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE UNDERGOING BARIATRIC SURGERY

Thomas Wiggers Møller[1], Ida Lønsmann Sorribes[2], Julie Steen Pedersen[3], Morten Karsdal[4], Flemming Bendtsen[5] and Diana J. Leeming[2], (1)Nordic Bioscience a/S, (2)Nordic Bioscience A/S, (3) Copenhagen University Hospital of Koege, (4)Nordic Bioscience a/S, Denmark, (5)Hvidovre Hospital

Background: One characteristic of liver fibrosis is increased degree of enzymatic cross-linking of collagens as well as collagen remodeling. We aimed to investigate differences in measuring the same protein in three different ways using serological biomarkers: MMP driven fibrolysis of cross-linked type III collagen (CTX-III), MMP driven fibrolysis of type III collagen (C3M), and fibrogenesis of type III collagen (PRO-C3). **Methods:** 70 patients had blood samples and liver biopsies collected on the day of bariatric surgery. Additional blood samples were collected at 3-, 6- and 12-months after bariatric surgery. 40 of the patients had a liver biopsy at twelve months. Serum CTX-III, C3M, and PRO-C3 were measured using fully validated immunoassays, and the markers were analyzed using a linear mixed-effect analysis on log-transformed data. **Results:** 61% of the included 70 patients were females and mean age and mean BMI were 44 years and 42 kg/m2, respectively. Patients had a median NAFLD activity score of 3 and mild-to-moderate fibrosis F0 (3%), F1 (86%), and F2 (11%). The general percent change of MMP degraded cross-linked type III collagen (CTX-III) from baseline was significantly elevated in patients with bariatric surgery ($p < 0.0001$), with the most dramatic change observed between baseline and 3-months follow-up ($p < 0.001$). Interestingly, the general percent change of MMP degraded type III collagen (C3M) from baseline was significantly decreased ($p < 0.0001$), with the biggest change observed from baseline to the 3-months follow-up ($p < 0.0001$), while type III collagen formation (PRO-C3) remained statistically unchanged.

Conclusion: This study indicates that in NAFLD patients undergoing bariatric surgery, induction of resolution may only be monitored assessing a cross-linked fragment generated by MMP, potentially being more specific to fibrotic tissue due to the increase in degree of collagen cross-links with fibrosis severity. A non-crosslinked version did not provide the same value but rather decreased potentially reflecting the inflammatory pathway.

2282-C | BREAKING THE LINK BETWEEN AGING AND NAFLD: UNRAVELING THE ROLE OF FERROPTOSIS

Kuo Du[1], Ji Hye Jun[1,2], Raquel Maeso Díaz[3], Rajesh Kumar Dutta[3], Seh-Hoon Oh[3], Jen-Tsan Ashley Chi[1] and Anna Mae Diehl[3], (1)Duke Universty, NC, (2)Duke Universty, Durham, NC, United States, (3)Duke University

Background: Non-alcoholic fatty liver disease (NAFLD) is a growing public health concern, and its prevalence is projected to increase due to the growing elderly population. Ferroptosis, a recently discovered form of regulated cell death, has been implicated in various age-related diseases such as cardiovascular diseases. However, the role of ferroptosis in aging-associated NAFLD susceptibility remains unclear. **Methods:** Liver tissues and primary hepatocytes were harvested from chow-fed aged (24 mo) and young (3 mo) mice to examine the role of aging on basal ferroptotic stress, inflammation and fibrosis. RNA sequencing was performed to characterize aged hepatocyte transcriptomes and define how aging affects the gene signatures associated with ferroptosis, NAFLD and insulin signaling. Aged and young mice were also fed with CDA-HFD diet to determine if/how aging impacts NAFLD, and aged mice were further treated with ferroptosis inhibitor Ferrastatin-1 to examine whether inhibiting ferroptosis improves aging-associated NAFLD susceptibility. **Results:** Aged liver exhibited increased basal steatosis, fibrosis, and inflammation, and this phenotype was associated with increased ferroptotic stress in hepatocytes. Characterization of aged hepatocytes revealed upregulation of gene signatures associated with aging, ferroptosis, and NAFLD, while gene signatures associated with insulin signaling were downregulated. When fed with a NAFLD-inducing diet, aged mice exhibited an exacerbated NAFLD phenotype, as evidenced by worse liver function and increased liver fibrosis and inflammation. These mice also demonstrated exaggerated ferroptotic stress, and inhibiting ferroptosis significantly protected against the exacerbated NAFLD phenotype in aged mice. **Conclusion:** Our study demonstrates that aging-associated ferroptosis is a fundamental pathogenic mechanism of NAFLD susceptibility. Targeting the ferroptosis pathway and its associated pathobiology holds promise to treat NAFLD in the aging population. These findings have significant implications for developing novel therapeutic strategies to manage NAFLD and improve liver health in the elderly.

2283-C | CATBOOST OUTPERFORMS OTHER MACHINE LEARNING METHODS TO PREDICT FATTY LIVER DISEASE IN THE UK BIOBANK

Yousif Alyousifi[1], Elizabeth K. Speliotes[2], Chinmay Raut[1], Antonino Oliveri[3], Ali Turfah[1] and Steven Dunne[1], (1)University of Michigan, (2)University of Michigan Medical School, (3)University of Michigan, Ann Arbor, MI

Background: Non-alcoholic Fatty Liver Disease (NAFLD) is a condition characterized by the accumulation of fat in the liver, unrelated to alcohol consumption, which can lead to potential health complications. Magnetic Resonance Imaging Proton Density Fat Fraction (MRI PDFF) is one of the most accurate measures for assessing fatty liver disease. However, obtaining MRI scans can be expensive or impractical. This study aims to predict MRI PDFF-measured liver fat using blood assay measurements and baseline data from the UK Biobank. **Methods:** We used the UK Biobank cohort individual's with MRI-PDFF measured 43,293, average age = 55.19, Male = 48.5% and Females = 51.5%. We used MRI PDFF > 3% to denote fatty liver disease. 248 predictors were taken from the baseline characteristics, physical measures, and serum values of these participants. We split the data into training (34,634) and testing (8,659) groups and applied machine learning methods including CatBoost, Support Vector Machine, Decision Tree, Random Forest, and Logistic Regression to estimate fatty liver disease. **Results:** CatBoost achieved the best performance with the highest accuracy of 0.776, second highest precision of 0.739, highest recall of 0.647, highest F1 score of 0.690 and highest ROC-AUC of 0.844 compared to the other methods (Table 1). The worst performing method was Decision Trees with an accuracy of 0.675, precision of 0.571, recall of 0.599, F1 score of 0.570 and ROC-AUC of 0.654 **Conclusion:** Using machine learning methods, we were able to predict the presence of fatty liver disease with high accuracy, precision, and recall. We are working to reduce the predictors to generalizable parameters that can be used more broadly to determine hepatic steatosis in other populations.

Table 1. Model evaluation results based on the common evaluation metrics

Model	Training					Testing				
	Accuracy	Precision	Recall	F1	ROC-AUC	Accuracy	Precision	Recall	F1	ROC-AUC
Logistic Regression	0.776	0.738	0.636	0.683	0.841	0.776	**0.740**	0.630	0.681	0.839
Random Forest	1.000	1.000	1.000	1.000	1.000	0.765	0.720	0.621	0.667	0.822
Decision Tree	1.000	1.000	1.000	1.000	1.000	0.675	0.571	0.599	0.570	0.654
SVM	0.775	0.736	0.634	0.681	0.840	0.776	**0.740**	0.629	0.680	0.837
CatBoost	0.859	0.850	0.761	0.803	0.926	**0.779**	0.739	**0.647**	**0.690**	**0.844**

Bold indicates the best-performing model.

2284-C | CHARACTERIZING DEVELOPMENT OF NON-ALCOHOLIC FATTY LIVER DISEASE IN HUMAN PRECISION-CUT LIVER SLICES

Mei Li[1], Vincent De Meijer[2], Anika Nagelkerke[1] and Peter Olinga[1], (1)University of Groningen, (2)University Medical Center Groningen

Background: Non-alcoholic fatty liver disease (NAFLD) is a growing healthcare problem, ranging from non-alcoholic fatty liver (NAFL) to non-alcoholic steatohepatitis (NASH) and often leading to fibrosis and cirrhosis along with hepatocellular carcinoma. Progress in this field depends on the availability of reliable preclinical models. Precision-cut liver slices (PCLS) provide a preserved multicellular environment that allows for the interaction of various liver cell types. In this study we characterized the development of NAFLD in human PCLS. **Methods:** Healthy human PCLS were cultured for up to 96 hours in either GFIPO medium (William's E Medium supplemented with Glucose (36 mM), Fructose (5 mM), Insulin (1 nM), Palmitic acid (0.24 mM) and Oleic acid (0.48 mM)) to mimic NAFLD-inducing conditions, or WEGG medium (William's E Medium supplemented with Glucose (25 mM)) as a control. PCLS and media were collected every 24 hours to assess viability and fat accumulation by measuring ATP levels and triglyceride (TG) content. Gene expressions of inflammatory and fibrotic markers were evaluated by RT-qPCR. Inflammatory cytokines and pro-collagen 1a1 secretion were measured using ELISA and a Luminex assay. Additionally, RNA-sequencing was performed to identify and evaluate significantly changed genes and pathways in response to incubation process. **Results:** Liver slices remained viable for up to 96 hours of incubation in both WEGG and GFIPO mediums as evidenced by ATP levels. The TG content was increased with 92% in the GFIPO group. In GFIPO, mRNA expression of the inflammatory biomarker interleukin 6 (*IL6*) was significantly upregulated compared to WEGG (6-fold), as well as interleukin 1b (*IL1β*) (42-fold). However, no significant differences were observed in the expression of tumor necrosis factor alpha (*TNFα*). Nevertheless, the protein levels of TNFα and IL6 produced and secreted during the culture were significantly up-regulated (2-fold and 14-fold, respectively) in GFIPO medium. Regarding pro-fibrogenic gene expression, the secretion of pro-collagen 1a1 was increased significantly (2-fold) as well, while no difference was found at the mRNA level except for

ACTA2, which was significantly increased (2-fold). RNA-sequencing data indicated that initially, carbohydrate metabolism and lipid metabolism were significantly elevated in PCLS incubated in GFIPO, followed by a subsequent decrease in the later stages (72h and 96h). However, pathways associated with the immune system and signal transduction initially showed a downward trend but demonstrated an upward trend in GFIPO upon longer incubation. **Conclusion:** GFIPO increased the TG content and enhanced the development of inflammatory and pro-fibrogenic signaling at the gene and protein levels in human PCLS mimicking human NAFL development. RNA sequencing data revealed a metabolic response at the early stage, and an immune response at the later stage of NAFL development in this model.

2285-C | CHOLESTEROL-ASSOCIATED LOCUS EHBP1 PROTECTS AGAINST NASH FIBROSIS

Fanglin Ma and Bishuang Cai, Icahn School of Medicine at Mount Sinai

Background: Elevated hepatic cholesterol content is frequently seen in human NASH and high-cholesterol diets have been found to promote NASH progression in mouse models. However, the regulation of cholesterol accumulation in hepatocytes during NASH is not completely understood. Genome-wide association studies (GWAS) have revealed that several single nucleotide polymorphisms (SNPs) in *EHBP1* are associated with LDL cholesterol. However, the mechanisms underlying this association and the role of EHBP1 in hepatic cholesterol metabolism is unknown. **Methods:** Wild type (WT) mice were injected (i.v.) with AAV8-H1-shEhbp1 and AAV8-TBGS1-EHBP1 viruses to knockdown or overexpress EHBP1 in hepatocytes. The mice were fed a Fat/NASH diet for 10 weeks and plasma cholesterol, hepatic free cholesterol, fibrosis, inflammation and steatosis were analyzed. **Results:** EHBP1 expression was decreased in NASH liver of human and mouse as well. Our mouse studies showed that hepatocyte-specific EHBP1 deficiency increased liver free cholesterol, liver fibrosis, inflammation, and steatosis. In contrast to EHBP1 silencing, EHBP1 overexpression alleviated NASH progression. Mechanistic study with primary hepatocytes revealed that EHBP1 promotes sortilin (SORT1)-mediated PCSK9 secretion, leading to LDLR degradation and less LDL uptake. Regarding the decreased EHBP1 expression in NASH livers, we demonstrated that NASH-relevant cytokine TNFa reduced the expression of PPARa, a novel transcription factor for EHBP1. These data not only provide new mechanistic insight into the role of EHBP1 in hepatic cholesterol metabolism and NASH fibrosis by uncovering the interaction between EHBP1 and other LDL cholesterol-related loci including SORT1, PCKS9, and LDLR, but also elucidate a novel interplay between inflammation and EHBP1-mediated cholesterol metabolism in the context of NASH. **Conclusion:** At the homeostasis status, cholesterol-associated GWAS locus EHBP1 protects against NASH by promoting PCSK9 secretion and LDLR degradation, which prevents LDL uptake into hepatocytes and alleviates liver fibrosis. However, as NASH progresses, TNFa abolishes the beneficial effect of EHBP1 by suppressing PPARa and EHBP1 expression.

