2440 | FROM PORTAL HYPERTENSION TO DECOMPENSATION: SHIFTING RISK PROFILES AND TIME TO EVENTS ACROSS CIRRHOSIS STAGES IN A US REAL-WORLD OBSERVATIONAL STUDY

Megan Schroeder[1] Salva Augustin[2] Eric Lawitz[3] Ronald Herrera[2] Mireia Raluy[4] Mark Yates[5] Ziyi Li[6] Harmony Omeife[7] Thomas Reiberger[8], [1]Boehringer Ingelheim International GmbH, Institute for Medical Information Processing, Biometry, and, [2]Boehringer Ingelheim International GmbH, Binger Straße 173, Ingelheim, 55218 Ingelheim am Rhein, Ger, [3]Texas Liver Institute, University of Texas Health San Antonio, San Antonio, TX, USA, [4]Evidera Ltd, Löfströms Allé 5 172 66 Sundbyberg Sweden, [5]Evidera Ltd. King's College London, [6]Evidera Ltd, PPD Pharmaceutical Development (Beijing) Co., Ltd. 23rd Floor, Raffles City, Beijing Of, [7]Evidera Ltd, The Ark, 2nd Floor 201 Talgarth Road London W6 8BJ United Kingdom, [8]Medical University of Vienna

Background: Portal hypertension (PH) is the key determinant of cirrhosis progression to decompensation and liver-related mortality. PH diagnosis is often delayed, limiting effective treatment by non-selective betablockers (NSBBs). Using a real-world data source, we evaluated PH-related event rates across cirrhosis stages. **Methods:** Observational cohort study using the US Optum Market Clarity Database. Three cohorts were identified between January 2016 and May 2021, and followed-up until the earliest of May 2022, liver transplantation, death, or loss to follow-up. Patients with: · Advanced chronic liver disease (cACLD) and PH (cohort 1); · Cirrhosis and a single decompensation event (cohort 2); · Cirrhosis and >1 decompensation event (cohort 3). Patient characteristics are reported. Cumulative incidence rates per 100 person-years (PY) and incidence proportions at 30-days and 1-year were calculated for all-cause mortality, liver transplant, first decompensation, further decompensation ($\geq$ 2 events at least 7 days apart) and hospital admissions. Time to events was calculated. **Results:** 14,344, 26,907 and 31,145 patients were identified in cohorts 1-3, respectively. Comorbidity burden increased with disease severity (Table 1); 94.2% of cohort 3 had a Charlson Comorbidity Index score of 4+. Depression ($>39\%$) and fatigue ($>45\%$) were prevalent. NSBBs were only used in 20.6% of patients in cohort 1. The 1-year all-cause mortality rate was 3.2%, 15.7% and 18.4% in cohorts 1-3, with a median time to death over the study period of 2 years in cohort 1, and <1 year in cohorts 2 and 3. Mortality incidence rates per 100 PY across the study period were 4.0, 12.5 and 15.5 in cohort 1-3. The 1-year first decompensation rate in cohort 1 was 19.6% with a median time to event of 1.2 years. 1-year further decompensation event rate was 73.3% and 77.3% in cohort 2-3, with the median time to event <0.1 years. First and further decompensation incidence rates were 18.5, 125.7 and 163.0 per 100 PY in cohorts 1-3. **Conclusion:** There is a significant disease burden in terms of quality of life indicators, comorbidities, decompensation and mortality in patients with cirrhosis, which is further aggravated in decompensated cirrhosis. Rates of NSBB treatment were alarmingly low. The study highlights the importance of preventing the first decompensation event in patients with cirrhosis and PH.

Table 1 Demographics, clinical characteristics, and outcome rates across cirrhosis cohorts

	Cohort 1: cACLD and PH	Cohort 2: First decompensated	Cohort 3: Further decompensated
N	14,344	26,907	31,145
Sociodemographic variables			
Age,years (median, IQR)	61 (55-68)	60 (53-68)	61 (54-69)
Male (n, %)	7,283 (50.7%)	14,769 (54.9%)	16,992 (54.6%)
% White Ethnicity	9,294 (64.7%)	17,990 (66.9%)	20,378 (65.4%)
Baseline Comorbidities (identified prior to index date)			
CCI, 4+ (n, %)	13,165 (91.9%)	23,409 (87.0%)	29,329 (94.2%)
Myocardial infarction	596 (4.2%)	1,468 (5.5%)	3,663 (11.8%)
Congestive heart failure	2,340 (16.3%)	7,195 (26.7%)	12,693 (40.8%)
Peripheral vascular disease	3,355 (23.4%)	7,174 (26.7%)	11,964 (38.4%)
Cerebrovascular disease	2,368 (16.5%)	5,505 (20.5%)	10,200 (32.8%)
Ischemic heart disease	1,763 (12.3%)	4,745 (17.6%)	7,868 (25.3%)
Hypertension	11,210 (78.2%)	21,324 (79.3%)	27,010 (86.7%)
Hemiplegia or paraplegia	279 (2.0%)	809 (3.0%)	1,856 (6.0%)
Dementia	294 (2.2%)	1,030 (3.8%)	2,511 (8.1%)
Chronic pulmonary disease	6,042 (42.1%)	11,784 (43.8%)	17,308 (55.6%)
Connective tissue disorder	1,389 (9.7%)	2,346 (8.7%)	3,197 (10.3%)
Diabetes with or without chronic complications	7,372 (51.4%)	12,786 (47.5%)	17,337 (55.7%)
Renal disease	2,451 (17.1%)	6,503 (24.2%)	12,045 (38.7%)
Any malignancy including leukaemia and lymphoma	2,442 (17.0%)	4,971 (18.5%)	6,910 (22.2%)
Metastatic solid tumour	473 (3.3%)	1,595 (5.9%)	2,037 (6.5%)
Mild liver disease	14,344 (100%)	25,797 (95.9%)	30,422 (97.7%)
AIDS/HIV	284 (2.0%)	434 (1.6%)	626 (2.0%)
QoL Indicators			
Fatigue	6,731 (46.9%)	14,505 (53.9%)	21,473 (69.0%)
Depression	5,695 (41.1%)	11,773 (43.8%)	17,914 (57.5%)
History of alcohol abuse	3,616 (25.2%)	13,059 (48.5%)	17,719 (56.9%)
Outcomes			
All-cause mortality			
30-days (%)	0.2 (0.2-0.3)	3.0 (2.8-3.2)	3.3 (3.1-3.5)
1-year (%)	3.2 (2.9-3.5)	15.7 (15.2-16.1)	18.4 (18.0-18.8)
Overall study period (per 100 person-years)	4.0 (3.9-4.2)	12.5 (12.2-12.8)	15.6 (15.2- 15.9)
Time to event (years)	2.0 (0.9-3.3)	0.6 (0.2-1.6)	0.7 (0.2-1.9)
Liver Transplant			
30-days (%)	0.02 (0-0.06)	0.2 (0.1-0.2)	0.2 (0.1-0.2)
1-year (%)	0.5 (0.4-0.6)	1.7 (1.6-1.9)	1.8 (1.7-2.0)
Overall study period (per 100 person-years)	1.0 (0.9-1.1)	2.0 (1.9-2.2)	2.1 (2.0-2.2)
Time to event (years)	2.3 (1.3-3.7)	1.2 (0.6-2.2)	1.2 (0.5-2.4)
Decompensation (First in cohort 1, further in cohort 2/3)			
30-days (%)	3.3 (3.0-3.6)	60.0 (50.4-51.6)	49.9 (49.3-50.4)
1-year (%)	19.6 (18.9-20.2)	73.3 (72.7-73.8)	77.4 (77.0-77.8)
Overall study period (per 100 person-years)	18.5 (18.0-18.9)	125.8 (124.1-127.4)	163.0 (161.1-165.0)
Time to event (years)	1.2 (0.4-2.5)	0.04 (0-0.3)	0.05 (0.01-0.3)
All-cause hospital admissions (per 100 person-years)	32.2 (31.6-32.9)	151.2 (149.3-153.1)	130.3 (128.8-131.9)

2441 | EFFICACY AND SAFETY OF ORAL IBANDRONATE IN PATIENTS OF LIVER CIRRHOSIS WITH HEPATIC OSTEODYSTROPHY: A RANDOMIZED, DOUBLE BLIND, PLACEBO-CONTROLLED TRIAL [NCT06022237]

Sudhir Verma[1] Chitranshu Vashishtha[2] Manoj Sharma[2] Rajan Vijaraghvan[2] VINOD ARORA[2] Satender Pal Singh[3] Sukriti Baweja[2] Ashok Choudhury[4] Shiv Kumar Sarin[3], [1]Institute of Liver and Biliary Sciences. New Delhi, [2]Institute of Liver and Biliary Sciences, New Delhi, [3]Institute of Liver and Biliary Sciences, [4]ILBS, New Delhi

Background: Hepatic osteodystrophy (HOD) is a metabolic bone disease associated with liver cirrhosis. Despite high prevalence, it is often overlooked. Oral bisphosphonates are a promising option, often discouraged in cirrhosis due to risk of upper gastrointestinal bleeding(UGIB) related to varices and esophagitis. Previous studies on HOD are either non-randomized or open labelled RCT and have focussed mainly in cholestatic liver diseases. **Methods:** Consecutive patients of HOD with low-risk varices between 18 to 70 years of age were included. Patients with high-risk varices, history of UGIB in last 2 months., grade 3 ascites, history of pathological fracture & taking drugs causing bone-loss were excluded. Primary objective was to compare changes in bone mineral density (BMD, ΔT score) at lumbar spine in DEXA scan after 1 year of oral ibandronate 150 mg once monthly (group I) and placebo (group II). The secondary objectives were to compare Δ T score at femur neck and adverse event profile. All patients received calcium 500 mg and Vit D3 500 IU twice daily **Results:** Of 240 patients screened, 173(72.08%) had HOD, and 80 fulfilled the criteria{mean age 51.14 $\pm$ 11.27 yrs, males 64(80%), alcohol 42 (52.5%), baseline MELD 14.9 $\pm$ 6.9, CTP score 8.5 $\pm$ 6.9 & ascites in 51.9%(grade I = 29,1%,gradeII = 22.8%)}. Prior bleeder were 14(17.5%) with low-risk gr II varices in 46.3%, grade I in 23.8%, eradicated varices in 22.5% and no varices in 7.5%. At lumbar spine, T-score improved from -2.46 $\pm$ 0.98 to -1.51 $\pm$ 1.27 (+38.61%, ΔT = -0.95 $\pm$ 0.17) in gr. I and from -2.66 $\pm$ 0.98 to -2.53 $\pm$ 0.96 (+10.54%, Δ T = -0.13 $\pm$ 0.31) in gr II ($p < 0.001$). At femur neck, T-score improved from -1.66 $\pm$ 0.82 to -1.37 $\pm$ 0.85 (+17.57%, ΔT = -0.29 $\pm$ 0.12) in gr I and from -1.653 $\pm$ 0.85 to-1.651 $\pm$ 1.11 (+0.12%, ΔT = -0.002 $\pm$ 0.31) in gr II ($p = 0.03$). Gr I showed significant reduction in bone turnover markers (ng/ml)[Δ osteocalcin = -76.82 $\pm$ 49.2($p = 0.004$), Δ procollagen type 1C propeptide(PICP) = -40.3 $\pm$ 24.2 ($p = 0.001$), Δ c-terminal telopeptide of type I collagen(CTX) = -0.41 $\pm$ 0.3 ($p = 0.021$), Δ amino-terminal telopeptide of type 1 collagen(NTX) = -8.42 $\pm$ 9.48 ($p = 0.020$)]. Liver frailty index significantly improved in gr I with reduction of 0.44 $\pm$ 0.18 and increased by 0.08 $\pm$ 0.04 in gr II ($p = 0.008$). Adverse events included dyspepsia, 3(3.75%) in group I (1 discontinued) and 2(2.5%) in gr II. **Conclusion:** Oral Ibandronate improves BMD both at lumbar spine and femur neck significantly better

2442 | VISCERAL ADIPOSITY AREA (VAT)-BASED SARCOPENIC OBESITY SIGNIFICANTLY INCREASES CIRRHOTIC PATIENTS' RISK OF LIVER DISEASE-RELATED MORTALITY

Yi Jiang[1] Guo Feng[2] Hong Yu[3] Jin-hua Jing[4] Wei Sun[5] Yu-yu Li[6] Lei Yang[6] Guzhenur Yiliyar[7] Xin Da[3] Xiao-zhong Wang[2], [1]The Chinese University of Hong Kong (Shenzhen) Affiliated Hospital No. 2 & Longgang District People, [2]Xinjiang Uygur Autonomous Region Hospital of Traditional Chinese Medicine, [3]Xinjiang Karamay Central Hospital, [4]Xinjiang Changji Prefecture Hospital of Traditional Chinese Medicine, [5]Shaanxi University of Traditional Chinese Medicine Hospital, [6]The Fourth Clinical College of Xinjiang Medical University, [7]Affiliated Hospital of Chengdu University of Traditional Chinese Medicine

Background: The prevalence of sarcopenia and obesity is increasing as a result of global urbanization, aging, and changing lifestyles, and has become an important public health problem worldwide.The aim of this study was to investigate the effect of sarcopenic obesity(SO), defined based on visceral adipose area (VAT), on the risk of liver disease-related mortality in cirrhotic patients. **Methods:** This study retrospectively included cirrhotic patients hospitalized in the Department of Hepatology of Xinjiang Autonomous Region Hospital of Traditional Chinese Medicine from January 2020 to December 2022, and CT scan images at the level of the third lumbar vertebrae were selected, and image post-processing was performed using the Slice-O-matic software to compute the skeletal muscle index (SMI) and VAT; based on the third lumbar vertebrae level skeletal muscle index (L3-SMI) <50 cm²/m² (male) or <39 cm²/m² (female) was used to diagnose sarcopenia; VAT >100 cm² was defined as obesity, and SO was defined as obesity by meeting the above criteria at the same time, and the patients were followed up every 3 months, and the time and cause of death were recorded. Survival curves were plotted by Kplan-Meier analysis, and cumulative risk curves were used to assess the survival of cirrhotic patients. **Results:** (1) A total of 258 cases were included in this study, and 208 patients with cirrhosis were finally included, in which the prevalence of SO was 46.15% (96/208). (2) All patients were followed up for 24 months, and death occurred in 36 patients, of which 34 died of liver disease-related deaths, 12 died of rupture and bleeding of esophagogastric fundal varices, 4 died of secondary infections, 7 died of hepatic encephalopathy,9 died of hepatic failure, and 2 died of hepatic malignant tumors; the liver disease-related mortality rates in the myxedematous obesity group and non-myxedematous obesity group were 25.00% (24/96) and 8.93% (96/96), respectively. 96), and 8.93% (10/112), respectively. (3) Survival analysis showed that the cumulative risk of death at 12 and 24 months was higher in the SO group compared with the non-sarcopenic obesity group(NSO) [HR: 4.260 (95% CI: 1.689-10.746), Log rankP <0.001; HR: 3.566 (95% CI: 1.704-7.446), Log rankP <0.001]. 0.001]. Subgroup analysis showed that the cumulative risk of death at 12 and 24 months was higher in the SO group compared with the obesity-only group and sarcopenia-only group [HR: 3.371 (95% CI: 1.140 to 9.969),Log rank P $=0.019$] vs [HR: 4.962 (95% CI: 1.150 to 21.402),Log rank P $=$ 0.016], [HR:3.076(95% CI:1.256~7.532),Log rankP $=0.009$] vs [HR:3.439(95% CI:1.192~9.921),Log rankP $=0.014$]. **Conclusion:** SO is prevalent in cirrhosis; SO based on VAT significantly increases the risk of liver disease-related death in cirrhotic patients; early identification of SO can help improve the prognosis and quality of survival in cirrhotic patients.

2443 | USE OF PIPERACILLIN-TAZOBACTAM IN PATIENTS HOSPITALISED WITH COMPLICATIONS OF CIRRHOSIS IN ATTIRE WAS ASSOCIATED WITH INCREASED MORTALITY

Gemma Wells[1] Harriett Fuller[2] Louise China[1] Eduard Atanasescu[1] Alastair O'Brien[1], [1]University College London, [2]Fred Hutchinson Cancer Research Center

Background: Infection is common in patients with advanced liver disease, who are often prescribed broad-spectrum antibiotics. These prescriptions are often empirical, chosen prior to microbiology results, and commonly continued if no micro-organism is cultured. However, broad-spectrum antibiotics may be harmful, with piperacillin-tazobactam previously associated with higher mortality in non-cirrhotic patients with sepsis. **Methods:** In the ATTIRE (Albumin to Prevent Infection in Chronic Liver Failure) trial, 777 patients were randomized to daily 20% albumin infusions or standard of care during hospitalization with decompensated cirrhosis across 35 United Kingdom (UK) hospitals (2016-2019). We analysed antibiotic prescribing in patients diagnosed with infection at trial entry reasoning that the antibiotic choice would be empirical i.e. prior to culture availability. We performed adjusted logistic regression modelling adjusted for age, gender, baseline albumin, creatinine, bilirubin, white cell count (WCC) and C-reactive protein (CRP) to evaluate whether use of certain antibiotics was associated with death at 90 days. **Results:** 211 patients were diagnosed with infection and prescribed antibiotics at trial entry, with data available for 205. 279 antibiotics were prescribed for these 205 patients, with the most frequent piperacillin-tazobactam (74). Baseline characteristics for those prescribed piperacillin-tazobactam were similar to the second most frequent antibiotic (co-amoxiclav, 46), with the only significant difference being creatinine levels (75 vs 61 mmol/L, p = 0.03). Patients prescribed piperacillin-tazobactam at baseline were found to be at increased risk of death at 90 days compared to those prescribed other antibiotics (OR = 2.89, 95% CI 1.44-5.91, P = 0.003). This association between piperacillin-tazobactam and death at 90 days remained when considering individuals only prescribed piperacillin-tazobactam at baseline (OR = 2.81, 95% CI 1.31-6.17, P = 0.01). Piperacillin-tazobactam prescription in combination with other empirical antibiotics was not associated with increased risk of death. Age consistently associated with increased risk of death (OR~ 1.06) throughout. The cause for the association between piperacillin-tazobactam and 90-day mortality is not clear. We note that incidence of renal dysfunction was similar to overall and for those prescribed co-amoxiclav, although only 2/14 of the piperacillin-tazobactam patients that developed renal dysfunction received reduced dosing. **Conclusion:** There was substantial variability in empirical antibiotic prescribing in this real-world cohort of patients, with piperacillin-tazobactam most frequently prescribed. However, our data suggest that the use of this antibiotic may cause harm. We encourage clinicians to be judicious in their antibiotic choices and dosing regimens, particularly in patients with renal dysfunction.

2444 | THE ALBI SCORE, A PROGNOSTIC MARKER IN ADVANCED HEPATIC FIBROSIS: A PROSPECTIVE SINGLE-CENTER STUDY

Maxence de Callataÿ[1] Alix Collard[2] Géraldine Dahlqvist[1] Nicolas Lanthier[1] Peter Starkel[1] Yves Horsmans[1] Bénédicte Delire[1], [1]Hepatology Department, Cliniques Universitaires Saint-Luc, Brussels, belgium, [2]Statistical Unit, Cliniques Universitaires Saint-Luc, Brussels, Belgium

Background: Advanced liver fibrosis (ALF) is associated with significant morbidity and mortality. The ALBI (albumin-bilirubin) score has been validated as a prognostic marker in HCC. Retrospective studies suggest ALBI as a prognostic marker in ALF. This study aims to prospectively evaluate ALBI in ALF. **Methods:** This is a prospective, single-centre study including all patients with ALF (F3-F4 according to Metavir classification) based on elastometry, histology or radiological data, excluding HCC. At inclusion, Child-Pugh,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

MELD and ALBI scores were calculated. The primary objective was to evaluate at 1 year according to ALBI grade the occurrence of: death, hospitalisation for all causes, hospitalisation for hepatic decompensation, admission to ICU and liver transplantation (LT). The secondary objective was to compare the ALBI score with other prognostic scores. **Results:** 106 patients were included: 67 ALBI grade I (63.2%), 32 grade II (30.2%) and 7 grade III (6.6%). Six deaths (5.7%) were observed, with a significant difference according to ALBI grade (I:1.5%, II:12.5%, III:14.3%; $p = 0.0364$). Patients were more likely to be hospitalised according to ALBI grade: for all causes (I:9%, II:56.3%, III:85.7%; $p < 0.001$); for ascitic decompensation (I:1. 5%, II :18.8% and III :42.9%; $p = 0.002$), for hepatic encephalopathy (I :3%, II :21.9% and III :71.4%; $p < 0.001$), for infections (I :0%, II :31.3% and III :57.1%; $p < 0.001$). ICU admissions were more frequent in the grade III group (I:16.7%, II:0% and III:60%; $p = 0.0039$). Three patients were transplanted in the grade III group and none in the other groups ($p = 0.002$). According to Kaplan-Meier method, the probability of survival was lower in the grade II and III group compared with the grade I group ($p = 0.0446$) and the probability of hospitalisation from all causes or associated with liver decompensation was significantly higher in grade II and III groups ($p < 0.0001$ and $p < 0.0001$). The AUROC for overall survival for the ALBI, Child-Pugh and MELD scores was 0.86, 0.83 and 0.74, while the AUROC for the occurrence of hepatic decompensation was 0.85, 0.89 and 0.82. According to the chi-square score, dichotomisation of the ALBI score is the best model for predicting overall survival in this cohort. **Conclusion:** This is the first prospective study showing the prognostic impact of the ALBI score in ALF. In our cohort, the prognostic performance for overall survival was superior with the ALBI score compared with the MELD and Child-Pugh scores. These results encourage the use of the ALBI score in daily clinical practice in ALF patients.

2445 | STRUCTURAL AND ENERGETICS-DIRECTED IDENTIFICATION OF NOVEL ALK5-AMPK AXIS AS A MEDIATOR OF HYPERAMMONEMIC STRESS AND SARCOPENIA IN CIRRHOSIS

Srinivasan Dasarathy[1] Sadashiva Karnik[1] Nicole Welch[1] Seshu Vardhan Pothabathula[1] Muaz Alsabbagh Alchirazi[1] Saurabh Mishra[1] Dhanachandra Khuraijam[1] Pugazhendhi Kannan[1] Annette Bellar[1] Dongmei Zhnag[1] Belinda Willard[1], [1]Cleveland Clinic

Background: Hyperammonemic stress response (HASR) causes sarcopenia in cirrhosis via myostatin, a transforming growth factorß (TGFß) superfamily member-dependent AMPKα2 activation. Canonical myostatin signaling occurs via activin IIB receptor-dependent activation of ALK4/5 kinase function, but whether AMPK is a direct target of the myostatin-ALK4/5 axis is unknown. Integrated molecular docking/dynamics and in vitro kinase/mass spectrometry approaches showed that myostatin-ALK5-AMPK axis mediates sarcopenia in HASR. **Methods:** To determine the ALK4-AMPKα2 and ALK5-AMPKα2 complexes, we performed molecular docking using HADDOCK 2.4 with the 3D structures of ALK4, ALK5, and AMPKα2. Clustered conformations are ranked by the HADDOCK score for binding energy. Top ranked conformations of ALK4-AMPKα2 and ALK5-AMPKα2 set for Molecular Dynamics Simulations (MD) using GROMACS tools using AMBER99SB force fileds continued to minimization, NVT/NPT equilibration at 300° K and (1 bar) followed by a 100ns production MD. Principal Component Analysis (PCA) and Free Energy Landscape (FEL) covariance matrix computed to obtain (PC1, PC2) components. Free energy is calculated for total complex and residual energy contribution to overall binding. Experimental validation was done by in vitro kinase assays and LC-MS to identify phosphorylation sites on AMPKα2. **Results:** Molecular docking of ribbon conformations exhibited the minimum binding energy for ALK4-AMPKα2 (-192 kcal/mol) and ALK5–AMPKα2 conformation-1 (–344 kcal/mol). MD simulations showed ALK4 and ALK5 establish stable conformation with AMPKa2 through distinct mechanisms that facilitate phosphorylation. Hydrogen bonds at Thr188, Asp185, and Ser168 on ALK4 orients the active site to AMPKα2. MD analysis showed RMSD equilibrated state at 40-100 ns had significant instability of 2.1 nm for ALK4-AMPKα2. Conversely, the ALK5–AMPKα2 conformation-1, interactions between Ser172, Glu173, and Asp179 on ALK5 with Arg171, Thr172, and Ser173 on AMPKα2, had stable RMSD (2.0 nm) by substrate anchoring. Free energy of ALK5–AMPKα2 exhibited a reduced total free energy ranging from -28.85 to -72.95 kcal/mol, and at stable state the total energy scored -50.90 kcal/mol. The polar solvation penalty 461.99 of ALK5–AMPKα2 had greater structural stability and electrostatic complementarity vs ALK4- AMPKα2. Consistently, in vitro kinase assay showed phosphorylation of AMPKα2 by ALK5, and mass spectrometry showed AMPKα2 phosphorylation at Thr172 with retention time shift and ~80Da increase in net mass. **Conclusion:** ALK5 is an optimal structural and energetic partner for AMPKα2, facilitating a phosphorylation-competent assembly via distinct catalytic interactions and stable conformations. Structural alignment of ALK5 with experimental validation of Thr172 phosphorylation shows ALK5–AMPKα2 as a target for designer

2446 | SARCOPENIA IS AN INDEPENDENT PREDICTOR OF FURTHER DECOMPENSATION AND MORTALITY AFTER ENDOSCOPIC AND ENDOVASCULAR INTERVENTIONS FOR SECONDARY PROPHYLAXIS OF GASTRIC VARICES IN PATIENTS WITH CIRRHOSIS: A MULTICENTRE, REAL-WORLD STUDY

Sagnik Biswas[1] Souveek Mitra[2] Santhosh Kumar[3] Piyush Aggarwal[4] R G Krishna Kumar[1] Shekhar Swaroop[1] Shubham Mehta[1] Arun Valsan[5] Sanchita Gupta[1] Falguni Hota[2] Goldwin H Cecil[3] Ravi Chaudhary[6] Rajkumar Bayye[1] Samagra Agarwal[1] Umang Arora[7] P Krishna Bharadwaj[3] Shivanand Gamanagatti[1] Ashish Goel[3] Rajesh Puri[8] Anurag Yadav[7] Abhijit Chowdhury[2] Raju Sharma[1] Ankur Goyal[1] . Shalimar[4], [1]All India Institute of Medical Sciences, New Delhi, [2]Indian Institute of Liver and Digestive Sciences, [3]Christian Medical College Vellore, [4]All India Institute of Medical Sciences. New Delhi, [5]Amrita Institute of Medical Sciences, Kochi, [6]Medanta the Medicity, [7]Sir Ganga Ram City Hospital New Delhi, [8]Medanta-The Medicity

Background: Sarcopenia is associated with adverse health-related outcomes and poor survival rates in patients with cirrhosis. However, the impact of sarcopenia on the long-term outcomes of patients with cirrhosis presenting with gastric variceal (GV) hemorrhage is not well known. **Methods:** In this multicentric retrospective analysis, patients with cirrhosis presenting with GV bleeding at 6 tertiary care centres in India from January 2017 to January 2023 were included. Baseline demographics, mortality and further decompensation events- rebleeding, ascites and hepatic encephalopathy (HE) were reviewed. Cross-sectional imaging was used to assess skeletal muscle index (SMI) and intramuscular adipose tissue (IMAT). Gender-specific threshold values of SMI <42 cm^2/m^2 for men and <38 cm^2/m^2 for women were used to identify sarcopenia. Propensity score matched (PSM) analysis (1:1) was performed and the rates of mortality, further decompensation and rebleeding were assessed. Competing risk analysis was done to assess the risk of rebleeding and further decompensation with mortality as a competing event. **Results:** Three hundred and eighteen patients with 214 (67.3%) males were included. The median CTP and MELD scores were 7 (6-9) and 11 (9-15) respectively. Seventy nine (24.8%) patients had sarcopenia. One hundred and sixty seven (52.5%) patients received endoscopic cyanoacrylate glue injection, while 70 (22%) patients underwent EUS guided coil and glue injection. BRTO and TIPS were performed in 61 (19.2%) and 20 (6.3%) patients, respectively. MASLD (49/79, 62%) was the leading cause of cirrhosis in patients with sarcopenia. Sixty (18.9%) patients died over a median follow-up period of 732 (397-1092) days. In the PSM cohort, sarcopenia was associated with higher mortality rates (22 [27.8%] vs 11 [14.1%]; $p=0.04$) and a 1-, 2- and 3-year probability of mortality of 15.3%, 24.9%, 41.1% as compared to 9.1%, 14.9%, 14.9% in non-sarcopenic patients (Fig 1A). Rates of further decompensation were also higher in those with sarcopenia (49 [62%] vs 31 [39.2%]; $p<0.01$) with 1-, 2- and 3-year probability of further decompensation being 41.5%, 57% and 65.1% as compared to 24.8%, 36.1% and 42.8% among non-sarcopenic patients (Fig 1B). Rebleeding rates were similar in both groups (sarcopenia: 27[34.1%] vs no sarcopenia 18[22.8%]; $p=0.113$), while ascites (39 [49.4%] vs 18 [22.8%]; $p<0.01$) and HE (21 [26.6%] vs 6 [7.6%]; $p<0.01$) were significantly higher on follow-up among those with sarcopenia. On multivariate analysis, sarcopenia was an independent predictor of both further decompensation (sHR: 2.45, 95% CI: 1.53-3.89; $p<0.01$) and mortality (HR: 3.32, 95% CI:1.32-8,31; $p=0.01$). **Conclusion:** While endoscopic and endovascular interventions are effective in preventing rebleeding, sarcopenia is a significant determinant of further decompensating events (ascites and encephalopathy) and mortality after GV hemorrhage in patients with cirrhosis.

2447 | CLINICAL PERSPECTIVES ON LONG-TERM ALBUMIN THERAPY IN DECOMPENSATED CIRRHOSIS: A NATIONWIDE DELPHI SURVEY IN SPAIN (THE ALBA STUDY)

Jose Ignacio Fortea[1] Diego Rincon[2] Agustín Albillos[3] Elsa Solà[4] Rafael Bañares[2], [1]Hospital Universitario Marqués de Valdecilla, [2]Hospital General Universitario Gregorio Marañon, [3]Hospital Universitario Ramón y Cajal, [4]Stanford University School of Medicine

Background: Albumin is well established for some acute indications in decompensated cirrhosis, but its long-term use remains controversial. The ALBA study explored clinical views, barriers, and implementation challenges of long-term albumin therapy in Spain. **Methods:** A two-round national Delphi study was conducted with 47 hepatology experts from Spanish hospitals with broad geographic coverage. The survey included 40 Delphi statements and 14 items on opinion, attitude, and behavior across five domains. Consensus was defined as Tastle's coefficient ≥ 0.8. Items with moderate consensus (0.7–0.79) and $<70\%$ agreement, or <0.7, were re-evaluated in round two. **Results:** Most centers used albumin for guideline-endorsed indications, though off-label use was also common. 25.5% reported long-term use in patients with ascites. Panelists agreed on its benefit, particularly to prevent ascites-related complications, and supported its use regardless of transplant eligibility. Use was prioritized in difficult-to-control ascites (89.3%) and renal impairment (55.2%), while acknowledging that the potential benefit may be lower in these late stages. Experts endorsed serum albumin and other biomarkers for monitoring, with day hospitals as the most feasible setting despite strain. Barriers included economic limits, logistical challenges, and protocol requirements. Therapy was viewed as safe overall, with dose-dependent cardiac risk. It was seen to improve quality of life and reduce hospital admissions. Concerns over increased demand underscored the need to optimize use. Cost savings via fewer admissions were expected. Strong support was expressed for a national registry to guide implementation. **Conclusion:** Overall, panelists considered long-term albumin administration to be clinically beneficial, and preferably used in those with advanced disease stages, regardless of transplant candidacy. However, its integration into routine practice remains limited by institutional, logistical, and economic barriers. A national registry and targeted strategies to optimize use and resource allocation were endorsed.

Selected Delphi Statements Included in Results

Item	Consensus Coefficient †	Agreement ‡
Long-term albumin reduces complications and improves survival	0.78	6.4 / 17.0 / 76.6
Long-term albumin treatment reduces the need for paracentesis and ascites-related complications	0.83	2.1 / 8.5 / 89.4
The decision to administer long-term albumin therapy is independent of liver transplant indication	0.83	14 / 6 / 78
Serum albumin levels throughout treatment may be useful to guide long-term therapy	0.87	14 / 6 / 78
Treatment should be supervised by the reference hospital.	0.82	8 / 8 / 84
Implementing this new albumin indication would significantly burden day hospital units	0.75	17.0 / 10.6 / 72.3
Implementing this new albumin indication in my hospital would require protocol approval	0.76	17.0 / 12.8 / 70.2
Long-term albumin treatment is safe and associated with few adverse effects	0.82	2.1 / 6.4 / 91.5
Long-term albumin therapy carries some risk of heart failure that may depend on the dose administered	0.84	11 / 0 / 89
Improves quality of life in cirrhotic patients with ascites	0.75	27.7 / 0 / 72.3
Local strategies should be developed to reduce inappropriate albumin use	0.83	4.3 / 8.5 / 87.2
Costs offset by reduction in complications	0.79	29.8 / 0 / 70.2
A national registry should be promoted	0.90	2.1 / 6.4 / 91.5

† Consensus Coefficient: Calculated using Tastle's method. Values ≥0.8 indicate strong consensus; values between 0.7 and 0.79 indicate moderate consensus.

‡ Agreement: Responses were grouped into three categories based on a 5-point Likert scale: Disagree (1–2), Neutral (3), and Agree (4–5). Items with moderate consensus were re-evaluated in the second round if fewer than 70% of responses clustered at either end of the scale (i.e., Agree or Disagree <70%).

2448 | SARCOPENIA IS ASSOCIATED WITH WORSE INPATIENT OUTCOMES AND INCREASED PROCEDURE UTILIZATION IN HOSPITALIZED CIRRHOTIC PATIENTS: A NATIONWIDE ANALYSIS

Mohamed Omar[1] David Maundu[2] Sandra Chehayeb[1] Hayder Alamily[3] Joshua Musalia[4] Matthew Stotts[5] Nathan Tofteland[1] William Salyers[1], [1]University of Kansas Medical Center, [2]University of Kansas School Of Medicine- Wichita, [3]University of Colorado, Department of Gastroenterology, [4]University of Cincinnati College of Medicine, [5]University of Kansas Medical Center, AdventHealth Transplant Institution-Porter Hospital, Denver

Background: Patients with chronic liver disease are at an elevated risk of developing sarcopenia due to impaired protein metabolism, among other pathophysiologic mechanisms. Few studies have explored the impact of sarcopenia on inpatient outcomes and healthcare utilization in cirrhotic patients on a national scale. This study aims to evaluate the effect of sarcopenia on inpatient mortality, resource utilization, and procedural burden among hospitalized cirrhotics using the National Inpatient Sample. **Methods:** We conducted a retrospective cohort study utilizing five years of data from the National Inpatient Sample (NIS) spanning from 2018 to 2022. Adults with cirrhosis were identified using validated ICD-10 codes, and those with sarcopenia as a secondary diagnosis were defined using a comprehensive set of diagnostic codes. The outcomes of interest included in-hospital mortality, length of stay, total charges, ICU stay (approximated through the need for mechanical ventilation), and the utilization of specific procedures. These procedures included esophagogastroduodenoscopy (EGD), colonoscopy, Transjugular Intrahepatic Portosystemic Shunt (TIPS) placement, and paracentesis. We performed multivariable logistic regressions adjusted for demographics, hospital characteristics, and comorbidities. The analysis was conducted using STATA 18. **Results:** Among an estimated 3,992,524 weighted hospitalizations for cirrhosis, 118,100 (3.0%) had co-diagnosed sarcopenia. Sarcopenic cirrhotics had higher in-hospital mortality (12.8% vs. 6.0%, $p < 0.001$), longer length of stay (8.35 vs. 6.21 days, $p < 0.001$), and higher total hospital charges ($104,585 vs. $79,733, $p < 0.001$). After adjusting for confounders, sarcopenia remained independently associated with increased odds of mortality [aOR 2.05 (95% CI 1.96–2.15, $p < 0.001$)]. Sarcopenic patients had increased odds of paracentesis [aOR 1.99 (1.93–2.05, $p < 0.001$)] and ICU stay [aOR 1.22 (1.16–1.28, $p < 0.001$)]. No significant differences were found in TIPS [aOR 1.03, $p = 0.72$], EGD [aOR 0.97, $p = 0.265$], or colonoscopy utilization [aOR 1.10, $p = 0.058$]. **Conclusion:** In hospitalized patients with cirrhosis, sarcopenia is associated with increased mortality, greater healthcare resource utilization, and a higher procedural burden. These findings suggest that this population needs more targeted management strategies to improve clinical outcomes and reduce costs

2449 | EFFICACY AND SAFETY OF AVATROMBOPAG IN CHRONIC LIVER DISEASE PATIENTS WITH THROMBOCYTOPENIA UNDERGOING ELECTIVE SURGERY

Weihua Cao[1] Yao Xie[1] Minghui Li[1], [1]Beijing Ditan Hospital, Capital Medical University

Background: To evaluate the efficacy and safety of avatrombopag in chronic liver disease (CLD) patients with thrombocytopenia scheduled for elective invasive or minimally invasive procedures, providing clinical guidance for patients requiring platelet count elevation. **Methods:** In this single-center, prospective study, CLD patients with platelet (PLT) counts $< 50\times10^9$/L scheduled for elective invasive/minimally invasive surgery were enrolled as shown in Figure 1. Patients received a 5-day avatrombopag regimen in addition to standard liver disease management. Baseline demographic and biochemical parameters were collected. PLT response, PLT count dynamics, and safety were monitored, with the proportion of patients achieving PLT counts $\geq 50\times10^9$/L on the procedure day recorded. Adverse event rates were assessed. **Results:** A total of 108 CLD patients (mean age: 55.69 $\pm$ 1.26 years; 68.52% male) with baseline PLT counts $< 50\times10^9$/L were enrolled, showing an 83.33% response rate. Responders exhibited significantly higher baseline white blood cell (WBC, $P = 0.009$), neutrophil (NE, $P = 0.016$), hemoglobin (HGB, $P = 0.011$), and PLT ($P = 0.001$) levels compared to non-responders. Baseline PLT correlated positively with age ($P = 0.014$), WBC ($P = 0.046$), HGB ($P = 0.001$), and prothrombin activity (PTA, $P = 0.023$), and negatively with international normalized ratio (INR, $P = 0.020$), as shown in Figure 2. Logistic regression identified baseline PLT as an independent predictor of treatment response ($P = 0.002$). PLT counts began rising by day 5 post-treatment, peaked around day 10, and declined to baseline by day 40 in both the overall cohort and responders. Non-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

responders showed only mild PLT elevation by day 5 (remaining $<50\times10^{9}$/L), with no further increase by day 10 and subsequent decline to baseline, as shown in Figure 3. No adverse events, including bleeding or thrombosis, were observed. **Conclusion:** Avatrombopag demonstrated an 83.33% response rate, with higher baseline PLT predicting better outcomes. PLT counts increased by day 5, peaked around day 10, and were well-tolerated with no safety concerns.

2450 | INFLAMMATORY HILAR MASS AND CAVERNOUS TRANSFORMATION IN DISSEMINATED HISTOPLASMOSIS: A RARE CAUSE OF NON-CIRRHOTIC PORTAL HYPERTENSION

Katharine Tippins[1] Elizabeth Townsend[2] Franklyn Wallace[1] Heip Phan[1] Charles Rohrer[1] Adnan Said[2], [1]University of Wisconsin Hospitals and Clinics, [2]University of Wisconsin School of Medicine and Public Health

Background: Disseminated histoplasmosis is a rare but serious fungal infection typically seen in immunocompromised individuals. Hepatic involvement is common, however non-cirrhotic portal hypertension secondary to extrahepatic lymphadenopathy has not been previously reported. We describe a unique case of disseminated histoplasmosis in an immunocompetent host complicated by fibrosing lymphadenitis in the porta hepatis causing portal vein compression and non-cirrhotic portal hypertension. **Methods:** A retrospective review of one patient's clinical course, imaging, histopathology, and treatment response was performed. The patient was followed across multiple hospitalizations for complications related to disseminated histoplasmosis, including cholangitis, spontaneous bacterial peritonitis, and portal hypertension. **Results:** A 68 year old male previously misdiagnosed with sarcoidosis and treated with steroids and methotrexate developed systemic symptoms and pancytopenia. Duodenal biopsy and bone marrow aspirate confirmed disseminated histoplasmosis involving the lungs, GI tract, lymph nodes, and marrow. Despite liposomal amphotericin B and prolonged itraconazole therapy, he developed progressive portal hypertension with ascites, varices, and recurrent spontaneous bacterial peritonitis. Imaging showed a growing porta hepatis mass causing segmental portal vein occlusion, biliary obstruction, and cavernous transformation (see figure). Liver biopsy confirmed non-cirrhotic parenchyma; hilar mass biopsy showed reactive fibrosing lymphadenitis without malignancy or fungal elements. Persistent histoplasma antigenemia and suboptimal antifungal response raised concern for immune reconstitution inflammatory syndrome (IRIS). He was treated with biliary stenting, antifungals, prednisone, diuretics, lactulose, and intermittent paracentesis, with subsequent improvement. This case highlights a rare extrinsic cause of non-cirrhotic portal hypertension due to fibrosing immune response in disseminated histoplasmosis. **Conclusion:** This is the first reported case of disseminated histoplasmosis presenting with non-cirrhotic portal hypertension due to fibrosing lymphadenitis compressing the portal vein. The compressive pathophysiology resembles sclerosing mediastinitis, a known fibrosing complication of histoplasmosis. Clinicians should consider external compression from reactive lymphadenopathy as a rare etiology of portal hypertension, particularly in patients with disseminated fungal infections and no intrinsic hepatic disease. Management requires a multidisciplinary approach including antifungal therapy, supportive care for portal hypertension, and consideration of immunomodulation in suspected IRIS.

2451 | A SYSTEMATIC REVIEW OF PATIENT AND CAREGIVER REPORTED OUTCOMES IN REFRACTORY ASCITES SECONDARY TO CIRRHOSIS

Yazan Haddadin[1] James Ryley[2] Lucia Macken[1] Sumita Verma[3], [1]University of Sussex, [2]University Hospitals Sussex, [3]Brighton and Sussex Medical School

Background: Refractory ascites (RA) in advanced chronic liver disease (ACLD) is associated with a poor prognosis, especially when a liver transplant is not an option. Developing effective palliative interventions in this cohort requires moving away from traditional clinical endpoints (infection/kidney injury /mortality) toward patient and caregiver reported outcomes (PcROMs). We aimed to examine the existing evidence on PcROMs in ACLD-related RA. **Methods:** A peer-reviewed search strategy was conducted (MEDLINE, Embase, CINAHL, the Cochrane Library, PsychINFO and Web of Science databases) from inception till October 2024. The systematic review was registered onto PROSPERO. Two independent reviewers screened titles/abstracts and full texts, resolving disagreements by consensus. Extracted data included study design/sample size/RA definition/HRQoL instruments/caregiver measures. **Results:** The search yielded 2260 records, 721 being duplicates. 187 full-text articles were assessed and 12 studies met our inclusion criteria. Authors of additional studies that had missing data sets have been contacted. Six were randomised controlled trials (RCT) while the rest were observational studies. The sample size of participants ranged from 13-409, 53-85% were male, the reported mean/median age was 52–72 years with 60%-82% having Child Pugh score B disease. Definition of RA and inclusion/exclusion criteria varied across studies. PcROMs were a primary outcome in only three studies. Tools assessing HRQoL covered both physical and psychological domains and included generic (most commonly SF-36, n = 4), disease-specific (most commonly Chronic Liver Disease Questionnaire, n = 4) and non-validated bespoke questionnaires. Determinants of HRQoL included hospitalisations, leg oedema, confusion, frequency and volume of paracentesis. Six studies looked at symptom burden using a range of instruments (ASI-7 n = 3, ASCITES-Q n = 2, FACIT-AI n = 1, CAS n = 1, IPOS n = 1). Only two studies provided health utility index values for patients with RA (0.56-0.57) and one assessed caregiver burden (using the Zarit Burden Interview), reporting high emotional distress, role strain and unmet support needs. Heterogeneity in the data across studies precluded a meta-analysis. Three studies included controls and showed a significant impact of RA on symptoms burden, physical functioning and role limitations due to physical health when compared to diuretic-controlled ascites. **Conclusion:** Evidence on PcROMs in ACLD-RA is scarce and heterogenous. It is limited by restrictive study designs and inconsistent definitions. The lack of a validated disease-specific instrument is a barrier to both high-quality palliative RCTs and to optimising the complex symptom burden of this cohort. Prioritising PcROMs in ACLD trials could generate the evidence needed to drive equitable, patient-centred palliative care.

2452 | CONSTRUCTION OF A RISK PREDICTION MODEL FOR PORTAL VEIN THROMBOSIS IN LIVER CIRRHOSIS BASED ON MACHINE LEARNING

Yaxi Zhang[1], [1]Beijing University of Chinese Medicine

Background: The incidence of portal vein thrombosis (PVT) in patients with cirrhosis is as high as 15% to 25%, which can significantly increase the risk of gastrointestinal bleeding, liver failure, and death. The existing prediction tools rely on a single indicator or traditional scoring, which has the limitations of low sensitivity and insufficient dynamic evaluation ability. The purpose of this study was to apply a variety of machine learning algorithms to construct an accurate PVT risk prediction model, screen the optimal model, and provide a basis for early identification of high-risk groups. **Methods:** A questionnaire on risk factors for the incidence of PVT in liver cirrhosis was developed through literature review and expert consultation. The data of 580 patients with liver cirrhosis who were hospitalized and managed from May 2019 to December 2022 were collected. The Lasso regression method was used to screen the predictors, and the training set (406 cases) and the validation set (174 cases) were randomly divided into a 7:3 ratio. The training set uses multi-layer perception (MLP), support vector machine (SVM), random forest (RF) and adaptive boosting (AdaBoost) to build a prediction model, and evaluates the performance on the validation set. The optimal model was determined according to the area under the receiver operating characteristic curve (AUC) of the validation set. **Results:** A total of 205 patients (35.34%) with cirrhosis developed PVT. Lasso regression

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

screened seven predictors, including Child-Pugh grade, history of splenectomy, D-dimer level, platelet count, portal vein diameter, ascites, and degree of esophageal varices. The evaluation results of the validation set showed that the random forest model had the best performance (AUC of 0.78 and accuracy of 0.75), which was better than that of other models (MLP: AUC = 0.69; SVM: AUC = 0.72; Adaboost: AUC = 0.74). **Conclusion:** The risk prediction model for PVT in liver cirrhosis based on random forest algorithm has the best overall performance, and can be used for early identification and screening of high-risk groups of PVT in patients with liver cirrhosis.

Disclosures: Yaxi Zhang: Nothing to Disclose

2453 | OPERATIONALIZING A WALKING EXERCISE PRESCRIPTION BASED ON 6-MINUTE WALK TEST RESULTS:

Joshua Sepic[1] Louis Guzman[2] Susanna Miranda[1] Fei-Pi Lin[3] Pamela Bloomer[4] Richard Lieber[5] James Sliwa[5] Andres Duarte-Rojo[1], [1]Northwestern Medicine, [2]Northwestern University, [3]University of Pittsburgh, [4]University of Pittsburgh Medical Center, [5]Shirley Ryan Ability Lab

Background: Providing an exercise prescription to liver transplant (LT) candidates as part of their prehabilitation processing can be challenging. Walking is a proven exercise intervention for improving physical frailty and waitlist mortality in LT candidates, however, access can become a limiting factor for these patients. Physical activity trackers (PAT) provide an opportunity to monitor and prescribe exercise, remotely. In order to operationalize an exercise prescription using walking as the main training strategy, we explored what would be the thresholds we would need to use by cross-referencing 6MWT and PAT data. **Methods:** We did a post-hoc analysis of previously published data. Daily steps from 1-week PAT monitoring data were cross-referenced with baseline 6MWT performance. The latter were categorized in 3 groups: <250 m, 250-349 m, and ≥ 350 m, both due to distribution of data and to align with published literature. The liver frailty index (LFI) was used to categorize patients as frail (≥ 4.5) vs. nonfrail (subcategorized as prefrail [3.2-4.4]; and robust [<3.2]). Kruskal-Wallis was used for comparisons. **Results:** In 107 participants with both PAT-daily steps and 6MWT (age 56 ± 11, male 57%), we found that that 19 (18%), 47 (44%) and 41 (38%) accomplished <250 m, 250-349 m, and ≥ 350 m in their 6MWT, respectively. Participants in the lowest performance category were most likely female (63% vs. 39%), less likely listed for LT (21% vs. 61%), had more ascites (100% vs. 68%) and hepatic encephalopathy (100% vs. 65%), and were most likely frail (79%, vs. 11%). The daily steps per 6WMT category are shown in *Figure 1A*. Grouping daily steps by LFI category produced similar results (*Figure 1B*). **Conclusion:** PAT are a proven, low-cost method of tracking exercise in LT, but have to date seen limited use in exercise prescription. Using these data, appropriate step counts can be prescribed to LT candidates based upon 6MWT performance. Further, these data can be used as a model to appropriately increase daily step counts to levels that correlate with improved 6MWT performance, improved physical frailty, and increased likelihood of listing for LT. We propose a walking prescription of 1500, 3000, and 6000 steps/day for LT candidates doing <250, 250-349, and ≥ 350 m, respectively.

2454 | DYNAMIC LACTATE CLEARANCE PREDICTS MORTALITY IN DECOMPENSATED CIRRHOSIS: A PROSPECTIVE MEXICAN COHORT

Emilio Sandoval-Gonzalez[1] Francisco Bosques-Padilla[2] Miguel Escobedo-Belloc[2] Jorge Zuñiga-Hernandez[2] Hannia Zumaya-Flores[3] Wendy Ruiz-Gallegos[3] Lilia Chavez-García[3] Leonel Castillo-Peña[3] Andres Zapata-Navarro[3], [1]Hospital Universitario Dr. José Eleuterio González, [2]Hospital Universitario Dr. José Eleuterio González, Universidad Autónoma de Nuevo León, Monterrey,Mx, [3]Facultad de Medicina, Universidad Autónoma de Nuevo León, Monterrey, Mexico

Background: Timely identification of high-risk patients during acute decompensation (AD) of cirrhosis remains a key clinical challenge. While hyperlactatemia is frequently observed, its dynamic behavior particularly lactate clearance remains undercharacterized in cirrhotic populations, especially in Latin America.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Methods: The prospective study included 83 adults with acute decompensation (AD) of cirrhosis admitted to an academic referral center in Mexico. Serial arterial lactate levels were measured through routine blood gas analysis at admission and at 72 hours, or earlier if new organ failure, discharge, or death occurred first. Although some patients had additional values (e.g., on day 8 ± 2), the primary analysis focused on paired measurements to assess dynamic change. Lactate clearance: [(lactate at admission – follow-up lactate) / lactate at admission] × 100. Impaired clearance was defined as < 20%. The primary outcome was in-hospital mortality. Predictive performance was assessed using ROC analysis and logistic regression. Kaplan–Meier analysis evaluated survival according to lactate clearance. **Results:** Among the 83 patients, in-hospital mortality was 27.7% (n = 23). Survivors showed a significant reduction in lactate (Δ = –0.96 ± 2.68 mmol/L), while non-survivors exhibited a marked increase (Δ = +1.10 ± 4.18 mmol/L; p = 0.0359). Mean clearance was +14.5% in survivors vs. –61.9% in non-survivors (p = 0.0125), reflecting divergent trajectories. Using a 20% threshold, impaired clearance was associated with significantly higher in-hospital mortality. On logistic regression, clearance < 20% remained independently associated with death (OR 0.19; 95% CI: 0.06–0.55; p = 0.0038). Kaplan–Meier curves confirmed worse survival in patients with impaired clearance (log-rank p = 0.0018). **Conclusion:** Lactate clearance is a dynamic, accessible biomarker associated with in-hospital mortality in decompensated cirrhosis. Unlike static values, serial trends reflect clinical deterioration and may guide early triage and care decisions, especially in resource-limited settings, where dynamic monitoring could enhance early recognition and guide timely intervention. This study also represents one of the first prospective Latin American cohorts evaluating lactate kinetics in this population.

2455 | PRIORITY OUTPATIENT PARACENTESIS PREVENTS UNPLANNED PRESENTATIONS

Janis Fernandes[1] Rohit Gupta[1] James O'Beirne[1],
[1]Sunshine Coast University Hospital

Background: Large volume paracentesis (LVP) for diuretic refractory ascites (RA) often requires regular hospital visits. Typically, this is facilitated through day units shared with other specialities. The unpredictable nature of ascites accumulation and lack of availability of day unit beds can result in unplanned hospital presentations for LVP. This increases clinical demands in the emergency department and skill mix availability may lead to unnecessary hospitalisation and increased patient length of stay (LOS). We implemented a Priority Outpatient Paracentesis (POP) Clinic using dedicated beds on the liver and gastroenterology ward to streamline care for patients requiring regular LVP. The primary outcome was a reduction in unplanned LVP, with secondary outcomes including an increase in planned LVP and a decrease in hospital length of stay (LOS). **Methods:** Single-centre retrospective cohort study analysed data from the 12 months pre implementation of the POP clinic where LVP was performed in the non-specialised Day Unit Investigation and Therapy (DUIT) and compared this to the 12 months following implementation of POP clinic. Across the 24-month study period, LVP was classified as planned or unplanned and LOS was recorded. **Results:** The cohort comprised 114 patients undergoing 373 LVPs, 9 patients overlapped both phases. In DUIT, 62 patients (44 male) underwent 168 paracenteses (52% unplanned, 48% planned). In POP Clinic, 61 patients (44 male) underwent 205 paracenteses (37% unplanned, 63% planned). POP Clinic implementation significantly increased planned LVPs (p = 0.004). Total number of LVPs increased by 22% in the POP clinic phase. Despite an increase in the number of LVPs, the total LOS was significantly reduced (p = 0.04). **Conclusion:** Implementation of POP clinic significantly reduced the number of unplanned admissions for LVP. LOS was significantly reduced reflecting improved access to timely LVP through a dedicated facility.

2456 | IMPACT OF HELICOBACTER PYLORI ON LIVER OUTCOMES IN CIRRHOTIC PATIENTS: A RETROSPECTIVE COHORT

Mohammed Al-Aquily[1] Abdellatif Ismail[2] Kamran Qureshi[3] Wing-Kin Syn[4], [1]Department of Internal Medicine, Norwalk Hospital/ Yale University, CT, USA, [2]University of Maryland Medical Center, Midtown Campus, [3]Department of Internal Medicine, Division of Gastroenterology and Hepatology, at Saint Louis Univers, [4]Saint Louis University School of Medicine

Background: Liver cirrhosis is a chronic liver disease that carries a guarded prognosis for affected patients. Helicobacter pylori (H. pylori) infection, while primarily known for causing gastrointestinal disease, has been increasingly reported to affect outcomes in patients with chronic liver disease. This study aims to evaluate whether H. pylori infection worsens clinical outcomes in patients with cirrhosis. **Methods:** We conducted a retrospective cohort study using the TriNetX US Collaborative Network, utilizing data from 69 healthcare organizations. Two cohorts were identified: Cohort 1 included patients with cirrhosis and H. pylori infection (n = 10,792); Cohort 2 included patients with cirrhosis but without H. pylori infection (n = 643,249). All etiologies of cirrhosis were included in the study using the International Classification of Diseases codes 10 (ICD). Propensity score matching (PSM) was performed between the two cohorts based on demographics, comorbidities, and MELD components (creatinine, bilirubin, INR, Sodium) resulting in 10,674 matched individuals in each cohort. Outcomes assessed included the development of hepatocellular carcinoma (HCC), ascites, spontaneous bacterial peritonitis (SBP), esophageal varices (EV), hepatorenal syndrome (HRS), hepatic encephalopathy (HE), mortality, and combined liver-related events. Comparative analyses used risk ratios and Kaplan-Meier survival estimates over a 10-year follow-up period, excluding patients with pre-existing outcomes. **Results:** Before PSM, remarkable differences were observed between the cohorts in terms of comorbidities and demographics. After PSM, groups were well balanced. As shown in Table 1, patients with H. pylori had significantly higher risks of developing HCC (RR 1.27; $p < 0.001$) compared to liver cirrhosis patients without H. pylori. Interestingly, H. pylori-infected patients had lower all-cause mortality (RR 0.86; $p < 0.001$). No significant differences were found for ascites, SBP, HE, HRS, EV, or combined liver-related events. **Conclusion:** In cirrhotic patients, a higher risk of HCC was observed in those with H. pylori infection compared to those without H. pylori. However, a lower risk of all-cause mortality was seen in patients with H. pylori infection. These findings raise questions for further studies regarding the relationship between H. pylori infection and HCC in cirrhotic patients, and the role of H. pylori eradication therapy.

Outcome	Cohort 1, N (%)	Cohort 2, N (%)	RR 95% CI	p-value
Number of patients in each cohort	10,674	10,674	-	-
Hepatocellular carcinoma (HCC)	629 (6.3%)	503 (5.0%)	1.27 (1.14–1.43)	<0.001
Ascites	1,492 (18.9%)	1,517 (18.0%)	1.05 (0.99–1.12)	0.115
SBP	408 (3.9%)	393 (3.7%)	1.05 (1.04–1.33)	0.496
EV	949 (12.7%)	1,332 (13.7%)	0.93 (0.86, 1.00)	0.060
HRS	464 (4.4%)	417 (4.0%)	1.12 (0.98, 1.27)	0.090
HE	747 (7.4%)	696 (6.7%)	1.09 (0.988, 1.205)	0.086
Mortality	2,254 (21.3%)	2,636 (24.9%)	0.86 (0.81, 0.90)	<0.001
Liver-related events combined	1,584 (21.2%)	1,671 (20.7%)	1.02 (0.96, 1.09)	0.451

2457 | PREDICTORS OF HYPOLGYCEMIA IN INDIVIDUALS WITH CIRRHOSIS WITHOUT DIABETES

Alan Hutchison[1] Mary Rinella[1] Celeste Thomas[2], [1]The University of Chicago, [2]University of Chicago

Background: Individuals with cirrhosis are at risk of disruptions in their glucose metabolism. We have reported

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

that approximately 50% of individuals with cirrhosis without diabetes have greater than 4% of the time with glucose less than 70 mg/dL in an outpatient setting. Underlying risk factors for ambulatory hypoglycemia in liver disease are unknown. **Methods:** We enrolled patients with cirrhosis without diabetes from pre-liver transplant clinic at the University of Chicago (IRB 23-0691). They were assessed with an Abbott Libre Pro continuous glucose monitor. Subject characteristics of age, BMI, creatinine-based eGFR, beta blocker usage, albumin, INR, TIPS presence, MELD 3.0, and CTP score were compared against the endpoint of time with glucose below 70 mg/dL. We conducted an interim analysis at the point when we had sufficient sample size (37 episodes) to identify a moderate effect size (Cohen's $f^2 = 0.15$) with a power of 0.80 and a significance of 0.05 using 2 variables. **Results:** We had 37 CGM measurement episodes for 28 separate subjects, with repeat measurements separated by at least 3 months. The median age was 51 (Q1–Q3: 45 – 58), the median MELD 3.0 was 15.5 (Q1-Q3: 12.0 – 20.0), and the median CTP score was 8 (Q1–Q3: 6-10) (Figure). 21/37 episodes (16/28 subjects) had greater than 4% time in hypoglycemia (glucose less than 70 mg/dL). 13 subjects were on a beta blocker, while 4 had a TIPS. When controlling for the subject, beta blocker usage was associated with decreased hypoglycemia ($p = 0.04$), but this association was suppressed ($p = 0.06$) when adjusting for CTP score, which itself was not associated with hypoglycemia ($p = 0.84$) (Figure). **Conclusion:** Despite the majority of CGM measurement episodes and subjects having greater than 4% time with glucose less than 70 mg/dL and being powered for a moderate effect size, no variables were predictive of hypoglycemia in this cohort of individuals with cirrhosis without diabetes under evaluation for liver transplant. Further work needs to validate the non-predictive ability of these variables – until then, screening individuals with cirrhosis for hypoglycemia with continuous glucose monitors may be the best modality for identifying dangerous hypoglycemia.

2458 | USE OF ENDOHEPATOLOGY TO SAFELY AND EFFECTIVELY STAGE FONTAN-ASSOCIATED LIVER DISEASE

Michael Dybala[1] Abdul Aadam[1] Jessica Nguyen[1] Amir Borhani[1] Daniel Ganger[1] Justin Boike[1] Dempsey Hughes[1], [1]Northwestern University

Background: Patients with congenital heart disease (CHD) status post Fontan palliation develop progressive congestive hepatopathy known as Fontan-associated liver disease (FALD) potentially leading to cirrhosis, clinically significant portal hypertension (CSPH), and hepatocellular carcinoma. FALD management including consideration for liver transplant is contingent on accurate disease staging. Yet staging FALD remains challenging for myriad reasons (e.g., limited tissue sampling from transjugular biopsy due to complex anatomy, barriers to noninvasive elastography due to heart failure or indwelling pacemaker). Endohepatology enables simultaneous CSPH assessment and biopsy-determined fibrosis but data on use in FALD patients is lacking. In this pilot study, we sought to determine feasibility and efficacy of endohepatology for FALD staging. **Methods:** This was a single center prospective study composed of patients age $\geq$ 18 years old with history of CHD, Fontan palliation and FALD. All patients completed combined upper endoscopy (EGD) for variceal screening with endoscopic ultrasound (EUS)-guided bilobar liver biopsies and direct portal manometry. Liver fibrosis stage was determined by Metavir score (F0-F4). Biopsy results were compared to noninvasive liver stiffness measurements (LSM) from shear wave elastography (SWE) or transient elastography (TE) within 1 year of endohepatology procedure (EGD-EUS). **Results:** Seven patients completed EGD-EUS. The majority of the cohort was male (86%), mean age was 33 years old (SD 7), mean time since Fontan palliation was 28 years (SD 7), most patients (57%) had clinical heart failure (AHA stage C [N = 1], stage D [N = 3]). Four patients had limited fibrosis (F1-F2) on biopsy. Three patients had advanced fibrosis ($\geq$ F3 [N = 1], F3-F4 [N = 2]). Five patients had LSM 7.1-22.9 kPa (mean 14.1 kPa $\pm$ 7.5). One patient with LSM $<$ 9 kPa had F1-F2 fibrosis on biopsy. Among patients with LSM $>$ 9 kPa, correlation with biopsy-proven fibrosis was variable (see figure). Four patients had esophageal varices on EGD, though only one patient had intrahepatic CSPH per mean hepatic venous pressure gradient $>$ 5 (8). Regarding feasibility, one patient experienced acute hypoxia due to laryngospasm prior to starting endoscopic exam but tolerated the rescheduled procedure without complication. Another patient experienced postprocedural fever. **Conclusion:** Endohepatology provides a well-tolerated, efficient and comprehensive method of FALD staging and determination of CSPH. Our results show some discordance between LSM versus EUS-guided biopsy, especially at more advanced disease stage. This potentially reflects limitations of elastography in heart failure patients, benefits of increased tissue sampling via bilobar EUS-biopsy and/or small cohort size. These results suggest endohepatology may safely provide superior staging in FALD patients though further data is needed.

Medical University, [2]Tianjin University Central Hospital (Tianjin Third Central Hospital)

Background: To explore factors influencing further decompensation within 1 year after transjugular intrahepatic portosystemic shunt (TIPS) placement in cirrhosis patients and establish a predictive model for identifying high-risk individuals. **Methods:** In this single-center retrospective study, we enrolled cirrhosis patients who underwent TIPS for decompensation events (ascites, esophagogastric variceal bleeding, or recurrent hepatic encephalopathy) and contrast-enhanced computed tomography (CT) at Tianjin University Central Hospital (China) between January 2018 and January 2024. All patients were followed for at least 1 year post-TIPS, with further decompensation as the primary endpoint. Patients were stratified into clinically stable and further decompensation groups based on 1-year outcomes. Predictors were screened using univariate logistic regression and least absolute shrinkage and selection operator (LASSO) regression, followed by multivariate logistic regression to build the predictive model. **Results:** 152 eligible cirrhosis patients were included. Median age was 57.50 years (IQR 50.00–66.00), with 89 (58.55%) males. Viral and alcoholic etiologies predominated (58.55%). Further decompensation occurred in 52 patients (34.21%) within 1 year post-TIPS. Univariate and LASSO regression identified liver-to-spleen volume ratio (LSVR), serum sodium, and reduction amplitude of portal pressure gradient (PPG) post-TIPS for multivariate analysis. LSVR (OR = 0.761, 95% CI = 0.678–0.853) and PPG reduction amplitude (OR = 0.956, 95% CI = 0.923–0.992) independently predicted further decompensation. The resulting model demonstrated excellent discrimination: AUC = 0.864 (95% CI: 0.804–0.923), sensitivity = 0.846, specificity = 0.790. **Conclusion:** LSVR and PPG reduction amplitude are strongly associated with further decompensation within 1 year post-TIPS. Our clinical prediction model (AUC = 0.864) effectively stratifies post-TIPS risk, informing therapeutic decision-making, postoperative surveillance, and individualized management.

2460 | SPLENIC STIFFNESS AND SIZE DIFFERENTIATES NON CIRRHOTIC PORTAL FIBROSIS AND EXTRA HEPATIC PORTAL VEIN OBSTRUCTION IN CHILDREN: PROSPECTIVE OBSERVATION STUDY

Sanjeev Verma[1] Anjali Singh[2] SUMIT RUNGTA[3] Dr Manisha Verma[2] Malti Maurya[4] Saurabh Kumar[5], [1]King George Medical University Lucknow, [2]Department Of Pediatrics, King George Medical University, [3]KGMU, [4]Department Of Pathology, King George Medical University, [5]Department Of Radio diagnosis, King George Medical University

Background: Noncirrhotic Portal Hypertension (NCPF) and Extra Hepatic Portal Vein Obstruction (EHPVO) have clinical presentation of unexplained portal hypertension with or without variceal bleed. At presentation it's difficult to differentiate the two conditions, so this liver and splenic stiffness based study carried out in children with portal hypertension (PHTN) without cirrhosis. **Methods:** This prospective observational study enrolled, 1-14 years old children, presented to tertiary care center of North India, over a period of 1 year, with evidence of unexplained clinical portal hypertension. Clinical, biochemical and radiological data was collected on predesigned format. Liver and splenic elastography done after stabilization. Those without portal cavenoma were subjected to liver biopsy. **Results:** Twenty three children (74% Male) with clinical (PHTN) without cirrhosis were enrolled, 16 were diagnosed as EHPVO and 7 as NCPF. Mean age of enrolled children was 8.43 ± 3.578 years. Seventy four percent children presented with hematemesis, 70% with upper abdominal distension, 22% have transient jaundice, and 87% have splenomegaly. Mean Liver and Splenic stiffness among EHPVO and NCPF were, 3.95 +1.13 vs 3.78+1.07 kpa ($p = 0.736$) and 28.25 +23.77 vs 69.44+62.33 kpa ($p = 0.029$) respectively. While comparing NCPF and EHPVO, NCPF have bigger Spleen size 3.71 ± 2.48 vs 11.93 ± 3.94 cm ($p = 0.001$) below costal margin. NCPF have higher odds (1.2) for Clinically Significant Varices as compared to EHPVO (Table 1). **Conclusion:** EHPVO and NCPF are important cause of PHTN in children without cirrhosis. Liver and splenic stiffness measurement may help to differentiate the two conditions. Higher splenic stiffness and bigger spleen size in absence of portal cavernoma is having good sensitivity to predict NCPF in these children.

2461 | WARNING NOTICE FOR A SHORT-TERM ELEVATION OF AMMONIA LEVELS FOLLOWING SPLENIC ARTERY EMBOLIZATION

Tsuyoshi Ishikawa[1] Aika Kirihara[1] Natsuko Nishiyama[1] Daiki Kawamoto[1] Ryo Sasaki[1] Tatsuro Nishimura[1] Taro Takami[1], [1]Yamaguchi University Graduate School of Medicine

Background: Partial splenic embolization (PSE) has attracted considerable attention as a fundamental treatment for portal hypertension-related diseases in terms of portal hemodynamic regulation. However, few studies have demonstrated effects of PSE on hepatic encephalopathy, a portal hypertensive symptom. The present study aimed to investigate ammonia-level changes by PSE and to identify determinants of postprocedural changes in patients with or without portosystemic shunts (PSSs). **Methods:** This retrospective study included 136 patients with hypersplenism undergoing PSE at our hospital. The patients were divided into the PSS (−) group, comprising 90 patients without PSSs with a diameter of ≥ 8 mm, and the PSS (+) group, comprising 46 patients with PSSs with a diameter of ≥ 8 mm. Ammonia levels as well as biochemical and imaging findings were assessed before and at 1 month after PSE. **Results:** Overall, PSE significantly increased ammonia levels (85.3 $\pm$ 41.6 to 99.7 $\pm$ 36.0 μg/dL, $p < 0.01$) despite postprocedural hepatic function amelioration and hepatic venous pressure gradient reduction. Elevated ammonia levels were observed postoperatively in 73.3% and 63.0% patients in PSS (−) and PSS (+) groups, respectively. The procedure significantly increased ammonia levels (74.0 $\pm$ 38.1 to 91.8 $\pm$ 31.6 μg/dL, $p < 0.01$) in the PSS (−) group; in contrast, the post-PSE ammonia-level elevation was not statistically significant (107.4 $\pm$ 39.5 to 115.1 $\pm$ 39.3 μg/dL, $p = 0.21$) in the PSS (+) group. Preprocedural Child-Pugh scores of < 8 and splenic non-infarction volume of ≥ 120.32 cm^3 were significantly and independently associated with postprocedural ammonia-level elevation in the PSS (−) group; the combination of two indicators showed a sensitivity and specificity of 44.6% and 87.0% for elevation prediction, respectively. Preprocedural splenic artery diameter-to-common hepatic artery diameter ratios of < 1.4 and concomitant splenic vein-derived shunt vessels were significant and independent determinants of postprocedural ammonia-level elevation in the PSS (+) group; the combination of two conditions exhibited a sensitivity and specificity of 40.0% and 100.0% for elevation prediction, respectively. **Conclusion:** PSE generally poses a high risk of short-term ammonia-level elevation, particularly in patients without PSSs. Preprocedural therapeutic indications and postprocedural follow-up strategies should be considered according to determinants of post-PSE ammonia-level changes individually.

2462 | FLUID IN THE LUNGS: EXPLORING THE ASSOCIATION BETWEEN B-LINE BURDEN ON POINT-OF-CARE ULTRASOUND AND MARKERS OF RIGHT-SIDED PRESSURE OVERLOAD IN HOSPITALIZED PATIENTS WITH CIRRHOSIS

Daniel Alvarez[1] Kelsie Pereyra-Bencosme[1] Suneet Waghmarae[1] Nicholas Samel[2] Ashley Choi[2] Zoe Verzani[3] Paola Mejia[1] Abhilash Koratala[4] Benjamin Galen[1] Brett Fortune[1], [1]Montefiore Medical Center/ Albert Einstein College of Medicine, [2]Albert Einstein College of Medicine, [3]Weill Cornell Medicine, [4]Montefiore Medical Center/Albert Einstein College of Medicine/Medical College of Wisconsin

Background: Patients with decompensated cirrhosis frequently experience cardiopulmonary complications, including pulmonary edema. Point-of-care ultrasound (POCUS) has emerged as a rapid, accessible bedside tool for evaluating volume status and pulmonary edema, particularly through the detection of B-lines on lung ultrasound. While B-lines are established markers of pulmonary congestion and elevated left-sided filling pressures in heart failure, their utility in hospitalized patients with cirrhosis is not well described. We aimed to determine whether B-line burden is associated with transthoracic echocardiographic (TTE) parameters of right-sided cardiac pressure overload in hospitalized patients with cirrhosis. **Methods:** We conducted a prospective observational cohort study of 37 hospitalized patients with decompensated cirrhosis, including three readmissions treated as separate encounters (total of 40 observations). Comprehensive POCUS was performed during admission, with 23 observations also having corresponding TTE data, though availability varied by parameter. Lung ultrasound was performed using a phased array probe in four bilateral lung zones: the midclavicular line at the 2nd, 4th, and 6th intercostal spaces, and the midaxillary line at the 8th–9th intercostal space. B-line burden was quantified as the number of zones with ≥ 3 B-lines in a single intercostal space (range: 0–8). We analyzed Spearman's correlation coefficients between B-line burden and TTE parameters, including right ventricular systolic pressure (RVSP), tricuspid regurgitation (TR) max velocity, and tricuspid annular plane systolic excursion (TAPSE). **Results:** The cohort had a median age of 54 years; 63% were male, 68% Hispanic and 68% had alcohol-related liver disease. The median MELD score at admission was 24. The leading reason for hospitalization was refractory ascites. B-lines were present in 82.5% of observations. Among the 23 with complete lung POCUS and TTE data, B-line burden showed a positive correlation with RVSP ($R = 0.8$, $p = 0.33$) and TR max velocity ($R = 0.53$, $p = 0.14$). There was no significant correlation between B-line burden and TAPSE ($R = 0.27$, $p = 0.28$) (Figure). **Conclusion:** In hospitalized patients with decompensated cirrhosis, B-line burden was associated with higher markers of right-sided pressure overload (RVSP and TR max velocity), but not with systolic function (TAPSE). While B-lines should not be interpreted in isolation as markers of venous congestion or right heart dysfunction, their presence should prompt further evaluation of right-sided cardiac parameters and Doppler markers of venous congestion. Ongoing enrollment and larger studies will be critical to validate these findings and determine their prognostic utility for adverse clinical outcomes.

2463 | IS SUBSTITUTING SERUM CREATININE FOR SERUM CYSTATIN C IN CALCULATING MELD SCORES MORE APPROPRIATE FOR ASSESSING THE SEVERITY OF CHRONIC LIVER DISEASE?

Jeff Angelo Taclob[1] Anjana Mary Jacob[1] Satheesh Nair[1], [1]University of Tennessee Health Sciences Center, Memphis

Background: Complications of portal hypertension are represented by renal dysfunction and hyponatremia in the MELD scoring system. However, it is well known that serum creatinine level underestimates renal dysfunction in patients with cirrhosis and sarcopenia. We have been measuring serum Cystatin C in patients undergoing liver transplant evaluation at our center. This study aims to demonstrate that a Cystatin C-based MELD score (MELD Cy) may more accurately reflect renal dysfunction, therefore better represent mortality risk in patients with complications of portal hypertension. **Methods:** A retrospective cohort study was performed on patients who underwent liver transplant evaluation at our institution between October 2024 and March 2025. A total of 96 patients were included in the study. Patient demographics, etiology of cirrhosis, presence of ascites, and pertinent laboratory data were obtained. Student t-test was used to compare the eGFR and MELD scores **Results:** A total of 96 individuals (49 females) were included in the study. 72 (75%) patients had ascites. The most common etiology of cirrhosis was MASH (35%), followed by Alcoholic liver disease (21%). Mean eGFR based on serum creatinine was 81.6 ml/min (CKD-EPI method) and 57.9 ml/min based on Cystatin C. Mean MELD scores with serum creatinine were 18.8 (+/- 6.04), while the mean MELD score obtained using Cystatin C was 22.2 (+/- 6.82) Most patients had a higher MELD Cy compared to MELD 3.0.

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Forty patients (41%) had an increase of 1 to 3 points, 34 (35%) patients had an increase of 4 to 6 points, and 10 (10%) patients had a significant increase of more than 6 points. The differences in MELD 3.0 vs MELD Cy (p value = 0.0005) and eGFR Creatinine vs eGFR Cystatin C (p value = 0.0002) were statistically significant. On further analysis of patients with ascites (n = 72), the disparity between the MELD 3.0 (18.97 (+/- 5.40)) and MELD Cy (22.99 (+/- 5.92)), and eGFR CKD -EPI Creatine (78.8 (+/- 26.94)) and eGFR with Cy (53.99 (+/- 20.84)) persisted (p value < 0.0005 for both variables). **Conclusion:** MELD Cy being higher than MELD 3.0 has the potential to improve accessibility for liver transplantation in patients with complications of portal hypertension.

2464 | THE SAFETY OF ACEI/ARBS IN PATIENTS WITH CIRRHOSIS

Nirmal Desai[1] Christine Son[1] Vineela Appalaneni[1] Irena Helenowski[1] Jonah Rubin[1], [1]Loyola University Medical Center

Background: The AASLD recommends against using ACEi and ARBs in decompensated cirrhosis with ascites. Recently published data suggests that ACEi/ARB use is associated with a lower risk of liver related adverse events in patients with compensated cirrhosis. We aimed to conduct a retrospective cohort study to assess the benefit and harm associated with ACEi/ARB use in both compensated and decompensated cirrhosis. **Methods:** This was a single center retrospective cohort study of the effect of exposure to ACEi/ARB compared to a no exposure cohort. Primary outcomes include transplant free and overall survival. Secondary outcomes include rate of decompensation, renal function and hospitalizations. Demographic and clinical variables were 1:1 propensity score matched to account for confounding. Significant differences were assessed via Wilcoxon rank-sum test for continuous variables and Fisher's exact test for categorical variables. Kaplan-Meier estimates were used for survival rates. A multivariable Cox regression was performed for a composite outcome of overall survival (OS) and transplant free survival (TFS). **Results:** After propensity score matching, there were 300 patients each in the ACEi/ARB cohort and the control group. Patients in the study group had a significant increase in transplant free survival (p = .003) and fewer decompensation events (p < .001) with univariate analysis. Multivariable Cox regression demonstrated a significant improvement in OS/TFS in the ACEi/ARB group (HR 0.65; 95% CI, 0.49 – 0.87). Subset analysis of compensated cirrhosis patients demonstrated fewer decompensation events (p = .005) for the study group, but the Cox regression analysis showed no difference (HR 0.81; 95% CI, 0.46-1.41). In decompensated cirrhosis patients, there was a significant improvement in OS/TFS in the ACEi/ARB group (HR 0.61; 95% CI, 0.43 – 0.88). Additionally, in patients with ascites, there was no difference in OS/TFS (HR 0.72; 95% CI, 0.48-1.07) with ACEi/ARB exposure. **Conclusion:** ACEi/ARB use was associated with a significant increase in OS/TFS in all cirrhotic patients. In decompensated cirrhosis patients with ascites, ACEi/ARB exposure had no effect on adverse outcomes. Therefore, these medications appear to be safe to administer in all cirrhotic patients and offer a potential benefit.

Figure 1: Kaplan-Meier estimates for decompensation event-free survival rates for the propensity-matched cohort by ACEi/ARB use. The log-rank test indicates significantly lower decompensation event-free survival in the no ACEi/ARB group.

2465 | IMPACT OF GUIDELINE-BASED ACUTE KIDNEY INJURY CARE PROCESSES ON OUTCOMES IN HOSPITALIZED PATIENTS WITH DECOMPENSATED CIRRHOSIS

Kavish Patidar[1] Yan Liu[2] George Cholankeril[2] Nagasri Shankar[2] Jennifer Kramer[2] Thomas Taylor[2] Kumar Jalal[2] Avegail Flores[2] Elsa Solà[3] Giuseppe Cullaro[4] Andrew Allegretti[5] Nikhilesh Mazumder[6] Fasiha Kanwal[7] Ruben Hernaez[2], [1]Baylor College of Medicine, Houston Methodist Hospital, [2]Baylor College of Medicine, [3]Standford University, [4]Columbia University, [5]Massachusetts General Hospital, [6]University of Michigan, [7]Michael E. DeBakey VA Medical Center

Background: Acute kidney injury (AKI) is a frequent and severe complication in cirrhosis, associated with high morbidity and mortality. While guidelines recommend specific process measures (PMs) for AKI care in cirrhosis, their impact on outcomes remains understudied. We investigated the association between adherence to PMs and clinical outcomes in hospitalized patients with decompensated cirrhosis and AKI. **Methods:** We conducted a retrospective cohort study of hospitalized adults with decompensated cirrhosis and ascites who developed AKI across 130 VA hospitals between 1/1/2018 and 12/31/2023. AKI was defined using 2015 ICA criteria (increase in serum creatinine (sCr) $\geq$0.3 mg/dl from baseline within 48hrs or $\geq$50% increase in sCr from baseline). PMs evaluated were avoidance of diuretic, non-selective beta blocker (NSBB) and other vasodilators use within 48hrs after AKI onset; volume expansion with albumin or crystalloids within 24hrs after AKI onset; infectious work-up within 48hrs of AKI onset, subspecialty consultation after AKI onset, and outpatient follow-up visit within 15-days of discharge. The primary outcome was in-hospital AKI resolution (return of sCr to within 0.3 mg/dL of baseline) and the secondary outcome was 90-day mortality from the time of discharge. Multivariable logistic and Cox regression analysis were performed to examine independent associations between PMs and outcomes. **Results:** Among 2,221 patients (median age 66yrs; 65% White; 46% alcohol-associated cirrhosis), NSBB, diuretics, and other vasodilators were avoided in 97%, 79%, and 80%, respectively; 21% and 29% received volume expansion with albumin and crystalloids, respectively; 47% had an infectious work-up and 29% had subspecialty consultation. Among patients who survived to hospital discharge (n = 1,811), 24%, 5%, and 1%, had outpatient post-discharge clinic visit with primary care (PC), gastroenterology/hepatology (GI/HEP), and nephrology, respectively. Overall, 53% achieved AKI resolution and 40% died within 90-days. After adjusting for confounders, avoidance of diuretics was associated with increased likelihood of AKI resolution (OR 1.30, 95%CI 1.04–1.64), while volume expansion with crystalloids was associated with lower likelihood (OR 0.81, 95%CI 0.66–0.99). Timely post-discharge outpatient clinic visit with PC (HR 0.53, 95%CI 0.28-0.69) or GI/HEP (HR 0.44, 95%CI 0.28-0.69) were independently associated with reduced 90-day mortality risk (Table). Notably, timely post-discharge clinic visits with all specialties demonstrated the greatest mortality reduction (HR 0.31, 95% CI 0.20-0.48). **Conclusion:** Our study reveals critical gaps in AKI management for hospitalized patients with cirrhosis, with suboptimal rates of albumin administration and timely post-discharge outpatient care. Diuretic avoidance and timely post-discharge outpatient care were associated with significantly improved outcomes. Implementing standardized protocols for medication management and post-discharge care coordination could substantially improve outcomes in this high-risk population.

Process Measures of AKI Care	AKI Resolution* OR (95% CI)	90-Day Mortality** HR (95% CI)
Avoidance of diuretics	1.39 (1.01-1.64)	0.94 (0.75-1.19)
Avoidance of NSBB use	0.97 (0.57-1.64)	1.08 (0.65-1.85)
Avoidance of other vasodilators	1.16 (0.92-1.45)	1.16 (0.91-1.49)
Volume expansion with albumin	0.86 (0.67-1.09)	1.29 (1.03-1.61)
Volume expansion with crystalloids	0.81 (0.66-0.99)	1.18 (0.96-1.44)
Infectious work up	0.89 (0.73-1.07)	1.04 (0.86-1.26)
Subspecialty consultation	1.13 (0.93-1.38)	1.07 (0.88-1.30)

2466 | NON-INVASIVE DIAGNOSTIC MODEL FOR HIGH-RISK GASTROESOPHAGEAL VARICES IN CIRRHOTIC PATIENTS USING SPLEEN VOLUME, PLATELET COUNT, AND SERUM ALBUMIN

Wenjun Wang[1] Jiaqi Li[1] Boyu Chen[1] Zhuoran Wang[1], [1]Second Affiliated Hospital of Xi'an Jiaotong University

Background: High-risk gastroesophageal varices (GEV) in cirrhotic patients pose a significant risk for life-threatening bleeding. While esophagogastroduodenoscopy (EGD) remains the gold standard for GEV

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

diagnosis, its invasive nature and patient discomfort limit its widespread use. This study aimed to develop a non-invasive model for high-risk GEV in cirrhotic patients. **Methods:** From October 2023 to January 2025, 164 patients with liver cirrhosis consecutively admitted to The Second Affiliated Hospital of Xi'an Jiaotong University were included. GEV was evaluated with EGD. Spleen volume was measured based on noncontrast-enhanced CT imaging. Multivariate logistic regression was performed to identify factors associated with high-risk GEV, and a diagnostic nomogram was constructed based on significant variables. The model's predictive performance was evaluated using the area under the receiver operating characteristic (ROC) curve, with internal validation conducted through 1000 bootstrap resampling iterations. **Results:** Three factors were significantly associated with high-risk GEV: spleen volume (OR = 1.002, 95% CI: 1.000–1.003, P = 0.010), platelet count (OR = 0.987, 95% CI: 0.975–0.998, P = 0.024), and serum albumin level (OR = 0.896, 95% CI: 0.826–0.973, P = 0.009). The diagnostic model incorporating these factors demonstrated excellent discriminative ability, with an area under the ROC curve of 0.814 (95% CI: 0.749–0.880). The model achieved a sensitivity of 81.5% (95% CI:71.0%-88.9%) and a specificity of 71.1% (95% CI:59.9%-80.3%) in identifying high-risk GEV. **Conclusion:** This study establishes a non-invasive model incorporating spleen volume, platelet count, and serum albumin to accurately identify high-risk GEV in patients with cirrhosis.

2467 | TRENDS IN MORTALITY DUE TO ESOPHAGEAL VARICES IN LIVER DISEASE PATIENTS AGED 65 AND OLDER IN THE UNITED STATES (1999-2024): DISPARITIES BY DEMOGRAPHICS, URBANIZATION, AND REGION

MOHAMED A ELNAGGAR[1] Ibrahim Hassan[2] Ayah Obeid[3] Hatem Eltaly[4] Mohamed Abd El Aziz[5] Houman Rezaizadeh[6], [1]Hospital Medicine department, Hartford Hospital. Harford, CT.USA, [2]Faculty of Medicine, Suez Canal University, Ismailia, Egypt., [3]Internal Medicine Department, Saint Luke's University network, Bethlehem, PA, USA, [4]Cleveland Clinic Main Campus, Cleveland, Ohio, USA., [5]Internal Medicine department, Deaconess health system. Henderson, KY. USA., [6]University of Connecticut school of Medicine. Hartford, CT, USA

Background: Esophageal varices represent a significant complication of liver disease with substantial mortality risk, particularly among older adults. This study examined temporal trends in mortality due to esophageal varices among liver disease patients aged 65 years and older, analyzing disparities across demographic groups, urbanization levels, and geographic regions. **Methods:** Using CDC WONDER data (1999-2024), we identified deaths attributed to esophageal varices (I85) in liver disease (K70-K76) in patients aged ≥65 years. Age-adjusted mortality rates (AAMR) were calculated per 100,000 person-years, standardized to the 2000 U.S. standard population. Joinpoint regression analysis was employed to determine trend segments, annual percent changes (APC), and average annual percent changes (AAPC) across demographic, urbanization, and regional strata. **Results:** Among 22,315 deaths recorded across 1.16 billion person-years, overall AAMR showed a U-shaped trend, declining from 2.33 (95% CI: 2.17-2.49) in 1999 to its lowest point around 2008, before increasing to 3.04 (95% CI: 2.90-3.19) by 2024 (AAPC: 1.05%; 95% CI: 0.78-1.35). Three distinct periods were identified: significant decline during 1999-2006 (APC: -8.43%), stabilization during 2006-2013 (APC: 1.53%), and substantial increase during 2013-2024 (APC: 7.26%). Males consistently experienced higher mortality rates than females (2024 AAMR: 4.02 vs. 2.20), though both groups followed similar temporal patterns. Among racial/ethnic groups, Hispanic populations showed the highest mortality rates throughout the study period, increasing from 4.82 to 5.17 (AAPC: 0.46%). White populations experienced the most pronounced relative increase (2.17 to 3.01; AAPC: 1.25%), while Black or African American populations showed a slight overall decline (1.93 to 1.42; AAPC: -0.50%). Regionally, the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

West maintained the highest mortality rates (2.78 to 3.77; AAPC: 1.33%), followed by the South, which demonstrated the steepest overall increase (2.13 to 3.12; AAPC: 1.36%). Rural areas exhibited a consistent increase after 2007 (APC: 5.67%), while urban areas showed a more complex pattern with an overall slight decline (AAPC: -0.41%). **Conclusion:** Mortality due to esophageal varices in older liver disease patients has demonstrated a concerning upward trajectory since 2013, with pronounced disparities across demographic groups and geographic regions. These findings highlight the need for targeted interventions to address rising mortality rates, particularly among Hispanic populations, in Western states, and in rural communities, where the burden is highest or increasing most rapidly.

2468 | EXPERIENCE AND CONFIDENCE OF GASTROENTEROLOGY FACULTY AND FELLOWS IN PLACEMENT OF BALLOON TAMPONADE DEVICES IN ACUTE VARICEAL HEMORRHAGE

Jessica Vadaketh[1] Farees Saqlain[2] Sarjukumar Panchal[3] Jonathan Nahas[3] Oscar Mitchell[4], [1]Hospital of the University of Pennsylvania, [2]Hospital of the University of Pennsylvania, Department of Internal Medicine, [3]Hospital of the University of Pennsylvania, Division of Gastroenterology and Hepatology, [4]Hospital of the University of Pennsylvania, Department of Pulmonary, Allergy, and Critical Care

Background: Esophageal variceal hemorrhage (AVH) and subsequent hemorrhagic shock remain a substantial cause of morbidity and mortality in patients with decompensated cirrhosis. Current AASLD guidelines indicate that placement of an esophageal balloon tamponade device (BTD) is indicated in acute variceal hemorrhage when endoscopic interventions fail. BTDs are rarely placed, and when they are needed, they must be assembled rapidly, inserted correctly, and maintained appropriately. Due to the high risk/low volume nature of BTD placement, these situations are stressful and error-prone. **Methods:** We sought to describe previous training, current confidence levels, and future training preferences for placement of BTDs in management of AVH within the gastroenterology (GI) division at our large academic center. A survey was created in REDCap with 26 questions and sent to 86 attendings and fellows, including 16 transplant hepatologists within the GI division. The survey questions were built to assess previous experience with BTDs, perceived levels of comfort with placement, and preferences for future educational initiatives. **Results:** Eighty-six participants were sent the survey, and 40% responded (74% were attendings and 26% were fellows). Less than half of the participants (44%) had never placed a BTD as the primary proceduralist (28% of attendings). Almost all respondents (94%) agreed/strongly agreed that they felt confident in knowing when a BTD was indicated, however, only half agreed/strongly agreed that they felt confident in being able to independently place one (similar between attendings and fellows, Figure 1). 36% of participants reported that they had never received prior training on BTD placement (44% of attendings and 22% of fellows). Some participants (42%) were interested in receiving further training on BTDs, with the most widely preferred training modalities being videos and simulation sessions. Additionally, 74% of respondents felt a step-by-step-guide would be very useful for assembly of BTDs. **Conclusion:** Gastroenterology physicians at our large academic center had varying degrees of previous experience in BTD placement. While almost all respondents expressed confidence in knowing when to place a BTD, we observed low levels of confidence in the ability to independently place BTDs across all levels of training and experience. Survey respondents indicated a desire for additional training. Our findings broadly support the need for further educational and practical tools to support clinicians in placing BTDs in treatment of variceal

bleeding. We have since created and started to use a step-by-step Ikea-like guide given to staff in our Medical Intensive Care Unit and Gastroenterology department and the preliminary feedback from our guide was that the instructions were clear and well developed and overall was well perceived, future directions include specific evaluation for this guide.

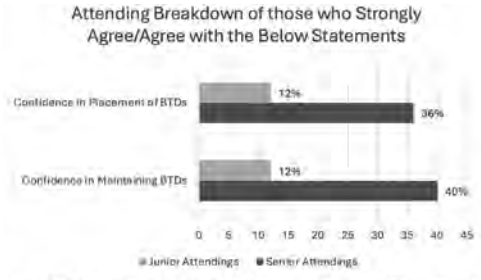

Figure 1: Attending Breakdown of those who Strongly Agree/Agree with the Below Statements. Senior attending is defined as 8 years or more as an attending.