Disclosures: The following people have nothing to disclose: Fanglin Ma, Bishuang Cai

2286-C | CircZBTB46 ALLEVIATES NON-ALCOHOLIC FATTY LIVER DISEASE BY TARGETING MIR-326/FGF1/AMPK AXIS

Qingmin Zeng[1], Chang-Hai Liu[1], Wei Jiang[1], Dongbo Wu[1] and Hong Tang[2], (1)West China Hospital, Sichuan University, (2)West China Hospital of Sichuan University

Background: Non-alcoholic fatty liver disease (NAFLD) is currently the most prevalent cause of chronic liver diseases worldwide. Due to its complex pathogenesis and limited treatment methods, further research is urgently needed. The role of circular RNA (circRNA) in NAFLD is increasingly being discovered, but the mechanism behind it is not yet fully understood. This study aims to explore the role and molecular mechanism of circZBTB46 in NAFLD by regulating the miR326/FGF1/AMPK signaling pathway. **Methods:** RNA-sequencing and bioinformatics analysis were conducted on liver tissues obtained from 3 healthy controls, 3 NAFLD, and 3 NASH patients to identify differentially expressed circRNA. Western diet (WD)-fed mice were used as the NAFLD model in vivo, and free fatty acid (FFA)-treated LO2 cells were used as the NAFLD model in vitro. The circRNA-miRNA binding site was predicted using miRanda and TargetScan, and the interaction was verified through dual-luciferase reporter gene assays, RNA immunoprecipitation, and RNA pull-down experiments. mRNA expression levels were measured using qRT-PCR, while protein expression levels were detected by western blot, immunohistochemistry, and immunofluorescence. Triglyceride (TG) and cholesterol levels were quantified using

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

ELISA, and lipid deposition was detected with Oil Red O and BODIPY 493/503 staining. **Results:** We identified a circular RNA, named circZBTB46, which is generated from ZBTB46 gene and is downregulated in NAFLD patients as well as in vitro and in vivo NAFLD models. Overexpression of CircZBTB46 significantly reduced hepatic lipid deposition and TG secretion. Mechanistically, circZBTB46 alleviates NAFLD progression through the circZBTB46/miR-326/FGF1 pathway. miR-326 is upregulated in NAFLD and inhibits FGF1 expression by binding to the 3' UTR region of FGF1, leading to hepatic lipid deposition. CircZBTB46 counteracts the inhibitory effect of miR326 on FGF1/AMPK by acting as a miR-326 sponge, promoting the expression of FGF1, and thus reducing hepatic lipid deposition. **Conclusion:** The circZBTB46-miR326-FGF1/AMPK signaling axis has a significant role in non-alcoholic fatty liver disease. Investigating the expression of circZBTB46 in the bloodstream of NAFLD patients may offer new insights for non-invasive diagnosis of this condition.

2287-C | CLINICAL TRANSLATABILITY OF LDLR-/-.LEIDEN MOUSE MODEL FOR NON-ALCOHOLIC STEATOHEPATITIS

Eveline Gart, José A. Inia, Martine M.C. Morrison, Robert Kleemann and Anita M. Van Den Hoek, The Netherlands Organization for Applied Scientific Research (TNO)

Background: Non-alcoholic steatohepatitis (NASH) is one of the most prevalent chronic liver diseases, which is closely associated with obesity, insulin resistance, dyslipidemia and cardiovascular disease. Preclinical validation of novel drug candidates for the treatment of NASH requires a translational animal model that should recapitulate these hallmarks of the human disease. The present study aimed to further investigate the translatability of the Ldlr-/-.Leiden mouse as translational NASH model. **Methods:** Ldlr-/-.Leiden mice fed a translational HFD without cholesterol supplementation were compared with human NASH patients on (a) obesity and insulin resistance; (b) lipoprotein profiles, endogenous cholesterol synthesis and de novo lipogenesis (DNL); (c) liver transcriptome and metabolome profile; (d) histological NASH endpoints and (e) atherosclerosis. In addition, the response to treatments with obeticholic acid (OCA), cenicriviroc and semaglutide was analyzed and compared to clinical trial results. **Results:** Ldlr-/-.Leiden mice fed a HFD develop severe obesity (with adipose tissue inflammation), insulin resistance and hyperlipidemia with humanized lipoprotein profiles (high triglycerides and LDL, low HDL). Similar to human NASH patients, Ldlr-/-.Leiden mice on HFD (without cholesterol supplementation) exhibit endogenous cholesterol synthesis and DNL. The mice recapitulate human NASH transcriptome and metabolome profiles and reveal a translational histopathology in the liver with steatosis, inflammatory aggregates and bridging fibrosis, as well as atherosclerosis development. Furthermore, the mice respond to the different treatments with NASH resolution (OCA & semaglutide, not with cenicriviroc) and improvement with fibrosis (OCA only), in line with clinical trials. **Conclusion:** Overall, the Ldlr-/-.Leiden mouse model shows good clinical translatability and accurately mimics the etiology and pathology of NASH and fibrosis in humans.

2288-C | COFFEE COMPOUNDS MODULATE ANTIOXIDANT RESPONSE AND LIPID DROPLETS FORMATION AGAINST PALMITATE-INDUCED LIPOTOXICITY IN HEPATOCYTES

Johanna C Arroyave Ospina[1,2], Magnolia Martínez[1], Manon Buist-Homan[1], Victoria Palasantzas[1] and Han Moshage[3], (1)University Medical Center of Groningen, (2)Universidad De Antioquia, (3)University Medical Center Groningen

Background: Metabolic dysfunction associated fatty liver disease (MAFLD) is the result of disturbed lipid metabolism. Accumulation of free fatty acids (FFAs) in hepatocytes causes lipotoxicity mediated by oxidative stress. Coffee compounds are known for its beneficial effects in MAFLD, however the mechanisms still need to be further explored. The aim of this study was elucidate the protective mechanisms of coffee compounds against palmitate-induced lipotoxicity in primary hepatocytes. **Methods:** Primary hepatocytes were isolated from Wistar male rats and treated with palmitate (1 mmol/L) in combination with caffeine (CF: 1 mmol/L) or chlorogenic acid (CGA: 5 μmol/L). Mitochondrial ROS production, palmitate-induced necrosis, antioxidant response markers SOD1, SOD2, HO-1 and GPx1, ER stress markers CHOP, ATF4 and GRP78 and, lipid droplets (LDs) formation were assessed. Monoacylglycerols 2-SG (2-Stearolylglycerol), 2-OG (2-Oleoylglycerol) and SCD-1 (Stearoyl-CoA Desaturase 1) Inhibitor were used to modulate LD formation. LD formation in steatotic Zucker hepatocytes was also investigated. **Results:** CF and CGA prevented palmitate-induced cell death and reduced ROS production. CF and CGA were found to induce the antioxidant response, especially HO-1 expression was increased, but did not significantly reduce palmitate-induced ER stress markers. CF and CGA increased LD formation in palmitate treated cells. This effect was significantly reduced by 2-SG and SCD-1 inhibitor, but enhanced by 2-OG. Lipid droplets accumulation was associated with lower palmitate toxicity and reduced ROS production. **Conclusion:** CF and CGA protect hepatocytes from lipotoxicity via inducing the antioxidant response and enhancing lipid droplet formation, likely via a SCD-1 dependent mechanism. Oxidative-stress related toxicity in hepatocytes can be prevented by enhancing LDs formation.

2289-C | COMPARATIVE ANALYSIS OF iPSC-DERIVED HEPATOCYTES (iPSC-HEPS) FROM NAFLD PATIENTS AND HEALTHY CONTROLS REVEALS IMPAIRED MITOCHONDRIAL FUNCTION IN NAFLD iPSC-HEPS

Dounia Le Guillou[1], Chris S. Her[1], Kevin Siao[1], Simaron K. Dhillon[1], Caroline C. Duwaerts[2], Jacquelyn J. Maher[3] and maher, (1)University of California, San Francisco, (2)University of California, San Francisco, Richmond, CA, (3)University of California, San Francisco, San Francisco, CA

Background: Mitochondria play a central role in the development and progression of NAFLD to NASH. We recently showed that NAFLD iPSCs differentiated into hepatocytes (iPSC-Heps) display a disease-specific gene expression profile with altered expression of genes related to lipid metabolism, inflammation, and insulin sensitivity. In this study, we investigated and compared mitochondrial function in NAFLD *vs*. control iPSC-Heps. **Methods:** iPSCs were differentiated to iPSC-Heps over 22 days. Mitochondrial function was assessed using the Seahorse XF Analyzer, measuring oxygen consumption rate (OCR) in the presence of either glucose or galactose, the latter designed to enhance oxidative phosphorylation. Endogenous and exogenous fatty acid oxidation (FAO) were evaluated by measuring OCR in the presence or absence of etomoxir (a FAO inhibitor) or palmitate, respectively. The generation of reactive oxygen species (ROS) in response to a 2h-palmitate treatment was measured using MitoSOX dye. Mitochondrial mass was determined by citrate synthase activity assay. **Results:** We investigated at least 9 NAFLD and 9 control patient-specific iPSC lines in this study. NAFLD iPSC-Heps spontaneously exhibited elevated triglycerides compared to control iPSC-Heps (129 *vs.* 71 nmol triglyceride/mg protein, $p = 0.02$). Seahorse experiments revealed that while mitochondrial respiration did not significantly differ between NAFLD and control iPSC-

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Heps under glucose conditions, NAFLD iPSC-Heps showed a significant increase in OCR when exposed to galactose. NAFLD iPSC-Heps exhibited higher endogenous FAO compared to controls (difference of 2772 pmol O_2/min/10^6 cells, $p = 0.006$). On the contrary, exogenous FAO was higher in control iPSC-Heps compared to NAFLD iPSC-Heps (difference of 2051 pmol O_2/min/10^6 cells, $p = 0.039$). Additionally, NAFLD iPSC-Heps displayed more ROS generation in response to palmitate than controls (155 % *vs*. 98 % MitoSOX intensity in response to palmitate *vs*. vehicle, $p = 0.012$)). Previous RNAseq data also revealed that even in the absence of any palmitate challenge, NAFLD iPSC-Heps already exhibited higher expression of genes involved in the oxidative stress response compared to controls. Assessment of mitochondrial mass did not reveal significant differences between NAFLD and control iPSC-Heps. **Conclusion:** Our results highlight distinct mitochondrial phenotypes in NAFLD iPSC-Heps, including an increased reliance on mitochondrial respiration, elevated endogenous FAO, and impaired utilization of exogenous fatty acids associated with enhanced ROS production, suggesting mitochondrial dysfunction when exposed to excess fatty acids. These findings support the notion of mitochondrial dysfunction in NAFLD, particularly in NASH, and highlight potential therapeutic targets for restoring normal hepatic metabolism in the disease.

2290-C | CONCOMITANT OBESOGENIC DIET AND ALCOHOL INDUCE A PRO-INFLAMMATORY ENVIRONMENT WITHOUT HISTOLOGIC STEATOHEPATITIS IN MICE

Joseph L Dempsey[1], Delfin Buyco[2], Joe Lim[1], Sina A. Gharib[1] and Rotonya M. Carr[1], (1)University of Washington, (2)Northwestern University

Background: Non-alcoholic fatty liver disease (NAFLD) and alcohol-associated liver disease (ALD) share many risk factors and have a similar histologic disease progression. However, the mechanisms by which fatty liver disease progresses to inflammatory conditions from concomitant obesity and alcohol consumption (here, termed the "syndrome of metabolic and alcoholic fatty liver disease" (SMAFLD)) are not fully known. **Methods:** We developed an experimental model of SMAFLD to examine the initial molecular changes that occur during early steatosis. Namely, we fed C57BL6/J mice a chow (Chow) or high-fat, fructose, cholesterol (FFC) diet and co-administered either saline or EtOH. EtOH-treated mice were given 5% EtOH in drinking water and 2.5 g EtOH/kg body weight per week for 8 weeks by gavage. We measured ALT, sectioned the liver for histology, and analyzed the hepatic transcriptome for immune signatures. We performed targeted lipidomics of hepatic ceramides (Cers) by LC-MS because of their established role in inflammation. Finally, we performed a glucose tolerance test and quantified hepatic levels of protein kinase B (AKT) given the known inhibitory role of inflammatory genes on insulin signaling. **Results:** FFC and FFC-EtOH diets induced steatosis and increased ALT compared to Chow. Despite the absence of histologic evidence of steatohepatitis or fibrosis, Gene Set Enrichment Analysis (GSEA) of RNA-seq data showed that FFC-EtOH had increased immune signaling, oxidative stress response, and energy and fatty acid metabolism compared to EtOH alone. STRING analysis showed that FFC and FFC-EtOH significantly upregulated genes that are associated with inflammasome activation. FFC diet is associated with CTP binding, sulfonylurea receptor binding, and dATP binding, whereas FFC-EtOH is associated with complement component C3b binding and RAGE receptor binding. Lipidomics revealed upregulation of the anti-inflammatory ceramide pre-cursor sphingolipids, dyhydrosphingosine and dyhydrosphingosine-1-phsophate, in FFC and FFC-EtOH diets. Finally, compared to Chow, glucose tolerance was impaired and protein levels of AKT were reduced in FFC-EtOH. **Conclusion:** Similar to NAFLD and ALD, SMAFLD induces immune signaling, an inflammatory environment, and glucose intolerance prior to histologic inflammation. The FFC and FFC-EtOH hepatic transcriptome have increased inflammatory signaling, specifically with inflammasome activation. However, at early stages of disease development, hepatic metabolites and other compensatory mechanisms may prevent histologic inflammation. Our study reveals the molecular and transcriptomic profile of early SMAFLD by the dysregulation of Cers, metabolic signaling, and inflammation. These metabolic targets at this early stage of SMAFLD may be used to develop therapeutics to prevent disease progression.