2469 | COMPARATIVE RISKS OF RESPIRATORY SYNCYTIAL VIRUS, COVID-19 AND INFLUENZA A IN IN HOSPITALIZED PATIENTS WITH ADVANCED LIVER DISEASE

Adil Fazir[1] Katherine Cooper[2] Ami Patel[3] Deepika Devuni[2], [1]University of Massachusetts Chan Medical School, [2]University of Massachusetts, [3]Univeristy of Massachusetts

Background: Viral respiratory infections in patients with cirrhosis are associated with increased morbidity and mortality. While COVID and influenza have been well studied, respiratory and liver related outcomes data on respiratory syncytial virus infection (RSV) have been limited. We aimed to assess respiratory and liver-related outcomes in patients with RSV compared to COVID and Flu. **Methods:** This retrospective analysis of patients with cirrhosis hospitalized between 1/1/2022 and 1/1/2025 was completed using TriNetX. Those with a positive test for RSV, COVID, or Influenza A within 5 days of admission were included. Respiratory outcomes included acute hypoxic respiratory failure (AHRF), oxygen saturation $<85\%$ (Spo2 <85), and intubation. Liver outcomes included bilirubin levels $>$ 4mg/dl and hepatic decompensation, which was a composite outcome of ascites, encephalopathy (HE), and variceal bleeding (EVB). Outcomes were assessed at 30-days following hospital admission. Crude risks were reported for each infection (Table 1). For comparisons, propensity score matching (PSM) was used to balance cohorts for age, race, cirrhosis etiology, albumin, bilirubin, and chronic lung disease. Associations were reported as adjusted odds ratios with 95% confidence intervals. **Results:** A total of 6,161 hospitalized patients with cirrhosis who tested positive for RSV ($n=585$, mean age 63.9), COVID ($n=4,450$, mean age 67.1) and Influenza A ($n=1,126$, mean age 64.1) were included. Most participants were white (69-72%) and about one third had baseline lung disease. Compared to Flu-A ($n=542$), RSV ($n=542$) was associated with higher odds of ARHF (1.29, $p=0.04$), SpO2 $<85\%$ (1.80, $p<0.01$), intubation (1.41, $p=0.04$) and bilirubin $>$ 4mg/dl (1.54, $p=0.03$), but similar odds of hepatic decompensation (1.06, $p=0.67$). Compared to COVID ($N=554$), RSV ($N=554$) was associated with higher odds of AHRF (1.94, $p=<0.001$) and SpO2 $<$ 85% (1.65, $p=0.003$) and similar odds of hepatic decompensation (0.96, $p=0.77$). Mortality was 1.62-fold higher in RSV compared to FluA (1.62, $p=0.241$) but did not differ in RSV and COVID (1.04, $p=0.848$). **Conclusion:** In this large nationally representative sample, RSV infection in patients with cirrhosis was associated with increased respiratory related complications, but similar or lower risks of hepatic decompensation compared to COVID and Flu infection, and 1 in 10 patients died within 30 days of admission. Additional research is required to further understand the reasons for which RSV exerts greater respiratory effects and lower hepatic effects relative to COVID and Influenza A.

	RSV	Flu	COVID	RSV vs. Flu A		RSV vs. COVID	
Subject #	584	1,126	4,450	aOR (95% CI)	p-value	aOR (95% CI)	p-value

2470 | PATIENTS WITH DECOMPENSATED CIRRHOSIS HAVE REDUCED FAT AND MUSCLE VOLUMES COMPARED TO COMPENSATED CIRRHOSIS: A WHOLE-BODY MRI STUDY

Maria Rydfjord[1] Mikael Forsgren[2] Danielle Kirkman[3] Amon Asgharpour[3] Vaishali Patel[3] Geneva Roache[3] Pontus Henriksson[4] Olof Dahlqvist Leinhard[2] Arun Sanyal[3] Mohammad Siddiqui[3], [1]Linköping University; AMRA Medical AB, [2]AMRA Medical AB; Linköping University, [3]Virginia Commonwealth University, [4]Linköping University

Background: Sarcopenia and myosteatosis are common in patients with liver cirrhosis and are associated with adverse outcomes. Magnetic resonance imaging (MRI) can be used to quantify both muscle quantity (volume) and quality (fat infiltration). The MRI-based thigh muscle volume z-score (MVZ), a sex and body size invariant measure of muscle volume, together with muscle fat infiltration (MFI), can be used to identify muscle composition (MC) phenotypes. The adverse MC phenotype (defined as low MVZ and high MFI) has previously been independently linked to all-cause mortality in liver disease and general population. The aim of this study was to compare body fat and muscle composition, and adverse MC prevalence between patients with compensated and decompensated cirrhosis as part of a rapid standardized whole-body MRI and reference-based muscle composition phenotyping. **Methods:** In a cross-sectional analysis of prospectively acquired data, patients with decompensated cirrhosis (n = 46) undergoing liver transplant evaluation and patients with compensated MASLD-related cirrhosis (n = 47) were compared. MRI-based body composition was quantified using AMRA® Researcher, assessing visceral adipose tissue (VAT), abdominal subcutaneous adipose tissue (ASAT), anterior thigh fat-free muscle volume (FFMV), and MFI. MVZ, sex-adjusted MFI, and adverse MC was defined using literature values. Group differences were assessed using t-tests, Chi-square tests, and linear regression analyses adjusted for age, sex, and BMI. **Results:** Patients with decompensated cirrhosis were younger (55.5 ± 10.3 vs. 62.0 ± 9.3 years, p = 0.002) and had lower BMI (29.9 ± 7.1 vs. 33.7 ± 7.0 kg/m², p = 0.007), compared to patients with compensated cirrhosis. They also had lower VAT (4.0 ± 2.7 vs. 6.6 ± 2.9 L, p < 0.001), ASAT (9.5 ± 5.0 vs. 11.9 ± 5.1 L, p = 0.026), FFMV (8.8 ± 2.1 vs. 9.8 ± 2.4 L, p = 0.025), and MVZ (-0.83 ± 1.27 vs. -0.32 ± 1.12 SD, p = 0.045) (Fig). MFI did not differ significantly. After adjusting for age, sex, and BMI, only VAT and MVZ remained significant (p = 0.020 and p = 0.034, respectively). In patients with decompensated cirrhosis 20% presented with adverse MC compared to 15% of patients with compensated cirrhosis. This difference was not statistically significant. **Conclusion:** We found that patients with decompensated cirrhosis had reduced visceral fat and muscle volume compared to those with compensated cirrhosis. It is possible that the loss of visceral adiposity with progression to decompensation is another radiomics marker to predict future risk of hepatic decompensation. Moreover, MRI-based body composition profiling may improve prognostic evaluation and guide targeted interventions aimed at preserving muscle quality and function.

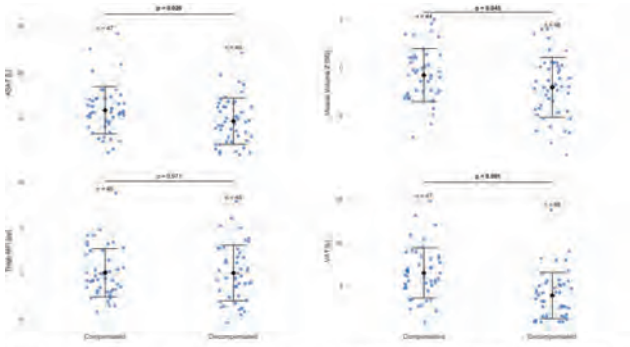

Figure. Group comparisons of adipose and muscle composition measures in patients with compensated and decompensated cirrhosis. Each panel shows individual participant data points (blue dots), group means (black diamonds), and error bars representing ± 1 standard deviation. Sample sizes per group are indicated above each category. P-values are derived from independent t-tests; significant results ($p < 0.05$) are shown in bold. MFI: anterior thigh muscle fat infiltration (sex-adjusted); MVZ: muscle volume z-score; ASAT: abdominal subcutaneous adipose tissue; VAT: visceral adipose tissue.

★ 2471 | PREDICTORS OF IN-HOSPITAL MORTALITY IN PATIENTS WITH CIRRHOSIS: A MULTICENTER RETROSPECTIVE STUDY FROM ETHIOPIA

Tamrat Petros Elias[1] Abate Bane Shewaye[2] Henok Fisseha Chichaybelu[3] Abdulsemed Mohammed Nur[4], [1]University of Rwanda, [2]Addis Ababa University, Tikur Anbessa Specialized Hospital & Adera Medical Center, [3]St. Paul's Hospital Millennium Medical College, [4]Addis Ababa University, Tikur Anbessa Specialized Hospital

Background: Cirrhosis is a major global health problem and a leading cause of liver-related mortality. In Ethiopia, it ranks as the sixth leading cause of death and contributes significantly to hospitalization and mortality. However, predictors of in-hospital mortality among patients admitted with cirrhosis-related complications remain poorly understood. This study aimed to identify predictors of in-hospital mortality among patients with cirrhosis in Ethiopia. **Methods:** A retrospective cross-sectional study using electronic medical records of patients admitted with cirrhosis-related complications between January 1, 2023, and March 31, 2024, at Adera Medical Center, St. Paul's Hospital Millennium Medical College, and Tikur Anbessa Specialized Hospital. Descriptive statistics were presented using frequencies and cross-tabulations. Variables with a p-value <0.25 in bivariate analysis were included in multivariable logistic regression. Adjusted odds ratios (AORs) with 95% confidence intervals (CIs) were calculated. A p-value <0.05 was considered statistically significant. **Results:** A total of 299 patients were included in the final analysis, of whom 79.6% were males. The median age of the study participants was 45 (IQR, 36-56) years. Hepatitis B virus (32.1%) was the most common etiology, followed by alcohol-associated liver disease (30.1%) and hepatitis C virus (13.4%). Ascites (69.2%), upper gastrointestinal bleeding (50.5%), and hepatic encephalopathy (44.8%) were the most common forms of presentation. More than half (52.9%) of the patients were in Child-Pugh class C, and 26.1% had other comorbidities. The in-hospital mortality rate was 25.4%. West Haven grade III or IV hepatic encephalopathy (AOR: 12.0; 95% CI 2.33-61.63; P < 0.01), hepatocellular carcinoma (AOR: 9.05; 95% CI 2.18-37.14; P: 0.01), history of previous admission within one year period (AOR: 6.80; 95% CI 2.18-21.18; P < 0.01), acute kidney injury (AOR: 6.47; 95% CI 1.77-23.64; P < 0.01), and model for end-stage liver disease - sodium score (AOR: 1.17; 95% CI 1.05-1.30; P: 0.02), were found to be predictors of in-hospital mortality. **Conclusion:** In-hospital mortality among patients with cirrhosis is high in Ethiopia. West Haven grade III or IV hepatic encephalopathy was the strongest predictor of mortality. Early recognition and treatment of hepatic encephalopathy and its precipitants are essential to improving outcomes.

2472 | THE ASSOCIATION OF LIVER FRAILTY INDEX AND CARDIAC DYSFUNCTION IN PATIENTS UNDERGOING TRANSPLANT EVALUATION

Hannah Laird[1] Jamey Cutts[2] Rebecca Turner[3] Curtis Argo[4], [1]University of Virginia Medical Center, [2]Division of Cardiovascular Medicine, University of Virginia Medical Center, Charlottesville, VA, [3]Division of Transplant Surgery, University of Virginia Medical Center, Charlottesville, VA, [4]University of Virginia

Background: Liver transplant candidates undergo cardiac evaluation with transthoracic echocardiogram (TTE) and assessment of frailty with the Liver Frailty Index (LFI). We aimed to evaluate the relationship between frailty and abnormal TTE findings to identify patients who may benefit from preoperative cardiac rehab. **Methods:** We conducted a retrospective chart review (January 2019-January 2025) of patients undergoing evaluation for liver transplant at a single academic medical center. Patients were included if they had documented LFI at initial evaluation and a comprehensive TTE performed at the transplant center within 6 months of initial LFI. The primary study aim was evaluation of the association of specific TTE parameters and frail status at the initial transplant evaluation visit. Univariate and multivariable statistical analysis were utilized. **Results:** 352 patients underwent TTE and LFI at initial transplant evaluation during the study period. On univariate analysis, female gender was significantly associated with frailty ($p=0.002$). Age ($p=0.02$), MELD ($p<0.0001$), body surface area ($p=0.04$), and tricuspid regurgitation maximum velocity (TR Vmax, $p=0.016$) were all significantly associated with frailty on univariate analysis but LV mass index, E/E', and LV diameter were not. Using multivariate logistic regression, TR Vmax did not remain

significant, but left ventricular ejection fraction (LVEF; p = 0.031), a criterion for cirrhotic cardiomyopathy (CCM) was significantly associated with frail status by LFI: for every 5% decrease in LVEF, a patient was 8% more likely to be frail (see table). **Conclusion:** Our study showed that for every 5% decrease in a patient's LVEF, a liver transplant evaluation patient is 8% more likely to be frail. This supports that LVEF may be an important predictor of frailty and may be able to estimate the tempo at which a patient is becoming frail over serial TTE exams and at risk of developing CCM. The possibility that cardiac rehab may be a helpful intervention in those who are frail with decreased LVEF warrants further investigation.

Odds Ratios Of Frailty in Liver Transplant Eval Candidates			
Variable	Odds Ratio (OR)	Confidence Interval (CI)	P-value
Age	1.0	1.0-1.0	0.05
Gender	2.7	1.3-5.4	0.008
MELD	1.1	1.04-1.16	0.0004
Body Surface Area	1.4	0.4-5.6	0.61
Tricuspid Velocity	1.005	0.998-1.01	0.15
LVEF	0.92	0.85-0.99	0.031
C-statistic = 0.734

2473 | NOMOGRAM OF CLINICAL PREDICTION MODEL FOR EVALUATING RISK OF PORTAL VEIN THROMBOSIS IN LIVER CIRRHOSIS BASED ON LASSO REGRESSION

Jinglan Jin[1] Zian Wang[1] Feng Jiang[2] Jintao Jiang[1] Yaya Li[1], [1]First Hospital of Jilin University, [2]Meihekou Central Hospital

Background: As one of the complications of liver cirrhosis, portal vein thrombosis (PVT) brings a significant clinical challenge in the treatment. To find the predictive clinical variables which can evaluate the probability of PVT in cirrhosis patients, a series of models were established and a nomogram was built for visualization. **Methods:** This study involved 263 liver cirrhosis patients admitted in First Hospital of Jilin University during July, 1, 2022 to June, 30, 2023. All patients were randomly separated into a training set (211 patients) and a validation set (52 patients) with a ratio of 4:1. Five different methods (Logistic regression, Ridge regression, Lasso regression, Decision tree and Randomforest) were utilized to build predictive models. **Results:** Among all patients, 65 of them had events of portal vein thrombosis within 12 months after their discharge. The C-index of five models in the training set was 0.776, 0.805, 0.783, 0.929 and 0.928, and got 0.816, 0.760, 0.839, 0.608 and 0.739 in the validation set, respectively. The variables selected by Lasso regression were weight, history of drinking, splenectomy, hemoglobin (HGB), platelet (PLT), alkaline phosphatase (ALP), γ-glutamyltransferase (GGT), albumin (ALB), fibrinogen (FBG) and portal vein width. History of drinking, ALP and GGT were excluded in the final nomogram for their prediction directions were obviously reverse to clinical experience. **Conclusion:** We finally screened out seven clinical variables predicting the probability of PVT in patients with liver cirrhosis, which can assist clinicians initially identify patients with high risk of thrombosis. Models built by Decision tree and Randomforest performed perfect in training set but performed moderately in validation set, which might be caused by model overfitting. These two machine-learning models also have potential for optimization, we look forward to new prediction models with more accuracy.

2474 | OUTCOMES ASSOCIATED WITH SECONDARY SPONTANEOUS BACTERIAL PERITONITIS (SBP) PROPHYLAXIS AFTER HOSPITAL DISCHARGE IN A NATION-WIDE SWEDISH COHORT

Max Schechter[1] Linnea Widman[2] Axel Wester[2] Ying Shang[2] Andrea Lindfors[2] Hannes Hagström[2],
[1]University of Pennsylvania, [2]Karolinska Institutet

Background: Secondary spontaneous bacterial peritonitis (SBP) prophylaxis reduces mortality amongst patients with a history of SBP. However, recent evidence suggests that SBP prophylaxis may lead to adverse outcomes such as antibiotic resistant infections. We evaluated proportions of secondary SBP prophylaxis and its impact on readmission with SBP, readmission with other infections, and mortality. **Methods:** We conducted a register-based cohort study identifying hospitalized patients in Sweden diagnosed with a first episode of SBP between 2006 and 2022 from the Swedish National Patient Register utilizing administrative coding. Secondary prophylaxis was defined as dispensing of at least 7 days of treatment with multiple refills within 7 days of discharge. The primary outcome was rates of rehospitalization with repeat SBP, and the secondary outcomes were rehospitalization with sepsis, *Clostridium difficile*, and mortality. Logistic regression was used to assess factors associated with receiving SBP prophylaxis and Cox regression was used to assess the association between secondary prophylaxis and subsequent rehospitalizations and mortality. **Results:** Of 896 patients that met study criteria, 117 (13%) dispensed secondary SBP prophylaxis within 7 days of discharge. There was no impact of year of diagnosis, cirrhosis etiology, or medical comorbidities on likelihood of receiving SBP prophylaxis. There was a trend towards higher SBP prophylaxis amongst patients discharged from a university hospital compared to community hospitals (53 of 117 patients (45%) vs. 287 of 779 patients (37%), p = 0.079). In a multivariable regression model, we found that receiving secondary SBP prophylaxis was associated with lower rates of readmission with SBP compared to patients that did not receive prophylaxis (aHR = 0.49, 95%CI = 0.28–0.87), with no significant increase in readmission with sepsis (aHR = 1.36, 95%CI = 0.28–6.67) or *Clostridium difficile* (aHR = 2.10, 95%CI = 0.71–6.30). No association with mortality was found (aHR = 0.96, 95%CI = 0.74–1.25). **Conclusion:** In this cohort, only 13% of patients hospitalized with a first episode of SBP dispensed secondary antibiotic prophylaxis within 7 days of discharge. These patients may experience lower rates of rehospitalization with SBP, however no effect on mortality was seen. Further investigation into the impact of secondary SBP prophylaxis will help clarify its role given emerging evidence into the potential harms of antibiotic prophylaxis.

University Hospital, Saga, Japan, [12]National University Hospital, Singapore

Background: Despite advancements in detection and treatment of hepatocellular carcinoma (HCC), prognosis remains poor with a low five-year survival rate (20%). Traditional survival analyses like the Cox model are limited in capturing its dynamic progression across different clinical states. This study aims to address these limitations by employing a Cox semi-Markov model (CSMM) to better inform risk stratification and clinical management strategies for HCC by accounting for transitions between disease states. **Methods:** This cohort study included 934 adult patients with HCC who underwent curative treatment across eight tertiary centers in Australia, China, Japan, Singapore, South Korea, and the United States. The primary objective was to assess the risk of HCC recurrence following curative and to evaluate death rates before and after HCC recurrence using CSMM analysis. **Results:** The median age of the cohort was 65, with overall high male (75.0%) and cirrhosis (72.2%) prevalence. Etiologies included MASLD, HCV, HBV, and ALD. Using CSMM, distinct clinical trajectories were identified: recurrence, death without recurrence, and death after recurrence. Analyses revealed advancing age and HCV increased recurrence risk, while obesity and liver transplantation were protective. RFA and downstaging or neoadjuvant therapies were associated with higher risks of recurrence and post-recurrence death. AFP, tumor size, INR, bilirubin, and advanced BCLC stage were key predictors of poorer outcomes. **Conclusion:** This study highlights the distinct impacts of various predictors on recurrence and survival through a multi-state lens. Our findings emphasize the value of dynamic, state-based modeling in guiding personalized risk stratification and treatment planning for HCC.

2476 | HERNIA INCARCERATION IS A COMMON COMPLICATION AFTER TIPS: AN ANALYSIS OF INCIDENCE AND ASSOCIATED RISK FACTORS

Anand Vissa[1] Aryana Far[1] Jennifer Lai[1] K. Pallav Kolli[1] Neil Mehta[1] Jin Ge[1], [1]University of California, San Francisco

Background: Transjugular Intrahepatic Portosystemic Shunt (TIPS) is commonly used to treat complications of portal hypertension. Hernia incarceration is a potential complication of TIPS that is poorly understood and not well documented. We examine this complication in a large single-center cohort of TIPS patients. **Methods:** We identified 259 adults who underwent TIPS at the University of California, San Francisco (UCSF) between 2015-2024. We extracted structured variables and unstructured documentation from the UCSF Clinical Data Warehouse. We used OpenAI's GPT-4o large language model (LLM) and manual chart review to identify post-TIPS hernia incarceration and clinical information from unstructured notes. We calculated time to events and used LASSO-Cox regression to identify risk factors associated with incarceration. **Results:** Of 259 patients, 12% (32) developed post-TIPS incarceration with a median time to event of 45.5 days (IQR 11.5-113). Compared to the non-incarcerated group, incarcerated patients were more likely to have existing umbilical hernias (87.5% vs. 29.5%, $p < 0.01$), higher serum creatinine (1.0 vs. 0.9, $p = 0.03$), and higher serum albumin (3.2 vs. 2.9, $p < 0.01$). Multivariate LASSO-Cox regression showed presence of an umbilical hernia pre-TIPS (HR3.08, 95% CI 1.78-5.33, $p < 0.01$), serum creatinine at TIPS (HR1.28, 95%CI 1.03-1.61, $p = 0.03$), serum albumin at TIPS (HR1.69, 95%CI 1.02-2.80, $p = 0.04$) were predictors of post-TIPS incarcerated hernia development. In the incarcerated group, 37.5% underwent hernia repair at a median 0.5 days [IQR 0.0–259.3], 18.8% received liver transplant at 55.5 days [IQR 6.3–152.8], and 25.0% died at 422 days [IQR 261.8–747.0] post-incarceration. In the non-incarcerated group, 6.2% underwent hernia repair, 22.9% received transplant, and 16.3% died post-TIPS. Kaplan-Meier analysis showed no significant difference in mortality between the incarceration and no-incarceration group (2-year probability of 13.8% vs 12.75%, log rank $p = 0.3$). **Conclusion:** Post-TIPS hernia incarceration is a common event with a rate of 12% in this single center cohort and a median event occurrence of 1.5 months post-TIPS. The presence of a known umbilical hernia prior to TIPS had the strongest association with this complication. Serum creatinine and albumin association also suggests ascites severity as a potential contributor. Identifying pre-TIPS risk

2477 | INVOLVEMENT OF THE ADAMTS13/VON WILLEBRAND FACTOR AXIS IN ACUTE KIDNEY INJURY IN MICE WITH ADVANCED FIBROTIC LIVER

NORIHISA NISHIMURA[1] Kosuke Kaji[1] Shinya Sato[1] Tadashi Namisaki[1] Hitoshi Yoshiji[1], [1]Nara Medical University

Background: Hepatorenal syndrome-induced acute kidney injury (HRS-AKI) is defined by the simultaneous occurrence of acute kidney injury (AKI) and liver cirrhosis (LC), and is a major risk factor for adverse clinical outcomes in LC patients. Recent studies have revealed that the decreased activity of a disintegrin-like metalloproteinase with thrombospondin type 1 motif 13 (ADAMTS13) in tandem with elevated von Willebrand factor (vWF) antigen levels is closely linked to LC progression. We investigated the role of the ADAMTS13/vWF axis in AKI using a mouse model with advanced fibrotic liver. **Methods:** In the primary experimental setup, wild-type (WT) and ADAMTS13-deficient (Adamts13$^{-/-}$) 129^{+Ter}/Sv mice were assigned as controls and experimental groups, respectively. AKI was induced by intraperitoneal administration of carbon tetrachloride (CCl_4), employing a regimen that included a standard CCl_4 protocol, a subsequent single injection of a double CCl_4 dose, and a final challenge with lipopolysaccharide (LPS) to emulate systemic inflammation on a fibrotic background. In a complementary approach, a secondary model using WT and vWF-deficient (vWF$^{-/-}$) C57BL/6J mice was employed to specifically address the role of vWF. The effects of ADAMTS13/vWF alterations on liver and kidney injuries were evaluated, with additional emphasis on the specific role of vWF in the fibrotic mouse model. **Results:** Both WT and Adamts13$^{-/-}$ mice subjected to the AKI protocol showed significant elevations in serum AST, BUN, and creatinine levels; however, these biochemical derangements were markedly exacerbated in the Adamts13$^{-/-}$ group. Doppler flow measurements revealed a significant reduction in hepatic and renal microcirculatory blood flow in Adamts13-/- mice, which was paralleled by pronounced histological evidence of tissue injury including extensive inflammatory cell infiltration, increased F4/80-positive macrophage accumulation, and higher expression of renal injury markers. Oxidative stress, as indicated by elevated malondialdehyde levels and reduced superoxide dismutase activity, was also significantly enhanced in the absence of ADAMTS13. By contrast, vWF-/- mice demonstrated substantial protection from both liver and kidney injury, exhibiting lower levels of serum injury markers, preserved tissue perfusion, attenuated inflammatory responses, and reduced oxidative stress indices. **Conclusion:** An imbalanced ADAMTS13/vWF axis may play a critical role in AKI progression with LC. Reduced ADAMTS13 activity permits the accumulation of prothrombotic and proinflammatory ultra-large vWF multimers, thereby aggravating tissue ischemia, inflammation, and oxidative damage. Conversely, the absence of vWF confers marked tissue protection, highlighting a potential therapeutic target. These results suggest that the regulation of ADAMTS13/vWF axis may be a novel therapeutic option for the progression of AKI in patients with LC.

2478 | CLINICAL OUTCOMES OF PATIENTS WITH CLINICALLY SIGNIFICANT PORTAL HYPERTENSION AWAITING ENDOSCOPIC VARICEAL SCREENING IN A METROPOLITAN AUSTRALIAN SETTING

Brandon-Joe Cilia[1] Nicholas Hannah[2] Neeraj Bhala[3] Ashok Raj[2], [1]University of Melbourne, [2]Royal Melbourne Hospital, [3]Royal Melbourne Hospital and Univeristy of Melbourne

Background: The Baveno VII guidelines recommend non-selective β-blockers (NSBBs) for those with chronic liver disease (CLD) and clinically significant portal hypertension (CSPH). Many centres still perform endoscopy in all patients with cirrhosis and little data exist on the potential negative impact of time on the waitlist. We investigated the clinical outcomes of patients with cirrhosis awaiting endoscopic variceal surveillance, between those with and without CSPH. **Methods:** Retrospective cohort study of patients with CLD awaiting endoscopic variceal screening at a large tertiary Australian centre, between July 2020 and March 2024. Primary outcomes were hepatic decompensation, hospitalisation, and liver-related mortality while on the endoscopy waitlist. CSPH was determined non-invasively by ultrasound or elastography prior to waitlisting. Kaplan-Meier curves were compared using the log-rank test with two-tailed P values < 0.05 considered significant. Hazard ratios (HR) with 95% confidence intervals (CI) were also reported using the Mantel-Haenszel method. **Results:** Two hundred and thirty-eight patients (170 (71.4%) with CSPH; 68 (28.6%) without CSPH) were included. Median wait time for endoscopy was 18 (IQR 7–44) weeks. On Kaplan-Meier curves, CSPH was associated with a higher rate of hepatic decompensation (42.4% versus 8.8%, $P < 0.001$), including: increased risk of ascites (HR 3.03, 95% CI 1.73–5.33, $P < 0.001$), hepatic encephalopathy (HR 2.55, 95% CI 1.13–5.76, $P = 0.025$), variceal bleeding (HR 3.21, 95% CI 1.01–10.21, $P = 0.048$), liver-related hospitalisation (HR 2.68, 95% CI 1.46–4.91, $P = 0.001$) and liver-related mortality (HR 3.23, 95% CI 1.12–9.31, $P = 0.03$). Of those with CSPH, 33.8% (23 patients) maintained NSBB use during follow-up, with a 63% reduction in liver-related admissions compared to 133 who did not receive NSBBs (HR 0.37, 95% CI 0.015–0.88, $P = 0.025$). The remaining 14 received NSBB for insufficient length of time. Overall, 167 (70.2%) underwent endoscopy and 46% had oesophageal varices. **Conclusion:** Patients with CLD and CSPH had worse liver-related outcomes while awaiting endoscopy compared to those without CSPH. These data support management guided by Baveno VII guidelines, rather than endoscopy for all, with scope for quality improvement projects to improve liver outcomes.

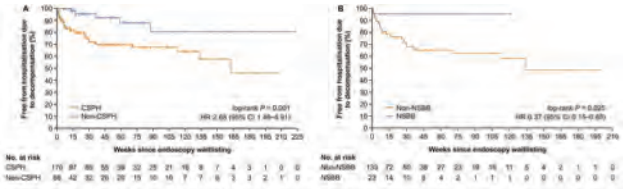

Figure 1: Kaplan-Meier estimates of survival free from hospitalisation for hepatic decompensation in (A) CSPH *versus* non-CSPH, and (B) non-NSBB *versus* NSBB.

2479 | RISK FACTORS AND PREDICTION MODEL FOR SARCOPENIA IN PATIENTS WITH CIRRHOSIS UNDERGOING TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

Shuyue Tuo[1] Jia Yuan[1] Ying Liu[1] Zhang Wen[1] Qiuju Ran[1] Yong Li[1] Chan Li[1] Quanxin Yang[1] Jinhai Wang[1] Lu Li[1] Shejiao Dai[1] Xinxing Tantai[1], [1]The Second Affiliated Hospital of Xi'an Jiaotong University

Background: Sarcopenia is highly prevalent and predicts poor outcomes in patients with cirrhosis undergoing transjugular intrahepatic portosystemic shunt (TIPS). However, the risk factors for the development of sarcopenia in this population remain unclear. In addition, validated predictive models based on easily accessible clinical variables have not been developed. This study aimed to address these issues in patients with cirrhosis undergoing TIPS. **Methods:** All patients with cirrhosis undergoing TIPS at the Second Affiliated Hospital of Xi'an Jiaotong University from January 2018 to March 2024 were screened. The risk factors for sarcopenia were identified using Least Absolute Shrinkage and Selection Operator regression and multivariate logistic regression. A new model and nomogram were developed based on the selected variables. The model was evaluated and compared using discrimination, calibration, and decision curve analysis. **Results:** A total of 202 patients with cirrhosis undergoing TIPS were included in the study. Six independent risk factors for sarcopenia were identified: Age (OR = 1.05; 95%CI: 1.01-1.10; p = 0.017); gender (female vs male: OR = 0.03; 95%CI: 0.01-0.11; p < 0.001); body mass index (BMI) (OR = 0.80; 95%CI: 0.70-0.91; p < 0.001); etiology (autoimmune vs viral: OR = 8.22; 95%CI:

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

2.26-29.83; p = 0.001), hepatic encephalopathy (HE) (OR = 31.33; 95%CI: 1.98-494.51; p = 0.014); and right psoas muscle thickness (RPMT) (OR = 0.77; 95% CI: 0.69-0.85; p < 0.001). A new model and nomogram for predicting sarcopenia were developed based on these risk factors (Figure 1). The model exhibited good overall performance (Nagelkerke R^2 = 0.473; Brier score = 0.139), discrimination (The area under the receiver operating characteristic curve = 0.857; 95%CI: 0.803-0.910), calibration (Hosmer-Lemeshow p = 0.855), and clinical utility, offering advantages over existing non-dedicated sarcopenia models. Patients were stratified into high-risk and low-risk groups based on the optimal cutoff value of 0.385, with a sensitivity, specificity, positive predictive value, negative predictive value, and accuracy for distinguishing sarcopenia of 78.5%, 85.4%, 71.8%, 89.3%, and 83.2%, respectively. **Conclusion:** In patients with cirrhosis undergoing TIPS, age, male sex, BMI, etiology, HE, and RPMT were identified as independent risk factors for sarcopenia. Based on these risk factors, the newly developed sarcopenia model showed good predictive performance and holds potential as a practical screening tool in clinical settings.

◆ 2480 | LEAN PATIENTS WITH METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE HAVE HIGHER LIVER-RELATED EVENTS AND MORTALITY

Abdellatif Ismail[1] Mohammed Al-Aquily[2] Ahmad Abdulraheem[3] Hanna Blaney[4] Wing-Kin Syn[5],
[1]University of Maryland Medical Center, Midtown Campus, [2]Norwalk Hospital/ Yale university program, [3]MedStar Georgetown Washington Hospital Center, [4]Georgetown University, [5]Saint Louis University School of Medicine

Background: The American Association for The Study of Liver Disease (AASLD) introduced a new definition & diagnostic criteria for metabolic dysfunction associated steatotic liver disease (MASLD) focused on the presence of cardiometabolic risk factors (CMRFs) & hepatic steatosis. A growing body of evidence indicates that patients without obesity may have similar or even worse outcomes compared to those with obesity when diagnosed with MASLD. We aimed to compare liver related events (LRE) & mortality between these two groups. **Methods:** This is a retrospective study using the TriNetX US Collaborative Network. Adult patients with hepatic steatosis (ICD-10 code: K76.0) were included. To minimize confounders, we excluded patients with ICD-10 code for alcohol associated liver disease (K70). *Cohort 1* consisted of patients with hepatic steatosis, BMI ≤24.90 kg/m2 and one or more of the CMRFs per the MASLD criteria by AASLD, 2024. *Cohort 2* consisted of patients with hepatic steatosis, BMI ≥ 25 mg/m2 and one or more of the CMRFs. Propensity score matching (PSM) was performed to balance demographic data and comorbidities resulting in two balanced cohorts. Outcomes were assessed over a 10-year period and included new diagnoses of cirrhosis, endpoint of LRE combined (ascites, hepatic encephalopathy [HE], spontaneous bacterial peritonitis [SBP], esophageal varices [EV] and hepatorenal syndrome [HRS]), hepatocellular carcinoma (HCC), receiving liver transplant (LT), cardiovascular mortality and all-cause mortality. **Results:** Patients in *Cohort 1* (lean or non-obese) had a significantly higher risk of developing cirrhosis (4.4% vs. 3.6%; RR: 1.20; p < 0.001), endpoint of LRE (7.1% vs. 3.7%; RR: 1.92; p < 0.001), HCC (0.9% vs. 0.6%; RR: 1.50; p < 0.001), and undergoing LT (0.5% vs. 0.3%; RR: 1.56; p < 0.001) compared to patients in *Cohort 2* (obese). In addition, patients in *Cohort 1* were found to have higher cardiovascular (1.7% vs 1.0%, RR: 1.64, p < 0.001) and all-cause mortality (14.3% vs. 7.1%; RR: 2.00; p = < 0.001) compared to patients in *Cohort 2*. **Conclusion:** Our findings showed that lean (non-obese) patients with MASLD have worse liver-related events, cardiovascular mortality & all-cause mortality compared to obese patients with MASLD. This is consistent with the notion that lean individuals with MASLD may have more pronounced metabolic dysfunction leading to a higher risk of progression to advanced fibrosis, cirrhosis, and cardiovascular disease compared to their obese counterparts with similar degrees of steatosis. Furthermore, lean patients with MASLD often have a higher prevalence of genetic variants such as PNPLA3 and TM6SF2, which are linked to more severe hepatic injury and fibrosis progression, independent of traditional CMRFs or obesity. Our findings build on the evidence that supports the use of alternative anthropometric indices, such as waist circumference, to identify CMRF.

◆ 2481 | PREDICTION AND PROGNOSTIC UTILITY OF A CIRRHOSIS RISK SCORE IN CHINESE ADULTS: DERIVATION AND VALIDATION COHORT STUDY

Xinyu Wang[1] Shuyao Song[2] Shanshan Wu[3] Dianjianyi Sun[2] Canqing Yu[2] Sailimai Man[2] Yining Zu[4] Xiaochen Yang[4] Menglu Liang[5] Zhengming Chen[6] Bo Wang[4] Jun Lv[2] Liming Li[2], [1]Harvard T.H. Chan School of Public Health, [2]School of Public Health, Peking University, [3]Beijing Friendship Hospital, Capital Medical University, [4]Meinian Institute of Health, [5]School of Public Health, University of Maryland, [6]Nuffield Department of Population Health, University of Oxford

Background: Identifying individuals at high risk for cirrhosis could enable timely interventions and reduce the disease burden, but no risk stratification tool has been designed for Chinese. We aimed to develop and validate a novel risk score to facilitate cirrhosis screening in Chinese adults. **Methods:** Based on the China Kadoorie Biobank (CKB), a population-based cohort across 10 regions in China, we developed the CKB Cirrhosis Score (CCS) using a penalized logistic regression. In parallel, an aggregate machine-learning algorithm, the ensemble SuperLearner (eSL), was developed to benchmark the performance of CCS. The scores were then externally validated in the Meinian Health Group (MHG), a nationwide study within China's largest health check-up chain, as well as the National Health and Nutrition Examination Survey (NHANES). The prognostic value of CCS for predicting liver-related events and mortality was assessed in two independent prospective cohorts within CKB and UK Biobank (UKB). **Results:** CCS consists of four clinical risk factors (age, sex, body mass index, and diabetes) and four readily available plasma biomarkers (total cholesterol, high-density lipoprotein cholesterol, aspartate transaminase, and γ-glutamyl transferase). In the CKB derivation cohort (N = 23,185), CCS showed good discrimination, with 10-fold cross-validated area under the receiver-operating characteristics curve (AUROC) of 0.762 (95% confidence interval: 0.744, 0.780). In external validation, the AUROC of CCS was 0.816 (0.799, 0.834) in MHG and 0.859 (0.788, 0.919) in NHANES, comparable to eSL (0.815 [0.796, 0.833] and 0.856 [0.806, 0.904]), and superior to other cirrhosis risk scores (Fibrosis-4 index: 0.684 [0.661, 0.708] and 0.695 [0.619, 0.764]). In prognostic evaluation, accounting for death without liver disease as a competing risk, CCS predicted liver-related mortality with a time-dependent AUROC at 10 years of 0.815 in CKB (N = 24,125) and 0.879 in UKB (N = 384,643). Compared to the low-risk group, the sub-distribution hazard ratios for liver-related mortality were 4.47 (3.83, 5.90) and 66.13 (50.11, 87.27) for the medium- and high-risk groups in UKB. **Conclusion:** CCS is the first cirrhosis risk score developed specifically for the general population of Chinese adults, with transportability to health check-up settings and Western populations. Based on eight easily accessible predictors, CCS could be used for identification of cirrhosis and risk stratification of liver-related mortality.

◆ 2482 | FAVORABLE TRENDS IN TRANSIENT ELASTOGRAPHY AND METABOLIC PARAMETERS IN CYSTIC FIBROSIS PATIENTS AFTER TWO YEARS OF ELEXACAFTOR/TEZACAFTOR/IVACAFTOR THERAPY

Souhir Hendis[1] Olivia Portolese[2] Marc Bilodeau[2] Helene Castel[2] Bernard WILLEMS[3] Genevieve Huard[4] Annick Lavoie[5] Catherine Vincent[2] Julian Hercun[6], [1]Université de Montréal, Centre hospitalier de l'Université de Montréal, [2]Université de Montréal, Centre hospitalier de l'Université de Montréal, Liver Unit, [3]University of Montreal, [4]Centre De Recherche Du Chum, [5]Université de Montréal, Centre hospitalier de l'Université de Montréal, Pulmonology Unit, [6]National Institutes of Health

Background: Cystic fibrosis (CF) is a genetic disease caused by CFTR mutations. While CFTR modulator therapy with Elexacaftor/tezacaftor/ivacaftor (ETI) improves pulmonary and nutritional outcomes, its long-term hepatic and metabolic effects remain undetermined. This study aims to assess changes in non-invasive tests of fibrosis and metabolic markers in adults with CF after two years of ETI therapy. **Methods:** We conducted a retrospective descriptive cohort study involving adults with CF treated with ETI for a minimum of two years followed at a CF referral center. Pre- and on-treatment serum-based non-invasive markers of fibrosis and transient elastography (TE) were assessed, as well as body mass index (BMI), HbA1c, lipid profile (triglycerides, high-density lipoprotein (HDL), low-density lipoprotein (LDL)), and liver fat content assessed by controlled attenuation parameter (CAP). Analysis was restricted to patients with longitudinal assessment through repeat TE measures. **Results:** A total of 154 patients were included (mean age 37; 64.5% male; 58.1% F508del homozygotes) with 31 having paired TE assessments. Alcohol use was reported in 39% and collected as a binary variable. BMI showed no significant change (median 23 [IQR 5.3] pre- and 23 [IQR 4.9] post-ETI; $p = 0.54$). HbA1c decreased from 6.0% [IQR 1.13] to 5.4% [IQR 1.2] ($p = 0.0084$). LDL was unchanged (1.48 [IQR 1.16] to 1.47 mmol/L [IQR 1.13]; $p = 0.78$). HDL increased from 1.06 [IQR 0.68] to 1.41 mmol/L [IQR 0.79] ($p = 0.002$), and triglycerides from 0.95 [IQR 0.80] to 1.07 mmol/L [IQR 1.0] ($p = 0.23$). CAP did not change significantly (202 to 223 dB/m; $p = 0.41$). Serum based non-invasive markers of fibrosis, FIB-4 (0.58 [IQR 0.36] to 0.81 [IQR 0.60]; $p = 0.30$) and Forns index (3.15 [IQR 2.56] to 3.17 [IQR 1.84]; $p = 0.62$) remained stable. While overall median TE remained stable over three yearly exams was 4.9, 4.9, and 4.6 kPa, paired analysis showed a significant improvement from pre-ETI to year two ($p = 0.02$), particularly in patients with baseline TE > 6.9 kPa, where 8/9 improved (median 9.2 [IQR 1.6] to 8.0 kPa [IQR 2.1]; $p = 0.023$). **Conclusion:** After two years of ETI, patients demonstrated improved glycemic control and HDL levels, with stable BMI, lipid profile, and no significant change in hepatic fat. Notably, liver stiffness decreased significantly, particularly in those with elevated baseline values suggestive of CF-related hepatic involvement, indicating a potential beneficial effect of ETI on liver health.

incidence in the general population with T2DM is still unknown. **Methods:** In this prospective, multicenter cohort study from the European LiverScreen project, we analyzed longitudinal liver stiffness measurement (LSM) data from three population-based cohorts (Barcelona, Rotterdam and Odense). Participants underwent baseline and follow-up screening by vibration-controlled transient elastography (VCTE) with an approximate 4-year interval. T2DM was based on medical history, antidiabetic treatment, HbA1c $\geq$6.5%, or a fasting glucose $\geq$126mg/dL. Incident fibrosis was defined as an LSM increase of $\geq$30% and crossing the 8kPa threshold. Fibrosis regression was defined as a $\geq$30% reduction in LSM and a drop below 8kPa. Logistic regression models were used to assess the associations between T2DM and fibrosis dynamics and adjusted for follow-up duration, baseline LSM, cohort, waist circumference, alcohol consumption, and tobacco use. **Results:** Among 7,884 participants with reliable baseline VCTE, 4,536 had a reliable follow-up VCTE after a median of 4.3 years [IQR: 4.1–8.2]. The follow-up cohort had a median baseline age of 62 years [56–68], 52% were female, 11% had T2DM and 5.5% had prevalent fibrosis (baseline LSM $\geq$8 kPa). During follow-up, incident fibrosis occurred in 2.1% of participants without T2DM versus 5.3% of those with T2DM. Of those without T2DM, 51% achieved fibrosis regression, compared with 33% of those with baseline T2DM. In adjusted regression models, prevalent T2DM (aOR 1.82 95%CI 1.13–2.94) and incident T2DM (aOR 3.10 95% CI 1.74–5.54]) were significantly associated with incident fibrosis. Prevalent T2DM was inversely associated with fibrosis regression (aOR 0.40 95% CI 0.21–0.74). Among participants with both baseline T2DM and fibrosis, 45% (14/31) of those who achieved normal glucose regulation by follow-up experienced fibrosis regression, compared to 26% (17/65) of those who remained hyperglycemic (aOR 2.80, 95% CI: 0.87–9.01). **Conclusion:** Prevalent T2DM is associated with an increased risk of incident fibrosis, and a reduced likelihood of fibrosis regression. Incident T2DM increases risk of incident fibrosis more than three-fold, stressing the importance of fibrosis screening in this population, possibly with a shorter screening interval.In patients with T2DM, achieving normal glucose regulation may contribute to liver fibrosis regression.

◆ 2484 | RISK FACTORS FOR DRUG-RELATED HEPATIC STEATOSIS: A PHARMACOVIGILANCE STUDY FROM THE FDA ADVERSE EVENT REPORTING SYSTEM (FAERS)

Yanjie Lin[1] Chi Zhang[1] Guiqiang Wang[1] Hong Zhao[1], [1]Peking University First Hospital

Background: Drug-induced hepatic steatosis is rare, but it is closely related to the adjustment of the treatment of the underlying disease and the prevention of hepatic steatosis and its inflammation. This study investigates risk factors for drug-induced hepatic steatosis by analyzing a large dataset from the FDA's Adverse Event Reporting System (FAERS). **Methods:** The reporting odds ratio (ROR) and information component (IC) were used to assess the report of hepatic steatosis from Q1 2004 to Q3 2024. Univariate, LASSO, and multivariate regression analyses were used to explore risk factors. In addition, the timing of the onset of hepatic steatosis was assessed. **Results:** Overall, 16,767 cases associated with fatty liver were identified in FAERS. A total of 117 drugs were found to be associated with hepatic steatosis, with antineoplastic drugs (28/117), antiviral drugs (18/117), psychotropic drugs (17/117), and immunomodulatory drugs (12/117) being the most common. Age under 41 years, heavier body weight, and 13 different medications, including 3 antineoplastic agents of interest, namely methotrexate, permenburgase, and tamoxifen, are risk factors for hepatic steatosis. The median time to onset was 123.50 days, while the onset of permenburgase was faster, with a median time of only 19 days ($P < 0.001$). **Conclusion:** With the increasing number of drug types, it is necessary to focus on the treatment of hepatic steatosis and steatohepatitis caused by drugs, and adjust the treatment drugs in time to reduce the incidence of liver fibrosis and liver cirrhosis and prevent the interruption of treatment of the primary disease.

◆ 2485 | OPTIMAL HEMOGLOBIN A_{1C} (HBA_{1C}) TARGET FOR PREVENTING LIVER-RELATED COMPLICATIONS IN INDIVIDUALS WITH TYPE 2 DIABETES MELLITUS (T2DM) WITH AND WITHOUT CIRRHOSIS: A TERRITORY-WIDE RETROSPECTIVE COHORT STUDY FROM 2000 TO 2023 OF 1,130,282 INDIVIDUALS

Mary Yue Wang[1] Sherlot Juan Song[2] Nana Peng[2] Grace Lai-Hung Wong[2] Vincent Wai-Sun Wong[3] Terry Cheuk-Fung Yip[3], [1]The Chinese University of Hong Kong, [2]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, [3]Department of Medicine and Therapeutics, The Chinese University of Hong Kong

Background: Glycemic control in individuals with T2DM and cirrhosis is challenging due to restricted options of anti-diabetic agents and the risk of hypoglycemia. This study aims to determine and compare optimal target HbA_{1c} for preventing liver-related events in individuals with T2DM, with and without cirrhosis. **Methods:** This retrospective study included adult

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

individuals with T2DM, with or without cirrhosis from 2000 to 2023 in Hong Kong after excluding individuals who had missing demographic data, human immunodeficiency virus infection, type 1 diabetes mellitus, and liver-related complications before T2DM diagnosis or within the first 2 years. The primary outcome was liver-related events including hepatic decompensation, hepatocellular carcinoma, liver transplantation, and liver-related death. Non-liver-related death was considered a competing event. Restricted cubic spline analysis was used to assess the nonlinear relationship between HbA_{1c} and liver-related events and to identify optimal HbA_{1c} levels associated with the lowest risk. **Results:** Of 1,130,282 individuals with T2DM, 42,622 (3.8%) had cirrhosis (mean age 70.9 years, 58.2% men). Over a mean follow-up of 9.7 years (IQR 4.9-13.1) in the non-cirrhotic group and 7.3 years (3.5-10.1) in the cirrhotic group, liver-related events developed in 4514 (0.6%) individuals without cirrhosis and 1588 (7.3%) individuals with cirrhosis. After adjustment for possible covariates, a non-linear relationship existed between HbA_{1c} level and risk of liver-related events in cirrhotic group (p for linearity = 0.01, p for cause-specific hazard ratio [CSHR] = 0.004). Individuals with HbA_{1c} between 6.5 and 7.7% had a lower risk of developing liver-related complications. In contrast, a linear relationship between HbA_{1c} level and risk of liver-related events was observed in individuals without cirrhosis (p for CSHR = 0.003), with an increased risk from 6.7% or above (Figure 1). **Conclusion:** A non-linear relationship between HbA_{1c} and the risk of liver-related complications is observed in cirrhotic group, while a linear association was found in those without cirrhosis. Compared to $<6.7\%$ in noncirrhotic group, a higher target HbA_{1c} $<7.7\%$ for cirrhotic group can reduce the risk of liver-related complications. Given the potential impact of extrahepatic complications and medication effects, caution is needed when HbA_{1c} level is excessively low in those with cirrhosis.

◆ 2486 | HEPATOCELLULAR CARCINOMA RISK STRATIFICATION IN NON-CIRRHOTIC MASLD: A POPULATION-BASED PREDICTION MODEL VALIDATED ACROSS COHORTS

Mei-Hsuan Lee[1] Yi-Ting Chen[1] Loggang Zhao[2] Szu-Ching Yin[1] Xinyuan Zhang[3] Hye Won Lee[4] Xia-Rong Liu[1] Chia-Wei Huang[1] Xuehong Zhang[2] Chien-Jen Chen[5], [1]Institute of Clinical Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan, [2]Yale University, [3]Harvard University, [4]Yonsei University, [5]Academia Sinica, Taipei, Taiwan

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects approximately 30% of the global population and is associated with an increased risk of hepatocellular carcinoma (HCC). However, specific risk prediction models tailored to MASLD patients remain limited, hindering efforts to enhance awareness and guide targeted lifestyle modifications. **Methods:** We conducted a large-scale study using two MASLD cohorts: a training cohort of 66,577 individuals enrolled from a private health examination center (1997–2013) and an external validation cohort of 198,453 individuals from a government-led population-based screening program (2012–2013). Participants were followed through computerized data linkage until 2019 and 2021, respectively. The HCC prediction model was developed based on widely available clinical predictors and validated internally and externally. Model performance was assessed using areas under the receiver operating characteristic curves (AUROC) with 95% confidence intervals (CI), Brier scores, and calibration plots. Cumulative HCC risk was stratified by risk score categories and compared using log-rank tests. **Results:** In the training cohort, 44,606 participants (67%) were used for model derivation, and 21,971 (33%) for internal validation. Advanced age, elevated alanine aminotransferase, central obesity, diabetes, and high-density lipoprotein cholesterol were identified as significant predictors of HCC ($p < 0.05$) and incorporated into the risk model. Individual risk scores (range: 0–18) were calculated based on these predictors, demonstrating a direct association with predicted HCC risk. The AUROC for predicting HCC at 3, 5, and

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

10 years in the internal validation cohort was 0.786 (95% CI: 0.653-0.918), 0.813 (95% CI: 0.712-0.913), and 0.824 (95% CI: 0.759-0.889), respectively. In the external validation cohort, the corresponding AUROC values were 0.785 (95% CI: 0.738-0.831), 0.805 (95% CI: 0.775-0.836), and 0.784 (95% CI: 0.765-0.804). Stratifying participants by risk scores revealed five distinct risk groups with significantly different cumulative HCC risks ($p < 0.01$). Notably, approximately 40% of HCC cases during follow-up were not preceded by a diagnosis of cirrhosis. The model demonstrated satisfactory predictive performance for non-cirrhotic HCC with AUROC of 0.777 (95% CI: 0.709-0.846), 0.784 (95% CI:0.733-0.836), and 0.766 (95% CI: 0.736-0.796) at 3, 5, and 10 years in the external validation cohort. **Conclusion:** The HCC risk in non-cirrhotic MASLD is low but not negligible. This validated model, integrating common clinical predictors, offers a scalable and practical tool for identifying high-risk groups, supporting targeted precision prevention strategies and public health initiatives.

Background: Hypertension is common in metabolic dysfunction-associated steatotic liver disease (MASLD), but its specific effects on long-term clinical outcomes and disease progression remain unclear. This study examined the association of hypertension with the risk of adverse clinical outcomes and liver stiffness/fibrosis progression in subjects with MASLD. **Methods:** Three multicenter prospective cohorts were analyzed: the UKB cohort to assess the risk of adverse clinical outcomes, the Serial VCTE cohort to assess liver stiffness progression, and the Paired Liver Biopsy cohort to assess histologic liver fibrosis progression. Adverse clinical outcomes were defined as all-cause mortality, cardiovascular events, and/or liver-related events. For MASLD patients with baseline LSM <10 kPa, liver stiffness progression was defined as achieving an LSM ≥ 10 kPa at follow-up.For MASLD patients with baseline LSM ≥ 10 kPa, liver stiffness progression was defined as a $\geq 20\%$ increase in LSM, while regression was defined as LSM <10 kPa or a $\geq 20\%$ decrease at follow-up. Liver fibrosis progression, defined as at least a 1-stage increase in liver fibrosis on histology, while the secondary outcome was fibrosis regression, defined as at least a 1-stage fibrosis decrease. Cox regression and Kaplan-Meier analyses were used to assess the impact of baseline hypertension on the outcomes. **Results:** A total of 107,566 individuals from the UKB, 8,169 from the Serial VCTE cohort, and 1,670 from the Paired Liver Biopsy cohort were included in the final analysis. In the UKB, with a median follow-up of 15.0 years, 23,499 adverse events were documented, including 10,254 deaths, 17,274 major cardiovascular events, and 1,089 LREs. Hypertension was identified as a significant risk factor for long-term adverse outcomes (adjusted HR: 1.30, 95% CI 1.26–1.33, $P<0.001$). In the Serial VCTE cohort, hypertension was associated with an increased risk of liver stiffness progression (adjusted HR: 1.57, 95% CI 1.30–1.90, $P < 0.001$) and a reduced probability of regression (adjusted HR: 0.77, 95% CI 0.64–0.93, $P = 0.005$).In the Paired Liver Biopsy cohort, hypertension was linked to higher liver fibrosis progression (adjusted HR: 1.41, 95% CI 1.12–1.78, $P < 0.001$) and a reduced chance of regression (adjusted HR: 0.78, 95% CI 0.64–0.95, $P = 0.014$). **Conclusion:** Hypertension plays a critical role in MASLD, acting as a significant clinical risk factor for adverse outcomes and the progression of liver fibrosis. However, its impact is frequently underappreciated in clinical practice, with management efforts often focusing more on diabetes and obesity. This lack of recognition highlights the need to prioritize hypertension as a key risk factor in the progression of MASLD and its associated major clinical complications.

◆ 2488 | BODY ROUNDNESS INDEX AND RISK OF LIVER-RELATED MORTALITY AND HEPATOCELLULAR CARCINOMA

Daniel Sikavi[1] Hanseul Kim[1] Prooksa Ananchuensook[1] Jiaxian Shen[1] Etienne Nzabarushimana[1] Amrisha Bhosle[1] Longgang Zhao[2] Xuehong Zhang[2] Tracey Simon[1] Wenjie Ma[1] Andrew Chan[1] Long Nguyen[3], [1]Massachusetts General Hospital, [2]Yale University School of Nursing, [3]Harvard University Medical School

Background: The body roundness index (BRI) is a novel, easy-to-calculate anthropometric measure that estimates visceral and total body adiposity. BRI uses an elliptical model that combines waist circumference and height (compared to height/weight for body mass index [BMI]) and has been associated with higher risk of metabolic dysfunction-associated steatotic liver disease (MASLD), cardiometabolic disease, and all-cause mortality. However, its association with risk and complications of chronic liver disease, including hepatocellular carcinoma (HCC), remains unclear. **Methods:** We conducted a prospective cohort study among 30,336 men (Health Professionals Follow-up Study) and 46,300 women (Nurses' Health Study) from 1986-2018, free of advanced liver disease at baseline and followed with biennial questionnaires querying anthropometrics, lifestyle, medical history, and disease outcomes with $>90\%$ follow-up. Deaths were reported by next-of-kin, postal authorities, or National Death Index, and cause of death was identified by review of death certificates and medical records. HCC cases were identified by medical records review. BRI was cumulatively averaged over the study period to capture long-term exposures and classified into quartiles. Time-varying multivariable Cox proportional hazards models were used to estimate hazard ratios (HR) for liver-related death or incident HCC by BRI. **Results:** We identified 225 liver-related deaths and 92 cases of incident HCC over 2,140,289 person-years of follow-up. As expected, BRI and BMI were correlated at baseline (Spearman $\rho = 0.78$, $p < 0.001$). Compared to participants at the lowest quartile, the HR for liver-related mortality or HCC was 1.18 (95% CI: 0.81-1.71) for Q2, 1.21 (95% CI: 0.83-1.74) for Q3, and 1.68 (95% CI: 1.17-2.41) for Q4 (P-trend = 0.003, Fig. 1). In secondary analyses, we did not adjust for BMI given collinearity with BRI (each use height in its calculation), but HRs remained robust and only slightly attenuated after additionally adjusting for weight (Fig. 1), suggesting that BRI may be an independent risk factor for complications of liver disease, regardless of weight (and BMI by proxy). When evaluating outcomes independently, the association was strongest for liver-related death (P-trend = 0.01) **Conclusion:** In a large prospective cohort free of advanced liver disease at baseline, higher BRI was strongly associated with a greater risk of a composite outcome inclusive of liver-related death and/or HCC, largely driven by liver-related mortality. BRI, independently of weight, predicted adverse hepatic outcomes beyond traditional anthropometric measures and may serve as a complementary adjunct for predicting liver disease risk at the population level.

◆ 2489 | EVALUATING THE ASSOCIATION OF PATIENT CHARACTERISTICS ON HOSPITALIZATIONS AMONG A COHORT OF CANADIAN MASLD PATIENTS IN PRIMARY CARE

Elizabeth Baguley[1] Juan Abraldes[2] Seungwon Lee[1] Abdel-Aziz Shaheen[1], [1]University of Calgary, [2]University of Alberta

Background: The impact of implementing a Canadian primary care pathway to risk-stratify patients with metabolic-associated steatotic liver disease (MASLD) on

hospitalizations is unknown. We evaluated patient characteristics associated with hospitalizations post-pathway enrollment. **Methods:** Adult patients enrolled in the Calgary MASLD risk-stratification pathway from March 2017-June 2022 were included (n = 12,070). The Discharge Abstract Database was linked to the Calgary MASLD pathway database to capture hospitalizations from pathway entry to March 31st, 2023. Primary cause for hospitalization was defined by the first diagnostic code. Multivariable negative binomial models were used to calculate the estimated adjusted incidence rate ratio (aIRR) of overall, liver- and cardiovascular-related hospitalizations, with a time offset function. Model covariates included age (> = 54 vs. < 54 years), sex (male vs. female), diabetes status (yes vs. no), rural status (rural vs. urban), body mass index (BMI) (> = 30 vs. < 30 kg/m^2), Charlson Comorbidity Index (CCI) (> = 3 vs. < 3), and liver stiffness measurements (LSM) by shear wave elastography (> = 8 vs. < 8 kPa). **Results:** Cohort mean age was 53.1 ± 13.3 years, and 51.9% were female. After adjusting for relevant covariates, several factors were significantly associated with overall hospitalizations including age > = 54 (aIRR: 1.36 [95% CI: 1.21-1.53], p < 0.001), male sex (0.82 [0.74-0.92], p = 0.001), diabetes (1.32 [1.17-1.48], p < 0.001), rural residence (1.32 [1.08-1.61], p = 0.006), BMI > = 30 kg/m^2 (1.24 [1.10-1.39], p < 0.001), CCI > = 3 (1.24 [1.20-1.27], p < 0.001), and LSM > = 8kPa (1.55 [1.32-1.82], p < 0.001), Figure 1. For liver-related hospitalizations, age > = 54 (aIRR: 6.93 [95% CI: 1.47-32.66], p = 0.014) and LSM > = 8kPa (7.45 [2.62-21.16, p < 0.001) were independently associated with use. Cardiovascular-related hospitalizations were significantly associated with age > = 54 (aIRR: 2.75, 95% CI: 1.97-3.84, p < 0.001), male sex (1.70 [1.29-2.25], p < 0.001), diabetes (2.14 [1.61-2.84], p < 0.001), CCI > = 3 (1.27 [1.20-1.34], p < 0.001), and LSM > = 8kPa (2.19 [1.58-3.05], p < 0.001). **Conclusion:** Among MASLD patients in primary care, patient age and LSM were associated with all types of hospital admissions. Patient sex, diabetes status, and CCI were associated with both overall and cardiovascular-related hospitalizations, while rural status and BMI were associated only with overall hospitalizations.

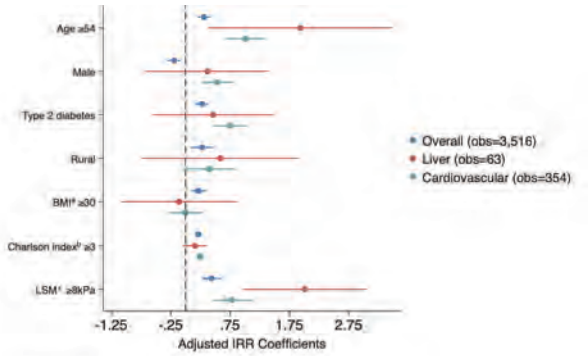

Figure 1. Adjusted Incidence Rate Ratio (aIRR) Coefficients for Hospitalization Admission Type

◆ 2490 | ELEVATED RISK OF GASTROINTESTINAL CANCERS IN LEAN MASLD: A PROPENSITY-MATCHED COHORT STUDY

Omar Al Ta'ani[1] Yahya Alhalalmeh[2] Marissa Gorvet[1] Pojsakorn Danpanichkul[3] Nabeeha Mohy-ud-din[1], [1]Allegheny Health Network, [2]New York Medical College-Saint Michael's Medical Center, [3]Texas Tech University Health Sciences Center

Background: Metabolic dysfunction associated steatotic liver disease (MASLD) is increasingly recognized as a risk factor for gastrointestinal cancers. However, cancer risk among individuals with lean MASLD remains poorly defined. Because these patients often lack traditional metabolic risk factors, clarifying their cancer risk is critical for improving risk stratification, guiding surveillance, and informing clinical care. **Methods:** We conducted a retrospective cohort study using the TriNetX research network, which aggregates electronic health records from multiple healthcare organizations. Adults with MASLD (ICD codes K76.0 or K75.81) were identified between January 1, 2005, and December 31, 2015. Lean MASLD was defined as body mass index (BMI) < 25 kg/m². Patients were grouped by BMI category and matched 1:1 using propensity scores to balance demographics, comorbidities, laboratory values, and medication use. Cox proportional hazards models were used to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) for incident gastrointestinal cancers with lifelong follow up. **Results:** Among 242,835 MASLD patients identified, 47,317 were lean and 195,518 were non-lean. After 1:1 matching, the final cohort included 47,317 individuals in each group with well-balanced baseline characteristics. Lean MASLD was associated with significantly elevated risks of both intestinal and extraintestinal gastrointestinal cancers compared to non-lean MASLD (Figure 1). For intestinal cancers, patients with lean MASLD had a higher risk for colorectal cancer (HR 1.47, 95% CI 1.35–1.61, p < 0.001) and small bowel cancer (HR 1.66, 95% CI 1.28–2.16, p < 0.001). For extraintestinal cancers, lean MASLD patients had increased risk of liver cancer (HR 1.82, 95% CI 1.54–2.14, p < 0.0001), pancreatic cancer (HR 1.96, 95% CI 1.76–2.19, p < 0.001), esophageal cancer (HR 1.76, 95% CI 1.40–2.21, p < 0.001), gastric

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

cancer (HR 2.04, 95% CI 1.69–2.48, p < 0.001), and biliary cancer (HR 1.70, 95% CI 1.36–2.12, p < 0.001). **Conclusion:** Lean individuals with MASLD face significantly elevated risks of gastrointestinal cancers compared to their non-lean counterparts. These findings suggest that mechanisms beyond traditional metabolic dysfunction, such as visceral adiposity not captured by BMI, immune dysregulation, gut-liver axis alterations, and possible genetic susceptibility, may contribute to cancer development in this population. Our results underscore the importance of tailored surveillance strategies and highlight the need for further prospective and mechanistic research to better characterize cancer risk in lean MASLD.

◆ 2491 | RISK FACTORS AND DEFINITION OF EARLY ONSET METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) CIRRHOSIS

Veeral Ajmera[1] Tae-Hwi Schwantes-An[2] Luis Díaz[1] Callie Zaborenko[2] Egbert Madamba[1] Katherine Yates[3] Naga Chalasani[4] Rohit Loomba[1], [1]University of California, San Diego, [2]Indiana University, [3]Johns Hopkins University, [4]Indiana University Medical Center

Background: Older age is associated with an increased risk for cirrhosis; however, a subset of patients presents with cirrhosis at an earlier age. We examined the association between genetic and modifiable factors with early-onset cirrhosis due to metabolic dysfunction-associated steatotic liver disease (MASLD). **Methods:** This prospective study included adults with biopsy proven MASLD enrolled in the Nonalcoholic Steatohepatitis Clinical Research Network (NASH CRN). DNA was genotyped in duplicate for risk alleles in PNPLA3, TM6SF2, and the protective variant in HSD17B13. A genetic risk score (GRS) was estimated as the sum of risk alleles in PNPLA3, TM6SF2 plus the wild-type allele in HSD17B13 and dichotomized at the median to low and high-risk groups. The primary analyses evaluated factors associated with early-onset cirrhosis defined as the lowest quartile of age among participants with cirrhosis in the NASH CRN. **Results:** Of 234 included patients with cirrhosis, the mean (SD) age and BMI were 56.9 (9.7) years and 35.6 (± 6.8) kg/m^2, respectively and 66% had type 2 diabetes (T2DM). Early-onset cirrhosis was defined as the lowest quartile, which was age < 50 years old. Participants with early-onset cirrhosis were more likely to be male and less likely to have hypertension or hyperlipidemia than those with non-early cirrhosis (P < 0.05). Early-onset cirrhosis vs non-early onset cirrhosis was not associated with significant differences in ALT, AST or platelet count, however it was associated with higher mean (SD) steatosis grade on liver histology, 1.5 (0.9) vs 1.2 (0.8) P = 0.009. Early-onset cirrhosis vs non-early onset cirrhosis was associated with a lower prevalence of the protective variant in HSD17B13 (T/TA or TA/TA) (24% vs 34%, P = 0.004) but no significant difference in PNPLA3 or TM6SF2 risk variants. When comparing characteristics of participants under age 50 with cirrhosis vs non-cirrhotic MASLD (N = 999), early presentation with cirrhosis vs non-cirrhotic MASLD was associated with T2DM, BMI ≥ 35 kg/m^2, higher alkaline phosphatase and lower ALT. In multivariable analysis adjusted for sex, Hispanic ethnicity, GRS, obesity, T2DM, HTN and alcohol intake only high GRS, aOR 2.30 (95% CI:1.24-4.19, P = 0.007) and T2DM, aOR 3.38 (95% CI: 1.88-6.16, P < 0.001) remained associated with cirrhosis in participants under 50 with an additive increase in the prevalence of cirrhosis (Figure). **Conclusion:** One-quarter of patients with MASLD cirrhosis present before age 50 years and have distinct features including elevated alkaline phosphatase, higher genetic risk and a greater prevalence of T2DM.

◆ 2492 | TAMOXIFEN IS ASSOCIATED MASLD PROGRESSION IN WOMEN WITH ER+ BREAST CANCER: A MULTICENTER RETROSPECTIVE COHORT STUDY

Emma Leipsner[1] Kate Johnson[1] Priyanka Gaur[1] Scarlet Yang[1] Tatyana Kushner[1], [1]Weill Cornell Medical College

Background: Tamoxifen, a Selective Estrogen Receptor Modulator (SERM), functions as an estrogen antagonist in breast tissue for estrogen receptor-positive (ER+) breast cancer. Its effect on liver outcomes in women with pre-existing Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) remains unclear. We evaluated whether tamoxifen influences MASLD progression in women with concurrent ER+ breast cancer compared to untreated controls. **Methods:** Using the TriNetX Research Network, we conducted a retrospective cohort study comparing liver disease outcomes in women with ER+ breast cancer and MASLD who received tamoxifen versus those who did not. Patients with prior decompensating events were excluded. Propensity score matching was conducted on 16 characteristics, including demographics and comorbidities. A composite decompensation outcome was defined as the presence of hepatic encephalopathy, variceal bleeding, portal hypertension, ascites, or hepatocellular carcinoma (HCC). **Results:** We identified 3,001 women with MASLD and ER+ breast cancer who had received tamoxifen (mean age 57.1 +/- 11.9) and 15,198 untreated controls (mean age 64.1 +/- 10.7) from 2005 to 2025. Most women were white (72% vs. 78%, $p < 0.001$), followed by Black (9.5% vs. 10.5%, $p = 0.0899$), Asian (8.7% vs. 5.3%, $p < 0.001$), and other races (3.7% vs. 2.4%, $p < 0.001$). After propensity score matching, 3000 women remained in each group, with median follow-up times of 1,220 and 1,098 days, respectively. Tamoxifen users had significantly higher rates of liver disease progression (Figure 1), including occurrence of MASH (RR 1.91), hepatic fibrosis (RR 1.99), and cirrhosis (RR 2.04). Composite liver decompensation was over twice as likely in tamoxifen users compared to non-users, with significantly increased risks of individual decompensation markers: portal hypertension (RR 3.98), jaundice (RR 3.33), and ascites (RR 2.36). Hepatic encephalopathy, HCC, esophageal variceal bleeding, and liver transplant sample sizes were too small to calculate. **Conclusion:** Tamoxifen-treated women with MASLD and ER+ breast cancer experience increased liver disease progression

compared to those not receiving tamoxifen. These findings highlight tamoxifen's important influence on liver disease progression. Interdisciplinary care between hepatology and oncology is necessary to optimize both oncologic and hepatic outcomes for this particular group. Duration of tamoxifen exposure and baseline MASLD disease status are likely important influencers of our observed association and warrant further investigation.

◆ 2493 | HYPOTHYROIDISM AND RISK OF LIVER-RELATED EVENTS IN PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Xinrui Jin[1] Sherlot Juan Song[1] Vincent Wong[1] Jimmy Che-To Lai[1] Grace Lai-Hung Wong[1] Alice Pik-Shan Kong[1] Terry Cheuk-Fung Yip[1], [1]The Chinese University of Hong Kong

Background: Hypothyroidism is associated with an increased risk of MASLD and possibly its histologic severity. However, its effects on the development of liver-related events (LREs) remain uncertain. We aimed to assess the association between hypothyroidism and LREs in patients with MASLD. **Methods:** A territory-wide retrospective cohort study was conducted between 2000 and 2024 in Hong Kong, including adult patients with MASLD who had thyroid function tests. Baseline thyroid status was identified using ICD-9-CM diagnosis codes and thyroid function tests (thyroid stimulating hormone [TSH] and free thyroxine [T4]), and thyroxine replacement treatment; time-varying thyroid status was determined by thyroid function tests. LREs, the primary outcome, were defined as a composite of hepatocellular carcinoma (HCC), hepatic decompensation, liver transplantation, and liver-related death. The association between baseline and time-varying thyroid status and incident LREs was assessed using Fine-Gray model and time-dependent cause-specific hazard model, respectively. **Results:** The study included 20478 patients, with 179 LREs over a median follow-up of 4.8 years. In univariate model, baseline hypothyroidism (subdistribution hazard ratio [SHR] 1.59, 95% CI 1.04-2.43, $p = 0.032$), but not hyperthyroidism (SHR 1.11, 95% CI 0.49-2.51, $p = 0.80$), was associated with LREs. Baseline TSH and free T4 levels, whether analyzed as continuous or categorical variables, were not linked to LREs. In contrast, time-varying TSH levels (adjusted cause-specific hazard ratio [aCSHR] 1.01, 95% CI 1.004-1.036, $p = 0.016$) and TSH groups (4-10 mIU/L: aCSHR 2.36, 95% CI 1.42-3.92, $p < 0.001$; >10 mIU/L: aCSHR 4.73, 95% CI 1.50-14.88, $p = 0.008$) were significantly linked to higher risk of LREs. The cumulative incidence of LREs differed significantly by thyroid status over time (Figure 1). Compared with patients who were euthyroid, time-varying hypothyroidism was also associated with a higher LRE rate (aCSHR 3.01, 95% CI 1.94-4.67, $p < 0.001$). The aCSHR was 2.60 (95% CI 1.56-4.31, $p < 0.001$) in patients with subclinical hypothyroidism and 6.31 (95% CI 2.92-13.63, $p < 0.001$) in those with overt hypothyroidism, while time-varying hyperthyroidism showed no association. **Conclusion:** Both subclinical and overt hypothyroidism are linked to increased LRE risk in patients with MASLD. As thyroid function can change over time and be modified with treatment, dynamic thyroid function assessment has a stronger correlation with LREs than a one-off assessment.

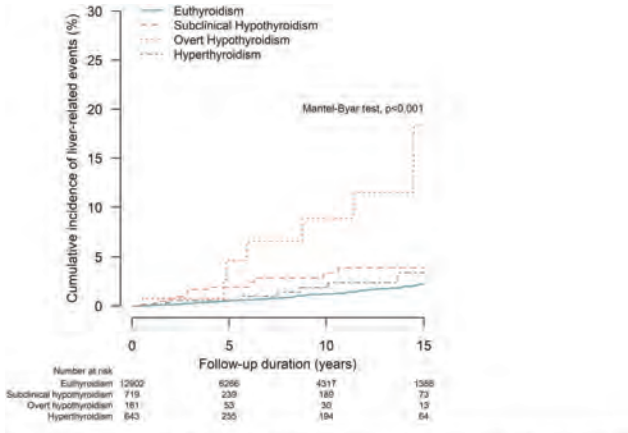

Figure 1. Cumulative risk of incident LRE in accordance with thyroid status during follow-up

Background: The first and further decompensation mark the natural history and the risk of mortality in patients with cirrhosis. We assessed the cumulative incidence of first and further (acute and non-acute) decompensation and evaluated their impact on both liver-related death (LR-D) in patients with compensated advanced chronic liver disease (cACLD) due to metabolic dysfunction-associated steatotic liver disease (MASLD). **Methods:** International multicenter retrospective study (17 centers) on 6,061 consecutive patients with clinical (LSM > 10 kPa) or biopsy-proven (F3-F4 fibrosis) diagnosis of cACLD due to MASLD. First and further decompensation were defined according to Baveno VII criteria. Competing risk analysis by cumulative incidence functions and Cause-specific Cox models with baseline and time-dependent variables were performed. A multistate model was built to better assess the clinical course of cACLD due to MASLD. **Results:** The cumulative incidence of the first decompensation was 3.5% at 5 years, increasing 19-fold the risk of LR-D using Cox analysis; the cumulative incidence of further decompensation was 43.9% (95% C.I 37.2-50.2) at 5 years among patients with first decompensation, additionally increasing 1.5-times the risk of LR-D. Ascites, followed by variceal bleeding, were the most common events in both first and further decompensation. Hepatocellular carcinoma (HCC) further independently increased the risk of LR-D by 3- and 1.4-fold in the whole cohort of cACLD due to MASLD

and in those who experienced first decompensation, respectively. **Conclusion:** The first and further decompensations represent tipping points in the clinical course of patients with cACLD due to MASLD, increasing 19-times and additionally 1.5-times the risk of LR-D. HCC is an independent predictor of LR-D in patients with cACLD due to MASLD, resulting in an additional risk of LR-D when associated with both first and further decompensation.

◆ 2495 | LONGITUDINAL CHANGES IN STEATOTIC LIVER DISEASE SUBTYPE CLASSIFICATION AND SUBSEQUENT RISK OF MAJOR ADVERSE LIVER OUTCOMES: A LANDMARK ANALYSIS

Pedro Ochoa-Allemant[1] Douglas Schaubel[1] Nadim Mahmud[1] David Kaplan[1] Marina Serper[1], [1]University of Pennsylvania

Background: Steatotic liver disease (SLD) includes metabolic dysfunction-associated steatotic liver disease (MASLD), alcohol-associated liver disease (ALD), and their intersection (MetALD). Patient classification by SLD subtype may change over time; however, the impact of these transitions on major adverse liver outcomes (MALO) is unknown. **Methods:** We conducted a retrospective cohort study of adults receiving outpatient care in the Veterans Health Administration (2010-2021) with imaging-confirmed hepatic steatosis identified using natural language processing. We excluded those with baseline cirrhosis, cirrhosis-related complications, or coexisting liver disease etiologies. The primary exposure was the change in SLD subtype classification between cohort entry (first imaging indicating steatosis) and a 2-year landmark. The primary outcome was incident MALO (cirrhosis, decompensation, HCC, liver transplant, or liver-related death). Follow-up started at the 2-year landmark and continued until the occurrence of MALO, non-liver-related death, loss to follow-up, or study end (December 31, 2021). We restricted analyses to patients alive and uncensored at the landmark. We calculated incidence rates per 100 person-years (PY). To examine the magnitude of the association between changes in SLD subtype classification with subsequent risk of MALO, we used cause-specific Cox proportional hazards regression to estimate hazard ratios (HRs) and 95% CIs, treating non-liver-related death as a censoring event. We identified confounders a priori and final models included age, sex, smoking status, social deprivation index, and index year. **Results:** Of 270,302 adults (mean age, 59.7 years; 7.8% female; 68.0% non-Hispanic White), 211,916 (78.4%) had MASLD, 46,545 (17.2%) had MetALD, and 11,841

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

(4.4%) had ALD at baseline. At the 2-year landmark, 17,281 (8.2%) of those with baseline MASLD were reclassified to MetALD or ALD, 15,922 (34.2%) of those with baseline MetALD were reclassified to MASLD or ALD, and 7,581 (64.0%) of those with baseline ALD were reclassified to MASLD or MetALD. Among patients with baseline MASLD, the risk of MALO was higher for those reclassified to MetALD (0.68 per 100 PY; HR 1.55, 95% CI 1.40-1.71) or ALD (0.95 per 100 PY; HR 2.13, 95% CI 1.66-2.74) compared with those who remained MASLD (0.43 per 100 PY). Among patients with baseline MetALD, the risk of MALO was lower for those reclassified to MASLD (0.47 per 100 PY; HR 0.55, 95% CI 0.48-0.64) and higher for those reclassified to ALD (1.64 per 100 PY; HR 1.80, 95% CI 1.58-2.06) compared with those who remained MetALD (0.88 per 100 PY). Among patients with baseline ALD, the risk of MALO was lower for those reclassified to MASLD (0.49 per 100 PY; HR 0.31, 95% CI 0.21-0.46) or MetALD (1.32 per 100 PY; HR 0.82, 95% CI 0.70-0.96) compared with those who remained ALD (1.63 per 100 PY). **Conclusion:** Changes in SLD subtype classification within 2 years are associated with distinct risks of MALO.

Table. Association of changes in steatotic liver disease subtype classification with major adverse liver outcomes

Baseline	2-Year Landmark	No. (%)	Events	Person-Years	IR per 100 PY (95% CI)	Hazard Ratio (95% CI)[a]
MASLD	MASLD	194,635 (91.8)	3,418	799,771	0.43 (0.41-0.44)	1 [Reference]
	MetALD	15,720 (7.4)	431	63,561	0.68 (0.62-0.75)	1.55 (1.40-1.71)
	ALD	1,561 (0.7)	62	6,515	0.95 (0.74-1.22)	2.13 (1.66-2.74)
MetALD	MetALD	30,623 (65.8)	1,125	127,571	0.88 (0.83-0.93)	1 [Reference]
	MASLD	11,688 (25.1)	229	48,907	0.47 (0.41-0.53)	0.55 (0.48-0.64)
	ALD	4,236 (9.1)	279	16,976	1.64 (1.46-1.85)	1.80 (1.58-2.06)
ALD	ALD	4,260 (36.0)	272	16,639	1.63 (1.45-1.84)	1 [Reference]
	MASLD	1,325 (11.2)	28	5,692	0.49 (0.34-0.71)	0.31 (0.21-0.46)
	MetALD	6,256 (52.8)	335	25,391	1.32 (1.19-1.47)	0.82 (0.70-0.96)

ALD, alcohol-associated liver disease; CI, confidence interval; IR, incidence rate; MASLD, metabolic dysfunction-associated steatotic liver disease; MetALD, metabolic dysfunction and alcohol-associated liver disease; No, number; PY, person-years.

Note: Percentages have been rounded and may not total 100.

[a] Major adverse liver outcome was defined as the first occurrence of cirrhosis, decompensation, hepatocellular carcinoma, liver transplant, and liver-related death. Hazard ratios were estimated using cause-specific Cox proportional hazards regression models, adjusted for age, sex, smoking status, social deprivation index, and index year.

◆ 2496 | ASSOCIATION OF END-STAGE LIVER DISEASE WITH STEATOTIC LIVER DISEASE AMONG PEOPLE WITH AND WITHOUT HIV INFECTION

Jessie Torgersen[1] Craig Newcomb[1] Janet Tate[2] Melissa Skanderson[2] Farah Kidwai-Khan[2] Dean Carbonari[1] Catherine Mezzacappa[2] Jennifer Price[3] Tamar Taddei[4] Joseph Lim[2] Debika Bhattacharya[5] Amy Justice[6] Vincent Lo Re, III[1], [1]University of Pennsylvania Perelman School of Medicine, [2]Yale University School of Medicine; VA Connecticut Healthcare System, [3]University of California, San Francisco School of Medicine, [4]Yale University, [5]David Geffen School of Medicine at UCLA; VA Greater Los Angeles Healthcare System, [6]Yale University School of Medicine; VA Connecticut Healthcare System; Yale School of Public Health

Background: Despite the high prevalence of steatotic liver disease (SLD), its association with end-stage liver disease (ESLD) remains unclear, particularly among people with HIV (PWH). HIV modifies the association between chronic viral hepatitis and ESLD; however, it is unknown if the association between SLD and ESLD differs by HIV status. **Methods:** We identified patients from the Veterans Aging Cohort-HIV (includes 1:2 matching to people without HIV [PWoH]) who underwent an abdominal ultrasound, CT, or MRI inclusive of the liver between 2001-2017. Patients with diagnosed cirrhosis or chronic viral hepatitis at baseline were excluded to more clearly identify effects associated with SLD. SLD was defined by a natural language processing (NLP) algorithm previously validated against manual clinician review of radiology reports. ESLD was defined as a composite outcome of hepatocellular carcinoma (defined by the VA Cancer Registry or ICD-9/-10) or hepatic decompensation (defined by validated ICD-9/-10 criteria). Follow-up began on the date of the imaging study and continued until first ESLD event, death, or December 31, 2021. Multivariable Cox regression was used to determine hazard ratios (HR, 95% confidence interval [CI]) of ESLD associated with SLD, by HIV status. **Results:** Among 19,545 patients with imaging inclusive of the liver (mean age: 55 years; 97.0% male; 28.7% PWH), 13,617 (69.7%) had an imaging report with SLD as determined by NLP. A total of 228 ESLD events were observed among PWH, and 513 events were observed in PWoH (incidence rates: 36.5 and 30.2/10,000 person-years, respectively; $p = 0.02$). In the overall multivariable model, there was a significant interaction between SLD and HIV on risk of ESLD (p for interaction < 0.001); thus, models were stratified by HIV status. Among PWH, SLD was associated with increased risk of ESLD (HR:1.66, 95% CI:1.19-2.33), independent of alcohol and metabolic comorbidities. Among PWoH, SLD was associated with an even greater risk of incident ESLD (HR:2.43, 95% CI:1.86-3.18) (Table 1). **Conclusion:** In PWH and PWoH, without known cirrhosis or chronic viral hepatitis, radiographic findings of SLD were associated with increased risk of ESLD independent of alcohol or metabolic comorbidities. Although PWH had higher incidence of ESLD compared with PWoH, the effect of SLD on risk of ESLD differs in the setting of HIV, suggesting HIV-specific factors may impact this risk. Future work is needed to understand how modifiable factors, such as HIV viremia or antiretroviral drugs, affect the association between SLD and ESLD in PWH.

◆ 2497 | REFINED INDICATORS FOR MASLD-INDUCED FIBROSIS DETECTION SAFELY REDUCE THE NEED FOR SCREENING BY MORE THAN 50% IN CLINICAL CARE PATHWAYS

Laurens van Kleef[1] Jesse Pustjens[1] Maja Thiele[2] Maurice Michel[3] Adriaan Holleboom[4] Manuel Castro Cabezas[5] Maarten Tushuizen[6] Harry Janssen[1] Jörn Schattenberg[7] Pere Ginés[8] Sven Francque[9] Zobair Younossi[10] Aleksander Krag[11] Willem Pieter Brouwer[1], [1]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Center, [2]Odense University Hospital, [3]Department of Internal Medicine II, University Medical Center Saarland, [4]Amsterdam UMC, [5]Sint Franciscus Gasthuis, [6]Department of Gastroenterology and Hepatology, Leids Universitair Medisch Centrum, [7]Department of Internal Medicine II, Saarland University Medical Center, [8]Liver Unit, Hospital Clinic of Barcelona, University of Barcelona, [9]Department of Gastroenterology and Hepatology, Antwerp University Hospital, [10]The Global NASH Council, Washington DC, [11]University of Southern Denmark

Background: Diabetes, obesity, and elevated ALT are commonly used indicators to screen for (advanced) liver fibrosis. However, current guidelines differ in their recommendations on who to screen. In light of the increasing prevalence of metabolic comorbidities, we sought to refine screening criteria using population-based data aiming to reduce the need for screening in the general population **Methods:** We analyzed participants without excessive alcohol consumption, aged 18-80 from NHANES 2017-2020, with data on indicators for screening and BMI ≥18.5 kg/m2. We estimated the weighted proportion of the population meeting screening criteria based on various international guidelines. Additionally, we assessed the prevalence of liver stiffness measurement (LSM) ≥8 kPa across the full spectrum of screening indicators through stratified analysis. All estimates were adjusted using NHANES-provided sampling weights. **Results:** We included 5,904 individuals (mean age 47 yr, 49% male) of whom 8.9% had LSM ≥ 8 kPa. Current screening guidelines identified 60–76% of the general population as target for screening, with a positive predictive value (PPV) of 11.1–13.5% for LSM ≥8 kPa. In contrast, among the 24–40% who did not meet any screening criteria, the prevalence of LSM ≥8 kPa was only 2.0–2.2%. Some subgroups were not at increased risk of LSM ≥8 kPa such as individuals with diabetes and normal ALT levels without obesity, or individuals with obesity class I and II without diabetes and normal ALT. Based on these findings, a refined screening strategy identified only 22% of the population as needing screening, while maintaining a high negative predictive value (NPV) of 96.3% and improving the PPV to 27.7% for LSM ≥ 8 kPa and an NPV of 98.9% with PPV of 10.0% for LSM ≥ 12 kPa. Similar results were obtained across age categories. **Conclusion:** Current guideline-based strategies classifies 60–76% of the U.S. population as eligible for liver fibrosis screening. Our findings suggest that refining these criteria could safely reduce the target

screening population by more than half to 22%, as certain metabolic risk subgroups, particularly in the absence of diabetes or class III obesity, do not exhibit substantially increased risk for (advanced) liver fibrosis.

◆ 2498 | MACHINE LEARNING MODELS ACCURATELY PREDICT CHANGES IN FIB-4 CATEGORY FOR PATIENTS WITH DIABETES MANAGED IN PRIMARY CARE – AN ANALYSIS OF 59,872 CASES

Chloe Yitian Guo[1] Christen Ong[1] Daniel Lim[2] Yiying Pei[2] Bochao Jiang[2] Chanda Ho[2] Kevin Kim Jun Teh[3] Yong Mong Bee[4] Hairil Rizal[5] Chee-Kiat Tan[2] George Boon-Bee Goh[2], [1]Yong Loo Lin School of Medicine, National University of Singapore, [2]Dept of Gastroenterology and Hepatology, Singapore General Hospital, [3]SingHealth, [4]Dept of Endocrinology, Singapore General Hospital, [5]Dept of Anaesthesiology, Singapore General Hospital

Background: The Fibrosis-4 (FIB-4) score is a non-invasive test that assesses the risk of liver fibrosis in patients with metabolic-associated steatotic liver disease (MASLD). Based on age-dependent FIB-4 score cut-offs, there are 3 risk categories for fibrosis: low, indeterminate and high. Patients in primary care are recommended for specialist referral when the FIB-4 is indeterminate or high. However, it is known that medications such as SGLT2 inhibitors (SGLT2is) and GLP-1 receptor agonists (GLP1RAs) may cause regression of liver fibrosis in MASLD. We sought to develop a risk model using demographic, laboratory and medication factors to predict risk of FIB-4 progression or regression, in patients with diabetes managed in primary care. **Methods:** Data from 59,872 patients in the SingHealth Diabetes Registry (SDR) was analyzed. Median age is 68 (IQR = 59, 77) with 54% male. Multivariable logistic regression was used to assess the effect size of the following predictor variables: gender, ethnicity, smoking status, current FIB-4 score, body mass index, lab values (HBA1C, selected liver and lipid panel results) and medications (oral glucose lowering drugs, insulins, antihypertensives, antiplatelets, lipid-lowering drugs). Four different machine learning (ML) models (logistic regression (LR), random forest (RF), gradient boosting (GB) and multilayer perceptron (MLP)) were used to predict whether the FIB-4 category is low (negative class) or not low (i.e. indeterminate or high, positive class) after 1 year, using the predictor variables. **Results:** Multivariable logistic regression showed that some antihypertensives and diabetes medications are independently associated with a low FIB-4 category after 1 year, such as angiotensin receptor blockers (ARBs) (OR = 0.949, CI = 0.905, 0.996, p = 0.033) and metformin (OR = 0.824, CI = 0.79, 0.86, $p < 0.001$). SGLT2is and GLP1RAs are not statistically significantly associated with low FIB-4 category. All 4 ML models could predict the 1-year FIB-4 category with high area under the receiving operator curve (AUROC) scores. GB performed best (AUROC = 84.2% ± 0.3%) followed by LR (AUROC = 82.4% ± 0.3%), MLP (AUROC = 82.0% ± 0.5%), and RF (AUROC = 80.8% ± 0.4%). **Conclusion:** Antihypertensives and diabetes medications are beneficial in improving FIB-4 category to low after 1 year. ML models are also able to accurately predict the FIB-4 category after 1 year. Optimisation of medications rather than upfront specialist referral may be a viable strategy for patients with indeterminate or high FIB-4.

◆ 2499 | SEMAGLUTIDE DISCONTINUATION AMONG PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Samantha Clark[1] Dominic Nunag[1] Matthew Davis[1] Arushi Chadha[1] Nipun Atreja[2] Blake Thomas[2] Francis Lobo[2], [1]Medicus Economics, LLC, [2]Madrigal Pharmaceuticals, Inc.

Background: MASLD and its more progressive subtype, MASH, are chronic liver conditions, with progression to the latter underdiagnosed in clinical practice. Subcutaneous (SC) semaglutide is currently being investigated for use in MASH in the ongoing ESSENCE clinical trial (NCT0482218). Interim trial results indicate that over 89% of participants remained persistent at 72-weeks of follow-up. In this study, we aim to assess alignment between real-world medication compliance and that observed in the ESSENCE trial among MASLD patients starting SC semaglutide for an approved indication. **Methods:** A retrospective cohort study including MASLD patients initiating SC semaglutide (both Ozempic® and Wegovy®) from 2017-2024 was conducted in Optum Market Clarity data. The 12-month period prior to the first SC semaglutide prescription claim (index date) was used for sample selection and covariate measurement. Patients with other liver diseases (e.g., viral hepatitis) or severe complications from MASH (e.g., cirrhosis) were excluded. Discontinuation was defined as a gap in medication coverage of $\geq$45 days. Patients were followed from their index date until death, dropout, or end of data availability. Kaplan-Meier (KM) curves illustrating persistence probability and time-to-discontinuation were constructed for the overall sample. **Results:** Of the 36,531 adults included in the final sample, 69.5% (n = 25,371) presented with type 2 diabetes. Mean (standard deviation) age was 52.6 (12.0) years old and 63.0% (n = 23,021) were female. Overall, 64.3% (n = 23,473) of patients discontinued SC semaglutide, with 56.3% (n = 20,566) doing so within a year and 60.1% (n = 21,966) doing so within 72 weeks. Mean time-to-discontinuation was 24.7 weeks (28.6) weeks and mean follow-up time was 77.9 weeks (57.6). Accounting for censoring, 64% of patients (95% confidence interval (CI): 63%-64%) discontinued by 1 year and 72% (95% CI: 71%-72%) discontinued by 72 weeks. **Conclusion:** The majority of MASLD patients discontinued SC semaglutide, with 72% doing so within 72 weeks of initiation. Results are consistent with findings from similar observational studies and highlight the importance of monitoring SC semaglutide use patterns in a real-world setting, especially with respect to the resultant impact on liver outcomes as well as BMI and glycemic goals.