2291-C | DASATINIB AND QUERCETIN AS SENOLYTICS ATTENUATE FAT DEPOSITION AND HAVE ANTIFIBROTIC EFFECTS IN MEDAKA NONALCOHOLIC STEATOHEPATITIS MODEL

Hiroyuki Abe[1], Shunta Yakubo[1], Norihiro Sakai[1], Yusuke Watanabe[1], Naruhiro Kimura[1], Toru Setsu[1], Takeshi Yokoo[1], Akira Sakamaki[1], Hiroteru Kamimura[1], Atsunori Tsuchiya[1], Kenya Kamimura[2] and Shuji Terai[1], (1)Graduate School of Medical and Dental Sciences, Niigata University, (2)School of Medicine, Niigata University

Background: Non-alcoholic steatohepatitis (NASH) is known to cause cellular senescence due to the effects of oxidative stress, endoplasmic reticulum stress, and autophagy in the liver caused by ectopic fat deposition. Recently, senolytic drugs to eliminate senescent cells have been reported, including a combination of dasatinib, an antitumor agent, and quercetin, a flavonoid used as a dietary supplement. In the present study, we evaluate the efficacy of dasatinib and quercetin as senolytic drug in NASH medaka model. **Methods:** Medaka fish were fed high-fat diet (HFD) for 7 weeks inducing to NASH. The models were kept in the tank with and without dasatinib (1.0 mg/L) and quercetin (0.01 mg/L) dissolved for the last week of treatment. Body weight, liver weight ratio, and histological fat deposition were evaluated to validate treatment efficacy. Fibrosis-related genes were analyzed by quantitative PCR. **Results:** Body weight was 0.41 ± 0.07 g in the normal diet group, 0.49 ± 0.05 g in HFD group, and 0.40 ± 0.06 g in the treatment group, showing an improvement in the treatment group ($P < 0.001$). Hepatic weight ratio was 0.016 ± 0.008 in the normal diet group, 0.034 ± 0.010 in HFD group, and 0.019 ± 0.006 in the treatment group, indicating improved hepatomegaly in the treatment group compared to HFD group ($P < 0.01$). Histologically, area of fat deposition in the liver was 21.4 ± 8.9% in the normal diet group, 40.1 ± 13.2% in HFD group, and 18.4 ± 13.9% in the treatment group, indicating improved fat deposition in the treatment group compared to HFD group ($P < 0.01$). The transcript levels of Col1 were 1.31 ± 0.39 fold in HFD group and 0.26 ± 0.29 fold in the treatment group compared to the normal diet group ($P < 0.001$). The transcript levels of Timp2b was 21.78 ± 36.11 fold in HFD group and 0.12 ± 0.08 fold in the treatment group compared to the normal diet group ($P < 0.01$). The transcript levels of TGF1 was 122.06 ± 171.03 fold in HFD group and 0.47 ± 0.51 fold in the treatment group compared to the normal diet group ($P < 0.05$). **Conclusion:** Dasatinib and quercetin improve body weight, liver weight ratio, and histological fat deposition in NASH, and decrease fibrosis-related gene expression, suggesting that they may be useful in the treatment of hepatitis and its associated fibrosis. Both drugs have been used as clinical therapeutic agents or supplements, which are expected to have potential for clinical application.

2292-C | DEFINITIVE SENESCENCE PHENOTYPES OF HEPATIC STELLATE CELLS (HSCs), AND EXPRESSION OF SENOLYTIC TARGETS IN MURINE AND HUMAN NONALCOHOLIC STEATOHEPATITIS

Chittampalli N Yashaswini, Icahn School of Medicine at Mount Sinai

Background: Recent studies implicate senescent HSCs as a driver of NASH and HCC, which has led to efforts to deplete these cells using CAR-T cells that target urokinase plasminogen activator, a candidate marker of senescence. However, the expression of uPAR may not be restricted to HSCs. Our aims were to determine the cellular distribution of uPAR expression in murine and human NASH, and to establish the definitive phenotype of senescent HSCs. **Methods:** Immunofluorescence, immunohistochemistry, senescence-associated beta galactosidase assays, bulk RNA sequencing, single nuclear RNA sequencing and single cell RNA sequencing were used to characterize patterns of HSC senescence and uPAR expression in human NASH and in a well validated mouse model of NASH (doi: 10.1016/j.jhep.2018.03.011). **Results:** Senescence markers are increased in murine and human NASH compared to healthy samples; regions of senescence in murine NASH overlap with HSC distribution. Senescent HSCs are in close proximity to macrophages, and

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

single nuclear RNA sequencing indicates the presence of senescent HSCs in murine and human datasets that express uPAR. Expression of uPAR fluctuates in intensity and cell-specificity throughout the progression of human and murine NASH. uPAR expression is strongest in early NASH, when it is most restricted to HSCs, but as NASH progresses, it is increasingly detectable in cells of myeloid lineage. Based on single cell RNA sequencing of murine NASH, uPAR is strongly expressed by neutrophils and non-inflammatory macrophages. Anti-uPAR CAR T cell treatment in murine NASH slightly reduces fibrosis, along with efficient depletion of neutrophils and macrophages. In patients with NASH there is increased HSC senescence, with significantly more HSCs expressing uPAR. Cells of monocyte lineage strongly express uPAR in patients with NASH as well. **Conclusion:** We have documented the presence of senescent cells in murine and human NASH. These data are the first comprehensive characterization of hepatic uPAR expression in human and murine NASH, demonstrating that uPAR is not only present in senescent HSCs, but also expressed by myeloid cells (neutrophils and non-inflammatory macrophages), proportionate to the severity of NASH. Our findings reinforce the therapeutic potential of anti-uPAR CAR T cell therapy in patients with NASH, but also suggest that CAR T-mediated clearance of both senescent HSCs and immune cells may contribute to its efficacy.

2293-C | DELETION OF CARNITINE PALMITOYLTRANSFERASE 1a FROM THE LIVER REDUCES HEPATIC POLYUNSATURATED FATTY ACIDS AND DRIVES MICROVESICULAR STEATOSIS IN FEMALE MICE

Mikala M. Zelows[1], Corissa Cady[1], Zachary Kipp[1], Evelyn Bates[1], Anna Mead[1], Nikitha Dharanipragada[1], Se-Hyung Park[1], Harrison A. Clark[2], Tara R. Hawkinson[2], Terrymar Medina[2], Ramon C. Sun[2], Todd A. Lydic[3], Terry Hinds[1], Samir Softic[1], Gregory A. Graf[1] and Robert N. Helsley[1], (1)University of Kentucky, (2) University of Florida, (3)Michigan State University

Background: Loss-of-function mutations in carnitine palmitoyltransferase 1a (CPT1a) associate with reductions in circulating polyunsaturated fatty acids (PUFAs). Loss of hepatic PUFAs contributes to the progression from nonalcoholic fatty liver disease (NAFLD) to more severe nonalcoholic steatohepatitis (NASH). Therefore, the goal of this study was to determine the impact of liver-specific CPT1a deletion (LKO) on PUFA metabolism and NAFLD. **Methods:** Eight-week old male and female LKO ($Cpt1a^{\Delta Alb}$) and littermate controls ($Cpt1a^{F/F}$) were placed on a low-fat or high-fat diet (HFD; 60% kcal fat) for 15 weeks. Glucose and insulin tolerance tests were completed after 10 and 12 weeks on the diet, respectively. Mice were necropsied after a 16 hour fast to induce hepatic fatty acid oxidation, and tissues and serum were collected and utilized for shotgun lipidomics, matrix-assisted laser desorption ionization for mass spectrometry imaging (MALDI-MSI), bulk RNA sequencing, histology, transmission electron microscopy, and protein expression by immunoblotting. **Results:** Male and female LKO mice did not exhibit a difference in total body weight or adiposity. Male LKO mice displayed improved insulin sensitivity, had lower circulating alanine aminotransferase (ALT) levels, but did not exhibit changes in hepatic triglycerides or cholesterol levels as compared to male control mice. Female LKO mice, however, displayed significant increases in serum ALT levels which associated with greater deposition of hepatic triglycerides and cholesterol, as compared to female control mice. Histologically, female LKO mice displayed diffuse, panlobular microvesicular steatosis, while male LKO mice exhibited slight periportal steatosis. Shotgun lipidomics revealed female LKO mice exhibited reductions in EPA and DHA-containing phospholipids. Utilizing MALDI-MSI, we observed spatial heterogeneity of 38:6 and 40:6 PE species in control mice, which was absent with *Cpt1a* deficiency. Bulk RNA-sequencing analysis revealed that male LKO mice increased PPARα-target genes involved in mitochondrial (*Cpt2*, *Acadm*) and peroxisomal oxidation (*Acaa1b*, *Acox1*), while female LKO mice increased genes more involved in lipid droplet formation (*Plin2*, *Plin5*, *Cidec*) and inflammation (*Tnfa*, *Cd63*, *Mmp12*). Consistent with gene expression, protein levels of PLIN2, PLIN5, and G0S2 were significantly elevated in female LKO mice, which associated with impaired protein kinase a (PKA)-mediated triglyceride hydrolysis in these mice. **Conclusion:** Liver specific deletion of CPT1a promotes sexually dimorphic NAFLD in female mice without influencing body weight or adiposity. Mechanistically, female LKO deplete their hepatic PUFAs and increase expression of genes involved in lipid droplet metabolism and inflammation, which collectively contribute to the more severe NAFLD observed in these mice.

2294-C | DEMOGRAPHIC OUTCOMES INVOLVING PRESCREENING FOR NAFLD

Jessica Kiarra King[1], Austin Vaughn[1], Joshua T. Ghansiam[1], Anna H.T. Nguyen[1], Gabrielle Bachtel[1], Brandon A Kapalko[1], Guy W. Neff[2] and Jasmine Tidwell[1], (1)Covenant Metabolic Specialists, LLC, (2) Tampa General Medical Group, Bradenton, FL

Background: As the prevalence of NAFLD increases, challenges are fraught with diagnosing this silent epidemic. Improvements are needed in noninvasive testing to identify NAFLD. And because few NAFLD patients present with disease state symptoms, the prevalence of NAFLD is continuing to increase. Work to educate and raise awareness has been disappointing which has led to vast demographic changes in clinical patients, with limited therapeutic options. The purpose of this project is to evaluate demographic settings of at risk NAFLD patients within a large clinical site network. **Methods:** A retrospective review of medical records of patients referred for NAFLD prescreening from 11/1/2021 to 4/30/2023 was conducted. Demographic information was collected and included gender, age, ethnicity, and BMI. Reports for overall NAFLD groups were broken into, White, Black/African American, Asian, American/Alaskan American, Non-Hispanic, and Hispanic. Total patients included in the study at the Sarasota location was 449, while at the Fort Myers location, it was 375. Patient demographic outcomes were collected from patient intake forms. **Results:** Total patients included in the study at the Sarasota location was 449, while at the Fort Myers location, it was 375. The review of data reveals an average age reporting of 59.4 and 56.2 at the Sarasota (SRQ) and Fort Myers (FTM) locations respectively. While average BMI found was 32.8 (SRQ) and 34.5 (FTM). Total female patients referred to both locations amounted to 469, while male patients referred to both locations totaled 315. Patients reporting as Non-Hispanic were 388 (SRQ) and 260 (FTM), totaling 648. While Patients reporting as Hispanic/Latino were 31 (SRQ) and 109 (FTM), totaling 140. While no correlation could be drawn from BMI or age, the data provided indicates a higher percentage of Non-Hispanic White women seeking treatment for NAFLD. **Conclusion:** The above results show a striking contrast to reported NAFLD prevalence data. The data is comparable to general medicine prevalence outcomes with Non-Hispanic white women presenting for healthcare utilization at a much greater rate than other groups. This above data collected suggests NAFLD population may vary geographically, and white females tend towards healthcare utilization for NAFLD assistance.

2295-C | DEMONSTRATION OF AN AUTOMATED IN VIVO RESEARCH TOOL FOR QUANTITATIVE NON-INVASIVE 3D ASSESSMENT OF LIVER DISEASE PHENOTYPES IN MULTIPLE NASH MOUSE MODELS

Tomasz Czernuszewicz[1], Alvin Chan[2], Kelsey Jarrett[2], Christopher Hamad[2], Zara Mamouei[1], Juan D Rojas[1], Thomas Kierski[1], Brian Velasco[3], Phillip G Durham[3], Kevin Francis[1], Nicholas Bernthal[2], Paul A Dayton[3], Thomas Vallim[4] and Ryan Gessner[1], (1)Revvity, (2) UCLA, (3)UNC Chapel Hill, (4)University of California, Los Angeles

Background: Ultrasound can be used to non-invasively stage NASH-related phenotypes (e.g. steatosis and fibrosis). These imaging tools are widely implemented in the clinic, and have recently been adapted for small animal use in a flatbed robotic in vivo imaging system. Our goal was to extend this platform's existing capabilities to enable 3D shear wave elastography (SWE) captures for more comprehensive whole-organ scanning, and high throughput acquisition. Noninvasive evaluation is of particular interest in rodent models, as individual mice can be tracked over time, each being their own controls in longitudinal studies. **Methods**: A prototype Vega system (Revvity, Inc.) was programmed to include 3D wide-field SWE region-of-interest (ROI) placement and stepped scanning. The 3D SWE workflow consisted of: (1) a wide-field multi-focal-zone 3D B-mode continuous scan to locate the liver; (2) a 3D ROI bounding box encompassing the left lateral/medial lobes using the gall bladder and stomach as landmarks; (3) a 3D SWE stepped scan acquired. B-mode and SWE capture regions were approximately 40x30 mm and 15x5 mm, respectively (1.0 mm step size). Reconstruction included voxel filling with importance-

mask blending. For analysis, 3D segmentations were defined to quantify median liver stiffness and median grayscale intensity for each liver. To demonstrate feasibility, the system was tested in several different preclinical rodent models for liver disease, including Controls (N = 8), HFD (N = 16), CDAHFD (N = 16), GAN diet (N = 5), and novel CRISPR modified mice (N = 5) over 5 timepoints between 0 and 16 weeks on diet. **Results**: The 3D images collected with the Vega scanner revealed significant increases in both liver brightness and stiffness (both have been shown previously to correlate with steatosis and fibrosis respectively) in the CDAHFD and CRISPR models of liver disease ($p < 0.05$). The HFD model had not yet increased either parameter within the first month of the study. The system was also high throughput, with median scan and analysis time per animal of < 6 min (including analysis). The 3D SWE acquisition required over half the time per animal due to stepped scanning approach and transducer cool down delays between each step. **Conclusion**: 3D SWE scanning using hands-free stepped scanning is feasible, and produces consistent liver stiffness and echogenicity measurements in different mouse models of liver disease. Future studies will look to improve throughput speed and evaluate the sensitivity of the instrument in treatment response studies.

2296-C | DEVELOPING A TRANSLATIONAL BIOMARKER PANEL FOR USE IN PRE-CLINICAL ADVANCED IN VITRO STUDIES OF NON-ALCOHOLIC STEATOHEPATITIS

Tudor Petreus, Ovidiu Novac, Raul Silva, Yassen Abbas and Tomasz Kostrzewski, CN Bio Innovations

Background: Significant effort has been made to identify non-invasive clinical biomarkers for non-alcoholic steatohepatitis (NASH) and to profile proteomic and transcriptomic changes in the different stages of disease progression. Pre-clinical animal models predominantly used to study NASH often express irrelevant pathways and expression profiles that do not mirror the human disease and therefore many translational biomarkers cannot be used consistently in these studies. The need for more human relevant pre-clinical models has led to the development of microphysiological systems (MPS) that model the human liver and NASH. For MPS NASH models to be effective tools in assessing the efficacy of novel therapeutics they must express a wide range of translational biomarkers. In this study we evaluated the profile of a collection of translational biomarkers in a well characterised NASH MPS model and determined whether their expression was altered following treatment with several probe anti-NASH compounds. **Methods:** Here we used the PhysioMimix™ MPS NASH assay that comprised a mix of highly differentiated primary hepatocytes with primary Kupffer and stellate cells, which are challenged with a media containing free fatty acids to induce a NASH phenotype. The profiles of twenty soluble (e.g. IL-6, IL-8, MCP-1 MMP1, CRP, TIMP-1) and microscopy biomarkers (e.g. collegen-type-1) with evidence of expression in clinical studies were assessed in up to six different donor combinations of primary cells in the NASH MPS model. We explored what effects ASK1 inhibition, SCD1 inhibition or CCR2/5 inhibition would have on the expression of these biomarkers in the NASH MPS model. **Results:** We observed dynamic changes in the expression of inflammasome markers in the MPS NASH model, with significant expression of IL-6, IL-8 and MCP-1 whilst levels of MMP1 and Lipocalin-2 were found to decrease at longer timepoints, as more advanced fibrosis occurred. Fibrotic biomarkers were also expressed with profiles in the NASH MPS

consistent with clinical findings. For example, thrombospondin-2 which is highly predictive for advanced fibrosis in patients (>F3) was found to increase over time in the MPS NASH model. Anti-NASH compounds tested on the MPS NASH model demonstrated efficacy on both inflammasome and fibrosis biomarkers, with most significant changes observed following SCD1 inhibition and CCR2/5 inhibition but limited effects of ASK-1 inhibition. **Conclusion:** Here we profile a range of clinically relevant NASH biomarkers in a MPS human liver model and demonstrate the expression of many of these biomarkers are altered, following therapeutic intervention, in a similar manner as observed clinically. We propose the set of biomarkers identified here could be used more widely across other pre-clinical models of NASH to standardise experimental design and data generation.

2297-C | DEVELOPMENT OF A NOVEL IN VITRO MITOCHONDRIAL TOXICITY TEST BASED ON ATP INHIBITION SUBSTRATE ASSAY

Hyunwoo Oh[1], Hyo Young Lee[1], Eileen Yoon[2], Huiyul Park[3], Sang Bong Ahn[4], Joo Hyun Sohn[2] and Dae Won Jun[2], (1)Uijeongbu Eulji Medical Center, (2)Hanyang University College of Medicine, (3)Hanyang University, (4)Eulji Medical Center

Background: Mitochondrial toxicity has led to the withdrawal of numerous drugs from the market, highlighting the importance of assessing mitochondrial dysfunction during drug development. However, there is currently a lack of globally accepted methods for evaluating mitochondrial toxicity. Therefore, the objective of this study was to propose a protocol for assessing mitochondrial toxicity. **Methods:** Mitochondrion-associated transcriptome analysis was conducted on liver samples obtained from patients with non-alcoholic fatty liver disease (NAFLD) and healthy individual's. Mitochondrial dysfunction was induced in H9C2 and HepG2 cells through treatment with doxorubicin, a chemotherapeutic agent known to cause mitochondrial dysfunction. The ATP inhibition substrate test, as well as mitochondrial DNA (mtDNA) copy number analysis, was performed on peripheral blood samples collected from patients before and after chemotherapy administration. **Results:** Analysis of hepatic mRNA transcriptome revealed upregulated expression of genes associated with the mitochondrial tricarboxylic acid (TCA) cycle and mitochondrial envelope in NAFLD patients, who exhibit characteristic mitochondrial dysfunction. Treatment with doxorubicin led to concentration-dependent cytotoxicity and decreased ATP levels in H9C2 and HepG2 cells. Furthermore, increased levels of reactive oxygen species (ROS) and disrupted mitochondrial cristae were observed, contributing to a significant reduction of ATP by more than 40-50%. In addition, the proposed ATP inhibition substrate test demonstrated decreased ATP levels in the peripheral blood of patients before and after chemotherapy administration. The mtDNA copy number, an indicator of mitochondrial dysfunction, was also reduced. **Conclusion:** The ATP inhibition substrate test represents a promising approach for assessing mitochondrial toxicity. By measuring ATP levels, this novel assay provides a valuable tool for evaluating drug-induced mitochondrial dysfunction and its potential implications in drug development and patient care.

2298-C | DIFFERENTIAL ANTI-FIBROTIC EFFECTS OF SEMAGLUTIDE AND LANIFIBRANOR DEMONSTRATED BY AI-DIGITAL PATHOLOGY IN THE BIOPSY-CONFIRMED GAN DIO-NASH MOUSE MODEL WITH ADVANCED FIBROSIS AND HCC

Xiao Teng[1], Desiree Abdurrachim[2], Ashmita Saigal[3], Qiang Yang[1], Gideon Ho[1], Malte Hasle Nielsen[4], Susanne E. Pors[4], Chih-Liang Chin[3], Saswata Talukdar[3], Asad Abu Bakar Ali[2] and Michael Feigh[5], (1)Histoindex Pte Ltd, Singapore, (2)Cardiometabolic Diseases, MSD, Singapore, (3)Cardiometabolic Diseases, Merck & Co., Inc., South San Francisco, CA, (4)Gubra a/S, Copenhagen, Denmark, (5)Gubra Aps

Background: Non-alcoholic steatohepatitis (NASH) increases the risk for the development of liver fibrosis which may progress to cirrhosis and hepatocellular carcinoma (HCC). Semaglutide (glucagon-like-receptor 1 agonist) and lanifibranor (pan-peroxisome proliferator-activated receptor agonist) are currently in late-stage clinical development for NASH. The present study aimed to evaluate the efficacy of semaglutide and lanifibranor monotherapy on disease progression in the Gubra Amylin NASH (GAN) diet-induced obese (DIO) model with biopsy-confirmed advanced fibrosing NASH and HCC (GAN DIO-NASH-HCC), using both stain and stain-free artificial intelligence (AI)-digital pathology. **Methods:** Paired-biopsy samples from the GAN DIO-NASH-HCC model (52 weeks of diet) treated for 16 weeks with either vehicle, 30 mg/kg lanifibranor or 30 nmol/kg semaglutide (N = 15-17 animals/group) were included. Histopathological NAFLD Activity Score and Fibrosis Stage were first

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

evaluated by Gubra Histopathological Objective Scoring Technique (GHOST) AI-deep learning-based image analysis on HE and PSR stained images. Next, more nuanced features of fibrosis and steatosis were also examined using stain-free images captured by Second-harmonic generation/two-photon excitation fluorescence (SHG/TPEF) microscopy (Genesis®200, HistoIndex Pte Ltd, Singapore) from formalin-fixed paraffin-embedded liver tissues, where AI-based algorithms recognized three zones, namely portal tract (PT), central vein (CV) and peri-sinusoidal (PS) for zonal analysis. Multiple parameters of steatosis and fibrosis, including their distribution, composition as well as co-localization changes, were quantified and compared among intervention groups. **Results:** Semaglutide and lanifibranor promoted e 2-point significant improvement in NAFLD Activity Score, via reduced numbers of hepatocytes with lipids and inflammatory foci evaluated by GHOST deep-learning. Neither semaglutide nor lanifibranor significantly improved fibrosis stages; however, SHG/TPEF AI-based microscopy revealed that lanifibranor improved fibrosis in the PS zone and in the portion that is colocalized with both macro- and micro-steatosis, while semaglutide improved fibrosis specifically in the area colocalized with macro-steatosis, which is one of the key features to characterize human NAFLD and is also the majority of steatosis found in this animal model. **Conclusion:** Our study demonstrated that stain-free AI digital pathology provides the sensitivity to detect differential fibrosis improvement in the GAN DIO-NASH-HCC mouse model treated with lanifibranor or semaglutide, which may have not been evident by fibrosis staging alone. Fibrosis zonal and co-localization analyses have the potential in providing insights into disease biology and drug mechanisms of action.

f 2299-C | DISSECTING THE ROLES OF THE TWO HOMOLOGOUS PHOSPHOLIPID SCRAMBLASES: TMEM41B AND VMP1, IN NAFLD/ NASH

Allen Chen, Wen-Xing Ding and Hong-Min Ni, University of Kansas Medical Center, Kansas City, KS