◆ 2500 | IMPACT OF PROTEIN AND ENERGY INTAKE AND PHYSICAL ACTIVITY ON SARCOPENIA IN CHRONIC LIVER DISEASE: A POPULATION-BASED STUDY

Ying Liu[1] Qiuju Ran[1] Shuyue Tuo[1] Zhang Wen[1] Jinhai Wang[1] Shejiao Dai[1] Lu Li[1] Xinxing Tantai[2], [1]The Second Affiliated Hospital of Xi'an Jiaotong University, [2]The Second Affiliated Hospital of Xi'an Jiaotong University

Background: The impact of protein and energy intake and physical activity on sarcopenia among patients with chronic liver disease (CLD) has not been determined. Additionally, the recommended amounts of protein, energy, and physical activity to effectively reduce the risk of sarcopenia in patients with CLD is unknown. A protein intake of ≥ 1.2 g/kg/day, an energy intake of ≥35 kcal/kg/day, and engagement in moderate-intensity physical activities (MPA) for≥150 minutes per week are recommended as goals for managing sarcopenia in patients with cirrhosis. Whether these goals are equally applicable to patients with less advanced CLD remains to be validated. **Methods:** This study selected data from the National Health and Nutrition Examination Survey (1999-2020). Weighted multivariate logistic regression models were used to estimate the associations between sarcopenia and quantitative measures of daily protein and energy intake, weekly moderate-intensity physical activity (MPA) time, their respective qualitative goals, and various combinations of these goals. **Results:** A total of 8298 participants with CLD were included. The highest tertile of daily protein intake [odds ratio (OR) = 0.71, 95% confidence interval (CI): 0.54-0.92), daily energy intake (OR = 0.63, 95%CI: 0.47-0.87), and weekly MPA time (OR = 0.77, 95%CI: 0.62-0.96) was significantly associated with a lower risk of sarcopenia compared with the lowest tertile group. Restricted cubic spline analyses and trend tests indicated that these associations were linear. Maintaining a daily protein intake of ≥ 1.2 g/kg, a daily energy intake of ≥ 35 kcal/kg, and a weekly MPA time totaling ≥ 150 min was associated with a 38%, 35%, and 21% reduction in the risk of sarcopenia, respectively (Figure 1A). The majority of subgroup analyses (Figure 1A) and various sensitivity analyses demonstrated consistent results. Four combinations of meeting the goals for protein intake, energy intake, and MPA were analyzed: (1) None of the goals were met; (2) One of the three goals was met; (3) Two of the three goals were met; (4) All goals were met. The risk of sarcopenia decreased progressively as the number of achieved goals increased (Figure 1B). Meeting all three goals was associated with the lowest risk of sarcopenia in individuals with CLD (Figure 1B). **Conclusion:** Increased daily protein and energy intake as well as higher weekly MPA levels were significantly associated with a reduced risk of sarcopenia among individuals with CLD. The established goals for these three measures were applicable, and achieving more of these goals was associated with a lower risk of sarcopenia.

2501 | NATURAL HISTORY OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS (MASH) IN HISPANIC PATIENTS: A REAL-WORLD COHORT STUDY STRATIFIED BY FIBROSIS SEVERITY

Robert Matson[1] Subash C[1] Steven Perrault[1] Jason Maron[1] Xiao Zhang[2] Gail Fernandes[2] Samuel Engel[2] Matthew Melaragno[2] Yuzhi Xi[2] Precious Ejelonu[2], [1]nference, Inc., Cambridge, MA, USA, [2]Merck & Co., Inc., Rahway, NJ, USA

Background: The Hispanic population is disproportionately affected by metabolic dysfunction-associated steatohepatitis (MASH), yet few disaggregated studies describe the clinical characteristics and progression to outcomes in Hispanic patients stratified by fibrosis severity at MASH diagnosis. **Methods:** A retrospective cohort study was conducted in Hispanic adults diagnosed with MASH between 1/1/2006–12/31/2023, using electronic health record (EHR) data from Mayo Clinic sites and affiliated healthcare systems in Minnesota, Arizona, Florida, Wisconsin, and Iowa. Fibrosis stage and risk of advanced fibrosis defined by fibrosis-4 (FIB-4) were used to describe fibrosis severity. Fibrosis stage (F0–F4) was assessed using diagnostic codes and liver biopsy results when available, or estimated from non-invasive tests based on published criteria from analogous liver diseases. FIB-4 of 2.67 was used to differentiate low/intermediate risk (≤ 2.67) and high-risk (> 2.67) of advanced fibrosis. Patient characteristics were assessed by fibrosis stage and FIB-4. Kaplan-Meier (K-M) analysis was performed to evaluate time to compensated cirrhosis, decompensation, and hepatocellular carcinoma (HCC) by fibrosis stage and FIB-4. **Results:** Among 892 Hispanic patients with MASH and fibrosis stage data (mean age 50.1 years, 56.3% female, median BMI 32.0 kg/m²), 59.8% had F0–F1, 9.0% had F2, 8.9% had F3, and 22.3% had F4; among 759 Hispanic patients with MASH and FIB-4 data, 79.8% had low/intermediate-risk and 20.2% had high-risk FIB-4. Increasing fibrosis stage was correlated with older age, higher AST, and lower platelet count. F4 and high-risk FIB-4 groups had higher prevalence of type 2 diabetes and chronic kidney disease than F0-F3 and low/intermediate-risk FIB-4, respectively. K-M estimates showed that patients with more advanced fibrosis stages and higher risk of advanced fibrosis had worse prognosis. Median time to compensated cirrhosis was 13.1, 9.1, and 7.8 years for F0–F1, F2, and F3, respectively; and 11.3 vs 8.0 years for low/intermediate- vs high-risk FIB-4. Compensated F4 and high-risk FIB-4 groups had significantly higher rates of decompensation and HCC compared to F0–F3 and low/intermediate-risk FIB-4, respectively. **Conclusion:** Hispanic MASH patients with more advanced fibrosis stages and higher risk of advanced fibrosis at diagnosis had more comorbidities and faster progression to liver-related endpoints. These findings underscore the need for early risk stratification and targeted interventions.

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Serum-based non-invasive tests (NITs) form the cornerstone for referral strategies aimed to detect liver disease in the general population. However, the associations between changes in NITs and progression of liver stiffness measurement (LSM) by vibration-controlled transient elastography (VCTE) remain unclear. **Methods:** In this multicenter cohort study, embedded within the European LiverScreen project, longitudinal data from three population-based cohorts (Barcelona, Rotterdam and Odense) were analyzed. Participants underwent baseline and follow-up screening by VCTE over an approximate four-year interval, alongside anthropometric and laboratory assessments. In participants with baseline LSM <8 kPa, incident fibrosis was defined as a $\geq 30\%$ increase crossing the 8 kPa threshold. In those with baseline LSM ≥ 8 kPa, fibrosis regression was defined as a $\geq 30\%$ reduction and falling below 8 kPa, while persistent fibrosis was defined as an LSM that remained ≥ 8 kPa. NIT-specific cut-offs were: APRI ≥ 0.5, FIB-4 ≥ 1.3, FORNS ≥ 4.2, LiverRisk Score (LRS) ≥ 6, and MAF-5 ≥ 1.0. **Results:** Among 7,884 participants with reliable baseline VCTE, 4,536 had a valid follow-up VCTE after a median of 4.3 years [IQR: 4.1–8.2]. The follow-up cohort had a median age of 62 years [56–68], and 52% were female. At baseline, 5.5% (251/4,536) had an LSM ≥ 8 kPa, of which 56% (141/251) had persistent fibrosis after follow-up. Of those with baseline LSM <8 kPa (4,285/4,536), 2.6% (112/4,285) developed incident fibrosis. The best performing scores predicting persistent fibrosis were the baseline MAF-5 (AUC: 0.875), and LRS (0.852), followed by FORNS (0.792), APRI (0.785) and FIB-4 (0.700). A baseline NIT score below the risk cut-off was associated with an increased likelihood of LSM regression compared to those with a concurrent high NIT and high LSM: LRS (OR 4.45, 95%CI 1.41–4.25), MAF-5 (OR 2.29, 95%CI 1.34–3.92), FIB-4 (OR 2.34, 95%CI 1.38–3.98), APRI (OR 2.24, 95% CI 1.18–4.27), except for the FORNS (OR 1.75, 95%CI 0.92–3.37). Among those with LSM <8 kPa at baseline, the proportion who changed from a low to a high NIT risk category was: MAF-5: 6.8%, LRS: 12%, FORNS: 21%, APRI: 2.9%, and FIB-4: 16%. For all tests, this was significantly associated with incident fibrosis: LRS (OR 5.12, 95%CI 3.02–8.69), MAF-5 (OR 4.83, 95%CI 2.46–8.80), FIB-4 (OR 1.95, 95% CI 1.05–3.63), APRI (OR 7.78, 95%CI 4.37–13.8) and FORNS (OR 1.27, 95%CI 1.50–6.95). **Conclusion:** Baseline MAF-5 and LRS best predicted persistent LSM elevation, potentially distinguishing true at-risk fibrosis from false positive LSM elevations. Transitions from low to high NIT risk-category identified individuals at-risk of incident fibrosis, while a low baseline NIT was associated with LSM normalization over time.

2503 | REAL-WORLD USE OF PETH IN A MASLD CLINIC

Timothy Daugherty[1] Erik Roepke[1] Dalton Caviness[1] Fernando Bril[1] Meagan Gray[1], [1]The University of Alabama at Birmingham

Background: In 2023, the term MetALD (metabolic dysfunction- and alcohol-associated liver disease) was introduced to identify patients with dual disease etiology. The diagnosis of these patients remains imprecise due to multiple factors, an important one being the reliance on self-reported alcohol consumption. Phosphatidylethanol (PEth) is a highly sensitive and specific serum biomarker to detect moderate to heavy alcohol consumption at levels 25 ng/mL. Therefore, we aimed to characterize alcohol consumption using PEth testing among patients referred to a MASLD clinic, and compare results with patient-reported alcohol intake. **Methods:** We retrospectively collected data on consecutive patients evaluated at the University of Alabama at Birmingham's MASLD clinic between February 2022 and January 2024. PEth testing was performed as part of standard clinical care on new and return patients. Patients were excluded if PEth testing was not performed or if decompensated cirrhosis was present. **Results:** We retrospectively collected data on consecutive patients evaluated at the University of Alabama at Birmingham's MASLD clinic between February 2022 and January 2024. PEth testing was performed as part of standard clinical care on new and return patients. Patients were excluded if PEth testing was not performed or if decompensated cirrhosis was present. **Conclusion:** A substantial proportion (10.9%) of patients referred to a tertiary MASLD clinic had evidence of significant alcohol use based on PEth testing, despite being presumed to have non-alcohol-associated liver disease. This suggests that alcohol use is frequently underestimated when relying solely on patient self-report. Objective alcohol biomarkers such as PEth may enhance diagnostic accuracy and facilitate more appropriate classification of liver disease, including the identification of patients who may meet criteria for MetALD.

Table 1. Clinical characteristics of patients with PETh-defined MetALD versus MASLD

	MASLD (n = 367)	MetALD (n = 45)	p-value
Age (years)	53±1	55±2	0.25
Male (%)	34	64	<0.001
Race			0.23
Non-Hispanic White (%)	78%	76%	
Non-Hispanic Black (%)	12%	20%	
Other	10%	4%	
Presence of diabetes (%)	42%	33%	0.28
BMI (kg/m^2)	34.7±0.3	32.5±1.1	0.035
HbA1C (%)	6.3±0.1	5.9±0.1	0.087
AST (U/L)	35±1	50±6	<0.001
ALT (U/L)	47±2	56±6	0.103
GGT (U/L)	57±4	188±44	<0.001
Triglycerides (mg/dL)	170±6	220±47	0.035

2504 | NATIONWIDE ASSESSMENT OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) PREVALENCE IN SAUDI ARABIA: INSIGHTS FROM THE GENESIS POPULATION-BASED COHORT STUDY

Saleh Alqahtani[1] Faisal Sanai[2] Haifa Alotaibi[3] Shadan AlMuhaidib[1] Duna Barakeh[1] Faisal Abaalkhail[1] Saleh Alessy[1] Waleed Alomaim[1] Samar Alqussayer[3] Ahmad Alshehri[4] Abdulraheem Bayameen[5] Basmah Khoja[1] Tagreed Mazi[6] Hani Tamim[7] Habeeb Razack[6] Mohammed Alghamdi[4] Mariam Seria[4] Fahad Alharbi[8] Saad Alghamdi[1] Bandar Aljudaibi[1] Waleed Al-Hamoudi[1] Waleed Alhazzani[3], [1]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [2]King Abdulaziz Medical City, KAIMRC, Jeddah, Saudi Arabia, [3]Ministry of Defense Health Services, Riyadh, Saudi Arabia, [4]King Fahad Military Medical Complex, Dhahran, Saudi Arabia, [5]King Fahad Armed Forces Hospital, Jeddah, Saudi Arabia, [6]King Saud University, Riyadh, Saudi Arabia, [7]Alfaisal University, Riyadh, Saudi Arabia, [8]Prince Sultan Military Medical City, Riyadh, Saudi Arabia

Background: MASLD is a common global cause of chronic liver disease. It is closely associated with obesity and type 2 diabetes (T2D), both of which are

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

rising rapidly in Saudi Arabia; yet national MASLD data remain limited. To address this gap, we aimed to estimate MASLD prevalence among Saudi adults in the first large-scale, population-based study using clinical, biochemical, and imaging data. **Methods:** GENESIS is a prospective, population-based cohort study assessing MASLD prevalence and severity. Adults with no history of liver disease, except for MASLD, were recruited between March 2024 and April 2025 from primary healthcare centers in three populous regions. Clinical assessments, blood tests, and liver elastography (FibroScan®) were performed. MASLD was defined as a controlled attenuation parameter (CAP) $\geq$268 dB/m and $\geq$1 cardiometabolic risk factor (CMRF) (e.g., BMI $\geq$25 kg/m², elevated HbA1c, hypertension, or dyslipidemia). Alternative definitions (CAP $\geq$220 dB/m; MASLD liver fat score [MASLD-LFS]) were used in sensitivity analyses. Significant fibrosis (F2–F4) was defined as liver stiffness $>$7.0 kPa. **Results:** Of the 2,073 participants, MASLD was found in 829 (40.0%; female: 32.9%, male: 48.2%), with prevalence increasing with age and consistently higher in males than females (Figure 1). Hepatic steatosis was present in 70.2%, with 22.5% showing severe steatosis (CAP $\geq$300 dB/m). Prevalence using CAP $\geq$220 dB/m and MASLD-LFS was 68.1% and 62.2%, respectively. Significant fibrosis was observed in 3.1%. The proportion of males was higher among those with MASLD (55.9% vs. 40.0%, $p<0.001$); they were older (48.0 vs. 41.6 years, $p<0.001$), and fewer had higher education (39.9% vs. 54.3%, $p<0.001$). No significant differences were seen in smoking or coffee intake. Participants with MASLD had higher BMI (31.6 vs. 27.3 kg/m²), waist-to-hip ratio (0.91 vs. 0.87), and more comorbidities (T2D: 37.8% vs. 16.2%; hypertension: 26.5% vs. 12.5%; dyslipidemia: 39.1% vs. 24.0%) (all $p<0.001$). Despite similar liver enzyme levels, participants with MASLD had higher insulin (14.2 vs. 8.8 μU/mL) and CRP (3.2 vs. 2.2 mg/L), and lower HDL cholesterol (1.2 vs. 1.4 mmol/L) (all $p<0.001$). **Conclusion:** Screening a segment of the general Saudi adult population revealed that MASLD was present in 4 out of 10 participants, with steatosis in 70%. Participants with MASLD were more often male, older, and more likely to have CMRFs. These concerning trends, highlighted by this first-of-its-kind national study, support the need for targeted public health strategies in Saudi Arabia.

Figure 1. MASLD prevalence by age group and gender in Saudi Arabia (N = 2,073).

2505 | CORRECTED T1 VALUE IN LIVER MRI IS ASSOCIATED WITH ALL-CAUSE, CARDIOVASCULAR-RELATED MORTALITY AND LIVER-RELATED OUTCOME WITH LOWER CUT-OFF VALUE OF 700MS

Ju Dong Yang[1] Min-Sun Kwak[2] Shelly Lu[1] Abdelrahman Attia[1] Hyunseok Kim[3] Mohammad Saeid Rezaee-Zavareh[4] Yufeng Wang[1] Lixia Wang[1] Walid Ayoub[1] Alexander Kuo[1] Hirsh Trivedi[1] Aarshi Vipani[1] Yun Wang[1] Martin Paul[1] Stephen Pandol[1] Debiao Li[1], [1]Cedars-Sinai Medical Center, [2]Seoul National University Hospital, [3]Cedars Sinai Medical Center, [4]Middle East Liver Diseases (MELD) center, Tehran, Iran

Background: Liver MRI-based corrected T1 (cT1) is an emerging non-invasive biomarker of hepatic fibro-inflammation. A threshold of 800ms has been associated with at-risk metabolic dysfunction-associated steatohepatitis and adverse outcomes; however, only ~5% of individuals exceed this level, limiting broader applicability. The prognostic significance of lower cT1 values is unclear. This study aimed to investigate the relationship between cT1 values and all-cause, cause-specific mortality, and liver-related outcomes in UK biobank cohort. **Methods:** Participants with MRI-derived cT1 were included. Cut-off values for outcome associations were determined based on P-spline curve taking into consideration on Harrell's C index. Participants were stratified by cT1 $<$700 vs. $\geq$700ms and $<$800 vs. $\geq$800ms. Outcomes included all-cause, cardiovascular, and cancer mortality, and liver-related events (cirrhosis, liver transplant, hepatocellular carcinoma, or liver-related death). Cox proportional hazard models were adjusted for age, sex, cardiometabolic risk factors, smoking, and alcohol. **Results:** Among 33,988 participants, 45% had cT1 $\geq$700ms. Over a median

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

follow-up of 5.3 years, those with cT1 ≥700ms had increased risks of all-cause mortality (adjusted hazard ratio [95% CI], 1.25 [1.08–1.45]), cardiovascular mortality (1.52 [1.08–2.13]), and liver-related events (2.28 [1.25–4.13]) vs. <700ms. Effect modification for all-cause mortality was noted by alcohol and smoking; increased mortality risk was confined to non-drinkers (1.97 [1.31-2.96] vs. 1.16 (0.99-1.36) in drinkers, *P* for interaction <0.01) or ever-smokers (1.42 [1.14-1.76] vs. 1.11 (0.90-1.36) in never-smokers, *P* for interaction < 0.05). cT1 ≥800ms was associated with higher all-cause mortality (1.40 [1.08–1.81]) and liver-related events (3.01 [1.56–5.83]) <800ms. Again, risk was elevated in non-drinkers (2.30 [1.49–3.55] vs. 1.12 [0.81–1.55] in drinkers; P for interaction <0.01). For cardiovascular mortality, significant association was observed only in females (4.99 [2.07–12.01] vs. 1.03 [0.53–1.99] in males; *P* for interaction = 0.01). **Conclusion:** Elevated liver cT1 values, even below the conventional high-risk threshold of 800ms, were independently associated with increased risks of mortality and liver-related outcomes. These associations were influenced by modifiable lifestyle factors. Broader application of cT1 thresholds may improve risk stratification and early identification of high-risk individuals.

Figure 1. P-spline curve for all-cause mortality and multivariate analysis for all-cause mortality, cause-specific mortality and liver-related outcomes in participants, according to different cT1 cut-off values, after adjusting for age, sex, cardiometabolic risk factors, smoking and alcohol.

	cT1≥700ms vs. cT1 <700ms	cT1≥800ms vs. cT1 <800ms
	Hazard ratio (95% CI)	Hazard ratio (95% CI)
All-cause mortality	**1.25 (1.08-1.45)**	**1.40 (1.08-1.81)**
Cardiovascular mortality	**1.52 (1.08-2.13)**	1.55 (0.93-2.61)
Cancer mortality	1.22 (1.00-1.48)	1.33 (0.92-1.91)
Liver-related outcome*	**2.28 (1.25-4.13)**	**3.01 (1.56-5.83)**

2506 | FREQUENCY AND SIGNIFICANCE OF VARIANTS IN LYSOSOMAL ACID LIPASE (LAL) GENE IN A LARGE COHORT OF INDIVIDUALS WITH METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Chaowapong Jarasvarapam Marco Antonio Abreu[1] Tae-Hwi Schwantes-An[1] David Kleiner[2] Miriam Vos[3] Katherine Yates[4] Callie Zabarenko[1] Jingyi Tan[5] Xiuqing Guo[5] Jerome I Rotter[5] Jean Molleston[6] Naga Chalasani[7], [1]Medical & Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, [2]National Cancer Institute, Bethesda, [3]Emory University, Children's Healthcare of Atlanta, [4]Department of Epidemiology, Johns Hopkins University, Baltimore, MD, [5]Department of Pediatrics, The Institute for Translational Genomics and Population Sciences, The Lund, [6]Division of Pediatric Gastroenterology, Hepatology and Nutrition, Indiana University School of Medic, [7]Indiana University Medical Center

Background: Lysosomal acid lipase deficiency (LAL-D) is as a rare autosomal recessive disorder caused by mutations in the *LAL* gene. LAL-D is a rare cause of steatotic liver disease but the frequency of LAL-D as a cause for MASLD or its severity is not well understood. We examined the prevalence of *LAL* genetic variants in a large cohort of patients with well-characterized MASLD and their relationship to histological severity. **Methods:** Children and adults with biopsy-proven MASLD enrolled into Non-Alcoholic Steatohepatitis Research Network studies were analyzed. Advanced fibrosis defined as fibrosis stage ≥ 3 and metabolic dysfunction-associated steatohepatitis (MASH) defined as NAFLD Activity Score ≥ 4. From the published literature, we curated a list of rare pathogenic or likely pathogenic variants in *LAL* gene, and subsequently searched for their presence in the whole exome sequencing (WES) and GWAS data of the NASH CRN cohort. WES and GWAS were performed by the Regeneron Genetics Center. Individuals carrying one or more of the *LAL* variants were defined as *LAL* carriers. For each *LAL* carrier, we identified ≥ 1control without *LAL* variants matched for age, sex, and 3-SNP candidate gene score (CGS). CGS was calculated by adding the number of risk alleles in *PNPLA3* (rs738409), *HSD17B13* ((rs72613567), and *TM6SF2* (rs58542926). **Results:** Our study cohort (N = 3,358) consisted of 2,553

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

non-Hispanic White and 961 Hispanic indviduals. The following seven *LAL* variants were present in the study cohort: rs143793106, rs201242614, rs756396844, rs116928232, rs147426329, rs746967258, and rs377251678. At least 1of the *LAL* variants was present in 22 individuals (22 carriers, 0.65%). 18 were adults and 4 children. The prevalence of MASH and advanced fibrosis in *LAL* carriers was 64% and 23%, respectively. There were no significant differences in anthropometry, co-morbidities, liver biochemistries, or lipid profile between 2 groups (Table). Grades of steatosis, portal and lobular inflammation, and ballooning, fibrosis stage, and proportion of advanced fibrosis and MASH were comparable between 2 groups (Table). No carriers showed histological changes of LAL deficiency. **Conclusion:** The frequency of pathogenic or likely pathogenic *LAL* variants in MASLD is less than 1% and they were present in both children and adults. Presence of LAL variants was not associated with biochemical or histological severity in MASLD. LAL carriers showed no evidence of LAL deficiency on histology.

Table: Baselines charactertistic between children and adults with MASLD without and with *LAL* genetic variant carriage

Variable	*LAL* Carriers (N=22)	Matched controls (N=82)	Non-*LAL* carriers (N=3,336)	P value for *LAL* carries vs. matched controls
Age at enrollment, mean (SD)	43.9 (17.4)	44.2 (17.7)	39.9(19.8)	0.93
Male (%)	46%	48%	48%	1.0

2507 | METABOLIC DYSFUNCTION IS ASSOCIATED WITH THE DEVELOPMENT OF HEPATOCELLULAR CARCINOMA, HEPATIC DECOMPENSATION, AND REDUCED SURVIVAL, INDEPENDENT OF LIVER DISEASE ETIOLOGY

Ming-Lun Yeh[1] Chung-Feng Huang[2] Jee-Fu Huang[2] Chia-Yen Dai[2] Wan Long Chuang[2] Ming-Lung Yu[3], [1]National Sun Yat-sen University, [2]Kaohsiung Medical University, [3]Kaohsiung Medical University/ Kaohsiung Medical University Hospital

Background: The importance of cardiometabolic risk factors (CMRFs) in influencing disease severity and long-term outcomes has been well established in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). However, the impact of CMRFs in patients with other etiologies of liver disease remains underexplored. This study aimed to investigate the influence of CMRFs on patients across different liver disease etiologies. **Methods:** We analyzed data from a nationwide cohort in Taiwan. Subjects with available assessments for liver fibrosis and CMRFs were included. SLD was diagnosed via abdominal ultrasound or blood-based indices, including the Hepatic Steatosis Index and Fatty Liver Index. Alcohol consumption was categorized as moderate or heavy according to the diagnostic criteria for alcoholic liver disease (ALD) and MetALD. We linked participants data with the national health insurance database, and cancer/death registry database of Taiwan for long-term outcomes. The primary outcome was the associations between metabolic dysfunction and long-term risks of hepatocellular carcinoma (HCC), hepatic decompensation, and survival. **Results:** A total of 612,051 subjects (mean age 39.9 years; 47.7% male) were included in the analysis. Among them, 13.3%, 1.8%, 3.1%, and 2.0% had hepatitis B virus (HBV) infection, hepatitis C virus (HCV) infection, moderate alcohol consumption, and heavy alcohol consumption, respectively. SLD was diagnosed in 33.1% of subjects, while advanced liver fibrosis (FIB-4 > 2.67) was present in 1.3%. At least one CMRF was identified in 442,917 subjects (72.4%), with overweight/obesity being the most prevalent (47.5%), followed by pre-diabetes/diabetes (32.9%).

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Subjects with CMRFs had significantly higher long-term risks of HCC, hepatic decompensation, and all-cause, acute myocardial infarction (AMI), and stroke-related mortality. After adjusting for factors including SLD and liver disease etiologies, the presence of CMRFs remained significantly associated with these outcomes. In stratified analyses of subjects with HBV, HCV, moderate, and heavy alcohol consumption, CMRFs were significantly associated with increased risks of HCC, all-cause mortality, AMI, and stroke-related mortality. Notably, the association between CMRFs and hepatic decompensation was observed only in HBV-infected subjects. Furthermore, the long-term risks of HCC, hepatic decompensation, all-cause mortality, AMI, and stroke-related mortality increased progressively with the number of CMRFs present. **Conclusion:** The presence and cumulative number of CMRFs were associated with poorer long-term outcomes, regardless of liver disease etiology.

2508 | DIFFERENT CARDIOVASCULAR RISK IDENTIFIED BY THE KASL/EASL TWO-STEP PATHWAY ACCORDING TO DIABETES STATUS IN INDIVIDUALS WITH MASLD

Jaehong Jeong[1] Jung Pyo Hong[1] Jae Seung Lee[1] Mi Na Kim[1] Beom Kyung Kim[1] Do Young Kim[1] Sang Hoon Ahn[1] Hye Won Lee[1] Seung Up Kim[1], [1]Yonsei University College of Medicine

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is an increasingly common risk factor for atherosclerotic cardiovascular disease (ASCVD). The Korean and European Associations for the Study of the Liver (KASL and EASL) include a two-step, non-invasive pathway in their guidelines for assessing advanced liver fibrosis in MASLD, based on the Fibrosis-4 index (FIB-4) and vibration-controlled transient elastography (VCTE). Given the overlap in risk factors between MASLD and ASCVD, we evaluated whether this pathway can also stratify ASCVD risk in MASLD, and whether stratification patterns differ according to diabetes mellitus (DM) status. **Methods:** Among 12,738 health check-up participants from 2012 to 2020, 6,519 individuals with MASLD were retrospectively analyzed. Participants were stratified into four risk groups (low, intermediate-low, intermediate-high, and high) based on the KASL/EASL pathway. Due to relatively small sample sizes in the intermediate-high-risk group and high-risk group (n = 35 and 114, respectively), these were combined into a single intermediate-high– and high-risk group to ensure statistical robustness. ASCVD risk was assessed using the 2025 ACC/AHA Pooled Cohort Equations. Group comparisons were performed using two-way ANOVA. **Results:** Among individuals with MASLD, the proportion of low-risk subjects was significantly higher in the non-DM group (n = 4,366 [74.1%] in low-risk; n = 1,419 [24.1%] in intermediate-low-risk; n = 107 [1.8%] in intermediate-high– and high-risk), whereas that of high-risk subjects was significantly higher in the DM group (n = 392 [62.5%] in low-risk; n = 193 [30.8%] in intermediate-low-risk; n = 42 [6.7%] in intermediate-high– and high-risk) ($P < 0.001$). ASCVD risk was consistently higher in diabetic than in non-diabetic individuals across all liver fibrosis risk groups (mean 14.5 vs. 4.3 in low-risk groups, mean 15.0 vs. 6.8 in intermediate-low-risk groups, mean 20.3 vs. 14.7 in intermediate-high– and high-risk groups), with a statistically significant interaction between liver fibrosis risk and diabetes status ($P < 0.001$). The proportion of individuals with high-risk ASCVD (≥ 20%) increased with fibrosis risk among non-diabetic individuals (2.9%, 4.7%, and 28.0%). In diabetic individuals, the highest proportion was observed in the intermediate-high– and high-risk group (38.1%), although the trend across lower-risk groups was non-linear. **Conclusion:** The KASL/EASL liver fibrosis risk stratification pathway correlates with ASCVD risk in individuals with MASLD, particularly among those without diabetes. However, in diabetic patients, ASCVD risk remained elevated regardless of fibrosis risk category, suggesting that additional risk assessment tools may be necessary for more accurate cardiovascular risk stratification in this population.

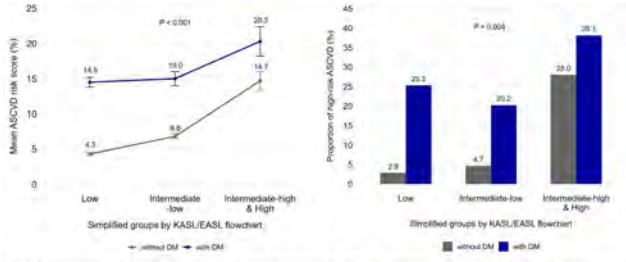

Figure 1. Comparison of ASCVD risk scores by diabetes status and KASL/EASL flowchart-based liver fibrosis risk groups. (A) Mean ASCVD risk scores. (B) Proportion of high-risk ASCVD (≥ 20%). ASCVD, atherosclerotic cardiovascular disease; DM, diabetes mellitus; KASL, the Korean Association for the study of the Liver; EASL, the European Association for the Study of the Liver.

2509 | HEPATIC FIBROSIS IS ASSOCIATED WITH DIASTOLIC DYSFUNCTION IN THE ABSENCE OF OVERT HEART FAILURE IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Rabab Ali[1] Alejandra Paredes-Marin[1] Vikram Sivakumar[1] Kim Le[1] Parth Trivedi[1] Maryfe Coronel Novoa[1] Julia Napoli[1] Asher Leviton[1] Xiaotao Zhang[1] Anuradha Lala[1] Meena Bansal[1], [1]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: The independent association of metabolic dysfunction-associated steatotic liver disease (MASLD) and heart failure with preserved ejection fraction (HFpEF) due to perturbed metabolic pathophysiology is often underrecognized. A hallmark finding in HFpEF is left ventricular diastolic dysfunction (LVDD), yet how subclinical echocardiographic (TTE) markers of LVDD track with hepatic fibrosis in MASLD remains understudied. **Methods:** Ambulatory MASLD patients enrolled in a longitudinal registry between 2021-2024 with ejection fraction (EF) > 40% on TTE and no prior HFpEF diagnosis were included. TTE parameters included EF and strain as markers of systolic function, while left atrial volume index (LAVi), wall thickness, E/A ratio, deceleration time, and E/e' represented LVDD. Relevant laboratory values and non-invasive fibrosis scores (FIB4, SAFE, NFS) were assessed. Fibrosis and steatosis were assessed using liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) from vibration-controlled transient elastography (VCTE). Spearman R and ANOVA were performed using fibrosis (LSM < 8 kPa or F0-1, n = 117 vs. LSM 8-12 kPa or F2-3, n = 33, vs. LSM > 12 kPa or F4, n = 32) and steatosis (CAP < 288 dB/m, n = 77 vs. > 288, n = 102). **Results:** 189 MASLD patients (60% female, mean age 57 years, mean BMI 32.2 kg/m^2) had a TTE and VCTE. There was no difference in LV systolic function when stratified by fibrosis or steatosis. Two LVDD parameters (LAVi and E/e') were elevated in F4 fibrosis (LSM p = 0.003, p = 0.035); but not in steatosis (CAP p = 0.63, p = 0.728). Association of LAVi and E/e' with F4 fibrosis remained significant when adjusted for age, gender, smoking, DM, HTN, CKD, BMI, lipid profile, CAP, and cardiac medications (Table 1). LAVi and E/e' were inversely associated with platelets and albumin; positively with FIB4, SAFE, NFS; and only LAVi positively with IgG and INR (Table 1). Change in LAVi with F4 fibrosis was only significant in the presence of obesity, DM, or HTN (p = 0.039, p = 0.014, p = 0.017). **Conclusion:** LVDD markers LAVi and E/e' are linked to advanced liver fibrosis independent of demographic and cardiometabolic covariates. They also correlate with serological markers of liver injury, hepatic dysfunction, and non-invasive fibrosis scores. These findings highlight a link between subclinical markers of HFpEF amongst patients with MASLD and fibrosis, potentially suggesting a lower threshold for HFpEF screening to mitigate cardiac-related adverse events in MASLD.

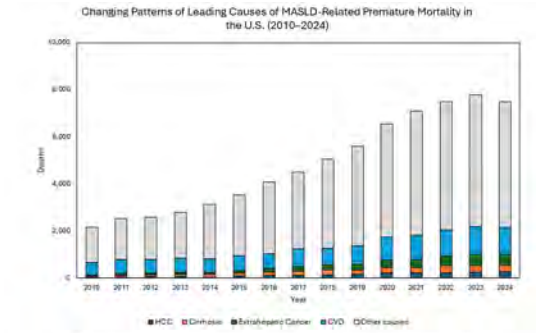
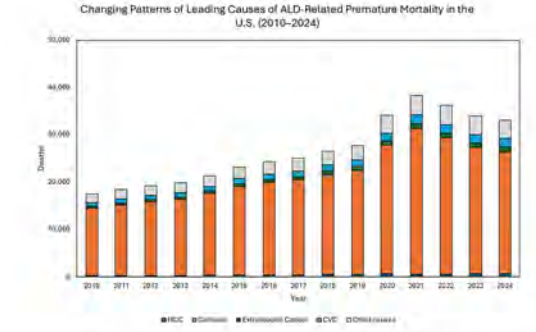
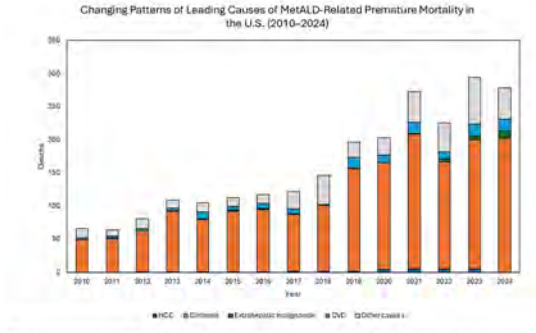
2510 | TRENDS IN PREMATURE MORTALITY AND LEADING CAUSES OF DEATH IN THE SPECTRUM OF STEATOTIC LIVER DISEASE (SLD) INCLUDING METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD), ALCOHOL-RELATED LIVER DISEASE (ALD), AND METABOLIC DYSFUNCTION AND ALCOHOL-RELATED LIVER DISEASE (METALD): A U.S. NATIONWIDE ANALYSIS (2010-2024)

Dana Ivancovsky Wajcman[1] James Paik[2] Shira Zelber-Sagi[3] Linda Henry[1] Saleh Alqahtani[4] Zobair Younossi[1], [1]The Global NASH Council, [2]Beatty Liver and Obesity Research Center, [3]Tel-Aviv Sourasky Medical Center, [4]Liver, Digestive, and Lifestyle Health Research Section, and Organ Transplant Center of Excellenc

Background: MASLD and ALD are growing causes of liver mortality in the U.S. MetALD, an increasingly recognized subtype of SLD, may be difficult to distinguish from misclassified MASLD or ALD due to overlapping clinical and coding features. We aimed to examine trends in premature mortality and leading causes of death from MASLD, ALD, and misclassified MASLD, presumed to represent MetALD. **Methods:** A cross-sectional analysis was conducted utilizing U.S. National Vital Statistics System data (2010–2024) for decedents aged ≤75 (men) and ≤80 (women). Decedents were classified as: (1) MASLD (ICD-10: K75.8, K76.0) without concurrent liver diseases (e.g., ALD, viral, autoimmune, toxic) or alcohol use disorder (AUD); (2) ALD: ALD-related codes without other liver diseases; (3) Misclassified MASLD: MASLD codes co-occurring with AUD codes, presumed to represent MetALD. Leading causes of death were categorized as cirrhosis (K70, K74), hepatocellular carcinoma (HCC, C22.0), cardiovascular disease (CVD, I00–I78), and extrahepatic cancers (C00–C97, excluding C22.0). COVID-19 (U07.1) deaths were excluded. Trends in age-adjusted premature mortality rates and proportional causes of death were evaluated using annual percent change (APC) from Joinpoint regression. **Results:** During the study period, MASLD-related premature mortality rate tripled from 1.01 (n = 2,151) to 3.12 per 100,000 (n = 7,490; APC = 9.01%). ALD-related mortality rose from 8.20 (n = 17,541) to 13.79 (n = 33,112; APC = 4.46%). MetALD mortality increased from 0.03 (n = 66) to 0.12 (n = 278; APC = 10.87%). In MASLD, CVD remained the leading cause but declined (24.2% to 15.5%; APC = -3.54%), while deaths from HCC (1.63% to 3.47%; APC = 4.51%) and extrahepatic cancers (2.14% to 6.11%; APC = 8.30%) increased, and cirrhosis remained stable (2.32% to 3.93%; APC = 3.14%, p = 0.312). In ALD, cirrhosis remained the leading cause but declined modestly (81.4% to 78.0%; APC = -0.23%), while deaths from HCC (1.23% to 1.87%; APC = 1.84%), extrahepatic cancers (2.23% to 2.98%; APC = 1.43%), and CVD (4.64% to 5.65%; APC = 0.94%) increased (Figure). **Conclusion:** Premature mortality from MASLD increased more rapidly than ALD. While cirrhosis remained the leading cause in ALD, MASLD saw a shift from CVD to malignancies, including HCC and extrahepatic cancers. The rise in presumed MetALD mortality highlights challenges in applying updated diagnostic definitions and underscores the need for clearer classification and coding guidelines across the SLD spectrum.







The "Other causes" category includes all non-specified causes of death beyond hepatocellular carcinoma (HCC), cirrhosis, extrahepatic cancers, and cardiovascular disease (CVD).

2511 | SEX DISPARITIES AND EPIDEMIOLOGY OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) GLOBALLY IN 2021 WITH FORECASTING TO 2050

Charles Levesley Xinrong Zhang[1] Scott Barnett[1] Linda Henry[1] Ramsey Cheung[1] Mindie Nguyen[1], [1]Stanford University Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is now the most common metabolic liver disease worldwide. Although its burden is rising globally, there remains a lack of literature investigating sex-specific trends in the disease. Understanding disparities in age-standardized prevalence, incidence, mortality and disability-adjusted life-year (DALY) rates, as well as forecasting future trends, is critical in shaping prevention and policy efforts. **Methods:** We analyzed MASLD-related age-standardized prevalence (ASP), incidence (ASIR), mortality (ASMR) and DALY rates from 1990 to 2021 using data from the Global Burden of Disease (GBD) 2021 database. Our analyses were stratified by sex, age, geographical region, country, and socio-demographic index (SDI). Joinpoint regression calculated annual percentage change (APC) values in each subgroup. Forecasts through 2050 were generated using Prophet, a time-series model suitable for long-term global health projections. To validate our findings, we performed sensitivity analyses using linear regression models. **Results:** From 1990 to 2021, ASP and ASIR increased more rapidly in females (APC +0.77%, +0.75%) than males (APC +0.65%, +0.70%), while ASMR and DALY rates rose more in males (APC +0.35%, +0.34%) than females (APC +0.07%, +0.05%). Across regions, the greatest increase in age-standardized prevalence (ASP) was observed in males from the Eastern Mediterranean (APC +0.72%) and females from the Western Pacific region (APC +0.80%). The Americas showed the steepest rise in age-standardized mortality rates (ASMR) for both sexes (APC +1.20% in males vs. +0.90% in females). For age-standardized incidence rates (ASIR), the highest APCs occurred among individuals in high SDI regions (APC +0.82% in males vs. +0.96% in females), as well as those aged less than or equal to 20 years (APC +0.92% in males vs. +1.02% in females). ASP and ASIR are projected to be highest by 2050 in the Eastern Mediterranean region, while ASMR and DALY rates are expected to increase most in the Americas overall and among males, however in the Eastern Mediterranean region for females. **Conclusion:** Our study demonstrates the growing burden of MASLD as prevalence and incidence rates rise globally from 1990 to 2021, with males demonstrating consistently higher prevalence and incidence rates compared to females. ASP of MASLD is estimated to increase to 19.03% in males and 17.64% in females by 2050. The Middle East and North Africa (MENA) region is particularly affected, demonstrating the highest ASP and ASIR, especially in countries such as Saudi Arabia and Egypt. Our findings highlight significant disparities in MASLD burden by sex and region, particularly in younger populations and areas with high MASLD burden due to increasing rates of metabolic diseases, including diabetes and obesity. Our study aims to inform effective global health strategies.

2512 | THE GENETIC ARCHITECTURE OF METABOLIC SYNDROME SUGGESTS COMMON UNDERLYING BIOLOGY AND GENETIC PREDISPOSITION WITH MASLD: INSIGHTS FROM ENHANCED POLYGENIC RISK SCORES

Carlos Pirola[1] Luis Diambra[2] Silvia Sookoian[1], [1]CONICET. CENITRES Maimónides University, [2]CONICET.

Background: Evidence indicates that the relationship between metabolic syndrome (MetS) and MASLD is bidirectional. MASLD can trigger MetS, while MetS can worsen MASLD or raise the risk of MASLD. MetS and MASLD share common lifestyle and environmental risk factors, creating a reciprocal causality between them. Nevertheless, the common genetic susceptibility of MASLD, the disease severity, and MetS is poorly understood. Enhanced polygenic risk scores (EPRSs) are powerful tools for assessing genetic predisposition to complex traits and clinical risks by integrating genetic data from the entire genome. Here, we used EPRSs linked to major MetS phenotypes to explore the mediation effects on MASLD and fibrosis. **Methods:** We used longitudinal data from the UK Biobank (application #485675), which included genetic and phenotypic information from 488,377 participants aged 40 to 69 years. MASLD and the disease severity (liver fibrosis) were identified using MRI-derived PDFF ($>5.5\%$) and iron corrected T1 (cT1) measurements (cutoff >800 ms), and ICD10 classifications. EPRS were generated using a Bayesian approach applied to meta-analysed summary statistics GWAS data, obtained from a combination of external and internal UK Biobank data. Explored EPRSs covered 148,835 participants of which 9520 have comprehensive

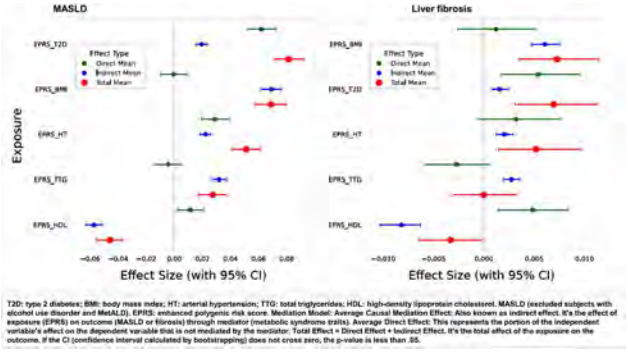
characterization of the liver phenotype: arterial hypertension (HT); type 2 diabetes (T2D); BMI; total triglycerides TTG) and high-density lipoprotein cholesterol (HDL-C). Causal mediation effects of EPRSs through corresponding phenotypes on MASLD and fibrosis, adjusted for age and sex, were examined using Statsmodels 0.14.4. **Results:** Mediation analysis suggests significant effects of EPRSs for traits of the MetS on MASLD and liver fibrosis (Figure). HT-EPRS has an indirect effect of 43.1% on MASLD and 39% on liver fibrosis; T2D-EPRS has an indirect effect of 24% on MASLD and 23% on fibrosis. HDL-EPRS directly affects MASLD and fibrosis, and protects indirectly through HDL-C. **Conclusion:** Consistent with the clinical and epidemiological evidence, our findings suggest a substantial degree of shared genetic risk between MASLD, the disease severity, and MetS. Furthermore, MetS-EPRSs may exhibit considerable pleiotropic effects. This underscores the potential for modulating the same pathways and targets as a viable therapeutic strategy when treating MASLD and traits of the MetS concurrently.



T2D: type 2 diabetes; BMI: body mass index; HT: arterial hypertension; TTG: total triglycerides; HDL: high-density lipoprotein cholesterol. MASLD (excluded subjects with alcohol use disorder and MetALD). EPRS: enhanced polygenic risk score. Mediation Model: Average Causal Mediation Effect: Also known as indirect effect. It's the effect of exposure (EPRS) on outcome (MASLD or fibrosis) through mediator (metabolic syndrome traits). Average Direct Effect: This represents the portion of the independent variable's effect on the dependent variable that is not mediated by the mediator. Total Effect = Direct Effect + Indirect Effect. It's the total effect of the exposure on the outcome. If the CI (confidence interval calculated by bootstrapping) does not cross zero, the p-value is less than .05.

2513 | RATE OF INCREASE IN APOLIPOPROTEIN B (APOB) DURING EARLY ADULTHOOD AND PREVALENT MASLD IN MID-LIFE: THE CORONARY ARTERY RISK DEVELOPMENT IN YOUNG ADULTS (CARDIA) STUDY

Seong Park[1] Hongyan Ning[1] Dempsey Hughes[1] John Wilkins[1] SeJong Bae[2] Ankeet Bhatt[3] Lisa VanWagner[4], [1]Northwestern University Feinberg School of Medicine, [2]Augusta University, [3]Kaiser Permanente San Francisco Medical Center, [4]University of Texas Southwestern Medical Center

Background: Optimizing cardiometabolic health at an earlier age is associated with lower prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) in midlife. Higher rates of triglyceride (TG) increase in early adulthood are positively associated with prevalent MASLD in midlife. Apolipoprotein B (apoB) concentration reflects the total number of atherogenic lipoproteins and can vary substantially across a given TG and cholesterol concentration. To date, no studies have examined how differences in apoB progression throughout young adulthood are linked with prevalent MASLD in midlife. **Methods:** We used data from participants (20-32 years at Year 2, 1987-88) of the Coronary Artery Risk Development in Young Adults (CARDIA) study who had liver fat assessed by non-contrast computed tomography at Year 25 (Y25, 2010-11) and apoB measured at $\geq$ 1 exam at Year 2, 7, 15, 20 or 25 using nuclear magnetic resonance. MASLD was defined as liver attenuation of $<$ 51 Hounsfield units after exclusions for other causes of liver fat. Random-effects mixed linear regression modeling was used to estimate slope of apoB from Y2 to Y25. Participants were stratified into groups based on quartile of slope estimates for apoB from Y2 to Y25 (Figure). Logistic regression models were used to assess the odds of Y25 MASLD prevalence across apoB quartiles. **Results:** Of 2641 study participants, Y25 MASLD prevalence was 23.5% (n = 620). Average annual change in apoB from Y2 to Y25 for all participants ranged from 0.21 (-0.39-0.37) mg/dL/year in the stable increase group to 0.96 (0.76-2.28) mg/dL/year in the major increase group. Participants with major increase in apoB were more likely to be male (47.6% vs. 37.0%) and current smoker at Y25 (18.0% vs. 12.6%) compared to those with stable apoB increase. These individuals also had higher absolute apoB, low-density lipoprotein, and total cholesterol levels at Y2 and Y25 as well as prevalent MASLD at Y25 (33.0% vs. 18.2%), compared to those with stable increase in apoB. The major increase group had the highest odds of Y25 MASLD prevalence when compared to the stable increase group (Figure). The odds of Y25 prevalent MASLD increased in those with moderate (aOR = 1.57, 95% CI: 1.03-2.40) and major (aOR = 2.45, 95% CI: 1.54-3.92) apoB increases throughout early adulthood, compared to the stable (reference) increase group. The associations between moderate and major apoB increase with MASLD remained strong even after adjusting for the baseline apoB value, suggesting that rapid increases in apoB blood levels are associated with higher risk of MASLD in midlife even if the absolute apoB level is low at younger age. **Conclusion:** Rates of increase in apoB ($>$ 0.5mg/dL/year) during early adulthood are positively associated

Background: Women with metabolic-associated steatotic liver disease (MASLD) exhibit distinct clinical characteristics different from men. Postmenopausal women undergo a decline in estrogen secretion, which subsequently leads to a reduction in HDL cholesterol levels. This study aimed to investigate the impact of cardiometabolic risk factors (CMRFs), including low HDL cholesterol, on MASLD onset in individuals without pre-existing steatotic liver disease (SLD). **Methods:** This is a registry-based, multicenter cohort study that used a health checkup database (n = 410,061). SLD was diagnosed by ultrasonography, and non-SLD individuals were followed for 65,657 person-years. The incidence rates of MASLD were assessed using Kaplan-Meier analysis. Independent risk factors for MASLD development were identified using Cox regression analysis, stratified by four groups: obese women, non-obese women, obese men, and non-obese men. Partial correlation analysis was performed to identify independent associations between metabolic parameters and MASLD development, stratified by obesity status. **Results:** The overall incidence rate of MASLD was 39.3/1,000 person-years, with a higher incidence in obese women than in non-obese men (13.7% vs. 7.2%). Women developed MASLD at an older age compared to men (non-obese: 58 vs. 54 years; obese: 56 vs. 55 years). Low HDL cholesterol was the most potent independent risk factor for MASLD in women, regardless of obesity status (HR [95% CI]: non-obese women 1.9 [1.5—2.4], obese women 1.4 [1.1—1.8]), while hypertriglyceridemia was the primary risk factor in men. Additionally, a partial correlation analysis demonstrated distinct patterns of risk among women. In non-obese women, low HDL cholesterol levels emerged as a central factor associated with MASLD development. In obese women, low HDL cholesterol also demonstrated a strong association with MASLD, acting as a key component within a cluster of other metabolic factors. **Conclusion:** The metabolic risk factors contributing to MASLD development differed by sex, with low HDL cholesterol being the most potent predictor in women. These findings suggest that MASLD prevention in women should consider not only the presence of obesity but also the potential impact of low HDL cholesterol levels, even in non-obese individuals. Furthermore, a greater emphasis on reproductive health, including menopausal status, may be necessary for a more comprehensive risk assessment.

2515 | A SYSTEMATIC REVIEW AND META-ANALYSIS: DOES LIVER DISEASE REPRESENT AN INDEPENDENT RISK FACTOR FOR CARDIOVASCULAR DISEASE IN PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE?

Alexander Hung[1] Ida Katharina Ziegler Spedtsberg[2] David Etoori[3] Maja Thiele[2] William Rosenberg[3], [1]Department of Hepatology, Royal Free Hospital, London, UK, [2]Odense University Hospital, [3]Institute for Liver and Digestive Health, UCL Division of Medicine, London, UK

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is associated with elevated risk of incident cardiovascular disease (CVD), the leading cause of death in people with MASLD. However, it is unclear whether liver disease is an independent risk factor (RF) for CVD or whether cardiometabolic RFs common to MASLD and CVD fully explain this risk. Equipoise exists in the literature, with studies conducted in liver centres suggesting MASLD confers higher CVD risk regardless of metabolic RFs, but large epidemiological studies suggesting the converse. Mendelian epidemiology cannot resolve this question. A systematic review and meta-analysis was conducted to delineate the relationship between MASLD and CVD. **Methods:** Medline, Embase, and Cochrane databases were interrogated from database inception to December 2024. Exclusion criteria incorporated: method of MASLD diagnosis (imaging, elastography or biopsy), alcohol intake (<30g/20g daily for males/females), pre-existing CVD, and follow-up period. Cross-sectional studies were excluded. The primary outcome was overall incident CVD. Secondary endpoints were fatal/non-fatal CVD events (CVEs), atrial fibrillation (AF), acute coronary syndrome (ACS), CVD mortality, and stroke. Raw outcome data were extracted from studies and meta-regression analyses performed using random-effects models to derive pooled odds ratios (ORs) with 95% confidence intervals (CIs). **Results:** Nineteen longitudinal cohort studies with various cardiovascular endpoints were identified, with aggregate data on 1,250,661 individuals (median follow-up 8.4 years [IQR 5.7-10.0]). MASLD was associated with an increased risk of any incident CVD (OR 1.90 [1.27–2.84]; $p=0.004$). After adjustment for age, sex and cardiometabolic RFs, this association remained but with CIs spanning 1.0 (OR 1.62 [0.06–3.18]; $p=0.043$). Further adjustment for follow-up duration yielded similar results (OR 1.83 [0.03–3.63; $p=0.048$). MASLD was associated with CVEs (OR 1.52 [0.12–2.91]; $p=0.037$) and CVD mortality (OR 1.51 [0.03–2.99]; $p=0.049$) in covariate-adjusted models, but CIs again spanned 1.0. MASLD was associated with elevated risk of incident ACS, AF, and stroke, but eligible study numbers precluded full adjustment for all cardiometabolic RFs. **Conclusion:** MASLD is associated with a nearly twofold increase in the risk of incident CVD. After adjusting for common cardiometabolic RFs, this association is equivocal due to the relatively wide CIs for ORs calculated in fully adjusted models. Thus, these data demonstrate no irrefutable evidence that there exists an association between MASLD and CVD independent of common cardiometabolic RFs. As such, further high-quality studies are needed to resolve the discrepancy between hepatological and epidemiological studies. Regardless, the association between MASLD and CVD highlights the importance of effective CVD risk management for people with MASLD.

Figure 1. Forest plot depicting the risk of overall incident CVD in the MASLD vs. non-MASLD groups for each of the included studies.

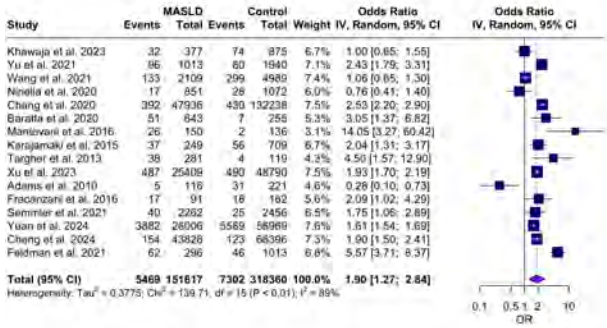

Figure 1. Forest plot depicting the risk of any incident CVD in the MASLD group as compared to non-MASLD controls. Unadjusted odds ratios (ORs) are given for each of the individual studies (*dark blue squares*) included in the meta-analysis ($n=16$), with the pooled OR presented at the base of the plot (*purple diamond*) alongside heterogeneity statistics.

2516 | STEATOTIC LIVER DISEASE PHENOTYPES IN INFLAMMATORY BOWEL DISEASE: A SCREENING STUDY IDENTIFYING MASLD AS THE PRIMARY DRIVER OF LIVER FIBROSIS

Dana Kablawi[1] Solomon Sasson[2] Roy Nitulescu[1] Raman Agnihotram[3] Faisal Aljohani[4] Riccardo Righetti[4] Gary Wild[1] Alain Bitton[1] Chiara Saroli Palumbo[1] Waqqas Afif[1] Peter Lakatos[1] Talat Bessissow[1] Giada Sebastiani[1], [1]McGill University Health Center, [2]University of British Columbia, [3]Research Institute, McGill University Health Center, Montreal, Canada, [4]McGill University Health Centre

Background: Steatotic liver disease (SLD) seems common in people living with inflammatory bowel disease (IBD). The newly proposed definition of metabolic dysfunction-associated steatotic liver disease (MASLD) highlights metabolic drivers of hepatic steatosis while recognizing its frequent coexistence with other chronic liver diseases, including alcohol and drug-induced liver injury. We aimed to characterize the distribution of SLD phenotypes in people with IBD and evaluate the association of coexisting MASLD and IBD with liver fibrosis. **Methods:** As part of a routine MASLD screening program, transient elastography was performed in consecutive people with IBD from a prospective cohort in Montreal, Canada. SLD was defined as hepatic steatosis with a controlled attenuation parameter ≥275 dB/m. MASLD was determined by the presence of steatosis with at least 1 cardiometabolic risk factor: elevated body mass index, prediabetes or diabetes, hypertension, or dyslipidemia. Significant liver fibrosis was defined as liver stiffness measurement ≥8 kPa. Factors associated with fibrosis were assessed using logistic regression models. Associations between clinical and demographic factors and the presence of significant fibrosis were evaluated using multivariable logistic regression models, with results reported as adjusted odds ratios (aORs) and 95% confidence intervals (CIs). **Results:** A total of 495 patients (mean age 45, 54% male, 64% Crohn's disease, mean IBD duration 14 years, mean BMI 25, diabetes prevalence 32%). SLD was identified in 35% of patients, of which 57% met the criteria for MASLD, 5% had alcohol-related SLD, and 38% had other forms. The overall prevalence of significant liver fibrosis was 8%, increasing to 13% and 22% in patients with 1-2 or 3-4 cardiometabolic risk factors, respectively. The prevalence of liver fibrosis was higher in patients with MASLD versus those without SLD (see Figure). In an exploratory analysis, methotrexate exposure was more frequent among patients with liver fibrosis (8%) compared to those without (2%). After adjusting for IBD subtype, biological sex, and disease duration, MASLD remained independently associated with a significantly increased likelihood of liver fibrosis aOR 3.1; 95%CI:(1.5–6.1). In contrast, no significant association was observed for non-MASLD steatotic liver disease (SLD) phenotypes. Notably, 3.5% of patients with IBD exhibited significant fibrosis despite the absence of detectable SLD. **Conclusion:** MASLD is the most frequent phenotype of SLD in people with IBD and it is strongly associated with liver fibrosis. A proportion of patients also exhibit SLD and liver fibrosis without metabolic comorbidities, suggesting a potential role for chronic medication exposure. Clinicians should prioritize the identification and management of cardiometabolic risk factors in IBD care to mitigate liver-related complications.

2517 | INFLUENCE OF CARDIOMETABOLIC RISK FACTORS AND ALCOHOL CONSUMPTION ON LIVER STIFFNESS IN PATIENTS WITH MASLD: A MULTICENTER STUDY IN COLOMBIA INFLUENCE OF CARDIOMETABOLIC RISK FACTORS AND ALCOHOL CONSUMPTION ON LIVER STIFFNESS IN PATIENTS WITH MASLD: A MULTICENTER STUDY IN COLOMBIA

ISMAEL YEPES[1] Juan Carlos Restrepo[2] Clara Milena Caez[3] Yohana Poveda[4] NICOLE CHAMORRO[5] Guillermo Donado[6] Jorge Ortiz[7] Pablo Osorio[8] Santiago Pino[9] Juan Ignacio Marin Zuluaga[10], [1]Universidad de Cartagena. Asociacion Colombiana de Hepatologia., [2]Hospital Pablo Tobon Uribe. Asociacion Colombiana de Hepatologia., [3]Asociacion Colombiana de Hepatologia., [4]Gastropack SAS. Asociacion Colombiana de Hepatologia., [5]Universidad de Cartagena. Gastropack SAS, [6]Universidad de Cartagena. Gastropack SAS, [7]Clinica IMAT. Asociacion Colombiana de Hepatologia, [8]Universidad de Cartagena., [9]Universidad de Antioquia., [10]Hospital Pablo Tobon Uribe. Asociacion Colombiana de Hepatologia

Background: A new nomenclature has been proposed to better classify steatotic liver disease based on etiology. The term *Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD)* includes all patients with steatosis and at least one cardiometabolic risk factor (CMRF). However, CMRFs differ in their impact on disease progression. Additionally, the alcohol thresholds in MASLD criteria are arbitrary, despite evidence suggesting liver risk may increase even below these cutoffs. Alcohol might interact with CMRFs—or CMRFs among themselves—promoting liver damage. This study aimed to explore how CMRFs and alcohol intake, independently and in interaction, relate to liver stiffness in MASLD patients. **Methods:** Patients with MASLD from four Colombian cities were included. All underwent transient elastography and other causes of liver disease were excluded. Significant alcohol intake ($\geq$30 g/day in men, $\geq$20 g/day in women) was an exclusion criterion. CMRFs were defined using ATP III criteria, and alcohol use was measured in standard drink units per week. A multivariate linear regression, including interaction terms between CMRFs and alcohol, was performed. Significance was set at $p \leq 0.05$. **Results:** A total of 354 patients were analyzed (39.3% male; mean age: 54 years). Regarding CMRFs, 30.2%, 31.9%, 29.4%, and 8.5% had 1, 2, 3, and 4 factors, respectively. Mean alcohol intake was 14.5 g/week, and 5% exceeded 100 g/week. Prevalence of ATP III criteria: glucose metabolism impairment (50.6%), hypertension (54.2%), dyslipidemia (68.6%), and increased waist circumference (42.7%). In univariate analysis, liver stiffness was associated with age, BMI, number of CMRFs, and impaired glucose metabolism. In multivariate analysis, only BMI (β = 0.14; 95% CI: 0.03–0.27; p = 0.012) and impaired glucose metabolism (β = 0.11; 95% CI: 0.08–2.6; p = 0.03) remained significant. Alcohol intake and its interactions showed no significant association. However, interactions between diabetes and waist circumference, hypertension and diabetes, and the three combined were linked to higher liver stiffness. Only the diabetes–waist circumference interaction remained significant. **Conclusion:** MASLD represents a heterogeneous condition. Diabetes, especially when combined with increased waist circumference, appears to be a key driver of liver stiffness. These findings warrant further validation.

Table 1. Factors associated with elastographic values. Univariate linear regression.

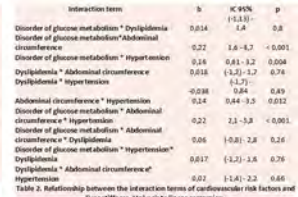

Table 2. Relationship between the interaction terms of cardiovascular risk factors and liver stiffness, Univariate linear regression.

Variable	b	p
Disorder of glucose metabolism*Abdominal circumference	0,19	< 0,01
BMI (Kgs/m2)	0,14	0,012
Disorder of glucose metabolism	0,11	0,03

Table 3. Factors associated with liver stiffness. Multivariate linear regression analysis

2518 | INFLAMMATORY BURDEN VARIES BY DIET QUALITY IN A SUSPECTED MASLD POPULATION

Sindhuja Battula[1] Adnan Said[1], [1]University of Wisconsin School of Medicine and Public Health

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common cause of chronic liver disease world-wide. Chronic inflammation plays a central role in the pathogenesis and progression of MASLD to advanced liver disease. Dietary composition is a modifiable factor that may influence systemic inflammation, but the relationship between diet quality and inflammatory biomarkers in individuals with MASLD remains unclear. **Methods:** We conducted a cross-sectional analysis of data from the 2017–2018 National Health and Nutrition Examination Survey (NHANES). MASLD was defined by the presence of hepatic steatosis (CAP $\geq$285 dB/m), low alcohol intake, and at least one cardiometabolic risk factor: elevated body mass index (BMI), impaired glucose metabolism, elevated blood pressure, hypertriglyceridemia, or reduced high-density lipoprotein (HDL) cholesterol. Participants under 18 years of age or with hepatitis B, hepatitis C, or hemochromatosis were excluded. Diet quality was assessed using the Healthy Eating Index (HEI-2015) and the Dietary Inflammatory Index (DII), both derived from Day 1 24-hour dietary recall data. Inflammatory biomarkers, including high-sensitivity C-reactive protein (hs-CRP) and serum ferritin, were analyzed as primary outcomes. Sample survey-weighted univariate analyses were performed to evaluate associations between diet quality and inflammatory markers in the MASLD population. **Results:** Among adults with MASLD (n = 881), higher Dietary Inflammatory Index (DII) scores were significantly associated with elevated hs-CRP levels (β = 0.61, SE = 0.17, p = 0.002) and lower serum ferritin levels (β = –10.39, SE = 2.46, p < 0.001). Conversely, higher Healthy Eating Index (HEI-2015) scores were significantly associated with lower hs-CRP levels (β = –0.063, SE = 0.021, p = 0.009), but not with ferritin levels (β = 0.60, SE = 0.39, p = 0.15). **Conclusion:** Our findings indicate that a pro-inflammatory diet is significantly associated with increased systemic inflammation, while better overall diet quality correlates with reduced inflammation in adults with MASLD. These results highlight diet as a modifiable risk factor in managing inflammation and suggest that anti-inflammatory dietary strategies could play an important role in the clinical care of MASLD. Following a pro-inflammatory diet, lower ferritin likely reflects impaired iron storage or absorption driven by poor nutritional quality and impaired iron homeostasis in the MASLD population. Moreover, hs-CRP may serve as a useful and accessible biomarker to help patients and clinicians better understand the impact of dietary habits on inflammation and motivate healthier lifestyle changes.

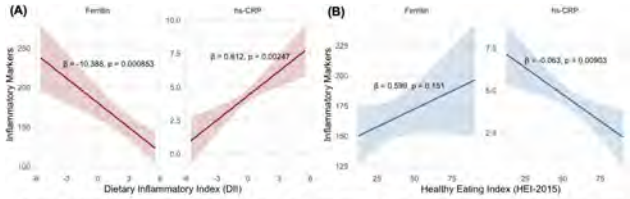

Figure 1: Survey-weighted univariate analyses showing associations between diet quality and inflammation in MASLD: **(A)** Dietary Inflammatory Index and **(B)** Healthy Eating Index (HEI-2015), each evaluated against serum ferritin and hs-CRP.

2519 | INDEPENDENT ASSOCIATION BETWEEN VITAMIN D INSUFFICIENCY AND LIVER FIBROSIS IN PEOPLE WITH HIV, REGARDLESS OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE OR HEPATITIS C COINFECTION

FRANCESCA FARINA[1,2], AURGHO DATTA[1], JOVANA MILIC[3], FELICE CINQUE[1], GIOVANNI GUARALDI[3], GIADA SEBASTIANI[1], [1]DEPARMENT OF MEDICINE, MCGILL UNIVERSITY HEALTH CENTRE, MONTREAL, CANADA, [2]SAN RAFFAELE HOSPITAL, MILAN, ITALY, [3]MODENA HIV METABOLIC CLINIC, UNIVERSITY OF MODENA AND REGGIO EMILIA, MODENA, ITALY, Francesca Farina[1] Aurgho Datta[1] Felice Cinque[1] Giovanni Guaraldi[2] Giada Sebastiani[1] Jovana Milic[2], [1]McGill University Health Centre, Montreal, Canada, [2]University of Modena and Reggio Emilia, Modena, Italy

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common liver disease in people with HIV (PWH), who are also at high risk of liver fibrosis. Vitamin D insufficiency is prevalent in PWH and frequently observed in individuals with MASLD, yet its role in liver fibrosis progression in this population remains unclear. **Methods:** We conducted a multicenter cohort study involving PWH screened for hepatic steatosis and fibrosis using transient elastography. Hepatic steatosis was defined as controlled attenuation parameter $\geq$275 dB/m, and significant liver fibrosis as liver stiffness measurement $\geq$8 kPa. Vitamin D insufficiency was defined as serum 25-hydroxyvitamin D levels <50 nmol/L. Incidence of significant liver fibrosis was assessed by survival analysis, and independent predictors were identified through logistic regression and generalized estimating equations

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

modelling. **Results:** A total of 4,746 PWH were included (mean age 60.2 years, 72% men, mean BMI 25 Kg/m^2, 11% with diabetes, 23% with hepatitis C coinfection, 5% with hepatitis B coinfection, all on antiretroviral therapy) between 2014-2024. Vitamin D insufficiency was observed in 42% of participants, hepatic steatosis in 19% and significant fibrosis in 14%. At baseline, independent cofactors of vitamin D insufficiency included hepatitis C coinfection (adjusted odds ratio [aOR] 1.15, 95% CI 1.02-1.31), BMI (aOR 1.1, 95% CI 1.03-1.08), and hepatic steatosis (aOR 1.71, 95% CI 1.35-2.18) after adjusting for HIV duration, diabetes, CD4 cell count, parathormone levels, sex, and ethnicity. Over a median 7-year follow-up, the cumulative incidence of significant liver fibrosis was 17%, and significantly higher among PWH with vitamin D insufficiency (see Figure). On multivariable generalized estimating equations models, vitamin D insufficiency was independently associated with development of liver fibrosis (aOR 1.44, 95% CI 1.14-1.80), adjusting for hepatic steatosis, diabetes, obesity, parathormone, CD4 cell count and HIV duration. **Conclusion:** Vitamin D insufficiency is common in PWH, particularly in those with MASLD and hepatitis C coinfection. It is independently associated with the development of liver fibrosis, beyond traditional metabolic risk factors. These findings suggest a potential role for vitamin D supplementation in MASLD prevention strategies in PWH, possibly through anti-inflammatory and insulin-sensitizing mechanisms.

Figure. Survival curves for incidence of significant liver fibrosis by category of vitamin D insufficiency.

2520 | STEATOSIS-ASSOCIATED FIBROSIS ESTIMATOR (SAFE) OUTPERFORMS OTHER BLOOD-BASED BIOMARKERS FOR PREDICTING MAJOR ADVERSE LIVER OUTCOMES IN THE COMMUNITY

Vincent Chen[1] Chinmay Raut[2] Antonino Oliveri[2] Yousif Alyousifi[2] Yanhua Chen[2] Elizabeth Speliotes[1], [1]University of Michigan Medical Center, [2]University of Michigan

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects >30% of adults in the US and is a leading cause of major adverse liver outcomes (MALO). Blood-based non-invasive tests (NITs) are recommended for risk stratification but may miss a significant proportion of incident MALO. Here we assess the performance of non-proprietary NITs for predicting risk of MALO. **Methods:** We utilized UK Biobank, a community-based cohort of >500,000 adults in the United Kingdom. We included all participants with non-missing values of all primary predictors; at least one MASLD cardiometabolic risk factor; and no diagnosis of non-MASLD chronic liver diseases or report of excess alcohol intake. The primary predictors were the blood-based NITs FIB4, APRI, NFS, and SAFE. The primary outcome was MALO, defined as hospitalization for cirrhosis or hepatocellular carcinoma, or liver-related death. We utilized a time-dependent area under the curve (tAUC) approach where cases were those with MALO in <= 2-10 years of follow-up and controls were those with no MALO in > 2-10 years of follow-up respectively. **Results:** We included 238,657 participants with non-missing data, of whom 375 developed MALO within <10 years. The 10-year tAUC for identifying MALO was highest for SAFE (0.840 [95% CI 0.816-0.864]), then APRI (0.820 [0.793-0.846]), FIB4 (0.780 [0.753-0.808]), and NFS (0.771 [0.744-0.798]); $p < 0.05$ for all vs. SAFE. SAFE remained superior to the other NITs in individuals with elevated alanine aminotransferase or who met criteria for screening based on AASLD guidance. We next assessed patients who developed MALO and determined what proportion of patients had high, intermediate, or low NIT values at baseline based on previously-reported cutoffs. High SAFE identified 23/28 (82.1%) of patients who went on to develop MALO within 2 years of measurement, vs. 16/28 (57.1%), 14/28 (50.0%), and 10/28 (35.7%) for high FIB4, NFS, and APRI, respectively. At 5 years, the corresponding values were 101/153 (66.0%), 75/153 (49.0%), 57/153 (37.7%), and 30/153 (19.6%) for SAFE, FIB4, NFS, and APRI,

respectively. This performance was primarily driven by very low incidence of MALO in the low and intermediate SAFE categories. **Conclusion:** SAFE more accurately identified risk of MALO in a community cohort than other non-proprietary NITs. High SAFE category (>100) identified nearly all MALO occurring within 2-3 years after measurement, suggesting that it may be more efficient of a screening cutoff to identify at-risk participants.

2521 | SPLEEN, LIVER, MUSCLE, AND FAT TRAITS ARE ASSOCIATED WITH MAJOR ADVERSE LIVER OUTCOMES AND LIVER-RELATED MORTALITY IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Vincent Chen[1] Brian Derstine[2] Brian Ross[2] June Sullivan[2] Peng Zhang[2] Grace Su[1], [1]University of Michigan Medical Center, [2]University of Michigan

Background: Muscle and fat quantity and density associate with disease severity in metabolic dysfunction-associated steatotic liver disease (MASLD), and data are emerging on importance of liver and spleen properties. However, data are limited on whether these factors are associated with major adverse liver outcomes (MALO). **Methods:** We included patients with MASLD diagnosed on computed tomography (CT) at Michigan Medicine between 2001-2024, with at least one cardiometabolic risk factor and no excess alcohol intake or alternative chronic liver diseases. CT scans were processed using Analytic Morphomics Platform (Matlab version 2024a) for axial predictors and TotalSegmenter version 2.4.0 for liver/spleen predictors. Predictors included axial L3 body composition measures (visceral fat, subcutaneous fat, and skeletal muscle area and attenuation, aortic calcification) and liver/spleen traits. Outcomes were MALO, liver-related death (LRD), and overall mortality. We deduplicated highly-correlated traits (r>0.8) and assessed the remaining features with a Cox proportional hazards model with a 12 month landmark. Models were adjusted for slice thickness and contrast phase (model 1), or model 1 plus age, sex, diabetes, and body mass index (model 2). Effects were reported per standard deviation (SD) in the predictor. Predictors were considered significant if p value in either model 1 or 2 met a Bonferroni corrected p value cutoff. **Results:** The cohort included 6,886 patients. Median age was 52 years and 55% were female. Median body mass index was 32.8 kg/m^2 and prevalence of diabetes, hypertension, and dyslipidemia were 40%, 67%, and 57% respectively. MALO, LRD, and death occurred in 112, 24, and 555 participants, respectively. 15, 16, and 37 features associated with MALO, LRD, and death, respectively. Factors associated with increased MALO or LRD included greater heterogeneity or asymmetry in liver or spleen attenuation, peak liver or spleen attenuation, greater spleen volume (Table). Greater muscle density and area were associated with lower risk of MALO and LRD, and greater subcutaneous and visceral fat density with LRD. Overall mortality-associated features were overall similar. Associations remained significant after stratification by contrast phase and Fibrosis-4 score. **Conclusion:** Subtle liver and spleen traits such as peak intensity and heterogeneity, along with muscle, subcutaneous fat, and visceral fat area/density, are associated with prognosis in MASLD. Automated quantitative image analysis of CT scans may serve to provide predictive biomarkers at the time of MASLD diagnosis.

Major adverse liver outcomes				
Predictor	Model 1		Model 2	
	Hazard ratio (95% confidence interval)	P value	Hazard ratio (95% confidence interval)	P value
Liver attenuation variability	1.12 (1.08-1.17)	<0.001	1.13 (1.08-1.18)	<0.001
Expected muscle attenuation	0.59 (0.49-0.71)	<0.001	0.58 (0.46-0.73)	<0.001
Spleen attenuation variable	1.21 (1.11-1.31)	<0.001	1.20 (1.10-1.31)	<0.001

2522 | SCREENING FOR FIBROTIC MASH IN SUBJECTS WITH DIABETES IN THE POPULATION: OPTIMIZING THE STRATEGY USING IMPERFECT TOOLS

Thuy-Duyen Nguyen[1] Alina Allen[2] Ajitha Mannalithara[3] W. Ray Kim[1], [1]Mayo Clinic Arizona, [2]Mayo Clinic Rochester, [3]Stanford University School of Medicine

Background: Type 2 diabetes is a strong risk factor for metabolic dysfunction-associated steatohepatitis (MASH). Guidelines have been developed to recommend proactive screening for fibrotic MASH, typically consisting of two steps, first using a laboratory-based risk stratification score, commonly the FIB4 score, followed by elastography (such as vibration controlled transient elastography, VCTE) for liver stiffness measurement (LSM). The Steatosis-Associated Fibrosis Estimator (SAFE) score was developed to enhance the performance of FIB4 by incorporating additional variables relevant for MASH, e.g., diabetes and body mass index. We investigate the extent to which the SAFE score may improve the detection of fibrotic MASH in subjects with diabetes in the US population. **Methods:** We interrogated the National Health and Nutrition Examination Survey data, 2017-2020, in which a sample of subjects, representative of the US civilian population, underwent a comprehensive medical examination including VCTE. The FIB4 and SAFE scores were calculated in all adult examinees with a diabetes diagnosis. The current recommendation using FIB4 ≥ 1.3 as the initial risk stratification modality was compared to using SAFE at the rule-out and rule-in thresholds (a score of 0 and 100, respectively), in identifying (1) the number of subjects correctly diagnosed with fibrotic MASH (defined by a median controlled attenuation parameter [CAP] ≥ 274 dB/m and LSM ≥ 8 kPa) and (2) the number of VCTEs to be performed. **Results:** The survey data projected that 75.8 million US adults had steatosis (CAP ≥ 274 dB/m), of whom 41.6 million had diabetes. The prevalence of fibrotic MASH was high in this group, with 21.8% of subjects with diabetes and steatosis having VCTE ≥ 8 kPa. Of those, only 35.5% had FIB4 ≥ 1.3, leaving 64.5% of those with fibrotic MASH uncaptured when guideline recommendations are followed to use FIB4 < 1.3 to avoid LSM evaluation. When utilizing SAFE, a SAFE ≥ 0 threshold would capture 87.4% of fibrotic MASH and SAFE ≥ 100 would detect 51.8%. In the Table, when compared to FIB4 ≥ 1.3, using SAFE ≥ 100 would diagnose 1.5 million more fibrotic MASH while utilizing fewer VCTE examinations. However, this strategy still misses nearly 50% of fibrotic MASH. With SAFE ≥ 0, much fewer (12.6%) fibrotic MASH would be missed, but it would require 16.4 million more VCTEs. **Conclusion:** These data support society guidelines recommending screening for fibrotic MASH in subjects with diabetes, given the high prevalence and available liver-diirected therapy. However, as the initial screening test, FIB4 has unacceptably high false negative rates, missing more cases than diagnosed. Using SAFE ≥ 100 is superior to FIB4, detecting more fibrotic MASH while utilizing fewer VCTEs. However, to maximize the sensitivity of the strategy, the detection threshold would need to be lowered, which would require systematic investment to deploy large numbers of elastography on the population level.

Stratification Test	Number of VCTEs	Fibrotic MASH	
		Diagnosed	Missed
FIB4 ≥1.3	13.1M	3.2M	5.8M
SAFE ≥100	12.3M	4.7M	4.4M
SAFE ≥0	29.5M	7.9M	1.1M

Hirokazu Takahashi[7] Meena Bansal[8] Mazen Noureddin[9] Mark Muthiah[10] Cheng Han Ng[11], [1]Mount Sinai Morningside and West Hospitals, [2]Yong Loo Lin School of Medicine, National University of Singapore, Singapore, [3]Texas Tech University Health Sciences Center, [4]Department of Medicine, Bridgeport Hospital, Yale New Haven Health, Bridgeport, Connecticut, USA, [5]University of Arizona College of Medicine-Phoenix, [6]National University Hospital, Singapore, [7]Division of Metabolism and Endocrinology, Department of Medicine, Faculty of Medicine, Saga Univer, [8]Icahn School of Medicine at Mount Sinai (ISMMS), [9]Houston Methodist Hospital, [10]Division of Gastroenterology and Hepatology, Department of Medicine, National University Hospital, [11]Division of Digestive Disease Information and Research, Department of Medicine, Kurume University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects up to 37% of individuals and is anticipated to rise alongside obesity and diabetes mellitus (DM) rates. Limited data exists on the impact of key diagnostic factors on mortality across steatotic liver disease (SLD) spectrum. This study evaluates the effect of diagnostic criteria on overall mortality across the SLD spectrum. **Methods:** A retrospective cohort study using the National Health and Nutrition Examination Survey registries from 1999-2018. All patients with hepatic steatosis were classified as SLD. Multivariate Cox-regression and Shapley value analysis assessed associations and relative contribution respectively on each diagnostic criterion influence on mortality. **Results:** A total of 20,510 individuals with SLD were included, with a median follow-up time of 113 months. DM increased mortality across the SLD spectrum, with a 63% increase (aHR: 1.63, 95%CI: 1.51-1.75, $P < 0.01$) in SLD, 61% (aHR: 1.61, 95%CI: 1.48-1.74, $P < 0.01$) in MASLD, 62% (aHR: 1.62, 95% CI: 1.29-2.03, $P < 0.01$) in MetALD, and 112% (aHR: 2.12, 95%CI: 1.58-2.85, $P < 0.01$) in ALD-predominant. Hypertension increased mortality by 37% (aHR: 1.37, 95%CI: 1.25-1.51, $P < 0.01$) in SLD, 38% (aHR: 1.38, 95%CI: 1.24-1.54, $P < 0.01$) in MASLD, and 48% (aHR: 1.48, 95%CI: 1.12-1.97, $P < 0.01$) in MetALD. Dominance analysis revealed hypertension as the strongest predictor of mortality across the SLD spectrum (52.83-69.16%), followed by DM (19.62-43.39%). **Conclusion:** This study highlights the association and relative contributions of key diagnostic factors to mortality across the SLD spectrum. DM and hypertension not only consistently increase mortality across SLD and its subtypes but also represent the predominant relative contributors to mortality risk. Alcohol intake most significantly affects MASLD and less on MetALD and ALD-predominant.

2524 | COMPREHENSIVE RISK ASSESSMENT OF GASTROINTESTINAL CANCER IN PATIENTS WITH MASLD, METALD, AND ALD

Nobuharu Tamaki[1] Takefumi Kimura[2] Shun-Ichi Wakabayashi[2] Naoki Tanaka[2] Namiki Izumi[1] Rohit Loomba[3] Masayuki Kurosaki[1], [1]Musashino Red Cross Hospital, [2]Shinshu University School of Medicine, [3]University of California, San Diego

Background: Steatotic liver disease (SLD), which includes metabolic dysfunction-associated SLD (MASLD), MASLD with increased alcohol intake (MetALD), and alcohol-associated liver disease (ALD), is recognized as a risk factor for gastrointestinal cancers. However, the comparative risk of gastrointestinal cancers among MASLD, MetALD, and ALD remains unclear. **Methods:** We conducted a nationwide, population-based cohort study involving 978,607 patients with MASLD, 366,152 with MetALD, 152,721 with ALD, and 4,884,398 control individuals. The primary outcome was the incidence of gastrointestinal cancers, including hepatocellular carcinoma (HCC), biliary tract cancer, esophageal cancer, gastric cancer, colorectal cancer, and pancreatic cancer. **Results:** Compared to controls, the adjusted hazard ratios (aHRs) for HCC were 4.47 (95% confidence interval [CI], 3.54–5.64) for MASLD, 3.55 (95% CI, 2.69–4.68) for MetALD, and 5.39 (95% CI, 3.96–7.35) for ALD. For biliary tract cancer, the aHRs were 1.66 (95% CI, 1.39–2.00) for MASLD, 1.45 (95% CI, 1.16–1.82) for MetALD, and 1.58 (95% CI, 1.17–2.12) for ALD. The risks of both HCC and biliary tract cancer were significantly elevated across all SLD subgroups compared to controls. For esophageal cancer, the aHRs were 0.75 (95% CI, 0.66–0.85) for MASLD, 1.28 (95% CI, 1.13–1.45) for MetALD, and 2.48 (95% CI, 2.18–2.83) for ALD. For gastric cancer, the aHRs were 1.00 (95% CI, 0.94–1.06) for MASLD, 1.09 (95% CI, 1.02–1.16) for MetALD, and 1.13 (95% CI, 1.03–1.24) for ALD. The aHRs for colorectal cancer were 1.26 (95% CI, 1.19–1.32) for MASLD, 1.44 (95% CI, 1.36–1.54) for MetALD, and 1.84 (95% CI, 1.70–1.99) for ALD. The risk of gastrointestinal cancers increased with higher levels of alcohol consumption, with the highest risk observed in the ALD group, followed by the MetALD group. The risk of pancreatic cancer was similar to that of controls in both the MetALD and ALD groups. **Conclusion:** Patients with SLD—including MASLD, MetALD, and ALD—have a significantly elevated risk of gastrointestinal cancers compared to controls. The degree of risk varies depending on the underlying liver disease subtype, particularly in relation to alcohol consumption. These findings underscore the need for risk-stratified cancer screening strategies in individuals with SLD.

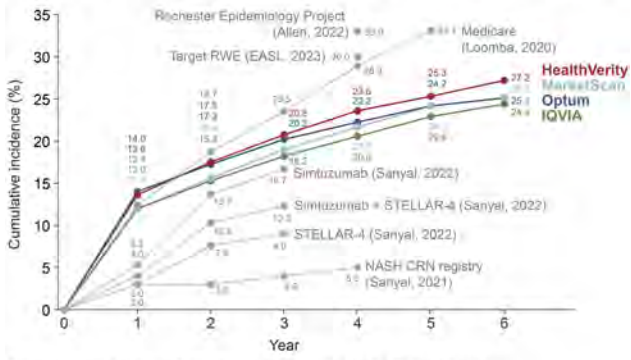
2525 | REAL-WORLD INCIDENCE OF LIVER DECOMPENSATION OR TRANSPLANTATION EVENTS IN PATIENTS WITH COMPENSATED METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS IN THE UNITED STATES

Steve Gao[1] Colin Anderson-Smits[1] Catherine Frenette[1] Lulu Wang[1] Fang Xia[1] Chunmay Fu[1], [1]Gilead Sciences, Inc., Foster City, CA, USA

Background: Patients with compensated cirrhosis (CC) due to metabolic dysfunction-associated steatohepatitis (MASH) or metabolic dysfunction-associated steatotic liver disease (MASLD) are at risk of decompensated cirrhosis. Decompensation events, liver transplantation (LT) and death are considered level-1 clinical endpoints for MASH/MASLD. This study used real-world data (RWD) to evaluate the incidence of and time to decompensated liver disease or LT in patients with CC in the US. **Methods:** This was a descriptive analysis of four databases (2007–2022): MarketScan (MS, n = 21,678), HealthVerity (HV, n = 42,472), Optum Clinformatics DataMart (OCDM, n = 23,267) and IQVIA PharMetrics (PM, n = 52,649). Eligibility criteria: 18–80 years old, MASH/MASLD, CC diagnosis $\leq$ 90 days before or after MASH/MASLD diagnosis, and $\geq$ 1 year of continuous enrollment before CC. Exclusion criteria: history of decompensated cirrhosis, alcohol-related liver disease, viral hepatitis, LT, hepatocellular carcinoma or other chronic liver disease causes. Primary outcome was the cumulative incidence of a composite of decompensated liver disease (variceal hemorrhage, hepatic encephalopathy, ascites or jaundice) or LT, by year 6. **Results:** The participants' median age (IQR) was 58 (13), 59 (14), 66 (16), and 57 (12) years in the MS, HV, OCDM, and PM databases, respectively. The proportion of males was 43%, 39%, 44%, and 49%, respectively. The proportion of patients with type 2 diabetes, portal hypertension, and non-bleeding esophageal varices were similar in MS (57%/12%/15%), HV (58%/12%/13%), and OCDM (57%/13%/14%) databases, but lower in the PM database (44%/6%/5%). There were 3066, 6695, 3564, and 9033 patients who experienced decompensated liver disease or LT in the four databases, respectively, with a mean follow-up duration of 1.4–2.5 years. The cumulative incidences by year 6 were 25.2% (MS), 27.2% (HV), 25.1% (OCDM) and 24.4% (PM) (Figure). **Conclusion:** Our estimates of decompensation events were higher than those reported in clinical trials, likely owing to differences in patient populations and outcome assessments. While our data are useful for informing future study design, limitations inherent to claims-based data (misclassifications, nonstandardized outcome definitions) should be considered. Prospective observational studies with defined sampling and clinical validation may yield more accurate incidence estimates.

Figure. Cumulative incidence of decompensated liver disease or LT over time in patients with CC in the MarketScan, HealthVerity, Optum ClinFormatics DataMart and IQVIA PharMetrics databases, compared with published studies.



CC, compensated cirrhosis; EASL, European Association for the Study of the Liver; LT, liver transplantation; NASH CRN, Clinical Research Network in Nonalcoholic Steatohepatitis; RWE, real-world evidence.

2526 | PREVALENCE AND ASSOCIATION OF LIVER STEATOSIS AND NON-ALCOHOLIC PANCREATIC STEATOSIS IN PATIENTS WITH HIGH CARDIOVASCULAR RISK

Eva Juárez-Hernández[1] Raúl Gómez-Mendoz[2] Vicente Toledo-Coronado[2] Javier Sánchez-Zavala[2] Graciela Castro-Narro[2] Iván López-Méndez[2], [1]Medica Sur Clinic and Foundation, [2]Medica Sur Clinic & Foundation

Background: In the last decade, the prevalence of metabolic-associated fatty liver disease (17-46%) and nonalcoholic fatty pancreas disease (NAFPD) (16-33%) has increased. The prevalence of obesity significantly affects the presence of liver and pancreatic steatosis in patients without excessive alcohol consumption and those with a high cardiovascular risk. Specific risk factors for pancreatic steatosis have not been fully described; thus, evaluating populations with a high cardiovascular risk, such as patients in coronary care units, could provide evidence regarding the prevalence of this condition and its relationship with cardiovascular risk. The aim of this study is to describe the prevalence and association of NAFPD and liver steatosis in patients with high cardiovascular risk. **Methods:** A retrospective review was conducted on the medical records of adult patients ($>$ 18 years) diagnosed with acute coronary syndromes who underwent a Computed Tomography (CT) scan at the Coronary Care Unit of a tertiary care private hospital in Mexico City. NAFPD was determined by the difference in pancreatic and splenic attenuation (-1.9), while hepatic steatosis was identified by hepatic attenuation $<$40 Hounsfield units. A logistic regression model was performed to estimate the odds ratio and 95% CI of factors associated with NAPFD in patients with high cardiovascular risk. **Results:** 106 medical records were collected, 69.8% (n = 74) were men, with a median age of 71 [IQR 65-85] years and 25.7 [IQR 22.9 – 28.2] kg/m2 of body mass index. According to the CT scans, 75.5% (n = 80) presented NAFPD, 35.8% (n = 38) had hepatic steatosis, and 34% (n = 36) had both. In the univariate analysis, dyslipidemia (OR 1.2 CI95% (1.0-1.5), p = 0.04), elevated levels of aspartate aminotransferase (AST) (OR 2.4 CI 95% (1.2-4.7), p = 0.02) and presence of liver steatosis (OR 6.5 CI95% (1.6-26.1), p = 0.001), shown association with NAPFD. Meanwhile, in multivariate analysis, hepatic steatosis, smoking, increased AST, and being overweight were independent factors associated with NAFPD (Figure 1). **Conclusion:** In a high cardiovascular-risk population, the prevalence of NAFPD is high, and it is independently associated with the presence of liver steatosis.

2527 | SEMAGLUTIDE TITRATION PATTERNS AMONG PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Samantha Clark[1] Dominic Nunag[1] Matthew Davis[1] Arushi Chadha[1] Nipun Atreja[2] Blake Thomas[2] Francis Lobo[2], [1]Medicus Economics, LLC, [2]Madrigal Pharmaceuticals, Inc.

Background: MASLD and its more progressive subtype, MASH, are chronic liver conditions. Progression to MASH is underdiagnosed in clinical practice. Subcutaneous (SC) semaglutide is being investigated for MASH in the ongoing ESSENCE clinical trial. Interim results indicate that 88% of participants followed the 16-week dose-escalation schedule and maintained a 2.4 mg target dose at 72-weeks of follow-up. We aim to assess alignment between real-world titration patterns and those observed in the ESSENCE trial among MASLD patients starting SC semaglutide for a currently approved indication. **Methods:** A retrospective cohort study including MASLD patients initiating SC semaglutide 2.4 mg (Wegovy®) from 2021-2024 was conducted in Optum Market Clarity data. The 12 months prior to the first SC semaglutide prescription claim (index date) served as the baseline period. Patients with other liver diseases (e.g., viral hepatitis) or severe complications from MASH (e.g., cirrhosis) were excluded. Patients

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

were followed for titration to a 2.4 mg SC semaglutide dose from their index date until death, dropout, or end of data availability. Kaplan-Meier (KM) curves illustrating titration probability and time-to-titration were constructed. **Results:** Of the 4,871 adults included in the final sample, 10.5% (n = 511) presented with type 2 diabetes. Mean (standard deviation) age was 47.2 (11.0) years and 68.0% (n = 3,313) were female, with a mean follow-up time of 59.3 weeks (33.1). Overall, 39.6% (n = 1,930) of patients titrated to 2.4 mg, with 17.5% (n = 852) doing so within 16 weeks, 39.0% (n = 1,902) doing so within 72 weeks, and a mean time-to-titration of 20.1 (15.6) weeks. Accounting for censoring, 17% (95% confidence interval (CI): 16%-19%) titrated by 16 weeks, 45% (95% CI: 43%-46%) titrated by 72 weeks, and 78% (95% CI: 77%-80%) discontinued within 72 weeks. Among the 1,930 patients who titrated, 34.4% (n = 663) subsequently discontinued and 16.8% (n = 325) subsequently reduced their dose. **Conclusion:** Less than 40% of MASLD patients titrated to a 2.4 mg SC semaglutide dose over the follow-up period, with only 17% doing so within 16 weeks and 78% discontinuing treatment within 72 weeks. Results are consistent with findings from similar observational studies and highlight the importance of monitoring SC semaglutide use patterns in a real-world setting. Further research is needed to assess the relationship between non-persistence and liver-related outcomes among patients prescribed GLP-1s.

2528 | MONITORING LIVER DISEASE PROGRESSION USING SERIAL TRANSIENT ELASTOGRAPHY ASSESSMENTS IN A LARGE REAL-WORLD COHORT OF PATIENTS WITH TYPE 2 DIABETES AND MASLD

Tiphaine Vidal-Trécan[1] Jean-Baptiste Julla[2] Yelena Schwartz[2] Helene Fontaine[3] Dominique Valla[3] Jean-Pierre Riveline[1] Jean-Francois Gautier[1] Laurent Castera[3], [1]Dept of Diabetology, Hopital Lariboisière, Paris, France, [2]Dept of Diabetology, Hopital Lariboisière, AP-HP, Paris, France, [3]Dept of Hepatology, Hopital Beaujon, AP-HP, Clichy, France

Background: Despite the recommendation to screen for MASLD and fibrosis in patients with type 2 diabetes mellitus (T2D), follow-up data is scarce. We examined the use of vibration-controlled transient elastography (VCTE) to monitor liver disease progression in a large real-world cohort of T2D outpatients with MASLD. **Methods:** A total of 1,518 patients with T2D and MASLD (steatosis and/or elevated ALT), who were seen at a tertiary diabetes clinic and underwent serial liver stiffness measurements (LSM) by VCTE between 2019 and 2024, were evaluated. The primary endpoint was the change in liver disease severity risk categories at follow-up: low (LSM < 8 kPa), intermediate (LSM 8-12 kPa), or high (LSM ≥ 12 kPa). The secondary endpoint was an increase in LSM of at least 30% at follow-up. A multivariate analysis was performed to identify factors independently associated with this increase. **Results:** The characteristics of the 1,518 patients were as follows: men 60.3%; median age 61 years [IQR 15]; diabetes duration 13 years [14]; BMI 28.9 kg/m² [6.9]; WC 103 cm [16]; HbA1c 7.5% [1.7]; LSM 5.6 kPa [3], and CAP 290 dB/m [78]). The median interval between two VCTE was 2.4 years [1.9]. The absolute median change during follow-up was -0.5 kPa [2.2] for LSM and -0.73 kg/m² [2.1] for BMI. At baseline, 1,178 patients (78%) were considered low risk, 235 (15%) intermediate risk, and 105 (7%) high risk. Changes in risk categories over time are shown in the Figure. At follow-up, 1,332 patients (88%) were in the low-risk category, while 111 (7%) in the intermediate risk, and 75 (5%) in the high risk. At follow-up, 1228 (81%) remained in the same risk group while 224 (15%) move to a lower risk category and 66 (4%) to a higher risk category. Of the 1,518 patients, 144 patients (9.5%) experienced an increase in LSM ≥ 30%, 1,046 (68.9%) had stable LSM, and 328 (21.6%) experienced a decrease in LSM ≥ 30%. Baseline age, diabetes duration, BMI, HbA1c and GGT levels were independently associated with an increase in LSM ≥ 30%. **Conclusion:** After 2.4 years of follow-up, most patients with T2D and MASLD remained in the same risk category according to LSM. Only a few patients (< 10%) displayed disease progression, which was associated with age, diabetes duration, BMI, HbA1c, and GGT levels.

Figure. LSM changes according to the 3 risk categories for advanced fibrosis (low (<8 kPa); intermediate (8 < < 12kPa); and high (>12 kPa) between baseline and follow-up (n=1,518).

2529 | IMPLICATIONS OF EXPANDED ADVANCED FIBROSIS SCREENING STRATEGIES FOR MASLD IN PRIMARY CARE

Kush Patel[1] Cecil Jnawali[1] Jingwen Zhang[1] Justin Marsden[2] Chloe Bays[1] Andrew Schreiner[1], [1]Medical University of South Carolina, [2]Medical Unversity of South Carolina

Background: Advanced fibrosis is associated with cirrhosis, cancer, and mortality in patients with metabolic dysfunction-associated steatotic liver disease (MASLD). Since MASLD is underdiagnosed in primary care, and diabetes mellitus type 2 (T2DM) is strongly associated with MASLD, the 2024 American Diabetes Association (ADA) guidelines recommend screening for advanced fibrosis in patients with T2DM and prediabetes using the Fibrosis-4 Index (FIB-4). We aimed to determine the proportion of primary care patients with T2DM and prediabetes who had FIB-4s at-risk for advanced fibrosis and required confirmatory testing. **Methods:** This cross-sectional study evaluated primary care patients with T2DM or prediabetes and a FIB-4 score between 2022 and 2024. The outcome of interest was a FIB-4 score in need of confirmatory fibrosis risk assessment. Univariate analyses were used to describe the cohort. Logistic regression models evaluated the association between T2DM and a FIB-4 score at indeterminate-risk or greater for advanced fibrosis. **Results:** Of 8,366 patients with T2DM and prediabetes, 2,064 (25%) had FIB-4s in need of confirmatory risk assessment. The expanded FIB-4 fibrosis screening for T2DM and prediabetes increased the number of patients needing confirmatory fibrosis risk assessment 9-fold compared to those with diagnoses of MASLD. Further, patients with T2DM were not more likely to have an indeterminate-risk or greater FIB-4 (OR: 0.86; 95% CI: 0.77-0.96) compared to those with prediabetes in the fully adjusted model. **Conclusion:** Expanded screening for advanced liver fibrosis would substantially increase the number of patients who need confirmatory testing for liver fibrosis, increasing cost and straining access.

Table 2. Cohort characteristics by FIB-4 advanced fibrosis risk (indeterminate-risk or greater) in need of confirmatory advanced fibrosis risk assessment (column percents).

Characteristics	Overall	FIB-4 Advanced Fibrosis Risk		p-value
		Indeterminate- or High-Risk	Low-Risk	
		n=2,064	n=6,302

2530 | IMPROVING ADVANCED FIBROSIS SCREENING AND REFERRALS FOR MASLD IN PRIMARY CARE

Alyssa Chen[1] Anna Mageras[2] Kelsey Bryant[1] Nikita Barai[1] Mayce Mansour[1] Eric Woods[1] Meena Bansal[3], [1]The Mount Sinai Hospital, [2]Icahn School of Medicine at

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Mount Sinai, [3]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: Patients with metabolic dysfunction-associated steatotic liver disease (MASLD) who develop advanced fibrosis are at increased risk for liver-related complications and mortality. [1] As new therapies emerge, screening at-risk patients and linking them to care is critical [2, 3] Liver, GI and Endocrine societies recommend screening for advanced liver fibrosis in patients living with Type 2 Diabetes (PWD) using the FIB-4 score. [4, 5] Primary care providers (PCPs) are uniquely positioned to have the greatest reach, but face multiple competing priorities. Clinical decision support (CDS) tools embedded into the electronic health record (EHR) can help streamline care and aid providers. This study aimed to identify barriers to screening and develop an intervention to increase screening and referrals for MASLD in PWD in the primary care setting. **Methods:** This single-site quality improvement evaluation included adult PWD seen by PCPs at Mount Sinai Internal Medicine Associates from April 2023 to April 2025. We conducted an anonymous survey to understand provider preferences and implemented a two-part intervention: (1) didactics on MASLD delivered to faculty and residents and (2) two EHR best practice advisories (BPAs). The first BPA prompted providers to order labs to calculate the FIB-4 score if unavailable. The second BPA was triggered when a patient was screened as intermediate or high risk by FIB-4, prompting referral to FibroScan. The BPAs were non-interruptive and visible only to providers during the primary care visit. We compared rates of FIB-4 score availability and appropriate referrals before and after the intervention using the Chi-Square test. **Results:** A total of 35 providers completed the survey. Common barriers were forgetting to screen and not knowing their PWD needed screening. Almost all providers (80%) agreed or strongly agreed that the EHR can help them screen better. Following implementation of didactics and BPAs, FIB-4 score availability increased by 32% (22.7% pre-intervention vs 29.9% post-intervention, $p < 0.0001$). Of the patients screened as intermediate and high risk, appropriate FibroScan referrals increased by 37% (8.6% pre vs 11.8% post, $p = 0.43$). **Conclusion:** Among PCPs, barriers to screening patients with T2DM for advanced liver fibrosis include forgetting to screen and not knowing that their patient was indicated for screening. An intervention combining education and CDS tools increased FIB-4 screening and appropriate FibroScan referrals.

2531 | TRENDS IN MORTALITY FROM METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE, CHRONIC KIDNEY DISEASE, AND DIABETES MELLITUS IN THE UNITED STATES, 1999-2020

Yash Hegde[1] Adnan Said[2], [1]University of Wisconsin Hospitals and Clinics, [2]University of Wisconsin School of Medicine and Public Health

Background: The incidence of metabolic dysfunction-associated steatotic liver disease (MASLD), chronic kidney disease (CKD), and diabetes mellitus (DM) has risen significantly in recent decades. This study aimed to investigate temporal trends in mortality from MASLD, CKD, and DM in the US from 1999-2020, and to identify demographic groups at higher risk. **Methods:** We analyzed deidentified data from the Centers for Disease Control and Prevention Wide-Ranging Online Data for Epidemiological Research (CDC WONDER) database on underlying causes of death in the United States from 1999 to 2020. Mortality attributable to MASLD, CKD,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and DM was determined using ICD-10 codes. Age adjusted mortality rates (AAMRs) per 100,000 population were calculated by race and sex, while crude mortality rates were used for age group comparisons. Temporal trends in mortality rates for MASLD, CKD, and DM were evaluated using linear regression. **Results:** From 1999-2020, MASLD and CKD related mortality rates increased, while DM related mortality declined. In 2020 men had higher AAMRs than women for CKD (10.8 vs 7.5) and DM (31.2 vs. 19.5), whereas women had higher MASLD related mortality (1.1 vs 0.7). The 75-84 age group had the highest crude mortality rates for MASLD (5.8), CKD (63.3), and DM (154.7). Hispanic individuals had higher AAMRs for MASLD (1.1 vs 0.9) and DM (39.1 vs 31.2) than non-Hispanic individuals. CKD mortality was similar across Hispanic and non-Hispanic groups (8.9). Black or African American individuals had the highest AAMRs for CKD (19.0) and DM (59.7), followed by American Indian, White and Asian or Pacific Islander (Figure 1). **Conclusion:** Mortality from MASLD and CKD has increased from 1999-2020, while DM related mortality declined. Notable disparities in mortality rates exist by sex, age, and race. These trends reflect the interconnected pathophysiology and shared risk factors among MASLD, CKD, and DM. The rising burden of MASLD, in particular, underscores its emerging role as both a consequence and driver of metabolic dysfunction, highlighting the urgent need for integrated strategies targeting liver and kidney health.

2532 | MULTIOMICS SIGNATURES OF ADIPOSITY AND ADVERSE LIVER OUTCOMES: A PROSPECTIVE COHORT STUDY

Longgang Zhao[1] Yun Chen[1] Jun Li[2] Tamar Taddei[3] Xiaomei Ma[4] Shuangge Ma[5] Deirdre Tobias[6] Edward Giovannucci[7] Howard Sesso[6] JoAnn Manson[6] Frank Hu[2] Xuehong Zhang[1], [1]Yale School of Nursing, [2]Harvard T.H. Chan School of Public Health, [3]Yale University, [4]Yale School of Medicine, [5]Yale School of Public Health, [6]Brigham and Women's Hospital and Harvard Medical School, [7]Harvard University Medical School

Background: Excess adiposity is a key risk factor for chronic liver disease (CLD), but the underlying metabolomic and proteomic mechanisms are unclear. We evaluated the association of excess adiposity and related metabolomic and proteomic signatures with the risk of adverse liver outcomes. **Methods:** We analyzed data from 450,412 UK Biobank participants (40-69 years at baseline). Adiposity was assessed by body mass index (BMI) and waist circumference (WC). CLD outcomes (metabolic dysfunction-associated steatotic liver disease [MASLD], cirrhosis, liver cancer, severe liver diseases [SLD, including hepatocellular carcinoma and other severe liver diseases], and CLD mortality) were ascertained from in-hospital records, cancer and death registries. We derived a novel metabolomic (NMR platform, 168 metabolites) and proteomic scores (Olink platform, 1459 proteins) related to BMI or WC using elastic net regression. We used Cox proportional hazards regression models to estimate hazard ratios (HRs) and 95% confidence intervals for the associations of the omic signatures with liver outcomes, adjusting for age, sex, ethnicity, Townsend deprivation index, alcohol drinking, smoking, physical activity, aspirin use, and history of diabetes. **Results:** After a median follow-up of 8.9 years, there were 4,077 cases of MASLD, 3,550 of cirrhosis, 755 of liver cancer, 2,253 of SLD, and 331 CLD deaths. Compared to participants with normal BMI (18.5-23.9 kg/m^2), obesity (BMI $\geq$ 30 kg/m^2) was positively associated with risk of all adverse liver disease outcomes. Central obesity showed similar magnitude. The BMI-related metabolomic (107 metabolites) and proteomic (116 proteins) scores were associated with higher risks of MASLD, cirrhosis, liver cancer, and SLD with HRs ranged from 1.18 to 2.26. The WC-related metabolomic (92 metabolites) and proteomic (116 proteins) scores were associated with higher risks of MASLD, liver cancer, and SLD with HRs ranged from 1.06 to 2.69. **Conclusion:** General and central obesity and their omic signatures were positively associated with long-term risk of liver diseases, revealing the molecular perturbations in metabolites and proteins associated with adiposity and liver health, which may inform the etiology and prevention of liver disease.

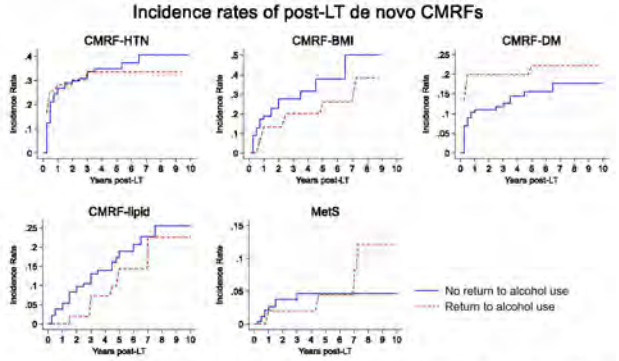
2533 | CARDIOMETABOLIC RISK FACTORS BEFORE AND AFTER EARLY LIVER TRANSPLANTATION FOR SEVERE ALCOHOL-ASSOCIATED HEPATITIS: AN ACCELERATE-AH STUDY

Matthew Dukewich[1] Neha Jakhete[2] Sheila Eswaran[3] Mohamed Shoreibah[4] Christine Hsu[5] George Therapondos[6] Ethan Weinberg[7] Manotri Chaubal[8] Adam Khalaf[8] Amol Rangnekar[9] Kirti Shetty[10] Cerise Kleb[2] Sevda Aghayeva[7] Ruona Ebial[6] Sameera Shuaibi[6] Chandler Shapiro[3] John Rice[11] Jessica Musto[11] R. Mark Ghobrial[12] Ashton Connor[13] Michael Lucey[11] Norah Terrault[14] Brian Lee[15], [1]University of Southern California- Keck Medicine, [2]University of Maryland, [3]Rush University Medical Center, [4]University of Alabama at Birmingham, [5]National Institute of Diabetes, Digestive, [6]Ochsner Medical Center, [7]University of Pennsylvania, [8]Georgetown University, [9]Georgetown University Hospital, [10]University of Maryland, Baltimore, [11]University of Wisconsin, [12]Houston Methodist JC Walter Transplant Center, [13]Houston Methodist, [14]University of Southern California, [15]Keck School of Medicine

Background: Early liver transplantation (ELT) for severe alcohol-associated hepatitis (AH) has increased significantly across the US. Data regarding cardiometabolic risk factors (CMRFs) in this population is a critical knowledge gap, representing a potentially important and intervenable driver of graft outcomes, given the synergistic effect of CMRFs with alcohol in the development and progression of steatotic liver disease. **Methods:** In this retrospective multi-center (9 US LT centers) cohort, we included consecutive LT recipients for clinically diagnosed severe AH between 2006-2021 and excluded those who did not survive to post-LT hospital discharge. *De novo* CMRFs during post-LT follow-up were defined according to the consensus SLD definition: 1) hypertension, if new diagnosis or new prescription of antihypertensives; 2) elevated BMI: if BMI $\geq$ 25 kg/m^2; 3) glucose intolerance, if new diagnosis of type II diabetes, new prescription of antidiabetic medications, or new A1c $\geq$ 5.7%; or 4) hyperlipidemia, if new diagnosis of hyperlipidemia or hypertriglyceridemia or new prescription of lipid-lowering therapy. Metabolic syndrome was defined as $\geq$ 3 CMRFs. Return to alcohol use was defined by first detection of any alcohol use post-LT. Multivariable Cox regression adjusted for age, sex, and MELD at LT was used to assess risk factors for development of *de novo* post-LT metabolic syndrome. **Results:** Among 310 included LT recipients (67% male, median age 43 years, median MELD-Na at LT of 37) with median post-LT follow-up of 4.4 years (IQR 1.5-7.0 years), 65 (20.6%) had pre-LT hypertension, 216 (68.4%) had elevated BMI, 27 (8.5%) had glucose intolerance, and 20 (6.3%) had hyperlipidemia. There was high post-LT incidence of *de novo* HTN (1 year: 26.2% [95%CI 21.1-32.5%]; 5 year: 32.2% [95%CI 26.0-39.3%]), BMI (1 year: 18.8% [95%CI 12.1-28.6%], 5 year: 33.8% [95%CI 23.5-47.0%]), glucose intolerance (1 year: 11.4% [95%CI 8.1-15.8%], 5 year: 15.4% [95%CI 11.2-21.0%]) and hyperlipidemia (1 year: 4.8% [95%CI 2.8-8.1%], 5 year: 18.2% [95%CI 13.1-24.8%]), while incidence of *de novo* metabolic syndrome was low (5 year: 4.9% [95%CI 2.7-8.8%]). These incidence rates differed by presence of return to any alcohol use post-LT (Figure). In multivariable analysis, active smoking at time of LT hospitalization (aHR 2.84, 95%CI 1.70-4.73) and African American race (vs. white race) (aHR 5.93, 95%CI 1.67-21.0) were associated with development of *de novo* post-LT metabolic syndrome. **Conclusion:** CMRFs (except being overweight) are relatively uncommon before ELT for AH, but development of *de novo* CMRFs after ELT is common and is influenced by return to alcohol use. Our findings highlight the importance of smoking cessation at time of LT and post-LT close monitoring and personalized interventions to prevent, identify, and treat CMRFs among ELT for AH recipients.

Figure. Incidence rates of post-LT *de novo* cardiometabolic comorbidities



BMI: body mass index; DM: diabetes mellitus; HLD: hyperlipidemia; HTN: hypertension; MetS: metabolic syndrome

2534 | EVALUATING THE ASSOCIATION OF PATIENT CHARACTERISTICS ON EMERGENCY DEPARTMENT USE AMONG A COHORT OF CANADIAN MASLD PATIENTS IN PRIMARY CARE

Elizabeth Baguley[1] *Juan Abraldes*[2] *Seungwon Lee*[1] *Abdel-Aziz Shaheen*[1], [1]*University of Calgary,* [2]*University of Alberta*

Background: Limited literature exists when examining emergency department (ED) use among Canadian primary care patients enrolled in a metabolic-associated steatotic liver disease (MASLD) risk-stratification pathway. We aimed to identify patient characteristics associated with ED use post-pathway enrollment. **Methods:** Adult patients enrolled in the Calgary MASLD risk-stratification pathway from March 2017-June 2022 were included (n = 12,070). The National Ambulatory Care Reporting System database was linked to the Calgary MASLD pathway database to capture ED visits from pathway entry to March 31st, 2023. Primary ED cause was defined by the first diagnostic code. Multivariable negative binomial models were used to calculate the estimated adjusted incidence rate ratio (aIRR) of overall, liver- and cardiovascular-related ED visits, with a time offset function. Model covariates included age (> = 54 vs. < 54 years), sex (male vs. female), diabetes status (yes vs. no), rural status (rural vs. urban), body mass index (BMI) (> = 30 vs. < 30 kg/m^2), Charlson Comorbidity Index (CCI) (> = 3 vs. < 3), and liver stiffness measurements (LSM) by shear wave elastography (> = 8 vs. < 8 kPa). **Results:** Patients mean age was 53.1 ± 13.3 years, and 51.9% were female. After covariate adjustment, age > = 54 (aIRR: 0.87 [95% CI: 0.81-0.94], p < 0.001), male sex (0.81 [0.76-0.87], p < 0.001), diabetes (1.17 [1.08-1.27], p < 0.001), rural residence (2.04 [1.80-2.32], p < 0.001), BMI > = 30 kg/m^2 (1.22 [1.14-1.32], p < 0.001), CCI > = 3 (1.17 [1.14-1.19], p < 0.001), and LSM > = 8kPa (1.25 [1.12-1.41], p < 0.001) were significantly associated with overall ED use, Figure 1. For liver-related ED use, LSM > = 8kPa (aIRR: 14.62, 95% CI: 5.34-40.08, p < 0.001) was the only variable significantly associated with use. However, cardiovascular-related ED use was significantly associated with age > = 54 (aIRR: 1.82, 95% CI: 1.47-2.26, p < 0.001), male sex (1.23 [1.00-1.51], p = 0.046), diabetes (1.66 [1.35-2.05], p < 0.001), rural residence (1.49 [1.06-2.09], p = 0.023), CCI > = 3 (1.21 [1.16-1.27], p < 0.001), and LSM > = 8kPa (1.58 [1.19-2.10], p = 0.002). **Conclusion:** Demographic and clinical characteristics of MASLD patients in primary care were significantly associated with both overall and condition-specific ED use. This highlights the importance of managing metabolic risk factors and improving access to care in patients with MASLD within the primary care setting.

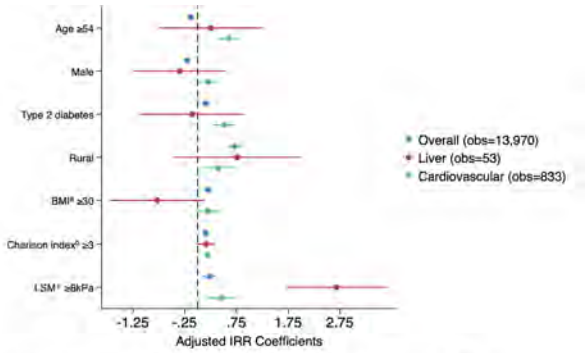

Figure 1. Adjusted Incidence Rate Ratio (aIRR) Coefficients for Emergency Department Admission Type

a. Body mass index
b. Charlson index excluded liver-related points (mild liver disease [+1], moderate to severe liver disease [+3]) and diabetes-related points (diabetes without complications [+1], diabetes with end organ damage [+2])
c. Liver stiffness measurement

2535 | AN INNOVATIVE SCREENING AND TREATMENT PATHWAY FOR METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE: THE UK-CURES APPROACH

Lindsey Sheehan[1] Christian Rhudy[1] Francis Lobo[2] Doug Welch[2], [1]UK HealthCare, [2]Madrigal Pharmaceuticals

Background: Metabolic-associated steatotic liver disease (MASLD) and its subtype metabolic-associated steatohepatitis (MASH) are the most common liver diseases in the United States, affecting an estimated 75-100 million people. There are few routinized screening and treatment pathway models for MASLD/MASH, leading to underdiagnosis and undertreatment. The Steatosis-Associated Fibrosis Estimator (SAFE) score could be used to identify high risk individuals in need of intervention. This project will characterize SAFE scores of a University of Kentucky HealthCare (UKHC) primary care patient population and how they are used to inform development of a screening and treatment pathway. **Methods:** This is an observational, single center, cross-sectional study including patients between 18 and 80 years of age with primary care encounters at an eligible UKHC clinic between 1/1/2024 and 5/22/2024. Patients with a history of hepatitis B or C; alcohol use disorder (AUD); conditions that may falsely elevate a SAFE score (e.g. chronic idiopathic thrombocytopenia, leukemias, other hepatic disease); or insufficient data to calculate a SAFE score are excluded. Eligible patients are classified as having a SAFE ≥ 100, and differences in demographics, medical history and laboratory study data were compared between groups. Categorical data has been analyzed using Chi-square test or Fisher exact test, while numeric variables have been assessed using Mann-Whitney U test as appropriate. **Results:** Of 10,550 patients eligible for inclusion, 6,339 are excluded (hepatitis B/C n = 254; AUD n = 496; false elevation n = 120; missing data n = 5,469). In 4,211 included patients, 831 (19.7%) have a SAFE ≥ 100. In this analysis, patients with SAFE ≥ 100 are more frequently male (n = 377, 45.4%; SAFE < 100 n = 1,319, 39%; $p < 0.0001$), Black or African American (n = 206, 24.8%; SAFE < 100 n = 539, 16%; $p < 0.0001$) with Medicare insurance (n = 465, 56%; SAFE < 100 n = 762, 22.5%; $p < 0.0001$). Comorbid cardiovascular disease are more common in SAFE ≥ 100 patients (n = 317, 38.2%; SAFE < 100 n = 536, 15.9%; $p < 0.0001$). 242 (29.1%) of patients with SAFE ≥ 100 have current or historic orders for glucagon-like peptide-1 receptor agonists. **Conclusion:** Significant differences in demographics and clinical attributes are observed between patients with SAFE ≥ 100 and SAFE < 100. Patients with SAFE ≥ 100 are eligible for further workup to identify and link to treatment for MASLD/MASH, highlighting an opportunity to improve screening and initiate appropriate therapy.

2536 | GLP-1 RECEPTOR AGONISTS USE IS ASSOCIATED WITH LOWER LIVER- AND CARDIAC-RELATED EVENTS IN PATIENTS WITH MASH CIRRHOSIS WITH TYPE 2 DIABETES: A MULTINATIONAL ANALYSIS

Do Han Kim[1] Donghyun Ko[2] Christina Lee[3] Paul Kroner[4] Frank Lukens[5] Donghee Kim[6] Vincent Chen[7] Karn Wijarnpreecha[8] Meena Bansal[9] Raffi Karagozian[3], [1]Department of Medicine, Mount Sinai Morningside and West, Icahn School of Medicine at Mount Sinai, [2]Department of Medicine, Bridgeport Hospital, Yale New Haven Health, Bridgeport, CT, USA, [3]Division of Gastroenterology and Hepatology, Tufts University School of Medicine, Boston, MA, [4]Department of Gastroenterology, Riverside Health System, Newport News, VA, USA, [5]Division of Gastroenterology and Hepatology, Mayo Clinic Florida, Jacksonville, FL, USA, [6]Stanford University Medical Center, [7]University of Michigan Medical Center, [8]University of Arizona College of Medicine-Phoenix, [9]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: The therapeutic landscape for metabolic dysfunction-associated steatohepatitis (MASH) and cirrhosis is evolving with the emergence of glucagon-like peptide-1 receptor agonists (GLP-1RAs) and sodium-glucose co-transporter 2 (SGLT2) inhibitors. Both classes have independently demonstrated survival and organ-specific benefits, including favorable cardiovascular and hepatic outcomes. However, comparative data in patients with MASH cirrhosis are limited. This study evaluates clinical outcomes in patients with MASH cirrhosis and type 2 diabetes (T2D) treated with either GLP-1RAs or SGLT2 inhibitors. **Methods:** We conducted a retrospective cohort study using the TriNetX global federated health research network. Adult patients with MASH cirrhosis and concurrent T2D were identified and stratified based on GLP-1RA or SGLT2 inhibitor use. Propensity score matching (1:1) was performed, balancing for demographics, comorbidities, and concomitant medications. Outcomes included all-cause mortality, hepatic decompensation, major adverse liver outcomes (MALO) and its components (ascites, hepatic encephalopathy, variceal bleeding, and liver transplant), major adverse cardiovascular events (MACE), as well as renal and cancer-related outcomes. Hazard ratio (HR) and 95% confidence intervals (95%CI) were calculated to quantify the associations between variables. **Results:** A total of 12,206 adult patients with MASH cirrhosis and concurrent T2D were identified, of whom 6,586 (54.0%) were on GLP-1 RA. After matching, 4,610 patients on GLP-1 RA (mean age 62.6 years, 56.9% female) were compared to 4,610 on SGLT2 inhibitors (mean age 62.7 years, 56.8% female). GLP-1 RA therapy was associated with significantly lower risk of hepatic decompensation (HR:0.86, 95%CI: 0.79-0.93), MALO (HR:0.87, 95%CI: 0.81-0.94), ascites (HR:0.85, 95%CI: 0.78-0.93), hepatic encephalopathy (HR:0.91, 95%CI: 0.82-0.99), and MACE (HR:0.86, 95%CI: 0.79-0.93). No significant differences were observed in all-cause mortality, kidney- and cancer-related outcomes. **Conclusion:** In patients with MASH cirrhosis and T2D, GLP-1 receptor agonists are associated with superior hepatic and cardiovascular outcomes compared to SGLT2 inhibitors. These findings support the potential of GLP-1RAs as a preferred therapeutic option in this high-risk population. Nonetheless, clinical decision-making should remain individualized, as tolerability and side effect profiles must be carefully considered.

Outcomes of GLP-1 RA versus SGLT2 Inhibitor Use in Patients with MASH Cirrhosis and Type 2 Diabetes

	GLP-1 RA		SGLT2 Inhibitor		HR (95% CI)
Outcomes	Included	Events	Included	Events	
Mortality	4,584	506	4,588	527	0.92 (0.81, 1.03)
Hepatic decompensation	4,610	1,198	4,610	1,309	**0.86 (0.79, 0.93)**
MALO	4,610	1,360	4,610	1,461	**0.87 (0.81, 0.94)**
Ascites	4,610	868	4,610	963	**0.85 (0.78, 0.93)**
Encephalopathy	4,610	780	4,610	814	**0.91 (0.82, 0.99)**
Variceal bleeding	4,610	213	4,610	240	0.85 (0.70, 1.02)

2537 | INCREASING PREVALENCE OF CHRONIC LIVER DISEASE IN THE U.S.: A STATE-LEVEL AND LIVER DISEASE ETIOLOGY-SPECIFIC MODELING STUDY

Michael Le[1] Sovann Linden[1] Etienne Lefranc[1] David Le[1] Thomas Baez[2] Isaac Le[1] Mindie Nguyen[1], [1]Stanford University Medical Center, [2]William Beaumont Army Medical Center

Background: The prevalence of chronic liver disease in the United States (USA) has evolved over the last two decades. With ongoing public health funding cuts in the U.S., granular state-level data are necessary for informing resource allocation and public policy at the local and national level. This current study aimed to estimate the state-level prevalence of chronic liver disease (CLD) in the U.S. using small area estimation techniques. **Methods:** We utilized data from three sources: the National Health and Nutrition Examination Survey (NHANES), CDC Wide-ranging Online Data for Epidemiologic Research (WONDER), and the American Community Survey (ACS). In short, age, sex, ethnicity, and Hispanic-origin specific prevalence, cause-specific mortality, and population data were gathered from each dataset and synthesized in a small area estimation model (Figure 1). The Fay-Herriot technique was applied, using NHANES-based direct prevalence estimates and mortality-based auxiliary data to generate yearly state-level CLD prevalence estimates. **Results:** From 1999 to 2020, national CLD prevalence increased from 28.6% to 36.6% ($p < 0.001$) primarily driven by a rise in metabolic dysfunction-associated steatotic liver disease (MASLD) from 23.1% to 32.7% ($p < 0.001$). Chronic hepatitis C (CHC) decreased sharply from 1.8% to 0.9% ($p = 0.01$). Chronic hepatitis B (CHB) and alcohol-associated liver disease (ALD) remained stable at 0.2-0.4% and 3-4% respectively ($p > 0.05$). Small area estimates in 2020 revealed highest burden of MASLD was in Indiana, West Virginia, and the Western states especially Idaho, Nevada, Arizona, and New Mexico. Meanwhile, the prevalence of ALD was concentrated mostly in the South and Southwest, with highest prevalence in Arizona, Indiana, North Carolina, and Alabama. The prevalence of CHB was low across the United States with no notable geographic pattern. The prevalence of CHC was concentrated in the Southern region, with the highest prevalence in Louisiana, Alabama, Georgia, and South Carolina (Figure 1). **Conclusion:** Using data from multiple population-based databases, this study provides updated granular, state-level insights into the evolving epidemiology of CLD in the U.S. These findings offer valuable insights to guide policy makers in making evidence-based decisions regarding resource allocation and public health policy to combat the growing burden of CLD.

2538 | ASSOCIATION OF CARDIOMETABOLIC RISK FACTORS WITH CLINICAL OUTCOMES IN PATIENTS WITH ALD- A RETROSPECTIVE STUDY

Ravi Nishad[1] Babu Meena[1] Ravinder Singh[1] Shasthry SM[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences

Background: Alcoholic hepatitis and cirrhosis are leading causes of liver-related morbidity and mortality, with cardiometabolic risk factors (CMRFs) playing a crucial role in disease progression and outcomes. In this retrospective study, we reviewed the electronic data of patients presented between 2018-2023. We aimed to evaluate the prevalence and association and impact of CMRFs in patients diagnosed with alcoholic hepatitis and cirrhosis. **Methods:** A total of 1,951 patients (1,906 males) were enrolled. Out of these 482 patients had alcoholic hepatitis and 1,469 with cirrhosis. The presence of CMRFs, including obesity, type 2 diabetes mellitus (T2DM), hypertension (HTN), hypertriglyceridemia, and low high-density lipoprotein (HDL), was assessed. **Results:** CMRFs were present in 71% of patients. Among those with alcoholic hepatitis, 71.25% had ≥ 1 CMRF, most commonly obesity (67.4%) and diabetes (46.1%). Mortality was high: 39% died during initial admission, and 24.5% during follow-up. While 18.3% were readmitted but survived, another 18.3% had no readmission. Non-survivors had significantly worse liver function: total bilirubin (20.5 $\pm$ 10.3 mg/dL), and INR (2.62 $\pm$ 1.08) (p

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

< 0.001). Renal dysfunction markers-urea (64.1 ± 51.3 mg/dL) was strongly associated with mortality (p < 0.001). Kaplan-Meier analysis showed significantly lower survival in those with CMRFs versus without CMRF (81% vs 58%, p < 0.001), particularly obesity, hypertension, and hypertriglyceridemia (p < 0.001). Among patients with alcohol associated liver cirrhosis, 70.7% had ≥ 1 CMRF, again most commonly obesity (62.3%) and diabetes (44.4%). Index admission mortality was 15.6%, with 27.5% dying during follow-up. Of the remainder, 27.6% required readmission and survived, while 29.3% had no further admission. Multivariate Cox regression showed CMRFs were independent predictors of mortality (HR 3.84, CI- 2.56 - 5.75, p < 0.001), with hypertension (HR1.56, CI 1.14 - 2.12, p = 0.005) and hypertriglyceridemia (HR 2.00, CI 1.336 - 3.001, p = 0.001) further increasing risk. Kaplan-Meier analysis confirmed significantly poorer survival with multiple CMRFs (p < 0.001). **Conclusion:** CMRFs significantly worsen outcomes in alcoholic hepatitis and alcohol-associated liver cirrhosis, increasing mortality and readmissions. Obesity, T2DM, hypertension, hypertriglyceridemia, and low HDL are key risk factors. Patients of ALD with CMRFs need closer monitoring and triage for improving outcomes.

2539 | DURATION OF TYPE 2 DIABETES MELLITUS IMPACTS DEVELOPMENT OF FIBROSIS IN LEAN VS OBESE METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE

Rajan Vijayaraghavan[1] Archana Rastogi[1] GURESH KUMAR[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences, New Delhi

Background: Metabolic dysfunction associated steatotic liver disease (MASLD) and diabetes mellitus (T2DM) are increasingly prevalent, with differing progression in obese MASLD vis-à-vis lean MASLD. Duration of T2DM and development of liver related events is known, however impact of T2DM duration in fibrosis development across different BMI categories is unknown. We aim to determine the association of duration of T2DM and development of fibrosis in obese and lean or overweight MASLD. **Methods:** Patients of T2DM and suspected liver disease and who underwent liver biopsy were prospectively enrolled. T2DM was defined as patients on anti-diabetic medication or HbA1c > 6.5%. All baseline parameters including BMI, biochemical parameters and liver stiffness by transient elastography (LSM) and controlled attenuation parameter (CAP) were assessed. Patients were categorized into BMI > = 25 (grA, obese MASLD) and BMI < 25 (grB, Lean/ overweight MASLD). Duration of T2DM was noted for each patient. Primary objective was to assess the association of 'diabetes duration' with grade of fibrosis in the groups. **Results:** A total of 162 patients (grA, n = 120, 74.1%; grB, n = 42, 25.9%) were enrolled with comparable baseline parameters (grA vs grB, age-49.5 ± 10.9 vs 49.4 ± 3.3; LSM-22.8 ± 16.3 vs 20.4 ± 14.3, p = 0.44; CAP-295 ± 42.6 vs 277 ± 46.2, p = 0.08), and Fib-4-2.85 ± 1.59 vs 2.35 ± 1.19, p = 0.18). The mean BMI was 29.7 ± 3.58 (grA) vs. 23.5 ± 1.33 (grB), p < 0.001) and serum triglycerides were high in non-obese patients (141 ± 63.3 vs 190 ± 56.6, p = 0.09). The histological spectrum was comparable for grade of inflammation (NAS > = 4, 56.7% vs 42.8%, p = 0.23) and stage of fibrosis (p = 0.89). The median T2DM duration was longer for development of advanced fibrosis (F3 fibrosis) in lean patients compared to obese patients [F3 fibrosis, grA median (IQR) 2.75 (2-5.0 yrs) vs grB 6.0 (5.5-11 yrs), p = 0.005; for F4 fibrosis, grA- 3.0 (2-7.75 yrs) vs grB-8.5 (2.5-11.5 yrs), p = 0.09]. On KM analysis, the cumulative development of significant fibrosis and advanced fibrosis was significantly higher in obese MASLD (> = F2 fibrosis, at 5-year, 62% vs 34%, at 10-year, 79% vs 62%, p = 0.014; > = F3 fibrosis, at 5-year, 59% vs 24%, at 10-year, 84% vs 70%, p = 0.017, fig1). **Conclusion:** Obese MASLD patients with T2DM develop fibrosis with a shorter diabetes duration compared to lean MASLD patients. More robust screening in obese MASLD patients with T2DM is required as they are metabolically different compared to lean or overweight MASLD patient.

2540 | ASSOCIATIONS BETWEEN PER- AND POLYFLUOROALKYL SUBSTANCES (PFAS) AND METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) IN CHILDREN AND YOUNG ADULTS

Shiwen Li[1], [1]University of Southern California

Background: Longitudinal studies on associations between per- and polyfluoroalkyl substances (PFAS) exposure and metabolic dysfunction-associated steatotic liver disease (MASLD) are limited, particularly among children and young adults. **Methods:** We evaluated two cohorts spanning distinct age ranges. In the Study of Latino Adolescents at Risk of Type 2 Diabetes (SOLAR), we followed children aged 8–13 years for 8 years (n = 74 at baseline; n = 88 at follow-up). In the Metabolic and Asthma Incidence Research (Meta-AIR) study, we assessed young adults aged 17–23 years (n = 122 at baseline). MASLD was defined as hepatic fat fraction > 5% on MRI plus ≥ 1 cardiometabolic risk factor. Eight PFAS were quantified in plasma by liquid chromatography–high-resolution mass spectrometry. Logistic regression models estimated associations between baseline PFAS levels and MASLD, incorporating an interaction term for PFAS and baseline age. **Results:** In SOLAR, cross-sectional analyses demonstrated that age modified the association of PFOA and PFNA with MASLD (p-interaction < 0.05). Longitudinally, one ng/mL increase in baseline PFOA was associated with 49% higher odds of MASLD (OR 1.49; 95% CI 1.00-2.23). No significant PFAS–MASLD associations were observed in Meta-AIR. **Conclusion:** Baseline PFOA exposure was linked to increased MASLD risk in children, both cross-sectionally and over time, with evidence that age amplifies susceptibility to PFOA and PFNA.

2541 | COST-EFFECTIVENESS OF SEMIANNUAL HEPATOCELLULAR CARCINOMA SURVEILLANCE (HCC) IN PATIENTS WITH METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) WITHOUT CIRRHOSIS: A MARKOV MODELING STUDY

Joanne Liu[1] Sovann Linden[1] Malvyn Lai[1] Xinrong Zhang[1] Ramsey Cheung[2] Rui Huang[1] Taotao Yan[1] Mindie Nguyen[1], [1]Stanford University Medical Center, Stanford, California, USA, [2]Palo Alto Veterans Affairs Health Care System, Palo Alto, CA, USA

Background: HCC is a leading cause of mortality in people with MASLD. HCC risk in people with MASLD and cirrhosis is well established, and routine HCC surveillance is recommended. A substantial proportion of MASLD-related HCC also occurs in MASLD patients without cirrhosis, but routine HCC surveillance is currently not recommended for this group. Cirrhosis is also often unrecognized (up to 40% in prior real-world studies), adding further challenges. HCC surveillance for the overall population with MASLD without cirrhosis is not cost-effective, but cost-effectiveness data based on other established risk factors such as age and sex are limited. Therefore, we aimed to fill in this gap. **Methods:** Based on a surveillance strategy of semiannual ultrasound and AFP test, a Markov model simulating a cohort of 100,000 patients with non-cirrhotic MASLD was constructed, with a 1-year cycle length. The primary study outcome was incremental cost-effectiveness ratio (ICER), with a willingness-to-pay (WTP) threshold of $100,000 per quality-adjusted life years (QALY) gained. Model inputs included age-dependent transition rates between health states, surveillance adherence, and HCC stage distribution that determined the percentage of patients assigned to early, intermediate and late-stage HCC upon diagnosis, as per published data, expert opinion, and/or large national databases. The rate of undiagnosed cirrhosis among people with MASLD of 25% was used for main analyses with sensitivity analyses performed for rates of 20% and 30%. Both costs and QALYs were discounted at an annual rate of 3%. **Results:** HCC surveillance was not cost-effective in the overall MASLD cohort (ICER: $131,598) or for either the overall male (ICER: $110,732) or female (ICER: $192,764) (Table). However, HCC surveillance was cost-effective among males aged ≥60 years (ICER: $78,488) in main as well as sensitivity analyses with undiagnosed cirrhosis rate of 20%. For females ≥60 years, ICER was above WTP threshold at $105,287 but below threshold at $95,827 in sensitivity analyses using undiagnosed cirrhosis rate of 30%. **Conclusion:** Semiannual HCC surveillance using ultrasound and AFP test is cost-effective in males 60 years or older and near WTP threshold for females 60 years or older.

Table 1: ICERs for the overall cohort and subgroups by sex and age, stratified by percent undiagnosed cirrhosis.

Percent Undiagnosed Cirrhosis	Overall	All Male	All Female	Male ≥60 years	Male <60 years	Female ≥60 years	Female <60 years
20%	162,658	126,868	274,058	84,556	296,161	124,965	117,017,011
25%	**131,598**	**110,732**	**192,764**	**78,488**	**200,859**	**105,287**	**573,331**
30%	115,118	100,713	157,931	73,996	162,932	95,827	333,289

2542 | DETERMINANTS OF HEPATIC STEATOSIS AMONG BALTIMORE PWID

Redeat Assefa[1] Jacquie Astemborski[1] Jacqueline Rudolph[1] David Thomas[1] Shurti Mehta[1] Gregory Kirk[1], [1]Johns Hopkins University

Background: Hepatic steatosis is an increasingly important comorbidity with a prevalence of 24% in the USA. However, the prevalence, associations and its interplay with substance use patterns is unclear among people who inject drugs (PWID). We investigated among PWID hepatic steatosis determinants and whether they are influenced by cocaine use. **Methods:** The study included 1,267 adults enrolled in the ALIVE (AIDS Linked to the Intravenous Experience) study with validated liver elastography measurements between January 2017 and February 2020. Hepatic steatosis was assessed using vibration-controlled transient elastography (VCTE) with controlled attenuation parameter (CAP) measured by the FibroScan device, with CAP $\geq$248 dB/m indicating significant (>5%) steatosis. Covariates examined included age, sex, race, current injection drug use, HCV RNA levels, liver stiffness, metabolic risk factors (waist circumference, blood pressure, diabetes, and serum cholesterol), HIV viral load, CD4 count, and ART regimen. Statistical analyses were performed using Generalized Estimating Equation (GEE) logistic regression, stratified by recent cocaine use. **Results:** Among 1267 people at baseline, the median age was 55 years. Most were Black (77%), male (68%), and HIV-negative (72%). 431(34%) had CAP $\geq$248. Measures of adiposity and metabolic risk factors were major determinants of hepatic steatosis, with a strong dose-response relationship that appeared to be enhanced by cocaine use. Among recent cocaine users, steatosis risk increased with 1 (aOR = 3.41, 95% CI: 2.13, 5.46), 2 (aOR = 6.68, 95% CI: 4.11, 10.85), and $\geq$3 (aOR = 13.50, 95% CI: 7.99, 22.80) metabolic risk factors versus none. Smaller associations were observed among PWID not using cocaine: 1 (aOR = 2.01, 95% CI: 1.35, 2.99), 2 (aOR = 3.91, 95% CI: 2.60, 5.89), and $\geq$3 (aOR = 8.73, 95% CI: 5.65, 13.50) risk factors. Current IV drug use (aOR = 0.68; 95% CI: 0.54-0.84) and detectable HCV RNA (aOR = 0.65; 95% CI: 0.50-0.85) were inversely associated with hepatic steatosis. No strong association was detected with alcohol use (aOR = 0.96; 95% CI:0.77-1.19) or HIV with viral load undetected (aOR = 0.84; 95% CI: 0.67-1.05). Neither did we detect significant changes in median CAP scores (dB/m) in PWID with changes in HIV viral load detectability: 211 (179–241) for consistently detectable, 213 (172–263) for undetectable-to-detectable, 224 (193–259) for detectable-to-undetectable, and 227 (193–274) for consistently undetectable viral loads across paired visits. **Conclusion:** A high prevalence of hepatic steatosis was observed among PWID, despite the protective effect of ongoing HCV infection. Metabolic factors chiefly contributed, with a clear dose-response relationship that may be exacerbated by cocaine use.

2543 | RACIAL DISPARITIES IN MAESTRO-NAFLD-1: A GEOGRAPHIC AND DEMOGRAPHIC ANALYSIS OF A PHASE 3 TRIAL FOR RESMETIROM

Rahul Thakkar[1] Neel Shah[1] Erik Rahimi[1], [1]Baylor Scott & White Health

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD), formerly non-alcoholic fatty liver disease (NAFLD), is a leading cause of chronic liver disease in the United States, with disproportionate prevalence and outcomes across racial and ethnic groups. While Hispanic Americans have the highest rates of NAFLD, Black and Asian populations are at increased risk for advanced liver disease and underdiagnosis. Ensuring that clinical trials reflect these affected populations is essential to equitable and generalizable therapeutic development. **Methods:** We evaluated demographic

representation in MAESTRO-NAFLD-1 (NCT04197479), a completed Phase 3 trial of resmetirom, using ClinicalTrials.gov site data and U.S. Census 2020 demographics. Trial site ZIP codes were matched to corresponding counties, and racial and ethnic participant distributions were compared to aggregated trial county and national data. **Results:** Among 1,113 participants at 77 U.S. trial sites, 88.8% identified as White, compared to 46.6% in trial counties and 61.6% nationally. Black participants comprised only 6.3% of the cohort, despite representing 14.7% of trial county populations and 12.4% nationally. Asian participants made up 2.1% of the trial but 8.3% of trial counties. Hispanic participation was 33.9%, closely aligned with trial counties (32.5%) and notably exceeding the national average (18.7%), reflecting commendable outreach to this high-burden group. **Conclusion:** MAESTRO-NAFLD-1 demonstrates meaningful inclusion of Hispanic individuals, a population disproportionately affected by MASLD. However, the underrepresentation of Black and Asian participants relative to trial site communities highlights ongoing gaps in equitable enrollment. Building on the success of Hispanic engagement, future MASLD trials should adopt broader equity-focused recruitment strategies to ensure trial populations reflect the full racial and ethnic diversity of those affected—thereby improving the generalizability and fairness of therapeutic development.

2544 | IMPACT OF CIRRHOSIS ETIOLOGY ON OUTCOMES AFTER TIPS: A NATIONAL COHORT STUDY

Gurmehr Brar[1] Brian Lee[2], [1]University of Southern California, [2]Keck School of Medicine

Background: Transjugular intrahepatic portosystemic shunt (TIPS) is an effective intervention for portal hypertension, but whether its benefits in alcohol and viral-associated cirrhosis differ in metabolic-dysfunction associated steatotic liver disease (MASLD) has been identified as a knowledge gap. We aimed to (i) characterize outcomes by cirrhosis etiology at 90 days and 1 year following TIPS and (ii) identify demographic and clinical features associated with post-TIPS outcomes. **Methods:** Using a national health system database between 2008-2023, we performed multivariable competing risk analysis by cirrhosis etiology with a primary outcome of overall mortality and competing risk of transplant. Competing risk regression was done using the Fine Gray model. **Results:** 2,846 patients with cirrhosis underwent TIPS (median age 63 [IQR 56-71], 61% male, 74% non-Hispanic White). Probability of transplant-free survival post-TIPS was 84.3% (95%CI 80.3-88.3) at 90 days and 72.1% (95%CI 67.2-77.0) at 1 year with MASLD, versus ALD (78.5% [95%CI 76.7-80.3] at 90 days, 68.7% [95%CI 66.7-70.8] at 1 year), viral hepatitis (78.5% [95%CI 75.6-81.4] at 90 days, 69.1% [95%CI 62.8-75.5] at 1 year), and other etiologies (76.4% [95%CI 73.5-79.4] at 90 days, 62.7% [95%CI 57.7-67.8] at 1 year). In multivariable competing risk analysis, MASLD (vs ALD) was associated with decreased mortality at 90 days (sHR 0.59[95CI 0.42-0.83]) and 1 year (sHR 0.76[95CI 0.60, 0.97]) post-TIPS, and similar to viral hepatitis and other etiologies. Younger age and more recent year undergoing TIPS were associated with decreased survival, whereas pre-TIPS ascites, hepatic encephalopathy, and increasing Charlson Comorbidity Index score were associated with increased mortality at 90 days and 1 year post-TIPS. **Conclusion:** TIPS is associated with excellent survival rates in MASLD cirrhosis and we identified risk factors that should be utilized to refine patient selection. Together these findings affirm that TIPS can be an effective intervention in reducing morbidity and mortality in MASLD cirrhosis, and provide areas for future research to improve patient selection and outcomes.

2545 | RISK OF MICROVASCULAR AND MACROVASCULAR COMPLICATIONS IN PATIENTS WITH TYPE 2 DIABETES AND CIRRHOTIC METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS: A RETROSPECTIVE COHORT STUDY

Semiu Gbadamosi[1] David Shi[1] Abdalla Aly[1] Caichen Zhong[1] Husam Albarmawi[1] Aidan McGovern[1] Anthony Hoovler[1] Carlos Campos[2], [1]Novo Nordisk Inc, [2]University of Texas Health Science Center

Background: Metabolic dysfunction-associated steatohepatitis (MASH) in patients with type 2 diabetes (T2D) is associated with increased risk of T2D complications. As MASH progresses to cirrhosis, it further alters hepatic function, impairs glucose regulation and exacerbates systemic inflammation. However, real-world data on the burden of T2D complications in patients with T2D and cirrhotic MASH are limited. This study compared risks of micro- and macrovascular complications between cirrhotic and noncirrhotic MASH in a T2D population. **Methods:** This retrospective cohort study identified patients (≥18 years) with T2D and MASH from 2016 to 2024 using Optum's Clinformatics® Data Mart Database – a large, national, de-identified, adjudicated claims database of medically insured patients in the US. Patients were required to have 12 months' continuous enrollment pre-index (baseline) and ≥1 month of follow-up through June 2024. Eligible patients were categorized into cirrhotic or noncirrhotic groups based on presence of cirrhosis or its complications. Propensity score matching was used to balance baseline characteristics between groups. Composite outcomes assessed were new onset of micro- and macrovascular complications of T2D. Cumulative incidences of T2D complications were calculated using the Aalen-Johansen estimator. Subdistribution hazard ratios (SHRs) and 95% confidence intervals (CIs) were computed using a Fine-Gray model, accounting for death as competing risk. Stratified analyses by age group (<65 vs ≥65 years) were also performed. **Results:** The analyses included 1197 and 966 matched pairs in the micro- and macrovascular complications cohorts, respectively. Over a 2-year follow-up period, incidence of microvascular complications was similar in the cirrhotic and noncirrhotic groups (36.7% vs 31.8%; risk ratio [RR] = 1.15, 95% CI: 0.99;1.33). Higher risks of macrovascular complications were observed in the cirrhotic vs noncirrhotic group (RR = 1.48, 95% CI: 1.24;1.78). Overall, patients in the cirrhotic group had significantly increased hazards of microvascular (SHR: 1.22, 95% CI: 1.08;1.38) and macrovascular complications (SHR:1.36, 95% CI: 1.19;1.57) vs the noncirrhotic group. A stronger effect was seen in patients <65 years for microvascular (SHR: 1.44, 95% CI: 1.17;1.79) and macrovascular complications (SHR: 1.62, 95% CI: 1.27;2.05) (Table). **Conclusion:** Patients with T2D and cirrhotic MASH face higher risks of T2D complications than those with T2D and noncirrhotic MASH, especially in younger populations.

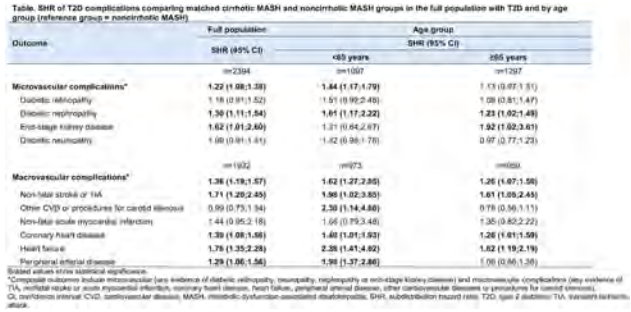

Table. SHR of T2D complications comparing matched cirrhotic MASH and noncirrhotic MASH groups in the full population with T2D and by age group (reference group = noncirrhotic MASH)

Outcome	Full population	Age group	
	SHR (95% CI)	SHR (95% CI)	
		<65 years	≥65 years
	n=2394	n=1097	n=1297
Microvascular complications*	1.22 (1.08;1.38)	1.44 (1.17;1.79)	1.13 (0.97;1.31)
Diabetic retinopathy	1.18 (0.97;1.52)	1.51 (0.99;2.48)	1.08 (0.81;1.47)
Diabetic nephropathy	1.30 (1.11;1.54)	1.61 (1.17;2.22)	1.23 (1.02;1.48)
End-stage kidney disease	1.62 (1.01;2.60)	1.31 (0.64;2.67)	1.92 (1.02;3.61)
Diabetic neuropathy	1.09 (0.91;1.41)	1.52 (0.98;1.78)	0.97 (0.77;1.23)
	n=1932	n=973	n=959
Macrovascular complications*	1.36 (1.19;1.57)	1.62 (1.27;2.05)	1.26 (1.07;1.50)
Non-fatal stroke or TIA	1.71 (1.20;2.45)	1.98 (1.02;3.85)	1.61 (1.09;2.45)
Other CVD or procedures for carotid stenosis	0.99 (0.73;1.34)	2.30 (1.14;4.60)	0.78 (0.56;1.11)
Non-fatal acute myocardial infarction	1.44 (0.95;2.18)	1.66 (0.79;3.46)	1.35 (0.82;2.22)
Coronary heart disease	1.39 (1.08;1.80)	1.40 (1.01;1.93)	1.26 (1.01;1.59)
Heart failure	1.76 (1.35;2.28)	2.38 (1.41;4.02)	1.62 (1.19;2.19)
Peripheral arterial disease	1.29 (1.00;1.66)	1.98 (1.37;2.86)	1.06 (0.86;1.30)

Bolded values show statistical significance.
*Composite outcome include microvascular (any evidence of diabetic retinopathy, neuropathy, nephropathy or end-stage kidney disease) and macrovascular complications (any evidence of TIA, nonfatal stroke or acute myocardial infarction, coronary heart disease, heart failure, peripheral arterial disease, other cerebrovascular diseases or procedures for carotid stenosis).
CI, confidence interval; CVD, cardiovascular disease; MASH, metabolic dysfunction-associated steatohepatitis; SHR, subdistribution hazard ratio; T2D, type 2 diabetes; TIA, transient ischemic attack.

2546 | FATTY LIVER INDEX (FLI) SHOULD NOT BE USED TO STUDY STEATOTIC LIVER DISEASE IN LEAN INDIVIDUALS

Mohammed Rifat Shaik[1] Nishat Anjum Shaik[2] Yaron Rotman[3], [1]National Institute of Health, [2]SSM Health/ Saint Louis University School of Medicine, [3]National Institutes of Health

Background: The Fatty Liver Index (FLI) is a widely used and validated serological tool for detection of steatotic liver disease (SLD) in population studies. While it has been used to study unique features of SLD in lean individuals, its performance in this subgroup has not been directly validated. We hypothesized that FLI would not identify lean SLD accurately due to its dependence on body size measures. **Methods:** Data from the National Health and Nutrition Examination Survey (NHANES) 2017-20 database

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

was utilized. Adult participants with available vibration-controlled transient elastography data and complete variables for FLI calculation were included. SLD was defined by a controlled attenuation parameter (CAP) ≥263 dB/m. Lean status was determined using ethnicity-adjusted BMI cutoffs. The diagnostic performance of FLI was assessed overall and in lean participants using standard rule-in (≥60) and rule-out (<30) thresholds, with additional subgroup analyses across BMI categories. **Results:** The study population included 7191 individuals, of whom 3602 (50%) had SLD. There were 1739 lean individuals, 238 of whom (13.7%) had SLD. In the overall population, FLI had adequate performance. SLD was detected by FLI ≥60 with a sensitivity of 73.8% and a specificity of 75.7%, with a positive predictive value (PPV) of 75.3%. FLI <30 had a negative predictive value of 86.9%. In contrast, among lean participants, FLI ≥60 detected only 15 of 238 SLD cases (sensitivity 6.3%, Figure) with PPV of only 45.5% with only modest improvement using the rule-out threshold. Lean individuals predicted to have SLD by FLI markedly differed from those with imaging-confirmed lean SLD. They were older, had higher body mass index(BMI), waist circumference, gamma-glutamyl transferase, and triglyceride levels, and had a greater burden of cardiometabolic comorbidities. **Conclusion:** Due to its inherent dependence on body size measures, FLI is not accurate in identifying lean participants with SLD. Moreover, using FLI in lean individuals tends to capture a distinct subgroup at the upper end of the lean BMI range with more pronounced metabolic abnormalities. The biases introduced by the inaccuracy and misrepresentation of true lean SLD phenotype imply that FLI should not be used in population-based studies focusing on lean SLD.

2547 | HISPANIC OR LATINO PATIENTS WITH COMPENSATED MASH CIRRHOSIS HAVE A HIGHER RATE OF ADVERSE OUTCOMES COMPARED TO NON-HISPANICS OR NON-LATINO

Aryan Ayati[1] Alexandre Watanabe[2] Shadera Azzam[1] Xiao Zhang[2] Eirum Chaudhri[2] Gail Fernandes[2] Melissa Vendetti[2] Vivek Rudrapatna[1] Jin Ge[3], [1]University of California San Francisco, [2]Merck & Co., Inc., Rahway, NJ, USA, [3]University of California, San Francisco

Background: Prior literature has indicated that Hispanic and Latino patients have a higher disease burden related to MASH compared to non-Hispanic and non-Latino patients. However, it is unclear whether this difference extends to clinical outcomes in compensated cirrhosis. This study characterizes the real-world trajectory of compensated MASH cirrhosis at a large academic medical center with a large population of Hispanic and Latino patients. **Methods:** We used a previously validated natural language processing algorithm for detecting MASH from clinical notes ("NASH Detection") to identify patients with compensated MASH cirrhosis at UCSF from 2012-2022. The cohort was stratified by race/ethnicity and characterized using clinical variables and residential-level measures of social determinants of health (SDOH). Outcomes of interest were defined as mortality, hepatic decompensations, and liver disease progression. We evaluated differences between subgroups using Chi^2, T-, and Mann-Whitney tests and Kaplan-Meier and Cox regressions for time-to-event analyses. **Results:** We identified 493 patients with compensated MASH cirrhosis with a median follow-up time of 3.4 years, of which 34% were Hispanic or Latino. Hispanic or Latino patients were younger, more likely female, lived further away from UCSF and in areas with higher Area Deprivation Indices, and had higher baseline MELDs compared to non-Hispanic or non-Latino patients (Table 1). In terms of outcomes, Hispanic or Latino patients had higher annual incidences of mortality and ascites compared to non-Hispanic or non-Latino patients (Table 1). Associations with outcomes were attenuated when adjusted for SDOH measures and clinical variables. Time-to-event analyses for Hispanic or Latino patients showed higher baseline FIB-4 (HR 1.4, $P < 0.01$), being male (HR 2.1, $P = 0.03$), and abnormal alkaline phosphatase (HR 2.6, $P = 0.01$) as predictors for hepatic decompensation. **Conclusion:** Hispanic or Latino

patients with compensated MASH cirrhosis are at greater risk for mortality and hepatic decompensation events compared to non-Hispanic or non-Latino patients. These differences may be partially explained by disparities in socioeconomic status and healthcare access. This study provides insights on the clinical burden of compensated MASH cirrhosis among Hispanic and Latino patients in a real-world setting, highlighting the need of strategies to mitigate socio-economic barriers and effective treatments to improve patient outcomes.

2548 | METABOLIC DYSFUNCTION–ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) IN INDIVIDUALS WITH OBSTRUCTIVE SLEEP APNEA (OSA): A META-ANALYSIS

Sarva Patel[1] Tanya Gupta[2] Eric Huang[1], [1]Kaiser Permanente SCAL, [2]Cornell University

Background: Obstructive sleep apnea (OSA) is a condition known for its recurrent episodes of upper airway obstruction resulting in periods of apnea. Metabolic dysfunction–associated steatotic liver disease (MASLD) is known for the excessive accumulation of lipids in the hepatic parenchyma with the potential of progressing to cirrhosis or hepatocellular carcinoma. While the relationship between both OSA and MASLD was explored in primary studies, a comprehensive meta-analysis is needed for quantifying this association and the possible role of OSA on liver enzymes. **Methods:** A systematic search process was conducted across PubMed, Web of Sciences and Scopus to identify observational studies exploring the co-occurrence of MASLD in OSA compared to controls for calculation of the pooled odds ratio (OR) of MASLD in OSA. Additionally, weighted mean differences (WMD) for alanine aminotransferase (ALT) and aspartate aminotransferase (AST) between OSA and non-OSA groups were calculated. **Results:** A statistically significant increase in the risk for MALD in individuals with OSA compared to controls was observed with an OR of 2.41 [95% CI: 1.857-3.127]. Individuals with severe OSA had higher pooled OR of MASLD compared with less severe OSA, OR = 2.68 [95% CI: 1.732-4.145] and 2.096 [95% CI: 1.511-2.907] respectively. A statistically significant WMD was found for both ALT and AST in OSA compared to controls, WMD = 4.006 [95% CI: 1.561-6.45] and 1.624 [95% CI: 0.855-2.393], respectively. No significant differences were found regarding study region, exclusion of individuals with prior OSA diagnosis, population type and method of MASLD detection. **Conclusion:** OSA is associated with an increased risk for MASLD, and the risk increases by increasing OSA severity. Those with OSA had higher liver enzymes compared to controls. These findings highlight the need for routine screening for MASLD in individuals with OSA

2549 | UNVEILING THE PROGNOSTIC BURDEN OF METALD: A MULTICENTER BIOPSY-BASED STUDY: A NATIONWIDE BIOPSY-BASED STUDY OF 2,131 PATIENTS

Takuma Nakatsuka[1] Takeshi Okanoue[2] Makiko Taniai[3] Rie Irie[4] Hanako Tsujikawa[4] Eisuke Murakami[5] yuya seko[6] Kanji Yamaguchi[7] Hirokazu Takahashi[8] Norio Akuta[9] Takumi Kawaguchi[10] Jun Arai[11] Kiyoaki Ito[11] Michiie Sakamoto[4] Mitsuhiro Fujishiro[1] Kazuhiko Koike[1] Ryosuke Tateishi[1], [1]The University of Tokyo, [2]Osaka Saiseikai Suita Hospital, [3]Tokyo Women's Medical University, [4]Keio University School of Medicine, [5]Hiroshima University, [6]Kyoto Prefectural University of Medicine, [7]Kyoto Prefectural University of Medicine Graduate School of Medical Science, [8]Saga University Hospital, [9]Toranomon Hospital and Okinaka Memorial Institute for Medical Research, [10]Kurume University School of Medicine, [11]Aichi Medical University

Background: Metabolic dysfunction-associated alcohol-related liver disease (MetALD), a recently defined subtype of steatotic liver disease (SLD), is characterized by excessive alcohol intake and cardiometabolic risk factors. Its prognosis remains unclear compared to metabolic dysfunction–associated steatotic liver disease (MASLD). **Methods:** We analyzed 2,131 patients with biopsy-proven SLD (2,014 MASLD; 117 MetALD) from a nationwide multicenter registry. Survival and clinical event incidence, including hepatocellular carcinoma (HCC), liver decompensation (LD), cardiovascular disease (CVD), and extrahepatic cancer (EHC), were assessed. Risks were estimated using multivariable Cox and Fine–Gray models. **Results:** Compared to MASLD, the MetALD group had more males (74.4% *vs.* 47.9%), diabetes (65.8% *vs.* 51.2%), and current smokers (24.8% *vs.* 10.4%), with no significant differences in liver histology. During a median follow-up of 8.3-years (17,627 person-years), 149 patients died. Overall mortality was significantly higher in MetALD (1.80 *vs.* 0.79 per 100 person-years; $P < .001$), primarily driven by nonliver-related causes ($P < .001$), whereas liver-related mortality was comparable ($P = .95$). Multivariate analysis identified older age (adjusted hazard ratio [aHR] 1.09; 95% CI, 1.07–1.11), higher BMI (aHR 1.05; 95% CI, 1.01–1.10), and MetALD (aHR 1.87; 95% CI, 1.06–3.30) as independent predictors of mortality, while dyslipidemia was protective (aHR 0.69; 95% CI, 0.48–1.00). Histologic features, including cirrhosis (aHR 1.85; 95% CI, 1.09–3.13), steatosis $< 33\%$ (aHR 1.68; 95% CI, 1.16–2.44), and moderate-

to-severe portal inflammation (aHR 1.64; 95% CI, 1.07–2.50), were also independently associated with mortality. During follow-up, 87 developed HCC, 77 LD, 112 CVD, and 130 EHC. Annual rates of liver-related events were comparable between groups (HCC: 0.59 *vs.* 0.50; LD: 0.56 *vs.* 0.43 per 100 person-years), whereas CVD (1.33 *vs.* 0.66; $P = .04$) and EHC (2.25 *vs.* 0.72; $P < .001$) were more frequent in MetALD. In multivariate analysis, MetALD was independently associated with EHC (aHR 2.58; 95% CI, 1.52–4.39), but not with HCC or LD. **Conclusion:** MetALD is associated with poorer overall survival than MASLD, primarily due to excess CVD and EHC. In contrast, liver-specific outcomes were comparable. Histologic features beyond fibrosis, particularly low-grade steatosis and portal inflammation, were independent predictors of worse survival. These findings underscore the need for comprehensive risk assessment in SLD, incorporating individual alcohol consumption, metabolic status, and the risk of extrahepatic complications.

2550 | PREVALENCE OF LIVER FIBROSIS IN RELATIVES OF PATIENTS WITH MASLD-RELATED CIRRHOSIS: A STUDY ON DEGREE OF KINSHIP

ISMAEL YEPES[1] NICOLE CHAMORRO[2] Juan Ignacio Marin Zuluaga[3] GUILLERMO DONADO[4], [1]Universidad de .Cartagena. Asociacion Colombiana de Hepatologia., [2]Universidad de Cartagena. Gastropack SAS, [3]Hospital Pablo Tobon Uribe. Asociacion Colombiana de Hepatologia., [4]Universidad de Cartagena. Gastropack SAS

Background: First-degree relatives of patients with MASLD-related cirrhosis are recommended to undergo systematic liver fibrosis screening, based on high prevalence rates reported in Europe and the U.S. Growing evidence supports a strong hereditary component in the development and progression of fatty liver disease, including genetic polymorphisms associated with fibrosis. However, it remains unclear whether the risk extends beyond first-degree relatives or if a family history of MASLD-related cirrhosis is a relevant risk factor in Latin American populations. This study aimed to determine the prevalence of liver fibrosis and associated factors in first-, second-, and third-degree relatives of patients with MASLD-related cirrhosis. **Methods:** Patients with confirmed MASLD-related cirrhosis were identified from a liver disease outpatient clinic in Cartagena, Colombia. Their first-, second-, and third-degree relatives were offered transient elastography (Echosens) and body composition analysis using bioelectrical impedance (InBody 270) after a 6-hour fast. Only elastography results with an interquartile range $\leq$30% of the median and success rate $\geq$60% were included. All participants underwent physical examination and a detailed interview on medical history and alcohol use. Those with abnormal elastography ($\geq$7.2 kPa) were referred to hepatology for follow-up. Written informed consent was obtained from all participants. Numeric and categorical variables were expressed as means (SD) and percentages (n), respectively. The chi-square test was used to compare fibrosis prevalence across kinship degrees. A univariate logistic regression identified predictors of liver fibrosis, with statistical significance set at $p \leq 0.05$. **Results:** A total of 99 relatives were included: 56 first-degree, 13 second-degree, and 30 third-degree. Mean age was 44 years (SD 14), and 32.3% were male. Mean CAP was 247 dB/m (SD 64), visceral fat 12.7% (SD 5.3), body fat 26.7% (SD 9.6), and skeletal muscle mass 27 kg (SD 7). Hypertension, diabetes, dyslipidemia, and overweight/obesity were found in 17.2%, 4%, 14.1%, and 74% of the sample, respectively. Overall liver fibrosis prevalence was 15.2%, and by kinship degree: 21.4% (first), 7.7% (second), and 6.7% (third), with no

significant differences (Figure 1). Five individuals had advanced but compensated liver disease (≥10 kPa). BMI, visceral fat, body fat percentage, and waist circumference were predictors of fibrosis (Table 1). **Conclusion:** Liver fibrosis prevalence is high in first-degree relatives of patients with MASLD-related cirrhosis. Although not statistically significant, a decreasing trend in prevalence was observed with increasing kinship degree. BMI, abdominal circumference, and fat distribution may help identify individuals at greater risk.

Variable	OR	95% CI	p-value
Male sex	1,05	0.32 – 3.3	0,92
Age	1,02	0.98 – 1.06	0,32
BMI	1,14	1.02 – 1.28	0,019

2551 | INCIDENCE OF HEPATOCELLULAR CARCINOMA IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE: A RECONSTRUCTED INDIVIDUAL PATIENT DATA META-ANALYSIS

Faith Tan[1] Glenn Jun Kit Ho[1] Ryan YanZhe Lim[1] Alfred Kow[2] Karn Wijarnpreecha[3] Vincent Chen[4] Hirokazu Takahashi[5] Cheng Han Ng[6] Mark Muthiah[7] Daniel Huang[7], [1]Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore, [2]Division of Hepatobiliary and Pancreatic Surgery, Department of Surgery, National University Hospita, [3]University of Arizona College of Medicine-Phoenix, [4]University of Michigan Medical Center, [5]Division of Metabolism and Endocrinology, Faculty of Medicine, Saga University, Saga, Japan, [6]"1) Division of Gastroenterology and Hepatology, Department of Medicine, National University Hospita, [7](1)Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore; (2) Divi

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the fastest-rising etiology of hepatocellular carcinoma (HCC). The time-dependent incidence of HCC in people with MASLD has not been reported. We performed a pooled analysis of time-to-event data to provide robust estimates for the incidence of HCC in MASLD. **Methods:** Medline and Embase were searched from inception to November 2024. Individual participant data were reconstructed from published Kaplan–Meier curves, and a pooled analysis of cumulative HCC incidence was performed using a random-effects model. **Results:** We screened 4,951 articles and included 26 studies (3,995,728 individuals). The 1-, 3-, 5-, and 10-year cumulative incidence of HCC in people with MASLD and known advanced fibrosis was 0.8%, 2.4%, 3.9%, and 8.8%, respectively in administrative database studies, and 3.9%, 11.7%, 21.0% and 48.5%, respectively in hospital/clinic-based studies. The cumulative incidence of HCC in people with MASLD but without advanced fibrosis was 0.1%, 0.5%, 0.7%, and 1.3%, respectively, inadministrative database studies, and 1.6%, 4.7%, 8.2%, and 18.3%, respectively, in hospital/clinic-based studies. The risk of HCC in patients with advanced fibrosis was significantly higher compared to those without advanced fibrosis in both administrative database (HR: 11.09 [95% CI: 2.68 – 45.89], $p < 0.001$) and hospital/clinic-based studies (HR: 10.50 [95% CI: 3.19 – 34.51], $p < 0.001$). **Conclusion:** This reconstructed individual participant data meta-analysis provides updated, robust estimates for the incidence of HCC in people with MASLD. The incidence of HCC is elevated in people with MASLD and advanced fibrosis. These data may have implications for further research in HCC surveillance and the future development of surveillance algorithms.

Background: Accurate MASLD risk stratification ensures high-risk patients receive specialty care while low-risk patients are managed in primary care. We evaluated whether implementing a FIB-4 Smart Tool—with an embedded score calculator and automated risk grouping—would improve adherence to MASLD referral guidelines or influence referral decision-making. Preliminary analysis revealed that many referrals involved patients with prior hepatology consultation, seemingly irrespective of current fibrosis risk. This prompted further examination of how consultation history may influence provider behavior and referral patterns. **Methods:** In 2024, our tertiary referral center's primary care clinic implemented a FIB-4 smartphrase calculator and risk categorizer in the EMR using age-adjusted thresholds. Forty-three primary care providers received education on its use and MASLD risk stratification. We retrospectively reviewed hepatology referrals made by these providers from January–July (pre) and July–December (post). We evaluated changes in inappropriate (low risk) referrals and associations between prior hepatology consultation and fibrosis risk at current referral. **Results:** A total of 125 hepatology referrals were analyzed—64 prior to and 61 following implementation of the FIB-4 smart phrase. The rate of inappropriate referrals did not significantly change following the intervention (76.6% pre vs. 73.8% post; $p = 0.72$), suggesting availability of FIB-4 tool did not meaningfully improve referral appropriateness. Prior hepatology consultation was present in 56.0% of all referred patients, and 61.25% of inappropriately referred (low-risk) patients. In contrast, among appropriate referrals (high-risk), prior hepatology contact was present in 48.65% of cases. Logistic regression showed no significant association between prior consultation and inappropriate referral (OR 1.22, 95% CI 0.57–2.62, $p = 0.616$). However, the higher frequency of prior consultation in inappropriate referrals suggests a reflexive referral pattern that may not take current fibrosis risk into account. **Conclusion:** Despite deployment of a FIB-4 smart phrase intended to improve MASLD triage, inappropriate referral rates remained high and unchanged—suggesting either limited tool utilization or a decision-making strategy that ignores current fibrosis risk. While repeat hepatology consultation is expected in high-risk patients, the even higher rate among low-risk, inappropriately referred patients suggests a referral pattern not grounded in current fibrosis severity. We term this behavioral phenomenon 'Legacy Referral Bias'—the reflexive tendency to refer based on historical specialist contact rather than present clinical need. We are assembling a larger real-world dataset including both referred and non-referred patients to better characterize the impact of reflexive referral behavior on MASLD care pathways.

2553 | PREDICTORS OF INCIDENT HEPATIC FIBROSIS AND STEATOTIC LIVER DISEASE–ASSOCIATED FIBROSIS AMONG WOMEN WITH AND WITHOUT HIV

Maria Duarte[1] Phyllis Tien[1] Yifei Ma[1] Mark Kuniholm[2] Michelle Floris-Moore[3] Margaret Fischl[4] Audrey French[5] Elizabeth Topper[6] Deborah Konkle-Parker[7] Howard Minkoff[8] Ighovwerha Ofotokun[9] Michael Plankey[10] Anjali Sharma[11] Jennifer Price[1], [1]University of California, San Francisco, [2]College of Integrated Health Sciences at the University at Albany, [3]University of North Carolina, Chapel Hill School of Medicine, [4]University of Miami Miller School of Medicine, [5]Stroger Hospital of Cook County, [6]Johns Hopkins Bloomberg School of Public Health, [7]University of Mississippi Medical Center, [8]SUNY Downstate Health Sciences University, [9]Emory University Rollins School of Public Health, [10]Georgetown University Hospital, [11]Albert Einstein College of Medicine

Background: Steatotic liver disease (SLD) is highly prevalent among women living with HIV (WWH). However, predictors of fibrosis and SLD-associated fibrosis in this population are not well established. **Methods:** We included participants from the MACS/WIHS Combined

Cohort Study (MWCCS), who underwent vibration controlled transient elastography between 2013–2018 and had at least one additional scan. Fibrosis was defined as liver stiffness ≥7.1 kPa and SLD-associated fibrosis (SLD-fibrosis) as fibrosis with concurrent hepatic steatosis (controlled attenuation parameter, or CAP ≥248 dB/m). Women with chronic viral hepatitis or baseline fibrosis were excluded. Poisson regression with robust standard errors clustered by participant was used to estimate incidence rate ratios (IRRs) for fibrosis incidence. Models included time-varying covariates and the log of follow-up interval as an offset to account for varying person-time between visits. Interaction terms were tested to assess differential effects by HIV status. **Results:** A total of 1,036 women were included: 709 WWH and 327 women living without HIV (WWOH). Median age was 49, median BMI was 32 and 14% were Hispanic. During follow-up (mean 24.5 months), 19% developed fibrosis, and 8% developed advanced fibrosis; 74% of all fibrosis cases were SLD-fibrosis. In models examining and adjusting for age, BMI, Hispanic ethnicity, alcohol use and tobacco use, only HIV infection and CAP score were independently associated with higher incidence rates of fibrosis (Table 1). The association of higher CAP with fibrosis differed by HIV status: among WWOH, each 10 dB/m increase in CAP was associated with an 11% increase in incident rate of fibrosis (IRR 1.11, 1.04–1.18), compared to a 1% increase in WLWH (IRR 1.01, (0.96–1.06) (interaction p = 0.02, 95% CI 0.84–0.98). In a separate model examining SLD-fibrosis, HIV was associated with higher rate of SLD-fibrosis (IRR 1.91, 1.10–3.31), and the effect of CAP appeared attenuated in WWH, however this did not achieve significance (Table 1, interaction p = 0.13, 95% CI 0.86–1.02). **Conclusion:** In a large cohort of women living with and without HIV, the amount of hepatic steatosis was associated with higher rates incident fibrosis and SLD-fibrosis. However, HIV infection modified and attenuated the impact of steatosis on fibrosis risk, suggesting that fibrosis in women with HIV may result from both steatotic and non-steatotic pathways.

Table 1: Multivariable predictors of incident fibrosis and SLD- fibrosis in women with and without HIV

Predictor	Model 1 Incidence Rate Ratio Fibrosis (95% CI)	p-value	Model 2 Incidence Rate Ratio SLD-Fibrosis (95% CI)	p-value
HIV infection (main effect)	1.74 (1.13–2.68)	0.01	1.91 (1.10–3.31)	0.02
CAP score (per 10 dB/m, main effect)	1.04 (1.00–1.08)	0.05	1.18 (1.14–1.23)	<0.001
CAP*HIV interaction	0.91 (0.84–0.98)	0.02	0.94 (0.86–1.02)	0.13
CAP (per 10 dB/m) in WWOH	1.11 (1.04–1.18)	0.001	1.23 (1.15–1.32)	<0.001
CAP (per 10 dB/m) in WWH	1.01 (0.96–1.06)	0.76	1.15 (1.10–1.20)	<0.001

*SLD-Fibrosis was defined as incident fibrosis (liver stiffness ≥7.1 kPa) with concurrent hepatic steatosis (CAP ≥248 dB/m). All models adjusted for age, BMI, Hispanic ethnicity, alcohol, and smoking.

2554 | EVOLVING EPIDEMIOLOGY OF MASLD AND ALCOHOLIC LIVER DISEASE IN SOUTH KOREA: A 13-YEAR NATIONWIDE ANALYSIS BASED ON PHYSICIAN DIAGNOSES

Son Gue[1], [1]Daejeon University

Background: Alcohol overuse and metabolic dysfunction are the primary contributors to steatotic liver disease (SLD), encompassing both metabolic dysfunction–associated steatotic liver disease (MASLD) and alcohol-associated liver disease (ALD). This study aimed to investigate the epidemiologic trends in the prevalence of MASLD and ALD among the Korean population from 2010 to 2022. **Methods:** We analyzed data from the Korean Health Insurance Review and Assessment Service (HIRA), a nationwide claims database based on physician-recorded diagnoses and treatments. Annual prevalence rates of MASLD and ALD-related fatty liver and hepatitis were calculated and stratified by year, age, and sex across the entire Korean population. **Results:** From 2010 to 2022, the annual prevalence of MASLD-related fatty liver increased from 15.6 to 34.3 per 1,000 persons (2.2-fold increase), while metabolic-associated steatohepatitis (MASH) rose nearly 20-fold (from 0.49 to 9.79 per 1,000 persons). In contrast, the prevalence of alcoholic fatty liver (AFL) remained stable (approximately 2.8 per 1,000), and alcoholic (steato)hepatitis (ASH) slightly declined (from 2.4 to 2.1 per 1,000). The mean MASLD-to-AFL ratio was approximately 10:1, and the MASH-to-ASH ratio was about 2:1, reflecting relatively faster progression to hepatitis among ALD patients. Unlike the persistent male predominance in AFL and ASH, MASLD and MASH showed a sex-dimorphic pattern: male predominance under age 50, but female predominance in individuals aged 50 and older. **Conclusion:** The prevalence of MASLD and MASH has increased rapidly in clinical practice over the past decade, while ALD prevalence has remained stable or declined slightly. These trends reflect a shifting burden of liver disease in South Korea and offer a valuable reference for future research and healthcare planning.

2555 | NATURAL HISTORY AND RISK FACTORS OF METABOLIC DYSFUNCTION–ASSOCIATED STEATOSIS LIVER DISEASE IN CHINESE COHORTS: A SCOPING REVIEW

Jing Zhang[0] Ruixi Zhan[2] Ying Wang[2] Yuemin Nan[3], [0]Department of Hepatology, Beijing Youan Hospital, Capital Medical University, Beijing, China, [2]Novo Nordisk (China) Pharmaceuticals Co., Ltd, Beijing, China, [3]Department of Traditional and Western Medical Hepatology, Hebei Medical University Third Hospital, S

Background: Metabolic dysfunction-associated steatosis liver disease (MASLD) has rapidly become the predominant chronic liver disorder in China. However, evidence on its natural history and determinants of progression remains fragmented. We conducted a scoping review to synthesize evidence from Chinese cohorts on disease trajectories from steatosis through fibrosis, cirrhosis, and hepatocellular carcinoma (HCC), and to identify key risk factors driving progression. **Methods:** Following PRISMA-ScR guidelines, we searched PubMed, EMBASE, Cochrane Library, CNKI, Wanfang, and VIP databases from January 2012 to January 2024. Eligible studies included Chinese MASLD cohorts reporting natural history outcomes or multivariate-adjusted risk factors for progression. We mapped outcomes: Metabolic dysfunction-associated steatohepatitis (MASH), fibrosis progression, cirrhosis, HCC, liver-related events, cardiovascular events, mortality, and tabulated risk factors evaluated across studies. **Results:** 41 articles (36 natural history; 21 risk factor) met the inclusion criteria, involving 247,502 participants for disease-course analyses (Figure 1) and 66,143 for risk modelling. For MASLD patients, in 5 years or less, fibrosis advanced in 27.5-38.4%, and cirrhosis developed in up to 1% (0.9%). Over longer follow-up (>5 years), 0-2.1% transitioned to cirrhosis and 0-2.7% to HCC (annual incidence 0.3-2%). Hepatic decompensation (ascites, encephalopathy, variceal bleeding) occurred in 0.1-1.1% by 11 years. Within 5 years, cardiovascular mortality (2.1-7.0%) and all-cause mortality (2.2-6.8%) outpaced liver-related mortality (0.3-0.6%). Key independent predictors of progression included older age, male sex, hypertension, and overweight/obesity, especially type 2 diabetes, each reported in ≥ 3 studies across endpoints. Additional risk factors variably linked to adverse outcomes were dyslipidemia, sarcopenia, elevated transaminases, viral hepatitis coinfection, and low albumin. Heterogeneity in study populations, endpoint definitions, and reporting of demographic covariates limited comparability. **Conclusion:** MASLD in China trends similarly to the global pattern but may exhibit notably rapid progression in specific populations or stages. Multiple risk factors contribute to disease advancement. Further large-scale prospective cohort studies are warranted to elucidate the associations between risk factors and MASLD, and to better inform early intervention strategies for this condition.

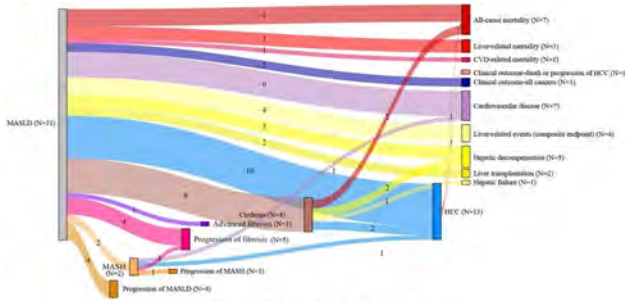

Figure 1. Overview of MASLD Progression

Notes: CVD, Cardiovascular disease; HCC, hepatocellular carcinoma; MASH, Metabolic dysfunction-associated steatohepatitis; MASLD, Metabolic dysfunction-associated steatotic liver disease.

University-Varanasi, India, [13]DMC Ludhiana, India, [14]Sir Gangaram Hospital, New Delhi, India, [15]Jaslok Hospital, Mumbai, India, [16]Medanta, The Medicity, Gurgaon, Haryana, India, [17]Amrita Institute of Medical Sciences, Kochi, [18]SNMC Medical College, Jodhpur, India, [19]IGMC, Shimla, India, [20]AII India Institute of Medical Sciences – Rishikesh, India, [21]SMS Medical College and Hospital, Jaipur, India, [22]Apollo Multi-Speciality Hospital, Kolkata, India, [23]Kalinga Institute of Medical Sciences, Bhubaneshwar, India, [24]Asian Institute of Gastroenterology, Hyderabad, India, [25]Seth GS Medical College & KEM Hospital, [26]SIDS Hospital and Research Center, [27]NSC Bose Medical College and Hospital Jabalpur, India, [28]Max Hospital, Saket, New Delhi, [29]Madras Medical College, Chennai, [30]Guwahati Medical College and Hospital, Guwahati, India, [31]VGM Hospital, Coimbatore, India, [32]Lakeshore Hospital, [33]Fortis Hospital, Noida, [34]Virginia Commonwealth University

Background: The recent classification of fatty liver disease under the Steatotic Liver Disease (SLD) spectrum, encompassing MASLD and MetALD, highlights the role of alcohol and metabolic dysfunction in liver injury. However, the impact of low-dose alcohol consumption (0–20 g/day), particularly within MASLD spectrum, remains underexplored. This study aimed to evaluate differences in disease severity and fibrosis risk across MASLD patients stratified by alcohol intake: abstinent MASLD, MASLD with 0–20 g/day alcohol use, and MetALD (30–60 g/day). **Methods:** Data were analyzed from 7,189 patients with SLD (median-age: 45 years, 66.9% males, 38.9% with metabolic syndrome, 29.7% with significant fibrosis) enrolled in 32 centers of the Indian Consortium on MASLD (ICOM-D) with information on alcohol consumption. Participants were stratified by alcohol intake. Liver fibrosis severity was assessed using non-invasive scores (FIB-4, APRI, NFS, FAST), and liver stiffness measurement (LSM) on elastography. Outcomes were compared across alcohol categories, and multivariable logistic regression models identified predictors of significant ($\geq$F2: 8.2Kpa) and advanced fibrosis ($\geq$F3: 9.7Kpa) as defined with LSM **Results:** Compared to abstinent MASLD (N = 6729), both low alcohol (0–20 g/day, N = 403) and MetALD (30–60 g/day, N = 57, all males) groups exhibited higher fibrosis scores (Mean FIB-4: 1.1 vs 1.2 and 1.4; Mean LSM: 6.4 vs 6.8 and 8.4 kPa; all $p < 0.01$). Prevalence of significant fibrosis ($\geq$F2) and fibrotic-MASH (FAST > 0.67) was 29.2% and 12.4% in MASLD, 33.5% and 15.9% in low alcohol group, and 54.4% and 22.8% in MetALD ($p < 0.001$). Metabolic risk factors adjusted models confirmed that even low-level alcohol use was independently associated with increased odds of significant fibrosis (aOR: 1.25, 1.01-1.56, $p = 0.041$), while MetALD conferred a threefold higher risk (aOR: 3.04, 1.79-5.17, $p < 0.001$). **Conclusion:** Among patients with MASLD, any alcohol intake increases the risk of significant fibrosis and fibrotic MASH. These findings underscore the need to refine risk stratification and counselling practices in MASLD.

2557 | PROGNOSTIC NUTRITIONAL INDEX (PNI) AS A PROGNOSTIC FACTOR FOR HCC PATIENTS STRATIFIED BY STATUS OF MASLD

Chun-Ting Ho[1] Wei-Yu Kao[2] Yi-Hsiang Huang[3] Ming-Chih Hou[3] Jaw-Ching Wu[4] Chien-Wei Su[3], [1]Taipei Veterans General Hospital/NYCU, [2]Taipei Medical University Hospital, [3]Taipei Veterans General Hospital, [4]National Yang Ming Chiao Tung University

Background: The impact of concurrent metabolic dysfunction-associated steatotic liver disease (MASLD) on patients with hepatocellular carcinoma (HCC) is still under debate. While the protective effect of concurrent MASLD was proposed in previous studies, the mechanisms of action and further subgroup analysis were lacking. Prognostic Nutritional Index (PNI), calculated by serum albumin level and lymphocyte count, demonstrated the ability to reflect the nutritional and inflammatory status of patients in different studies. Our research aimed to evaluate and compare the prognostic role of PNI in HCC patients stratified by their disease status of MASLD. **Methods:** This retrospective study included 991 consecutive treatment-naïve HCC patients from 2016 to 2023 with baseline serum biochemistry, image, and pathological data. Patients were categorized into MASLD and non-MASLD groups according to their pathology specimens, serum biochemistry data, and medication records. The two groups were then divided into four subgroups according to their PNI levels. COX proportional hazard models (COX PH) were performed to identify independent factors affecting overall survival (OS) and recurrence-free survival (RFS). Kaplan-Meier survival analysis was performed to compare the prognosis between different subgroups. **Results:** After a median follow-up of 38.0 months (interquartile range 10.0–68.0 months), 207 patients had died, and the 5-year OS was 71.4%. The four subgroups demonstrated significant differences in baseline characteristics, including age, tumor characteristics (size, stage, numbers, vascular invasions, distant metastasis), serum biochemistry profile (platelet, albumin, ALT, AST, ALK-P, AFP), and liver function reserve. COX PH identified high PNI as an independent protective factor against poor OS for all patients. In the KM analysis, while comparing the four groups, the MASLD with high-PNI group had the best OS, and the non-MASLD with low-PNI group had the worst OS. The OS of the MASLD with low-PNI and the non-MASLD with high-PNI was comparable. Regarding RFS, the non-MASLD with low-PNI group had the worst RFS, while the three other groups had better RFS, but no difference between groups. Subgroup COX PH analysis identified high-PNI as an independent protective factor for OS in the non-MASLD group but not for the MASLD group. **Conclusion:** PNI can serve as an important factor to differentiate HCC patients into different risk groups and can even serve as an independent protective factor against poor outcomes, especially in patients without concurrent MASLD.