Background: Transmembrane Protein 41B (TMEM41B) and Vacuolar Membrane Protein 1 (VMP1) are homologous endoplasmic reticulum (ER)-resident scramblases with important roles in autophagy and VLDL secretion. Hepatic loss of these proteins leads to defective autophagy and rapid development of non-alcoholic steatohepatitis (NASH) in mice. Previous studies showed that VMP1 over-expression alleviates choline-deficient amino acid-defined high-fat diet (CDAHFD)-induced NASH in mice (PMID:35452693). However, whether TMEM41B has related, albeit distinct roles from VMP1 in regulating autophagy and VLDL secretion in mouse livers is unknown. **Methods:** Liver-specific TMEM41B knockout (L-TMEM41B KO), TMEM41B KO/VMP1 KI (KOKI), and TMEM41B/VMP1 double knockout (DKO) mice were generated by crossing with Albumin-Cre mice. Serum and liver were assayed at 1, 2, and 4 months for short-and long-term changes associated with scramblase expression changes. **Results:** L-TMEM41B single KO mice had massive hepatic steatosis by 1 month with a decrease in VLDL secretion. L-TMEM41B KO mice also had increased liver LC3-II and p62 levels, confirming autophagy defect. Lipidomics analysis revealed decreased hepatic phospholipids in L-TMEM41BKO mice. Transmission electron microscopy and western blot in TMEM41B KO hepatocytes revealed decreased MAM structure and levels of PSD1 and PEMT, two enzymes critical for mitochondrial-associated ER membrane (MAM) phospholipid (PL) synthesis. Cellular fractionation identified TMEM41B and VMP1 are localized on MAM. Strikingly, defective VLDL secretion, hepatic steatosis, and LC3-II and p62 accumulation significantly resolved in 2- and 4-month-old L-TMEM41B KO mice. Impaired VLDL secretion and hepatic steatosis partially resolved in 1-month-old KOKI mice, but not increased LC3-II and p62, suggesting VMP1 may improve impaired VLDL secretion but not autophagy defect. DKO mice had impaired VLDL secretion, hepatic steatosis, and inflammation at 1 month, though they also recovered from hepatic steatosis and impaired VLDL secretion, suggesting adaptive response for VLDL secretion. Lineage tracing assay revealed clonal expansion of hepatocytes possibly derived from hepatic progenitor cells that may assist in L-TMEM41B KO and DKO mice recovery. **Conclusion:** Lack of VMP1 or TMEM41B leads to impaired VLDL secretion and steatosis that can be reversed via selective clonal hepatocyte expansion. VMP1 overexpression may partially compensate for loss of TMEM41B with respect to lipid accumulation, though it has little effect on autophagy.

2300-C | DOXAZOSIN INHIBITS PALMITIC ACID-INDUCED LIPOTOXICITY IN PRIMARY RAT HEPATOCYTES BY INHIBITING THE GENERATION OF REACTIVE OXYGEN SPECIES

Sandra A. Serna Salas[1], Magnolia Martínez[2], Aniek Vlasma[3], Manon Buist-Homan[2] and Han Moshage[1], (1) University Medical Center Groningen, (2)University Medical Center of Groningen, (3)Umcg

Background: Metabolic Dysfunction-Associated Fatty Liver Disease (MAFLD) is the most common liver disorder worldwide. It is associated with excessive accumulation of lipids in the liver. The deleterious effects of this accumulation of lipids is termed lipotoxicity. Lipotoxicity can induce cell death, persistent inflammation and eventually lead to fibrosis, cirrhosis and hepatocellular carcinoma. Doxazosin is a synthetic drug with alpha-1 adrenergic antagonistic properties. Moreover, it has anti-inflammatory properties and has been shown to reduce fibrogenesis. Aim: to elucidate whether doxazosin can protect against palmitic acid-(PA)-induced lipotoxicity in primary rat hepatocytes. **Methods:** Primary rat hepatocytes (rHeps) were challenged with PA at 1 mmol/L or 250 µmol/L. Cell death was determined by Sytox green staining and caspase-3 activity. Lipid accumulation was assessed by Oil Red O and Bodipy staining using oleic acid as a positive control. Triglyceride (TG) content was also measured. ROS generation was analyzed by MitoSox and endoplasmic reticulum stress markers were determined using qPCR and Western blot. **Results:** Cell necrosis and apoptosis were significantly induced by PA in a dose dependent manner. Doxazosin (DX) protected rHep from PA-induced cell death by either apoptosis or necrosis. Lipid accumulation was slightly increased by PA and strongly by OA. DX did not modulate the accumulation of lipids within rHeps. ROS generation by PA was abolished by DX. ER stress markers were not diminished by DX in rHep in the presence of PA, but phosphorylated JNK was significantly reduced by DX in PA-treated hepatocytes **Conclusion:** DX protects rHep against PA-induced cytotoxicity. DX reduces the generation of mitochondrial ROS and the phosphorylation of JNK which explains the protective effect of DX against hepatocyte cell death.

2301-C | E3 UBIQUITIN LIGASE NEDD4 IS A KEY NEGATIVE REGULATOR FOR GSDMD-MEDIATED PYROPTOSIS IN NON-ALCOHOLIC STEATOSIS

Rui Jin, Xiaoxiao Wang, Baiyi Liu, Zilong Wang, Yuyun Song, Xiaohe Li, Feng Liu and Huiying Rao, Peking University People's Hospital, Peking University Hepatology Institute, Beijing Key Laboratory of Hepatitis C and Immunotherapy for Liver Diseases, Beijing International Cooperation Base for Science and Technology on NAFLD Diagnosis

Background: Pyroptosis mediated by GSDMD is thought to be involved in NASH development, but the roles of GSDMD in the pathogenesis of NASH are not fully understood. In this study, we aim to illustrate the exact regulation mechanisms of GSDMD in NASH. **Methods:** We knocked down hepatocellular GSDMD and Caspase-1 in mice via the CRISPR-AAV-Sacas9 system respectively, and mice fed a methionine-choline deficient (MCD) diet to induce NASH. After confirming the pathway of pyroptosis in NASH mice, Co-IP and multidimensional mass spectrometry(MS) was performed to identify the ubiquitinates/deubiquitinases co-acting with GSDMD. NEDD4 was knocked known or overexpressed in mice livers by injection of AAV vectors. 293T and AML12 cells were used for in vitro studies. **Results:** We confirmed the canonical inflammasome pathway in MCD-induced NASH mice by detecting the increased protein levels of NLRP3, GSDMD, GSDMD-N, Caspase-1, and Caspase-1 P20 in NASH mice. The knockdown of hepatocellular GSDMD or Caspase-1 could ameliorate pathological manifestations in NASH mice. Interestingly, we found that GSDMD mRNA levels were downregulated in NASH mice compared with control mice, a discrepancy between GSDMD mRNA levels and GSDMD protein levels indicated that GSDMD protein might undergo post-translational modifications. And we found that ubiquitination levels of GSDMD, especially K48 polyubiquitination levels of GSDMD were decreased in the liver of NASH mice compared with control ones. The knockdown of Caspase-1 could decrease the protein level of GSDMD and increase the ubiquitination levels of GSDMD but did not affect GSDMD mRNA, indicating that Caspase-1 might not directly regulate GSDMD. Multiple ubiquitinates/deubiquitinases co-acting with GSDMD were identified by co-IP combined with MS. The interaction between NEDD4 and GSDMD was confirmed by further co-IP both in vivo and in vitro. It was found that the knockdown of NEDD4 in AML12 cells can up-regulate the protein expression level of GSDMD, and the overexpression of NEDD4 can reduce the protein expression level of GSDMD. We also confirmed the

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

overexpression of NEDD4 can increase the k48-linked polyubiquitination of GSDMD in 293T cells and AML12 cells, the ubiquitination of GSDMD was significantly reduced after PA and LPS treatment in AML12 cells. Besides, the knockdown of Caspase-1 could increase the protein levels of NEDD4. The overexpression of NEDD4 in mice liver could decrease the protein levels of GSDMD, and increase the the k48-linked polyubiquitination of GSDMD while. In NASH mice, the overexpression of NEDD4 effectively reduced the protein levels of GSDMD and GSDMD-N compared with OE-Vector group. **Conclusion:** NEDD4 directly interacts with GSDMD, and mediates k48-linked polyubiquitination of GSDMD, regulating the protein level of GSDMD in NASH. Our findings revealed NEDD4 is a key negative regulator of GSDMD, GSDMD ubiquitination may be considered as a novel therapeutic target for NASH.

2302-C | EFFECTS OF HEPATOCYTE-SPECIFIC DELETION OF EGFR IN A DIET-INDUCED NAFLD MOUSE MODEL

Shehnaz Bano, Matthew Avery Copeland, Anne Orr, Silvia Liu, Joseph Locker, John Stoops, Wendy M. Mars, George K. Michalopoulos and Bharat Bhushan, University of Pittsburgh

Background: Nonalcoholic fatty liver disease (NAFLD) is a most prevalent liver disorder that is linked to an increased risk of developing liver fibrosis and hepatocellular carcinoma. Epidermal growth factor receptor (EGFR) is well known to regulate hepatocyte proliferation and regeneration in liver. In our previous study, we found that chemical inhibition of EGFR utilizing Canertinib, dramatically reduced hepatocyte steatosis, liver injury, and fibrosis, in a murine fast-food diet (FFD) model, indicating a potential role for EGFR in regulating NAFLD. **Methods:** We extended our studies of the EGFR role in NAFLD by investigating the effect of hepatocyte-specific EGFR deletion in a murine NAFLD model. 8-10 weeks old $EGFR^{flox/flox}$ mice were injected adeno associated virus 8 (AAV-8) expressing Cre recombinase with a thyroxin binding globulin (TBG) promoter (hepatocyte-specific promoter) to knockout EGFR in hepatocytes (EGFR KO). The EGFR KO or wild-type (WT) mice were fed normal chow diet or FFD for 2 months. **Results:** FFD-fed EGFR KO mice displayed significant reduction in serum triglyceride levels with histologically evident lower fat accumulation, mainly in the periportal areas of liver, compared to WT mice. At transcriptional level, EGFR deletion significantly reduced expression of SREBF1 (a major transcriptional regulator of fatty acid synthesis) along with its downstream fatty acid synthase gene and increased expression of lipolysis genes such as PNPLA2. FFD-fed EGFR KO mice showed lower protein expression of PPARγ compared to FFD-fed WT mice. Further, our transcriptomic analysis via RNA sequencing and subsequent Ingenuity Pathway Analysis revealed significant alteration of hepatic fibrosis/stellate cell activation pathways along with inhibition of TGFβ1 signaling (a key driver of liver fibrosis) in EGFR KO mice compared to FFD-fed WT mice. However, the overall effect of hepatocyte-specific EGFR deletion on steatosis and gene signatures associated with NAFLD was much weaker compared to systemic pharmacological inhibition observed in our previous study. Lastly, deletion of EGFR enhanced expression and phosphorylation of the other ErbB family members (HER2 and HER3), indicating a potential compensatory mechanism for the loss of EGFR signaling in hepatocytes. **Conclusion:** The hepatocyte-specific deletion of EGFR alters lipid metabolism and fibrosis signaling in a murine FFD model of NAFLD, but is much less effective compared to pharmacological inhibition of EGFR.

Guo[2], (1)Rutgers University, (2) Rutgers University, Piscataway, NJ, (3)Environmental and Occupational Health Sciences Institute, Rutgers, the State University of New Jersey, Piscataway, NJ

Background: Bile acids (BA) are synthesized in the liver from cholesterol and function as signaling molecules that aid in fat absorption and regulate lipid and glucose homeostasis. BA species selectively activate nuclear receptors, including the farnesoid X receptor (FXR), to regulate their synthesis and induce target gene expression including fibroblast growth factor 19 (FGF19). BA dysregulation is a key feature of liver diseases, such as nonalcoholic steatohepatitis (NASH), with modulation of the FXR-FGF19 axis as a promising therapeutic target for

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

treatment. Acute feeding of individual BAs differentially affects lipid, inflammation, and oxidative stress pathways in low BA mice, *Cyp7a1/Cyp27a1* double knockout (DKO). The current study determines effects of individual BAs in the DKO mice on NASH development. **Methods:** Eight-week old male wild-type (WT) and DKO mice were fed a low-fat (LFD) or high-fat-high-sugar-high-cholesterol (HFHSD) diet composed of 49% sucrose, 20% fat, and 1.25% cholesterol containing vehicle (0% w/w) or individual BAs DCA (0.1% w/w); UDCA (0.1% w/w); CA (0.2% w/w) for 16 weeks. Serum and tissues were collected following feeding. Hepatic injury, steatosis, inflammation, and fibrosis were assessed by H&E, IHC, hepatic lipid extraction (cholesterol, triglycerides), and qPCR. **Results:** DKO mice on HFHSD were found to be insulin sensitive compared to WT diet controls. HFHSD DKO mice were resistant to weight gain and accumulation of white adipose tissue compared to WT mice, which was unaffected by BA feeding. DKO mice fed LFD CA and DCA had increased hepatic cholesterol and triglycerides compared to WT and DKO vehicle, while DKO mice fed HFHSD with CA or DCA only had elevated hepatic cholesterol compared to respective to vehicle. IHC and mRNA data suggest dietary exposure to CA or DCA, in LFD or HFHSD, induced inflammation in DKO mice compared to vehicle. Fibrosis was promoted in WT LFD CA and DKO HFHSD CA and DCA compared to respective vehicle groups per genotype. Individual BA feeding significantly altered classical BA synthesis pathway and subsequent downstream FXR gene expression in LFD treatments. UDCA acts as an intestinal FXR activator, while CA and DCA activate liver and intestinal FXR. **Conclusion:** UDCA may act as an intestinal FXR agonist in low BA states. Individual BAs, CA and DCA, promoted fibrosis and inflammation in WT mice on LFD and DKO mice on HFHSD. Significant alterations in lipid uptake and metabolism following BA feeding indicate differences in cholesterol and lipid handling across genotypes.