2558 | CARDIOVASCULAR RISK OF METABOLIC DYSFUNCTION–ASSOCIATED STEATOTIC LIVER DISEASE AND FATTY LIVER DISEASE: RESULTS: FROM TWO NATIONWIDE COHORT

Juhee Ahn[1] Moon Haeng Hur[2] Hyunjae Shin[2] Min Kyung Park[3] Sungho Won[4] Jeayeon Park[2] Yunmi Ko[2] Yun Bin Lee[5] Eun Ju Cho[3] Jeong-Hoon Lee[3] Su Jong Yu[3] Jung-Hwan Yoon[2] Yoon Jun Kim[2], [1]Division of Data Science, College of Intelligent Software Convergence, University of Suwon, [2]Seoul National University College of Medicine, [3]Seoul National University Hospital, [4]Institute of Health and Environment, Seoul National University, [5]Seoul National University

Background: There is a lack of evidence on whether metabolic dysfunction-associated steatotic liver disease (MASLD) is associated with an increased risk of cardiovascular disease (CVD) or whether it outperforms metabolic dysfunction-associated fatty liver disease (MAFLD) in predicting CVD risk. This study aimed to compare the incidence of CVD according to MASLD and/or MAFLD status using two independent nationwide cohorts. **Methods:** A population-based cohort was established using data from the general health screening program provided by the National Health Insurance Service (NHIS) of Korea in 2009. In parallel, we also utilized UK Biobank phenotype data, which is a population-based prospective cohort consisting of UK residents enrolled between 2006 and 2010. Hepatic steatosis was identified using a fatty liver index greater than 30. The primary outcome was the incidence of composite CVD events, which included myocardial infarction, ischemic stroke, heart failure, and CVD-related death. **Results:** A total of 7,198,643 patients were included in the Korean NHIS, and they were categorized as MASLD ($n = 2,056,609$) or MAFLD ($n = 2,388,436$). Patients with MASLD or MAFLD had a higher risk of CVD compared to the control group (MASLD: subdistribution hazard ratio [SHR] = 1.43, 95% confidence interval [95% CI] = 1.42–1.44, $P < 0.001$; MAFLD: SHR = 1.42, 95% CI = 1.40–1.43, $P < 0.001$). Patients satisfying both MASLD and MAFLD criteria showed a significantly higher risk of CVD (SHR = 1.79, 95% CI = 1.75–1.82, $P < 0.001$), followed by those with MAFLD only (SHR = 1.31, 95% CI = 1.18–1.46, $P < 0.001$). Similar results were reproduced in the UK Biobank cohort ($n = 485,895$), where both MASLD (SHR = 1.65, 95% CI = 1.60–1.71, $P < 0.001$) and MAFLD (SHR = 1.61, 95% CI = 1.55–1.66, $P < 0.001$) were associated with a greater risk of CVD compared to the control group. **Conclusion:** Patients with MASLD had a significantly higher risk of CVD compared to those without steatotic liver disease. MASLD criteria are comparable to MAFLD criteria in reflecting CVD outcome risk.

2559 | INTERACTING EFFECT OF ALCOHOL, ADIPOSITY AND GENETIC RISK ON STEATOTIC LIVER DISEASE IN YOUNG ADULTS

Luis Bertot[1] Eduardo Vilar-Gomez[2] Oyekoya Ayonrinde[3] John Olynyk[4] Trevor Mori[5] Lawrence Beilin[5] Philip Melton[6] Gerald Watts[5] Leon Adams[7], [1]Medical School, The University of Western Australia, [2]Indiana University School of Medicine, [3]University of Western Australia, [4]Department of Gastroenterology, Fiona Stanley Hospital, Western Australia, Australia, [5]Medical

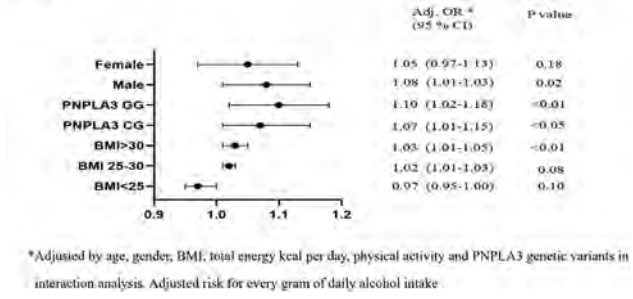
School, University of Western Australia, Western Australia, Australia, [6]Menzies Institute for Medical Research, University of Tasmania, Hobart, Australia, [7]Medical School, The University of Western Australia

Background: Steatotic liver disease (SLD) maybe due to excessive alcohol consumption, excess adiposity or genetic effects. The independent or modifying effects of these risk factors for SLD are unclear. We examined the association between alcohol, adiposity and PNPLA3 genetic variants on the risk of SLD in a population-based cohort of young adults **Methods:** Participants of the Raine Study Gen2 27-year-old cohort (n = 710) underwent assessments including, questionnaires, anthropometry, magnetic resonance imaging (MRI) and genotyping. SLD was determined by MRI volumetric liver fat fraction (HepaFat). Associations and interactions between BMI, PNPLA3 variants, sex and alcohol were assessed using logistic regression and restricted cubic spline analysis with adjustment for physical activity and total kilocalories per day. **Results:** SLD was detected in 111(16%) participants (55% male). On multivariable analysis, BMI (OR: 1.40, P < 0.001), PNPLA3 variants (OR: 1.65, P < 0.05) and alcohol/grams per day (OR: 1.08, P = 0.02), were associated with increased risk of SLD. Restricted cubic spline analysis showed a nonlinear increase in the risk of SLD for every gram of daily alcohol intake (p = 0.04). Significant interactions between alcohol and BMI, PNPLA3 variants and sex were observed (see Figure). The risk of SLD per daily gram of alcohol consumed was incrementally higher in participants who were overweight (BMI 25-30 kg/m2) and obese (BMI > 30kg/m2) but not among those with a normal BMI (< 25 kg/m2). Similarly, the impact of alcohol was greater in people with increasing number at-risk PNPLA3 alleles (CG variant, Adj. OR: 1.07, p < 0.05, GG variant Adj. OR 1.10, P < 0.01). The risk of SLD with alcohol consumption was also greater in male participants (Adj. OR: 1.08, P = 0.02). **Conclusion:** In young adults, the risk of SLD related to alcohol is greater in male participants, in the presence of obesity and in those with at-risk PNPLA3 variants.

Joint effects between alcohol and sex, PNPLA3 variants and BMI categories on the risk of steatotic liver disease.



*Adjusted by age, gender, BMI, total energy kcal per day, physical activity and PNPLA3 genetic variants in interaction analysis. Adjusted risk for every gram of daily alcohol intake

2560 | PREVALENCE OF GLUCAGON-LIKE PEPTIDE-1 RECEPTOR AGONIST USE AMONG PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS AND COMPENSATED CIRRHOSIS IN USUAL CLINICAL CARE IN THE USA

Steve Gao[1] Eva Flahavan[1] Grace Chee[1] Lisa Albert[1] Fang Xia[1], [1]Gilead Sciences, Inc., Foster City, CA, USA

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is a progressive phenotype of metabolic dysfunction-associated steatotic liver disease (MASLD), which includes simple liver steatosis, chronic liver inflammation with/without fibrosis, and cirrhosis. Several glucagon-like peptide-1 receptor agonists (GLP-1 RAs) are approved to treat type 2 diabetes mellitus (T2D) and/or obesity, which are common comorbidities of MASH. Since 2021, the approval of three new GLP-1 RAs has rapidly changed the treatment landscape for patients (pts) with compensated cirrhosis due to MASH. Understanding GLP-1 RA use is crucial to inform trial design and to evaluate their therapeutic benefit in MASH and its comorbidities. **Methods:** This was a retrospective, cross-sectional analysis of the HealthVerity closed claims database in the USA. Pts aged 18–80 years who had a diagnosis of MASH/MASLD and compensated cirrhosis within 90 days before or after a MASH/MASLD diagnosis from Jan 1, 2015 to Oct 30, 2024 were included. One year of continuous enrollment before a diagnosis of compensated cirrhosis was required for excluding any pts with other causes of chronic liver disease. GLP-1 RA users were defined as those who had a pharmacy claim for any approved GLP-1 RA in the USA. The prevalence of GLP-1 RA use was calculated as the proportion of GLP-1 RA users among pts with compensated cirrhosis due to MASH enrolled during the observation period. Descriptive statistics were used for demographics and comorbidities. **Results:** Overall, 91,837 pts with compensated cirrhosis due to MASH were identified. The median (IQR) age was 59 (15) years; 54,845 (59.7%) pts were women; 54,848 (59.7%) had T2D; and 56,659 (61.7%) had obesity. In total,

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

17,754 (19.3%) pts were GLP-1 RA users; of which, 15,991 (90.1%) had T2D and 13,711 (77.2%) had obesity. Since 2018, the prevalence of GLP-1 RA use has increased. Since the last 3 years of the observation period, the prevalence increased from 11.2% in Q1 2022 to 15.0% in Q1 2023, and further to 18.3% in Q1 2024. **Conclusion:** The prevalence of GLP-1 RA use for underlying comorbidities has increased over time in pts with MASH and compensated cirrhosis under usual clinical care. Monitoring GLP-1 RA use is crucial to inform future trial design, such as enrollment strategy and eligibility criteria related to GLP-1 RA use.

2561 | ASSOCIATIONS OF DEVICE-MEASURED SEDENTARY BEHAVIOR WITH HEALTH-RELATED QUALITY OF LIFE IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE PATIENTS

Hadeel Saad[1] Khalid Alswat[2] Sulaiman Aljaloud[1] Maram Alkhammash[2] Amani Alsadoon[2] Abdullah Alansare[3], [1]Department of exercise physiology,College of sports sciences and physical activity,KSU, [2]Liver Disease Research Center, College of Medicine, King Saud University,Riyadh, Saudi Arabia, [3]College of sports sciences and physical activity,King Saud University,Riyadh,Saudi Arabia

Background: Robust evidence suggests that sedentary behavior (SB), such as prolonged sitting, is associated with low quality of life among the general population. Of clinical significance, SB is also a significant risk factor for metabolic dysfunction-associated steatotic liver disease (MASLD), independent of physical inactivity. Both excessive SB and low health-related quality of life (HRQol) are prevalent among MASLD patients. However, the relationship between device-measured SB and HRQoL in this population remains unexplored.Objectives: To examine the association between device-measured SB and both overall and domain-specific HRQoL in patients with MASLD. **Methods:** We conducted a cross-sectional analysis of 101 (50.0 years old; 57% males) MASLD patients, who routinely visited hepatology clinic. Participants wore the wActiSleep-BT accelerometer on their non-dominant wrist for 7 days to measure their total SB (hours/day). The Chronic Liver Disease Questionnaire for Non-Alcoholic Fatty Liver Disease (CLDQ-NAFLD) was utilized to assess the overall and domain-specific (i.e., abdominal symptoms, fatigue, systemic symptoms, emotion, worry, and activity) HRQol. Associations between SB and HRQoL were analyzed using multiple and multivariable linear regression, adjusting for relevant covariates. **Results:** Participants spent on average 12.8 hours/day in total SB, with 97% exceeding the high-risk SB threshold ($>$ 8 hours/day). The mean overall HRQoL score was 4.14 out of 7. Each additional hour of SB was independently associated with lower overall HRQol (ß = -0.056; p = 0.017), greater fatigue (ß = -0.120; p = 0.004), and more systemic symptoms (ß = -0.089; p = 0.016). **Conclusion:** This study is the first to demonstrate that higher levels of device-measured SB are independently associated with poorer overall and domain-specific HRQoL in MASLD patients, particularly in fatigue and systemic symptoms. These findings underscore the need to consider SB reduction intervention as a potential target to improve patient-centered outcomes. Longitudinal and interventional studies are warranted to confirm the associations and explore causality.

2562 | GENETIC RISK OF STEATOTIC LIVER DISEASE AND ITS SEVERITY AMONG PEOPLE LIVING WITH HIV

Eduardo Vilar-Gomez[1] Samer Gawrieh[1] Tiebing Liang[1] Jordan Lake[2] Susanna Naggie[3] Tinsay Woreta[4] Jennifer Price[5] Richard Sterling[6] Sonya Heath[7] Kathleen Corey[8] Laura Wilson[9] Rohit Loomba[10] Mark Sulkowski[11] Naga Chalasani[12], [1]Indiana University School of Medicine, [2]University of Texas - Houston, [3]Duke Clinical Research Institute, [4]Johns Hopkins University School of Medicine, [5]University of California, San Francisco, [6]Virginia Commonwealth University, [7]University of Alabama, [8]Massachusetts General Hospital, [9]Johns Hopkins University, [10]University of California, San Diego, [11]Johns Hopkins Medicine, [12]Indiana University Medical Center

Background: The role of genetic risk variants in modulating steatotic liver disease (SLD) has been extensively studied in general populations but not in persons with HIV (PWH). We investigated the associations between candidate gene variants and the risk of SLD and clinically significant fibrosis (CSF) in PWH. **Methods:** Adult PWH prospectively enrolled in US multicenter studies underwent detailed phenotyping including VCTE for controlled attenuation parameter (CAP) and liver stiffness measurement (LSM). CAP $\geq$ 263 dB/m and LSM $\geq$ 8 kPa were used to define SLD and CSF, respectively. PWH with a history of excessive alcohol use or other liver diseases were excluded.

PNPLA3 rs738409, *TM6SF2* rs58542926, *HSD17B13* rs72613567, *MBOAT7-TMC4* rs641738, *GCKR* rs1260326, were genotyped by TaqMan assay. Associations between SLD and CSF and genetic variants were analyzed under an additive genetic model with logistic regression models. **Results:** 1089 PWH were enrolled, median age 52 years, male 74%, White 27%, Black 46%, Hispanic 23%, median BMI 30 kg/m^2, 48% SLD (37%, MASLD; 11%, MetALD), and 18% of SLD with CSF. Minor allelic frequencies were as follows: *PNPLA3*-G, 27.1%; *TM6SF2*-T, 4.8%; *HSD17B13*-A, 14.5%; *TMC4-MBOAT7*-T, 36.8%, and *GCKR*-T, 28.7%. Compared to non-SLD PWH, those with SLD, were more likely to be White/Hispanic and older, had diabetes and abdominal obesity, higher triglycerides, ALT, and higher frequency of *PNPLA3-G (*48% vs 41%), and *GCKR*-T (50% vs 45%) alleles, $p < 0.05$ for all. HIV-related factors such as HIV duration, viral load, and ART were not significantly different between the two groups. Variants in *PNPLA3*, *TM6SF2, MBOAT7-TMC4, and GCKR,* but not *HSD17B13* were independently associated with higher odds of SLD (Figure). Among PWH and SLD, those with CSF vs. without CSF had a higher frequency of *PNPLA3-G (59% vs* 45%), *MBOAT7-TMC4*-T (68% vs 61%), and GCKR-T (61% vs 47%) alleles, $p < 0.05$ for all. On multivariable analysis, variants in *PNPLA3, MBOAT7-TMC4, and* GCKR but not HSD17B13 were associated with higher odds of CSF (Figure). Among PWH, an unweighted polygenic risk score (PRS) that sums the total number of risk alleles for *PNPLA3*, *TM6SF2, MBOAT7-TMC4, and GCKR* was strongly independently associated with SLD and CSF. **Conclusion:** Several genetic variants influence the risk of SLD and CSF in PWH. An unweighted PRS comprising *PNPLA3, TM6SF2, MBOAT7-TMC4*, and *GCKR* predicts HIV-SLD disease risk and severity.

Figure. Association of genetic variants (additive genetic model) with SLD, MASLD, MetALD, or CSF. Results based on multivariable[a] analyses.

	SLD[b]		MASLD		MetALD		CSF[c]	
	OR (95% CI)	P value	OR (95% CI)	P value	OR (95% CI)	P value	OR (95% CI)	P value

2563 | STATIN USE REDUCES LIVER FIBROSIS PROGRESSION IN PATIENTS WITH LOW-RISK CHRONIC LIVER DISEASE

Vy Nguyen[1] Jonggi Choi[2] Eric Przybyszewski[3] Jiunn Song[4] Allison Carroll[5] Megan Michta[4] Erik Almazan[6] Raymond Chung[4], [1]Harvard Medical School, [2]Department of Gastroenterology, Liver Center, Asan Medical Center, [3]Massachusetts General Hospital, [4]Liver Center, Gastroenterology Division, Massachusetts General Hospital, Boston, MA, USA, [5]Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA, [6]Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Background: Previous studies have demonstrated that statin use is associated with slower hepatic fibrosis progression. However, their preventative benefit in low-risk chronic liver disease (CLD) remains uncertain. We therefore aimed to characterize whether early statin use in CLD patients with minimal fibrosis attenuates fibrosis progression and adverse liver-related outcomes. **Methods:** We performed a retrospective cohort study of adult patients with CLD and a baseline Fibrosis-4 index (FIB-4) of 1.3 or lower. Patients were categorized into statin users (cumulative defined daily dose [cDDD] ≥ 30) and nonusers (cDDD < 30). We used inverse probability of treatment weighting (IPTW) to minimize potential confounding. **Results:** Among 16,360 patients with low-risk CLD (4256 statin users and 12,104 nonusers), statin users were older and had higher rates of hypertension (75.4% vs 42.3%), diabetes (42.7% vs. 20.1%), and hyperlipidemia (79.6% vs. 35.0%). After IPTW adjustment, statin use was associated with significantly fewer upward transitions in FIB-4 risk categories over a median of 42.5 months of follow-up (7.4% vs 11.0%, $P < 0.0001$, Figure). This finding held in a sensitivity analysis requiring ³ 2 higher risk FIB-4 measurements (3.2% vs. 5.3%, $P < 0.0001$). Fibrosis progression rates were similar between hydrophilic and lipophilic statin users (7.7% and 7.4%, $P = 0.12$), whereas patients with cDDD > 600 had significantly lower odds of fibrosis progression compared to those with cDDD <30 (OR: 0.83, $P = 0.03$). In a 10-year follow-up, statin users and nonusers had similar cumulative incidence of cirrhosis (7.9% vs. 6.3%, respectively, $P = 0.49$), hepatic decompensation (4.9% for both, $P = 0.66$), and HCC (0.6% for both, $P = 0.81$). After additionally adjusting for age, hyperlipidemia, diabetes mellitus, GLP-1, metformin, and SGLT-2 use in a multivariable Cox regression model, statin use was not associated with significant risk reductions for incident cirrhosis (HR: 0.95, $P = 0.67$), hepatic decompensation (HR: 0.82, $P = 0.14$), or HCC (HR: 0.81, $P = 0.53$). **Conclusion:** In patients with low-risk CLD, statin use was associated with reduced fibrosis progression with a clear dose-response effect but did not demonstrate significant effects on incident cirrhosis, hepatic decompensation, or HCC, though likely due to the early-stage disease profile of this group. These findings suggest anti-fibrotic activity of statins even in early, low-risk patients with CLD and warrant further prospective trials to validate these effects.

University College of Medicine, Seoul, South Korea, [3]Department of Information Statistics, Andong National University, Andong-si, Gyeongsangbuk-do, South, [4]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong

Background: Previous studies suggested a high degree of overlap in the non-alcoholic fatty liver disease (NAFLD) and metabolic dysfunction-associated steatotic liver disease (MASLD) population, but the same may not apply to lean patients with a lower degree of cardiometabolic risk factor (CMRF) burden. This study aims to investigate the overlap between NAFLD and MASLD in lean patients with normal body mass index (BMI), and to compare the risk of fibrosis and liver-related events (LRE) in patients with lean vs. non-lean MASLD. **Methods:** This study included participants with SLD from six cohorts in Hong Kong (HK), South Korea and the United States (US). The participants were recruited from hospital, community, or health check-up settings. Individuals meeting the definitions of MASLD were classified into lean vs. overweight or obese group. Follow-up data were captured in two cohorts for longitudinal analyses, where the primary outcome was LRE. LRE were defined as the occurrence of clinical events, including hepatic decompensation, hepatocellular carcinoma, liver transplantation and liver-related deaths. Patients were categorized into lean, overweight and obese groups based on their BMI levels to examine clinical outcomes. **Results:** This study included 1,058,175 participants with SLD from six cohorts, of whom 858,950 patients met the diagnosis of MASLD. In hospital-based cohorts, 0-2.1% of lean patients with NAFLD did not fulfil the definition of MASLD. (Figure) In contrast, 8.6%-11.9% of lean patients with NAFLD in community and health check-up settings did not have MASLD, and the proportion was up to 40% in the Korean national health insurance cohort (KNHIS cohort). The lean MASLD group shared a similar prevalence of CMRF2-5 but a less total amount of CMRFs compared with overweight/obese MASLD. Lean MASLD was significantly associated with a reduced risk of LRE in the KNHIS cohort (Gray's test $p < 0.001$), but not in the Hong Kong CDARS cohort (Gray's test $p = 0.54$). **Conclusion:** The shift from NAFLD to MASLD results in a discrepancy of around 10% in the general lean population. Caution is warranted when applying the findings from previous studies based on lean NAFLD to the current lean MASLD definitions.

2565 | GLOBAL PREVALENCE AND RISK OF HIGH-RISK GENETIC POLYMORPHISMS IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD): A SYSTEMATIC REVIEW AND META-ANALYSIS

Kaanthi Rama[1] Vinay Jahagirdar[1] Ronnie Li[2] Natalia Baeza Radmilovic[3] Anas Aljabi[1] Ambuja Banerjee[1] John Cyrus[1] Stephen Hoang[1] Anand Kulkarni[4] Luis Antonio Diaz[5] Juan Pablo Arab[1], [1]Virginia Commonwealth University, [2]Virginia Commonwealth University Health, [3]Pontificia Universidad Católica de Chile, Virginia Commonwealth University, [4]Asian Institute of Gastroenterology, [5]University of California San Diego

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading global cause of chronic liver disease, with notable variation in prevalence and progression across populations. Genetic susceptibility plays a key role, particularly with variants *PNPLA3* (rs738409, rs2294918), *TM6SF2* (rs58542926), *MBOAT7* (rs641738), and *HSD17B13* (rs72613567). We aimed to determine the global prevalence of these high-risk polymorphisms in MASLD and quantify their disease association using pooled effect estimates. **Methods:** MEDLINE, EMBASE, and CENTRAL were systematically searched from inception to 9/2024, to identify case-control studies evaluating the presence of high-risk variants in individuals with MASLD compared to healthy controls. Regional prevalence of each polymorphism was calculated using weighted proportions for healthy and MASLD cohorts, defined as the proportion of individuals with at least one copy of the minor allele. To evaluate the association between polymorphisms and MASLD, pooled odds ratios were generated using a linear mixed effects model in R (metafor package) to account for intra-study variance and inter-study heterogeneity. For external benchmarking, prevalence rates were compared against corresponding allele frequencies from the Genome Aggregation Database (gnomAD v4), which is a population-level reference for global variant prevalence. **Results:** From 2,370 abstracts screened, 39 studies comprising 63,435 individuals were included. The PNPLA3 rs738409 variant showed the higher enrichment among MASLD individuals compared to healthy (Fig A, C): Europe (62% vs 42%), USA/Canada (48% vs 37% in Admixed, 93% vs 31% in Hispanic), and East Asia (69% vs 54%). The MBOAT7 rs641738 allele also showed high prevalence in MASLD cases in Europe (72%) and East Asia (48%). In Latin America, the PNPLA3 rs738409 allele was highly prevalent in both healthy (77%) and MASLD (75%) individuals. In contrast, the protective HSD17B13 variant demonstrated a lower prevalence in MASLD adults compared to healthy in Europe (30% vs. 68%). Meta-analysis showed increased MASLD risk with: 1. PNPLA3 rs738409: OR 1.7 (95% CI: 1.3-2.2, $p < 0.0001$) for heterozygotes and OR 3.3 (2.0-5.4, $p < 0.0001$)for homozygotes; 2. TM6SF2 (heterozygous OR 1.6, 95% CI 1.2-2, $p = 0.002$; homozygous OR 2.5, 95% CI 1.1-5.6, $p = 0.030$); 3. MBOAT7 (heterozygous OR 1.17, $p = 0.24$) (Fig C, E). TM6SF2 estimates in Europe aligned closely with gnomAD. Deviations were observed in few variants across regions, likely reflecting sampling bias (Fig B). **Conclusion:** This global synthesis demonstrates substantial variation in the prevalence of high-risk polymorphisms associated with MASLD, particularly for PNPLA3, which shows the strongest and most consistent association with disease across all regions. These findings underscore the need for ancestry-informed genetic screening approaches and region-specific risk models in liver disease management.

2566 | BMI AND DIETARY INTAKE AS MODIFIABLE PREDICTORS OF POSTPARTUM STEATOTIC LIVER DISEASE: RESULTS: FROM THE PROSPECTIVE FATTY LIVER IN PREGNANCY (FLIP) COHORT

Cecilia Katzenstein Nina Rodriguez[1] Keith Sigel[1] Rhoda Sperling[1] Norah Terrault[2] Tatyana Kushner[3] Xiaotao Zhang[1] [1]Icahn School of Medicine at Mount

Sinai, [2]University of Southern California, [3]Weill Cornell Medicine

Background: Steatotic liver disease (SLD) affects an estimated 14% of women in pregnancy and may persist or develop de novo in the postpartum period. While elevated BMI and poor diet are suspected contributors, data on modifiable risk factors remain limited. We aimed to evaluate the influence of these factors on postpartum SLD. **Methods:** We leveraged the prospective Fatty Liver in Pregnancy (FLIP) cohort to evaluate the prevalence of SLD during pregnancy and postpartum using vibration-controlled transient elastography (VCTE), defining SLD as a CAP score ≥ 248 dB/m. Pre-pregnancy BMI and BMI at delivery were obtained from the medical record, and postpartum weight at the time of follow-up VCTE. Participants also completed the NIH Dietary Screener Questionnaire in the postpartum period. Adequate nutrition intake was defined per USDA guidelines. Chi-squared tests were used to compare SLD prevalence by diet, paired t-tests evaluated changes in CAP scores over time, and age adjusted logistic regression identified predictors of postpartum SLD. **Results:** Among participants with intrapartum and postpartum assessment ($n = 28$), the mean age was 29, 54% identified as Hispanic, 14% had persistent SLD, and 32% developed new postpartum SLD. Mean CAP scores significantly increased from pregnancy to postpartum, with a mean difference of 35.64 (95% CI: 16.62-54.67; $p < 0.001$). Higher BMI at delivery was the strongest predictor of postpartum SLD (aOR 1.35, 95% CI: 1.06-1.72; $p = 0.01$). Pre-pregnancy BMI was also significantly associated with postpartum SLD (aOR 1.25, 95% CI: 1.04-1.51; $p = 0.02$). While postpartum weight was higher among those with SLD than those without (89.8 kg vs 72.6 kg; $p = 0.028$), inadequate weight loss postpartum based on pregnancy weight gain was not significantly associated. Among patients with postpartum SLD, mean daily intake of fiber, calcium, whole grains, dairy, fruits, and vegetables were significantly below recommended levels, while added sugar intake exceeded guidelines. Adequate fiber intake and adequate calcium intake were associated with a significantly lower prevalence of postpartum SLD (0% vs 68%, $p < 0.001$; 20% vs 68%; $p = 0.01$). **Conclusion:** In this cohort, CAP scores increased significantly after pregnancy, with over one-third of participants developing new SLD in the postpartum period. Elevated BMI—particularly at delivery—was the strongest predictor, highlighting the role of gestational weight trajectory. Poor dietary quality, especially inadequate fiber and calcium intake, was common among those with SLD and may represent modifiable risk factors.

Table 1. Participant Characteristics and Dietary Intake by Postpartum SLD Status

	No Postpartum SLD (n=15)	Postpartum SLD (n=13)	*p* value
Demographic features			
Mean age (years)	29.3 (5.0)	29.3 (5.2)	0.983
Hispanic ethnicity (%)	53%	54%	0.978
BMI, Weight, and SLD Features			
SLD in pregnancy (%)	7%	31%	0.097
Pre-pregnancy BMI (kg/m²)	24.3 (5.7)	31.8 (7.0)	0.005*
BMI at delivery (kg/m²)	30.0 (4.2)	36.1 (6.0)	0.006*
Weight postpartum (kg)	72.6 (17)	89.8 (21.5)	0.028*
Dietary features

2567 | PERSISTENT BINGE DRINKING IS ASSOCIATED WITH ADVANCED LIVER FIBROSIS AND ALL-CAUSE MORTALITY IN METALD

Ru-Tao Lin[1] Zhe-Kun Xiong[2] Bi-Wei Chen[2] Xin Xin[1] Tao-Ying Deng[2] Qin-Mei Sun[1] Li-Ming Gan[2] Yiyang Hu[1] qin feng[1], [1]Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, [2]Department of Spleen, Stomach and Hepatobiliary, Zhongshan Hospital of Traditional Chinese Medicine

Background: Metabolic and alcohol related/associated liver disease (MetALD) is characterized by the coexistence of metabolic dysfunction and moderate alcohol intake. In this population, the impact of specific drinking patterns, particularly persistent binge drinking (PBD), on disease severity and prognosis remains unclear. The study aimed to evaluate the association between a history of PBD and the risks of advanced liver fibrosis and all-cause mortality in individuals

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

with MetALD. **Methods:** We analyzed data from NHANES 1999–2016, including adults with MetALD. PBD is defined as having had a history of drinking ≥ 5 alcoholic beverages almost every day, based on ALQ150/151 questionnaires. Advanced fibrosis was defined as FIB-4 >2.67, and mortality outcomes were obtained from the National Death Index. Multivariable logistic and Cox regression models were used to examine the associations between PBD and both liver fibrosis and all-cause mortality, adjusting for alcohol intake and other confounders. Survival analyses excluded individuals who died within the first two years of follow-up. **Results:** Among 896 individuals with MetALD, 344 (38.4%) reported a history of PBD. Compared to those without PBD, participants with PBD had a higher risk of advanced fibrosis (adjusted OR = 3.23, 95% CI: 1.34–7.76, $p < 0.01$) (Table 1). PBD was also associated with increased all-cause mortality (adjusted HR = 1.62, 95% CI: 1.14–2.32, $p < 0.01$). These associations were more pronounced in individuals with elevated liver enzymes. Sensitivity analyses supported the robustness of the findings. When participants aged <35 or >65 years were excluded, the association between PBD and advanced fibrosis remained significant (adjusted OR = 3.05, 95% CI: 1.20–7.77, p = 0.02). When individuals who died within the first two years of follow-up were re-included, PBD was still associated with increased all-cause mortality (adjusted HR = 1.88, 95% CI: 1.22–2.91, p < 0.01). **Conclusion:** Persistent binge drinking is associated with increased risks of advanced fibrosis and mortality in MetALD, especially among individuals with elevated liver enzymes. In clinical assessment, attention should be paid to drinking patterns, particularly the presence of a persistent binge drinking history.

Table 1. Multivariable logistic regression models for advanced liver fibrosis (FIB-4 > 2.67) by persistent binge drinking, and Cox regression models for all-cause mortality stratified by persistent binge drinking.

	Crude model		Model 1		Model 2	
	OR (95%CI)	p	OR (95%CI)	p	OR (95%CI)	p
Advanced liver fibrosis (FIB-4 > 2.67)						
Never persistent binge drinking	Reference	-	Reference	-	Reference	-
Persistent binge drinking	1.97 (1.13, 3.43)	0.016	2.04 (1.11, 3.72)	0.021	3.23 (1.34, 7.76)	0.009

	Crude model		Model 1		Model 2	
	HR (95%CI)	p	HR (95%CI)	p	HR (95%CI)	p
All-cause mortality						
Never persistent binge drinking	Reference	-	Reference	-	Reference	-
Persistent binge drinking	1.50 (1.08, 2.09)	0.016	1.62 (1.14, 2.30)	0.007	1.62 (1.14, 2.32)	0.008

Model 1 was adjusted for age, sex, race, education level, and body mass index.

Model 2 was further adjusted for ALT > 40 U/L, AST > 40 U/L, and GGT > 40 U/L, HbA1c, triglycerides, uric acid, and average daily alcohol intake.

2568 | THE OBESITY EPIDEMIC AND ITS IMPACT ON ADULT LIVING LIVER DONATION: A DECLINING DONOR POOL

Puneet Bansal[1] MUHAMMAD AHMAD NADEEM[1] Valberto Sanha[1] Sapana Verma[1] Leandro Sierra[2] Katey Hellickson[1] Saleh Alghsoon[1] Alejandro Pita[1] Koji Hashimoto[1] Jamak Modaresi Esfeh[2] Chase Wehrle[1] Sobia Laique[1], [1]Cleveland Clinic, [2]Cleveland Clinic Foundation

Background: The global obesity epidemic increasingly impedes living donor liver transplantation (LDLT). Obesity-associated comorbidities, especially MASLD, frequently lead to donor exclusion. This study characterized donor attrition patterns related to obesity at a single center and evaluated national graft outcomes for recipients of grafts from living donors with obesity. **Methods:** A retrospective cohort study analyzed adult LDLT referrals at a single academic center (2018–2024). Donor outcomes were categorized: (1) declined pre-evaluation, (2) evaluated and declined, or (3) donated. Reasons for exclusion were documented. Institutional policy favored BMI <30 kg/m2; BMI 30.0−34.9 kg/m2 (Class I obesity) was considered case-by-case, while BMI ≥35.0 kg/m2 (Class II/III obesity) generally resulted in exclusion due to steatosis concerns. National LDLT recipient graft survival data (SRTR, 2013–2024) were analyzed, stratified by donor obesity, using Kaplan-Meier and log-rank tests. A sensitivity analysis excluded pediatric recipients/donors, multiorgan/re-transplants, and missing data. Statistical significance was p < 0.05. **Results:** Of 844 adult referrals, 166 underwent LDLT. 296 (35.1%) had Class I/II obesity. 345 (40.9%) potential donors completed evaluation. Individuals with obesity were less likely to complete evaluation (31% [91/296] vs. 46% [254/548]). Two hundred and five of them (69.3%) were declined pre-evaluation (81% due to obesity). An additional 49 (16.6%) were evaluated but declined (53% had MASLD). Only 42 (14.2%) potential donors with obesity proceeded to donation (28.6% had MASLD), following a mandated median weight loss of 2.4 kg (IQR 0–5.4 kg). [Fig 1A] The median BMI of accepted donors declined, while that of declined donors increased (p < 0.001), reflecting heightened selection pressure. [Fig 1B] At our center, recipients of grafts from carefully selected donors with obesity showed similar graft survival to donors without obesity (log-rank p = 0.154). However, national SRTR data revealed reduced recipient survival for LDLT from Class II/

III obesity donors (BMI ≥35 kg/m2) (log-rank p<0.001). [Fig 1C]. **Conclusion:** Obesity is a barrier to adult LDLT, causing significant donor attrition. While selected donors with obesity yield acceptable single-center outcomes, national data indicate increased graft risk with higher donor BMI. Proactive donor metabolic optimization strategies are crucial to safely expand the living donor pool.

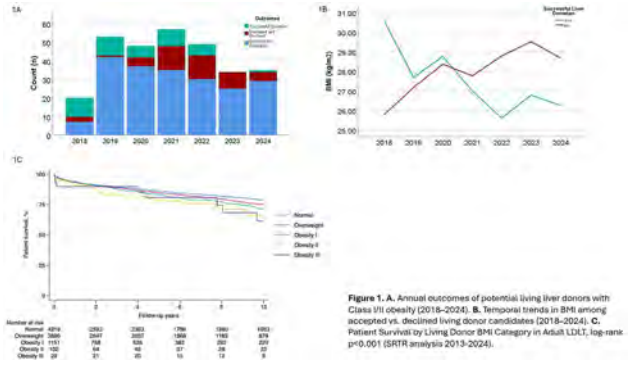

Figure 1. A. Annual outcomes of potential living liver donors with Class I/II obesity (2018–2024). **B.** Temporal trends in BMI among accepted vs. declined living donor candidates (2018–2024). **C.** Patient Survival by Living Donor BMI Category in Adult LDLT, log-rank p<0.001 (SRTR analysis 2013-2024).

2569 | SEX-BASED DIFFERENCES IN LIVER FIBROSIS PROGRESSION AMONG ADULTS AGED 55 AND OLDER WITH MASLD: AN ANALYSIS OF A NATIONAL DATABASE

Kate Solpari[1] Emma Leipsner[1] Priyanka Gaur[1] Scarlet Yang[1] Jessica Siguencia[1] Tatyana Kushner[1], [1]Weill Cornell Medical College

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) progression may differ by sex, but the impact of post-menopausal estrogen decline on these patterns relative to men remains unclear. Previous research in older adults has often been hampered by limitations such as small cohorts, cross-sectional designs, and insufficient control for metabolic confounders. This study used a large, propensity-matched national database to determine if women aged 55 and older with MASLD exhibit distinct liver fibrosis progression compared to age-matched men with similar metabolic risk. **Methods:** We queried the TriNetX Research Network (100 healthcare organizations) for adults ≥55 years old with an incident diagnosis of MASLD and ≥5 years of follow-up. Patients with competing liver diseases or women on hormone-replacement therapy were excluded. A 1:1 propensity-score match (nearest-neighbor, caliper 0.1) balanced sex cohorts on age, race/ethnicity, obesity, diabetes, hypertension, dyslipidemia, alcohol use, and tobacco use. Outcomes included new-onset fibrosis, cirrhosis, liver-enzyme elevations, individual features of hepatic decompensation, liver transplantation, and hepatocellular carcinoma. Adjusted relative risks and hazard ratios are reported with 95 % confidence intervals. **Results:** The analysis included 27,204 women (≥55 years) and 27,204 men (≥55 years). The population was 76.9% White, 10.3% Hispanic, 101% Black or African American, and 6.0% Asian. Women demonstrated significantly lower risk of hepatic fibrosis compared to men (RR 0.830, 95% CI 0.705–0.976, p=0.024) (Table 1). Women with MASLD also had lower rates of ascites (RR 0.774, 95% CI 0.638–0.939, p=0.008), jaundice (RR 0.426, 95% CI 0.331–0.548, p<0.001), liver transplantation (RR 0.341, 95% CI 0.189–0.614, p<0.001), and hepatocellular carcinoma (RR 0.556, 95% CI 0.325–0.951, p=0.029). Women demonstrated a 22.1% lower hazard of developing any hepatic decompensation (HR 0.779, 95% CI 0.647–0.939, p=0.008) and an 11.1% lower hazard of cirrhosis (HR 0.889, 95% CI 0.791–0.998, p=0.045) (Table 1). **Conclusion:** Despite post-menopausal estrogen decline, women aged 55+ with MASLD demonstrated significantly lower fibrosis progression and decompensation than age-matched men with similar metabolic risks. This finding suggests a persistent female protective advantage not solely reliant on estrogen, potentially driven by other intrinsic sex-specific biological factors like genetic or immune differences. This challenges simpler estrogen-centric views and highlights the need to explore these non-estrogenic mechanisms.

Outcome	Female Events	Male Events	Risk Ratio (95% CI)	Hazard Ratio (95% CI)	*p*-value
Fibrosis	264 (1.0%)	318 (1.2%)	0.83 (0.71–0.98)	0.83 (0.71–0.98)	0.027
Cirrhosis	522 (1.9%)	590 (2.2%)	0.89 (0.79–0.99)	0.89 (0.79–1.00)	0.043
Decompensation (composite)	190 (0.7%)	244 (0.9%)	0.78 (0.65–0.94)	0.78 (0.65–0.94)	0.010
Ascites	187 (0.7%)	242 (0.9%)	0.77 (0.64–0.94)	0.77 (0.65–0.94)	0.008
Jaundice	92 (0.3%)	216 (0.8%)	0.43 (0.33–0.54)	0.43 (0.33–0.54)	<0.001
Esophageal varices	56 (0.2%)	64 (0.2%)	0.88 (0.61–1.25)	0.87 (0.61–1.25)	0.447
ALT ≥2x ULN	2,944 (10.8%)	4,559 (16.8%)	0.65 (0.62–0.67)	0.62 (0.59–0.65)	<0.001
AST ≥2x ULN	610 (2.2%)	773 (2.8%)	0.79 (0.71–0.88)	0.79 (0.71–0.88)	<0.001
Liver Transplant	15 (0.1%)	44 (0.2%)	0.34 (0.19–0.61)	0.34 (0.19–0.61)	<0.001

2570 | COMPARING THE RISK OF MAJOR ADVERSE CARDIOVASCULAR AND LIVER OUTCOMES IN PATIENTS WITH PROBABLE MASH TO THOSE WITH DIAGNOSED MASH AND WITHOUT MASH

Caichen Zhong[1] Nana Boame[2] Semiu Gbadamosi[3] Maximilian Kurt Jara[1] Rakesh Luthra[3] Yu Hong[2] Bret Zeldow[2] Abdalla Aly[4] Mary Rinella[5], [1]Novo Nordisk Inc., [2]Genesis Research Group, [3]Novo Nordisk Inc, [4]Novo Nordisk, [5]The University of Chicago

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is associated with adverse outcomes, particularly major adverse cardiovascular events (MACE) and major adverse liver outcomes (MALO). MASH is highly underdiagnosed, and the clinical burden of probable MASH remains unclear. The study aimed to assess the clinical burden experienced by patients with probable MASH, evaluating the risk of MACE, heart failure (HF) hospitalization, and MALO, and comparing these risks to those in patients with diagnosed MASH and those without MASH. **Methods:** This retrospective study used Komodo Healthcare Map™ data from 2017 to 2022. Probable MASH was defined by an adapted metabolic dysfunction-associated steatotic liver disease Decision Tree: hepatic steatosis index >36 or ICD-10-CM code K76.0, plus ≥ 1 cardiometabolic risk factor, during a 12-month baseline period. Patients with diagnosed MASH had an ICD-10-CM code K75.81: ≥ 1 primary inpatient code or ≥ 2 outpatient codes ≥ 30 days apart. Patients without MASH met none of these criteria. Propensity score weighting was applied to balance baseline characteristics. Hazard ratios and 95% confidence intervals estimated the risk of 2-point MACE (non-fatal acute myocardial infarction [AMI] or stroke), expanded MACE (AMI, stroke, coronary revascularization, HF hospitalization, or all-cause mortality), HF hospitalization, and MALO. MACE and MALO outcomes were evaluated in patients without previous events, respectively. **Results:** The study comprised patients with probable MASH (n = 1,893,764), diagnosed MASH (n = 18,252), and without MASH (n = 647,652). Patients with probable MASH compared to those without MASH were more likely to develop 2-point MACE (1.08 [1.05, 1.10]), expanded MACE (1.07 [1.05, 1.08]), and HF hospitalization (1.40 [1.37, 1.44]). The hazard of MALO was not significantly different (1.00 [0.99, 1.01]). Patients with probable MASH had a similar hazard of 2-point MACE compared to patients with diagnosed MASH, (0.99 [0.86, 1.14]) but a lower hazard of expanded MACE (0.90 [0.82, 0.99]), HF hospitalization (0.79 [0.69, 0.90]), and MALO (0.43 [0.41, 0.45]). **Conclusion:** Patients with probable MASH had a higher rate of cardiovascular events compared to those without MASH, but a lower rate of MACE and MALO events than those with diagnosed MASH. These findings show that probable MASH adds to clinical burden, which is higher than patients without MASH, and closer to patients with diagnosed MASH, emphasizing the importance of early screening and management of patients.

2571 | THE IMPACT OF HIGH FRUCTOSE CORN SYRUP ON LIVER INJURY AND GLUCOSE METABOLISM: A SYSTEMATIC REVIEW

Maimuna Marenah[1] Zane Yu[2] Sneha Varahala[1] Sean Lim[1] Julia Wattacheril[3], [1]Mailman School of Public Health, Columbia University, [2]Warren Alpert Medical School, Brown University, [3]Columbia University

Background: High fructose corn syrup (HFCS) is a popular dietary sweetener that is used in a substantial portion of food and beverages. Recent evidence has cited dietary HFCS as a risk factor in the development of obesity, metabolic syndrome and liver disease. In particular, HFCS has been implicated in the pathogenesis of non-alcoholic fatty liver disease (NAFLD). Preclinical studies suggest that HFCS induces cellular damage, oxidative stress, impairs molecular signaling, and causes dysfunction in metabolic pathways. This systematic review provides a new evaluation of the potential hepatic and metabolic risks posed by HFCS to inform both clinical practice and public health policy. **Methods:** We conducted a systematic review of English-language, human studies of adults ($\geq$ 18 years) with low to no alcohol intake using the most recent version of Covidence. Only quantitative studies that specified a link supported by direct evidence between HFCS and markers of liver injury or glucose metabolism in the setting of MASLD or NAFLD were included in this review. **Results:** The literature search yielded 23,006 studies. After removing duplicates, 16,955 studies were screened and 16,930 were excluded after abstract screening. 20 texts were reviewed in full; 5 texts were not found, and 19 were excluded. 1 study was included after study selection. **Conclusion:** This review identifies and critically appraises the methodological strengths and limitations of the sole study meeting eligibility criteria for the systematic review. The 2022 study by Sigala et al. involved a non-randomized, controlled dietary intervention examining the dose-response effects of high-fructose corn syrup (HFCS) on hepatic lipid accumulation and insulin sensitivity in healthy adults. The identification of only a single eligible study – despite an exhaustive search strategy – emphasizes a stark absence of focused investigations in this area. Given the increasingly widespread consumption of HFCS and its prevalence in the modern food supply, this scarcity of research is concerning. Further research in this area should focus on clinical studies of longer duration, comparative studies of HFCS and other sugars, and incorporate greater demographic and geographic diversity.

Chintalapati[3] Aishwarya Yannamani[1] Qusai Al Zureikat[1] Ujjwala Narang[1] Isha Isha[1] Sahana Karkera[1] Arul Thomas[4], [1]MedStar Georgetown/Washington Hospital Center, [2]MedStar Union Memorial, [3]Georgetown University- School of Medicine, [4]MedStar Georgetown University Hospital

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) has a global prevalence of approximately 25% and is expected to increase parallel with rising rates of obesity and type 2 diabetes mellitus. In 2023, AASLD guidelines emphasized the role of primary care providers (PCPs) in screening for MASLD and ruling out advanced fibrosis using the Fibrosis-4 (FIB-4) index, which has a high negative predictive value. A survey conducted in our primary care clinic found that although 15% of internal medicine residents screened for MASLD, only 7% felt comfortable using the FIB-4 index, and 15.4% routinely counseled patients about the condition. This study aims to enhance awareness, screening practices, and risk assessment for MASLD within our primary care clinic. **Methods:** We included patients aged $\geq$ 18 years who were seen in the primary care clinic and had type 2 diabetes mellitus (HbA1c $\geq$ 7%) or morbid obesity (BMI $\geq$ 35 with hypertension or hyperlipidemia) during the pre-intervention period (Oct 2023 – Mar 2024) and the post-intervention period (Jun – Nov 2024). Exclusions were chronic liver disease or alcohol use disorder. The intervention (Apr–May 2024) included didactic sessions, clinic huddles, reminder emails, and the addition of MASLD screening to the general screening dot phrase bundle in the Electronic Health Record (EHR). Outcomes included MASLD documentation, FIB-4 use, and referrals. Data were analyzed using t-tests and chi-square/Fisher's exact tests. A p-value <0.05 was considered statistically significant. **Results:** A total of 557 patients were included (296 pre-intervention and 261 post-intervention). The demographics and comorbidities were similar between the two groups, as shown in Table 1. Most patients were African American (86.3% vs. 84.9%, p-value = 0.97) and non-Hispanic (95.7% vs. 94.8%, p-value = 0.61). Documentation of MASLD increased significantly after the intervention, from 0% to 16.0% (p-value < 0.001). Medical management, including counseling about lifestyle modifications and hepatology referrals, increased significantly post-intervention, from 7.1% to 16.5% (p-value < 0.001) **Conclusion:** Our study underscores the positive impact of a targeted educational intervention on improving MASLD documentation and increasing awareness among internal medicine residents. These findings highlight the critical role of PCPs in the early detection and risk stratification of MASLD, reinforcing the importance of integrating focused training and EHR-based tools into routine primary care practice to enhance long-term patient outcomes

shunt (TIPS) is limited to retrospective observational studies. This leads to the question of whether the clinical outcomes of TIPS among the different etiologies of cirrhosis are similar. Given that no decisive Conclusion: can be drawn from the current evidence regarding TIPS placement among different etiologies, this study aims to explore the outcomes of TIPS placement between cirrhosis by MASH vs. ALD. **Methods:** A retrospective cohort study was performed using TriNetX. Patients with cirrhosis who underwent TIPS were identified and stratified by etiology into two groups: MASH cirrhosis and alcoholic cirrhosis. The cohorts were matched using propensity score matching (1:1) based on gender, demographics, comorbidities, and medications. Outcomes assessed included all-cause mortality, hepatic decompensation, major adverse liver outcomes (MALO), hepatic encephalopathy (HE), spontaneous bacterial peritonitis (SBP), and portal vein thrombosis (PVT). These outcomes were analyzed at 1- and 3-year follow-up following the index event. Hazard ratios (HRs) and 95% confidence intervals (CIs) were calculated to evaluate associations between variables. **Results:** A total of 5,096 adult patients with cirrhosis who underwent TIPS were identified, of which 1,326 had MASH cirrhosis. 1,035 patients with MASH cirrhosis (mean age 62.1 years, 46.6% female) were matched with 1,035 patients with alcoholic cirrhosis (mean age 62.3 years, 45.2% female). No differences were observed in all-cause mortality, hepatic decompensation, MALO, HE, SBP, and PVT. **Conclusion:** Discussion: Our study demonstrated that there is no significant clinical difference following TIPS placement between MASH and ALD cirrhosis. This finding suggests that decompensated cirrhosis necessitating TIPS has a similar progression of the disease regardless of the inciting event. Although our study is limited to the available data in the database, it gives rise to the hypothesis that such behavior might be expected in cirrhosis arising from other causes. Further longitudinal studies are warranted to validate this hypothesis.

2574 | ASSESSING MASLD AND LIVER FIBROSIS WITH TRANSIENT ELASTOGRAPHY: FINDINGS FROM A MULTICENTER POPULATION-BASED STUDY IN MEXICO

Luis Enrique Gutiérrez Rosas[1] Carlos Martinez-Cabrera[1] Berenice Roman-Calleja[2] Victor Montoya Guzman[1] Marcela Castillo-Medina[1] Alma Ladron-De-Guevara-Cetina[1], [1]Centro de Investigación y Gastroenterología, [2]Universidad Nacional Autónoma de México

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects up to 30% of the global population and over 44% in Latin America. In Mexico, prevalence is estimated between 41–52%, mostly based on ultrasound or clinical indices. The Mexican population is of particular interest due to its genetic predisposition, high burden of metabolic diseases, and frequent use of potentially hepatotoxic herbal supplements. We aimed to describe the prevalence and clinical characteristics of liver health in a general population using transient elastography. **Methods:** We conducted a cross-sectional study including 981 participants from the general population between September 2024 and May 2025, recruited from different states of Mexico, at two clinical sites belonging to the "Centro de Investigación y Gastroenterología, Mexico City", a facility with experience in clinical trials. All participants underwent the FibroScan® Compact 530 model to assess hepatic steatosis (CAP $\geq$288 dB/m) and liver fibrosis (LSM $\geq$8.2 kPa). Clinical and metabolic data were collected to explore associations with MASLD. **Results:** A total of 981 adults from the general population were included with a median of 54 (41-63) years and 64.2% were female. MASLD was present in 33.4 % (n = 328),of which 59 (18.0%) had significant fibrosis. From the whole sample, we identified significant fibrosis in 16.3% (n = 161). Among those with significant fibrosis, 31 (19.2%) had F2, 37 (23.0%) had F3, and 93 (57.8%) had F4. When stratified by fibrosis stage, CAP values tended to decrease with advancing fibrosis, from a median of 294 dB/m in F2 to 238 dB/m in F3 and 217 dB/m in F4 ($p = 0.021$). Participants with advanced fibrosis (F2–F4) also had higher BMI ($p = 0.002$), with values up to 30.5 kg/m², and a higher prevalence of diabetes or prediabetes, reaching 50.5% in F4 ($p < 0.001$). Hypertension was more frequent in advanced fibrosis (up to 45.2% in F2,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

$p < 0.001$). **Conclusion:** MASLD and significant liver fibrosis are common in the general Mexican population. CAP values decreased with advancing fibrosis, likely reflecting the replacement of steatotic hepatocytes by fibrotic tissue. The presence of fibrosis at a young age raises concern for disease progression and highlights the need for early identification and targeted interventions.

Table 1. Characteristics of the study population according to presence or absence of MASLD and liver fibrosis.

	MASLD (N=328)	Non-MASLD (N=653)	P value	F0-F1 (n=820)	F2 (N=31)	F3 (N=37)	F4 (N=93)	P value

2575 | FROM HOTSPOTS TO BLINDSPOTS: A GLOBAL VIEW OF MASH RESEARCH DISPARITIES OVER TIME

Renan Prado[1] Melissa Lou Silva[2], [1]Cleveland Clinic Foundation, [2]University of California San Diego

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD), previously known as nonalcoholic fatty liver disease (NAFLD), and its progressive form, metabolic dysfunction-associated steatohepatitis (MASH, formerly NASH), represent a major cause of chronic liver disease worldwide. MASLD is now recognized as a systemic metabolic disorder with significant cardiovascular and malignant complications. With evolving nomenclature and rising global prevalence, publication trends and research impact across regions warrant evaluation. **Methods:** A bibliometric analysis was performed using the Web of Science Core Collection. All articles and reviews published between 1980 and 2024 containing the terms “NASH”, “MASH”, “NAFLD”, or “MASLD” were included. Bibliometric indicators were analyzed using the Bibliometrix package in R, including annual productivity, citation impact, authorship, and international collaboration. **Results:** A total of 51,619 relevant publications were identified, with 15,351 with Meeting Abstract. The total percentage of publications from the most recent 10 years (January 2016– May 2025) accounts for approximately 70.3% of all records. This highlights the interest the interest of MASH/MASLD in the most recent years. We evaluated the 1,000 most cited articles, among the 36,268 evaluated. The United States led with 425 publications, followed by Italy (113), China (96), Japan (81), and the UK (70). Low- and middle-income countries collectively accounted for approximately 18% of the total output. *Hepatology*(169 articles), *Journal of Hepatology* (105), and *Gastroenterology* (74) were the top 3 journals with most prolific sources. The most cited paper, published in *Hepatology* (Kleiner et al., 2005), accrued 8,489 citations. The USA, Italy, and Japan ranked highest in total citations. While the USA dominated both single-country and multi-country collaborations, international engagement varied by region. **Conclusion:** Global research output on MASH/NASH and MASLD/NASLD continues to grow rapidly, yet significant disparities persist. High-income countries dominate authorship and citation impact, emphasizing the need for more inclusive and collaborative research efforts involving underrepresented regions.

2576 | HORMONE REPLACEMENT THERAPY AND METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Garvita Singhal[1] Shahid Habib[2] Elias Shamieh[3], [1]Tucson Medical Center, [2]Liver Institute PLLC, Tucson, [3]University of Cincinnati

Background: MASLD is increasingly recognized in postmenopausal women, likely due to estrogen deficiency. While estrogen influences metabolic and hepatic function, the impact of hormone replacement therapy (HRT) on MASLD progression remains unclear. This

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

study evaluated associations between estrogen therapy and clinical, metabolic, and hepatic parameters related to MASLD in women. **Methods:** We conducted a retrospective analysis of IRB-approved, prospectively collected liver registry data (July 2015–Dec 2020). Inclusion required ≥6 months of estrogen use and complete exposure data. Of 684 women, 400 (58.5%) had estrogen exposure (via contraception, HRT, or both), and 284 (41.5%) did not. Clinical, metabolic, liver, and immunologic parameters were compared. Multivariable logistic regression (adjusted for age, alcohol, comorbidities) assessed associations with cirrhosis (by biopsy/imaging) and metabolic syndrome (≥3 criteria). Spearman's correlation examined estrogen duration and insulin resistance (HOMA-IR). Stratified analyses used Mantel-Haenszel method. **Results:** Among estrogen users, indications were contraception (n = 123), HRT (n = 232), or both (n = 46). Mean age was 57.3 years; mean estrogen duration 5.2 years. Estrogen duration (combined contraception and/or HRT) negatively correlated with HOMA-IR ($r = -0.149$, $p = 0.001$), suggesting reduced insulin resistance. This correlation was lost when subgroups were analyzed separately. Estrogen use (HRT or combined) was not independently associated with metabolic syndrome or cirrhosis in adjusted models. On unadjusted analysis, contraception-only users had lower cirrhosis risk vs. nonusers (OR 0.57, $p = 0.003$), but this lost significance after adjustment. Predictors of metabolic syndrome included hypertension, NAFLD/NASH, diabetes/prediabetes, hypertriglyceridemia, low HDL, high NAFLD fibrosis score, and low Fib-4 (all $p < 0.05$). Independent cirrhosis predictors included autoimmune disease (OR ~5.4–5.8), elevated Fib-4 and NFS, AST/ALT ratio, alcohol use, hypertension, ANA positivity, and BMI ≥29. **Conclusion:** Lifetime estrogen use was not independently associated with cirrhosis or metabolic syndrome but was linked to improved insulin sensitivity, a key MASLD factor. Findings underscore MASLD's multifactorial nature in women and the need for prospective studies to clarify HRT's impact on liver outcomes.

2577 | PNPLA3 P.I148M POLYMORPHISM IS ASSOCIATED WITH THE RISK OF LIVER FIBROSIS IN PATIENTS WITH BREAST CANCER RECEIVING LONG-TERM TAMOXIFEN THERAPY

Wonseok Kang[1] Sangdeok Shin[1] Myung Ji Goh[1] Byeong Geun Song[1] Dong Hyun Sinn[1] Geum-Youn Gwak[1] Yong-Han Paik[1] Moonseok Choi[1] Joon Hyeok Lee[1] Jonghan Yu[1], [1]Samsung Medical Center

Background: Estrogen upregulates PNPLA3 gene expression and activates energy-consuming hepatic metabolism. Recent studies suggest that estrogen may induce metabolic dysfunction-associated steatotic liver disease (MASLD) in women carrying the PNPLA3 p.I148M variant. Tamoxifen, a selective estrogen receptor modulator, is widely used for the prevention and treatment of estrogen receptor-positive breast cancer but is associated with steatotic liver disease (SLD). However, the relationship between PNPLA3 genotypes and tamoxifen-associated SLD remains unexplored. We aimed to investigate the prevalence and progression of MASLD in breast cancer patients receiving tamoxifen therapy, stratified by PNPLA3 genotype, to identify high-risk populations who may benefit from enhanced monitoring and personalized treatment strategies. **Methods:** This retrospective analysis utilized a prospective cohort of breast cancer patients from Samsung Medical Center between January 2015 and May 2020. Of 909 women screened, 548 breast cancer patients treated with tamoxifen for ≥2 years were included in the final analysis. PNPLA3 genotyping was performed using the TaqMan SNP Genotype Assay. Patients were classified into low-risk (CC/CG types, n = 467) and high-risk (GG type, n = 81) groups. Data were analyzed over five years using FIB-4 scores to detect fibrosis progression, with patients stratified by baseline liver fibrosis status. **Results:** In multivariable analysis, the PNPLA3 GG genotype had a significantly increased risk of fibrosis progression (HR 2.69, 95% CI 1.18-6.11; p = 0.018) compared to CC/CG genotype. In patients with low baseline fibrosis risk (FIB-4 <1.3), the GG genotype was associated with a 5.08-fold increased risk (HR 5.08, 95% CI 1.85-14.0; p = 0.002) compared to CC/CG genotypes, with cumulative incidence curves diverging after 24 months of treatment. In patients with moderate baseline fibrosis risk, no significant association was found (HR: 0.60; 95% CI: 0.07-4.94; P = 0.600). Subgroup analysis revealed significantly elevated fibrosis risk associated with GG genotype in patients aged ≥65 years (HR 3.73, 95% CI 1.25-11.20), those without diabetes mellitus (HR 3.27, 95% CI 1.18-9.07), patients with pre-existing MASLD (HR 2.53, 95% CI 1.01-6.35), and postmenopausal status (HR: 3.10; 95% CI: 1.26-7.61). **Conclusion:** The PNPLA3 GG genotype is associated with accelerated liver fibrosis in breast cancer patients undergoing tamoxifen therapy, particularly in those with low baseline fibrosis risk. Our findings suggest that PNPLA3 genotyping could serve as a valuable risk stratification tool, especially for older, postmenopausal women with pre-existing MASLD, who may benefit from enhanced liver monitoring during tamoxifen therapy.

2578 | INTEGRATING FIB-4 SCORING INTO PRIMARY CARE TO DETECT ADVANCED FIBROSIS IN PATIENTS WITH METABOLIC RISK: A MULTICENTER PILOT IMPLEMENTATION STUDY

Noor Albusta[1] Ammar Kheyami[2], [1]Lahey Hospital and Medical Center, [2]Bahrain Government Hospitals

Background: The global burden of metabolic dysfunction-associated steatotic liver disease (MASLD) underscores the need for early identification of advanced fibrosis, particularly in primary care settings where liver disease is often overlooked. The Fibrosis-4 (FIB-4) index, calculated from age, AST, ALT, and platelet count, is a validated, low-cost, non-invasive fibrosis risk tool using routine labs. Despite its simplicity, FIB-4 remains underutilized in primary care workflows. This study evaluated the feasibility, diagnostic yield, and real-world challenges of implementing FIB-4 screening across a network of public primary care clinics in a high-risk population. **Methods:** We conducted a 12-month prospective pilot across 10 government-affiliated primary care centers in Bahrain. Adults aged $\geq$35 years with at least one metabolic risk factor (type 2 diabetes, obesity, hypertension, or dyslipidemia) and recent laboratory tests were included. FIB-4 scores were calculated and stratified into low ($<$1.3), indeterminate (1.3–2.66), and high ($\geq$2.67) risk. High-risk patients were referred for hepatology review, with transient elastography performed where available. Outcomes included FIB-4 completion rate, referral follow-through, fibrosis detection, and provider-reported barriers. **Results:** Of 2,450 eligible patients, FIB-4 was successfully calculated in 2,136 (87.2%). High-risk scores were found in 262 patients (12.3%), of whom 188 (71.8%) were referred. Among 113 who completed elastography, 34.5% had advanced fibrosis ($\geq$F3), and 6.2% had cirrhosis. The number needed to screen (NNS) to detect one case of advanced fibrosis was 55. The positive predictive value (PPV) of a high FIB-4 score for advanced fibrosis was 34.5%, with a 95% confidence interval of 25.5%–43.5%. Referral efficiency (confirmed fibrosis per referral) was 20.7%. Referral adherence was high (89%). Providers reported moderate ease of implementation. Common barriers included inconsistent lab ordering (38%), limited familiarity with interpreting FIB-4 scores (31%), patient reluctance to attend hepatology (16%), and lack of automated FIB-4 calculators within the EMR (15%). **Conclusion:** This multicenter pilot confirms that FIB-4–based screening in primary care is feasible and effective in detecting undiagnosed advanced fibrosis in patients with metabolic risk. These findings support integrating simple non-invasive tools into frontline workflows, with potential for national-level scale-up to reduce MASLD-related liver disease burden.

2579 | DISPARITIES IN OUTCOMES AND COMPLICATIONS OF ALCOHOL-RELATED AND NASH-RELATED CIRRHOSIS: A NATIONWIDE PERSPECTIVE

Abdelhaleem Sideeg Fatima Elmustafa[1] Mohammad Adam[2] Ali Osman[3] Miqdad Dafaallah[4] Blaire Burman[5] Asma Siddique[5] Richard Kozarek[5], [1]Henry Ford Hospital, [2]University of Missouri - Kansas City, [3]Washington University School of Medicine in St. Louis, [4]Mercyone Des Moines Medical Center, [5]Virginia Mason Medical Center

Background: Liver cirrhosis caused 1.48 million deaths globally in 2019. While cases of hepatitis B and C are declining, those linked to heavy alcohol consumption and nonalcoholic steatohepatitis (NASH), recently renamed metabolic-associated steatohepatitis (MASH), are increasing. The current literature offers limited comparison data on the outcomes and complications associated with these etiologies. This nationwide study aimed to fill this knowledge gap and enhance the quality of patient care. **Methods:** This cohort study analyzed 419,144 adult patients ($\geq$18 years) hospitalized for alcohol-related cirrhosis (n = 336,829) or NASH-related cirrhosis (n = 82,315) between 2017 and 2021, using the National Inpatient Sample database. ICD-10 codes were used to identify patient groups, and multivariate logistic regression was adjusted for demographic, socioeconomic, and hospital factors. Patients with concurrent alcohol-related and NASH-related cirrhosis were excluded. The primary outcome was in-hospital mortality. Secondary outcomes included total charges, length of stay (LOS), and cirrhosis complications, including hepatocellular carcinoma (HCC), portal hypertension, variceal bleeding, ascites, hepatic encephalopathy, spontaneous bacterial peritonitis (SBP), hepatorenal syndrome (HRS), coagulopathy, and liver failure. **Results:** Patients with alcohol-related cirrhosis were younger (mean age 56 years; 69.4% male) than those with NASH-related cirrhosis (mean age 64 years; 60.6% female, $p < 0.001$). Crude median charges were higher for NASH-related cirrhosis ($43,777, IQR $24,388–$83,794) than for alcohol-related cirrhosis ($41,792, IQR $23,623–$78,045, $p < 0.001$). Adjusted analysis showed that alcohol-related cirrhosis was associated with longer hospital stays by 0.78 days (95% CI 0.72–0.85, $p < 0.001$), higher odds of HCC (OR 1.36, 95% CI 1.29–1.43; $p < 0.001$), in-hospital mortality (OR 1.95, 95% CI 1.88–2.04, $p < 0.001$), ascites (OR 1.86, 95% CI 1.82–1.89, $p < 0.001$), hepatic encephalopathy (OR 1.41, 95% CI 1.37–1.45, $p <$

0.001), and coagulopathy (OR 1.82, 95% CI 1.76–1.88, p < 0.001). **Conclusion:** Our study revealed notable differences in the outcomes of alcohol consumption and NASH -related cirrhosis. Alcohol-related cirrhosis leads to extended hospital stays, more complications, and higher rates of mortality during hospitalization. These findings highlight the considerable impact of alcohol consumption on both the healthcare system and patient outcomes. Additional studies are needed to investigate the underlying causes of these disparities and assess management strategies tailored to specific etiologies.

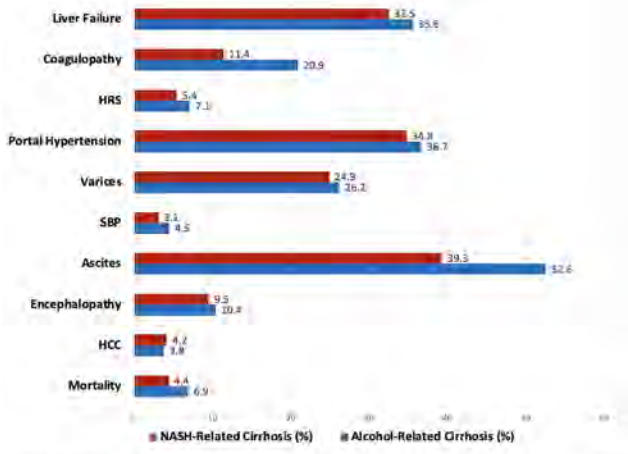

Fig 1: Comparison of Crude Complications Rates Between Alcohol-Related and NASH-Related Cirrhosis

In- Hospital variable	OR (95% CI)	p-value
Mortality	1.95 (1.88–2.04)	<0.001
Hepatocellular carcinoma (HCC)	1.36 (1.29–1.43)	<0.001
Hepatic encephalopathy	1.41 (1.37–1.45)	<0.001
Esophageal or gastric Varices	1.03 (1.01–1.05)	0.012
Ascites	1.86 (1.82–1.89)	<0.001
Spontaneous bacterial peritonitis (SBP)	1.4 (1.33–1.47)	<0.001
Portal hypertension (PHT)	1.29 (1.26–1.32)	<0.001
Hepatorenal syndrome (HRS)	1.61 (1.55–1.68)	<0.001
Coagulopathy	1.82 (1.76–1.88)	<0.001
Liver Failure	1.45 (1.42–1.48)	<0.001

2580 | ASSOCIATIONS OF CARDIOVASCULAR HEALTH WITH HEPATIC FIBROSIS, MASLD AND METALD IN THE FRAMINGHAM HEART STUDY

Alejandro Campos[1] Tianyu Liu[2] Brenton Prescott[3] Jiantao Ma[4] Maura Walker[5] Vanessa Xanthakis[6] Arpan Mohanty[1], [1]Boston University Chobanian & Avedisian School of Medicine - Boston Medical Center, [2]Boston University School of Public Health, [3]Boston University Chobanian & Avedisian School of Medicine, [4]Friedman School of Nutrition Science and Policy, Tufts University, [5]Sargent College of Health and Rehabilitation, Boston University, [6]Boston University and National Heart, Lung, and Blood Institute's Framingham Heart Study

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD), metabolic and alcohol-associated liver disease (MetALD), and hepatic fibrosis are increasingly common with shared cardiometabolic risk factors. The American Heart Association's (AHA) Life's Essential 8 (LE8) score assesses cardiovascular health (CVH) using four health behaviors (diet, physical activity [PA)], nicotine exposure, sleep) and four risk factors (Body Mass Index [BMI], blood glucose, blood pressure [BP], and non-HDL cholesterol). The associations of LE8 and its behavioral subset (LE4), with MASLD, MetALD, and hepatic fibrosis remain understudied. **Methods:** We evaluated the association of LE4 with MASLD and MetALD, and of LE8 with hepatic fibrosis among Framingham Heart Study participants with valid and complete CVH and transient elastography data (n = 2,968). Steatosis was defined as controlled attenuation parameter ≥274 dB/m; significant fibrosis as liver stiffness ≥8.2 kPa. MASLD and MetALD were defined as steatosis plus ≥1 cardiometabolic risk factor with mild alcohol use (women < 140g/wk; men < 210g/wk) and moderate alcohol use (women 141–350g/wk; men 211–420g/wk), respectively. The LE8-Fibrosis analysis was performed in participants with complete LE8 data (n = 2,884). We used multivariable logistic mixed-effects models adjusted for age, sex, education, and familial relatedness to estimate odds ratios (ORs) per 10-point increase in LE4 or LE8. **Results:** Among 2,968 participants (57% women; mean age 58.6 years), 2,703 reported mild and 265 moderate alcohol use. MASLD was present in 33.7% of the mild group and MetALD in 39.2% of the moderate group. Significant fibrosis was present in 8% of all participants. Median LE8 and LE4 scores were 70 and 76.9 in the fibrosis group, 68.4 and 77.5 in mild, and 67 and 73.1 in moderate alcohol use groups. Higher LE8 scores were associated with a 17% lower odds of fibrosis (OR 0.83; 95% CI:0.78–0.88; p < 0.0001), primarily driven by BMI, glucose, BP, sleep, and PA. Higher LE4 scores were associated with 14% lower odds of MASLD (OR 0.86; 95% CI:0.81–0.91; p < 0.001), driven by diet, PA, and nicotine exposure. There was no association between LE4 and MetALD. **Conclusion:** Better CVH was associated with lower odds of fibrosis and MASLD. Among individual CVH components, physical activity showed the strongest inverse association with both outcomes, while healthier BMI, blood glucose, and

blood pressure were associated with lower odds of fibrosis.

2581 | MUSCLE FUNCTION CORRELATES WITH DISEASE SEVERITY IN PATIENTS WITH MASLD. A PROSPECTIVE STUDY

Mary Olayiwola[1] Pinelopi Manousou[1] Michael Yee[1] Maria Kalafateli[1] Roberta Forlano[1] Benjamin Mullish[1] Mark Thursz[1], [1]Imperial College London

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects over 30% of adults globally, yet non-invasive predictors of disease progression remain suboptimal. Muscle function assessments remain underutilised in clinical practice, despite growing evidence that sarcopenia contributes to MASLD progression and adverse outcomes. **Methods:** We conducted a prospective cross-sectional study of 382 MASLD patients at a UK tertiary centre (2023-2025). Liver stiffness measurement (LSM) via transient elastography (TE), FIB-4, Mediterranean Diet Score (MDS), International Physical Activity Questionnaire (IPAQ), Short Form-36 (SF36), and muscle function assessments (Handgrip Strength [HGS], Five Times Sit-to-Stand Test [FTSST]) were collected. Advanced fibrosis was defined as LSM $\geq$8 kPa. **Results:** The median age was 58 years, 56% male, median BMI 32.6 kg/m², and 64.9% had Type 2 Diabetes. Advanced fibrosis (LSM $\geq$8 kPa) was present in 57.3% of patients. Patients with advanced fibrosis had significantly lower emotional well-being scores (61.6 vs 68.9, $p = 0.028$), lower physical activity (median MET 1614 vs 2338 min/week, $p = 0.024$), and impaired lower limb muscle function (FTSST 13.3 vs 11.2 sec, $p = 0.004$). FTSST times were significantly longer in patients with advanced fibrosis ($r = 0.164$, $p = 0.001$), indicating a positive correlation between slower lower limb performance and fibrosis severity. Also, FTSST times negatively correlated with all SF36 domains ($p < 0.05$), with the strongest association seen for physical functioning ($r = -0.453$, $p = 0.001$). Higher HGS values were positively correlated with improved QoL across all SF36 domains. Overall, greater muscle function—reflected by higher HGS and faster FTSST performance—was strongly associated with better QoL. **Conclusion:** This study demonstrates the critical associations between muscle function, physical activity, QoL, and MASLD severity. Impaired muscle strength, particularly lower limb function assessed via the Five Times Sit-to-Stand Test (FTSST), was significantly associated with advanced fibrosis and lower QoL, outperforming FIB-4 as a marker of disease severity. These findings underscore the need to incorporate routine muscle function assessments—especially FTSST—into MASLD care.

2582 | MASLD VS METALD: DISTINCT CLINICAL PHENOTYPES IN A CENTRAL EUROPEAN COHORT

Jerzy Jaroszewicz[1] Karol Zmudka[1] Marlena Dubatówka[2] Małgorzata Chlabicz[2] Damian Piotrowski[1] Karol Kaminski[2], [1]Department of Infectious Diseases and Hepatology, Medical University of Silesia in Katowice, Poland, [2]Department of Population Medicine and Lifestyle Diseases Prevention, Medical University of Bialystok

Background: There is a lack of data regarding the prevalence and clinical characteristics of metabolic dysfunction-associated steatotic liver disease (MASLD), as well as the role of alcohol consumption as a cofactor in disease progression in Central and Eastern Europe. This study aims to address this gap. **Methods:** This analysis is part of the Bialystok PLUS (Polish Longitudinal University Study), an ongoing prospective, population-based epidemiological study. We assessed the prevalence of MASLD and MetALD in a random sample of adult residents of Bialystok, Poland. Additionally, we analyzed anthropometric, epidemiological, clinical, and lifestyle data from 2,456 participants, comparing individuals with MASLD and MetALD to a control group without liver steatosis. **Results:** In the studied cohort, 22.72% of participants met the diagnostic criteria for MASLD, and 2.08% for MetALD. Age-adjusted for standard population prevalence per 1,000 inhabitants was 126.48 [95% CI: 96.32–170.84] for MASLD and 20.77 [95% CI: 15.83–27.20] for MetALD. Distinct cardiometabolic patterns were observed: MASLD was associated with a higher prevalence of obesity and type 2 diabetes, whereas MetALD was more frequently linked to hypertension and dyslipidemia. Significant liver fibrosis (LSM $\geq$ F2) was more prevalent in the MetALD group (17.78%) compared to MASLD (15.64%) and controls (5.12%, $P < 0.001$). Similarly, cirrhosis was more common in MetALD (4.44%) than in MASLD (0.58%) and controls (0.12%). Additional analyses of anthropometric, clinical, epidemiological, and lifestyle characteristics were conducted,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and risk factors for significant fibrosis in MASLD and MetALD were evaluated. **Conclusion:** Both MASLD and MetALD represent significant public health challenges, yet they exhibit distinct clinical phenotypes. Understanding the interplay between metabolic dysfunction and alcohol consumption is crucial for improving diagnosis, treatment, and prevention strategies.

2583 | PROGRESSION TO CIRRHOSIS IN PEOPLE WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS (MASH) IN REAL-WORLD COHORTS IN THE US AND JAPAN

Jörn Schattenberg Zuleika Aponte-Torres[1] Ronald Herrera[2] Mireia Raluy[3] Mark Yates[3] Ramy Younes[2] Claudio Sartini[2] [1]Boehringer Ingelheim Pharmaceuticals, Inc., [2]Boehringer Ingelheim International GmbH, [3]Evidera, Data Analytics

Background: MASH, formerly called non-alcoholic steatohepatitis (NASH), can progress to cirrhosis and increase mortality risks. As real-world evidence on MASH progression in different countries is limited, we estimated progression to cirrhosis, mortality, and associated risk factors in MASH real-world patient cohorts from the United States (US) and Japan to inform clinical decision-making. **Methods:** This was a retrospective observational study using electronic health records and claims data from two databases: Optum® Market Clarity (OMC) in the US and Medical Data Vision (MDV) hospital data in Japan. Eligibility criteria included ≥1 claim or medical encounter with a diagnosis code for MASH (ICD-10-CM: K75.81) during the identification period (OMC: January 2016–May 2021; MDV: January 2016–June 2021), age ≥18 years at the diagnosis date, and laboratory values for aspartate aminotransferase (AST), alanine aminotransferase, and platelets in the 3 months before or after diagnosis (to calculate Fibrosis-4 score [FIB-4]). Individuals with a diagnosis code or medical claim for other liver diseases were excluded, as were those with evidence of cirrhosis (claim or medical encounter with a diagnosis code for cirrhotic conditions in the 3 months before or after diagnosis date). Patients were followed from the MASH diagnosis date to the earliest of liver transplant, death, loss to follow-up, or end of study (OMC: May 2022; MDV: June 2022). **Results:** Out of 18,710 patients with MASH in OMC, 13,754 (73.5%) did not have cirrhosis (mean age 42.1 years, 7,181 [52.2%] female, 10,796 [78.5%] non-Hispanic White, 10,028 [72.9%] FIB-4 <1.3). Of 452 patients with MASH in MDV, 386 (85.4%) did not have cirrhosis (mean age 46.8 years, 228 [59.1%] female, 251 [65.0%] FIB-4 <1.3). At a median follow-up of 1,169 days in OMC and 941 in MDV, the cumulative incidence of progression to cirrhosis was 5.7% and 7.8% in OMC and MDV, respectively. The respective incidence rates per 100 patient-years in OMC and MDV were 1.8 and 2.9 for progression to cirrhosis and 0.8 and 0.5 for all-cause mortality (Figure). Risk factors for elevated all-cause mortality in OMC included age, comorbidities, increased AST and glycated hemoglobin, and FIB-4 >1.3. **Conclusion:** Prevention of cirrhosis is key to avoiding further progression to mortality in MASH patients. Rates of progression to cirrhosis may vary depending on data source and patient population (claims vs hospital data or younger vs older patients).

2584 | LONGITUDINAL ASSOCIATION BETWEEN CHANGE IN CARDIOVASCULAR HEALTH AND INCIDENT HEPATIC STEATOSIS

Alejandro Campos[1] Tianyu Liu[2] Brenton Prescott[3] Jiantao Ma[4] Vanessa Xanthakis[5] Maura Walker[6] Arpan Mohanty[1], [1]Boston University Chobanian & Avedisian School of Medicine - Boston Medical Center, [2]Boston University School of Public Health, [3]Boston University Chobanian & Avedisian School of Medicine, [4]Friedman School of Nutrition Science and Policy, Tufts University, [5]Boston University and National Heart, Lung, and Blood Institute's Framingham Heart Study, [6]Sargent College of Health and Rehabilitation, Boston University

Background: The American Heart Association's Life's Essential 8 (LE8) quantifies cardiovascular health (CVH) using four health behaviors (diet, physical activity, nicotine exposure, sleep) and four health factors (body mass index, blood pressure, blood glucose, non-HDL cholesterol). Adherence to LE8 metrics or higher LE8, has been associated with lower odds of hepatic steatosis in cross-sectional studies. However, the longitudinal association of changes in LE8 (ΔLE8) with incident hepatic steatosis remains understudied. **Methods:** We evaluated participants from the Second and Third Generation cohorts of the Framingham Heart Study who underwent two abdominal multidetector computed tomography scans between 2002–2005 and 2008–2011, with corresponding complete LE8 and covariate data. Participants with prevalent steatosis or cardiovascular disease (CVD), or heavy alcohol use ($>350/>420$ g/week for women/men) were excluded. Binary steatosis was defined as a liver-to-phantom attenuation ratio (LPR) ≤ 0.33. Baseline and follow-up LE8 were dichotomized at the sample median. Participants were categorized as high-high (LE8 > median at both exams; referent), low-high, high-low, or low-low. Multivariable logistic and linear mixed-effects models assessed associations of ΔLE8 categories with steatosis at follow-up exam and change in LPR (ΔLPR), adjusting for age, sex, baseline LE8, education, alcohol intake, familial relatedness, cohort and interim CVD. **Results:** Among 1,250 participants (mean age 50 ± 9 years; 53% women), 222 (18%) developed steatosis over a mean follow up of 6.3 years. Median LE8 was 71.9 at both baseline (IQR: 63.1–80.0) and follow-up (IQR: 63.8–80.6). There were 455 participants (38%) in the high-high group, 148 (12%) in the low-high, 166 (13%) in the high-low, and 481 (38%) in the low-low group. Compared to the high-high group, the high-low (OR 1.84, 95% CI: 1.04–3.23) and low-low (OR 2.23, 95% CI: 1.19–4.19) groups had higher odds of steatosis; there was no association between the low-high and the referent group. ΔLPR was lower in the high-low (−0.010, 95% CI: -0.018– -0.002, $p = 0.02$) and low-low (−0.011, 95% CI: -0.021– -0.001, $p = 0.03$) groups compared to referent, but not in the low-high group. **Conclusion:** Compared to participants maintaining high CVH, declining or persistently low LE8 scores conferred significantly higher odds of developing steatosis and increase in hepatic fat over 6 years. These findings emphasize the need for early intervention and sustained CVH to prevent hepatic steatosis.

2585 | METABOLIC MATCHUP: COMPARING SGLT2, GLP-1, AND DUAL AGONISTS IN NASH/MASLD RISK AMONG DIABETICS

Muhammad Ali Ibrahim Kazi Qetevan Gvazava MD[1] Zurabi Lominadze[2] Maia Tavadze[1] [1]Anne Arundel Medical Center, [2]Baltimore VA Medical Center

Background: Nonalcoholic steatohepatitis (NASH) is a progressive form of metabolic dysfunction-associated steatotic liver disease (MASLD), characterized by hepatic inflammation and fibrosis, often leading to cirrhosis, hepatocellular carcinoma, and increased cardiovascular mortality. Type 2 diabetes mellitus (T2DM) is a major risk factor for NASH/MASLD, contributing to its development through insulin resistance, chronic inflammation, and dyslipidemia. Recent studies have suggested that certain antidiabetic medications, including GLP-1 RAs, SGLT2 inhibitors, and dual GLP-1/GIP, may have differential effects on hepatic steatosis and fibrosis. However, comparative real-world data on their impact on NASH incidence remain limited.

This study aims to evaluate whether GLP-1 RAs, Tirzepatide, or SGLT2 inhibitors increase or decrease the risk of developing NASH after at least one year of continuous therapy in patients with diabetes. **Methods:** A retrospective cohort study was conducted using the TriNetX Global Health Research Network. The study population included adults ($\geq$18 years) with type 2 diabetes mellitus (T2DM) who initiated treatment with GLP-1 RAs, Tirzepatide, or SGLT2 inhibitors. To ensure comparability among the treatment groups, propensity score matching (PSM) was performed, balancing cohorts based on demographics, clinical characteristics, and medication use of antidiabetic agents such as metformin, sulfonylureas, DPP-4 inhibitors, and insulin, as well as antilipidemic drugs including statins and fibrates.

Patients were followed for a minimum of 12 months from the date of drug initiation. The primary outcome was the incidence of newly diagnosed nonalcoholic steatohepatitis (NASH). Statistical analyses included risk difference and risk ratio, each reported with 95% confidence intervals to assess the association between medications and the development of NASH. **Results:** Results:

1. GLP-1 RAs vs. Tirzepatide (50,522 patients each)

   NASH incidence: 1.324% (GLP-1) vs. 0.224% (Tirzepatide)
   RD: 1.101% (95% CI: 0.993%–1.208%), p < 0.0001
   RR: 5.92 (95% CI: 4.852–7.224)

2. SGLT2 inhibitors vs. GLP-1 RAs (384,228 patients each)

   NASH incidence: 0.857% (SGLT2 inhibitors) vs. 1.158% (GLP-1)
   RD: -0.301% (95% CI: -0.346% to -0.256%), p < 0.0001
   RR: 0.74 (95% CI: 0.708–0.774)

3. SGLT2 inhibitors vs. Tirzepatide (49,379 patients each)

   NASH incidence: 1.118% (SGLT2 inhibitors) vs. 0.221% (Tirzepatide)
   RD: 0.897% (95% CI: 0.796%–0.999%), p < 0.0001
   RR: 5.064 (95% CI: 4.125–6.217). **Conclusion:** Tirzepatide demonstrated the most significant reduction in NASH incidence among diabetic patients, followed by SGLT2 inhibitors, while GLP-1 receptor agonists were associated with a higher risk. These findings highlight the potential of newer antidiabetic agents in mitigating NASH risk and emphasize the need for prospective trials to confirm these associations and explore underlying mechanisms.

2586 | ACCULTURATION IS ASSOCIATED WITH IMPROVED LIVER MEASUREMENTS AMONG MEXICAN AMERICANS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Sharan Poonja[1] Rithvik Vutukuri[2] Molly Delk[1] Wei-Ting Lin[1] Hui-Yi Lin[3] Tung-Sung Tseng[3] Po-Hung (Victor) Chen[4] Peng-Sheng Ting[1], [1]Tulane University, [2]Tulane University School of Medicine, [3]Louisiana State

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

University Health Sciences Center, [4]Johns Hopkins University

Background: Latin America holds the highest global prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD), affecting up to 44.4% of the population. The growing Hispanic population in the U.S. makes understanding MASLD in this population increasingly relevant. Acculturation, or the process by which immigrants adopt host country behaviors and norms, influences disease patterns through shifts in socioeconomic and lifestyle factors. This study examines the prevalence of MASLD, metabolic dysfunction-associated steatohepatitis (MASH), and fibrosis in different levels of acculturation among Mexican Americans and other Hispanic adults in a nationally representative sample. **Methods:** NHANES 2017–2020 pre-pandemic data was analyzed for Hispanic adults ≥20 years without non-steatotic liver disease and significant alcohol use (>20g for females and >30g for males daily). An acculturation index (scored 0–5) was adapted from prior literature using the sum of scores assigned for US born or foreign born and years in the U.S., and language spoken at home, and categorized as low (0–1), medium (2–3), and high (4–5); see Table 1 note. MASLD was defined as ≥1 cardiometabolic risk factor with CAP ≥294 dB/m, MASH as MASLD with elevated ALT (>25 U/L in females, >33 U/L in males), and fibrosis measured by fibroscan as liver stiffness measurement (LSM). All analyses were conducted using survey weights adjusted. **Results:** Among Mexican Americans, higher acculturation to the US was significantly associated with a lower prevalence of MASLD and MASH. MASLD prevalence declined from 53.3% in those classified as low acculturation to 30.9% in those with high acculturation ($p = 0.035$), while MASH declined from 18.7% to 8.2% ($p = 0.024$). In other Hispanics, there were no differences in prevalence of MASLD, MASH or fibrosis by acculturation level, but more acculturated individuals had a lower diet quality by HEI-2020 (p = 0.021). **Conclusion:** Among Mexican Americans, a lower prevalence of MASLD and MASH was found in those with increasing acculturation, contrasting with prior literature linking Westernization to increased metabolic risk. In contrast, these patterns were not observed in the non-Mexican Hispanic subgroup, suggesting the link between acculturation and liver health is distinct between these two Hispanic subgroups. Mexican Americans with low acculturation may benefit from additional screening and early counseling, as they appear to be an at-risk group for MASLD.

Table 1 Demographic, Lifestyle Patterns, and Metabolic Liver Disease Among Mexican Americans and other Hispanics Stratified by Level of Acculturation to the United States

	Acculturation level (0–5 score, 5 = most acculturated)							
	Mexican Americans (n=627)				Other Hispanics (n=560)			
	0-1	2-3	4-5	P value	0-1	2-3	4-5	P value

2587 | DISTINCT PHENOTYPIC AND COMORBIDITY PROFILES OF LEAN VERSUS NON-LEAN YOUNG ADULTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD): A STUDY FROM "ALL OF US" RESEARCH PROGRAM

Thanathip Suenghataiphorn[1] Vitchapong Prasitsumrit[2] Pojsakorn Danpanichkul[3] Narathorn Kulthamrongsri[4], [1]Yale/Griffin Hospital, [2]Texas Tech Lubbock Health Science Center, [3]Texas Tech University Health Sciences Center, [4]Univesity of Hawaii

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly prevalent in adolescents and young adults (AYAs), but the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

characteristics of MASLD in lean AYAs (BMI <25 kg/m ^{2}) remain poorly understood. We aimed to compare the demographic, metabolic, and comorbidity profiles of lean versus non-lean AYAs with MASLD in a large, diverse national cohort. **Methods:** We identified AYA (18-39 years) participants with MASLD (from the "All of Us" Research Program. AYAs were stratified into lean (BMI <25 kg/m ^{2}) and non-lean (BMI ≥ 25 kg/m ^{2}) groups. Demographics, prevalence of MASLD-defining, and 19 predefined comorbidity groups were compared. **Results:** Of 2,097 AYAs with MASLD (mean age 31.7 yrs), 85 (4.1%) were lean. Lean AYA MASLD patients were more likely to be male (41.2% vs. 26.5%, $p=0.009$) and of Black or African American (22.4% vs. 8.6%) or Asian (8.2% vs. 3.4%) race ($p<0.001$ vs. non-lean). Lean AYAs more frequently met blood pressure criteria (62.4% vs. 34.8%, $p<0.001$) and glucose dysregulation criteria (12.9% vs. 6.0%, $p=0.018$) for their MASLD diagnosis. Compared to non-lean AYAs, lean AYAs had a significantly higher prevalence of chronic kidney disease (7.1% vs. 2.3%, $p=0.016$), thyroid disorders (8.2% vs. 2.2%, $p=0.002$), and heart failure (5.9% vs. 1.6%, $p=0.014$), despite a lower overall comorbidity count (mean 1.1 vs. 1.6, $p=0.003$). Conversely, obesity-related comorbidities like obstructive sleep apnea and polycystic ovary syndrome were less common in lean AYAs. **Conclusion:** Lean AYA MASLD represents a distinct phenotype characterized by specific demographic features, a greater reliance on non-obesity metabolic drivers like hypertension and glucose dysregulation, and a unique, concerning pattern of non-obesity-related comorbidities including heart failure. These findings underscore the need for heightened awareness and tailored management strategies for this underrecognized MASLD subgroup.

2588 | LONG-TERM HEALTH AND ECONOMIC IMPACT OF CIGARETTE TAXATION ON SMOKING-ATTRIBUTABLE BURDEN OF METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE (MAFLD) IN THE UNITED STATES: A GBD LIFETIME SIMULATION STUDY

Thanathip Suenghataiphorn[1] Kanachai Boonpiraks[2] Vitchapong Prasitsumrit[3] Pojsakorn Danpanichkul[4] Narathorn Kulthamrongsri[5], [1]Yale/Griffin Hospital, [2]University of Kansas Medical Center · Kansas City, USA, [3]Texas Tech Lubbock Health Science Center, [4]Texas Tech University Health Sciences Center, [5]University of Hawaii

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) is a growing public health concern in the U.S. While metabolic factors are primary drivers, smoking is a modifiable co-factor. We projected the long-term impact of cigarette taxation on DALYs and healthcare costs associated with the smoking-attributable component of MAFLD. **Methods:** An age-sex stratified dynamic population cohort model simulated the U.S. population from 2022-2100. Baseline smoking prevalence (SEV) and smoking-attributable MAFLD DALY rates were from GBD 2021, with future trends projected via ARIMA. Three tax scenarios ($1 specific, 10% & 20% ad valorem) reduced smoking prevalence based on U.S. price elasticity. Health benefits accrued over a 10-year distributed lag. Discounted (3%) DALYs averted and healthcare cost savings (2021 USD) were estimated from a healthcare perspective. Probabilistic sensitivity analysis (PSA, 1000 iterations) assessed uncertainty. **Results:** Over a lifetime (2022-2100), a $1 specific cigarette tax was projected to avert a mean of 14,889 (95% UI: 9,552–21,031) discounted DALYs from smoking-attributable NAFLD burden and save $6.18 billion (95% UI: 3.06B–10.32B) in healthcare costs. A 20% ad valorem tax averted ~21,490 DALYs and saved ~$8.93 billion. All tax scenarios were consistently cost-saving (probability $>99\%$). **Conclusion:** Implementing or increasing cigarette taxes is a robustly cost-saving strategy projected to yield substantial long-term reductions in DALYs and healthcare expenditures related to the smoking-attributable burden of MAFLD in the U.S., supporting tobacco control as a component of liver health promotion.

2589 | STEATOTIC LIVER DISEASE SUBTYPES AND COLORECTAL CANCER: A LARGE-SCALE RISK ANALYSIS INCLUDING FIBROSIS

takefumi kimura[1] Shun-Ichi Wakabayashi[1] Nobuharu Tamaki[2], [1]Shinshu University School of Medicine, [2]musashino red cross

Background: The recently proposed subtypes of steatotic liver disease (SLD), MASLD, MetALD, and ALD, may differ in their risk for extrahepatic cancers. However, colorectal cancer (CRC) risk stratification in these subgroups remains unclear. This study aimed to evaluate CRC incidence across SLD subtypes and assess the impact of advanced fibrosis. **Methods:** We analyzed data from 6.3 million individuals in a nationwide Japanese claims and health check-up database. Among these, 1,497,813 patients had MASLD, MetALD, or ALD; 4,885,536 served as controls without liver disease. CRC was defined using ICD-10 and treatment codes. Multivariable Cox regression adjusted for age, sex, smoking, diabetes, dyslipidemia, hypertension, colonoscopy frequency, aspirin/metformin use, and advanced fibrosis. Advanced fibrosis ($\geq$F3) was included as an independent covariate and defined using a validated algorithm (PMID: 40191781). **Results:** During a median follow-up of 4.5 years, 12,065 individuals developed CRC. The 10-year cumulative incidence was highest in ALD (0.97%), followed by MetALD (0.73%), MASLD (0.48%), and controls (0.32%) (all $p < 0.001$). Adjusted hazard ratios (95% CI) for CRC were 1.28 (1.20–1.33) for MASLD, 1.35 (1.26–1.44) for MetALD, and 1.70 (1.57–1.84) for ALD. Advanced fibrosis was independently associated with CRC risk (HR 1.08, 95% CI 1.03–1.15, $p = 0.003$). **Conclusion:** SLD is associated with an increased risk of CRC, with the highest risk observed in ALD, followed by MetALD and MASLD. The presence of advanced fibrosis further elevates CRC risk, highlighting the need for tailored surveillance strategies based on liver disease subtype and fibrosis severity.

2590 | MILD ALKALINE PHOSPHATASE ELEVATION ASSOCIATES WITH INCREASED MORTALITY AND MAJOR ADVERSE LIVER OUTCOMES IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Jingyi Hu[1] Blake Czapla[1] Kira Zhao[1] Christopher Okarski[1] Karn Wijarnpreecha[2] Vincent Chen[3], [1]University of Michigan, [2]University of Arizona College of Medicine-Phoenix, [3]University of Michigan Medical Center

Background: Alkaline phosphatase (ALP) elevation is commonly observed in patients with metabolic dysfunction-associated steatotic liver disease (MASLD), but its clinical implications in this context remain unclear. We aimed to evaluate the impact of mild ALP elevation (1-1.5x upper limit normal [ULN]) on clinical outcomes in MASLD. **Methods:** We conducted a retrospective cohort study of patients at Michigan Medicine. We included patients with MASLD defined as hepatic steatosis on imaging and at least one cardiometabolic comorbidity, with at least 1 ALP measurement within 1 year of the index date (date of imaging). Patients were excluded if they had excessive alcohol use, other chronic liver diseases, or chronic bone disease at any time, or malignancy, fracture, or pregnancy within 1 year of the index date. Elevated ALP was defined as >1-≤ 1.5x ULN (115 IU/L at our center). Outcomes were overall mortality, major adverse liver outcomes (MALO), and major adverse cardiovascular events (MACE). Mortality was modeled as a Cox proportional hazards model and non-mortality outcomes as Fine-Gray competing risk models. **Results:** We included 13,046 MASLD patients. 11,085 (85.0%) had persistently normal ALP, 615 (4.7%) had transiently elevated ALP, and 1,346 (10.3%) had persistently elevated ALP. In total, 779 deaths, 129 MALO, and 3,110 MACE occurred. We manually reviewed the medical records of all patients with MALO and found no patient with other chronic liver diseases. Persistently elevated ALP was associated with higher risks of mortality (adjusted hazard ratio [aHR], 1.48; 95% CI, 1.19–1.86; $p < 0.001$) and MALO (aHR, 2.40; 95% CI, 1.54–3.74; $p < 0.001$) compared to persistently normal ALP. These associations remained significant in sensitivity analyses excluding patients with baseline cirrhosis: mortality (aHR, 1.53; 95% CI, 1.21–1.95; $p < 0.001$) and MALO (aHR, 2.10; 95% CI, 1.01–4.35; $p = 0.046$). Stratification by FIB-4 scores showed elevated ALP was significantly associated with mortality among patients with FIB-4 <1.3 and FIB-4 1.3–2.67. The risk of MALO associated with elevated ALP was significant in patients with FIB-4 1.3–2.67. In contrast, no significant associations were observed with FIB-4 >2.67, nor for the risk of MALO with FIB-4 <1.3. ALP elevations were not significantly associated with MACE. **Conclusion:** Even mild (1-1.5x ULN) ALP elevations were associated with increased risk of mortality and MALO in MASLD, particularly among patients with low-intermediate FIB-4 scores. These findings suggest that ALP may serve as a clinically meaningful biomarker for risk stratification in early MASLD and warrants further prospective validation.

2591 | MORTALITY BY CARDIOMETABOLIC RISK FACTOR AND ALCOHOL CONSUMPTION IN STEATOTIC LIVER DISEASE: A NATIONWIDE COHORT STUDY

Yewan Park[1] Gi-Ae Kim[1], [1]Kyung Hee University Hospital

Background: Steatotic liver disease (SLD) emerged as a nomenclature encompassing metabolic dysfunction-associated steatotic liver disease (MASLD) and alcohol-associated liver diseases (ALD). We aimed to investigate the all-cause and cause-specific mortality risk across SLD subtypes by cardiometabolic risk factors (CMRFs) and alcohol consumption. **Methods:** Health checkup results of 2,049,641 Korean individuals were analyzed. SLD was defined as a fatty liver index $\geq$30. Multivariable Cox proportional hazard models were used to calculate the adjusted hazard ratios (HR) for mortality in MASLD, metabolic dysfunction and alcohol-related liver disease (MetALD), and ALD. **Results:** Compared to no SLD, MASLD (HR, 1.27; 95% confidence interval [CI], 1.24−1.30), MetALD (HR, 1.40; 95% CI, 1.36−1.44), and ALD (HR, 1.71; 95% CI, 1.66−1.77) showed higher risks of all-cause mortality. All SLD subtypes had an increased cause-specific mortality risk from liver-related disease, extrahepatic cancer, and cardiovascular disease with liver-related mortality being the most prominent (HR, 2.57 for MALSD; HR, 4.35; 95% CI, 3.94−4.80 for MetALD; HR, 6.32; 95% CI, 5.72−7.00 for ALD). The cumulative incidence of all-cause mortality increased as the number of CMRF increased in all SLD subtypes. The impact of CMRF numbers on the mortality risk was the most pronounced in MASLD but the least pronounced in ALD. **Conclusion:** This study demonstrated that MASLD, MetALD, and ALD had an increased risk of all-cause and cause-specific mortality and the impact of CMRF numbers on the mortality risk was the most pronounced in MASLD. A profound insight into the mortality risk by CMRF and alcohol consumption was provided, ushering in more customized management strategies.

Risk of all-cause mortality by the number of cardiometabolic risk factors and SLD subtypes

2592 | SHIFTING TRENDS IN U.S. STEATOTIC LIVER DISEASE CARE: PATIENT-REPORTED INSIGHTS FROM THE 2022-2025 SLD CARE SURVEY

Neeraj Mistry[1] Tiffany Mensah[1] Jennifer Jones[2] Henry Chang[1] Wayne Eskridge[1], [1]Fatty Liver Foundation, [2]Sober Livers

Background: The State of Steatotic (Fatty) Liver Care in America (SLD Care) survey is an annual, patient-facing survey tracking the social and medical experiences of people living with steatotic liver disease (SLD) in the United States. This analysis includes data from 2022 to 2025. Capturing patient-reported experiences is essential to identifying care gaps and informing targeted interventions and policies. **Methods:** Data from survey years 2022 to 2025 were analyzed and compared to identify trends. The survey included U.S. adults diagnosed with SLD and consisted of 49 items across four domains: diagnosis and staging, medical management and physical impact, psycho-social and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

environmental impact, and current health. Items were developed in collaboration with the patient community, Fatty Liver Foundation Medical Advisory Group, and the SLD Care Survey Analysis Group. **Results:** Respondents across all years were mostly white women with undergraduate degrees. Among those living with metabolic dysfunction-associated steatotic liver disease (MASLD) or metabolic dysfunction-associated steatohepatitis (MASH), the majority reported a diagnosis staging of MASLD or Stage 4 MASH. A sizable portion reported they were unaware of their disease stage at diagnosis. Starting in 2023, referrals to hepatologists and gastroenterologists after diagnosis have increased. An emerging downward trend was observed in the proportion of respondents who reported being told there was "nothing to worry about" after diagnosis. Respondents continue to report that dietitians and fitness professionals are not integrated into their care teams. Preliminary 2025 data reveal increased use of medications including resmetirom and GLP-1 receptor agonists such as semaglutide and tirzepatide compared to previous years. **Conclusion:** Analysis of shifting trends revealed two primary patterns. On the patient side, while general awareness of MASLD has increased, understanding of disease staging and nuanced diagnosis remains limited. Involving patients more actively in their care may help close persistent gaps in education and engagement. On the provider side, a shift towards more proactive disease management is reflected in rising specialist referrals and a decline in the persistent "nothing to worry about" reassurance. However, gaps remain in multidisciplinary care, particularly in integrating dieticians and fitness professionals. Additionally, increased off-label use of medications suggests a growing interest in pharmacologic approaches to disease management.

2593 | SIGNIFICANT DIFFERENCES IN DIETARY PATTERNS BETWEEN RURAL VERSUS URBAN PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE: A PROSPECTIVE STUDY

Swetha Tummala[1] *Trevor Dean*[1] *Renwei Wang*[1] *Jessica Izenas*[1] *Olivia Popovich*[1] *Oscar Shaver*[1] *Olivia Hansol Lee*[1] *Jian-Min Yuan*[1] *Jaideep Behari*[1], [1]*University of Pittsburgh*

Background: Unhealthy dietary patterns are associated with metabolic dysfunction-associated steatotic liver disease (MASLD). Rural communities in the U.S. have a higher burden of MASLD-associated chronic conditions, such as obesity, compared to urban populations. We aimed to study the differences in dietary patterns associated with MASLD across urban-rural populations in a mid-Atlantic region-based healthcare system. **Methods:** We prospectively enrolled adult patients with MASLD referred to a subspecialty clinic between 2021 and 2025. Demographic and clinical characteristics were recorded at enrollment. Dietary patterns were assessed at the baseline visit using two validated dietary questionnaires, the Automated Self-Administered 24-Hour Dietary Assessment Tool (ASA24), for 24-hour dietary recall, and Diet History Questionnaire III (DHQ III) for dietary intake over the past year. The Healthy Eating Index (HEI-2015) was calculated to determine the adherence to the Dietary Guidelines for Americans. Rural versus urban status was determined using Rural-Urban Commuting Area (RUCA) codes matched to ZIP code of primary residence. **Results:** Among the 729 subjects, 81 were from rural and 648 from urban areas. Age, sex, ethnicity, smoking status, and Type 2 diabetes prevalence were similar between the two groups, with a higher proportion of Whites in the rural group (98.8% vs 88.7%, $p = .02$). There was a trend towards higher body mass index in the rural group (36.4 vs 34.8 kg/m^2, $p = .06$) but no difference in physical activity level. There was no difference among the groups in Transient Elastography-determined CAP score (302 vs 292 dB/m, $p = .14$), a measure of steatosis, and liver stiffness score (9.1 vs 9.2 kPa, $p = .78$), a measure of liver fibrosis, or in Fibrosis-4 index (1.4 vs 1.3, $p = .85$). No differences were found between the two groups in dietary patterns on the ASA24 survey and in the HEI-2015 scores. When evaluating the past year's nutrient intake via DHQ III, the rural cohort had similar total energy intake but significantly higher carbohydrate (230 vs 196 g/day, $p = .03$), total sugar (122 vs 96 g/day, $p < .01$), and added sugar (84 vs 62 g/day, $p = .05$). Both groups had low, but similar, intake of fiber (17.4 vs 16.2 g/day, $p = .28$). **Conclusion:** Rural and urban patients with MASLD have significant dietary differences. Nutritional interventions targeting MASLD at the health system-wide level may require distinct strategies for rural vs urban communities.

2594 | DEMOGRAPHIC AND METABOLIC DISPARITIES IN STEATOTIC LIVER DISEASE PROGRESSION DURING COVID USING THE NATIONAL HEALTH AND NUTRITION EXAMINATION SURVEY (NHANES) 2021–2023

Kimberly Ho[1] Samiran Mukherjee[2] Paige McLean Diaz[3], [1]Brown University, [2]University of Pennsylvania, [3]Brown Medicine/Brown University Health

Background: Before COVID, metabolic-dysfunction associated steatotic liver disease (MASLD) affected 25-30%, and recent estimates show an increase to 38%. MASLD's burden may have worsened in the pandemic, intensifying barriers to care and widened existing healthcare disparities. In this study, we aimed to characterize demographic and clinical patterns associated with MASLD and progression to fibrosis and cirrhosis, using the 2021–2023 NHANES database. **Methods:** We analyzed 6,337 adults from NHANES 2021–2023 in a cross-sectional study. MASLD severity was defined using FibroScan thresholds: steatosis (CAP >288), advanced fibrosis (LSM >13.5 kPa), and cirrhosis (LSM >20 kPa). Multivariate logistic regression identified factors associated with each phenotype. We compared MASLD without fibrosis, with fibrosis, and with cirrhosis using race/ethnicity, BMI, alcohol use, diabetes, age, and sex. **Results:** 26% of participants had MASLD in NHANES 2021-2023. Among Non-Hispanic (NH) Whites, 73% had cirrhosis and 65% had advanced fibrosis. MASLD with advanced stages of fibrosis showed disproportionately higher representation among NH White individuals compared to Asian ($p = 0.01$ for cirrhosis; $p = 0.04$ for advanced fibrosis) and non-Mexican Hispanic individuals ($p = 0.01$ for cirrhosis). No significant differences were observed between NH White and other groups including Mexican American, NH Black, or other racial/ethnic groups. (Figure 1A). Results from multivariate regression reveal BMI to be strongly associated with both steatosis and cirrhosis ($p<0.001$). It was also associated with disease progression, with differences noted in the overweight and obese categories in fibrosis, and across all BMI classes in cirrhosis particularly obesity classes I, II, and III ($\chi^2 = 13.2$, $p < 0.001$; $\chi^2 = 4.74$, $p = 0.03$; $\chi^2 = 69.7$, $p < 0.001$, respectively) (Figure 1B). Alcohol use also differed among the various groups. Patients with fibrosis or cirrhosis had significantly higher rates of frequent alcohol consumption in a dose dependent manner ($p < 0001$). Comorbid diabetes was associated with disease severity compared to those with prediabetes ($\chi^2 = 3.71$ for fibrosis; $\chi^2 = 10.0$ for cirrhosis; all $p < 0.001$). **Conclusion:** NH White individuals were overrepresented in MASLD with fibrosis and cirrhosis, potentially reflecting disparities in access to care and retention in follow-up among minority populations post-COVID. Obesity, diabetes, and alcohol use emerged as key modifiable factors associated with disease severity.

Figure 1. **Widening Demographic and Metabolic Disparities with Increasing MASLD Severity Among US Adults.** (A) Bar plots of demographic trends specifically in race/ethnicity. *Non-Hispanic Whites were overrepresented in steatotic liver disease, advanced fibrosis, and cirrhosis compared to other racial/ethnic groups, indicating potential disparities in MASLD screening and outcomes captured in NHANES 2021-2023.* (B) Violin plots of advance fibrosis and cirrhosis vs BMI. *Participants with cirrhosis and advanced fibrosis had significantly higher BMI compared to subjects without MASLD complications (mean 36.87 and 37.06, respectively).*

2595 | HIGH BURDEN OF MASLD AND RISK OF FIBROSIS IN TYPE 1 DIABETES: PRELIMINARY RESULTS: FROM FIBROSCAN-BASED SCREENING

Khalid Alswat[1] Metib Alotaibi[2] Khaled Aburisheh[3] Mohamed El-Sharkawy[4] Hazim Bajri[5] Amani Alsadoon[6] Maram Alkhammash[6] Abdullah Alguwaihes[7], [1]Liver Disease Research Center, College of Medicine, King Saud University, Riyadh, Saudi Arabia., [2]University Diabetes Center, King Saud University Medical City, Riyadh, Saudi Arabia, [3]University Diabetes Center, King Saud University Medical City, KSU Riyadh, Saudi Arabia, [4]Diagnostic Radiology and Medical Imaging Department,College of Medicine,KSU, Riyadh,Saud Arabia, [5]King Saud University Diabetes Center,Riyadh,Saudi Arabia, [6]Liver Disease Research Center, College of Medicine, King Saud University,Riyadh, Saudi Arabia, [7]Division of Endocrinology,Department of Internal Medicine,College of Medicine,KSU,Riyadh,KSA

Background: The burden and and clinical significance of metabolic dysfunction–associated steatotic liver disease (MASLD) is well-established in type 2 diabetes, yet remains remain poorly characterized in type 1 diabetes mellitus (T1DM). Emerging data suggest that individuals with T1DM may also be at considerable risk, independent of traditional metabolic risk factors.Aims:To evaluate the prevalence of MASLD and its clinical and metabolic predictors, as well as disease severity, in individuals with type 1 diabetes mellitus (T1DM) using FibroScan. **Methods:** This ongoing cross-sectional study includes individuals aged ≥14 years with ≥1-year T1DM. Data collected include demographics, BMI, comorbidities, insulin regimen, HbA1c, CGM-derived time-in-range (TIR), and liver biochemistry. Imaging involves ultrasound and FibroScan (CAP for steatosis, LSM for fibrosis). MASLD is defined as CAP ≥248 dB/m with ≥1 metabolic risk factor; advanced fibrosis as LSM ≥8.2 kPa. **Results:** Among the first 92 participants (mean age 27.8 ± 11.4 years), 30.4% met MASLD criteria. The mean CAP was 235 ± 45.3 dB/m and liver stiffness was 4.67 ± 1.1 kPa. MASLD prevalence peaked in the 40–49 age group (50%) and was slightly higher among those using multiple daily injections (36.1%) compared to insulin pump users (33.3%). Notably, 8.7% had LSM ≥8.2 kPa, indicating a meaningful subset at high risk for significant fibrosis despite young age and absence of clinical liver disease. Liver stiffness showed weak correlations with HbA1c ($r = -0.17$), time-in-range ($r = 0.19$), and diabetes duration ($r = 0.11$), suggesting that traditional glycemic markers may not reliably predict liver involvement. FibroScan and ultrasound demonstrated poor agreement ($\kappa = -0.047$), with FibroScan detecting more cases of steatosis, highlighting the potential underdiagnosis associated with ultrasound. **Conclusion:** Preliminary findings reveal a substantial prevalence of MASLD in individuals with T1DM, including a notable proportion at high risk for significant fibrosis despite young age and lack of overt liver disease. FibroScan outperformed ultrasound in detecting steatosis, reinforcing its utility in early liver assessment. These results challenge the assumption that MASLD is exclusive to type 2 diabetes and underscore the need for routine, non-invasive liver screening in the T1DM population.

2596 | PRIMARY CARE PERSPECTIVES ON DIAGNOSIS AND MANAGEMENT OF MASLD: IDENTIFYING GAPS AND OPPORTUNITIES IN THE DALLAS-FORT WORTH AREA

Jeevin Sandhu[1] Muskaan Sandhu[2] Simran Joshi[3] Kyle Schneider[1] Marquise Soto[4] Matthew Manoj[5] Corinne Caissie[3] Charitha Karanam Ramapathy[6] Parvez Mantry[1], [1]Methodist Dallas Medical Center, [2]University of California, San Francisco, [3]Bridgeport Hospital - Yale New Haven Health, [4]Massachusetts General Hospital, [5]Beth Israel Deaconess Medical Center, [6]UAB Montgomery

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a growing global health concern. As MASLD becomes increasingly endemic, primary care physicians (PCPs) often serve as first-line identifiers and managers. However, many PCPs underestimate its prevalence and report low confidence in managing it. This study aims to evaluate current knowledge gaps, comfort levels, and perceived barriers in MASLD diagnosis and management among PCPs, as well as explore trends across racial and ethnic groups in the Dallas-Fort Worth area. **Methods:** This was a cross-sectional survey study of primary care physicians (PCPs) in North Texas, primarily in the Dallas-Fort Worth area. A link to a survey was distributed via email to PCPs in the Methodist Medical Group (MMG) network. The survey assessed PCPs' confidence in diagnosing MASLD, comfort with management, use of non-invasive tools, and referral criteria to hepatology. Additional questions addressed frequency of Fib-4 score use, management approaches, nutritional counseling, use of GLP-1 agonists and statins, and referrals to weight loss programs. Perceptions of local trends among racial and ethnic groups was also evaluated. **Results:** Among 56 PCPs surveyed, 75% rated their confidence in diagnosing MASLD as "more or less," "not very," or "not at all" confident; 86% selected similar

categories regarding MASLD management. The most commonly used tools were abnormal LFTs (85.5%), ultrasound findings (83.6%), and history of metabolic syndrome (52.7%). Imaging suggestive of cirrhosis (37.5%), abnormal LFTs (17.9%), and Fib-4 >1.3 (16.1%) were top reasons for hepatology referral. Over half (57.1%) never calculated Fib-4 scores for at-risk patients. PCPs referred 32.3% of MASLD patients to weight management (median 20%, IQR 60%). Most PCPs (57.1%) did not observe racial/ethnic disparities in MASLD prevalence; among those who did, Hispanic/Latino (83%) and South Asian (25%) populations were most cited. Nearly all PCPs (96.4%) reported specialists were "very" or "moderately" accessible. **Conclusion:** This study reveals that the majority of PCPs rely primarily on incidental imaging and abnormal liver function tests to diagnose MASLD, with limited use of non-invasive fibrosis tests such as Fib-4. PCPs also report low confidence in both diagnosis and management, underscoring gaps in education and clinical practice. Given that PCPs are the frontline providers facing the growing MASLD burden, establishing standardized clinical pathways is essential to improve early detection, risk stratification, and appropriate referral. Encouragingly, nearly all PCPs in our network reported moderate to high access to hepatology specialists, providing a strong foundation for multidisciplinary care coordination.

2597 | HIGH PREVALENCE OF PORTOSINUSOIDAL VASCULAR DISEASE IN EARLY STAGE METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE

Diederick van Doorn[1] Lotte Schoenmakers[2] Sebastiaan de Jager[3] Marten Alexander Lantinga[3] Adriaan Holleboom[3] Joost Drenth[3] Sven Francque[2] Bart Takkenberg[4] Ann driessen[2] Joanne Verheij[5], [1]Amsterdam University Medical Center, [2]UZ Antwerpen, [3]Amsterdam UMC, [4]Amsterdam University Medical Centers, location AMC, [5]Academic Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver disease worldwide. Liver stiffness measurement (LSM) is routinely to assess the stage of fibrosis, but results are often discordant. Another phenomenon of MASLD is the occurrence of portal hypertension-related complications such as ascites or variceal bleeding in the absence of cirrhosis. This might be explained by fibrotic features not assessed in the currently used Brunt staging system or by features of portosinusoidal vascular disease (PSVD). Therefore, we aimed to assess the presence of PSVD in early stage MASLD and its correlation with markers of portal hypertension (PH). **Methods:** We conducted a cohort study in patients with MASLD who underwent liver biopsy between 2015 and 2022. All biopsies with early-stage disease, defined as F0-F2 according to NASH/MASH CRN staging, were revised by two expert liver pathologists in tandem-read for histological features of PSVD. Clinical

data was collected from the patient medical files. Primary endpoint was the presence of PSVD. Secondary endpoint was the correlation of histology with LSM (Fibroscan®) and other signs of PH. **Results:** We included 136 patients, 60% male, median age 50y, median BMI 30 kg/m^2, 15% F1 and 85% F2. Median LSM was 8.2 kPa [IQR 6.2-11.2]. Clinical signs of PH were present in 11 patients (8%) One patient had esophageal varices, 10 out of 11 patients had splenomegaly, 3 patients had thrombocytopenia, and 2 patients had ascites. In total 74% of patients fulfilled the VALDIG criteria for the diagnosis of PSVD. Portal vein stenosis as a specific histological sign of PH was the most relevant finding in our cohort, occurring in 74% of biopsies. However, portal vein stenosis did not correlate with LSM or platelet count at time of biopsy. Perisinusoidal fibrosis (grade 0-3) was present in 97% of biopsies, with 62% grade 1, and 32% grade 2. We observed a correlation between the LSM value and the grade of perisinusoidal fibrosis ($r = .25$, $p = 0.03$), but not with platelet count. **Conclusion:** PSVD is a frequent finding in early stage MASLD, with portal vein stenosis as the most frequent PSVD-specific histological lesion and perisinusoidal fibrosis as the most frequent PSVD non-specific lesion. PSVD can possibly explaining the presence of portal hypertension in early, non-cirrhotic MASLD and its presence should trigger further investigation for clinical signs of portal hypertension.

2598 | THE IMPACT OF STATIN THERAPY ON MASLD PREVALENCE AND SEVERITY: ANALYSIS OF A COMMUNITY-BASED, PROSPECTIVE COHORT OF 717 ADULTS WITH OVERWEIGHT AND OBESITY

Monica Tincopa[1] Suruchi Ramanujan[2] Lisa Richards[1] Egbert Madamba[2] Harris Siddiqi[2] Seema Singh[2] Ricki Bettencourt[2] Veeral Ajmera[1] Rohit Loomba[1],
[1]University of California, San Diego, [2]UCSD

Background: Given anti-inflammatory and antioxidant properties, it is posited that statins may reduce prevalence and severity of metabolic dysfunction-associated steatotic liver disease (MASLD), though available data is conflicting. The aim of this study was to determine the prevalence and severity of MASLD by statin use using advanced MRI biomarkers in a prospective, well-phenotyped cohort of community-dwelling adults with overweight and obesity. **Methods:** This is a cross-sectional analysis of prospectively enrolled adults with overweight [body mass index (BMI) >25 kg/m^2] and obesity, aged 40-75 from primary care and community-based settings. Participants underwent a standardized clinical research visit with magnetic resonance imaging proton-density-fat-fraction (MRI-PDFF) and MR Elastography (MRE) liver stiffness measurement (LSM). Individuals with other causes of chronic liver disease, secondary causes of hepatic steatosis, and those meeting AASLD definition for alcohol-associated liver disease (ALD) and MetALD were excluded. MASLD was defined as MRI-PDFF of $\geq 5\%$, at-risk metabolic dysfunction-associated steatohepatitis (MASH) by histology, significant and advanced fibrosis by LSM on MRE as ≥ 3.14 and ≥ 3.63 kPa respectively. Linear and logistic regression were used to assess the association of statin use with outcomes of interest. **Results:** The cohort included 717 adults with mean ($\pm$SD) age 51.3 (13.2) years, BMI 32.5 (6) kg/m^2, with 45% male sex, 41% Hispanic ethnicity and 26% with type II diabetes (T2DM). In the overall cohort, 246 (34.3%) participants were on a statin, 19.5% of which were lipophilic. Those on a statin were older (58 vs 47), had lower BMI (31.7 vs 32.9), had higher prevalence of T2DM (48 vs 14.7%), hypertension (54.5 vs 26.5%), incretin therapy (13.8 vs 5.9%) and less physical activity. The only significant difference in disease prevalence and severity was higher prevalence of at-risk MASH among those on statins (Table 1a). On multivariate analysis accounting for differences in baseline characteristics, statin use was not significantly associated with risk of MASLD nor MASLD severity (Table 1b). **Conclusion:** Using advanced MRI methods in a prospective cohort of adults with overweight and obesity, statin use was not associated with statistically significant differences in risk of MASLD nor MASLD severity after adjusting for differences in baseline characteristics. Higher unadjusted prevalence of at-risk MASH among those on statins highlights the importance of screening and liver-directed pharmacotherapy for these individuals.

Table 1a. Prevalence and Severity of MASLD by Statin Use

	N	Statin	No Statin	p-value
Overall Cohort				
	N=717	N=246	N=471	
MASLD	717	168 (68.3%)	341 (72.4%)	0.25
At-risk MASH	83	19 (63.3%)	18 (34.0%)	**0.009**

2599 | TYPE 2 DIABETES MELLITUS IS ASSOCIATED WITH ACCELERATED PROGRESSION TO CIRRHOSIS AND CHRONIC KIDNEY DISEASE IN PATIENTS WITH MASLD: A REAL-WORLD MULTI-CENTER COHORT STUDY

Vaishnavi Modi[1] Rishi Chowdhary[2] Megh Patel[3] Simran Joshi[4] Dhruvi Shah[5] Prachi Dawar[6], [1]MacNeal Hospital Loyola Medicine, [2]Metrohealth Medical Center, [3]BJ Medical College, [4]Yale New Haven Health/Yale University School of Medicine, [5]University of Maryland Midtown, [6]UCMS Delhi

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a growing public health concern with known hepatic and extrahepatic complications. Type 2 diabetes mellitus (T2DM) is a well-established risk factor, but data on its impact across organ systems in real-world longitudinal cohorts remain limited. We aimed to quantify the association between T2DM and progression to cirrhosis, portal hypertension, and chronic kidney disease (CKD) among MASLD patients using a large multi-institutional electronic health record (EHR) network. **Methods:** We conducted a retrospective cohort study using TriNetX's US Collaborative Network. Adults ($\geq$ 18 years) with MASLD (ICD-10 K76.0 or K75.81) were stratified into two cohorts: MASLD with T2DM (E11.x) and MASLD without diabetes. Patients with baseline cirrhosis, portal hypertension, varices, CKD, ESRD, or other chronic liver diseases were excluded. Propensity score matching (1:1) was performed across 16 covariates, including age, sex, BMI, comorbidities, and medication use. Kaplan-Meier curves and Cox proportional hazards models were used to evaluate time-to-event outcomes. **Results:** After 1:1 propensity score matching, 341,177 patients were included in each cohort. The median follow-up duration was 861 days for the MASLD+T2DM cohort and 770 days for the MASLD-only group. Patients with T2DM exhibited significantly greater risk and faster progression to both hepatic and renal complications. The incidence of cirrhosis was higher among MASLD+T2DM patients (1.0% vs 0.4%), with a hazard ratio (HR) of 2.11 (95% CI: 2.00–2.23; $p < 0.0001$). At five years, cirrhosis-free survival declined from 98.0% in MASLD-only to 94.3% in MASLD+T2DM. Similar trends were observed for portal hypertension (0.3% vs 0.1%; HR: 2.39; 95% CI: 2.16–2.64) and esophageal varices (0.2% vs 0.1%; HR: 2.64; 95% CI: 2.30–3.04), confirming an accelerated hepatic disease course in the diabetic cohort.

Renal outcomes demonstrated even greater disparities. CKD was diagnosed in 44.8% of MASLD+T2DM patients versus 23.2% of MASLD-only, corresponding to an HR of 1.68 (95% CI: 1.64–1.72; $p < 0.0001$). CKD-free survival at five years dropped from 76.8% in non-diabetic patients to 55.2% in those with T2DM. Furthermore, the incidence of ESRD was nearly fivefold higher in the diabetic group (0.2% vs 0.05%; HR: 4.45; 95% CI: 3.86–5.11). The association remained consistent across CKD stages 1 through 5, with stage-specific hazard ratios ranging from 1.67 to 4.87. Kaplan-Meier survival curves demonstrated significantly steeper declines in event-free survival for all outcomes in the T2DM cohort, reinforcing the finding of accelerated progression. **Conclusion:** T2DM is linked to increased risk and faster progression to cirrhosis, portal hypertension, and CKD in MASLD. These findings highlight the need for proactive multi-organ surveillance and metabolic control.

2600 | CARDIOMETABOLIC BURDEN INCREASES THE RISK OF KIDNEY FAILURE IN A DOSE-DEPENDENT MANNER AMONG PATIENTS WITH STEATOTIC LIVER DISEASE

Han-Tse Cheng[1] Hsin-Yun Wu[2] Tung-Hung Su[3] Kai-Chun Chang[3] Shang-Chin Huang[1] Tai-Shuan Lai[3] Tai-Chung Tseng[3] Chun-Ming Hong[1] Chen-Hua Liu[3] Hung-Chih Yang[3] Chun Jen Liu[3] Jia-Horng Kao[3], [1]National Taiwan University, [2]National Taiwan University Hospital, Jinshan Branch, Taipei, Taiwan, [3]National Taiwan University Hospital

Background: Emerging evidence links metabolic dysfunction–associated steatotic liver disease (MASLD) with renal outcomes. However, few studies have assessed how cumulative cardiometabolic risk factors (CMRFs) influence kidney failure in MASLD patients. We aimed to examine the impact of metabolic burden on the incidence of kidney failure among individuals with steatotic liver disease (SLD). **Methods:** We conducted a retrospective cohort study using the National Taiwan University Hospital Integrated Medical Database from 2006 to 2019. A total of 14,343 patients with persistent steatosis confirmed by abdominal ultrasound were included. MASLD was defined by hepatic steatosis with at least 1 CMRF, based on the 2023 multisociety consensus. Patients were classified as "MASLD" (n = 12,296), "SLD with later MASLD" (n = 1,442), and "SLD without later MASLD" (n = 605) groups. The primary outcome was kidney failure, defined by chronic kidney disease (CKD) stage 5 or receiving renal replacement therapy. The Fine–Gray subdistribution hazard model was used to adjust for competing mortality. **Results:** MASLD patients were older and had more comorbidities than other groups. After adjusting for age, sex, estimated Glomerular filtration rate (eGFR), malignancy, HBV, HCV, cirrhosis, and rheumatologic disease, MASLD was significantly associated with kidney failure (Sub-distribution Hazard Ratio [SHR] 3.415; 95% CI: 1.092–10.678; P = 0.035) compared with the SLD without later MASLD group. There is also a trend of increased kidney failure risks in patients with SLD who later developed MASLD (SHR: 1.270, 95% CI: 0.380–4.244).

When analyzing CMRFs separately, there was a significant dose-dependent association with kidney failure risk. Compared to individuals with no CMRFs, the risk for kidney failure increased with each additional risk factor, with the SHR: 2.01 (95% CI: 1.28–3.15, P = 0.002), 1.85 (95% CI: 1.17–2.91, P = 0.008), 2.93 (95% CI: 1.91–4.50, P < 0.0001), 3.85 (95% CI: 2.50–5.93, P < 0.0001), and 5.84 (95% CI: 3.68–9.26, P < 0.0001) in patients with 1, 2, 3, 4 and 5 CMRFs, respectively. Diabetes mellitus and hypertension were the most significant contributors (SHR 2.17 and 1.76, respectively; both P < 0.0001). In contrast, dyslipidemia and BMI ≥23 kg/m² were not associated with kidney failure development. **Conclusion:** There is a dose-dependent relationship between metabolic burden and kidney failure risks in patients with SLD. The cumulative number of CMRFs—particularly diabetes and hypertension—strongly predicts kidney failure. These findings highlight the need for early identification and management of metabolic risks in MASLD to prevent kidney-related complications.

Table. The univariate and multivariable analyses for the risks of kidney failure in patients with steatotic liver disease

N= 14343	Univariate analysis		Multivariable analysis	
	SHR (95%CI)	P value	SHR (95%CI)	P value
Age	1.048 (1.041 , 1.056)	<.0001	1.006 (0.998 , 1.015)	0.137
Sex	1.778 (1.486 , 2.128)	<.0001	2.065 (1.713 , 2.489)	<.0001
Baseline_eGFR	0.949 (0.944 , 0.953)	<.0001	0.953 (0.947 , 0.959)	0.000
Malignancy	1.086 (0.856 , 1.378)	0.496	1.150 (0.894 , 1.479)	0.276
Rheumatologic disease	1.064 (0.673 , 1.683)	0.79	1.175 (0.708 , 1.950)	0.533
HBV	0.646 (0.515 , 0.811)	<.0001	0.831 (0.655 , 1.054)	0.127
HCV	1.044 (0.730 , 1.492)	0.814	1.021 (0.695 , 1.499)	0.916
Cirrhosis	0.772 (0.319 , 1.868)	0.566	0.610 (0.238 , 1.562)	0.303
CMRF (1 Vs 0)	2.337 (1.488 , 3.671)	<.0001	2.006 (1.279 , 3.147)	0.002
CMRF (2 Vs 0)	2.495 (1.589 , 3.916)	<.0001	1.848 (1.173 , 2.912)	0.008
CMRF (3 Vs 0)	4.413 (2.885 , 6.749)	<.0001	2.930 (1.906 , 4.504)	<.0001
CMRF (4 Vs 0)	6.150 (4.029 , 9.390)	<.0001	3.849 (2.498 , 5.931)	<.0001
CMRF (5 Vs 0)	9.277 (5.915 , 14.549)	<.0001	5.836 (3.677 , 9.264)	<.0001

SHR: Subdistribution Hazard Ratio, eGFR: estimated Glomerular filtration rate.
CMRF: Cardiometabolic risk factor.

2601 | UNRECOGNIZED FIBROSIS RISK IN MASLD: A REAL-WORLD ANALYSIS AND THE CASE FOR AI-AUGMENTED STRATIFICATION

Ruona Ebiai[1] Leonardo Seoane[2] Lisa Birdsall Fort[2] George Therapondos[2], [1]Ochsner Clinic Foundation, [2]Ochsner Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common chronic liver disease globally, affecting nearly one in four adults. While non-invasive fibrosis risk stratification tools such as the FIB-4 index are guideline-recommended, real-world implementation is inconsistent. We aimed to quantify care gaps in MASLD risk stratification and evaluate the potential role of artificial intelligence (AI) in addressing them. **Methods:** We performed a retrospective analysis of all abdominal ultrasounds conducted from January 1, 2023, to December 31, 2024, across all South Shore campuses of our academic health system. Studies were included if the liver was visualized, regardless of indication (n = 34,926). Using natural language processing (NLP) string-matching, we identified patients with ≥5% hepatic steatosis (n = 5,399; 15.5%). MASLD was defined by ≥1 cardiometabolic risk factor documented in the structured problem list. FIB-4 scores were calculated and stratified by standard age-adjusted thresholds. Referral patterns and primary care continuity were assessed via EMR review. **Results:** Among 5,399 patients with ≥5% hepatic steatosis on imaging, 4,395 (81.4%) met MASLD criteria based on ≥1 cardiometabolic risk factor documented in the EMR. However, FIB-4 stratification was performed on all-comers with steatosis (n = 5,399) to reflect real-world imaging-based identification. Of these, 574 (10.6%) were high-risk and lacked hepatology referral, while only 257 (4.8%) were appropriately referred. Among indeterminate-risk patients, 662 (12.3%) had a primary care provider (PCP) but no referral, compared to 346 (6.4%) who were referred—highlighting missed triage opportunities. At our institution, hepatologists—not PCPs—typically initiate secondary risk assessment (e.g., FibroScan, ELF), underscoring the importance of referral in this group. Additionally, 189 (3.5%) low-risk patients had no documented PCP, suggesting missed opportunities for longitudinal re-evaluation. **Conclusion:** Despite validated tools, MASLD care remains fragmented. Most high-risk patients are not referred to hepatology, and many indeterminate-risk cases lack appropriate follow-up—even when a primary care provider is involved. These gaps highlight systemic shortcomings in risk recognition and adherence to guideline-based care. AI-powered solutions that automate FIB-4 calculation, flag high-risk and indeterminate cases, and trigger referrals or highlight care gaps may represent the only scalable path to closing these implementation failures and improving MASLD outcomes.

Risk Stratification Table

Group	Category	Criteria	Count (%)
A	High Risk, Unmanaged	FIB-4 > 2.67; no hepatology referral	574 (10.6%)
B	High Risk, Managed	FIB-4 > 2.67; hepatology referral present	257 (4.8%)
C	Indeterminate, No PCP	FIB-4 1.3–2.67 (<65) or 2.0–2.67 (≥65); no PCP or referral	15 (0.3%)
D	Indeterminate, Managed	Indeterminate FIB-4; hepatology referral present	346 (6.4%)
E	Indeterminate, Unmanaged	Indeterminate FIB-4; has PCP but no referral	662 (12.3%)
F	Missing FIB-4	No sufficient labs to calculate FIB-4	78 (1.4%)
G	Low Risk, No PCP	FIB-4 below threshold; no documented PCP	189 (3.5%)
H	Low Risk, With PCP	FIB-4 below threshold; PCP documented	3,219 (59.6%)

Legend

FIB-4 thresholds:

- Under 65 years: Low <1.3, Indeterminate 1.3–2.67, High >2.67
- 65 years and older: Low <2.0, Indeterminate 2.0–2.67, High >2.67

Definitions:

- Managed: Documented hepatology referral in EMR.
- Unmanaged: No referral documented.
- PCP: Presence of a named primary care provider in the EMR field.
- Missing FIB-4: Lacking labs (AST, ALT, or platelets) to compute FIB-4.

2602 | ASSOCIATION OF PULMONARY HYPERTENSION WITH HEPATIC OUTCOMES IN PATIENTS UNDERGOING RIGHT HEART CATHETERIZATION: A PROPENSITY-MATCHED COHORT STUDY

Akshay Sharma[1] Muhammad Kazi[1] Nirav Agrawal[1] Simran Joshi[2] Sushrut Ingawale[3] Sanmeet Singh[1], [1]Luminis Health Anne Arundel Medical Center, [2]Yale New Haven Health/Bridgeport Hospital, [3]Quinnipiac University Frank H Netter MD School of Medicine

Background: Pulmonary hypertension (PH) is a progressive condition characterized by elevated pulmonary arterial pressure, often diagnosed through right heart catheterization (RHC) or bilateral heart catheterization (BHC). PH affects systemic circulation and may alter liver hemodynamics, increasing the risk of hepatic complications. Despite its known impact on portal pressure and hepatic perfusion, the PH–liver disease link remains underexplored. Patients with PH often exhibit increased systemic inflammation, endothelial dysfunction, and altered blood flow, which are risk factors for developing liver pathologies such as non-alcoholic steatohepatitis (NASH), cirrhosis, and other hepatobiliary conditions. Given the potential for these complications to contribute to adverse clinical outcomes, it is imperative to explore this association further. This study investigates the association between PH and hepatic outcomes—NASH, varices, ascites, hepatic encephalopathy (HE), and cirrhosis—using a propensity-matched cohort design, which may inform early screening strategies and guide preventive interventions in high-risk populations. **Methods:** This retrospective cohort study utilized the TriNetX database. Patients who underwent RHC or BHC were identified and divided into two cohorts: with PH and without PH. Propensity score matching was performed to balance baseline characteristics. Outcomes measured included NASH, varices, ascites, HE, cirrhosis. Risk ratios (RR) with 95% confidence intervals (CI) calculated. **Results:** A total of 158,096 patients were included, with 79,048 in each cohort. The PH group demonstrated significantly higher risks for the following outcomes compared to the non-PH group:

- NASH: PH 1.1% vs. Non-PH 0.8% (RR: 1.316, CI: 1.187- 1.459)
- Varices: PH 1.1% vs. Non-PH 0.7% (RR: 1.528, CI: 1.374- 1.698)
- Ascites: PH 5.3% vs. Non-PH 2.6% (RR: 2, CI: 1.900- 2.107)
- Hepatic Encephalopathy: PH 0.5% vs. Non-PH 0.4% (RR: 1.299, CI: 1.125- 1.501)
- Cirrhosis: PH 4.4% vs. Non-PH 2.6% (RR: 1.697, CI: 1.608- 1.791) **Conclusion:** Patients diagnosed with PH following RHC or BHC had a significantly higher risk of developing hepatic complications, including NASH, varices, ascites, HE, and cirrhosis, compared to matched controls without PH. These findings highlight the need for heightened surveillance and multidisciplinary care in this vulnerable population. Given the substantial burden of hepatic complications observed, routine screening for liver dysfunction may improve early diagnosis and timely interventions in patients with PH. Future research should investigate the underlying mechanisms linking PH and hepatic disease progression, with a focus on potential therapeutic strategies to reduce liver-related morbidity and mortality in this patient population. Expanding the understanding of these interactions may guide clinical decisions and improve outcomes for individuals with PH at risk of liver disease.

2603 | LOW FAT AND LOW CARBOHYDRATE DIETS ARE ASSOCIATED WITH WORSE SURVIVAL IN SUBJECTS WITH METABOLIC DYSFUNCTION AND ALCOHOL ASSOCIATED STEATOTIC LIVER DISEASES.

Nicholas Dunn[1] Abdelhaleem Sideeg[2] Fatima Elmustafa[3] Sheel Patel[4] Naim Alkhouri[5] Luis Antonio Diaz[6] Robert Wong[7] Juan Pablo Arab[8] Shira Zelber-Sagi[9] Aleksander Krag[10] Zobair Younossi[11] Ashwani Singal[12], [1]Pembroke Hill School, [2]Virginia Mason University, [3]Henry Ford Hospital, [4]University of Louisville School of Medicine, [5]Summit Clinical Research, [6]Pontificia Universidad Católica de Chile, [7]VA Palo Alto Healthcare System, [8]Virginia Commonwealth University, [9]Tel-Aviv Medical Center,

[10]University of Southern Denmark, [11]The Global NASH Council, [12]University of Louisville

Background: Limited data exist regarding the association of diet and survival in subjects with steatotic liver disease (SLD). In another abstract, we showed the association of dietary patterns with liver fibrosis in SLD. In this analysis, we examined the association of dietary patterns with overall survival in subjects with SLD. **Methods:** We performed an unsupervised clustering analysis using NHANES III (1988-94) adult participants. Dietary patterns were derived using unsupervised clustering of % calories from protein, carbohydrates, sugar, fiber, alcohol, saturated, and polyunsaturated fats. We performed survival analysis on adult participants with ultrasound-defined hepatic steatosis and ≥ 1 cardiometabolic risk factor (CMRF) who were stratified based on self-reported alcohol use to metabolic dysfunction-associated SLD (MASLD, n = 3,657; 37.4 million U.S. adults), metabolic dysfunction and alcohol associated liver disease (MetALD, n = 217; 2.5 M), or alcohol-associated liver disease (ALD, n = 84; 0.8 M). Cox regression models examined the association between dietary clusters and all-cause mortality, adjusting for demographics, income, urban/rural residence, number of CMRFs, smoking, leisure-time physical activity, and caffeine intake. **Results:** Four dietary patterns were identified in SLD subjects: general diet (14.7M $\pm$1.1M), high-fat low-carb diet (18.6M $\pm$1.3M), low-fat high-carb diet (3.4M $\pm$0.4M), and high-alcohol diet (11.0M $\pm$0.7M) (Fig. 1A). Prevalence estimates represent US adults with SLD 1988-94. NHANES III SLD cohort (n = 4538) median (IQR) follow-up was 313 (229-336) mo., with 1882 deaths. Diet patterns were not associated with survival in MASLD subjects. However, in those with MetALD/ALD, high-fat low-carb and low-fat high-carb diets were associated with mortality with HR (95% CI) of 1.80 (1.08–3.03) and 1.75 (1.06–2.91), respectively (Fig.1B). **Conclusion:** Specialized dietary patterns characterized by either very high or very low carbohydrate content are associated with higher mortality in subjects with MetALD/ALD. These findings reinforce the potential risks of restrictive dietary strategies in patients with alcohol-associated liver disease, emphasizing the need for cautious dietary guidance in this population. Further prospective studies are needed to validate these findings, examine dietary fat (saturated vs. unsaturated) and carbohydrates (sugar vs. non-sugar), and explore mechanistic insights to help tailor diet recommendations for subjects with SLD.

2604 | DECOUPLING OF HEPATIC STEATOSIS AND LIVER DISEASE AMONG BALTIMORE PWID

Jacqueline Rudolph Jacquie Astemborski[1] Redeat Assefa[1] Gregory Kirk[1] Shruti Mehta[1] David Thomas[2], [1]Johns Hopkins Bloomberg School of Public Health, [2]Johns Hopkins School of Medicine

Background: Steatotic liver disease (SLD) is a growing concern in the general population and may be particularly significant among people who inject drugs (PWID) in whom there is a high burden of cirrhosis from hepatitis C virus (HCV), alcohol, and HIV. **Methods:** Between 2017 and 2024, we performed binannual vibration controlled transient elastography (TE) with controlled attenuation parameter (CAP) on 6172 visits contributed by 1664 participants from the AIDS Linked to the IntraVenous Experience cohort. FIB-4 was calculated annually. Another analysis focused on the initial tests for 1,267 participants and the risk factors for SLD. Here, we considered the association between steatosis and liver disease, overall and by HCV status. SLD was characterized as CAP scores (dB/m) $\geq$248 and $\geq$268, corresponding to S1 and S2 steatosis, and $\geq$288, corresponding to Rinella et al. Cirrhosis was defined as TE measures $\geq$12.3 kPa. We considered data (FIB-4, demographics, current substance use, and comorbidities) nearest to the TE visit. **Results:** There was no correlation between CAP and TE scores (correlation coefficient, r = 0.05) or FIB-4 (r = -0.03) (Figure 1). SLD was detected at 1867 (30%), 1296 (21%), and 871 (14%) participant visits, using the 248, 268, and 288 dB/m cutpoints, respectively. Cirrhosis was detected at 437 (7%) visits. SLD and cirrhosis were concurrently detected at 3% (248 dB/m), 2% (268 dB/m), and 1% of visits (288 dB/m); the prevalence of cirrhosis was higher at visits with SLD (288 dB/min) than at visits without SLD (11% vs. 6%). Once persons with ongoing HCV were removed, over 90% of those with CAP scores $\geq$288 dB/m did not have cirrhosis, and the prevalence was only marginally higher than persons with scores $<$288 dB/m. At visits with SLD ($\geq$288 dB/m) and concurrent cirrhosis, compared to visits with SLD but without cirrhosis, participants were more likely to be HCV RNA positive and report heavy alcohol use. At visits with cirrhosis and concurrent SLD, compared to visits with cirrhosis but without SLD, participants were more likely to be female, have BMI $\geq$30, have $\geq$2 chronic conditions, and report heavy alcohol use and less likely to be HCV RNA positive and report active injection, heroin use, and cocaine use. Age, race, and HIV status were similar across groups. **Conclusion:** In a community-based cohort of PWID with routine measurement of SLD and liver fibrosis, the two forms of liver disease were not correlated, suggesting that in most persons there was steatosis but not concurrent liver disease.

2605 | SEDENTARY LIFESTYLE IS ASSOCIATED WITH STEATOTIC LIVER DISEASE (SLD): RESULTS: FROM THREE LARGE US PROSPECTIVE COHORTS.

Prooksa Ananchuensook[1] Hanseul Kim[1] Daniel Sikavi[1] Jiaxian Shen[1] Etienne Nzabarushimana[1] Xuehong Zhang[2] Edward Giovannucci[3] Amrisha Bhosle[1] Yin Cao[4] Tracey Simon[1] Andrew Chan[3] Long Nguyen[3], [1]Massachusetts General hospital, [2]Yale University School of Nursing, [3]Harvard University Medical School, [4]Washinton Universty School of Medicine in St Louis

Continuing Medical Education

Background: The prevalence of steatotic liver disease (SLD), including metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic and alcohol-associated liver disease (MetALD), is rising globally. Sedentary behavior has been linked to MASLD in cross-sectional studies, which are limited by concerns about reverse causation. Given their established links to other metabolic disorders, we investigated the relationship between sedentary times, specifically TV watching and total sitting time, and SLD in large prospective cohorts. **Methods:** We analyzed data from three US prospective cohorts - Nurses' Health Study (NHS) I, II and Health Professionals Follow-up Study (HPFS) which included participants with ≥1 metabolic risk factor and alcohol intake <60 g/day for males and <50 g/day for females. Sedentary lifestyle was assessed using biennial (HPFS) or quadrennial (NHSI, II) questionnaires and represented by the cumulative average total sitting time and TV watching time (hours/week). Self-reported SLD (PPV >88% vs. medical records review) and the year of diagnosis were recorded. Hazard ratios (HR) for sedentary lifestyle and SLD incidence were assessed using time-varying Cox proportional hazard models to estimate relative risk (RR), adjusting for demographics, comorbidities, and lifestyle factors, including moderate-vigorous physical activities.

Results: A total of 7,517 SLD cases among 196,604 participants were identified across three cohorts: NHS I (1,241 cases/1,527,657 person-years [p-y]), NHS II (6,044 cases/1,645,345 p-y and HPFS (232 cases/770,976 p-y). Compared to <28, total sitting time of 28-56 hours/week and >56 hours/week significantly increased risk of SLD with a pooled multivariable RR of 1.10 (95% CI 1.04-1.16) and 1.20 (1.05-1.37), respectively (P-trend, 0.002; Table 1A) Compared to < 14, watching TV ≥14 hours/week was linked to SLD (RR 1.09 [95% CI 1.05-1.14], Table 1A) Subgroup analyses demonstrated a significant association between sedentary behaviors and SLD in participants with alcohol intake <30 g/day for males or <20 g/day for females, BMI ≥25 kg/m², and physical activity <15 MET-hours/day (Fig. 1B). **Conclusion:** Prolonged sitting and excess TV viewing were significantly associated with SLD incidence, particularly in individuals with low alcohol intake, non-lean and physically inactive individuals. Limiting time spent sitting or TV viewing may help prevent SLD independently of other risk factors or measures of physical expenditure.

Table 1A. Sedentary total sitting and TV watching time and risk of steatotic liver disease from three cohorts.

Cohort		Total sitting time				TV viewing time		
		< 28 hrs/wk	28-56 hrs/wk	>56 hrs/wk	P trend*	< 14 hrs/wk	≥ 14 hrs/wk

2606 | GCKR POLYMORPHISMS INCREASE THE RISKS OF LOW BONE MINERAL DENSITY IN YOUNG AND NON-OBESE PATIENTS WITH MASLD AND HYPERURICEMIA

Ying-Ying Yang[1] Tzu-Hao Li[2] Hsiao-Yun Yeh[3] Chien-Wei Su[4] Hwai-I Yang[5] Ming-Chih Hou[6], [1]Department of Medical Education, Department of Internal Medicine, Division of Gastroenterology and H, [2]Division of Allergy, Immunology, and Rheumatology, Department of Internal Medicine, Shin Kong Wu Ho-, [3]Department of Medical Education, Taipei Veterans General Hospital, Taipei, Taiwan, [4]Department of Internal Medicine, Division of Gastroenterology and Hepatology, Taipei Veterans Genera, [5]Genomics Research Center, Academia Sinica, Taipei, Taiwan, [6]Taipei Veterans General Hospital

Background: Metabolic-associated steatotic liver disease (MASLD) encompasses common comorbidities

including low bone mineral density (BMD) and hyperuricemia (HU), yet relevant genetic analyses are limited. This study aimed to investigate the genetic effects of risk single nucleotide polymorphisms (SNPs) on the occurrence of low BMD in patients with MASLD and HU, particularly focusing on relatively young or non-obese populations. **Methods:** We conducted a cross-sectional study utilizing data from the Taiwan Biobank, screening a total of 150,709 participants who were prospectively enrolled over a period of 13 years. The risk SNPs of MASLD were identified. Genotype analyses of HU and its effects on the occurrence of low BMD in the general population were evaluated, with further analyses of common SNPs focusing on patients with MASLD, including subgroup analyses on relatively young and non-obese populations. **Results:** A total of 20,496 participants were eligible for analysis, including 7,526 patients with MASLD. Several risk SNPs for MASLD were identified. Furthermore, MASLD patients carrying the PNPLA3-rs738409 C_C, PNPLA3-rs2896019 T_T, GCKR-rs780094 T_T, and GCKR-rs1260326 T_T genotypes exhibited an increased risk of comorbidity with HU. Trend analysis revealed that the T alleles in GCKR-rs780094 and GCKR-rs1260326 were associated with the occurrence of low BMD in MASLD individuals comorbid with HU, particularly among relatively young or non-obese populations. In relatively young, non-obese patients with MASLD and HU, genetic effects significantly increase the risk of occurrence of low BMD. **Conclusion:** Although the risk of BMD loss may seem ostensibly low due to age and anthropometric characteristics, genetic effects are still significant in this subgroup. Therefore, heightened awareness and close follow-up are recommended.

2607 | REAL-WORLD OBSERVATIONAL DATA ON MASLD IN A DIVERSE COHORT FROM A SINGLE HEPATOLOGY CLINIC IN SOUTHERN CALIFORNIA: RACIAL AND ETHNIC DISPARITIES AND IMPACT OF THE METABOLIC SYNDROME ON FIBROSIS

Sabrina Alff[1] Orlinda Ventura[1] Daniel Joseph[1] Irene Arevalo[1] Michel Mendler[1] Edward Mena[2], [1]California Liver Research Institute, [2]California Liver Reasearch Institiute

Background: MASLD is a common progressive condition influenced by socioeconomic, lifestyle, and metabolic syndrome (MS) factors. This study aimed to characterize racial and ethnic disparities in MASLD within a diverse, non-academic hepatology clinic in Los Angeles County (LAC). **Methods:** Retrospective cohort study of patients with MASLD diagnosed by accepted AASLD criteria including only non-invasive testing (NIT). Demographic, socioeconomic, metabolic, biochemical data and degree of disease (FibroScan® CAP and stiffness) were compared by univariate and multivariate analysis. **Results:** 333 patients seen between 2009 and 2023 met inclusion criteria. 210/333 self-identified as White (51.9%) or Non-White (11.9% Asian, 1.4% African American, 34.8% Other). 249/333 self-identified as Hispanic/Latino (HL, 65.8%) or Non-Hispanic/Latino (NHL, 34.1%). Median age was 55y (17-88), 65.4% were female. 63.3% of patients were married. 177 had either blue-collar (19.7%) or white-collar (80.3%) jobs. Versus NHL, HL had a higher rate of blue-collar jobs (27.7% vs. 12.2%, $p = 0.0321$) and a higher Area Deprivation Index score [(ADI, 1-10, least to most disadvantaged) 1-3: 20.7% vs. 48.2%; 4-6: 53.5% vs. 38.8%; 7-10: 26.2% vs. 12.9%; $p < 0.0001$]. 14.4% drank minimal to moderate amounts of alcohol. 36.0% had DMT2, 33.9% had dyslipidemia, and 45.7% had HTN. Median BMI was 32(20-59.9): of 275/333, 5.5% were lean, 28.8% overweight and 65.7% obese. Of 274/333, 0.7% had 0, 35.0% had 1, 30.3% had 2, 23.7% had 3 and 10.2% had 4 components of the MS. Versus NHL, HL were more obese (Lean: 4.9% vs. 6.8%; Overweight: 26.1% vs. 41.9%; Obese: 69.0% vs. 51.4%; $p = 0.0389$). 10.5% of patients had clinical cirrhosis. 182/333 had a Fibroscan® [median stiffness kPa 6.7(3.2-61.2)], IQR 12(2.4-29), CAP 315(157-400)]: 53.8% stage F0/F1, 23.1% F2, 10.4% F3, 12.6% F4; and 3.3% grade S0 (steatosis confirmed on other imaging), 9.3% S1, 20.9% S2, 66.5% S3. Median HbA1c was 6.1(4.4-13.4), platelets 239K(50-528)], and AST/ALT ratio 0.80(0.22-2.8)]. 277 patients had a Fib-4 calculated (< 1.45: 62.8%; 1.45-3.25: 27.4%; > 3.25: 9.7%). The number of MS components was positively associated with a higher marriage rate ($p = 0.0042$), HbA1c levels ($p < 0.0001$), fibrosis stage ($p = 0.0017$), and Fib-4 ($p = 0.0140$). By multivariate analysis, BMI [OR: 1.17(1.07-1.32), $p = 0.0003$], platelet levels [OR: 0.98(0.97-0.99), $p < 0.0001$], and blue-collar work [OR: 7.99(1.47-67.3), $p = 0.0142$] were independently associated with stage F2-4. **Conclusion:** This real-world study from a diverse MASLD population in LAC suggests that HLs had higher rates of obesity, metabolic risk, and fibrosis. More MS components were linked to marriage, unmanaged diabetes, and fibrosis. Increasing BMI, lower platelet counts, and blue-collar employment were independently associated with F2-4.

2608 | METABOLIC-DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE IN INFLAMMATORY BOWEL DISEASE: PREVALENCE AND PROGRESSION

Grazia Pennisi Emanuele Bracciamà[1] Miriam Iacono[1] Francesca Maria Di Giorgio[1] Piera Melatti[1] Livia Maria Amato[1] Ivan Alberto Salerno[1] Roberto Ajovalasit[1] Lavinia Di Prima[1] Simone Scalia[1] Domenico Gambadauro[1] Salvatore Petta[1] Calogero Camma[1] Maria Cappello[1], [1]University of Palermo

Background: Prevalence of MASLD in patients with Inflammatory Bowel Disease (IBD) has been reported 24.4% in a recent metaanalysis and 21.6% in a previous cross-sectional study from our center. However, data on the progression of MASLD in IBD patients are scanty. We aimed to investigate the prevalence and the progression of MASLD, diagnosed by non-invasive tools, in a homogeneous cohort of patients with IBD followed in our referral center. **Methods:** Consecutive IBD patients without known chronic liver disease were retrospectively enrolled and prospectively followed between 2020 and 2024. MASLD was defined as Controlled Attenuation Parameter (CAP) $\geq$275 dB/m according to EASL criteria. Significant fibrosis was defined as Liver Stiffness (LSM) $\geq$8 kPa by FibroScan©. Demographic, metabolic and biochemical data were collected at baseline and at the last follow-up visit. All patients were genotyped for PNPLA3 rs738409 C > G by Taqman assay. Univariate logistic regression analysis was performed to identify risk factors associated with the prevalence of MASLD and its progression. **Results:** 230 patients (mean age was 46.1 $\pm$ 13.4 years, 49.2% were males, 50.8% had Crohn's disease, mean disease duration was 9.4 $\pm$ 7.5 years) were recruited. 14.8% of them were obese (BMI > 30 kg/m^2), 9.8% diabetic. 49.2% were PNPLA3 rs738409 CG/GG. 62 out of 230 patients had complete metabolic and biochemical assessment at follow-up. Mean follow-up time was 4 years. At baseline, according to EASL criteria, 31.1% (19/62) had MASLD. 19.1% (8/42) of patients without steatosis at baseline, developed steatosis at follow-up; while 42.1% of those having steatosis at baseline, did not show steatosis at follow-up. Two patients without fibrosis assessed by LSM at baseline developed significant fibrosis, while two patients with fibrosis at baseline experienced fibrosis regression. 13.5% developed obesity. Obesity was significantly associated with the prevalence of MASLD both at baseline (p = 0.01) and on follow-up (p = 0.01) and was a predictor of steatosis progression (p = 0.01); no association was found in relation to sex, PNPLA3 polymorphism, disease characteristics and the use of biologics. Diabetes was not significantly associated with MASLD in our cohort, but the number of patients was low. **Conclusion:** One third of IBD patients had MASLD and obesity was the main predictor of its prevalence and progression, highlighting the relevance of active surveillance of MASLD and appropriate nutritional and lifestyle counselling especially in obese IBD patients. The use of biologics to control inflammation seems to have no influence on MASLD progression but data need further confirm in larger cohorts.

2609 | THE OBESITY-MASH-SARCOPENIA CASCADE: METABOLIC PARADOX IN ADVANCED LIVER DISEASE

ATSUSHI NAKAMURA[1] Takeshi Ichikawa[2], [1]Nippon koukan hospital, [2]Nippon koukan hospital

Background: Obesity and metabolic dysfunction-associated steatotic liver disease (MASLD) are increasing in chronic liver disease (CLD), emphasizing the need for weight management. Meanwhile, sarcopenia (SP) is a key prognostic factor in liver cirrhosis (LC), and the coexistence of obesity and SP complicates treatment. We investigated the prognostic impact of obesity and SP using liver stiffness (LS) by MR elastography, liver fat by proton density fat fraction (PDFF), and muscle mass by MRI. **Methods:** We enrolled 865 patients (mean age: 61 years; mean BMI: 25 kg/m²; 60% male; HCC: 32 patients). Etiologies: MASLD (M, n = 276), non-MASLD (n-M, n = 589; viral 349, alcohol 128, others 112). Disease staging was determined by LS (F0–1, F2–3, F4), with F4 further divided into compensated (cLC) and decompensated (dLC) cirrhosis. SP was diagnosed based on low paraspinal muscle area by MRI. Obesity was defined as BMI $\geq$ 25, and the combination defined as sarcopenic obesity (SO). Prognostic analysis was conducted using Cox hazards modeling. **Results:** 1) Nutritional status: Obesity was present in 35% (M group / n-M group: 74% / 27%), SP in 28% (12% / 36%, both P < 0.01), and SO in 7% (8% / 6%, P = 0.47).
2) By stage (F0–1/F2–3/cLC/dLC): (a) M group (n = 184 / 45 / 33 / 14): Obesity: 68 / 89 / 82 / 93 %, SP: 8 / 11 / 18 / 50%, SO: 3 / 11 / 12 / 50%, (P < 0.01 for all). (b) n-M group (n = 246 / 197 / 81 / 65): Obesity: 19 / 29 / 43 / 27%, SP: 24 / 33 / 43 / 78%, SO: 3 / 5 / 10 / 16%, (P <

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

0.01 for all). (c) LS and ALBI scores correlated with stage progression, and median PDFF showed a decrease in dLC in both groups, suggesting a *"burnout"* (M group: 10.8 / 15.0 / 12.5 / 3.3%, n-M group: 3.3 / 3.7 / 4.3 / 2.7%, both $P < 0.01$).
3) Analysis of SO: In obese patients ($n = 363$), multivariate analysis showed age, CRP, and ALBI score were positively associated with SP, while BMI and PDFF were negatively associated (all $P < 0.05$). ALBI ≥ -2.36 emerged as the root node in the decision-tree analysis for predicting SP.
4) Prognosis (33 ± 22 months, 57 liver-related deaths): Kaplan-Meier analysis of 328 ACLD patients (LS $\geq$ 3kPa) divided into 4 groups (no obesity / SP: 75, obesity only: 110, SP only: 100, and SO: 43) showed that SO had as poor prognosis as SP ($P < 0.01$), with no difference in the presence/absence of obesity. In the Cox model, HCC (HR: 3.20), MELD score (1.10), and SP (2.57) were independent poor prognostic factors (all $P < 0.01$). **Conclusion:** The increase in MASLD drives SO, worsening prognosis. We propose a novel pathophysiological model, the "Obesity–MASH–Sarcopenia Cascade," where obesity-induced liver injury induces SP, identifying ALBI ≥ -2.36 as a phenotype switch in energy metabolism (anabolic to catabolic). Improvement of liver fibrosis may prevent this switch, highlighting the need for a shift in nutritional therapy in obese ACLD patients—from weight loss to muscle preservation and appropriate energy supplementation.

2610 | GREATER CONTRIBUTION OF ALCOHOL TO STEATOTIC LIVER DISEASE EPIDEMIOLOGY THAN PREVIOUSLY ESTIMATED AMONG VETERANS IN THE UNITED STATES

Robert Wong[1] Mandana Khalili[2] Meimei Liao[3] Michael Ostacher[4] Steven Batki[5] Derek Satre[5] Ramsey Cheung[6], [1]VA Palo Alto Healthcare System, [2]University of California, San Francisco, [3]VA Palo Alto Health Care System, [4]Stanford University School of Medicine, [5]University of California San Francisco, [6]Stanford University Medical Center

Background: Steatotic liver disease (SLD) is the leading cause of chronic liver disease, with studies reporting that SLD is predominated by metabolic dysfunction-associated SLD (MASLD). However, the contribution of alcohol to SLD epidemiology is likely underestimated due to underreporting and limited alcohol use data from existing datasets. We aim to accurately characterize the impact of alcohol use on SLD epidemiology among U.S. Veterans, a population where alcohol use is routinely assessed in primary care settings. **Methods:** Consecutive adults seen in hepatology clinic from 1/1/2020 to 12/31/2024 with evidence of hepatic steatosis (HS) on transient elastography (TE) (controlled attenuation parameter $\geq$ 263 dB/m) were identified. Alcohol use was assessed via manual chart review and categorized based on documented AUDIT-C score within 6 months of TE: no alcohol (AUDIT-C = 0), low-risk alcohol (AUDIT-C = 1-2 for women, 1-3 for men), high-risk alcohol (AUDIT-C $\geq$3 for women, $\geq$4 for men). SLD subtypes were defined as: MASLD = HS + no alcohol; MetALD = HS + low-risk alcohol; alcohol-associated liver disease (ALD) = HS + high-risk alcohol. Proportion of SLD patients with MASLD vs. MetALD vs. ALD were stratified by sex, age, and race/ethnicity, and compared using chi-square tests. **Results:** Among 798 adults with HS, 695 (87.1%) had AUDIT-C documented within 6 months of TE, among whom 46.0% had MASLD, 39.1% MetALD, and 14.8% ALD (Figure). Across the three groups, majority were men (92-96%) and median age was 64-68yr. Median body mass index (BMI) and proportion with diabetes was significantly higher in MASLD and MetALD vs. ALD (median BMI: 31.6 and 32.3 vs. 30.0, $p < 0.01$; diabetes: 58.1% and 51.5% vs. 35.9%, $p < 0.01$). The proportion with advanced fibrosis (AF) (liver stiffness measurement (LSM) $\geq$12kPa) or cirrhosis (LSM $\geq$20kPa) was higher in ALD (33.0%, 24.3%) vs. MetALD (22.8%, 10.3%) or MASLD (21.6%, 8.1%), $p = 0.05$ for AF, $p < 0.01$ for cirrhosis. The proportion with MetALD or ALD was higher in women (60% vs. 53.6% in men), higher in younger patients (70.7% in age 20-40y vs. 49.7% in age $\geq$60yr, $p < 0.01$), and highest in non-Hispanic whites (57.2%) and Asians (58.3%) and lowest in African Americans (40.0%). **Conclusion:** Among consecutively identified Veterans with SLD and documented alcohol assessment, the proportion with MetALD and ALD is much higher than existing reports, suggesting that the impact of alcohol use on SLD epidemiology may be significantly under-estimated.

2611 | FEMALE SEX HORMONES ARE NEGATIVELY ASSOCIATED WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE IN CHILDREN WITH OVERWEIGHT AND OBESITY

Judith Lubrecht[1] Robert Kleemann[2] Bjorn Winkens[3] Eveline Gart[4] Annemieke Heijboer[5] Anita Vreugdenhil[1], [1]Maastricht University Medical Centre+, [2]The Netherlands Organization for Applied Scientific Research (TNO), [3]Maastricht University, [4]The Netherlands Organisation for Applied Scientific Research, [5]Amsterdam University Medical Centre

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the leading cause for chronic liver disease in children and adolescents. Studies in adults demonstrate that MASLD is more prevalent in males compared to females of reproductive age, implicating sex hormones in the pathogenesis of MASLD. Currently, there is a lack of pediatric research examining the relationship between sex hormones and MASLD. This study investigates the associations between sex hormones and MASLD in children with overweight and obesity. **Methods:** A cross-sectional study was performed at Maastricht UMC+. A comprehensive sex hormone panel was quantified via liquid chromatography-tandem mass spectrometry (LC-MS/MS) in 290 participants. Additionally, serum alanine aminotransferase (ALT) and hepatic steatosis on ultrasound (HS) were assessed. Continuous Attenuation Parameter (CAP, Fibroscan©) data were available for 75 participants. The relationships between sex hormones and MASLD parameters (ALT, HS, and CAP) were analyzed using linear and logistic regression models. **Results:** Estradiol, anti-mullerian hormone (AMH) and sex hormone-binding globulin (SHBG) inversely associated with ALT, whereas dehydroepiandrosterone sulfate (DHEAS) positively associated, independent of BMI z-score, sex and age. Total, free and bioavailable testosterone (TT, FT and BioT) also positively associated with ALT, independent of BMI z-score and sex. AMH and SHBG inversely associated with HS, independent of BMI z-score and sex, while FT, BioT and DHEAS positively associated with HS, independent of sex. AMH and SHBG inversely associated with CAP, while follicle stimulating hormone, TT, androstenedione and DHEAS positively associated, independent of sex and BMI z-score. FT and BioT also positively correlated with CAP, independent of BMI z-score. **Conclusion:** This pioneering study reveals that estradiol, AMH and SHGB inversely associate with MASLD parameters, while androgens, including TT, FT, BioT, and DHEAS, positively associate with MASLD parameters in children with overweight and obesity. Our findings support the hypothesis that sex hormones contribute to MASLD development

2612 | CLINICAL AND GENETIC PREDICTORS OF CRYPTOGENIC STEATOTIC LIVER DISEASE AS COMPARED TO METABOLIC-ASSOCIATED STEATOTIC LIVER DISEASE IN LEAN INDIVIDUALS

Angela Sato Espinoza[1] Robert Vierkant[2] Perapa Chotiprasidhi[1] Filippo Pinto e Vairo[3] Shulan Tian[4] Jun Ma[5] Konstantinos Lazaridis[1] Alina Allen[6] Kirk Wangensteen[1], [1]Mayo Clinic, [2]Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, [3]Department of Clinical Genomics, Mayo Clinic, Rochester, [4]Division of Computational Biology, Mayo Clinic, [5]Division of Computational Biology, Mayo Clinic, Rochester, [6]Mayo Clinic Rochester

Background: Steatotic liver disease (SLD) is characterized by liver fat accumulation exceeding 5%. Lean individuals (BMI $\leq$ 25 kg/m2) with SLD can be classified into lean metabolic-associated liver disease (MASLD)—characterized by comorbid diabetes, hypertension, or hyperlipidemia—and cryptogenic SLD, with no metabolic disorders or other known cause of SLD. This study aimed to identify clinical and genetic predictors distinguishing cryptogenic SLD from lean MASLD. **Methods:** We conducted a retrospective cohort analysis using the Mayo Clinic Biobank and Tapestry databases. Lean individuals with SLD were identified using International Classification of Diseases (ICD) codes, radiological assessments, and pathology reports. Patients were subcategorized into lean MASLD or cryptogenic SLD based on thorough clinical review of comorbidities, imaging findings, and biochemical data. Exome sequencing data were analyzed for germline variants in PNPLA3 (rs738409), GCKR (rs1260326), MBOAT7 (rs641738), and TM6SF2 (rs58542926). Advanced fibrosis (F3-F4) was classified using FibroScan, imaging evidence of cirrhosis on CT, or advanced fibrosis

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

indicated by magnetic resonance elastography (MRE) or biopsy. **Results:** Among 177 patients with lean SLD, 47 had cryptogenic SLD, and 130 had lean MASLD. The MASLD group predominantly exhibited hyperlipidemia (88%), followed by hypertension (62%), and diabetes (25%). Compared to lean MASLD, cryptogenic SLD was associated with younger mean age (58 vs 65 years, $p = 0.001$), lower rates of coronary artery disease (10.6% vs 33.8%, $p = 0.002$), and chronic kidney disease (4.3% vs. 23.1%, $p = 0.003$). Gender distribution and BMI did not differ significantly between groups.

Additionally, lean MASLD was associated with homozygosity for the risk allele T of *GCKR* (20% vs. 9%, $p = 0.04$), which was attenuated in multivariable analysis that included diabetes. However, there was no difference between the groups in *PNPLA3* ($p = 0.257$), *TM6SF2* ($p = 0.766$), or *MBOAT7* ($p = 0.824$).

Advanced fibrosis was present in 4 out of 47 (8.5%) cases of cryptogenic SLD and 12 out of 114 (10.5%) cases of lean MASLD, which was not significantly different. **Conclusion:** Individuals with cryptogenic SLD tend to be younger and healthier than those with MASLD, exhibiting more favorable metabolic profiles. Additionally, the homozygosity for the risk allele in GCKR was associated with lean MASLD, which may reflect a link between diabetes and SLD in lean people. Advanced fibrosis is present in 8-10% of patients with lean SLD.

Table 1. Lean cryptogenic SLD vs lean MASLD

Variables	Lean cryptogenic SLD (N=47)	Lean MASLD (N=130)	p-value
Gender, n (%)			0.711
Male	11 (23.4%)	34 (26.2%)	
Female	36 (76.6%)	96 (73.8%)	
Age, Mean (SD)	57.9 (14.1)	65.1 (12.4)	0.001
BMI, Mean (SD)	22.9 (2)	23.1 (1.6)	0.512
CAD, n (%)	5 (10.6%)	44 (33.8%)	0.002
CKD, n (%)	2 (4.3%)	30 (23.1%)	0.003
Hyperlipidemia, n (%)	0 (0%)	114 (87.7%)	<0.001
Hypertension, n (%)	0 (0%)	81 (62.3%)	<0.001
T2DM, n (%)	0 (0%)	32 (24.6%)	<0.001
HDL, Mean (SD)	70.2 (22)	60.2 (21.7)	0.036
Total Cholesterol, Mean (SD)	160.1 (38)	174.2 (50)	0.130
Triglyceride, Mean (SD)	95.9 (60)	165.4 (190)	0.040
Glucose, Mean (SD)	98.3 (16.4)	106.9 (21)	0.018
AST, Mean (SD)	32.3 (16.8)	36.7 (28)	0.334
ALT, Mean (SD)	33.5 (22)	36.5 (36.2)	0.611

2613 | SEMAGLUTIDE USE AMONG INDIVIDUALS DIAGNOSED WITH METABOLIC-DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE IN A MEDICARE ADVANTAGE POPULATION.

Francis Lobo[1] Rich Sheer[2] Brandon Suehs[2] Nipun Atreja[1] Scott Farris[1], [1]Madrigal Pharmaceuticals, Inc., [2]Humana Healthcare Research, Inc.

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a condition that is associated with fat build up in the liver. Risk factors for MASLD include obesity and type 2 diabetes. Semaglutide is a glucagon-like peptide-1 receptor agonist medication approved for the treatment of diabetes and weight loss and has been studied as a treatment for MASLD that has progressed to steatohepatitis (metabolic dysfunction-associated steatohepatitis; MASH). In this study, we describe patient characteristics and real-world treatment patterns among patients with MASLD or MASH receiving treatment with semaglutide. **Methods:** Individuals ≥ 18 years with a diagnosis of MASLD or MASH and initiated on semaglutide SC weekly (sema SC) between July 1, 2018 and June 30, 2023 were identified from the Humana Research Database. All Individuals were enrolled in a Medicare Advantage (MA) plan and the index date was the first dispensing of sema SC. Twelve months pre-index and 72 weeks post-index enrollment was required. Patients with other causes of liver disease or advanced liver disease were excluded. Patient demographics, baseline clinical characteristics, and sema SC treatment patterns were summarized. Treatment discontinuation was defined as gap in therapy of ≥ 45 days (sensitivity analyses conducted using 60- and 90-day gap threshold). **Results:** A total of 8,432 individuals with MASLD or MASH initiating sema SC were identified. Mean (SD) age in this MA

population was 64.8 (9.6) years, with 39.5% being under the age of 65, 68.0% were female, and 77.1% classified as white race. Diagnoses of diabetes (87.6%), hyperlipidemia (84.0%), and obesity (73.1%) were common. Discontinuation rate during 72 weeks of follow-up was 77.5% (range including sensitivity analyses from 66.8%-77.5%), and mean time to discontinuation was 139.4 (±107.3) days. Among N = 6,538 individuals that discontinued treatment, 42.7% reinitiated sema SC with mean (SD) days to reinitiation 127.4 (90.5). Among individuals with both baseline and follow-up observations, HbA1c reduced from 7.8% to 7.0%, and only 24.8% had a reduction in BMI classification observed during follow-up. **Conclusion:** Semaglutide treatment discontinuation rates were high among individuals with metabolic conditions and MASLD enrolled in MA plans. Given this observation, future research should be directed at assessing the relationship between treatment persistence and outcomes in patients receiving treatment for hepatic disease.

TABLE 1. Semaglutide Discontinuation Rates Among Individuals with Diagnosis of MASH/MAFLD.

	Patients with MASH/MAFLD N=11,432					
Discontinuation Gap Threshold	45-day Gap		60-day Gap		90-day Gap	
Discontinued semaglutide, n %	6,538	77.5%	6,169	73.2%	5,634	66.8%
Time to discontinuation, mean SD	139.4	107.3	141.2	105.4	141.1	100.8
Time to discontinuation, med IQR	102	56 - 190	108	56 - 196	111	59 - 200
Restarted semaglutide after d/c, n %	2,794	42.7%	2,274	36.90%	1,608	28.5%
Time to restart of semaglutide, mean SD	127.4	90.5	149.4	90.2	185.1	86.7
Time to restart of semaglutide, med IQR	91	61 - 166	117	79 - 196	157	115 - 236

2614 | DEMOGRAPHIC AND METABOLIC PREDICTORS OF MASLD PROGRESSION IN SAUDI ARABIA: A RETROSPECTIVE CROSS-SECTIONAL ANALYSIS

Amani Alsadoon[1] Khalid Alswat[2] Mohammed Kaouache[3] Wadi Alonazi[4], [1]Liver Disease Research Center, Collage of Medicine, King Saud University, Riyadh, Saudi Arabia, [2]Liver Disease Research Centre, College of Medicine, King Saud University, Riyadh, Saudi Arabia, [3]Department of Mathematics and General Sciences, Prince Sultan University, Riyadh, Saudi Arabia, [4]Health Administration Department, College of Business Administration, King Saud University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a significant public health concern in Saudi Arabia and globally. However, data on population-specific risk factors for progression to advanced disease stages, namely metabolic dysfunction-associated steatohepatitis (MASH) and cirrhosis, remain underexplored in Middle Eastern populations. Aim:
To identify the demographic and metabolic predictors associated with MASLD severity, specifically MASH and cirrhosis, in a Saudi clinical sample. **Methods:** This retrospective cross-sectional study analyzed anonymized data from 780 adult patients diagnosed with MASLD at the Liver Disease Research Center, King Saud University. MASH and cirrhosis were diagnosed based on Fibroscan stiffness values (≥7.9 kPa and ≥13.0 kPa, respectively) and elevated liver enzymes. Multivariable logistic regression was performed to identify independent predictors, including age, sex, body mass index (BMI), type 2 diabetes mellitus (DM), triglycerides (TG), high-density lipoprotein (HDL) cholesterol, and hypertension. Discriminative ability was evaluated using receiver operating characteristic (ROC) curves. **Results:** Among 780 MASLD patients, 6.5% had cirrhosis and 5.8% met criteria for MASH based on liver stiffness and enzyme thresholds. Multivariable logistic regression identified male sex as a consistent and robust predictor for both outcomes. Male patients had a 2.8-fold higher odds of cirrhosis (OR = 2.82; 95% CI: 1.36–5.59; $p = 0.003$) and were 2.4 times more likely to have MASH (OR = 2.38; 95% CI: 1.24–4.53; $p = 0.009$) compared to females. Age was significantly associated with MASH progression (OR = 1.04 per year; 95% CI: 1.01–1.08; $p = 0.012$), but not with cirrhosis after adjusting for metabolic confounders. Paradoxically, type 2 diabetes mellitus was inversely associated with cirrhosis risk (OR = 0.31; 95% CI: 0.16–0.65; $p = 0.002$), suggesting earlier diagnosis or referral bias in diabetic patients. Traditional risk indicators such as BMI, triglycerides, HDL cholesterol, and hypertension were not statistically significant in predicting either outcome. Model performance demonstrated moderate to strong discriminatory power, with an area under the ROC curve (AUC) of 0.77 for cirrhosis and 0.69 for MASH, supporting the validity of the predictive models. **Conclusion:** Age and sex are key demographic predictors of MASLD severity in this Saudi clinical population. The unexplained inverse relationship of diabetes with cirrhosis may suggest some early clinical diagnosis or selection bias. These findings underscore the need for demographic-specific screening strategies, which align with the goals of Vision 2030 for Saudi Arabia regarding the prevention of non-communicable diseases (NCDs) and the promotion of liver health.

2615 | THE USEFULNESS OF NON-INVASIVE SCORING SYSTEMS FOR HEPATOCARCINOGENESIS, EXTRAHEPATIC MALIGNANCIES AND CEREBROCARDIOVASCULAR DISEASE IN MASLD PATIENTS

Takashi Nishimura[1] Yukihisa Yuri[1] Tomoyuki Takashima[1] Nobuhiro Aizawa[1] Naoto Ikeda[1] Hiroko Iijima[1] Hirayuki Enomoto[1], [1]Hyogo Medical University

Background: In MASLD patients, to estimate the risk of hepatocarcinogenesis, extrahepatic malignancies and cerebrocardiovascular events is crucial. The aim of this study is to clarify the usefulness of non-invasive scoring systems including FAST score, Agile 3+ and Agile 4 for hepatocarcinogenesis, extrahepatic malignancies, and cerebrocardiovascular disease in MASLD patiens. **Methods:** We retrospectively analyzed 922 MASLD patients (female/male: 446/476; median age: 57 years [IQR: 46–68]) who underwent vibration controlled transient elastography (VCTE) and controlled attenuation parameter (CAP) between October 2014 and March 2024. Inclusion criterias were as follows. 1) no history of HCC 2) followed more than at least 180 days. VCTE/CAP measurements were expressed as the median of 10 valid measurements. FAST score, Agile 3+, and Agile 4 was investigated and each cutoff value was adopted from previously manuscript. **Results:** HCC developed in 12 of 922 patients (1.30%), with cumulative incidence rates of 0.33%, 1.00%, and 1.25% at 1, 3, and 5 years, respectively. The predictive performance of each non-invasive scoring system for HCC was as follows:

- FAST score (cutoff 0.67): HR 4.821 (95% CI: 1.449–16.04, $p = 0.010$), C-index 0.587
- Agile 3+ (cutoff 0.679): HR 8.366 (95% CI: 1.829–38.25, $p = 0.006$), C-index 0.689
- Agile 4: (cutoff 0.251): HR 8.623 (95% CI: 1.887–39.41, $p = 0.005$),C-index 0.695 (cutoff 0.565): HR 9.277 (95% CI: 2.785–30.90, $p < 0.001$), C-index 0.680

No MASLD patients with less than each cutoff value for Agile 3+ in 0.679 and Agile 4 in 0.251 or 0.565 had HCC development at more than 3 years later from baseline. In contrast, extrahepatic malignancies occurred in 30 patients (3.25%) and cerebrocardiovascular disease in 11 patients (1.19%), but none of the non-invasive scoring systems demonstrated sufficient discriminatory ability for these outcomes. **Conclusion:** Non-invasive scoring systems were useful markers for the prediction of HCC development in MASLD patients. Follow-up strategies for MASLD patients using these non-invasive scoring systems should be needed. On the other hands, the developments of extrahepatic malignancies and cardiovascular disease should be investigated furthermore.

2616 | STEATOTIC LIVER DISEASE: A KEY UPSTREAM RISK FACTOR IN THE EMERGENCE OF METABOLIC SYNDROME-RELATED DISORDER

Yoshihiro Kamada[1] Hitoshi Nishizawa[1] Makoto Fujii[1] Shiro Fukuda[1] Iichiro Shimomura[1] Eiji Miyoshi[1], [1]Graduate School of Medicine, The University of Osaka

Background: Steatotic liver disease (SLD) is the most common chronic liver disease, strongly linked to obesity and metabolic risk factors. SLD is thought to be one of the metabolic syndrome (MetS), and often coexists with conditions like type 2 diabetes (T2D), hypertension (HT), and dyslipidemia (DL), and may accelerate disease progression. While SLD is considered a hepatic manifestation of MetS, its role as a risk factor for the development of individual MetS-related diseases is not fully understood. This study examines whether SLD is an upstream risk factor for the development of MetS-related diseases using longitudinal health checkup data. **Methods:** A total of 2,167 individuals who underwent a health examination at a health check-up center from 2009–2011 (baseline) were initially recruited into the study, and 806 of these subjects received a follow-up health examination after 7 years (follow-up after 7 years. In this study, the subjects were the same individuals (n = 714 (521 men, 193 women)) who underwent health checkups and abdominal ultrasound examinations one year and seven years later. All data obtained during a health checkup: Age, sex, physical findings, blood pressure, and blood data collected during health checkups, interview data (medication, lifestyle etc.). Logistic regression analysis was used to estimate odds ratios and quantify the impact of steatotic liver on the development of metabolic syndrome-related diseases. **Results:** At baseline, 60.9% were diagnosed with SLD, and 59.1% at follow-up. SLD was more common in males and those with higher BMI, as well as elevated levels of liver enzymes, triglycerides, LDL cholesterol, uric acid, and fasting blood glucose, while HDL cholesterol was lower in SLD subjects. The SLD group had higher rates of obesity, T2D, HT, and DL both at baseline and after seven

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

years. Logistic regression analyses revealed that baseline SLD was an independent risk factor for developing T2D, HT, and DL, while obesity was not. Conversely, obesity and DL at baseline independently predicted new SLD cases after seven years, but T2D and HT did not. Notably, improvement in SLD status was linked to a reduced risk of developing metabolic syndrome-related diseases, suggesting that targeting SLD may help prevent these conditions. **Conclusion:** This study revealed that SLD is an important upstream risk factor for the development of MetS-related diseases. The findings of this study highlight the strong association between SLD and metabolic disorders and highlight the importance of early detection and intervention of SLD.