2304-C | EFFECTS OF URSODEOXYCHOLIC ACID ON NASH DEVELOPMENT IN MICE WITH HEPATIC DEFICIENCY OF FXR

Zakiyah Henry[1,2,3], Syeda Maliha[2], Bo Kong[1,2,3] and Grace L. Guo[1,2,3], (1)Environmental and Occupational Health Sciences Institute, Rutgers, the State University of New Jersey, Piscataway, NJ, (2)Department of Pharmacology and Toxicology, Rutgers, the State University of New Jersey, Piscataway, NJ, (3)Rutgers Center for Lipid Research, Rutgers, the State University of New Jersey, New Brunswick, NJ

Background: Farnesoid X Receptor (FXR) has been identified as a therapeutic target for non-alcoholic steatohepatitis (NASH). FXR agonism and antagonism have both proven to be beneficial in the mitigation of NASH, leading to much controversy in the field, particularly regarding FXR signaling in the gut. The objective of this study was to determine the effects of ursodeoxycholic acid (UDCA), a postulated gut FXR antagonist, on the mitigation and prevention of NASH development in mice. **Methods:** Six- to eight-week-old male and female Liver FXR knockout ((*Fxr*$^{floxed/floxed}$, albumin Cre (+), *Fxr* LKO) and control (Cre-) mice were fed either a low-fat control diet or a NASH "Fast Food" (FF) diet (Western diet with 21% milk fat, 1.25% cholesterol, and 34% sucrose) both supplemented with 0.1% (w/w) UDCA for 16 weeks. Body weights were recorded weekly, and an oral glucose tolerance test (GTT) was performed at 3 months. Serum biochemistry was analyzed, and liver-to-body weight ratio was calculated. The expression levels of genes involved in NASH development were determined. Moreover, liver pathology was assessed, and immunohistochemistry staining was conducted for activated macrophages as an indirect measurement of inflammation. **Results:** Over the course of treatment, no alterations were seen in body weight, food intake, GTT, and serum biochemistry from UDCA feeding. Gene expression data showed that UDCA feeding resulted in a significant induction of *Fxr* in the ileum and a trending increase in the liver. The FXR target gene, *Fgf15*, was also significantly increased in the ileum of UDCA-fed mice. Lipocalin 2 (*Lcn2*) was induced by FF + UDCA-feeding, whereas lipocalin 13 (*Lcn13*) was obliterated by FF + UDCA feeding. Regarding bile acid synthesis, the gene expression results suggested that the classical pathway is upregulated in UDCA-fed mice. Furthermore, total serum levels of bile acids were significantly increased in FF-fed mice. **Conclusion:** The data strongly suggest that in contrast to the report that UDCA is a gut FXR antagonist, in this study, UDCA seems to act as an FXR agonist, especially in the ileum. In addition, UDCA may not be as protective in NASH development in male mice as originally reported, manifested by the increase in Lcn2, an inflammation indicator, and decrease in Lcn13, an FXR function indicator in male mouse livers, upon FF + UDCA feeding. This effect will be determined in female mice in the future.

2305-C | EFFECTS OF VERTICAL SLEEVE GASTRECTOMY IN MICE WITH INTESTINE SPECIFIC DEFICIENCY OF FIBROBLAST GROWTH FACTOR 15

Katherine Otersen[1,2], Bo Kong[3], Monica D. Chow[1,4], Andrew Wassef[1], Daniel Rizzolo[1,5], Somwya Yamathy[1], Vik Meadows[1], Rulaiha E Taylor[1], Laura Armstrong[6], Leonid Kagen[2], Yi-Horng Lee[7] and Grace L. Guo[2,3,8], (1) Rutgers University, Piscataway, NJ, (2)Department of Pharmacology and Toxicology, Rutgers, the State University of New Jersey, Piscataway, NJ, (3) Environmental and Occupational Health Sciences Institute, Rutgers, the State University of New Jersey, Piscataway, NJ, (4)University of Miami Leonard M. Miller School of Medicine, Miami, FL, (5)Charles River Laboratories, Wilmington, MA, (6)Bristol Myers Squibb, (7)Rutgers Robert Wood Johnson Medical School, Rutgers, the State University of New Jersey, New Brunswick, NJ, (8)Rutgers Center for Lipid Research, Rutgers, the State University of New Jersey, New Brunswick, NJ

Background: Obesity prevalence is rising and comorbidities like non-alcoholic liver disease (NAFLD), which impairs liver function and bile acid signaling, are of growing concern. Vertical sleeve gastrectomy (SGx), the surgical removal of 80% of the stomach, is the main medical intervention for weight reduction. The molecular mechanisms by which SGx improves liver disease in morbidly obese patients remains elusive. A key finding associated with SGx shows increased circulating bile acids (BAs) and fibroblast growth factor 19 (FGF19). The endocrine factor FGF15/19 (mouse FGF15, human FGF19) is highly expressed in ileal enterocytes and released postprandially to critically suppress BA synthesis in the liver. Emerging studies show that FGF15/19 improves energy expenditure and decreases body weight, providing a therapeutic strategy for obese patients. Therefore, we hypothesize that the resolution of NAFLD in mice undergoing SGx is due to the induction of FGF15 by increased BAs. **Methods:** The current study used wild-type (WT) and intestine-specific *Fgf15* knockout (*Fgf15*$^{ile-/-}$) mice fed a high-fat diet (HFD) for 3 months to induce obesity, at which point mice underwent sham surgery or SGx and were continued on HFD for 1-3 months. Following feeding determination of metabolic effects and gene expression changes were measured in all mice. **Results:** In obese WT mice, SGx produced improved metabolic effects including decreased weight and adiposity, improved insulin sensitivity, and diminished NAFLD progression. Interestingly, *Fgf15*$^{ile-/-}$ mice showed a marked improvement of metabolism including NAFLD characteristics compared to WT mice post-SGx. This improvement was also seen in the relative expression of genes involved in BA and lipid homeostasis. This includes decreased expression of genes associated with BA transport in the intestine and liver, increased BA synthesis and improved lipid metabolism. Despite improved NAFLD progression, *Fgf15*$^{ile-/-}$ mice showed increased inflammatory and fibrotic gene expression following SGx compared to WT mice. **Conclusion:** The marked improvement seen in Fgf*15*$^{ile-/-}$ suggests that the metabolic benefits and reversal of NAFLD progression may be associated with, but independent of, FGF15 induction. Since the *Fgf15*$^{ile-/-}$ mice had a larger BA pool size and maintained higher serum concentrations of BAs post-SGx, the improved metabolic effects associated with SGx may be due to increased serum levels and altered composition of BAs post-SGx.

2306-C | ENDOGENOUS Has2-MEDIATED HYALURONAN SYNTHESIS LIMITS AGE-ASSOCIATED WEIGHT GAIN, ADIPOSE HYPERTROPHY, AND HEPATIC TRIGLYCERIDE CONTENT

Michele T. Pritchard, Ian Ensley, Vanessa Schmidt and Wendena S. Parks, University of Kansas Medical Center

Background: Advanced physiologic age is often associated with increased body mass, fat to lean body mass ratio, and hepatic triglycerides (TG), and this can promote metabolic perturbations characteristic of non-alcohol associated fatty liver disease (NAFLD). Hyaluronan (HA), an extracellular matrix glycosaminoglycan, is increased in non-alcohol-associated steatohepatitis patient liver and blood, HA increases in parallel with fibrosis score, and hyaluronan synthase (*Has)2* mRNA correlates with increased plasma and hepatic HA content. While overexpressing *Has2* in hepatic stellate cells enhances liver fibrosis in mice, overexpressing *Has2* in hepatocytes and/or adipocytes reduces body mass, liver TG and adipocyte hypertrophy in a diet-induced mouse fatty liver disease model. Here, we tested the hypothesis that mice expressing only endogenous *Has2* (no functional Has1 or Has3) would be protected from age-associated weight gain, adipocyte hypertrophy, and hepatic steatosis. **Methods:** Female wild-type (WT) and *Has1,Has3* double knockout (*Has1,3* dko) mice were aged to 7 weeks (young) or 17 months (old) and fed normal mouse chow (5% calories from fat). Liver, white adipose tissue (WAT), and blood were collected; whole body and organ mass was measured. Liver TG was quantified using a biochemical assay. Adipocyte area

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

was determined using ImageJ. Plasma HA was measured using an ELISA-like assay. **Results:** Plasma HA content did not differ between genotypes or with age but tended to be lower in *Has1,3* dko mice. All following study parameters were not different between young WT and young *Has1,3* dko mice. While both strains increased body mass with age, body mass doubled in old relative to young WT mice. Body mass increased only 30% in old *Has1,3* dko mice and was less than old WT mice. With age, WAT/body weight ratios increased in WT mice (0.8 +/- 0.1% young, 4.1 +/- 0.3% old) and *Has1,3* dko mice (0.8 +/- 0.01% young, 2.3 +/- 0.2% old) but this increase was 44% less in old *Has1,3* dko mice. Consistently, average adipocyte area doubled in WT mice while it increased only 1.5-fold with age in *Has1,3* dko mice and was less than WT mice. Finally, hepatic TG content increased with age in WT mice, but not in *Has1,3* dko mice. **Conclusion:** Together, these data suggest that HA synthesized by Has2 protects mice from age-associated alterations of liver and adipose tissue. Thus, increasing Has2-mediated HA production may offer therapeutic promise to limit progressive age-associated changes in metabolic tissues.

2307-C | ENDOPLASMIC RETICULUM STRESS INDUCES HEPATIC STEATOSIS VIA CHAPERONE-MEDIATED AUTOPHAGY INHIBITION

Wonseok Lee[1,2], Karin Diggle[1], Tatiana Kisseleva[1], David A. Brenner[1,3] and Byung-Hoon Lee[2], (1) University of California, San Diego School of Medicine, (2)Seoul National University, (3)Sanford Burnham Prebys Medical Discovery Institute

Background: Nonalcoholic fatty liver disease (NAFLD) progresses from steatosis (nonalcoholic fatty liver, NAFL) to nonalcoholic steatohepatitis (NASH). NAFL is characterized by the accumulation of lipids in hepatocytes, and endoplasmic reticulum (ER) stress is associated with hepatic lipid accumulation. Chaperone-mediated autophagy (CMA), a specific type of autophagy, facilitates the breakdown of lipid droplets (LD) by lysosomes. Using ER stress inducers and diet-induced NASH in mice, we investigated the molecular mechanism by which ER stress leads to impaired CMA activity and hepatic lipid accumulation. **Methods:** C57BL/6 mice were injected with tunicamycin through intraperitoneal injection. C57BL/6 mice were fed with a methionine-choline deficient diet (MCD) for 4 weeks, or a choline-deficient L-amino acid-defined high-fat diet (CDHFD) for 8 weeks for diet-induced NASH mice models. **Results:** Treatment of tunicamycin and thapsigargin (ER stress inducers) significantly decreased the protein level of LAMP2A, the critical regulator of CMA in primary mouse hepatocytes. Intraperitoneal injection of tunicamycin into mice led to reduced LAMP2A expression, along with an increase in CMA substrates, including LD-coated protein perilipin 2 (PLIN2), in the liver tissues. Treatment of CMA activator, AR7, or ER stress inhibitor, taurodeoxycholic acid, in primary mouse hepatocytes restored the level of PLIN2 induced by tunicamycin. Activating transcription factor 3 (ATF3), one of the transcription factors involved in regulating ER stress, was responsible for the reduction of LAMP2A expression under the ER stress condition. Knockdown of ATF3 with siRNA significantly induced the expression of LAMP2A, and overexpression of ATF3 decreased the expression of LAMP2A in primary mouse hepatocytes. Based on the GEO dataset (GSE48452), an inverse correlation was observed between the expression of LAMP2A and the severity grade of NASH in human liver samples from patients. We confirmed an increase in ER stress markers, including ATF3, and a decrease in LAMP2A expression in NASH livers induced by MCD or CDHFD in mice. **Conclusion:** Our findings revealed that ER stress induces lipid accumulation through the inhibition of CMA in liver. The upregulation of ATF3, caused by ER stress, led to the inhibition of CMA and subsequent hepatic lipid accumulation.