2617 | RAMADAN FASTING ENHANCES HEPATIC AND CARDIOMETABOLIC PROFILES IN MASLD: A PROSPECTIVE REAL-WORLD STUDY

Khalid Alswat[1] Abdullah Alansare[2] Maha Alhussain[3] Salwa Asswini[3] Mohamed Elbadry[4] Samy Zaky[5] Moshira Mohamed[6] Mahmoud Hagag[7] Mona Kaddah[8] Mohammed Medhat[9] Nariman Zaghloul[9] Mohamed Abdel-Samiee[10] Eman Abdelsameea[10] Essam Zayed[10] Nermeen Abdeen[11] Faisal Sanai[12] Mohamed El-Kassas[13], *[1]Liver Disease Research Center, College of Medicine, King Saud University, Riyadh, Saudi Arabia, [2]The Department of Exercise Physiology, College of Sports Science and Physical Activity, [3]Department of Food Sciences and Nutrition, College of Food and Agricultural Sciences, KSU, [4]Endemic Medicine department, Helwan University, Cairo, Egypt, [5]Professor emeritus of Hepatogastroenterology and infectious diseases Al-Azhar University, [6]Lecturer of Hepatogastroenterology and Infectious diseases, [7]Gastroenterologist and hepatologist, Ministry of health, Cairo Egypt, [8]Lectured of Endemic Medicine and hepatogastroenterology, [9]Tropical medicine and gastroenterology department, Assiut University, Assiut, Egypt, [10]Hepatology and gastroenterology department, National Liver Institute, Menoufia University, Egypt, [11]Tropical Medicine, Alexandria University, Egypt, [12]Gastroenterology Section, Department of Medicine, King Abdulaziz Medical City, KAIMRC, Jeddah, KSA, [13]Endemic Medicine Department, Faculty of Medicine, Helwan University, Cairo, Egypt*

Background: Lifestyle modification is central to managing metabolic dysfunction-associated steatotic liver disease (MASLD). Ramadan, a lunar month observed by most Muslims through dry, diurnal fasting, represents a natural model of time-restricted eating. However, the hepatic and metabolic impacts of Ramadan diurnal intermittent fasting (RDIF) in MASLD remain understudied. Objective: To evaluate the effects of RDIF on liver health and cardiometabolic parameters among MASLD patients, with additional assessment of dietary and physical activity changes. **Methods:** This prospective observational study enrolled 79 adults with MASLD (median age: 47 years; 58.2% male) who fasted for ≥ 21 consecutive days during Ramadan. Assessments were conducted within 7 days before and at the end of Ramadan, and included anthropometric measurements, liver biochemistry, transient elastography (liver stiffness and controlled attenuation parameter [CAP]), lipid and glycemic profiles, 24-hour dietary recall, and physical activity using the IPAQ-Short Form. Data were analyzed using multivariable regression and linear mixed-effects models, adjusting for demographic and clinical covariates. **Results:** Despite a 6% increase in caloric intake (+178 kcal/day, $p = 0.016$), RDIF was associated with significant reductions in AST (−11.5 U/L, $p = 0.001$), liver stiffness (−0.5 kPa, $p = 0.003$), LDL cholesterol (−6.8 mg/dL, $p = 0.002$), and total cholesterol (−12.8 mg/dL, $p = 0.016$). CAP declined non-significantly (−16 dB/m, $p = 0.086$). Fasting glucose rose modestly (+1.0 mmol/L, $p = 0.048$), while HbA1c remained stable ($p = 0.056$). Light-intensity physical activity increased substantially (+180 min/day, $p < 0.001$). Sedentary behavior duration, however, remained unchanged ($p = 0.573$). Higher Physical Activity and Sedentary Time (PAST index) correlated with lower ALT ($\beta = -3.56$, $p = 0.005$) and LDL ($\beta = -3.68$, $p = 0.012$). Carbohydrates increased (+2.2 g/day, $p < 0.001$), protein decreased (−2.1 g/day, $p = 0.007$), and fat declined (−12.6 g/day, $p = 0.19$). Changes in micronutrient intake (e.g., vitamin A, C, fiber) were observed but not significantly linked to hepatic outcomes. **Conclusion:** RDIF was associated with favorable hepatic and cardiometabolic changes in MASLD patients, independent of increased energy intake. These findings highlight RDIF as a potential lifestyle intervention warranting validation in larger, multiethnic cohorts.

2618 | CLINICAL CHARACTERISTICS AND OUTCOMES OF PATIENTS WITH PRESUMED MASLD WHO MEET METALD CRITERIA IN THE TARGET-NASH COHORT

Alfred Barritt IV[1] Ellen Green[1] Andrea Mospan[2] Breda Munoz[2] Heather Morris[2] Rohit Loomba[3] Vincent Wong[4] Brent Neuschwander-Tetri[5] Arun Sanyal[6], [1]University of North Carolina, [2]Target RWE, [3]University of California, San Diego, [4]The Chinese University of Hong Kong, [5]Saint Louis University, [6]Virginia Commonwealth University

Background: Many patients with hepatic steatosis are presumed to have metabolic dysfunction associated steatotic liver disease (MASLD) due to comorbid cardiovascular (CV) risk factors. However, alcohol use may not be accurately quantified by providers or fully disclosed by some patients. The characteristics and outcomes of patients with MASLD and increased alcohol intake (MetALD) are unknown. We sought to describe these patients in the TARGET-NASH cohort. **Methods:** Study participants were enrolled in the US TARGET NASH cohort which did not exclude moderate alcohol use from 2016 through 2024. Patients with MetALD were defined as those with an Alcohol Use Disorders Identification Test (AUDIT) score >7. Baseline demographic and clinical data were compared between the MetALD and MASLD groups. Hazard ratios were calculated for time to event analyses. Major adverse cardiovascular events (MACE), decompensation events, and cancer were the longitudinal outcomes of interest. **Results:** Overall, 4714 patients with ≥ 1 year follow-up were included in the analysis. The MetALD group had 124 (2.6%) patients with an AUDIT score >7. 4590 patients were included in the MASLD group. MetALD patients were younger (median 55 vs 59 years $p=0.05$), male (67% vs 39% $p<0.01$), and non-Hispanic white (82% vs 73%). Clinical characteristics and outcomes are reported in Table 1. A smaller proportion of MetALD patients had diabetes, obesity, and prevalent CV disease (all $p<0.05$). MetALD patients were more likely to be current tobacco and alcohol users ($p<0.01$). Five patients denied alcohol use yet had AUDIT scores >7. There were no differences in incident MACE between MetALD (4.8.%) and MASLD (6.9%) patients, however, MetALD patients experienced these events sooner than MASLD patients (median time to event 71 months vs 79 months, $p=0.02$). A smaller proportion of patients with MetALD had cirrhosis at index. The Hazard Ratios for decompensation events and incident cancers were not statistically significant when controlling for liver disease severity. **Conclusion:** Among patients presumed to have MASLD, 124 (2.6%) had AUDIT scores >7 and were reclassified at MetALD for this analysis. Despite younger age and fewer metabolic risk factors, MetALD patients suffered a similar number of incident MACE events on a faster timeframe compared with traditional MASLD patients. It is critical for providers to address alcohol use among patents with presumed MASLD to accurately risk stratify adverse events.

Table 1. Clinical and behavioral characteristics at enrollment and incident outcomes

Patient characteristic	MetALD (N=124)	MASLD (N=4590)	p-value

2619 | PATIENT EXPERIENCE OF COMPENSATED AND DECOMPENSATED LIVER CIRRHOSIS: A PATIENT INTERVIEW STUDY

Elin Gruffydd[1] Rebekah Hall[1] Ginny Shand[1] Villum Wittrup-Jensen[2] Preety Gautam[2] Andrew Lloyd[1] Jeff McIntyre[3] Norah Crossnohere[4], [1]Acaster Lloyd, [2]Boehringer Ingelheim International GmbH, [3]Global Liver Institute, [4]The Ohio State University College of Medicine

Background: Liver cirrhosis is a growing cause of morbidity and mortality in the United States (US). It is a progressive disease, categorized as compensated liver cirrhosis (CLC) (i.e., liver is scarred but functioning) or decompensated liver cirrhosis (DLC) (i.e., impaired liver function), with high burden on health-related quality of life (HRQL), particularly at the DLC stage. CLC has historically been considered a "silent" condition. The symptoms and impacts of CLC on patients' daily activities are not well understood. This study aimed to explore patient-reported symptoms and impacts of CLC and DLC using qualitative methods. **Methods:** Qualitative semi-structured interviews were conducted between February–April 2023 with US adults, with confirmed diagnosis of CLC or DLC who provided informed consent. Interviews covered symptoms and impacts of CLC/DLC, summarized using content analysis. Diagnosis, symptoms and HRQL impacts were explored using thematic analysis. **Results:** In total, 10 CLC and 10 DLC patients were interviewed (80% female, mean age 58 years, mean 2.3 years since diagnosis). Patients with CLC and DLC, respectively, described experiencing fatigue (n = 8; n = 10), bloating (n = 3; n = 10), cognitive problems (n = 6; n = 5), weight loss (n = 5; n = 8), appetite loss (n = 4; n = 5), and nausea (n = 1; n = 7). Patients attributed some symptoms directly to cirrhosis, but other problems (e.g., sleeping difficulties [n = 5; n = 8]), were sometimes attributed to anxiety, skin itch or pain. Nearly all patients experienced psychological impacts, most frequently anxiety relating to uncertainty about disease progression. Patients described how their symptoms affected day-to-day functioning. Daily activities (e.g., housework, work) required more effort and planning due to fatigue. Additionally, CLC patients in particular reported making lifestyle changes (e.g., diet, exercise, alcohol abstinence) to manage their condition. Some patients reported reduced time spent socializing and perceived stigma, whilst others reported some improvements in their relationships since their diagnosis. **Conclusion:** Patients described various impacts associated with CLC, as well as DLC, despite CLC being previously described as a silent condition. These findings show the complexity of liver cirrhosis, with symptoms often linked to both the disease and the psychological impacts it causes. Symptoms and impacts in CLC and DLC all influence patients' HRQL and

should be considered to fully understand the HRQL burden and inform treatment management.

2620 | LIVER FIBROSIS IS MORE PREVALENT IN MASLD PATIENTS WITH ACUTE MYOCARDIAL INFARCTION AND SIGNIFICANT CORONARY HEART DISEASE

Wouter Robaeys[1] Leen Heyens[1] Koen Ameloot[2] Jan Stassen[3] Matthias Dupont[2] Liesbeth Bruckers[4] Geert Robaeys[1] Mathieu Struyve[5] Joris Penders[6] Ger Koek[7] Sven Francque[8], [1]Hasselt University Faculty of Medicine and Life Sciences, Diepenbeek, Belgium, [2]Department of Cardiology, Ziekenhuis Oost Limburg, Genk, Belgium, [3]Department of Cardiology, Jessa Ziekenhuis, Hasselt, Belgium., [4]I-BioStat, Data Science Institute, Hasselt University, 3500 Hasselt, Belgium., [5]Department of Gastroenterology and Hepatology, Ziekenhuis Oost Limburg, Genk, Belgium., [6]Department of Laboratory Medicine, Ziekenhuis Oost Limburg, Genk, Belgium, [7]Maastricht University Medical Centre+ Internal Medicine, Maastricht, The Netherlands, [8]Department of Gastroenterology Hepatology, University Hospital Antwerp, Antwerp, Belgium

Background: The stage of Metabolic Dysfunction–Associated Steatotic Liver Disease (MASLD)-related liver fibrosis has previously been identified as a risk factor for cardiac mortality. The prevalence and characteristics of MASLD in people with an acute myocardial infarction (AMI) are not fully elucidated. Therefore, we compared the prevalence and the characteristics of liver steatosis and fibrosis in patients presenting with an AMI to those without. **Methods:** In this Belgian, multicentric, prospective, cohort study (n = 1,274; included from March 2018 till May 2024) patients who had significant coronary stenosis (>70%) on angiography at the occasion of an AMI (group A, n = 191) were compared to patients without an AMI (group B, n = 1083; recruited both in primary and secondary care, of whom 33% had type 2 diabetes). The occurrence of steatosis and fibrosis was assessed with Controlled Attenuation Parameter (CAP^{TM}), Liver Stiffness Measurement (LSM) (FibroScan®) and non-invasive tests (NITs) (hepatic steatosis index (HSI), fibrosis 4 (FIB4), NAFLD Fibrosis Score (NFS) and AST-to-platelet ratio index (APRI). **Results:** MASLD patients (CAP^{TM} >215 dB/m) in the two groups were compared after correction for age, gender, Body Mass Index (BMI) and presence of type 2 diabetes. Group A had a higher odds of metabolic syndrome, showed significantly less steatosis (both as a continuous variable, CAP^{TM} 282 ± 48 vs 299 ± 50 dB/m (p = 0.022), or as a dichotomous diagnosis of steatosis yes/no) and had more fibrosis measured with LSM and NITs. (Table) Fibrotic (LSM > 8 kPa) MASLD patients with AMI were on average 6 years older than MASLD patients without AMI (p < 0.001), more often male (85% vs. 56%; p < 0.001) and more frequently current smokers (41% vs. 15%; p < 0.001). They also had a lower prevalence of type 2 diabetes (24% vs. 60%; p < 0.001). Among AMI patients with liver fibrosis, a positive relationship was observed between the severity of fibrosis and the number of coronary arteries affected. Among patients with LSM values between 8–10 kPa, 79% had single-vessel disease; in those with LSM between 10–15 kPa 33% had single-vessel, 44% two-vessel and 22% three-vessel disease; in LSM ≥ 15 kPa 86% had three-vessel disease (Chi-square p = 0.003; Fisher's Exact p = 0.0005). Conversely, mean LSM values increased with the number of affected arteries (p = 0.0049). **Conclusion:** AMI MASLD patients were diagnosed with significantly lower steatosis and increased fibrosis compared to non-AMI MASLD patients. There was a positive relationship observed between the severity of fibrosis and the number of coronary arteries affected. Fibrotic MASLD AMI patients were older, more often male and current smokers. Larger population studies are warranted to distinguish those MASLD patients who are at a high risk of developing the extrahepatic CVD manifestations.

Table: Comparison of MASLD AMI patients versus MASLD control patients. The table presents the number of patients with indications for steatosis or fibrosis (n), the total number of patients (ntot), and their corresponding proportions (%). Formal comparisons of the MASLD AMI and MASLD control groups are made using a logistic regression model adjusted for age, gender, BMI, and type II diabetes. The adjusted odds ratios (OR) and p-values are derived from this logistic regression model, with no correction for multiple testing applied.

	AMI with CAP >215	Control with CAP >215		
	n/ntot (%)	n/ntot (%)	OR (95%CI)	p value
Steatosis				
HSI > 36	76/154 (49.35%)	692/859 (80.56%)	0.31 (0.18;0.56)	< 0.001
Fibrosis				
LSM > 8.0 kPa	29/131 (22.14%)	116/655 (17.71%)	1.74 (1.02;2.95)	0.042
FIB-4 > 1.3	107/154 (69.48%)	289/833 (34.69%)	2.37 (1.55;3.66)	<0.001
FIB-4 > 3.25	57/154 (37.01%)	153/833 (18.37%)	2.13 (1.42;3.19)	<0.001
NFS > 0.676	21/116 (18.10%)	36/527 (6.83%)	4.38 (1.93;9.97)	<0.001
APRI > 0.5	36/154 (23.38%)	101/841 (12.01%)	2.91 (1.79;4.71)	<0.001
Metabolic syndrome	79/149 (53.02%)	442/871 (50.75%)	1.63 (1.08;2.44)	0.020

2621 | HEALTH-RELATED QUALITY OF LIFE (HRQOL) IN ADULTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD): FINDINGS FROM THE GENESIS STUDY IN SAUDI ARABIA

Saleh Alqahtani[1] Faisal Sanai[2] Haifa Alotaibi[3] Shadan AlMuhaidib[1] Faisal Abaalkhail[1] Saleh Alessy[1] Waleed Alomaim[1] Heba Alharith[1] Basmah Khoja[1] Daliah AbdulHafiz[4] Abdulmohsen Alshammari[1] Abdullah Alharbi[5] Albandari Almotairi[5] Fahad Alkhayal[5] Ahmad Almalky[5] Badr Almutairi[5] Layan Alsubki[1] Alwaleed Almojel[6] Abdulraheem Bayameen[4] Khalid Bzeizi[1] Dieter Broering[1] Saad Alghamdi[1] Bandar Aljudaibi[1] Waleed Alhazzani[3], [1]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [2]King Abdulaziz Medical City, KAIMRC, Jeddah, Saudi Arabia, [3]Ministry of Defense Health Services, Riyadh, Saudi Arabia, [4]King Fahad Armed Forces Hospital, Jeddah, Saudi Arabia, [5]Prince Sultan Military Medical City, Riyadh, Saudi Arabia, [6]King Fahad Military Medical Complex, Dhahran, Saudi Arabia

Background: MASLD is a leading cause of chronic liver disease worldwide. While research interest in MASLD is increasing in Saudi Arabia, representative data on its population-level burden and impact on HRQoL remain limited. The GENESIS study, a prospective, population-based cohort, was established to address this gap by generating the first comprehensive national data on MASLD prevalence and outcomes. In this analysis, we aimed to evaluate and compare HRQoL in adults with and without MASLD using the RAND 36-Item Health Survey (SF-36) to understand MASLD's broader impact. **Methods:** Adults aged ≥ 18 years were recruited between March 2024 and April 2025 from three populous regions in Saudi Arabia using a multistage stratified sampling approach. MASLD was defined by transient elastography (FibroScan®) with a controlled attenuation parameter (CAP) ≥ 268 dB/m plus ≥ 1 cardiometabolic risk factor. HRQoL was assessed using the SF-36, which comprises eight domains: physical functioning, role limitations due to physical health (role-physical), role limitations due to emotional problems (role-emotional), energy/fatigue, emotional well-being, social functioning, bodily pain, and general health. Composite scores for physical component summary (PCS), mental component summary (MCS), and overall SF-36 were calculated. Mean scores were compared between MASLD and non-MASLD groups using t-tests. **Results:** Of 2,073 participants, 829 (40.0%) had MASLD. Participants with MASLD reported significantly lower mean scores in physical functioning (79.8 ± 25.2 vs. 86.5 ± 21.0, $p < 0.001$), role-physical (83.4 ± 23.0 vs. 87.0 ± 21.0, $p < 0.001$), bodily pain (82.1 ± 19.0 vs. 85.4 ± 17.6, $p < 0.001$), and general health (70.0 ± 19.2 vs. 72.1 ± 18.0, $p = 0.01$) compared to those without MASLD. Emotional well-being scores were slightly higher (81.3 ± 17.9 vs. 79.1 ± 19.1, $p = 0.008$) in the MASLD group. No significant differences were seen in role-emotional, energy/fatigue, or social functioning. PCS scores were lower in the MASLD group (78.8 ± 17.3 vs. 82.7 ± 15.0, $p < 0.001$), while MCS scores were similar (81.1 ± 15.3 vs. 81.0 ± 16.4, $p = 0.89$). Overall, the SF-36 score was modestly lower in those with MASLD (80.0 ± 14.6 vs. 81.9 ± 14.1, $p = 0.003$) (Table 1). **Conclusion:** In this nationally representative cohort, adults with MASLD reported lower HRQoL, particularly in physical and general health domains. These findings underscore the impact of MASLD on HRQoL and highlight the need for integrated, patient-centered care, aligning with Saudi Vision 2030's goals to improve population health.

Table 1: SF-36 health-related quality of life scores by MASLD status in the GENESIS study cohort.

Variable	Full cohort (n = 2073)	MASLD (n = 829)	No MASLD (n = 1244)	P-value
Physical functioning	83.8 ± 23.0	79.8 ± 25.2	86.5 ± 21.0	<0.001
Role-physical	85.5 ± 21.9	83.4 ± 23.0	87.0 ± 21.0	<0.001
Role-emotional	84.9 ± 22.6	84.5 ± 22.7	85.2 ± 22.5	0.51
Vitality energy/fatigue	69.9 ± 21.4	69.2 ± 20.4	70.4 ± 22.0	0.20
Mental health emotional well-being	80.0 ± 18.7	81.3 ± 17.9	79.1 ± 19.1	0.008
Social functioning	89.5 ± 18.5	89.6 ± 18.1	89.4 ± 18.8	0.90
Bodily pain	84.1 ± 18.3	82.1 ± 19.0	85.4 ± 17.6	<0.001
General health	71.3 ± 18.5	70.0 ± 19.2	72.1 ± 18.0	0.01
Physical component summary (PCS)	81.2 ± 16.1	78.8 ± 17.3	82.7 ± 15.0	<0.001
Mental component summary (MCS)	81.1 ± 15.9	81.1 ± 15.3	81.0 ± 16.4	0.89
Quality of life SF-36 overall score	81.1 ± 14.3	80.0 ± 14.6	81.9 ± 14.1	0.003

Note: Values are reported as mean ± standard deviation. MASLD was defined as CAP ≥268 dB/m plus ≥1 metabolic risk factor. Scores range from 0 (worst) to 100 (best). P-values are from independent t-tests comparing MASLD vs. non-MASLD participants.

2622 | EVALUATING THE IMPACT OF CARDIOMETABOLIC RISK FACTORS ON NON-INVASIVE TESTING AND HISTOLOGICAL FINDINGS IN MASH: A TERTIARY CENTER EXPERIENCE IN NORTH TEXAS

Jeevin Sandhu[1] Muskaan Sandhu[2] Carlos Huerta[1] Adil Khetani[1] Shaheen Mehrara[1] Affan Ahmed[1] Parker Woods[1] Corinne Caissie[3] Matthew Manoj[4] Marquise Soto[5] Simran Joshi[6] Marquise Soto[1] Parvez Mantry[1], [1]Methodist Dallas Medical Center, [2]University of California, San Francisco, [3]Bridgeport Hospital- Yale New Haven Health, [4]Beth Israel Deaconess Medical Center, [5]Massachusetts General Hospital, [6]Bridgeport Hospital- Yale New Haven Health

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is a leading cause of chronic liver disease and liver transplantation in the U.S. Accurate non-invasive evaluation is critical for risk stratification and monitoring. While non-invasive tests (NITs) like FIB-4, liver stiffness measurement (LSM), and controlled attenuation parameter (CAP) from vibration-controlled transient elastography (VCTE) are widely used to assess fibrosis and steatosis, liver biopsy remains the diagnostic gold standard. Real-world data comparing NITs and biopsy findings across varying cardiometabolic (CM) risk burdens are limited. This study evaluates correlations between NITs, liver biopsy, and CM risk factors in patients at a tertiary liver and transplant center in North Texas and the Dallas-Fort Worth Metropolitan Area. **Methods:** We performed a retrospective analysis of 450 ICD confirmed MASH patients who underwent VCTE, Liver Biopsy and various NITs at our tertiary liver center. Demographic and clinical data, including the presence of CM risk factors (type 2 diabetes, obesity, hypertension, dyslipidemia, and coronary artery disease), were collected. Non-invasive tests (FIB-4, LSM, CAP) and Liver Biopsy were analyzed and compared across subgroups defined by the number of CM risk factors present. Patients were grouped with either having less than or greater than 3 CM factors. Continuous outcomes (CAP, LSM, and Fib-4 Scores) were compared using Welch's t-Tests. The categorical outcome (Brunt Scoring System) was evaluated through a Pearson-Chi Square test. **Results:** Patients with 3+ CM risk factors had a significantly higher FIB-4 score (Mean ± SD: 2.7 ± 3.6; P-value: 0.030) than those with less than 3 CM risk factors (Mean ± SD: 2.0 ± 3.1). The Chi Square test also revealed a significant association between the Brunt Scoring system for severity of NASH with the amount of CM risk factors present (P-value: 0.006). Both outcomes for the Fibroscan, liver stiffness (kPa) and liver steatosis (CAP scores), did not differ between patients with 3+ CM risk factors and those with less than 3 CM risk factors. **Conclusion:** Patients with ≥3 cardiometabolic risk factors had significantly higher FIB-4 scores and histologic findings were significantly associated with the presence of CM risk factors, highlighting the impact of metabolic burden on MASH severity. In contrast, LSM and CAP values did not significantly differ between groups, suggesting limitations of VCTE parameters in this setting, potentially via user variability and BMI limitations. These findings support the utility of FIB-4 and biopsy in risk stratification and underscore the need for improved non-invasive tools in high-risk, tertiary care populations.

	<3 Comorbidities	3+ Comorbidities	P-Val

2623 | SEX-BASED DISPARITIES IN ADVANCED LIVER DISEASE OUTCOMES AMONG METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) PATIENTS: A 5-YEAR REAL-WORLD MULTICENTER ANALYSIS

Rishi Chowdhary[1] Kirti Arora[2] Dhruvi Shah[3] Rohit Goyal[4] Simran Joshi[5] Prachi Dawar[6], [1]Metrohealth Medical Center, [2]Cleveland Clinic Akron General, Akron, Ohio, [3]University of Maryland Medical Center, Midtown, [4]Louisiana State University, [5]Yale New Haven Health/Yale University School of Medicine, [6]University College Of Medical Sciences, India

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver disease and its complications. Hormonal, immunologic, and metabolic differences may underlie sex-based variation in disease progression. This study aimed to evaluate disparities in liver-related outcomes between male and female MASLD patients over a 5-year period using a large, real-world EHR dataset. **Methods:** We performed a retrospective cohort study using TriNetX, a federated EHR network encompassing 69 U.S. healthcare organizations. Adults ($\geq$18 years) diagnosed with MASLD or NASH (ICD-10: K76.0, K75.81) were included, excluding those with alcohol-related, viral, or other chronic liver diseases. Male and female cohorts (n = 604,256 each) were matched 1:1 using propensity scores for age, race/ethnicity, BMI, diabetes, hypertension, hyperlipidemia, atrial fibrillation, and nicotine use. Outcomes assessed over 5 years included cirrhosis, portal hypertension, hepatic failure, hepatocellular carcinoma (HCC), and esophageal varices. Odds ratios (ORs) with 95% confidence intervals (CIs) and Kaplan-Meier survival analyses were used for comparisons. **Results:** Males demonstrated significantly increased odds of developing all adverse liver outcomes. Compared to females, males had 9.6% higher odds of cirrhosis (OR 1.096; 95% CI: 1.046–1.147; $p < 0.001$), 24.8% higher odds of portal hypertension (OR 1.248; 95% CI: 1.151–1.352; $p < 0.001$), 12.3% higher odds of hepatic failure (OR 1.123; 95% CI: 1.027–1.229; $p = 0.012$), 75.9% higher odds of HCC (OR 1.759; 95% CI: 1.526–2.028; $p < 0.001$), and 32.7% higher odds of esophageal varices (OR 1.327; 95% CI: 1.173–1.502; $p < 0.001$). Kaplan-Meier survival curves showed significantly lower event-free survival among males for all outcomes (*log-rank* $p < 0.001$), although median survival was not reached within 5 years.
Among MASLD patients with BMI <30, male sex remained associated with higher odds of portal hypertension (OR 1.295), HCC (OR 1.473), and esophageal varices (OR 1.226), while differences in cirrhosis and hepatic failure were not statistically significant. In the BMI ≥ 30 group, males had increased odds for all outcomes, including cirrhosis (OR 1.115), HCC (OR 1.824), and portal hypertension (OR 1.346), with statistical significance across the board. **Conclusion:** In this large multicenter matched cohort of MASLD patients, males were at significantly higher risk of developing cirrhosis, portal hypertension, hepatic failure, HCC, and esophageal varices within 5 years. These findings highlight the need for sex-specific surveillance and management strategies in MASLD and warrant further investigation into the biological mechanisms underlying these disparities.

2624 | RISK FACTORS FOR SEVERE HEPATIC STEATOSIS (SS) AND RENAL RISK: LESSONS FROM NATIONAL HEALTH AND NUTRITION EXAMINATION SURVEY 2017-2020 (NHANES)

Juliana Pava De Los Rios[1] Franklyn Vega Batista[1] Maria Jose Lorenzo Capps[1] Song Ang[1] Riddhi Machchhar[2] Eunseuk Lee[1] Jose Iglesias[1], [1]Rutgers Health/Community Medical Center, [2]Hackensack Meridian Ocean University Medical Center

Background: In Western developed nations the most common cause of severe hepatic steatosis is non-alcoholic fatty liver disease (NAFLD). This can lead to progressive liver inflammation and cirrhosis. NAFLD is associated with obesity, metabolic syndrome, insulin resistance, and diabetes. These clinical conditions are also linked to chronic kidney disease (CKD) and inflammation. In the current study employing the NHANES 2017-database we sought to investigate if there is an association with severe hepatic steatosis, CKD, renal risk and systemic inflammation. **Methods:**

In order to determine which variables were associated with severe steatosis (SS) defined as a controlled attenuation parameter of >289 dB/m, we performed a univariate and multivariate complex samples analysis choosing variables that were clinically relevant variables and included them in a multivariate logistic regression model. **Results:** There was an inverse relationship between age and SS suggesting a protective role (OR = 0.955, p = 0.018). Both hemoglobin A1C and BMI emerged as major contributors to SS (OR = 1.428, p = 0.028, OR = 1.204, p < 0.001). Additionally, the neutrophil-to-lymphocyte ratio (nlratio) is associated with increased odds of SS (OR = 1.591, p = 0.002), indicating a possible inflammatory component in the severity of steatosis. Neither estimated GFR, the degree of albuminuria or renal risk were associated with SS. **Conclusion:** This study highlights the intricate relationship between obesity, insulin resistance, and inflammation in the pathogenesis of SS. The lack of association between parameters of renal dysfunction and SS suggest that the relationship is complex and nonlinear in nature. In comparison to the risks of renal dysfunction associated with the metabolic syndrome, it is possible that the liver maybe more sensitive to the detrimental effects of the metabolic syndrome.

2625 | REAL-WORLD PREVALENCE OF DIAGNOSED METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS AMONG MEDICARE BENEFICIARIES

Husam Albarmawi[1] Abdalla Aly[1] Anthony Hoovler[1] Caichen Zhong[1] Anran Tan[2] Jamieson Vaccaro[2] Joanna Harton[2] Parvez Mantry[3], [1]Novo Nordisk Inc., [2]Genesis Research Group, [3]Methodist Dallas Medical Center

Background: The prevalence of metabolic dysfunction-associated steatohepatitis (MASH) among older adults is under documented. Accurate assessment of MASH prevalence is crucial for understanding disease burden and population health, and guiding screening, diagnosis, and treatment. This study sought to estimate prevalence of diagnosed MASH in the Medicare Fee-for-Service (FFS) population. **Methods:** This observational study used 100% Medicare FFS data to assess the prevalence of diagnosed MASH among beneficiaries ≥ 65 years of age from Jan. 1, 2016 to Dec. 31, 2022. The MASH cohort included patients with ≥ 1 ICD-10-CM diagnosis code for MASH (K75.81). Annual prevalence of MASH was estimated as the number of patients with continuous enrollment in Medicare FFS for the entire year (or until death) who were diagnosed with MASH in that year, or any prior year in the study period, out of the number of patients with continuous enrollment for that entire year (or until death). To account for changes in age distribution over time, age-standardized prevalences were estimated using direct standardization to the 2022 US Census Bureau age distribution. MASH annual prevalence was stratified by age, sex, race, region and state of domicile. **Results:** From 2016 through 2022, between 22.2 and 23.5 million beneficiaries were assessed per year. Annual prevalence of MASH was: 0.22% (n = 50,997) in 2016, 0.35% in 2017, 0.47% in 2018, 0.59% in 2019, 0.69% in 2020, 0.80% in 2021, and 0.91% (n = 202,455) in 2022. Age-standardized estimates were similar. Across time, lower prevalence was observed in those who were older, male, Black, and from the West. In 2022, the highest prevalence was observed in those aged 70-74 (1.16%) and lowest in those aged 85+ (0.36%). Prevalence was greater in females vs males (2022: 0.99% vs 0.81%). By race/ethnicity, prevalence in 2022 was lowest for Black patients (0.53%) and highest for Native American patients (1.67%). By region and state, 2022 prevalence was lowest for the West (0.77%) and Montana (0.53%), respectively, and highest for the South (1.04%) and Mississippi (1.31%), respectively. **Conclusion:** Prevalence of diagnosed MASH increased from 2016 to 2022 with more than 200,000 patients living with MASH in the Medicare FFS population in 2022. However, the reported prevalence of MASH is likely to be underestimated due to underdiagnosis and undercoding in clinical practice.

2626 | EROSIVE ESOPHAGITIS AND MASLD: A NATIONWIDE CROSS-SECTIONAL ANALYSIS OF HOSPITALIZED ADULTS IN THE UNITED STATES

Hima Varsha Voruganti[1] Rohit Sekandlapuram[2] Yeongjin Kim[3] Rahul Karna[4] Manasa Ginjupalli[2], [1]North Alabama Medial Center, [2]The Brooklyn Hospital Center, [3]North Albama Medical Center, [4]University of Minnesota Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) and erosive esophagitis (EE) are common conditions linked to obesity and metabolic syndrome. While both share overlapping risk factors, the population-level association between MASLD and EE remains unclear. Understanding this relationship is essential to guide screening and management strategies in at-risk populations. **Methods:** We conducted a cross-sectional analysis of the National Inpatient Sample (2018–2020) to examine the association between MASLD and EE. Adults aged ≥18 years were included. Survey-weighted logistic regression was used, adjusting for demographics, hospital characteristics, Charlson Comorbidity Index, diabetes, hypertension (HTN), hyperlipidemia (HLD), obesity, smoking, alcohol use, and obstructive sleep apnea. **Results:** The survey estimated approximately 953,705 hospitalizations with EE and 1,864,820 cases of MASLD between 2018 and 2020. Among hospitalizations with MASLD, mean age did not differ significantly between those with and without EE (53.5 vs. 53.8 years).Females comprised 51% of MASLD patients with EE vs. 52% without ($p = 0.055$), and White race was more prevalent in the EE group (72% vs. 66%, $p < 0.001$). Multivariable survey-weighted logistic regression showed that EE was independently associated with MASLD (OR 2.63, 95% CI 2.55–2.70). Alcohol use (OR 3.71), HTN (OR 2.25), and obesity (OR 2.08) also showed strong associations. MASLD was strongly associated with higher odds of EE (OR 2.39, 95% CI 2.32–2.46; $p < 0.001$). Other independent predictors included HTN (OR 1.30), HLD (OR 1.13), smoking (OR 1.07), and alcohol use (OR 2.06), all with $p < 0.001$. **Conclusion:** MASLD and EE are strongly associated at the population level, with each condition significantly increasing the odds of the other. Shared metabolic risk factors—including obesity, hypertension, and alcohol use—likely contribute to this bidirectional relationship. These findings highlight the need for integrated screening and management strategies targeting metabolic risk factors to prevent and mitigate both conditions.

2627 | MASLD: SCREENING FOR CARDIOVASCULAR DISEASE

Sindhu Chadalawada[1] Katherine Jones[2] Jeffrey Liu[2] Charizza Besmanos[2] Marina Roytman[2], [1]University of California San Francisco, [2]UCSF Fresno

Background: Metabolic associated steatotic liver disease (MASLD) or steatohepatitis (MASH) has been

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

associated with increased risk of cardiovascular disease (CVD). At present, there are no cardiovascular screening guidelines for patients with MASLD. **Methods:** A single center retrospective cohort study in Fresno, California aimed to assess CVD risk in patients ages > 18 years with biopsy or transient elastography proven MASLD or MASH between January 2015 - May 2025. Those with preexisting CVD at the time of their initial hepatology encounter were excluded from the study. The American Heart Association's Predicting Risk of Cardiovascular Disease Events (PREVENT) score was used to determine the 10-year risks of CVD, atherosclerotic cardiovascular disease (ASCVD), and heart failure (HF) for the entire cohort. Thirty-year risk estimates were calculated for patients ages 30-59 years. Secondary outcomes, including progression of liver disease, liver transplantation, and major cardiovascular events were also studied. Descriptive statistics were reported for continuous variables including mean, median interquartile range (IQR), and standard deviation. **Results:** In total, 290 cases were reviewed, of which 96 patients met inclusion criteria. Of these, 74% were female, 46% non-Hispanic whites, 90% English speaking, and 80% married. Mean age was 53 years (median 56 [IQR 46-64] SD 12), body mass index (BMI) 32.5 kg/m2 (median 33 [IQR 28.4 - 37.3] SD 6.9), and HbA1c of 6% (median 5.8% [IQR 5.5-6.4] SD 1.1). Patients with advanced fibrosis (F3) had a 10-year CVD risk of 9%, ASCVD risk of 5.1%, and HF risk of 6.6%. PREVENT 30-year estimates for individuals ages 30-59 demonstrated a mean CVD risk of 16.6% (median 18.3 [IQR 10.4-29.2] SD 12.8), ASCVD risk of 9.9% (median 10.2 [IQR 6.2-16.7] SD 7.9), and HF risk of 10.3% (median 11.2 [IQR 6.1-18] SD 10.3). When examined geographically by zip code, elevated CVD risk profiles correlated with lower socioeconomic strata, as identified by the United States Department of Agriculture (USDA). **Conclusion:** In this single center study, a clear trend of increased CVD, ASCVD, and HF risk is demonstrated with advancing fibrosis, particularly among younger and middle-aged adults. These high-risk profiles were concentrated in underserved regions defined by limited access to nutritious, unprocessed food, contributing to the development of obesity and its downstream effects. Therefore, noninvasive cardiovascular disease screening should be considered in MASLD patients 30 years and older in the presence of fibrosis.

2628 | EXPLORING THE LINK BETWEEN EOSINOPHILIC ESOPHAGITIS AND MASLD IN U.S. HOSPITALIZED ADULTS

Hima Varsha Voruganti[1] Rohit Sekandlapuram[2] Yeongjin Kim[3] Pratiksha Moliya[4] Rahul Karna[5], [1]North Alabama Medial Center, [2]Brooklyn Hospital Center, [3]North Alabama Medical Center, [4]University of Nebraska Medical Center, [5]University of Minnesota Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is strongly linked to components of metabolic syndrome, while eosinophilic esophagitis (EoE) has traditionally been viewed through an allergic or inflammatory lens. Although both conditions have individually seen rising prevalence, their potential intersection has not been thoroughly investigated. Using a large, nationally representative database, we sought to explore this potential association in hospitalized adults. **Methods:** We analyzed adult hospitalizations (≥ 18 years) from the National Inpatient Sample (2018–2020). MASLD and EoE were identified using ICD-10-CM diagnosis codes. A multivariable survey-weighted logistic regression was performed to evaluate the association between EoE and MASLD, adjusting for demographics, hospital characteristics, Charlson Comorbidity Index, obesity, obstructive sleep apnea (OSA), diabetes, hypertension (HTN), hyperlipidemia (HLD), asthma, Crohn's disease (CrD),

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

ulcerative colitis (UC), celiac disease (CD), smoking, and alcohol use. **Results:** Among 174,776,205 adult hospitalizations, an estimated 1,864,820 had MASLD and 31,550 had EoE. Among MASLD patients, those with EoE were younger (mean age 43.3 vs. 53.8 years) and had a similar sex distribution (female: 48.8% with EoE vs. 51.9% without; $p = 0.42$); however, racial distribution differed significantly ($p = 0.0498$), with a higher proportion of White individuals among those with EoE (77.9% vs. 65.8%). EoE was independently associated with higher odds of MASLD (OR 2.61; 95% CI: 2.21–3.08; $p < 0.001$). Other significant predictors included obesity (OR 2.07), OSA (OR 1.58), and alcohol use (OR 3.78). MASLD was significantly associated with increased odds of EoE (OR 2.45; 95% CI: 2.07–2.90; $p < 0.001$). Other conditions with strong positive associations included asthma (OR 2.91), UC (OR 2.78), CrD (OR 2.33), and CD (OR 5.68). **Conclusion:** Our study demonstrates a significant association between MASLD and EoE in hospitalized adults. These findings highlight the importance of considering comorbid conditions in patients with either diagnosis. Further investigation is needed to better understand the clinical relevance of this relationship.

2629 | PREVALENCE AND CHARACTERISTICS OF STEATOTIC LIVER DISEASE ACCORDING TO THE NEW NOMENCLATURE IN A JAPANESE HEALTH CHECKUP POPULATION

Satoko Tajirika[1] Takao Miwa[2] Tatsunori Hanai[2] Masahito Shimizu[2] Mayumi Yamamoto[1], [1]Gifu University, Gifu, Japan, [2]Graduate School of Medicine, Gifu University, Gifu, Japan.

Background: The recently introduced nomenclature for steatotic liver disease (SLD) aims to better classify patients based on metabolic dysfunction and alcohol intake. However, the prevalence of SLD based on recently introduced nomenclature in the Japanese population is yet to be explored. This study examined the prevalence and characteristics of SLD and its subclasses in Japanese individuals. **Methods:** This cross-sectional study included 694 participants who underwent health checkups. SLD was evaluated using liver ultrasonography, and participants were categorized into metabolic dysfunction-associated steatotic liver disease (MASLD), MetALD, alcohol-associated/related liver disease (ALD), and cryptogenic SLD groups using consensus nomenclature. The prevalence and characteristics of the SLD subclasses were assessed, and subgroup analyses were conducted for the non-obese (body mass index [BMI] $\leq$ 25 kg/m^2) and lean (BMI $\leq$ 23 kg/m^2) populations. **Results:** Among participants with a median age of 47 years and 54% males, the prevalence of MASLD, MetALD, ALD, and cryptogenic SLD in the total population was 26%, 2%, 1%, and 2%, respectively. A remarkable difference was observed in the prevalence of SLD subclasses according to age, sex, and BMI (Figure) . Subgroup analyses revealed heterogeneous demographic, clinical, and biochemical parameters between the SLD categories. Notably, individuals with MetALD had higher gamma-glutamyl transferase levels, lower platelet counts, and higher fibrosis-4 index than those with MASLD. Furthermore, the prevalence of non-obese and lean MASLD was 13% and 6%, respectively. **Conclusion:** This study provides information on the prevalence of SLD based on a new nomenclature in the Japanese population. The findings of our study highlight potential areas for further research, particularly in relation to different BMI categories and SLD subclasses.

2630 | MASLD ETIOLOGY INDEPENDENTLY PREDICTS 3-MONTH HOSPITAL READMISSION IN DECOMPENSATED CIRRHOSIS – A SINGLE-CENTER STUDY

Rohit Mehtani[1] Ananya Nanda[1] Prerna Agarwal[1] Shankey Garg[1] Akash Roy[2] Mahendra Rajput[1] Suraj Bhagat[1] Bhaskar Nandi[1], [1]Amrita Institute of Medical Sciences and Research Center, Faridabad, Haryana, India, [2]Apollo Multispeciality Hospital, Kolkata

Background: Readmission in patients with decompensated cirrhosis is common and leads to significant morbidity and healthcare costs. The role of underlying etiology in predicting readmission risk, particularly metabolic dysfunction associated steatotic liver disease (MASLD) remains unexplored. The study was done to assess 3-month readmission risk and identify predictors of readmission in patients with decompensated cirrhosis, focusing on the impact of disease etiology. **Methods:** A retrospective analysis of admitted patients with decompensated cirrhosis in a tertiary care center in North India was done. Data on demographic parameters, etiology & severity of liver disease, comorbidities, laboratory parameters, decompensations and complications of liver cirrhosis (ascites, Hepatic encephalopathy [HE], gastrointestinal [GI] bleeding, acute kidney injury [AKI], jaundice, hepatocellular carcinoma [HCC], hepatopulmonary syndrome [HPS], portal vein thrombosis [PVT], sarcopenia), survival, 3-month readmissions and reasons for readmission was collected. Primary outcome was hospital readmission within 3 months of discharge. Logistic regression analysis was performed to identify independent predictors of readmission, adjusted for baseline age and MELD-Na score. **Results:** Of 124 patients, 57 (46%) required hospital readmission within 3 months. Baseline parameters including disease severity scores – CTP (10 [9–11.5] vs 10 [8-12]; p = 0.384) and MELD-Na (19.5 [13.5-25.5] vs 20 [14-24]; p = 0.726) were similar irrespective of readmission status. MASLD was the most common etiology of liver disease (29%) in our cohort. Patients with MASLD were older, more often females, had more comorbidities and lower liver disease severity scores (CTP and MELD-Na) as compared to patients without MASLD (Table 1). Readmission rate was high in patients with MASLD related cirrhosis (61.11% vs 39.77%; p = 0.030). On logistic regression analysis, MASLD etiology was the only significant predictor of readmission (Odds ratio [OR] 2.40, 95% CI 1.01 – 5.74; p = 0.048) even after adjusting for baseline age and MELD-Na score. Symptomatic ascites recurrence (n = 25, 43.86%) was the most common reason for hospital readmission followed by HE (n = 8, 14%). Readmission due to hepatic hydrothorax was more common in MASLD group (13% vs 0%; p = 0.025). **Conclusion:** MASLD etiology is a significant independent predictor of 3-month hospital readmission in patients with decompensated cirrhosis. Our study highlights the need for targeted post-discharge monitoring and interventions in patients with MASLD to reduce readmission rates.

Table 1 – Baseline and follow-up data of patients with cirrhosis stratified by MASLD as etiology of liver disease

Variable	Non-MASLD (n=88)	MASLD (n=38)	p-value

2631 | MIND THE GAP: THE DISCONNECT BETWEEN PERCEIVED AND ACTUAL LIFESTYLE IN MASLD

Lorenzo Ciocca[1] Francesco Mignone[2] Alessia Siribelli[2] Sara Menchi[1] Federica Invernizzi[3], [1]Vita-Salute San Raffaele University, Center for Liver Disease, Division of Internal Medicine, [2]Vita-Salute San Raffaele University, [3]IRCCS San Raffaele Scientific Institute, Center for Liver Disease, Division of Internal Medicine

Background: Metabolic-associated steatotic liver disease (MASLD) affects nearly 30% of the global population and can progress to steatohepatitis, advanced fibrosis, and hepatocellular carcinoma, posing a growing burden on healthcare systems. Its pathogenesis is strongly associated with modifiable factors such as obesity, physical inactivity, and insulin resistance. As lifestyle modification remains the cornerstone of treatment, this study aims to evaluate the discrepancy between self-reported lifestyle behaviors and objective clinical indicators, focusing on diet and physical activity. **Methods:** This cross-sectional observational study includes individuals with MASLD followed at the outpatient clinic of San Raffaele Hospital (Milan) between June 2024 and April 2025. Participants complete two validated lifestyle questionnaires: the Mediterranean Diet Scoring Tool (MDS) and the International Physical Activity Questionnaire (IPAQ). Clinical data collected include abdominal circumference, BMI, HOMA-IR, liver ultrasound, liver elastography, and Doppler ultrasound of supra-aortic trunks. **Results:** 148 participants are enrolled (108 male, 73%), with a median age of 63 years (range 20–92) and a median BMI of 27 kg/m² (range 16–42). Major comorbidities include type 2 diabetes [38 (26%)], hypertension [78 (53%)], and dyslipidemia [80 (54%)]. Significant alcohol consumption is reported in 52 individuals (35%), with a mean intake of 92 g/week. Steatosis is mild in 57 (40%), moderate in 62 (43%), and severe in 24 (17%). Median liver stiffness is 6.4 kPa (range 4–35), and 70 participants (42%) show signs of atheromasia. MDS scores show low adherence to the Mediterranean diet in 8%, moderate in 44%, and high in 48%. According to IPAQ, 11% are inactive, 30% have low activity, 50% moderate, and 9% high. **Conclusion:** Despite 48% of participants reporting high adherence to the Mediterranean diet and around 60% engaging in at least moderate physical activity, a substantial proportion presents with clinically relevant steatosis, increased liver stiffness, and signs of vascular disease. These findings suggest that self-reported lifestyle questionnaires may not adequately guide interventions, as individuals often overestimate their adherence due to a misperception of healthy behaviors. Addressing this gap may require moving beyond questionnaires alone, incorporating direct clinical assessment to better identify and address lifestyle misperceptions. **Disclosures:** Lorenzo Ciocca: Nothing to Disclose, Francesco Mignone: Nothing to Disclose, Alessia Siribelli: Nothing to Disclose, Sara Menchi: Nothing to Disclose, Federica Invernizzi: Nothing to Disclose

2632 | SPONTANEOUS PROGRESSION AND REGRESSION OF FIBROSIS IN METABOLIC DYSFUNCTION ASSOCIATED STEATOHEPATITIS (MASH)

Zobair Younossi[1] Maria Stepanova[1] Brian Lam[2] Daisong Tan[3] Andrei Racila[1] Manirath Shirshord[3] Linda Henry[1] Fatema Nader[4], [1]The Global NASH Council, [2]INOVA Fairfax Hospital, [3]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, [4]Center for Outcomes Research in Liver Diseases, CORLD

Background: In patients with MASH, fibrosis may increase or spontaneously decrease. The aim was to assess factors associated with progression or regression of fibrosis in patients with MASH. **Methods:** Patients with MASH (N = 1,060; F1: 9%, F2: 20%, F3: 49%, F4: 22%) with two liver biopsies (9-24 months apart) who did not receive specific MASH treatment were included. Fibrosis regression and progression were defined as a decrease or increase of ≥ 1 fibrosis stage or hepatic decompensation in cirrhosis. Clinical and laboratory parameters associated with regression and progression of fibrosis were assessed. **Results:** Over a follow-up of 1.14 ± 0.22 years, 20% of MASH patients experienced fibrosis regression, 62% did not have changes in fibrosis, 18% had progression. Patients with fibrosis regression were younger (54 ± 12 years vs. 57 ± 10 years in unchanged fibrosis, 56 ± 10 years in progressed fibrosis), less likely to have type 2 diabetes (T2D) (54% vs. 65% and 67%, respectively) ($p < 0.05$). Patients with fibrosis regression had lower noninvasive test (NIT) scores at baseline: mean FIB-4 = 1.40 (improved) vs. 2.03 (unchanged) vs. 2.14 (progressed); mean ELF = 9.45 vs. 9.94 vs. 10.0; mean liver stiffness (LS) by transient elastography = 13.2 kPa vs. 16.2 kPa vs. 15.4 kPa (all $p < 0.01$). Patients with fibrosis improvement had the greatest reductions in BMI (mean -0.63 vs. -0.31 vs. -0.10), ALT (-15.3 U/L vs. -8.0 U/L vs. -8.5 U/L), AST (-9.8 U/L vs. -5.7 U/L vs. -3.7 U/L), ALP (-3.4 U/L vs. -1.5 U/L vs. +1.5 U/L), and GGT (-12.2 U/L vs. -7.8 U/L vs. -2.5 U/L) ($p < 0.05$). In multivariate analysis, factors associated with regression of fibrosis were younger age, lower baseline AST and GGT levels, higher baseline platelet count, decreases in AST and ALP, increase in platelet count ($p \leq 0.05$) (Table). Association of fibrosis regression with a decrease in BMI or HbA1c showed a positive trend (OR (95% CI) = 1.08 (0.98-1.18) per -1 kg/

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

m^2 and 1.18 (0.93-1.49) per -1%%). In contrast, factors associated with fibrosis progression in F1-F3 were higher baseline AST and HbA1c, an increase in AST from baseline ($p < 0.05$) (Table). Only older age, higher baseline BMI and lower baseline platelet count were associated with decompensation in patients with MASH-F4 (Table). **Conclusion:** Patients with MASH may experience spontaneous regression or progression of fibrosis. Lower baseline or decreasing liver enzymes and possibly a reduction in BMI and HbA1c could explain fibrosis regression in MASH.

Table

Predictor / outcome	OR (95% CI)	p
Fibrosis regression		
Age, per year	0.984 (0.968 - 1.000)	0.0508
Baseline AST, per 1 U/L	0.983 (0.973 - 0.993)	0.0009
Baseline platelet count, per 1 unit	1.006 (1.003 - 1.008)	<.0001
Baseline GGT, per 1 U/L	0.997 (0.994 - 0.999)	0.0153
Change in AST, per 1 U/L	0.982 (0.972 - 0.992)	0.0007
Change in platelet count, per 1 unit	1.006 (1.001 - 1.010)	0.0188
Change in ALP, per 1 U/L	0.987 (0.976 - 0.999)	0.0340
Fibrosis progression (in F1-F3)		
Baseline AST, per 1 U/L	1.013 (1.006 - 1.020)	0.0003
Baseline HBA1C, per 1 %%	1.151 (1.001 - 1.323)	0.0490
Change in AST, per 1 U/L	1.013 (1.006 - 1.021)	0.0002
Decompensation (in F4)		
Age, per year	1.114 (1.019 - 1.219)	0.0182
Baseline BMI, per 1 kg/m^2	1.087 (1.010 - 1.171)	0.0263
Baseline platelet count, per 1 unit	0.970 (0.956 - 0.985)	<.0001

2633 | ASSESSMENT OF PRIMARY CARE PHYSICIAN MANAGEMENT OF PATIENTS WITH MASLD SINCE THE 2023 DELPHI CONSENSUS STATEMENT

Ariana Stuart[1] Ashley Dotson[1] Katya Swarts[1] Marion Granich[1] Jessica Yeung[1] Arthi Thirumalai[1] Manish Dhyani[1] James Perkins[1] Rotonya Carr[2], [1]University of Washington, [2]University of Washington Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects ~30% of US adults. Despite AASLD management guidelines, confusion remains regarding diagnosis and management. We developed an Artificial Intelligence (AI) algorithm identifying patients meeting MASLD criteria within electronic health records. Our algorithm found only half of these patients had a MASLD-associated ICD diagnosis, with <5% receiving appropriate risk stratification. We aim to increase primary care physician (PCP) comfort and competency of MASLD management with an educational quality improvement (QI) intervention. **Methods:** Our AI algorithm identified 1869 patients meeting MASLD criteria (between January 1, 2022 and December 31, 2023) without associated MASLD-related ICD codes. These patients had 259 unique PCPs within our medical system. We sent PCPs a one-page infosheet on AASLD-based MASLD management guidelines, including risk stratification by FIB-4 and referral for elastography or specialty care. A survey was then sent to assess PCP comfort with, perceived importance of, and effectiveness of the material. Data on baseline fibrosis risk assessment methods used by PCPs were collected. **Results:** 58 PCPs who completed the survey and their 58 patients were included in the study. Risk Stratification: Automatic FIB-4 calculation was able to be performed in 53 patients. 15.1% (n = 8) were intermediate risk for significant fibrosis (FIB-4 $\geq$ 1.3) and 3.8% (n = 2) were high risk (FIB-4 $\geq$2.67). Yet only 5.2% (n = 3) of patients had FIB-4 documented by PCPs. No patients had elastography; one high risk patient was referred to hepatology. Survey Assessment: 7.4% of PCPs felt the information was "completely new", and 33.3% felt it was "somewhat new". 67.3% rated their comfort with risk stratification for MASLD patients as 3/5 or less. Based on ratings of 4/5 or greater, 88.3% were eager to use the educational material and 87.5% felt they would have opportunity to use it; 84.5% felt the material was both effective and would be easy to integrate into practice. **Conclusion:** MASLD is underrecognized in our population, with significant gaps in risk stratification and referral to specialty care. Many PCPs are not familiar with or comfortable implementing guideline-based management, but the majority are motivated to do so and feel it would be easy to integrate into practice.

2634 | TEMPORAL TRENDS IN HEPATIC STEATOSIS AND ITS RISK FACTORS AMONG YOUNG ADULTS: A COMPARATIVE COHORT STUDY

Abdullah Alsaeed[1] Khalid Alswat[1] Maram Alkhammash[2] Khaled Alsulaim[1] Ajeed Alrashoud[3] Badr Alhumayyd[1] Rakan Aldoghmani[1] Noura Alkathiri[1] Yazeed Alsulaim[1], [1]Department of Medicine, College of Medicine, King Saud University, [2]Liver Disease Research Center,KSU, [3]Department of Medicine, King Fahad Medical City

Background: The burden of metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

shifting to younger populations. However, early-phase data, particularly from low-risk, health-literate groups, remain limited. This study evaluates the temporal changes in hepatic steatosis prevalence and associated risk factors across two independent cohorts of medical students, six years apart. **Methods:** A total of 489 students from King Saud University were enrolled in two cross-sectional cohorts 301 in 2017 and 188 in 2023. All participants underwent non-invasive hepatic assessment via vibration-controlled transient elastography (FibroScan®). Steatosis was defined as CAP $\geq$248 dB/m. Anthropometric indices and lifestyle parameters were collected through standardized protocols and questionnaires. Univariable and multivariable logistic regression models were constructed to identify independent predictors of steatosis. **Results:** The overall prevalence of hepatic steatosis was 21.1%, increasing from 18.6% in 2017 to 25.0% in 2023 ($p = 0.092$). Students with steatosis had significantly higher BMI, waist circumference, and obesity prevalence (all $p < 0.01$). Advanced fibrosis ($\geq$F2) was rare (1.6%). Male sex and central adiposity were strongly associated with steatosis. Strength training showed a protective effect in 2023 cohort (34.8% vs. 69.4%, $p = 0.002$). Fast-food consumption and reduced intake of antioxidant-rich foods were associated with steatosis in univariable analysis but lost significance in adjusted models. On multivariable analysis, a prior self-reported fatty liver diagnosis remained the only independent predictor (aOR = 6.28, 95% CI: 1.14–47.8; $p = 0.042$). **Conclusion:** This dual-cohort analysis reveals a rising burden of hepatic steatosis among young, apparently healthy adults, many of whom exhibited anthropometric features suggestive of metabolic dysfunction. Although advanced fibrosis was rare and MASLD could not be fully diagnosed in all individuals with steatosis due to the absence of laboratory data, these findings underscore the importance of early identification and targeted lifestyle interventions to mitigate long-term MASLD risk.

2635 | HYPERTENSION ASSOCIATED WITH THE RISK OF FEMALE REPRODUCTIVE SYSTEM CANCERS IN MASLD POPULATION

Xinyue Zhao[1] Yuchao Lu[1] Feng Xue[1] Shanshan Wang[2] Haiyun Ding[2] Shuangqing Gao[2] Ming Yang[1] Lai Wei[1], [1]Beijing Tsinghua Changgung Hospital, School of Clinical Medicine, Tsinghua University, [2]Beijing North Medical & Health Economic Research Center

Background: Female reproductive system cancers have been confirmed that associated with metabolic dysfunction-associated steatosis liver disease (MASLD). We aimed to investigate the association of five cardiometabolic risk factors, as well as liver fibrosis, and female reproductive system cancers in the MASLD population. **Methods:** The MASLD population and those with comorbid female reproductive system cancers-including ovarian cancer, cervical cancer, endometrial cancer-were derived from a hospital-based database across 11 canters in Chinese nationwide, according to MASLD and female reproductive system cancers diagnostic criteria based on keywords and ICD-10 codes. Logistic regression was used to estimate odds ratio (OR) and 95% confidence interval (CI) between risk factors and female reproductive system cancers. **Results:** Totally 36,231 female MASLD individuals were identified with 631 cases diagnosed female reproductive system cancers. The primary outcome showed that diagnosed hypertension (OR 1.35, 95%CI:1.12,1.63) and its combination with hyperglycemia (OR 1.93, 95%CI 1.53,2.43) significantly associated with female reproductive system cancers in MASLD population. Diagnosed type 2 diabetes (OR 1.50, 95%CI: 1.25,1.81), fasting glucose 5.6-6.9mmol/L (OR 1.28,95%CI:1.00,1.63) and menopause (OR 1.92,95%CI:1.38,2.68) associated with the risk of the cancers respectively as well. MASLD population aged 35 to 65, FIB-4 over 1.3, between 1.3-2.67, over 2.67, over 3.48 were associated with approximately 1.5-fold,1.96-fold, 1.62-fold risky possibilities of the cancers compared with FIB-4 less than 1.3, which was consistent with aged over 65 whose FIB-4 over 2 5-fold associated with the risk in MASLD population. **Conclusion:** Hypertension and its combination with hyperglycemia, menopause and elevated FIB-4

★ 2636 | PHENOTYPIC AND METABOLIC FEATURES OF MASLD IN CENTRAL ASIAN POPULATIONS LIVING IN MODERATE-ALTITUDE HYPOXIA

Nurgul Toktogulova[1], [1]Kyrgyz State Medical Academy

Background: Metabolic dysfunction-associated fatty liver disease (MASLD) is one of the leading causes of chronic liver disease globally. Its clinical manifestations vary widely depending on ethnicity, lifestyle, and environmental conditions. Among ethnic residents of Central Asia living at moderate altitudes, the effects of hypobaric hypoxia on metabolic processes remain understudied. **Methods:** The study included 733 individuals living at low altitudes (750–800 m above sea level; n = 319: control = 36, with MASLD = 283) and moderate altitudes (2046–2300 m; n = 414: control = 24, with MASLD = 392) in Kyrgyzstan. Clinical assessments included BMI, waist circumference, body composition via bioimpedance analysis, lipid and glucose metabolism markers, cytokine profile (IL-6, TNF-α), and cytosolic ATP levels. Liver fibrosis stage was determined using elastography. **Results:** Among Kyrgyz patients with MASLD, 25% exhibited the so-called "lean phenotype," with BMI < 23 kg/m² (Asian criteria), but pronounced visceral adiposity. This group showed notable insulin resistance, hypertriglyceridemia, and decreased HDL levels. Hypobaric hypoxia modulated transaminase levels and reduced cytolytic activity in patients without T2DM. However, in individuals with coexisting MASLD and T2DM, fibrosis progression (≥F2 METAVIR) was significantly accelerated. Levels of IL-6 and TNF-α positively correlated with the degree of steatosis and fibrosis. The results indicate that MASLD in ethnic Central Asians living in moderate-altitude hypoxia displays phenotypic variability and dissociation between body weight and metabolic abnormalities. Hypoxia appears to reduce biochemical markers of cytolysis, potentially masking active disease. When combined with T2DM, this effect is overridden, necessitating distinct clinical strategies. The use of inflammatory markers and functional tests alongside elastography is recommended for more accurate assessment of liver damage. **Conclusion:** • MASLD in Central Asian populations frequently presents with a normal-weight phenotype yet marked metabolic dysfunction. • Hypobaric hypoxia modulates cytolytic activity but does not prevent fibrosis in the presence of T2DM. • Comprehensive diagnostics that consider ethnic and geographic context can help identify subclinical forms of MASLD.

2637 | PREVALENCE OF AT-RISK MASLD IN PATIENTS WITH TYPE 2 DIABETES MELLITUS

Martin Kluge[1] Gregor Wilken[1] Jakob Weglage[1] Jana Knorr-Klocke[1] Frank Tacke[1] Münevver Demir[2], [1]Charité - Universitätsmedizin Berlin, [2]Charité - Universitätsmedizin

Background: Globally, the prevalence of MASLD is high and likely to continue to rise. A key challenge for healthcare providers is to identify those patients with at-risk MASLD (fibrosis grade F ≥ 2) to provide them with specialized care. The European and American guidelines do not recommend the comprehensive screening of the general population but recommend the case-finding in individuals with risk factors, such as type 2 diabetes (T2D). The aim of this study is to evaluate the prevalence of at-risk MASLD in T2D patients without previously known MASLD. **Methods:** Between March 2023 and February 2025, 1008 patients were referred from primary care and/or diabetology practices to our hepatology outpatient clinic to test for MASLD. For n = 432 patients with T2D lab values and medical history were available. To identify at-risk MASLD (F ≥ 2) in T2D we used vibration controlled transient elastography (VCTE, Fibroscan®) for liver stiffness measurement (LSM), FIB-4 and FAST score, as independent non-invasive tests (NITs). Patients were ruled-in for the assumption of at-risk MASLD when LSM indicated significant fibrosis (LSM ≥ 8.0 kPa), FIB-4 ≥ 1.3 for age ≤ 65 and FIB-4 ≥ 2.0 for age > 65, as well as FAST ≥ 0.67. **Results:** In the cohort of T2D patients 30.32% (n = 131) were ruled out by each NIT. 69.68% (n = 301) of the study population were ruled in by at least one of the NITs (LSM: 54,86%, n = 237; FIB-4 48.61%, n = 210; FAST 28.70%, n = 131). Among these patients, 15.51% (n = 67) were ruled in only by LSM, 14.12% (n = 61) were ruled in only by FIB-4 and only 0.69% (n = 3) were ruled in by FAST alone. 4.86% (n = 21) were ruled in by a combination of FAST and LSM, whereas 11.34% (n = 49) were ruled in by a combination of FIB-4 and LSM. A large proportion of patients were classified by all 3 tests as at-risk MALSD (23.15%; n = 100). Those patients have the highest likelihood of being at risk with MASLD and a fibrosis stage F ≥ 2. **Conclusion:** Using a combination of NITs the prevalence of at-risk MASLD in T2D is estimated to be 23.15%. The high prevalence in T2D emphasizes the need for routine case-finding for at-risk MASLD in individuals with cardiometabolic risk factors.

2638 | PHENOTYPIC DIFFERENCES BETWEEN ALD AND MASLD: INSIGHTS FROM A VETERAN COHORT USING REVISED SLD CRITERIA- A RETROSPECTIVE STUDY

Thanita Thongtan[1] Navila Sharif[1] Anand Shah[2] Thuy-Van Hang[1], [1]Emory University School of Medicine, [2]Joseph Maxwell Cleland Atlanta VA Medical Center

Background: Steatotic liver disease (SLD) remains a major global health issue. In December 2023, a multi-society Delphi consensus redefined SLD categories, introducing Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD), Alcohol-Associated Liver Disease (ALD), and a new overlapping subtype, MetALD (MASLD with increased alcohol intake). This shift enables better phenotyping of liver disease, but comparative data on ALD, MetALD, and MASLD under this new framework remain limited. **Methods:** We retrospectively analyzed adult patients with non-viral SLD who had abnormal FibroScan at the our Vetarans Affairs Medical Center between November 2017 and February 2024. Liver stiffness measurement (LSM) and controlled attenuation parameter (CAP) were compared among ALD, MASLD, and MetALD groups using one-way analysis of variance (ANOVA). **Results:** Out of 262 patients (mean age 62.5 years; 87.8% male), ALD patients had significantly higher LSM values than MASLD patients (18.82 vs 10.95 kPa, $p = 0.003$). In contrast, MASLD patients had significantly higher CAP values than ALD (309.6 vs 276.3 dB/m, $p < 0.001$) [Figure1]. There was no significant different with LSM or CPAP when comparing MetALD to MASLD or ALD groups. **Conclusion:** Our study revealed distinct phenotypic differences between ALD and MASLD. ALD patients demonstrated significantly higher liver stiffness measurements (LSM), consistent with a greater fibrosis burden, while MASLD patients had higher controlled attenuation parameter (CAP) values, indicating more pronounced steatosis. These differences may reflect underlying pathophysiology—alcohol-related steatohepatitis and inflammation in ALD, versus insulin resistance and chronic metabolic stress in MASLD. Prior studies support these findings, noting transient elastography (TE) overestimates fibrosis in ALD due to inflammatory activity, and artificial intelligence-powered histologic analysis has identified structural differences in fibrosis architecture between the two. Additional histologic comparisons show steatosis is more severe and centrally distributed in MASLD, aligning with our CAP results. Together, these data highlight the value of noninvasive tools in distinguishing SLD subtypes under the revised nomenclature.

2639 | ROLE OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS (MASH) AS A RISK FACTOR FOR HEPATOCELLULAR CARCINOMA (HCC) DEVELOPMENT

Samantha Clark[1] Yestle Kim[2] Erik Zuk[1] Arushi Chadha[1] Robert Gish[3], [1]Medicus Economics, LLC, [2]Madrigal Pharmaceuticals Inc, [3]Robert G Gish Consultants LLC

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related deaths worldwide. Metabolic dysfunction-associated steatohepatitis (MASH), has become one of the fastest growing risk factors of HCC in the US. While clinical evidence indicates that MASH predisposes an individual to HCC development, the strength and relative impact of this relationship with respect to other underlying etiologies is less well understood. **Methods:** A matched case-control study was conducted using SEER-Medicare linked data from October 2015 through December 2020. Eligible controls (non-HCC cases) were matched to cases using k:1 exact matching without replacement based on birth year, race/ethnicity, and sex. Control

index date was assigned as the HCC diagnosis date of their matched case. MASH was defined using the K75.81 ICD-10 code, with exposure status ascertained during the 36-months prior to a patient's index date. This interval additionally served as the washout and baseline period for covariate measurement and application of inclusion/exclusion criteria. Logistic regression with robust standard errors was used to calculate adjusted odds ratios (OR) and 95% confidence intervals (CI) controlling for matching factors (race/ethnicity, sex, birth year) and obesity, diabetes, cirrhosis, and index year. **Results:** A total of 4,875 HCC cases were matched to 5,030 controls from a 5% random subsample of non-cancer Medicare beneficiaries. Exposure status was heavily skewed, with MASH identified in 5% of HCC cases and only 0.1% of non-cancer controls. MASH was found to be significantly associated with a 4.88-fold (95% CI: 1.36 - 17.5, $p < 0.001$) increase in the odds of HCC development relative to non-MASH patients over the study period. **Conclusion:** In this analysis, clinically rich SEER-Medicare data were used to generate additional insight into the relationship between MASH and HCC development. Results suggesting that MASH patients are at a higher risk of HCC relative to patients with other precipitating liver conditions highlight the importance of expanded surveillance and effective treatment in reducing the clinical burden of HCC in the MASH population.

2640 | RACIAL DISPARITY IN MASLD/MASH USING A PREDOMINANTLY AFRICAN AMERICAN ACADEMIC MEDICAL CENTER

Sriraj Atluri[1] Michael Mello[1] Reema Smadi[1] Abigail Limary[1] Cyra Kharas[1] Izabel Thomas[1] Astha Saini-Goeman[2] Paul Naylor[1] Milton Mutchnick[1], [1]Wayne State University School of Medicine, [2]Wayne Statw University School of Medicine

Background: African Americans (AA) are reported to have a lower MASLD (Metabolic dysfunction Associated Steatotic Liver Disease) incidence as compared to non-AA individuals, but two recent meta-analysis studies suggest only moderate overall differences (Cau = 12-14% vs AA = 11-13%). Due to the variability in data and under representation of AA in the literature, evidence with respect to severity of disease manifestation and racial disparity remain elusive. This study evaluates racial disparity using a predominant AA clinic population and defined MASLD/MASH criteria. **Methods:** ICD-10 codes K76.0 and K75.8 identified MASLD/MASH patients seen between 2017 and 2023. Imaging defined steatosis was available for 85% of the 317 patients with the remaining having documented cardiometabolic risk factors, such as obesity, diabetes and lipidemia. Only 61% had a GI visit and 15% had missing laboratory information. Patients were defined as MASH (Metabolic disfunction Associated Steatohepatitis) if significant fibrosis (F2-4) was present as defined by at least one laboratory result (NAFLD Fibrosis Score (NFS), Fib-4 or APRI, FibroSure) or FibroScan (kPa > 14). **Results:** MASLD/MASH patients were racially similar between AA (56%) and non-AA (44%) with 64% being female. The majority were MASLD (60%; n = 187), with 25% MASH (n = 79). As shown in Figure 1, for the 266 patients with Fibrosis evaluation, there was no difference in the proportion of MASH patients in AA vs non-AA. When evaluated by racial sub-categories there was also no variation. With respect to the issue of defining MASH, NAFLD Fibrosis Score yielded higher levels of advanced fibrosis (14%) as compared to FIB-4 (5%) and APRI (8%). While FibroScan (50% Advanced Fibrosis) and FibroSure (55% Advanced Fibrosis) scored higher, only 31 patients were evaluated (31/317 = 10%) as compared to NFS patients where the results were available for the most patients (255/317 = 80%). **Conclusion:** Consistent with the literature, although the clinic's population was 80% AA, MASLD/MASH rates among AA were only slightly higher compared to non-AA. The primary observation of this study is that if AA patients are diagnosed with MASLD (liver steatosis on imaging or metabolic disease) they are at similar risk for developing advanced fibrosis (MASH) as non-AA individuals (30%). Given the similar risk of MASH regardless of race, the importance of referral to GI for evaluation of advanced fibrosis needs to be emphasized.

2641 | HIGH RISK OF OBSTRUCTIVE SLEEP APNEA (OSA) AMONG ADULTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD): INSIGHTS FROM THE GENESIS STUDY USING THE BERLIN QUESTIONNAIRE

Waleed Alhazzani[1] Faisal Sanai[2] Haifa Alotaibi[1] Shadan AlMuhaidib[3] Faisal Abaalkhail[3] Saleh Alessy[3] Waleed Alomaim[3] Abeer Alabdullah[3] Abdulmohsen Alshammari[3] Eman Alanazi[4] Hani Tamim[5] Abdulmajeed AlMutairi[4] Reem Alakeel[4] Basmah Khoja[3] Abdullah Alharthi[4] Nayef AlJohani[6] Moawad Alotaibi[4] Samar Alqussayer[1] Khalid Alswat[7] Bandar Aljudaibi[3] Saleh Alqahtani[3], [1]Ministry of Defense Health Services, Riyadh, Saudi Arabia, [2]King Abdulaziz Medical City, KAIMRC, Jeddah, Saudi Arabia, [3]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [4]Prince Sultan Military Medical City, Riyadh, Saudi Arabia, [5]Alfaisal University, Riyadh, Saudi Arabia, [6]King Fahad Armed Forces Hospital, Jeddah, Saudi Arabia, [7]King Saud University, Riyadh, Saudi Arabia

Background: MASLD is closely associated with obesity, diabetes, and metabolic syndrome. Sleep disturbances, especially OSA, have been increasingly implicated in the pathogenesis and progression of metabolic diseases, including MASLD. This study aimed to assess and compare the prevalence of high OSA risk among adults with and without MASLD in a large, population-based cohort from Saudi Arabia using the Berlin Questionnaire, a validated screening tool for identifying individuals at risk of OSA. **Methods:** Data were drawn from the GENESIS study, a prospective, population-based cohort conducted in three major regions of Saudi Arabia. MASLD was defined by transient elastography (FibroScan®) with a controlled attenuation parameter (CAP) $\geq$268 dB/m plus $\geq$1 cardiometabolic risk factor. Between March 2024 and April 2025, participants underwent clinical assessment for MASLD and completed the Berlin Questionnaire, which categorizes OSA risk into three symptom domains: snoring/apnea (Category 1), fatigue/sleepiness (Category 2), and body mass index (BMI) $>$30 kg/m² or hypertension (Category 3). BMI was assessed through direct clinical measurements; all other responses were self-reported, in accordance with the questionnaire structure. High OSA risk was defined as positive scores in $\geq$2 categories. Differences between MASLD and non-MASLD groups were analyzed using chi-square and t-tests. **Results:** Of 2,073 adults, 829 had MASLD and 1,244 did not. High OSA risk was significantly more prevalent among participants with MASLD than those without (35.6% vs. 16.7%, $p<0.001$). Category 1 (snoring/apnea) was positive in 29.4% of participants with MASLD compared to 16.4% in the non-MASLD group ($p<0.001$), and Category 3 (BMI/hypertension) was positive in 73.1% vs. 39.7%, respectively ($p<0.001$). No significant difference was observed in Category 2 (fatigue/sleepiness) (21.8% vs. 19.4%, $p=0.19$). Self-reported OSA diagnosis was low and similar in both groups (3.1% vs. 2.5%, $p=0.46$) (Table 1). **Conclusion:** Adults with MASLD exhibited a significantly higher prevalence of Berlin Questionnaire–defined OSA risk, primarily driven by increased rates of elevated BMI/hypertension and snoring/apnea symptoms. The low rate of self-reported OSA diagnosis suggests potential under-recognition in this population. These findings support the integration of sleep disorder screening into MASLD management. Early identification of OSA risk may offer critical opportunities for intervention to prevent disease progression.

Table 1: Sleep habits and Berlin questionnaire scores by MASLD status in the GENESIS cohort.

Variable	MASLD (n=829)	No MASLD (n=1244)	P-value
Sleeping hours (weekdays), mean ± SD	6.5 ± 1.3	6.5 ± 1.3	0.99
Sleeping Hours (weekend), mean ± SD	6.7 ± 1.3	6.8 ± 1.3	0.09
Sleep apnea (OSA), n (%)	26 (3.1%)	31 (2.5%)	0.46
Berlin Category 1, n (%)	244 (29.4%)	204 (16.4%)	<0.001
Berlin Category 2, n (%)	181 (21.8%)	241 (19.4%)	0.19
Berlin Category 3, n (%)	606 (73.1%)	494 (39.7%)	<0.001
High OSA risk (≥2 positive Berlin categories), n (%)	295 (35.6%)	208 (16.7%)	<0.001

Note: Berlin Questionnaire categories—Category 1: snoring/apnea; Category 2: fatigue/sleepiness; Category 3: BMI >30 kg/m² or hypertension. High risk for OSA is defined as a positive score in two or more categories.
Abbreviations: MASLD, metabolic dysfunction-associated steatotic liver disease; OSA, obstructive sleep apnea; SD, standard deviation; BMI, body mass index.

2642 | MUSCLE QUALITY, DEFINED BY LOW MUSCLE VOLUME AND MUSCLE FAT INDEX ON MRI, IS WORSE IN DECOMPENSATED NASH CIRRHOSIS, BUT NOT IN COMPENSATED MASH CIRRHOSIS

Niharika Samala[1] Mikael Forsgren[2] Kate Scheetz[3] Jake McCarty[3] Eduardo Vilar-Gomez[3] Naga Chalasani[4], [1]Indiana University, [2]AMRA Medical AB, [3]Indiana University School of Medicine, [4]Indiana University Medical Center

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Muscle health is often stated to be poor in patients with MASH cirrhosis; however, rigorous interrogation of muscle quality in MASH cirrhosis is lacking. We investigated skeletal muscle characteristics via MRI and their relation to health-related quality of life (HR-QoL) and frailty in MASH cirrhosis. **Methods:** 75 Individuals with MASH cirrhosis were prospectively investigated for their muscle quality, HR-QOL, and frailty. Muscle quality was determined by muscle volume index (MVI) which captures fat-free muscle mass and muscle fat index (MFI) which encompasses T2-corrected fat by AMRA® MAsS, a specialized neck-to-knee rapid MRI protocol. Myosteatosis was defined as thigh MFI >1.25 pp in males and >1.31 pp in females. Low muscle volume (LMV) was defined as thigh MVI <-0.67SD in males and <-0.68SD in females. Frailty was determined using Liver Frailty Index (LFI) and HR-QoL by CLDQ. Muscle quality of this cohort (stratified by decompensation status) was compared to two control groups: 39,804 general population and 160 non-cirrhotic MALD. Further, we also examined the frequency of sarcopenia in our cohort via DEXA based on European Working Group on Sarcopenia in Older people 2 (EWGSOP2) criteria. **Results:** Of 75 individuals with MASH cirrhosis, 45% were decompensated, 59% female, mean age 62 $\pm$ 7 years, mean BMI 35 $\pm$ 6 kg/m^2, and mean MELD3.0 of 11.5 $\pm$ 4.7. LMV was seen in 45%, myosteatosis in 36% and frailty in 32% (Table1 Panel A). A higher proportion of decompensated cirrhotics had LMV (59% vs 34%, $p=0.03$), lower HR-QoL (38% vs 15%, $p=0.02$), and frailty (53% vs 15%, $p=0.002$). Compared to general population and MASLD controls, MVI and MFI were significantly different in decompensated cirrhosis, but not in those with compensated cirrhosis (Table1, Panel B). Interestingly, no one in our cohort met the EWGSOP2 definition for sarcopenia (appendicular lean mass/height^2 cutoffs <7Kg/m^2 (males) or <5.5Kg/m^2 (females)). Low muscle volume was associated with poor HR-QoL ($b=0.65$, 95% CI:0.43 – 0.98, $p=0.04$) and LFI ($b=1.99$, 95% CI:1.03 - 3.87, $p=0.04$), after adjusting for age, sex and MELD3.0. **Conclusion:** Muscle quality, defined by low muscle volume and muscle fat index on MRI, is worse in decompensated MASH cirrhosis, but is relatively preserved in compensated MASH cirrhosis. Low muscle volume is significantly associated with poor quality of life and greater frailty. DXA underestimates sarcopenia in MASH cirrhosis.

Panel A: Baseline characteristics of MASH Cirrhosis cohort stratified by decompensation

	Entire Cohort N=75 N (%) or Mean ± SD	Decompensated N=34 N (%) or Mean ± SD	Compensated N=41 N (%) or Mean ± SD	P-value
MELD 3.0	11.5 ± 4.7	15 ± 5	9 ± 3	<0.001
Muscle Volume Index by MRI	-0.75 ± 1.17	-1.3 ± 1.14	-0.4 ± 1.05	0.002
Muscle Fat Index by MRI	1.03 ± 2.98	2.2 ± 2.3	0.2 ± 2.3	0.008
Low Muscle Volume, n(%)*	36 (48%)	20 (59%)	14 (34%)	0.03
Myosteatosis, n(%)*	27 (36%)	16 (47%)	11 (27%)	0.07
Adverse Muscle Composition, n(%)*	19 (25%)	13 (38%)	6 (15%)	0.02
Liver Frailty Index	4.3 ± 0.9	4.6 ± 0.9	4.0 ± 0.7	0.002
Frailty (LFI ≥ 4.5)	24 (32%)	18 (53%)	6 (15%)	0.002
CLDQ total score	4.8 ± 1.3	4.2 ± 1.3	5.2 ± 1.2	<0.001

Panel B: Muscle Volume Index and Muscle Fat Index in compensated and decompensated cirrhosis, compared to general population and non-cirrhotic MASLD

	General Population (n=39,804)	MASLD non-cirrhotic (N=160)	MASLD with compensated cirrhosis (N=41)	MASLD with decompensated cirrhosis (N=34)
Muscle Volume Index	0.1 ± 0.98	0.2 ± 1.02 p=NS vs. gen population	-0.4 ± 1.1 p=NS vs. gen population or non-cirrhotic MASLD	-1.3 ± 1.14 p<0.01 vs all other groups
Muscle Fat Index	0.27 ± 1.81	-0.21 ± 1.96 p=0.04 vs. gen population	0.2 ± 2.3 p=NS vs. gen population or non-cirrhotic MASLD	2.2 ± 2.3 p<0.01 vs all other groups

◆ 2643 | IMPLEMENTATION OF A WECHAT MINI-PROGRAM-DRIVEN LIFESTYLE INTERVENTION AMONG OVERWEIGHT OR OBESE INDIVIDUALS WITH METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE

CHAO SUN[1], [1]Shanghai Jiao Tong University

Background: Weight loss is the standard recommendation for patients with metabolic dysfunction-associated fatty liver disease (MAFLD), but its successful implementation is difficult in practice. Digital lifestyle interventions may provide an efficient and scalable solution to enhance patient self-management. This study aimed to assess the effects of a WeChat mini-program-delivered lifestyle intervention on weight loss and hepatic steatosis among overweight or obese individuals with MAFLD. **Methods:** Overweight or obese adults with clinically diagnosed MAFLD with transient elastography examination were enrolled in this prospective randomized controlled trial. Patients were randomly assigned to receive either WeChat mini-

program management (intervention group) or standard care (control group) at a 1:1 ratio. Body weight and clinical parameters were assessed at baseline and then at 6 months. **Results:** Among the 89 included MAFLD patients, 60.0% achieved ≥5% weight loss, and 24.4% had ≥10% weight loss in the intervention group, which were greater than those in the control group ($P < 0.05$). Importantly, patients receiving the intervention were significantly more likely to achieve a ≥10% controlled attenuation parameter (CAP)reduction or CAP normalization than those in the control group were (57.8% vs. 31.8%, $P < 0.05$). In parallel, the intervention group presented greater reductions in liver enzymes (ALT, AST, and GGT) and metabolic parameters (fasting insulin, HbA1c, TG, and HDL-C) than the control group ($P < 0.05$). According to the fibrosis assessment, only the FibroScan-aspartate aminotransferase (FAST) score decreased more in the intervention group than in the control group ($P < 0.05$). No significant difference was found in the liver stiffness measurement (LSM) values or noninvasive scores (APRI, FIB-4, NFS, and Agile 3+) between the groups ($P > 0.05$). **Conclusion:** Digital lifestyle coaching via a WeChat mini-program demonstrates efficacy in enhancing weight reduction, improving hepatic steatosis, and ameliorating metabolic disorders, offering novel perspectives regarding the practicality and therapeutic value of digital tools in managing MAFLD through behavioral interventions.

2644 | EFFECTS OF AEROBIC EXERCISE ON LEAN NON-ALCOHOLIC FATTY LIVER DISEASE: A RANDOMIZED CLINICAL TRIAL

Ci Song[1] Chengxiao Yu[2] Pei Qin[2] Wentao Yao[1] Siyu Wang[1] Xuanyu Chen[1], [1]Nanjing Medical University, [2]The First Affiliated Hospital of Nanjing Medical University

Background: Exercise represents a remarkably cost-effective lifestyle intervention for preventing and treating non-alcoholic fatty liver disease (NAFLD). However, the benefits of exercise in lean NAFLD patients remains incompletely understood. In this study, we conducted a 3 months aerobic exercise to assess the multifaceted effects of exercise on lean NAFLD. **Methods:** 100 participants of lean NAFLD (BMI < 24) were randomly assigned to either the aerobic exercise (n = 50) or control group (n = 50). The aerobic exercise group underwent high-intensity exercise training three times per week (60 minutes per session), while the control group maintained their usual physical activity levels. The primary outcome was the difference between the two groups in the change from baseline in liver fat content (LFC) at 3 months. The secondary outcomes included changes in body weight, waist circumference, body fat, body lean mass, metabolic risk factors, blood pressure, lipids, glucose levels, insulin resistance, and beta cell function. The trial is registered at ClinicalTrials.gov (NCT0148027). **Results:** By intention-to-treat analysis, the mean LFC change from baseline to 3 months was -2.71% (95% confidence interval [CI], -4.23% to -1.19%; P = 0.001) in the intervention group and -0.59% (95 CI, -2.32% to 1.14%; P = 0.505) in the control group, with a mean between-group difference (of intervention vs control) of -2.11 (95% CI -3.14 to -1.10; P < 0.001). Among the secondary outcomes, there were greater reductions in Abdominal visceral fat and Abdominal subcutaneous fat area in the exercise group compared with controls, with significant between-group differences of -14.22 (95% CI -20.01 to -8.42; P < 0.001), and -22.82 (95% CI -32.32 to -13.33; P < 0.001), respectively. No adverse events were noted in either study group. **Conclusion:** Over 3 months, aerobic exercise alleviates LFC and other relevant clinical phenotypes among lean-NAFLD patients. Our study identifies the benefits of aerobic exercise in patients with lean NAFLD.

2645 | IMPACT OF LIVER HISTOLOGY AND MASLD-ASSOCIATED GENETIC VARIANTS ON INSUFFICIENT WEIGHT LOSS AFTER BARIATRIC SURGERY

Felice Cinque[1] Sara Badiali[2] Marica Meroni[1] Miriam Longo[1] Erika Paolini[1] Elisa Galfrascoli[2] Giovanna Oberti[1] Giuseppina Pisano[1] Emma Calzavara[1] Annalisa Cespiati[1] Luigi Boni[2] Anna Ludovica Fracanzani[3] Paola Dongiovanni[4] Rosa Lombardi[5], [1]Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, Milan, Italy, [2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, [3]University of Milan, [4]SC Medicina ad Indirizzo Metabolico, Fondazione IRCCS Cà Granda Ospedale Maggiore Policlinico, [5]University of the Study of Milan

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is now the leading global

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

cause of liver disease, closely linked to rising rates of obesity and diabetes. In Europe, no pharmacological treatment is approved; thus, weight loss remains the only effective option, with bariatric metabolic surgery (BMS) being the most durable intervention. However, a substantial proportion of patients experience insufficient weight loss (IWL), limiting liver-related benefits. While IWL is associated with demographic, metabolic, and psychological factors, the role of MASLD and genetics remains poorly defined. **Methods:** We retrospectively analyzed patients undergoing BMS (2008–2023) at Policlinico Hospital of Milan with intraoperative liver biopsy and 12–18 month weight follow-up. IWL was defined according to Reinhold criteria: $<50\%$ excess weight loss or BMI >35 kg/m² at 12–18 months. MASLD ($>5\%$ steatosis), MASH (NAFLD Activity Score ≥ 3), and significant fibrosis (stage ≥ 2) were histologically diagnosed. Genotyping for MASLD-related variants (PNPLA3, TM6SF2, GCKR, HSD17B13) and insulin resistance (IRS1) was performed. **Results:** Among 308 patients (77.9% female; median BMI 42.1 kg/m²), MASLD was present in 84.7%, MASH in 50.1%, and significant fibrosis in 7.5%. IWL occurred in 29.5%, and was more frequent in patients undergoing gastric banding (75.8% vs 24.2%) and with higher preoperative BMI (46.3 vs 40.9 kg/m², $p < 0.001$) and higher prevalence of hypertension (54.1% vs 29.5%, $p = 0.008$). Notably, IWL occurred most frequently in patients with baseline significant fibrosis (12.1% vs 5.6%, $p = 0.048$). In 109 genotyped patients, IWL was less frequent in carriers of the IRS1 rs2972146 T allele (78% vs 95%, $p = 0.009$), while other variants showed no significant association. On multivariable analysis, higher preoperative BMI and gastric banding remained independently associated with IWL, while the IRS1 T allele was protective (Table). **Conclusion:** In this well-characterized bariatric cohort with integrated liver histology and genetic profiling the prevalence of MASLD, MASH, and significant fibrosis was notably high. IWL affected nearly one-third of patients and was independently associated withgastric banding and higher baseline BMI, but not with underlying liver comorbidities. Notably, the IRS1 genetic variant—implicated in insulin signalling and adiposity regulation—was found to be protective against IWL, highlighting the potential influence of insulin pathways on post-BMS outcomes. Given the central role of weight reduction in the management of MASLD, particularly in individuals with obesity, identifying predictors of suboptimal response to bariatric surgery is critical to improving long-term hepatic and metabolic outcomes.

Table: Multivariable logistic regression analysis of factors associated with IWL

Variable	Odds Ratio	95% CI	p-value
Male Sex	1.46	0.31–6.98	0.63
Age	1.01	0.96–1.06	0.80
Hypertension	1.31	0.45–3.84	0.62
Significant fibrosis (≥F2)	0.71	0.13–3.91	0.70
Preoperative BMI	**1.22**	**1.11–1.34**	**<0.001**
Gastric banding	**16.61**	**3.79–72.87**	**<0.001**
IRS1 rs2972146 T allele	**0.18**	**0.04–0.81**	**0.03**

2646 | A SYSTEMATIC REVIEW OF THE EFFECTIVENESS OF LIFESTYLE INTERVENTIONS IN IMPROVING LIVER HEALTH FOR PATIENTS WITH STEATOTIC LIVER DISEASE

Laura Temperley[1] Stephanie Landi[2] Fanyi Su[2] Tonia Momoh[2] Varinder Athwal[2] Gabriel Rogers[2], [1]Barts Health Trust, UK, [2]University of Manchester, UK

Background: Steatotic liver disease (SLD), which includes alcohol-related liver disease (ALD), metabolic dysfunction-associated steatotic liver disease (MASLD), and metabolic and alcohol-related steatotic liver disease (MetALD), is a widespread condition with few treatment options. Although global guidelines recommend lifestyle interventions, the definitive evidence supporting their effectiveness in improving liver outcomes is limited. This systematic review aims to evaluate the impact of lifestyle interventions on clinical outcomes in patients with SLD, while identifying key areas for future research. **Methods:** A systematic review was conducted, including randomized controlled trials (RCTs) for MASLD and MetALD populations and both RCTs and cohort studies for ALD populations. A protocol was registered with PROSPERO (CRD42024516755). We searched MEDLINE and Embase to identify studies comparing lifestyle interventions with usual care in SLD populations, with two reviewers performing the screening. The risk of bias was assessed using RoB-2 and ROBINS-I tools.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Random-effects meta-analyses were performed for various outcomes, stratified by intervention type. Findings were summarized using the GRADE approach. **Results:** 47 studies were included, with 38 focusing on MASLD populations, eight on ALD populations, and one in a MetALD population, comprising 3,696 participants in MASLD groups and 103,127 participants in ALD groups. Meta-analyses showed statistically significant pooled effects favouring interventions for MRI/1H-MRS, ultrasound, and histology-measured outcomes in MASLD populations, as well as cirrhotic decompensation and mortality outcomes in ALD populations. Only the meta-analysis of MRI/1H-MRS showed low heterogeneity, with a mean difference of −3.37 percentage points [95% CI −4.44 to −2.70] in favour of the intervention groups ($p < 0.01$). The quality of evidence for all outcomes was rated as low or very low. **Conclusion:** This review is the first to evaluate the impact of lifestyle interventions on liver outcomes in ALD and MetALD populations and serves as an up-to-date assessment for MASLD populations. The evidence is insufficient to draw conclusions about the effectiveness of lifestyle interventions in improving liver outcomes in SLD due to the low quality of included studies. This was driven by high risk of bias, heterogeneity, and indirectness in the studies. The review highlights the urgent need for well designed RCTs focusing on patient-important outcomes, such as progression to cirrhosis and mortality, with longer follow up periods to better inform clinical practice. Additionally, further research in MetALD populations is necessary, given the growing evidence of its high prevalence. Finally, exploring the role of newly developed pharmacological interventions alongside lifestyle changes is crucial, as a combined approach could significantly influence future treatment strategies.