2308-C | ESCHERICHIA COLI PROMOTES ENDOTHELIAL TO MESENCHYMAL TRANSFORMATION OF LIVER SINUSOIDAL ENDOTHELIAL CELLS AND EXACERBATES NON-ALCOHOLIC FATTY LIVER DISEASE VIA ITS FLAGELLIN

Bo Shen and Lungen Lu, Shanghai General Hospital, Shanghai Jiao Tong University School of Medicine

Background: Gut bacteria translocate into liver through disrupted gut vascular barrier, which is an early common event in the development of non-alcoholic fatty liver disease (NAFLD). Liver sinusoidal endothelial cells (LSECs) are directly exposed to the translocated gut microbiota in portal vein blood. *Escherichia coli* (*E.coli*), a gut commensal bacteria with flagella, is significantly enriched in gut microbiota in NAFLD patients. However, whether and how *E.coli* affect NAFLD progression remain

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

unclear. **Methods:** The abundance of *E.coli* in a cohort of NAFLD patients and healthy controls was analyzed by 16S ribosomal RNA sequencing. The role of *E.coli* was estimated in NAFLD mice after 16 weeks of administration, and features of NAFLD were assessed. *E.coli*–derived epithelial to mesenchymal transition (EndMT) in LSECs was also analyzed by western blot and immunofluorescence. **Results:** The abundance of gut *Enterobacteriaceae* was increased in NAFLD patients with severe fat deposition and fibrosis. Importantly, the translocated *E.coli* in the liver aggravated hepatic steatosis, inflammation and fibrosis in NAFLD mice. Mechanistically, *E.coli* induced EndMT in LSECs via TLR5/MYD88/TWIST1 pathway during NAFLD development. TLR5 inhibitor attenuated *E.coli*-induced EndMT in LSECs and liver injury in NAFLD mice. Interestingly, flagellin-deficient *E.coli* promoted less EndMT in LSECs and liver injury in NAFLD mice. **Conclusion:** *E.coli* promoted the development of NAFLD and promoted EndMT in LSECs through TLR5/NF-κB-dependent activation of TWIST1 mediated by flagellin. Therapeutic interventions targeting *E.coli* and/or flagellin may represent a promising candidate for NAFLD treatment.

2309-C | ESCULETIN PROTECTS AGAINST LIPOTOXICITY IN PRIMARY RAT HEPATOCYTES VIA ATTENUATING JNK-MEDIATED OXIDATIVE STRESS AND AMPK-MEDIATED LIPID ACCUMULATION

Mengmeng Xia, Zongmei Wu, Manon Buist-Homan and Han Moshage, University Medical Center Groningen

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) is currently the most prevalent chronic liver disease and the major indication for liver transplantation. There is no effective drug-based therapy for it. Impaired lipid metabolism, leading to lipotoxicity, is the main contributor to MAFLD, making lipotoxicity an important therapeutic target. There is evidence that both JNK and AMPK play critical roles in regulating lipotoxicity. Coumarin-like compounds, e.g. esculetin, have been shown to regulate activation of JNK and AMPK in liver injury and to exhibit hepatoprotective effects. This study aims to explore the potential protective effect of the coumarin-derivative esculetin in lipotoxicity. **Methods:** Primary rat hepatocytes were isolated using two-step collagenase perfusion. Palmitate (PA) and free fatty acids (FFAs, a mixture of thepalmitate and oleate) were used to mimic lipotoxicity. Oxidative stress was measured *via* detection of cellular ROS and mitochondrial superoxide. Cell necrosis was assessed by SYTOX green nuclear staining and LDH release assay. Lipid accumulation was determined by Oil Red O, BODIPY-LD staining and triglyceride measurement. The levels of anti-oxidant genes Nrf2, GpX1 and Sod1 and lipid metabolism-associated genes Srebp1c, Ppar-α, and Cd36 were measured by RT-PCR. Activation (phosphorylation) of JNK and AMPK were detected by Western Bot. **Results:** Esculetin significantly alleviated oxidative stress in PA-treated primary hepatocytes by reducing ROS production and increasing expression of anti-oxidant genes, including Nrf2 and Gpx1. Esculetin suppressed PA-induced necrosis in primary hepatocytes. Compared to PA, FFA induced lipid accumulation rather than toxicity in primary hepatocytes. Esculetin improved lipid metabolism in FFA-treated primary hepatocytes by decreasing expression of Srebp1c and increasing expression of Ppar-α as well as reducing lipid accumulation. The protective effect of esculetin was dependent on the inhibition of JNK and activation of AMPK. Treatment with the JNK inhibitor SP600125 reduced oxidative stress and necrosis and treatment with the AMPK inhibitor Compound C increased lipid accumulation. **Conclusion:** Esculetin prevented lipotoxicity via reducing JNK-induced oxidative stress and improving AMPK-dependent lipid metabolism. Esculetin might be a promising compound to target lipotoxicity in MAFLD.

2310-C | EXACERBATION OF LIVER INJURY IN A MOUSE MODEL OF NON-ALCOHOLIC FATTY LIVER DISEASE THROUGH INDUCTION OF GUT FUNGAL DYSBIOSIS

Vijay Pandyarajan, Cedars-Sinai Medical Center, Los Angeles, CA and Ekihiro Seki, Cedars-Sinai Medical Center, Torrance, CA

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Non-alcoholic fatty liver disease (NAFLD) is projected to become the leading cause for liver transplantation within the next 30 years. However, there are currently no approved therapies for NAFLD other than targeted weight loss. Recently, the gut microbiota has gained attention as a potentially modifiable risk factor for disease due to its association with obesity. Despite being present in smaller quantities, fungi, an often-overlooked component of the gut microbiota may play a significant role in liver pathophysiology. Our objective therefore was to understand the impact of manipulating the gut mycobiota on the development or progression of NAFLD. **Methods:** In our study we employed a long-term high fat/high sugar feeding animal model of NAFLD. To manipulate the gut mycobiota, we utilized amphotericin B or fluconazole in the animal's drinking water. Additionally, we employed a genetic knockout of Caspase Recruitment Domain-9 (CARD9), which impairs the immune response against fungi. After a 6-month feeding period, animals were sacrificed. Liver, blood and stool samples were collected for analysis. Liver histology was performed to evaluate the amount of steatosis and fibrosis. Stool samples collected from these mice were subjected to next-generation sequencing analysis targeting both bacterial and fungal populations. **Results:** Our study revealed significant findings regarding the impact of specific interventions on gut fungal populations in mice. Administration of fluconazole or presence of a CARD9 knockout resulted in a notable reduction in fungal alpha-diversity while mice consuming amphotericin B had preserved fungal alpha-diversity. Importantly, mice with reduced fungal alpha-diversity displayed elevated markers of liver injury and fibrosis. Analysis of the taxonomic composition of the gut microbiota found in the stool revealed variations in the abundance of several mold genera in the groups with lower fungal alpha-diversity. Reductions were seen in the following mold genera: Aspergillus, Cladosporium, Penicillium, Trichoderma and Ustilago. When bacterial alpha-diversity is taken into account, groups with a reduced fungal to bacterial alpha diversity ratio exhibited the most severe disease. **Conclusion:** Our study establishes an association with fungal dysbiosis and liver injury in the context of a diet-induced obesity animal model of NAFLD. Specifically, we observed a correlation between reductions in fungal alpha-diversity and liver injury markers. However, further research is warranted to elucidate the underlying mechanisms that drive this phenomenon. Future studies should focus on the interaction of specific fungal species or the crosstalk between gut fungi and bacteria. Extending these results to human cohorts will be important to determine the relevance of these findings. Targeting and manipulating gut mycobiota could therefore hold promise as a novel approach to treating NAFLD.

2311-C | EXPOSURE TO PERFLUOROALKYL SUBSTANCES ALTERS LIPID METABOLISM AND TRIGGERS CANCER PATHWAYS IN HUMAN LIVER SPHEROIDS

Ana C. Maretti-Mira[1], Matthew P. Salomon[1], Chikako Matsuba[1], Veronica Wendy Setiawan[2], Brittney O. Baumert[3], David V. Conti[3], Lida Chatzi[3] and Lucy Golden-Mason[1], (1)USC Research Center for Liver Diseases, Division of Gastrointestinal and Liver Diseases, Department of Medicine, Keck School of Medicine, University of Southern California, (2) Department of Population and Public Health Sciences, Keck School of Medicine and Norris Comprehensive Cancer Center, University of Southern California, (3) Department of Population and Public Health Sciences, Keck School of Medicine, University of Southern California

Background: Exposure to steatogenic environmental pollutants increases the risk of non-alcoholic fatty liver disease (NAFLD) development and progression to non-alcoholic steatohepatitis (NASH). Poly- and perfluoroalkyl substances (PFAS) are highly stable synthetic chemicals widely used in industry and consumer products. PFAS persist in the environment, contaminating air, soil, and drinking water throughout the United States. Perfluorooctane sulfonate (PFOS) is associated with changes in metabolism and an increased risk of non-viral hepatocellular carcinoma (HCC), although the mechanisms remain elusive. Perfluorohexane sulfonate (PFHxS), a PFAS analogous to PFOS, has raised concerns as potentially hazardous. However, its effects on human health are not defined. Our study explores the molecular mechanisms whereby PFOS/PFHxS disrupt liver metabolism and facilitate NAFLD development. **Methods:** We combined 3D human primary liver spheroids and single-cell RNAseq (scRNA-Seq) analysis to investigate metabolic disruption induced by PFOS/PFHxS. 3D InSight^{TM} human liver spheroids (InSphero) are composed of hepatocytes (10 donors: 5 males and 5 females), endothelial cells, and macrophages (1 donor). Liver spheroids were maintained in low glucose medium (lean medium) and exposed to 20μM of PFOS or 20μM of PFHxS for 7 days. Control spheroids were cultured in lean medium

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

© 2023 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

for the same time. We dissociated spheroids with Trypsin, generating suitable cells for 10x genomics scRNAseq (kit 3' v3.1). **Results:** PFOS modified the expression of almost 2,000 genes in liver spheroids, while PFHxS only affected 205 genes. Both PFAS changed the global gene expression of hepatocytes and macrophages. We observed a significant upregulation of pathways involved in lipid metabolism, with PFHxS affecting mainly the hepatocytes. Regarding the inflammatory pathways in macrophages, PFOS inhibited overall cell activation, while PFHxS upregulated oxidative stress and IL-10 signaling. PFOS induced significant enrichment of cancer-related pathways, especially in macrophages. PFOS inhibited the expression of metallothioneins in hepatocytes, a family of peptides involved in cell detoxification. **Conclusion:** Our findings suggest that PFOS and PFHxS have distinct effects on liver spheroids. PFOS remarkably induced cancer-related pathways, while PFHxS primarily affected the lipid metabolism of hepatocytes. Metallothioneins may be involved in counteracting the pro-oncogenic effects of PFAS in the liver.

2312-C | EXTRACELLULAR VESICLES DERIVED FROM LIVER SINUSOIDAL ENDOTHELIAL CELLS INHIBIT THE ACTIVATION OF HEPATIC STELLATE CELLS AND KUPFFER CELLS IN VITRO

Junyu Wang, Zongmei Wu, Mengmeng Xia, Sandra A. Serna Salas, Johanna C Arroyave Ospina, Manon Buist-Homan, Martin C. Harmsen and Han Moshage, University Medical Center Groningen

Background: Liver sinusoidal endothelial cells (LSECs) play a crucial role in maintaining liver microcirculation and homeostasis. In chronic liver diseases, hepatic stellate cells (HSCs) and Kupffer cells (KCs) become activated and LSECs undergo dedifferentiation and capillarization, hampering their normal function. Although KCs and HSCs are intimately involved in the onset and progression of inflammation and fibrosis in chronic liver disease, the role of LSECs in the development of chronic liver diseases remains unclear. Extracellular vesicles (EVs) are released from a variety of cells and contain a plethora of bioactive molecules, including proteins and RNAs and are important mediators of intercellular communication. Aim: to investigate the effect of LSEC-derived EVs on the activation of KCs and HSCs. **Methods:** Primary rat LSECs, HSCs and KCs were isolated from male Wistar rats. EVs were isolated from condition medium (CM) of LSECs by ultracentrifugation and evaluated by nanoparticle tracking analysis, transmission electron microscopy and determination of specific markers. EVs were added to target cells for 24/72 hours. Gene expression was determined by qPCR and protein expression was determined by Western blot and immunofluorescence and proliferation of cells by Xcelligence and BrdU assay. **Results:** LSECs-derived EVs reduced the expression of the fibrotic markers collagen type 1 and α-smooth muscle actin (αSMA) in activated HSCs. LSECs-derived EVs significantly suppressed proliferation of activated HSCs. EVs also decreased the expression of inflammatory genes in activated KCs *in vitro*: *iNOS* by 72.6%, *TNF-α* by 54.9%, *IL-6* by 35.6%, and *IL-1β* by 59.5%. **Conclusion:** EVs released from normal LSECs inhibit the activation of HSCs and the inflammatory phenotype of KCs. LSECs are therefore crucial in maintaining normal liver homeostasis. Elucidating the content of these EVs may lead to the identification of novel therapeutic and/or diagnostic targets for chronic liver diseases.

2313-C | EXTRAHEPATIC/ INTRAPANCREATIC CYTOKINE PRODUCTION PROMOTES HEPATOCARCINOGENESIS FROM NONALCOHOLIC STEATOHEPATITIS

Seita Kataoka[1], Atsushi Umemura[1], Kanji Yamaguchi[1], Yuya Seko[1], Michihisa Moriguchi[1], Toshihide Shima[2], Takeshi Okanoue[3] and Yoshito Itoh[1], (1)Kyoto Prefectural University of Medicine, (2)Saiseikai Suita Hospital, Suita, Osaka, Japan, (3)Saiseikai Suita Hospital

Background: Nonalcoholic fatty liver disease (NAFLD), the leading etiology of chronic liver disease, is mainly caused by insulin resistance and can lead to hepatocellular carcinoma (HCC). Hyperglycemia, a risk factor for NAFLD, induces *KRAS* mutations in pancreatic cells; thus, NAFLD and pancreatic *KRAS* mutations can exist simultaneously. Here, we aimed to determine the impact of pancreatic *Kras* mutations on the pathogenesis of nonalcoholic steatohepatitis (NASH) in mice. **Methods:** MUP-uPA mice (MUP mice) were used as the NASH model, and a conditional KrasG12D model (KC mice: *LSL-Kras$^{G12D/+}$;PDX-1-Cre*) was used as the pancreatic

Symbols: **f** , Poster of Distinction; ★, Foundation Award Recipient

Kras mutation model. MUP, KC, and MUP-KC mice (progeny from a cross between KC and MUP mice) were fed a high-fat diet until 24 weeks of age for analysis. **Results:** HCC developed in 33 of 34 MUP-KC mice, 6 of 45 MUP mice, and 1 of 14 KC mice, with a significantly higher rate in MUP-KC mice. In RNA analysis using next-generation sequencing, 236 genes involved in the inflammatory pathways were significantly upregulated in MUP-KC mice compared with MUP mice. Interestingly, 125 of these genes were transcriptional targets of signal transducer and activator of transcription 3 (STAT3). In western blotting analysis, STAT3 phosphorylation was significantly increased in noncancerous areas in MUP-KC mice. Antibody microarray analysis of the portal vein showed increased expression of cytokines, such as regenerating family member 3 gamma, representing inflammatory changes in the pancreas. **Conclusion:** *Kras* mutations may increase STAT3 phosphorylation in the liver via cytokine production, accelerate HCC cell proliferation, and promote HCC development in the NASH liver.

f 2314-C | Fgl2-C3aR AXIS MEDIATED NEUTROPHIL EXTRACELLULAR TRAPS PROMOTE INTRAVASCULAR COAGULATION AND LIVER FIBROSIS IN NASH PROGRESSION

Xitang Li[1], Suping Hai[1], Junjian Hu[1], Qiang Gao[1], Wenhui Wu[1], Binghui Yu[1], Erliang Xie[1], Qin Ning[2] and Xiaojing Wang[3], (1)State Key Laboratory for Diagnosis and Treatment of Severe Zoonotic Infectious Diseases, Department and Institute of Infectious Disease, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, (2)Institute and Department of Infectious Disease, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, (3)Tongji Medical College and State Key Laboratory for Diagnosis and Treatment of Severe Zoonostic Infectious Disease, Huazhong University of Science and Technology

Background: Procoagulant imbalance was observed in non-alcoholic steatosis (NASH) patients with liver fibrosis, but the role of coagulation in NASH fibrosis remains largely unclear. Neutrophil extracellular traps (NETs) served as an essential factor in immuno-thrombosis. Here, we aim to study the role of NETs-mediated coagulation in NASH fibrosis and the underlying mechanism. **Methods:** NETs were depleted by intraperitoneal injection of DNase 1. Anti-Ly6G was used to deplete neutrophils. Wild type (WT) and *fgl2*$^{-/-}$ C57BL/6 mice were treated either with 60% high fat diet (HFD) or methionine/choline-deficient (MCD) diet to induce NASH fibrosis. To explore the role of C3aR in NASH fibrosis, MCD mice received C3aR antagonist (SB290157). Whole transcriptome sequencing of hepatic tissues or liver leukocytes were conducted in WT and fgl2-/- mice. For in vitro study, bone marrow neutrophils from WT and *fgl2*$^{-/-}$ mice were subjected to palmitic acid (PA) and LPS, NETs formation and related proteins were detected following treatment. **Results:** Abundant neutrophil accumulation and NETs formation were observed in NASH progression. NETs depletion improved liver fibrosis, inflammatory response and lipid accumulation both in HFD and MCD mouse models. Meanwhile, decreased hepatic fibrin deposition, plasma thrombin-anti-thrombin complex and fibrinogen expression were observed following DNase 1 treatment. Fibrinogen-like protein 2 (FGL2) was highly expressed on hepatic neutrophils in NASHmodels. *Fgl2*$^{-/-}$ mice showed significant reduction of NETs levels and hepatic fibrin deposition, along with decreased complement and coagulation factors, including TAT, fibrinogen, C3a and C5a expression. Combined with RNA-sequencing results, we found that *fgl2*$^{-/-}$ mice showed significantly decreased C3aR expression. *In vitro* experiment showed C3aR mediated NETs formation following PA and LPS

treatment. C3aR antagonist treatment showed improved liver fibrosis and alleviated inflammatory response *in vivo*. In detail, decreased NETs formation, hepatic fibrin deposition as well as complement and coagulation factors expression were observed in NASH models following C3aR antagonist treatment. **Conclusion:** NETs mediated coagulation dysregulation promotes NASH fibrosis progression. FGL2 mediated NETs formation was regulated by C3aR. NETs act as amplifiers of immune-thrombosis in NASH fibrosis progression, and targeting NETs might serve as a potential therapeutic target in NASH fibrosis.

2315-C | GENOME-WIDE ANALYSIS OF DNA METHYLATION CHANGES ASSOCIATED WITH NAFLD PROGRESSION TO ADVANCED FIBROSIS OR NASH

Jin Li, Texas a&M University and Robert Tsai, Texas a&m University

Background: Non-alcoholic fatty liver disease (NAFLD) has become a leading cause of hepatocellular carcinoma (HCC) in western countries. NAFLD includes a wide spectrum of liver diseases, ranging from simple steatosis to HCC. The majority of NAFLD-related HCCs (f-HCC) are detected at an advanced stage when cure is rarely possible. Hence, there is an urgent unmet need to understand the molecular events driving the progression of NAFLD for risk assessment and prevention of f-HCC. Two major risk factors preceding f-HCC are advanced liver fibrosis (ALF) and non-alcoholic steatohepatitis (NASH). To date, the mechanisms driving NAFLD progression remain unclear. To address this question, we analyzed DNA methylation changes that occurred as simple steatosis developed into ALF or NASH. **Methods:** Genome-wide methylomic data using the Human Methylation 450K Beadchip on human NAFLD samples were collected from datasets of five independent cohorts (2 in Germany, 2 in US, 1 in Japan), processed and analyzed using the ChAMP package. Meta-analyses were performed to identify differentially methylated regions (DMRs) associated with f-ALF (by comparing NAFLD-F3/4 to NAFLD-F0/1) and non-fibrotic NASH (by comparing NASH-F0/1 to NAFLD-F0/1). Genomic distributions of DMRs were determined by Hotspot analysis. Pathways of DMR-associated genes were analyzed using Gene Set Enrichment Analysis (GSEA) and Gene Ontology (GO). **Results:** 263 f-ALF hypo-DMRs and 444 hyper-DMRs were identified by comparing NAFLD-F3/4 (n = 38) against NAFLD-F0/1 (n = 61). Eight non-fibrotic NASH hypo-DMRs and three hyper-DMRs were identified by comparing NASH-F0/1 (n = 22) to NAFLD-F0/1 (n = 61). The majority (~90%) of those DMRs were distributed in the promoter region within 1 kb of the transcriptional start site (TSS). Analysis of age/sex-matched samples revealed 18 f-ALF hypo-DMRs and 732 hyper-DMRs. GO analyses showed that genes associated with the 732 hyper-DMRs are highly enriched in metabolic pathways, such as RNA metabolism, fatty acid oxidation, and lipid oxidation. Homer analysis discovered five transcription factors associated with f-ALF hyper-DMRs (KLF1, KLF3, KLF6, Sp2, and Isl1). Notably, 23 f-ALF hypo-DMRs and 30 hyper-DMRs were also found differentially methylated in viral HCC compared to normal tissue adjacent to the tumor. **Conclusion:** This study identified novel targets that might regulate the progression of NAFLD from simple steatosis to advanced fibrosis and/or NASH via DNA methylation mechanisms, thereby increasing the risk of HCC formation.

2316-C | GPNMB CONTRIBUTES TO NASH PROGRESSION WITH M2 POLARIZATION OF HEPATIC MACROPHAGES AND ACTIVATION OF HEPATIC STELLATE CELLS

Kenji Fukumoto[1], Hayato Hikita[1], Shusuke Kumazaki[1], Seiya Kato[1], Yoichi Sasaki[1], Kazuhiro Murai[1], Takahiro Kodama[2], Tomohide Tatsumi[1] and Tetsuo Takehara[2], (1)Osaka University, Graduate School of Medicine, (2) Osaka University Graduate School of Medicine

Background: Recently, with the advent of single cell RNA analysis, NASH-associated macrophages (NAMs) characterized by high expression of TREM2 and GPNMB have attracted much attention. However, the details of the effects of NAMs and GPNMB on the pathogenesis of NASH have not been elucidated, and we aimed to clarify these effects. **Methods:** In vivo experiments, wild-type mice were fed western diet for 12 or 24 weeks to induce NASH. STAM mice were used as a model of NASH carcinogenesis, in which wild-type mice were treated with streptozotocin and fed a high-fat diet for 14 weeks. We performed single cell RNA analysis of liver tissue from NASH patients and measured serum GPNMB levels of NAFLD patients. In vitro experiments were performed using THP-1, a human monocytic cell line, HepG2, a human hepatocellular carcinoma cell line, and LX-2, a human stellate cell line. **Results:** Single cell analysis of liver tissues from NASH model mice showed that GPNMB was highly expressed in CD68-positive macrophages. GPNMB gene expression was markedly upregulated in

macrophages isolated from liver tissues of NASH model mice compared to that of normal diet group. Fluorescent immunostaining of NASH model mouse liver tissue showed a Hepatic Crown-like structure with TUNEL-positive cells surrounded by GPNMB-positive cells. Serum GPNMB levels in the NASH mouse model showed a high positive correlation with GPNMB and COL1A1 gene expression levels in liver tissue. Gene expression of GPNMB was upregulated in the liver tumor area of STAM mice compared to the non-tumor area. Single-cell RNA sequencing of liver tissue from two NASH patients showed that GPNMB was highly expressed in CD68-positive macrophages. Serum GPNMB levels were measured in 467 NAFLD patients and were significantly higher in the NASH group compared to the NAFL group. Serum GPNMB levels increased with the progression of NAFLD activity score and liver fibrosis stage. Gene expression and protein levels of GPNMB increased when THP-1 macrophages were treated with palmitic acid and cholesterol, and also increased when THP-1 macrophages phagocytosed apoptotic bodies prepared by irradiating HepG2 with UV light. Administration of recombinant GPNMB enhanced gene expression of COL1A1, ACTA2, and TGFB1, which are activation markers of LX-2. The expression of M2 macrophage marker genes such as TGFB1 and CD163 in THP-1 macrophages was enhanced by treatment with recombinant GPNMB. On the other hand, knockout of GPNMB gene by CRISPR-Cas9 system suppressed the expression of these genes. **Conclusion:** GPNMB derived from liver macrophages was suggested to contribute to the development of liver fibrosis and carcinogenesis in NASH by promoting macrophage differentiation into M2 type and activating hepatic stellate cells.