2647 | MARS: A SIMPLE, READILY AVAILABLE, NON-INVASIVE SCORE TO ASSESS TREATMENT RESPONSE IN PATIENTS WITH MASH

Jérôme Boursier Adele Delamarre[1] Christophe Bureau[2] Yasmina Chouik[3] Lucia Parlati[4] Stephanie Faure[5] Cyrielle Caussy[3] Vincent Leroy[6] Vlad Ratziu[7] Laurent Castéra[8], [1]Bordeaux University Hospital, [2]Toulouse University Hospital, [3]Lyon University Hospital, [4]APHP Cochin Hospital, [5]Montpellier University Hospital, [6]APHP Mondor Hospital, [7]APHP La Pitie Salpetriere Hospital, [8]APHP Beaujon Hospital

Background: With the recent approval of pharmacologic treatments, the non-invasive assessment of treatment response in MASH is a crucial unmet need. Although recent data suggest that regression of liver steatosis, as measured by MRI-PDFF, is a promising surrogate for MASH resolution, MRI is expensive and has limited availability. Controlled Attenuation Parameter (CAP) is a point-of-care ultrasound technology developed to assess and quantify liver steatosis. We aimed to evaluate CAP and to develop a new score for the non-invasive assessment of MASH resolution. **Methods:** A total of 205 adult patients with MASH who had undergone paired liver biopsies and contemporaneous CAP examinations were retrospectively included from ten tertiary centers. The study endpoint was MASH resolution, defined as no or mild inflammation (NASH CRN grade 0-1), no hepatocyte ballooning (NASH CRN grade 0), and no worsening of fibrosis on the second liver biopsy. The relative deltas of biomarkers (relΔ, %) were calculated as follows: [follow-up - baseline] / baseline results. **Results:** The median age of the patients included was 60 years (IQR: 54-66), 50% were female, median BMI was 33 kg/m^2 (IQR: 30-36), and 65% had type 2 diabetes. The median interval between the baseline and the second liver biopsy was 18 months (IQR: 15-22). MASH resolution occurred in 29 patients (14%). CAP decreased was -55 dB/m (IQR: -87; -25) in patients with MASH resolution, compared to -9 dB/m (IQR: -47; +22) in those without resolution ($p < 0.001$). The AUROC of relΔCAP was 0.708 ± 0.054. Multivariate analysis showed that relΔCAP, relΔgammaGT, baseline AST, and baseline CAP were independent predictors of MASH resolution. Combining these four parameters in the MASH Resolution Score (MARS, ranging from 0 to 1) increased the AUROC for MASH resolution to 0.854 ± 0.037. The 90% sensitivity threshold (< 0.07) provided an excellent negative predictive value (NPV: 97%). As expected in this population with a low prevalence of MASH resolution, the 90% specificity threshold (> 0.30) provided moderate positive predictive value (PPV: 48%). Simulations showed that the PPV reached 90% at a prevalence rate of 60%, which corresponds to the MASH resolution rate in the ESSENCE Phase 3 Trial (Sanyal et al. NEJM 2025). **Conclusion:** MARS enables an accurate evaluation of MASH resolution. This new score, which is based on simple routine parameters and the results

of a point-of-care device, can easily be calculated in an outpatient clinic. It will facilitate the assessment of treatment response in patients with MASH.

2648 | IN TREATMENT OF METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE (MASLD), PATIENT&RSQUO;S CHOICE MATTERS

Sandeep Khurana[1] G. Craig Wood[2] Wesley Hill[2] Christopher Seiler[2] Lyndell Wright[2] Allison Naylor[2] Christopher Still[2], [1]Geisinger Medical Center, [2]Geisinger Health System

Background: For MASLD, weight loss is an effective strategy to reduce hepatic steatosis and fibrosis. However, among the various weight loss strategies, the impact of *patient's choice* of intervention on outcomes and their sustainability remains unclear. To address this gap, we performed a prospective pilot study. **Methods:** We screened 198 patients, 64 consented to participate, 11 withdrew, and 53 completed the study. Patients were offered five choices of intervention. We assessed their weights, liver function tests, elastography, CK18 levels, body composition analysis via bioimpedance, and quality of life (QOL) using SF36 and CLDQ at baseline, 6 and 12 months. **Results:** Mean age was 49.6 years, 60% were females. Patients chose: Group exercise + RDN (n = 40), RDN (n = 6), Medication + RDN (n = 4), Bariatric surgery (n = 2), and Medication + RDN + Group exercise (n = 1). The RDN protocol involved bi-weekly phone calls focusing on motivational interviewing, goal setting, nutritional education, Fitbit tracking, and diet reviews. This cohort demonstrated significant weight loss at 6 and 12 months, averaging 4.6% and 4.7% respectively ($p < 0.0001$). Reductions in ALT, AST, CK-18, and CAP scores were observed at both 6 and 12 months ($p < 0.05$ *for all*), though reduction in liver stiffness was not significant. Thirty percent achieved ≥ 7% wight loss. Patients achieving ≥7% weight loss at 12 months showed greater improvements in outcomes, particularly in CK-18 levels (p = 0.0007). Significant reductions in HbA1c, ferritin, and iron binding capacity were also noted ($p < 0.05$ *for all*). SECA analysis indicated a non-significant decrease in body fat, with significant reductions in fat mass index z-score and visceral adipose at 6 months, and fat-free mass index z-score at 12 months ($p < 0.05$ *for all*). Quality of life improved at 6 and 12 months, with those achieving ≥7% weight loss at 12 months showing higher improvements in SF-36 and CLDQ scores. Activity level was not associated with study outcomes.Greater adherence was associated with improved ALT and CLDQ scores.The sub-group analysis results for the largest group (Group exercise+ RDN) were consistent with the overall analysis. **Conclusion:** In MASLD, patient's choice of weight loss strategy improves compliance, effectiveness, and QOL. Strategies involving intensive interactive dietitian engagement increase weight loss that is sustained up to 12 months. This approach shows promise and warrants further investigation in controlled trials, particularly in conjunction with emerging pharmacological therapies for weight loss.

2649 | THE IMPORTANCE OF WEIGHT REDUCTION IN MASH MANAGEMENT

Lizy Gill[1] Ramya Logendra[1] Roberto Cortese[1], [1]Ipsos

Background: Metabolic dysfunction-associated steatohepatitis (MASH) and associated cardiometabolic conditions are major causes of morbidity and mortality. A prevalent comorbidity of MASH patients is obesity, underscoring the critical role of effective weight management in mitigating the disease's progression and impacts. **Methods:** Data are from the Ipsos Syndicated MASH Therapy Monitor, an online medical chart review and physician perceptual study including 663 physicians in the US (205), Germany (158), Japan (100), China (100) and Brazil (100) treating MASH patients, collected between Oct 2024-Jan 2025. Participants consisted of primary care physicians (PCPs), diabetologists/endocrinologists and gastroenterologists/hepatologists and were screened for caseload. Physicians reported on 2536 MASH patients in the US (735), Germany (541), Japan (420), China (500) and Brazil (340) seen in the last 3 months. **Results:** When aggregating regional data, 87% of all reported MASH patients are also obese/overweight (US/DE/BR BMI ≥ 27; CN/JP BMI ≥ 24) and weight gain is one of the most common symptoms MASH patients presented with; an average of 34% patients. Consequently, weight reduction is a leading treatment goal for 44% of the reported

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

patients, with over two-thirds engaging in exercise and/or nutritional programs, predominantly alongside drug treatment. Among patients on exercise and nutrition therapy, physicians reported control over their MASH in 66% and 62% of cases, respectively. However, when choosing a treatment for this condition, 'reduces weight' falls outside of the top 3 attributes important to physicians; it is also less likely to be cited by them as an expectation of future treatments compared to several efficacy and safety attributes. **Conclusion:** The study findings reiterate the pivotal role of weight management in MASH treatment, particularly given the high rate of obesity/overweight among this population. Nutrition and exercise therapies, often used alongside medication, provide substantial control over the disease and help towards weight reduction as a key treatment goal. However, more may need to be done to join up the continued importance of weight loss in physicians' minds with unmet efficacy needs when deciding on pharmacotherapy for their MASH patients. It will be interesting to see if these attitudes shift as more treatments become available for MASH which also demonstrate weight reduction potential.

2650 | ASSOCIATION BETWEEN CHANGE IN RELATIVE FAT MASS (RFM), BODY MASS INDEX (BMI) WITH NON-INVASIVE MARKERS OF MASH

Brandon Rodgers[1] Theja Channapragada[1] Hannah Mohr[1] Breianna Hummer-Bair[1] Ian Schreibman[1] Christopher Sciamanna[1] Jonathan Stine[1], [1]Penn State Health - Milton S. Hershey Medical Center

Background: Lifestyle intervention remains crucial in the treatment of metabolic dysfunction-associated steatotic liver disease (MASLD) and metabolic dysfunction associated steatohepatitis (MASH). Body mass index (BMI) is a well-established independent risk factor for MASLD, however, BMI is unable to differentiate fat mass from lean mass and can misclassify body fat defined obesity. Relative fat mass (RFM) has been proposed as a superior estimator of whole-body fat percentage. Whether RFM is more sensitive to lifestyle intervention than BMI remains unknown in individuals living with MASLD. **Methods:** A post-hoc analysis of the NASHFit trial was performed to compare improvement in RFM vs. BMI and in particular, their association with improvement in non-invasive biomarkers of MASH activity and metabolic risk. The NASHFit trial investigated the efficacy of 20 weeks of moderate-intensity aerobic exercise in adults with histologically confirmed MASH. In total, 24 patients completed the trial and paired data was available for analysis for 23 patients [exercise = 16, standard of care (SOC) = 7]. **Results:** The mean RFM pre-intervention was 41.5 and 37.8 in the exercise arm and SOC arm respectively. There was no statistically significant difference in mean RFM pre and post intervention, although an increase in RFM was observed in the SOC post intervention (38.1) which trended toward significance ($p = 0.066$). Greater than or equal to 5% reduction in RFM, the clinically significant threshold of response that is predictive of patient outcomes, was seen in 13% ($n = 2$) and 0% ($n = 0$) in the exercise arm and SOC arm respectively. Change in RFM and BMI were both positively correlated in most noninvasive markers of MASH (Table 1), with RFM more strongly correlated with visceral adipose tissue. Change in RFM and BMI were equivocal in their correlation with change in both total body fat and subcutaneous adipose tissue. **Conclusion:** Changes in RFM and BMI both correlate with change in noninvasive biomarkers of MASH and metabolic risk. While either RFM or BMI can be used as tools to guide clinicians in their monitoring of treatment response to lifestyle intervention, RFM appears more sensitive to change in visceral adipose tissue. This is of particular importance as RFM can be readily performed in clinic, thus making it a cost effective and time-efficient tool not requiring formal body composition testing with either bioelectric impedance or dual x-ray absorptiometry (DXA) scans.

Table 1: Correlation between RFM, BMI and noninvasive biomarkers of MASH

Change	RFM (r)	BMI (r)
Body Mass Index (BMI)	+0.43	—
Relative Fat Mass (RFM)	—	+0.43
Abdominal skin fold	+0.30	+0.54
Body fat	+0.37	+0.41
Visceral adipose tissue (VAT)	+0.58	+0.45
Subcutaneous adipose tissue (SAT)	+0.44	+0.46
Homeostatic model assessment of insulin resistance (HOMA-IR)	+0.36	+0.47
Hemoglobin A1c	+0.45	+0.02
Triglyceride	+0.55	+0.22
MRI proton density fat fraction (MRI-PDFF)	+0.36	+0.41
Maximal oxygen uptake (VO2peak)	-0.33	-0.40

2651 | EFFECT OF BARIATRIC SURGERY ON MAJOR ADVERSE CARDIOVASCULAR AND CEREBROVASCULAR EVENTS IN MASLD PATIENTS: INSIGHTS FROM THE NATIONAL INPATIENT SAMPLE DATA (2016–2022)

Omar Alkasabrah[1] Abdullah Hafeez[1] Ritu C .Tated[2] Siddharth Agrawal[1] Radhe Shah[3] Hritvik Jain[4] Faiza Jajja[1] Muhammad qasim Chaudhry[1] Jatin Thukral[1] Tanuj Sharma[1], [1]NYMC/Landmark Medical Center, [2]New York Medical College, [3]Beth Israel Deaconess Medical Center, [4]All India Institute of Medical Sciences

Background: The prevalence of MASLD continues to rise, affecting approximately 25% of the global population, with strong associations to obesity and cardiometabolic diseases. Bariatric surgery has shown metabolic benefits in MASLD, but its long-term impact on cardiovascular and cerebrovascular outcomes remains unclear. This study aims to evaluate the trends and effect of bariatric surgery on major adverse cardiovascular and cerebrovascular events (MACCE), as well as inpatient outcomes, among MASLD patients using national data. **Methods:** National Inpatient Sample (NIS) from 2016 to 2022 were utilized to identify adults >18 years with a diagnosis of MASLD using ICD-10 codes. Patients were stratified by the history of bariatric surgery. Multivariable logistic regression was used to assess associations with outcomes, adjusting for potential confounders. **Results:** Among MASLD patients, 394,535 underwent bariatric surgery. These patients demonstrated a significant reduction in inpatient mortality (aOR 0.33, 95% CI 0.317–0.344, $P<0.001$), LOS (–1.54 days, 95% CI –1.59 to –1.49, $P<0.001$), and THC (–$4,495.74, 95% CI –$5,365.01 to –$3,626.46, $P<0.001$). Moreover, there was a notable decrease in the risk of myocardial infarction (aOR 0.377, 95% CI 0.364–0.391), stroke (aOR 0.872, 95% CI 0.863–0.881), atrial fibrillation (aOR 0.729, 95% CI 0.718–0.739), arrhythmias (aOR 0.779, 95% CI 0.753–0.805), AKI (aOR 0.500, 95% CI 0.494–0.506), respiratory failure (aOR 0.362, 95% CI 0.352–0.372), liver failure (aOR 0.508, 95% CI 0.499–0.517), deep vein thrombosis (aOR 0.594, 95% CI 0.577–0.611), and sepsis (aOR 0.500, 95% CI 0.339–0.737); all $P<0.001$. However, the risk of bleeding was higher (aOR 1.277, 95% CI 1.262–1.293, $P<0.001$) which may be related to altered coagulation profiles, micronutrient deficiencies, or perioperative anticoagulant use in this population. **Conclusion:** Bariatric surgery significantly lowers the risk of MACCE, mortality, and resource utilization in the MASLD population, though it is associated with a higher risk of bleeding. With the increasing burden of MASLD and advancements in endo-bariatric techniques, these findings support bariatric surgery as a promising therapeutic option for MASLD.

2652 | IMPACT OF BODY WEIGHT CHANGES ON NEW-ONSET DIABETES IN INDIVIDUALS WITH NON-DIABETIC METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Aryoung Kim[1] Geum-Youn Gwak[2], [1]Ilsan Paik Hospital, [2]Samsung Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is associated with an increased risk of diabetes. While weight reduction is the primary recommended intervention for MASLD and is known to improve hepatic steatosis and fibrosis, its effect on the development of diabetes remains unclear. This study aimed to investigate the association between body weight changes and the risk of new-onset diabetes in individuals with non-diabetic MASLD. **Methods:** This study included 14,126 adults with MASLD and no diabetes at baseline, all of whom underwent at least two health examinations between 2003 and 2021. MASLD was diagnosed by ultrasonography. Changes in body weight were calculated as the percentage change from baseline to the last available measurement. **Results:** Over a follow-up of 75,496 person-years (mean duration, 5.3 years), 2,258 individuals with non-diabetic MASLD developed diabetes. Compared to participants with no significant body weight change ($>-5.0\%$ to $<5.0\%$), the adjusted hazard ratios (aHRs) for incident diabetes were 1.16 (95% CI, 1.00–1.33) and 1.33 (95% CI, 1.00–1.76) for weight gains of 5.0–9.9% and $\geq 10.0\%$, respectively. Conversely, the aHRs were 0.52 (95% CI, 0.44–0.60) and 0.48 (95% CI, 0.37–0.63) for weight reductions of 5.0–9.9% and $\geq 10.0\%$, respectively. In spline regression models, body weight change showed a dose–response relationship with incident diabetes risk, with increasing weight gain associated with an elevated risk, while greater weight loss associated with a reduced risk. Notably, the association between body weight reduction and reduced diabetes risk was consistently observed in all subgroups analyzed. **Conclusion:** In individuals with MASLD without diabetes, changes in body weight were significantly associated with the risk of new-onset diabetes in a dose-dependent manner. Weight loss was strongly associated with a lower risk of

developing diabetes, with greater reductions conferring greater benefit, while weight gain increased the risk. These findings emphasize the critical role of weight reduction in diabetes prevention and underscore the importance of avoiding weight gain in participants with MASLD.

2653 | INTERMITTENT CALORIE RESTRICTION MODULATES GUT MICROBIOTA IN PATIENTS WITH MASLD: A DIFFERENTIAL IMPACT ON MEGAMONAS, LACHNOSPIRA, AND ENTEROBACTER IN OBESE AND NON-OBESE PATIENTS

Hwi Young Kim[1] Hanah Lee[2] Eun-Kyoung Kim[3] Won-Jae Lee[3], [1]Ewha W. University College of Medicine; University of Nebraska Medical Center, [2]Chung-Ang University College of Medicine, [3]Seoul National University

Background: In our previous randomized controlled trial (RCT), we demonstrated that a 12-week intermittent calorie restriction (ICR) diet effectively reduced liver fat content (LFC) compared to the standard of care (SOC) diet, particularly in patients with obesity. This study aims to investigate the changes in gut microbiome composition following a 12-week dietary intervention in patients with MASLD to identify the underlying mechanisms of this effect. **Methods:** Patients with MRI-proton density fat fraction (PDFF) $\geq 8\%$ were randomly assigned to either the ICR group (5:2 diet) or the SOC group (80% of recommended calorie intake). The primary outcome was the proportion of patients achieving a $\geq 30\%$ reduction in LFC measured by MRI-PDFF. **Results:** ICR increased microbiome diversity and was associated with a reduction in Megamonas (linear discriminant analysis [LEfSe] = 4.14; $P < 0.001$) and Enterobacter (LEfSe = 2.71; $P = 0.01$), while promoting an increase in beneficial bacteria, including Alistipes (LEfSe = 3.87; $P < 0.001$), Clostridium (LEfSe = 3.51; $P = 0.03$), Romboutsia (LEfSe = 3.67; $P = 0.04$), and Lachnospira (LEfSe = 3.16; $P = 0.02$), compared to the SOC group. In patients with obesity, Enterobacter significantly decreased in the ICR group, whereas it increased in the SOC group. Megamonas showed no significant change in the ICR group, whereas it significantly decreased in the SOC group. In patients without obesity, Megamonas significantly decreased in both groups, but the reduction was significantly greater in the ICR group compared to the SOC group. Ruminococcus, Lachnospira, and Parabacteroides increased in the ICR group, whereas no significant changes were observed in the SOC group. In the group with relative LFC reduction $\geq 30\%$, Megamonas and Enterobacter decreased, while Bacteroides and Alistipes increased. However, in the group with LFC reduction $< 30\%$, Megamonas and Enterobacter increased and Lachnospira decreased. **Conclusion:** Changes in gut microbiome could be one of the mechanisms through which ICR contributes to LFC improvement in MASLD patients.

2654 | YOGA IS NON INFERIOR TO EXERCISE IN IMPROVING HEPATIC STEATOSIS IN MASLD - AN OPEN LABEL, NON-INFERIORITY, RANDOMISED CONTROLLED TRIAL

Sunil Taneja[1] Balaraja S[1] Akshay Anand[1] Nancy Sahni[1] Naveen Kalra[1] Vikram Kumar[1] Sweta Rose[1] Arpit Shastri[1] Ganesh CP[1] Dr. Ashwin Vinod[1] Muhammad Uwais Ashraf[1] Kannupriya .[1] Arka De[1] Nipun Verma[1] Madhumita Premkumar[2] Ajay Duseja[1], [1]Postgraduate Institute of Medical Education & Research, [2]Postgraduate Institute of Medical Education & Research,

Background: There is lack of data on efficacy of yoga in improving steatosis in patients with metabolic dysfunction associated steatotic liver disease(MASLD). This study aimed to compare effectiveness of Yoga combined with dietary calorie restriction with Exercise and dietary calorie restriction in reducing hepatic steatosis in MASLD. **Methods:** 110 overweight/obese patients with MASLD with hepatic steatosis(CAP > 248 on transient elastography) were randomized(1:1) into Yoga and Exercise group. Patients were advised Obesity yoga protocol. Duration of yoga session was 1 hour daily for 6 days per week. All the patients were assessed by a dietician and advised dietary calorie restriction of 500-1000 kcal/day using a diet chart according to local dietary practices and culinary tastes. 20 patients in each group underwent MRI PDFF pre and post intervention. Primary outcome was improvement in hepatic steatosis at six months. **Results:** There was a significant reduction in hepatic steatosis 325(305.5-343.5) to 278(268-298), ($p < 0.001$) in yoga group vs 332(307.5-367.5) to 300(277-328.5),($p < 0.001$) in exercise group with higher delta change improvement seen in yoga group compared to control group -47(-65 to-19) versus -27(-55to-9),(p-0.025) at six months. There was significant reduction in MRIPDFF 16.4(12.9-21.23) to 14.4(9.45-17.88,($p < 0.014$) in yoga group vs 17.3 (13.25-22.67) to 15(12.65-22.1),(p-0.065) in exercise group. On logistic regression analysis, delta weight reduction(OR2.36,95%CI 1.49–3.73;p < 0.001) and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

weight loss ≥ 10%(OR1.1,95%CI 1.01- 1.7;p-0.03) were independent predictors of improvement in steatosis. There was significant improvement in weight 80 (74-84.35) to 75(70-79), ($p < 0.001$) in yoga group vs 80 (71-85.5) to 75(67.5-82.25), ($P < 0.001$) in exercise group, BMI 28.09(26.93-30.14) to 26.3(25.25-28.24), ($p < 0.001$) vs 28.273(27-31.54) to 27.7(25.71-29.60), ($p < 0.001$) in exercise group and waist circumference 100(96.5-104.5) to 95(91.5-101), ($p < 0.001$) in yoga group vs 102(96-108) to 99(93-106.5), ($p < 0.001$) in exercise group. There was significant reduction in ALT and delta ALT reduction was more in yoga group-16 (-53.1to -0.5)vs-5(-34 to 3.3) in exercise group(p-0.042). There was significant improvement in fasting insulin, HbA1c, triglycerides, HDL and insulin resistance as measured by HOMA-IR in both groups with no inter-group differences. There was a significant improvement in frailty and sarcopenic obesity seen in yoga group[22 (40%) to 11(20%)](p-0.02) as compared to control group. **Conclusion:** Yoga with dietary calorie restriction, is non-inferior to exercise with dietary calorie restriction in improving hepatic steatosis, liver inflammation, and fibrosis. Additionally, yoga demonstrates significant benefits in improving metabolic parameters, reducing body weight and sarcopenic obesity.

Table-2. Improvement in Hepatic steatosis at six months of follow-up.

Parameters	Diet + Yoga			Diet + Exercise			P value between the groups at six months
	Baseline (n=55)	Six months (n=55)	P value within the group	Baseline (n=55)	Six months (n=55)	P value within the group	
CAP	325.00 (305.50 - 343.50)	278.00 (268.00 - 298.00)	<0.001	332.00 (307.50 - 367.50)	300.00 (277.00 - 328.50)	<0.001	0.022
Δ CAP		-47.00 (-65.00 - -19.00)			-27.00 (-55.00 - -9.00)		0.025
Improvement of steatosis by ≥1 category		32 (58.2%)			15 (27.3%)		0.001
Improvement from severe to moderate steatosis		19(34.5%)			10(18.2%)		0.083
Improvement from severe to mild steatosis		9(16.4%)			4(7.3%)		0.184
Resolution of steatosis (CAP <248dB/m)		4(7.3%)			2(3.6%)		0.401
MR PDFF (20 patients in each group)	16.4(12.9-21.23)	14.4(9.45-17.88)	0.014	17.3(13.25-22.67)	15(12.65-22.10)	0.065	0.632

2655 | A TRADITIONAL MEXICAN DIET AGAINST VIRAL HEPATITIS B AND C, AND MASLD: AN INTEGRATIVE BIOINFORMATIC ANALYSIS

Leonardo Leal-Mercado[1] Arturo Panduro[1] Sonia Roman[1], [1]Universidad de Guadalajara

Background: Viral hepatitis B (HBV), hepatitis C (HCV), and metabolic dysfunction-associated steatotic liver disease (MASLD) are significant causes of cirrhosis and hepatocellular carcinoma (HCC) worldwide. Despite their clinical impact, there is a lack of specific nutritional guidelines for the management of viral hepatitis. Regional diets have been shown to influence liver health positively. In this context, the traditional Mexican diet is rich in bioactive compounds with potential antiviral and hepatoprotective effects. This study aimed to find and examine nutrients from traditional Mexican foods that might affect important biological processes related to HBV, HCV, and MASLD. **Methods:** A comprehensive review of existing research (from PubMed and Google Scholar, 2000–2024) was done to find studies on nutrients from traditional Mexican foods that have antiviral and anti-MASLD effects, including experimental (in silico, in vitro, in vivo) and clinical studies. Next, a detailed analysis using bioinformatics tools like CTD, STRING, DAVID, and Enrichr was performed to see how genes work with these nutrients, how they connect to KEGG pathways, and their links to liver diseases. Data analysis and visualization were done using RStudio. **Results:** Five key foods (maize, beans, chili, tomato, and avocado) were found to influence genes that are important for immune response (*TNF, IL6*), dealing with oxidative stress (*NFE2L2, CAT*), fat metabolism (*PPARA, FASN*), cell death (*BAX, CASP3*), and cancer growth (*TP53*). The functional enrichment analysis indicated that the beneficial compounds in these foods have various effects on important processes like metabolism, antioxidant activity, immune function, tissue formation, and cancer. The network analysis indicated that all five foods were linked to viral hepatitis, MASLD, and HCC, influenced by different beneficial nutrients. The network analysis revealed that distinct bioactive nutrients interconnected all five ingredients with viral hepatitis, MASLD, and HCC. Both viral hepatitis and HCC shared vitamin E as a modulator, and both viral hepatitis and MASLD shared potassium. Lycopene and anthocyanins were associated with both MASLD and HCC. In contrast, folate, monounsaturated fatty acids, and phytosterols were associated with MASLD.

Conclusion: Bioactive compounds in traditional Mexican foods modulate critical pathways in the pathogenesis of HBV, HCV, MASLD, and HCC. These findings support culturally and genome-based nutrition strategies to prevent liver diseases in populations facing limited access to antiviral therapy and high prevalence of metabolic dysfunction diseases.

◆ 3001 | A VALUE-BASED HEALTHCARE DELIVERY MODEL FOR MASH-RELATED COMPENSATED CIRRHOSIS AND OBESITY: INTEGRATED SHARED MEDICAL APPOINTMENTS

Sobia Laique[1] Keren Zhou[1] Yael Mauer[1] Chase Wehrle[1] Christine Eisengart[1] Annmarie Madera[1] Ron Gambino[1] Shannon Browne[1] Kelli Cleary[1] Erka Staneff[1] Marcio Griebeler[1] Jessie Lewis[1], [1]Cleveland Clinic

Background: MASH-related compensated cirrhosis with obesity is a complex, high-burden disease. Current care often lacks the necessary comprehensive, accessible, and multidisciplinary structure to optimize outcomes and manage costs. Value-based healthcare models are vital for delivering efficient, high-quality care to this vulnerable population. **Methods:** A novel three-part monthly Shared Medical Appointment (SMA) series was developed and piloted within a Multidisciplinary MASLD Clinic (MMC) for patients with MASH-related compensated cirrhosis and obesity. The series integrated structured lifestyle interventions with ongoing anti-obesity medication (AOM) management. Each 90-minute SMA session accommodated up to 8 patients and was led by a physician and a facilitator (registered dietician, exercise physiologist, or behavioral psychologist, varying by theme). Session themes were: 1) Nutrition and Dietary Counseling, 2) Exercise and Physical Activity, and 3) Behavioral Health, utilizing Screening, Brief Intervention, and Referral to Treatment (SBIRT) principles. Regular physician oversight and individual check-ins facilitated AOM titration and adjustment, with comprehensive laboratory and lean mass tracking (via SECA DEXA). [Fig 1]This pragmatic approach aimed to integrate with existing care, minimize patient burden, and foster peer support. **Results:** Early pilot data reveal promising initial findings across key tracked areas. Process and efficiency outcomes included rapid patient enrollment (within 4 weeks of MMC referral) and high session utility, with a 94% attendance rate. Patient engagement outcomes were strong, evidenced by high attendance and the formation of a vital peer support group. Early clinical outcomes tracked over the three-month SMA period showed an average of 14% total body weight loss (%TBWL), alongside systematic monitoring of body composition and liver frailty index. Additionally, AOM management outcomes were positive: 91.6% of patients were successfully initiated on AOMs, with 100% adherence among those initiated. The model also effectively facilitated safe, individualized AOM and cardiometabolic disease pharmacotherapy titration and adjustments. **Conclusion:** This innovative and scalable SMA model enhances access to integrated MASH cirrhosis and obesity care by optimizing resources, patient engagement, and clinical oversight, offering a sustainable route to improved clinical outcomes and quality of life for this complex disease.

◆ 3002 | BASELINE SYMPTOM BURDEN AND NETWORK ANALYSIS IN ADULTS WITH PSC, PBC, AND CIRRHOSIS ENROLLED IN THE EMPOWER RCT

Emily Johnson Serena Isley[1] Shaina Corrick[1] Gail Wright[2] Joanne Hatchett[3] Holly Minckler[1] Alan Bonder[4] Mark Swain[5] Prasun Jalal[6] Jennifer Lai[7] Andrew Mason[1] Mina Niazi[8] Cynthia Levy[9] Raj Vuppalanchi[10] Gideon Hirschfield[11] Christopher Bowlus[12] Ben Vandermeer[1] Yinggan Zheng[1] Ashley Hyde[1] Puneeta Tandon[1], [1]University of Alberta, [2]Canadian PBC Society, [3]PSC Partners Seeking a Cure, [4]Harvard University, [5]University of Calgary, [6]Baylor College of Medicine, [7]University of California, San Francisco,

[8]University of Saskatchewan, [9]University of Miami, [10]Indiana University, [11]Toronto General Hospital, [12]University of California, Davis

Background: Fatigue is among the most debilitating and under-treated symptoms in chronic liver disease, significantly affecting quality of life. In Primary Biliary Cholangitis (PBC), Primary Sclerosing Cholangitis (PSC), and cirrhosis, fatigue is common, multidimensional, and closely linked to mental health and frailty. Anxiety and depression are also common yet remain underrecognized and undertreated in hepatology care. However, few studies have examined how these symptoms co-occur or interact across chronic liver disease populations. **Methods:** This is a prespecified subgroup analysis of liver participants (n = 255) enrolled in the 3-arm eMPower RCT (NCT05786482). The eMPower RCT evaluated a 12-week online mind-body wellness intervention combining acceptance and commitment therapy informed strategies, breathwork, meditation, mindful movement, and disease-specific education. Validated baseline surveys assessed fatigue (Modified Fatigue Impact Scale [MFIS]), mental health (Hospital Anxiety and Depression Scale [HADS]), demoralization (Demoralization-II), frailty (online Fried Frailty Phenotype, Edmonton Frail Scale), sleep disturbance (PROMIS Sleep SF-8a), and quality of life (EQ-5D-5L, Short Form-12 (SF-12)). Symptom networks were constructed using LASSO-regularized partial correlations. **Results:** Of 255 participants (PBC: 72.2%; cirrhosis: 20.0%; PSC: 7.8%), mean age was 59 ± 11.1 years, and 88% were female. At baseline, fatigue was moderate to severe (MFIS: 46.7 ± 15.1), with physical fatigue most affected. Mental health symptoms were common, with mean HADS-Anxiety scores of 7.6 ± 3.7 and HADS-Depression scores of 4.9 ± 3.0., Demoralization scores averaged 9.7 ± 6.6, indicating moderate existential distress in the overall sample. Frailty was prevalent, with a mean Fried Frailty score of 2.7 ± 1.4 and EFS score of 6.3 ± 1.8, indicating that many participants were in the pre-frail to mildly frail range, with increased vulnerability to physical and functional decline. Symptom network analysis (Figure 1) revealed three interconnected clusters: 1) mental health, 2) fatigue/frailty, and 3) quality of life. Physical fatigue was the most central node in the network, followed by demoralization-II and SF-12 Mental Component Summary score. **Conclusion:** Baseline data highlight a substantial and overlapping symptom burden among individuals with chronic liver disease, with physical fatigue emerging as the most central and interconnected symptom. These findings support the need for targeted interventions that address fatigue alongside mental health and frailty in liver care.

◆ 3003 | EXPLORE B POST HOC ANALYSIS OF CHRONIC SYMPTOMS IN PATIENTS WITH ACUTE HEPATIC PORPHYRIA

Susana Monroy[1] Manish Thapar[2] Raili Kauppinen[3] Encarna Guillén-Navarro[4] Desmond Murphy[5] Teresa Kauf[5] Weiming Du[5] David Cassiman[6], [1]Centro Médico ABC, Mexico City, Mexico, [2]Thomas Jefferson University, Philadelphia, PA, USA, [3]Helsinki University Central Hospital, Helsinki, Finland, [4]Sant Joan de Deu University Hospital, Barcelona, Spain, [5]Alnylam Pharmaceuticals, Cambridge, MA, USA, [6]University Hospital Leuven, Leuven, Belgium

Background: Acute hepatic porphyria (AHP) is a group of rare disorders with acute attacks of pain, and neurological symptoms, which can lead to altered mental status. Patients have chronic symptoms with significant disease burden, as reported in part B of the observational EXPLORE study, which included patients aged $\geq$12 years with symptomatic AHP ($\geq$1 acute attack in the past 12 months) and/or receiving hemin or gonadotrophin-releasing hormone (GnRH) treatment to prevent attacks. The International Porphyria Network (IPNET) has categorized two profiles of what is referred to as symptomatic AHP, as per their assessments, by attack frequency ($\geq$4 or 1-3 attacks/year [a/y]). **Methods:** This cross-sectional, *post hoc* analysis of baseline EXPLORE B data evaluated chronic disease burden and health-related quality of life (HRQoL) in patients with $\geq$4 a/y or hemin/GnRH use or with $<$4 a/y without hemin/GnRH use. Chronic symptoms (those not necessarily associated with an AHP attack) were self-reported by patients. Pain and its impact were assessed with the Brief Pain Inventory short form (BPI-SF), and HRQoL with the EQ-5D-5L. Results are descriptive, and *p* values are nominal. **Results:** Among 136 patients (mean [SD] age 41.0 [12.6] years; 90.4% female), 100 had $\geq$4 a/y, and 36 had $<$4 a/y. Demographics were similar, and patients with $\geq$4 a/y were older with more years since diagnosis (Table). Most patients in both groups reported chronic symptoms; other than 'trouble sleeping' (higher with $<$4 a/y: odds ratio, 3.52; 95% CI [1.10-11.24]; $p = 0.0276$), no notable between-group differences were observed.

No differences in pain intensity were found in BPI-SF scores, and in 4 of 7 items the impact of pain interfering with daily activities was higher in patients with $\geq$4 a/y than with $<$4 a/y (Table). Pain values were in the mild range, and the mean difference did not exceed the minimal clinically-important difference of 2 points for any item.

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

EQ-5D-5L index scores were slightly worse in patients with ≥4 a/y (p = 0.0253, Table). However, visual analog scale scores and the odds of having moderate or worse problems in any EQ-5D-5L dimension did not differ significantly between groups (all $p > 0.05$, Table). **Conclusion:** Patients in EXPLORE B had chronic symptoms irrespective of which profile of AHP they met. While a greater burden was reported for some outcomes in patients with ≥4 a/y, many were similar between groups. The results suggest a considerable chronic impact of AHP in both patient groups.

Table: Disease Burden and Health-Related Quality of Life

Parameter, mean (SD)*	<4 attacks/year and no hemin/GnRH (n=56)	≥4 attacks/year or hemin/GnRH (n=100)	Mean difference (95% CI) p value

95% CI and p value were calculated from two sample t-test for BPI-SF, EQ-5D-5L index and VAS scores, and from a Mantel-Haenszel chi-square test for EQ-5D-5L dimensions.

Significant p values (p<0.05) are in bold. Pain ranges in the BPI-SF are mild (1-5), moderate (5-6), and severe (7-10). EQ-5D-5L score is derived using the US reference value given for that particular set of responses in the 5 domains. The US reference values are provided in the Crosswalk value dataset associated with this instrument. All EQ-5D-5L scores presented are asymptomatic scores.

◆ 3004 | ASSESSING THE ENVIRONMENTAL IMPACT OF PATIENT TRAVEL TO A LIVER TRANSPLANT CLINIC: CAN WE MAKE THE LIVER TRANSPLANT OUTPATIENT SERVICE MORE SUSTAINABLE?

Mhairi Donnelly[1] Lisa Norman[2] Katherine Connor[2] Zareena Khan-Orakzai[2] Ben Stutchfield[2], [1]Royal Infirmary of Edinburgh, [2]Edinburgh Transplant Centre

Background: The Scottish Liver Transplant Unit (SLTU) is the single referral centre in Scotland for liver transplantation. Patients travel long distances to attend the transplant clinic. Our specialty is increasingly aware of the need to reduce our carbon footprint. This study aimed to assess the carbon footprint of patient travel to the SLTU clinic (a suspected carbon hotspot), and the potential carbon savings offered by virtual consultations and outreach services. **Methods:** A one year period was studied, 09/06/2022-08/06/2023. A travel questionnaire was distributed to patients attending one in-person SLTU clinic to provide an accurate snapshot of travel-related emissions. A carbon footprint calculator for (avoided) patient travel produced by the Centre for Sustainable Healthcare was used for virtual and outreach consultations. **Results:** The carbon footprint of patient travel to one SLTU clinic (calculated using questionnaire data) was 753kg CO2e. Extrapolated to 102 clinics per year, patient-related travel created 76,806kg CO2e (equivalent to 22 economy class return flights from London to Hong Kong).

218 virtual consultations were delivered via SLTU over this year, saving 7080kg CO2e and 29,762 miles travelled.

Patients seen in outreach clinics do not travel to SLTU; outreach appointments resulted in 164,761 avoided miles, and 43,965kg CO2e saved compared with travel to SLTU. These patients still travelled to their outreach centre however, so overall the total saving was 130,670 avoided miles and 34,634kg CO2e.

Patients seen in outreach clinics are well and may be suitable for virtual consultations. If all outreach appointments were delivered virtually, instead of patients attending their local centre, this would avoid 34,091 patient miles travelled and save 9331kg CO2e. **Conclusion:** Delivery of an in-person clinic in the transplanting centre is associated with a significant carbon footprint through patient travel. Patient travel is a carbon hotspot, which could be addressed by using novel technology to deliver more virtual appointments.

◆ 3005 | EUS-SHEAR WAVE ELASTOGRAPHY EFFECTIVELY EXCLUDES ADVANCED CHRONIC LIVER DISEASE DURING ROUTINE EUS PROCEDURES

Umang Arora[1] SHIVAM KHARE[1] Shrihari Anikhindi[1] Ashiesh Khandelwal[1] Ashish Kumar[1] Praveen Sharma[1] Naresh Bansal[1] Anil Arora[1], [1]Sir Ganga Ram Hospital

Background: Noninvasive assessment of liver stiffness is essential for evaluating hepatic fibrosis. While transient elastography (TE, FibroScan®) is widely established, endoscopic ultrasound shear wave elastography (EUS-SWE) offers potential advantages, particularly in patients already undergoing EUS for other indications. This study aimed to assess the agreement between EUS-SWE and FibroScan liver stiffness measurements (LSM), and to evaluate the diagnostic accuracy of EUS-SWE for identifying advanced chronic liver disease (ACLD). **Methods:** In this cross-sectional study, consecutive patients undergoing EUS evaluation between Jan-May 2025 for any indication (liver biopsy, lymph node sampling, pancreatitis evaluation) in the absence of biliary obstruction were included. Liver stiffness was measured in the right hepatic lobe using EUS-SWE with the Olympus ME3 system, and by FibroScan (Echosens) using the standard M or XL probe at the right midaxillary line. The median of ten valid measurements was used for each modality. Correlation analysis was performed using Spearman's method. Agreement between the two modalities was assessed using Bland-Altman analysis. For assessing clinical utility, we categorized patients as having high likelihood of advanced chronic liver disease (ACLD) based on LSM values >15 kPa (Baveno criteria). The ability of EUS-SWE to predict ACLD was evaluated using area under the receiver operating characteristic curve (AUROC) analysis and Liu's method to identify optimum threshold. **Results:** Among 139 patients identified in the cohort, 128 patients with complete LSM and EUS-SWE data were analyzed. The mean age was 45 ± 14 (range 14 – 83) years, and 30% were female. The median LSM by TE was 5.8 kPa (range: 3–49 kPa), with 48 and 32 patients fulfilling criteria for advanced fibrosis (LSM ≥ 8 kPa) and cirrhosis (LSM ≥ 12 kPa), respectively. Spearman's correlation analysis demonstrated a moderate positive correlation between EUS-SWE and FibroScan LSM measurements ($\rho = 0.61$, $P < 0.001$). Bland-Altman analysis demonstrated a mean percentage difference of 35.4%, with 95% limits of agreement from –67.34% to 138.3% (Figure 1). Diagnostic accuracy for EUS-SWE in predicting ACLD was 0.90, indicating excellent diagnostic performance, at an optimum threshold of 15.5 kPa. Visual inspection of the Bland-Altman plot, as well as a positive regression slope of 0.15 for the difference against the mean, indicated the presence of proportional bias, with greater differences observed at higher liver stiffness values. **Conclusion:** EUS-Shear Wave Elastography (EUS-SWE) tends to overestimate liver stiffness compared to FibroScan and demonstrates only moderate agreement, suggesting the two modalities are not interchangeable. Nevertheless, incorporating EUS-SWE into routine EUS procedures may offer clinical value in excluding advanced chronic liver disease in patients undergoing EUS for unrelated indications.

◆ 3006 | THE NATIONAL UNDER-UTILIZATION OF HEPATOCELLULAR CARCINOMA ADHERENCE AND ITS PREDICTORS IN THE UNITED STATES

Dominic Vitello[1] Mitchell Paukner[2] Laura Kulik[3] Saad Hussain[1] Bima Hasjim[4] Aditya Jain[5] Andres Duarte-Rojo[6] Filip Obradovic[5] Joy Obayemi[7] Federico Crippa[5] Michael Gmeiner[8] Therese Banea[5] Oriana Dentici[5] Lihui Zhao[5] Charles Manski[5] Daniela Ladner[5], [1]Northwestern University Feinberg School of Medicine, [2]Wake Forest University School of Medicine, [3]Northwestern Medical Faculty Foundation, [4]University of California, Irvine, [5]Northwestern University, [6]Northwestern Medicine, [7]University of Michigan / Northwestern University, [8]London School of Economics and Political Science

Background: National guidelines recommend hepatocellular carcinoma (HCC) surveillance every 6 to 8 months for patients with cirrhosis. However, rates of adherence are estimated to be extremely low. This study aimed to determine the rate of HCC surveillance adherence and identify its predictors. **Methods:** Validated ICD-9/-10 codes were used to identify patients with cirrhosis between 2011-2020 within a large, national, insurance, claims database. Clinicodemographic factors were also identified including cirrhosis

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

etiologies and decompensation. CPT-identified surveillance exams included serum alpha fetoprotein level with an abdominal ultrasound (AFP with US) or contrast-enhanced CT or MRI. Patients were considered adherent for 8 months following any surveillance exam. A multivariable generalized linear mixed-effects model was used to identify predictors of HCC surveillance adherence. **Results:** 270,686 patients were included in the analysis. Among other etiologies, 95,618 (35.3%) had metabolic dysfunction-associated steatotic liver disease (MASLD) and 21,084 (7.8%) had hepatitis C-associated (HCV) cirrhosis. Patients were followed for a mean (SD) of 3.9 (2.5) years. During follow up, 81,737 (30.2%) had a gastroenterology visit and 14,828 (5.5%) developed HCC. Within the 12 months following cirrhosis identification, 26,825 (9.9%) had an AFP with US, 24,406 (9.9%) had an MRI, and 14,635 (5.4%) had a CT. Only 97,102 (35.9%) patients ever received any surveillance over the entire course of follow-up. Figure 1 shows the longitudinal rate of adherence. Following with gastroenterology (OR 7.1 CI 7.0-7.2), having HCV cirrhosis (OR 3.0 CI 2.9-3.1), and decompensation (OR 1.4 CI 1.3-1.5) were significant predictors of better HCC surveillance adherence. MRI was the costliest mode of surveillance at $486.00 on average per exam, followed by CT ($278.70) and US ($114.90). Fewer than 2% of claims were denied. **Conclusion:** Despite its reported benefits, in this study of a large, national, insured cohort of patients with cirrhosis, HCC surveillance adherence was estimated to be low. Following with a gastroenterologist was a significant predictor of higher adherence. Further involvement of gastroenterologists and heightened incentives for patients are needed to maximize the population-level benefits of HCC surveillance.

◆ 3007 | DEVELOPMENT AND FEASIBILITY OF A PATIENT-REPORTED EXPERIENCE SURVEY FOR OUTPATIENTS WITH LIVER DISEASE

Oliver Tavabie[1] Amy Johnson[2] Felicity Williams[3] Vanessa Hebditch[4] Safa Al-Shamma[5] Dina Mansour[6], [1]Leeds Liver Unit, [2]Northumbria Healthcare NHS Foundation Trust, [3]University of Birmingham, [4]British Liver Trust, [5]University Hospitals Dorset, [6]Gateshead Health NHS Foundation Trust

Background: In the United Kingdom, regional variations in care provision and outcomes for patients with liver disease have been repeatedly highlighted. Whilst initiatives, such as Improving Quality in Liver services, as well as care bundles have been developed to address variation, there is currently no standardised patient-reported experience tool for outpatient services. This presents a challenge when comparing service provision. We aimed to develop a patient-reported experience survey (PRES) and undertake a feasibility study to understand the challenges in delivering it in the outpatient setting. **Methods:** A PRES working group was developed with healthcare professionals (HCP) from specialist and non-specialist centres, trainee, allied health professional and patient charity representatives. A survey was developed utilising existing literature. Patient feedback was provided from the British Liver Trust and HCP feedback was provided from the British Society of Gastroenterology Liver Section and Quality Standards working group. The PRES was then trialled for one month at Leeds Teaching Hospitals (LTH),

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

University Hospitals Dorset (UHD) and Gateshead Health NHS Foundation Trust (GH). Projected margin of error was calculated with a target of $<10\%$ to demonstrate adequate power. **Results:** 122/1182 surveys were completed (65/848 LTH, 27/146 UHD, 30/188 GH). Margin of error for the entire sample was 8.4% meaning commonalities across sites were likely true. However, individual site margin of error was greater than 10% (LTH 11.7%, UHD 17.1%, GH 16.5%) which prevented comparison between sites. Most PRES responses were online with 22.1% completed through written format. Responses were predominately from patients with face-to-face appointments with 12.3% of respondents from telephone appointments. Appointments were mostly with Consultants (61.5%) although a broad range of HCPs were represented. 9.8% of respondents saw an HCP that they were not expecting to see.

Most respondents were happy with their overall care. All patients felt like they were treated with respect and knew why they were being seen and why tests were taken. 1.6% were unsure if they were involved with decisions around their care. 6.6% did not know how to raise questions following the appointment. 9.0% were dissatisfied with frequency of appointments. Free-text comments highlighted the challenges in seeing their team frequently enough (particularly face-to-face appointments) and with communication of appointments and tests. **Conclusion:** We have developed a PRES which can be utilised to understand patient experience of outpatient encounters. Further work is required to improve engagement with surveys to allow for this tool to be used to benchmark services.

◆ 3008 | HEPATITIS C DETECTION TO PREVENT LIVER DISEASE: IMPLEMENTATION OF OPT-OUT SCREENING WITHIN A SOUTH TEXAS EMERGENCY DEPARTMENT

Makayla Tey[1] Racquel Owino[1] Serena Gaultier-Soliz[1] Dianita Gamino[1] Delana Gonzales[1] Ralph Riviello[2] Tatiana Emanuel[2] Anna Taranova[1], [1]University Health, [2]University Health Science Center San Antonio

Background: Hepatitis C virus (HCV) remains a significant public health challenge with 40% of individuals unaware of their status until late stage liver disease. Emergency departments (ED) often serve as a primary point of care for underserved populations, providing a critical opportunity for early identification and linkage to care. Opt-out HCV testing in the ED is a strategy to increase detection rates among high risk and underdiagnosed groups. University Health (UH) is the only Level I trauma center in South Texas providing the highest level of care in the San Antonio community. **Methods:** UH implemented an opt-out HCV screening program in the ED. Providers notified of eligible patients via silent Best Practice Advisory via the electronic medical record (EMR). All patients aged 18 years and older were screened for HCV antibody with reflex to RNA testing to identify an active infection. EMR data was used to identify positive individuals and collect diagnosis data. Patients with confirmed RNA-positive results were notified of their diagnosis and referred to a patient navigator to facilitate linkage to care. **Results:** From March 2024 to March 2025, 20,637 individuals were tested for HCV in the ED. Among those screened, 17.3% (n = 1190) were antibody positive and 2.9% (n = 594) were RNA confirmed positive. Of confirmed positives 41.4% (n = 246) is a new diagnosis, 55.4% (n = 329) have a history of HCV and 3.2% (n = 19) have an unknown history of HCV. Of these, 22.6% (n = 134) were linked to care and 77.4% (n = 460) were either unreachable, incarcerated, pending diagnosis notification or deceased. **Conclusion:** Opt-out HCV testing in the ED significantly increased case identification, highlighting the ED's role as a key access point for HCV screening. There is a need for improved linkage to care among the vulnerable and transient populations however substantial barriers remain in linking patients to care to prevent liver disease.

◆ 3009 | LARGE-LANGUAGE-MODEL-ASSISTED VALIDATION OF ICD-10-CM CODES FOR LIVER DISEASE IN 865,079 DOCUMENTATIONS

Yichen Wang[1] Yan Yan[1] Yuting Huang[2], [1]Mayo Clinic, [2]Mayo Clinic Florida

Background: Robust health-services and population studies increasingly depend on administrative datasets,

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

yet the fidelity of International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) codes remains uncertain and manual chart review is impractical at scale. Ensuring that coded diagnoses truly mirror what was documented is critical for accurate disease surveillance, reimbursement, quality benchmarking, and resource planning in hepatology and public-health programs. **Methods:** We applied a GPT-4o-based text-analysis pipeline – built with iterative prompt optimization and majority-vote aggregation – to MIMIC-IV, a de-identified database containing full clinical text and corresponding ICD-10-CM assignments. For each code we calculated the positive predictive value (PPV), defined as the proportion of assigned codes whose target condition was explicitly documented in the source note. Performance metrics were benchmarked against physician adjudication in a 971-record validation set. **Results:** GPT-4o accurately confirmed or rejected codes (overall accuracy 97.8%, sensitivity 98.5%, specificity 94.5%). Among 865,079 total codes, 15,614 (1.8%) were liver-related. Etiology distribution was: alcohol-associated liver disease (ALD) 2,343 (15.0%), metabolic dysfunction-associated fatty liver disease or steatotic hepatitis (MAFLD/MASH) 1,448 (9.3%), hepatitis C 615 (3.9%). Stage distribution was: acute liver failure 392 (2.5%), compensated cirrhosis 1,751 (11.2%), decompensated cirrhosis 3,861 (24.7%), hepatocellular carcinoma 726 (4.7%) (Table 1). Liver codes showed higher PPV than non-liver codes at any diagnostic position (90.2 % vs 84.5 %; OR 1.69, 95 % CI 1.60-1.78; $p < 0.001$) but similar PPV when listed as the principal diagnosis (94.0 % vs 93.9 %; OR 1.01, 95 % CI 0.81-1.27; $p = 0.903$). Within liver codes, PPV varied by condition: ALD 92.7 %, hepatitis C 95.3 %, MAFLD/MASH 84.5 %, toxic/drug-induced liver injury 78.7 %, and acute liver failure 66.8 % (Table 2). Detailed PPVs for every individual ICD-10-CM code are available at https://huggingface.co/datasets/wangyichen25/ICD-10-CM_Validation_Results.

Conclusion: Most liver-related ICD-10-CM codes faithfully captured the underlying clinical conditions and out-performed non-liver codes, supporting their use in large-scale health-services research and public-health monitoring. Nevertheless, the lower reliability observed for emerging metabolic entities, toxic/drug-induced injury, and acute liver failure highlights priority areas for coder education and refinement of coding guidelines, reinforcing the need for ongoing validation to maintain data quality across administrative datasets.

Table 1. Distribution of liver-related ICD-10-CM codes (N = 15 614)

Category	ICD-10-CM group(s)	n	% of liver codes
Etiology			
Alcohol-related	K70.*	2 343	15
MAFLD / MASH	K75.81, K76.0	1 448	9.3
Hepatitis C	B17.1, B18.2	615	3.9
Hepatitis B	B16.*, B18.0, B18.1	371	2.4
Cholestatic (PBC/PSC)	K74.3, K83.01	131	0.8
Autoimmune hepatitis	K75.4	171	1.1
Metabolic (HH, Wilson, A1AT)	E83.11, E83.01, E88.01	218	1.4
Malignancy (HCC, ICC)	C22.*	726	4.6
Toxic / drug-induced	K71.*	141	0.9
Congenital (biliary atresia)	Q44.2*	2	< 0.1
Other / unspecified	Various‡	9 448	45.7
Total		15 614	100
Stage			
Acute liver failure	K72.0*	392	2.5
Compensated cirrhosis	K74.3–K74.6	1 751	11.2
Decompensated cirrhosis / PHT	I85., K72.1, K76.6, R18*	3 861	24.7
Hepatocellular carcinoma	C22.0	726	4.6
Other liver disease (non-cirrhotic)	K70., K73., K75.*, etc.	8 884	56.9
All liver codes		15 614	100

† Liver-specific codes that did not map neatly to an etiology category (e.g., K76.2, K76.8).
‡ Includes broad descriptors such as "unspecified chronic liver disease."
Abbreviations: ALD, alcohol-associated liver disease; A1AT, alpha-1 antitrypsin; CI, confidence interval; HCC, hepatocellular carcinoma; HH, hereditary haemochromatosis; ICC, intrahepatic cholangiocarcinoma; ICD-10-CM, International Classification of Diseases, Tenth Revision, Clinical Modification; MAFLD, metabolic dysfunction-associated fatty liver disease; MASH, metabolic dysfunction-associated steatohepatitis; PBC, primary biliary cholangitis; PSC, primary sclerosing cholangitis; PHT, portal hypertension

Table 2. Positive-predictive value (PPV) of liver-related ICD-10-CM codes

	n	Correct	PPV %	95 % CI
Etiology				
Hepatitis C	615	584	95.0	92.9 – 96.4
Hepatitis B	371	346	93.3	90.2 – 95.4
Alcohol-related	2 343	2 107	89.9	88.6 – 91.1
MAFLD / MASH	1 448	1 224	84.5	82.6 – 86.3
Cholestatic (PBC / PSC)	131	116	88.6	82.0 – 93.0
Autoimmune hepatitis	171	162	94.7	90.3 – 97.2
Metabolic (HH, Wilson, A1AT)	218	181	83.0	77.5 – 87.4
Malignancy (HCC, ICC)	726	699	96.3	94.6 – 97.4
Toxic / drug-induced	141	111	78.7	71.3 – 84.7
Congenital (biliary atresia)	2	2	100.0	34.2 – 100.0
Other / unspecified	9 448	8 550	90.5	89.9 – 91.1
All liver codes	15 614	14 082	90.2	89.6 – 90.8
Stage				
Acute liver failure	392	262	66.8	62.03 – 71.31
Compensated cirrhosis	1 751	1 636	93.4	92.17 – 94.50
Decompensated cirrhosis / PHT	3 861	3 648	94.5	93.72 – 95.16
Hepatocellular carcinoma	726	699	96.3	94.64 – 97.43
Other liver disease (non-cirrhotic)	8 884	7 837	88.2	87.53 – 88.87
All liver codes	15 614	14 082	90.2	89.60 – 90.76

PPV = positive predictive value (true-positive codes ÷ total codes).

◆ 3010 | REDUCING ROUTINE CONSULTATION WAIT TIMES AT A LARGE TERTIARY CARE OUTPATIENT HEPATOLOGY CLINIC

Ofodile Joe-Uzuegbu[1] Stephen Congly[1] Peter Wang[2] Alexandra Frolkis[1] Meredith Borman[1] Matthew Sadler[2] Kelly Burak[2] Laura Stinton[1] Carla Coffin[1] Mark Swain[2] Henry Nguyen[2] Abdel-Aziz Shaheen[1] Mayur Brahmania[1] Alex Aspinall[2], [1]University of Calgary Cumming School of Medicine, Calgary, AB, [2]University of Calgary

Background: Prolonged wait times for outpatient hepatology consultations can negatively affect patient outcomes and healthcare system efficiency. This quality improvement (QI) project aimed to reduce the median wait time for routine referrals from 79 weeks to 39 weeks (a 50% reduction). **Methods:** The QI project took place at Foothills Medical Centre Hepatology Clinic in Calgary, Alberta, which serves a catchment population of over 1.5 million residents. Between October 2023 and April 2025, five Plan-Do-Study-Act (PDSA) cycles were implemented: (1) re-coding and reorganization of referral diagnoses using ICD-10 classifications; (2) establishment of a dedicated hepatitis B virus (HBV) clinic to address high referral volume in this subgroup; (3) development of optimized triage guidelines for the Central Access and Triage (CAT) system to eliminate redundancies and ensure acuity-aligned prioritization; (4) structured waitlist management processes, including new protocols to fairly remove long-standing inactive referrals while ensuring equitable access to care; and (5) re-triaging benign liver neoplasm cases back to primary care with management guidelines. **Results:** Routine wait times decreased steadily over the study period, with special cause variation first observed in June 2024 and sustained improvement from February to April 2025. By April 2025, the median wait time for routine cases decreased from 78.4 to 32.9 weeks (Figure 1). Notably, although the intervention was designed to address routine wait times, its system-wide effects contributed to significant reductions in urgent wait times (from 28.3 to 4.9 weeks), while preserving access for emergent cases (stable at 2.1 weeks). Overall, the waitlist size declined from 1,426 to 252 patients, a reduction of over 80%. Statistical process control (SPC) charts were used throughout to monitor variation and system stability (Figure 1). **Conclusion:** A multi-pronged, data-driven, and clinically aligned QI project supported by leadership and embedded within clinic workflows can significantly reduce wait times without compromising timely access for higher-priority patients.

Figure 1: Statistical process chart showing sustained reduction in wait times for routine cases.

◆ 3011 | BURDEN OF CHRONIC LIVER DISEASE AND CIRRHOSIS BY ETIOLOGY IN U.S. VETERANS

Akshatha Kiran[1] Pedro Ochoa-Allemant[2] Catherine Mezzacappa[3] David Kaplan[2] Nadim Mahmud[4], [1]Hospital at the University of Pennsylvania, [2]University of Pennsylvania, [3]Yale University, [4]Hospital of the University of Pennsylvania

Background: Steatotic liver disease, encompassing metabolic dysfunction-associated steatotic liver disease (MASLD), alcohol-associated liver disease (ALD), and metabolic and alcohol-associated liver disease (MetALD), is the leading cause of liver disease worldwide. The epidemiology of chronic liver disease and cirrhosis according to the revised nomenclature is incompletely characterized. This study aimed to determine temporal trends and distribution of underlying etiologies of chronic liver disease and cirrhosis over the past decade in the Veterans Health Administration (VHA). **Methods:** We conducted a retrospective cohort study of adults with newly diagnosed chronic liver disease (imaging-confirmed steatosis or primary liver disease) and cirrhosis (at least 1 inpatient or 2 outpatient ICD codes) receiving care in the national VHA between 2010 and 2020. Etiology of liver disease was determined using a previously validated hierarchical approach incorporating laboratory values, vital signs, anthropometric measurements, diagnosis codes, and validated alcohol use assessments. We quantified annual incident cases of chronic liver disease and cirrhosis and examined changes in distribution of underlying liver disease etiologies over time. **Results:** Between 2010 and 2020, incident chronic liver disease due to MASLD increased by 70%, rising from 374,020 to 623,520 cases (absolute increase, 20,994 per year; 95% CI, 8,345 to 33,644; $P = 0.005$). In contrast, the number of incident cases of chronic liver disease due to hepatitis C virus (HCV) infection gradually declined, from 110,180 to 14,520 cases (absolute decrease, 6,868 per year; 95% CI, -10,212 to -3,523; $P = 0.001$). By 2020, MASLD accounted for over 70% of all newly diagnosed cases of chronic liver disease. In comparison, the number of incident cases of cirrhosis due to HCV infection progressively increased through 2015, followed by a drastic decline thereafter, from 5,292 to 1,258 cases (absolute decrease, 791 per year; 95% CI, -947 to -635; $P < 0.001$). Since 2017, MASLD has become the leading cause of newly diagnosed cases of cirrhosis. There were no substantial changes in the number of incident cases of chronic liver disease or cirrhosis due to other liver disease etiologies over the study period. **Conclusion:** The burden of chronic liver disease and cirrhosis have changed over the past decade in the VHA. MASLD has emerged as the main cause of both chronic liver disease and cirrhosis. Cirrhosis due to HCV infection has notably declined since 2015. These epidemiological shifts reflect the success of the highly effective direct-acting antiviral therapies and underscores the importance of early identification and treatment of MASLD to prevent progression of disease.

◆ 3012 | SOCIAL RISK PHENOTYPES PREDICT STAGE, TREATMENT, AND MORTALITY IN HEPATOCELLULAR CARCINOMA: A LATENT CLASS ANALYSIS

Lauren Nephew[1] Allie Carter[2] Katherine Ross-Driscoll[3] Dipika Gupta[4], [1]Indiana University, [2]Department of Biostatistics, IUSM, [3]Department of Surgery, IUSM, [4]Indiana University School of Medicine-Northwest, Gary, IN, United States

Background: Disparities in hepatocellular carcinoma (HCC) outcomes are shaped by intersecting social determinants of health (SDOH), but most studies assess individual risk factors in isolation. We hypothesized that patients cluster based on SDOH into distinct social risk phenotypes associated with differences in cancer stage at diagnosis, treatment receipt, and mortality. **Methods:** We analyzed data from 4,117 adults diagnosed with HCC in the Indiana State Cancer Registry (2009–2020). Latent class analysis (LCA) was used to empirically identify social risk profiles using sex, race, insurance, marital status, occupation, neighborhood Social Deprivation Index (SDI), and geographic access to care. Outcomes included early-stage diagnosis, curative therapy receipt, and two-year mortality. Associations were assessed using logistic regression. **Results:** Among 4,117 patients, 74% were men, 26% women, and15.8% non-White. Most were publicly insured

(67.6%), and 54.9% were unemployed, retired, or disabled. Just over half had localized disease (51.1%), 16.2% received curative therapy, and 67.4% died within two years. LCA identified six distinct social risk classes with variation in structural and geographic characteristics (Figure 1A). Class 1 ("Minimal Barriers") had the best outcomes while Class 6 ("Unseen and Uninsured") had the worst with 55.4% vs. 39.7% early diagnosis, 24.4% vs. 10.5% curative therapy, and 55.4% vs. 83.6% mortality. The OR for 2-year mortality for Class 6 vs. Class 1 was 4.12, (95% CI 3.06–5.54). Rural patients (Class 4) and racially marginalized, publicly insured patients (Class 5) also had lower odds of early detection and treatment. When grouped into three tiers, outcomes declined progressively: Tier 1 (Classes 1–3) had 60.2% early-stage diagnosis, compared to 47.6% in Tier 2 (Class 4) and 39.7% in Tier 3 (Classes 5–6) (Figure 1B).

Figure 1 Legend

Panel A illustrates the distribution of demographic, socioeconomic, and geographic variables that informed an empirically derived latent class analysis. This analysis identified six distinct social risk phenotypes.

Panel B presents odds ratios for key clinical outcomes (e.g., early-stage diagnosis, treatment receipt, mortality) by class, demonstrating clear gradients in disease burden and care access. **Conclusion:** Social risk phenotypes were strongly associated with stage, treatment, and mortality in HCC. These findings support the use of risk-based stratification to guide tailored, scalable strategies to improve early detection and outcomes.

◆ 3013 | A NOVEL CLINICAL TOOL FOR DECOMPENSATION PREDICTION AND RISK STRATIFICATION IN CIRRHOSIS

Dominic Vitello[1] Federico Crippa[2] Saad Hussain[1] Saad Hussain[1] Bima Hasjim[3] Filip Obradovic[2] Joy Obayemi[4] Gil Peled[2] Melvin Adams[2] Paola Barrios Martinez[1] Aditya Jain[2] Kelly Bates[1] Michael Gmeiner[5] Andres Duarte-Rojo[6] Laura Kulik[7] Therese Banea[2] Oriana Dentici[2] Lihui Zhao[2] Lisa VanWagner[8] Charles Manski[2] Daniela Ladner[1], [1]Northwestern University Feinberg School of Medicine, [2]Northwestern University, [3]University of California, Irvine, [4]University of Michigan / Northwestern University, [5]London School of Economics and Political Science, [6]Northwestern Medicine, [7]Northwestern Medical Faculty Foundation, [8]University of Texas Southwestern Medical Center

Background: Care for patients with cirrhosis is chronic, complex, and costly. There are no tools available to stratify decompensation risk in a generalizable cirrhosis population. The aim was to develop a model for decompensation risk that can be used as a clinical decision support tool. **Methods:** Validated ICD-9, -10, and CPT codes were used identify patients with baseline compensated cirrhosis between 2012-2023 within a large, national, insurance, claims database. Demographics, cirrhosis etiology, and laboratory values were also identified. Multivariable logistic regression was used to predict 6- and 12-month decompensation risk. The model was internally temporally cross-validated. **Results:** 188,526 patients were included. 50.8% were male with a median age of 63. Among other etiologies, 47.1% had metabolic dysfunction-associated liver disease (MASLD), 14.2% had hepatitis C-associated liver disease (HCV) 12.2% had MASLD with increased alcohol intake (MetALD), 8.3% had biliary cirrhosis, and 2.1% had alcohol-associated liver disease (ALD). 9,841 (5.2%) and 18,907 (11.3%) decompensated by 6 and 12 months respectively. The model had excellent calibration in derivation and validation sets, with predicted risks within 0.8% of true risk, on average (Figure 1a). The 12-month decompensation risk was highest for those with ALD (OR 1.9 95% CI 1.6-2.3) and MetALD (OR 1.3 95% CI 1.1-1.5), but lowest for those with biliary cirrhosis (OR 0.5 95% CI 0.4-0.6). The presence of hepatocellular carcinoma (OR 1.9 95% CI 1.6-2.2) or chronic kidney disease requiring dialysis (OR 1.4 95% CI 1.1-1.7) conferred substantial increases in risk (Figure 1b). **Conclusion:** The risk of decompensated

◆ 3014 | PERSISTENT USE OF MEDICATIONS FOR ALCOHOL USE DISORDER IN ALL OF US PARTICIPANTS

Phuc Le[1] Yihua Yue[1] Michael Rothberg[1] Daniel Jonas[2] Hamlet Gasoyan[1] Sudie Back[3] Ha Tran[1] Olajide Adekunle[1] Katharine Bradley[4], [1]Cleveland Clinic, [2]Ohio State University College of Medicine, [3]Medical University of South Carolina, [4]Kaiser Permanente Washington Health Research Institute

Background: Pharmacotherapy for alcohol use disorder (AUD) is effective yet underutilized. While the initiation of medications has been studied, less is known about the persistence of AUD medication use. **Methods:** We conducted a retrospective cohort study using the All of Us nationwide database (N = 633,540 participants with data up to September 2023) to assess AUD medication persistence. Adults (aged ≥ 18 years) with any AUD diagnosis who received ≥ 1 prescription for FDA-approved medications (naltrexone, acamprosate, or disulfiram) were included. Persistent AUD medication treatment was defined as orders for AUD medication(s) covering ≥ 180 continuous days (with < 20% or 36 days total gap, i.e. days without medication). Descriptive analyses compared characteristics between patients with ≥ 1 persistent episode and those without. Multivariable mixed-effects logistic regression was used to examine factors associated with persistence, adjusting for demographic, socioeconomic, and clinical characteristics, with a random intercept to account for patient-level clustering. Analyses were restricted to treatment episodes that began in 2010 or later and were shorter than three times the standard deviation of the overall mean episode length. **Results:** Among 26,211 patients with AUD identified from the database, 3,457 patients were treated with 46,121 episodes (median 2 per patient ever treated). Over one-third of patients (N = 1,236) had ≥ 1 treatment episode lasting ≥ 180 days ("persistent treatment"), but most episodes (N = 44,354; 96.2%) were < 180 days. Compared to those without persistent treatment, patients with ≥ 1 persistent episode were more likely to be non-Hispanic White, employed, married, have a college degree or higher, annual income > $100k, and private insurance, and reside in the least deprived areas (1st quintile of the Area Deprivation Index—ADI). In the multivariable model, factors associated with decreased odds of persistent treatment included having a substance use disorder (OR = 0.72; 95% CI: 0.61-0.85), annual income < $10k (OR = 0.66; 95% CI: 0.45-0.96), living in 2nd-4th ADI areas, and having VA (OR = 0.41; 95% CI: 0.30-0.56) or no insurance (OR = 0.56; 95% CI: 0.38-0.83). In contrast, receipt of individual psychotherapy sessions was associated with higher odds of persistence (OR = 1.51; 95% CI: 1.23-1.86). **Conclusion:** Persistent treatment with AUD medications remains uncommon, with < 4% of episodes lasting ≥ 180 days. People with low income, living in more deprived areas, having VA or no insurance, and substance use disorder were less likely to be persistent, while individual psychotherapy sessions were positively associated with persistence. These findings emphasize the need to address barriers to sustained pharmacotherapy for AUD.

◆ 3015 | THE PREVALENCE AND IMPACT OF ALZHEIMER'S AND RELATED DEMENTIA ON CIRRHOSIS: A RETROSPECTIVE STUDY USING REAL-WORLD DATA

Sijia Wei[1] Suyangpeng Zhang[2] Saad Hussain[3] Salva Balbale[4] Oriana Dentici[3] Alona Furmanchuck[4] Nikhilesh Mazumder[5] Lisa VanWagner[6] Liui Zhao[4] Andres Duarte-Rojo[7] Sanjay Mehrotra[2] Daniela Ladner[1] CAPriCORN Consortium[8], [1]Department of Surgery, Northwestern University Feinberg School of Medicine, [2]McCormick School of Engineering and Applied Science, Northwestern University, [3]Northwestern University Transplant Outcomes Research Collaborative, [4]Northwestern University Feinberg School of Medicine, [5]Department of Gastroenterology, University of Michigan, [6]Department of Medicine, University of Texas Southwestern Medical Center, [7]Northwestern Medicine, [8]CAPriCORN Consortium

Background: Alzheimer's and related dementia (ADRD) complicate cirrhosis management; particularly, its symptoms overlap with hepatic encephalopathy. However, ADRD prevalence and impact on cirrhosis remain unclear. This study examined ADRD prevalence and its association with mortality and 1-year hospitalization in cirrhosis after ascertaining ADRD diagnostic certainty. **Methods:** We retrospectively analyzed 36,971 patients diagnosed with cirrhosis between 2011 and 2021 at seven health systems in a US metropolitan area using electronic health records data. ADRD diagnosis and diagnostic certainty were determined using ICD-9/10 codes, medications, specialist involvement, and diagnostic timing. Multivariable logistic regressions and the Cox proportional hazards models assessed ADRD risk factors and ADRD influence on mortality and hospitalization. **Results:** The cohort had a mean age of 59.6 years, with 41.9% female, 43.0% White, 21.8% Black, and 20.6% Hispanic. Common etiologies included MASLD (24.0%), MetALD (20.4%), HCV (13.9%), and ALD (10.3%), with a mean MELD score of 15.5 and Charlson Comorbidity Index of 6.8. At initial cirrhosis diagnosis, 2.0% (n = 727) had an ADRD diagnosis. After adjusting for covariates, having ADRD was associated with increased risk of mortality (HR = 1.81, $p < 0.001$) and likelihood of 1-year hospitalization (OR = 2.60, $p < 0.001$) in compensated, but not in decompensated cirrhosis (HR = 0.89, $p = 0.44$; OR = 1.44, $p = 0.12$). Key factors associated with ADRD diagnosis and outcomes included age, MetALD, ALD, and Area Deprivation Index. **Conclusion:** Early detection and management of ADRD and developing tailored interventions based on the underlying mechanisms of cognitive decline may improve cirrhosis outcomes. Further development of new psychometric tools to better differentiate ADRD from HE in routine care is needed.

◆ 3016 | SARCOPENIA, OBESITY, AND THEIR ASSOCIATIONS WITH INCIDENT CIRRHOSIS, HEPATOCELLULAR CARCINOMA, AND LIVER-RELATED MORTALITY: SYNERGISTIC RISK OF SARCOPENIA AND ALCOHOL IN A METABOLICALLY AT-RISK POPULATION: A PROSPECTIVE COHORT STUDY

Hyunseok Kim[1] Abdelrahman Attia[2] Minsun Kwak[2] Derin Celtik[2] Beza Mengistu[3] Kelsy Larios[3] Walid Ayoub[2] Alexander Kuo[2] Paul Martin[2] Hirsh Trivedi[2] Aarshi Vipani[2] Yun Wang[2] Suthat Liangpunsakul[4] Stephen Pandol[2] Debiao Li[2] Shelly Lu[2] Ju Dong Yang[2], [1]Cedars Sinai Medical Center, [2]Cedars-Sinai Medical Center, [3]UCLA, [4]Indiana University Medical Center

Background: Sarcopenia and obesity are each associated with adverse liver outcomes, but their combined effects—and potential interaction with alcohol use—in populations at risk for metabolic dysfunction-associated steatotic liver disease (MASLD) or Metabolic dysfunction–Associated Alcohol-Related Liver Disease (MetALD) are not well understood. We evaluated the associations of sarcopenia, obesity, and sarcopenic obesity with incident cirrhosis, hepatocellular carcinoma (HCC), and liver-related mortality, and assessed effect modification by excessive alcohol intake. **Methods:** We included UK Biobank participants with ≥1 metabolic risk factor (diabetes, hypertension, dyslipidemia, or obesity) at baseline to define a metabolically at-risk population. Sarcopenia was defined using sex- and age-specific 20th percentile cutoffs for handgrip strength and appendicular lean mass index; obesity was defined as body fat percentage ≥25% in men and ≥35% in women by bioimpedance. Outcomes were identified through linked national health records. Cox proportional hazards models estimated adjusted hazard ratios (aHRs) and 95% confidence intervals (CIs), adjusting for demographic, lifestyle, and metabolic factors, as well as PNPLA3 genotype. Interaction with excessive alcohol use was also evaluated. **Results:** Among 354,495 participants (mean age 56 years; 54% women), 2.1% had sarcopenia alone, 54.5% obesity alone, and 0.8% sarcopenic obesity. Over a median follow-up of 13 years, all phenotypes were associated with significantly increased risk of incident cirrhosis compared to those without either condition: sarcopenia alone (aHR 1.65 [1.27–2.15]), obesity alone (1.77 [1.60–1.95]), and sarcopenic obesity (1.87 [1.23–2.83]). Sarcopenic obesity was also associated with the highest observed hazard ratios for liver-related mortality (2.53 [1.38–4.65]) and comparably elevated risk for HCC (2.51 [1.12–8.03]). The association between sarcopenia and cirrhosis was significantly stronger among individuals with excessive alcohol use (aHR 2.34 [1.00–3.45]) compared to non-excessive drinkers (aHR 1.55 [1.17–2.06]; p-interaction <0.01). **Conclusion:** In this large metabolically at-risk cohort, sarcopenia and obesity were independently associated with increased risks of cirrhosis, HCC, and liver-related mortality. Sarcopenic obesity conferred the highest overall risk, highlighting the importance of evaluating both muscle and fat composition. Sarcopenia was particularly prognostic in the context of excessive alcohol use, identifying a potentially high-risk subgroup relevant to MetALD.

Table. Associations Between Sarcopenia-Obesity Phenotype and Liver Outcomes

Phenotype	Incident Cirrhosis HR (95% CI)	Incident HCC HR (95% CI)	Liver-related Mortality HR (95% CI)
Neither sarcopenia nor obesity	Reference	Reference	Reference
Sarcopenia only	1.65 (1.27-2.15)	2.96 (1.56-5.63)	2.21 (1.54-3.19)
Obesity only	1.77 (1.60-1.95)	2.85 (2.14-3.79)	2.01 (1.71-2.37)
Sarcopenic obesity	1.87 (1.23-2.83)	2.51 (1.12–8.03)	2.53 (1.38-4.65)

Adjusted for age, sex, race/ethnicity, smoking status, socioeconomic deprivation, alcohol use, diabetes, hypertension, dyslipidemia, and *PNPLA3* genotype

◆ 3017 | AUTOMATED SCREENING OF BLOODBORNE VIRUSES IN HEALTH SYSTEMS: REGIONAL MODEL FOR SYNDEMIC TESTING

Su Wang[1] Ruth Brogden[2] Jaymie Yango[2] Nandanie Budhoo[2] Eric Handler[2] Stephen O'Mahony[3], [1]RWJBarnabas Health, Barnabas Health Medical Group, [2]Cooperman Barnabas Medical Center, [3]RWJBarnabas Health

Background: Hepatitis B and C surveillance in the US is at risk due to public health funding cuts. In April 2025

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

the CDC viral hepatitis reference laboratory was shut down which conducts hepatitis testing for the NHANES national survey and is essential for surveillance and monitoring of viral hepatitis (VH). Thus, regional testing efforts in health care systems will be important to assess local prevalence and detect rises in VH cases. Integrated testing of blood borne viruses (BBV) to include hepatitis and HIV will be critical to elimination efforts of syndemics. Electronic medical record (EMR) based automated screening at hospitals can be a streamlined approach for syndemic BBV testing. In a 597-bed community hospital with an Emergency Department (ED) of 100,000 yearly visits, an algorithm was implemented to scale up HCV, HBV, HDV and HIV screening and linkage to care (LTC). **Methods:** In 2018, the EMR was modified at Cooperman Barnabas Medical Center (CBMC) to implement automated HCV (HCVAb reflex to HCV RNA) and HBV (HBsAg) screening, in 2020 screening criteria was expanded to meet CDC recommendations (universal HCV screening) and to increase identifying undiagnosed (urine/serum toxicology and peer recovery specialist orders added), in 2021 at-risk automated HIV screening was included in ED, and in 2022 automated hepatitis delta (HDV Ab) reflex testing (HBsAg+ reflex HDV Ab) was implemented. Positive results are sent to patient navigators (PN) in real-time who initiate individualized linkage-to-care for evaluation and treatment.
Results: A total 140,064 HCV screenings were conducted with 504 (0.36%) current HCV infection and 432 (86%) LTC. Since 2021, ED at-risk HIV screenings totalled 7,892 with 121 (1.5%) infected and 117 (97%) LTC. Patients screened for HBV totalled 61,730 with 511 (0.83%) infected and 437 (86%) LTC. Since August 2022, when HDV Ab reflex testing began, there were 115 HBsAg+ and in those,100 HDV Ab tests were reflexively tested. There were 3 (3.0%) HDV Ab+ and only one had HDV RNA tested with was negative. One patient followed up with provider and HDV RNA was negative. One patient was lost to follow up. **Conclusion:** Automated EMR based screening in a community hospital was able to scale up population level hepatitis and HIV screening and found about 1,000 individuals with VH, a prevalence rate of 0.8% for HBV and 0.4% for HCV and more than 80% were LTC. The program successfully piloted HBsAg reflex to HDV Ab testing, though no cases were found. With risk based HIV testing, more than 100 HIV infected individuals were found with a prevalence of 1.5% and 97% were linked to care. This emphasizes the need to continue scaled-up system-based screening and LTC to combat the VH and HIV epidemics. This screening program was partially funded by the NJ Department of Health, and such private-public partnerships are important with federal public health funding challenges.

◆ 3018 | IMPACT OF PRIOR AWARENESS OF CHRONIC LIVER DISEASE ON THE RISK OF FURTHER DECOMPENSATION IN PATIENTS WITH HEPATIC DECOMPENSATION

Junlong DAI[1] Jan Catherine Carrera[2] Terry Cheuk-Fung Yip[1] Grace Lai-Hung Wong[1] Vincent Wai-Sun Wong[1] Jimmy Che-To Lai[1], [1]The Chinese University of Hong Kong, [2]Chong Hua Hospital, Republic of the Philippines

Background: Chronic liver disease often begins insidiously and lacks specific clinical symptoms, leading the diagnosis only be made at the first hepatic decompensation event in some patients. This study aimed to evaluate the proportion of patients with decompensated cirrhosis who were aware of the diagnosis at initial decompensation and whether that affected clinical outcomes and the risk of further decompensation. **Methods:** We conducted a territory-wide cohort study of 9,748 patients with confirmed chronic liver disease who developed hepatic decompensation between 2000 and 2020. Decompensation and further decompensation were defined by Baveno VII criteria. Patients were categorized as "aware" or "unaware" group based on the presence of ICD-9-CM diagnosis codes for chronic liver disease or relevant laboratory results < 1 month versus ≥ 1 month, respectively, before their first decompensation. We compared baseline characteristics, initial decompensation patterns and further decompensation. Fine-Gray regression was used to assess the association between prior awareness and further decompensation, accounting for death and liver transplantation. **Results:** Overall, 44.7% of patients were unaware of their liver disease at the time of first

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

decompensation (Unaware group: 4,357 vs. Aware group: 4,760). The two groups were comparable in age (62.9 ± 13.4 vs. 62.6 ± 13.0 years, p = 0.259) and sex (male: 72.7% vs. 73.4%, p = 0.486). The unaware group had lower Model for End-stage Liver Disease score) but higher rates of variceal hemorrhage (30.3% vs. 26.7%, p < 0.001) and ascites (49.5% vs. 46.2%, p < 0.001) at the index decompensation. However, the unaware group had a lower crude incidence of further decompensation (13.6 vs. 17.1 per 100 person-years, p <0.001). In multivariable analysis, prior awareness (adjusted sHR 1.06, 95% CI 1.01-1.11), viral hepatitis, and diabetes were independently associated with further decompensation. **Conclusion:** A high proportion of patients are unaware of their liver disease at the time of the first decompensation. However, patients who still develop decompensation despite being under medical care have worse liver function and a higher risk of further decompensation.

◆ 3019 | CHINESE PHYSICIANS&RSQUO; PERSPECTIVES ON HUMAN ALBUMIN FOR THE TREATMENT OF CIRRHOSIS COMPLICATIONS: INSIGHTS FROM A NATIONWIDE QUESTIONNAIRE STUDY

Zhan Zeng[1] Jinghang Xu[1] Yifan Han[1] Ning Lin[1] yanyan yu[2] Xiaoyuan Xu[1], [1]Peking university first hospital, [2]Peking universtiy first hospital

Background: Previous studies in Europe and the United States have investigated the use of human albumin (HA) in patients with liver disease, but no such research has been conducted in China. This study investigated patterns of HA use among Chinese physicians. **Methods:** A questionnaire-based survey was conducted among physicians across 29 provinces in China. The primary objectives of this study were to assess the use of HA for indications and other complications. Additionally, we compared HA use between different hospital levels and between physicians with different job titles. **Results:** A total of 531 valid responses were collected from physicians. Among them, 19.8% were chief physicians, 29.5% were associate chief physicians, 34.5% were attending physicians, and 16.2% were residents. Among all the physicians, 80.0% worked in tertiary hospitals, whereas 20.0% worked in secondary hospitals. The physicians were from various specialties: infectious disease (37.3%), gastroenterology (23.5%), hepatology (17.1%), general internal medicine (8.7%), and other departments (13.4%). The primary reasons for initiating HA therapy were ascites (44.4%) and hypoalbuminemia (28.4%). The main concerns regarding HA use, as cited by 56.7% of the physicians, were medical insurance restrictions, followed by cost concerns (20.0%).

HA was used to treat ascites, spontaneous bacterial peritonitis (SBP), and hepatorenal syndrome (HRS) by 95.7%, 75.3%, and 87.4% of the physicians, respectively. An initial dosage of 10–20 g/day was used for ascites, SBP, and HRS by 82.5%, 82.6%, and 79.6% of the physicians, respectively. The median durations of HA use to treat ascites, SBP, and HRS were 7, 5, and 7 days, respectively.

The use of HA for other complications varied by condition, with 50.0% of the physicians using HA to treat shock and pleural effusion (PE), 30.0% using HA to treat gastrointestinal bleeding and non-SBP infections, and 27.0% using HA to treat primary liver cancer. Compared with those in secondary hospitals, physicians in tertiary hospitals were more likely to prescribe an initial dose of 10–20 g/day ($P < 0.001$) and more likely to use HA to treat shock ($P < 0.001$). For other complications, such as hepatic encephalopathy, hyponatremia, portal vein thrombosis (PVT), sarcopenia in cirrhosis, and non-SBP infections, chief physicians were

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

more likely than attending physicians to use HA ($P < 0.05$). Additionally, chief physicians used HA more often than residents to treat PE, hyponatremia, and shock ($P < 0.05$). Associate chief physicians prescribed HA more frequently than attending physicians to treat hyponatremia, PVT, and sarcopenia ($P < 0.05$). **Conclusion:** HA is primarily used in China for treating ascites and hypoalbuminemia, with insurance restrictions being a major concern. While HA is used in accordance with clinical guidelines, notable variations exist on the basis of hospital level and physician job title.

◆ 3020 | A POCKET OF UNTAPPED POTENTIAL: A NOVEL APPROACH TO ENSURING TIMELY PARACENTESIS

Joseph Abraham[1] Frank Nelson[1] Vasundhara Singh[1] Lance Maresky[2], [1]Mount Sinai Morningside-West, [2]Mount Sinai West

Background: The imperative to perform diagnostic paracentesis as proximal to admission as possible has been firmly established, but a simple, cost-effective, and consistently reliable solution to ensuring timely performance has proven elusive to date. With increasing subspecialization in the field of Internal Medicine, the role of the hospitalist has metamorphosed, and the expectation for certification in specialized procedures, such as paracentesis, has diminished. Many hospitals have traditionally relied on procedure services to manage specialized procedures. As a result, the majority of clinicians are uncertified to perform these procedures, which were previously squarely in their scope of practice. This gap in certification poses challenges for procedural safety and operational efficiency. **Methods:** The pilot project involved several key components: 1) secure chat integration, 2) certification program, 3) rigorous training modules, and 4) strict guidelines and protocols. A secure Epic chat group was established, containing members who are either already certified in performing paracenteses or those who are seeking certification. As soon as the need for a paracentesis is identified, a chat is started with this Paracentesis Team. Once suitable clinicians are identified to perform the paracentesis, the trainee is encouraged to review our proprietary online modules which provide comprehensive insight into the procedure. A high bar is set for the minimum requirement of procedures successfully completed before becoming independently certified. **Results:** Prior to implementation of the intervention, only 16 out of 256 Internal Medicine residents (6.3%) in our residency program were certified to independently perform abdominal paracentesis. Between November 19, 2024, and March 10, 2025: • 68 chats in 111 days (~4.5/week). • Mean pairing time: 1.4 minutes. • 71 procedures logged vs. 39 prior year → 55% increase. • 18 new certifications vs. 16 pre-existing prior to our intervention. **Conclusion:** Preliminary results from this pilot strongly suggests that real-time secure chat enables rapid performance and supervision of paracenteses. The decentralized model improves access and scalability and has led to significant gains in volume and certification. The skill building loop inherent in the program means that increased access of trainees to procedures leads to more certified supervisors in a positive feedback cycle. Ultimately, this initiative has proven so far to be a sustainable, low-burden alternative to traditional services. Further investigation is ongoing into the effects of this initiative on metrics like length of stay, mortality, and antibiotic use.

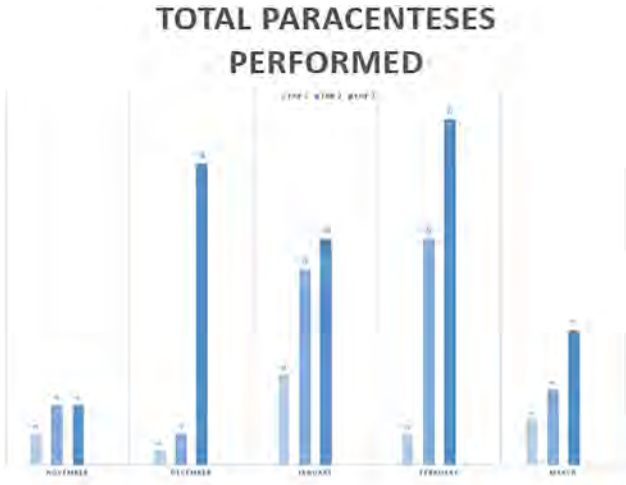

Table 1: Total number of procedures 1 and 2 years prior to our intervention, as well as during the intervention period (Year 3).

◆ 3021 | COMPREHENSIVE HEPATITIS B PERINATAL PREVENTION INTERVENTIONS IN DELTA STATE, NIGERIA

Catherine Freeland[1] Prince Okinedo[2] Gregsonil Idibofu[2] Anita Abifade[2] Dafe Akokotu[3] Kevin Igweh[4] Sandra Igah[4] Linda Peter-Enyi[4] Ossai Theresa[5] Aki-Famous Betty[5] Ubiri Obaherhekre[6] Idanesi Stella[7] Kelechi Okorie[8] Kiyem wamari[9], [1]Hepatitis B Foundation, [2]Hepatitis Advocacy Foundation, [3]Central Hospital Agbor, [4]State Ministry of Health, [5]General Hospital Ozoro, [6]Central Hospital Sapele, [7]Central Hospital Warri, [8]Asaba Specialist Hospital, [9]Central Hopsital Agbor

Background: Chronic hepatitis B remains a global health challenge, with 250 million people infected. Perinatal transmission is the primary route, preventable through WHO-recommended interventions: antiviral prophylaxis (second trimester), timely birth dose (within 24 hours), and the pentavalent vaccine (6, 10, 14 weeks). In Africa, uptake of these measures is low due to limited screening, treatment access, and knowledge. Nigeria has offered the birth dose since 2004, but coverage remains inconsistent. In Delta State, where HBV prevalence is ~8%, a pilot found just 5.7% coverage within facilities. This study evaluated the impact of a community-driven perinatal prevention program in five public hospitals. **Methods:** The program, implemented across five state-run hospitals, involved routine hepatitis B screening for pregnant women, free antiviral prophylaxis for those testing positive, and timely birth dose vaccination for newborns. Healthcare workers received training, and logistical support was provided to ensure vaccine cold storage and delivery. Qualitative and quantitative data were collected to assess uptake and implementation barriers. **Results:** Of 1,623 pregnant women screened, 35 (2.5%) tested positive for HBV; none were HCV positive. Birth dose was administered to 100% of exposed infants—73% within 3 hours. Prophylaxis uptake was limited (2/35) due to late ANC booking. Key barriers included low provider awareness, vaccine misconceptions, and concerns about wastage. Post-training, provider knowledge and timely birth dose coverage significantly improved. **Conclusion:** This intervention improved screening, timely vaccination, and provider capacity. Sustained progress requires continued investment in healthcare training, public awareness, and policy support for integrated, cost-covered perinatal hepatitis B prevention.

◆ 3022 | HEALTH-RELATED QUALITY OF LIFE (HRQOL) OF PATIENTS WITH LIVER DISEASE: A CROSS-SECTIONAL ANALYSIS BY DISEASE SEVERITY AND AETIOLOGY

Stephanie Landi[1] Christopher Mysko[1] Huw Purssell[1] Karen Piper Hanley[2] Neil Hanley[3] Varinder Athwal[1], [1]Manchester NHS Foundation Trust / University of Manchester, [2]University of Manchester, [3]University of Birmingham / University Hospitals Birmingham NHS Foundation Trust

Background: Liver disease is a major cause of premature mortality and working lives lost, which has significant personal and national consequences. Understanding the impact of Health-Related Quality of Life (HRQoL) in patients with chronic liver disease, across a spectrum of aetiology and fibrosis, can help assess the burden of disease on the individual and inform clinical management, public health policies and resource allocation to help address these consequences. **Methods:** 1914 EQ5D5L (EuroQol, Netherlands) questionnaires were analysed from two prospective studies to assess the association between HRQoL, aetiology and fibrosis. Participants were divided into four groups based on liver stiffness measurement (LSM) or pre-existing chronic liver disease: Group 1: <8kPa ($n=1171$); Group 2: 8.1-15 kPa ($n=210$); Group 3: >15 kPa ($n=89$); and Group 4: pre-existing cirrhosis/chronic liver disease ($n=444$). 1108 (57.9%) had Metabolic Dysfunction Associated Liver Disease (MASLD), 212 (11.1%) Metabolic and Alcohol Associated Liver Disease (MetALD), 335 (17.5%) Alcohol-Related Liver Disease (ALD) ($n=335$), 92 (4.8%) viral hepatitis, 10 (0.5%) auto-immune liver disease, 12 (0.6%) hereditary haemochromatosis, 76 (4.0%) other liver-related aetiology and 62 (3.2%) no identifiable liver disease. Along with the surmised EQ5D5L value, the five dimensions of EQ5D5L were individually assessed: "mobility", "usual activities", "self-care", "pain" and "anxiety and depression". Statistical analysis was adjusted for age, gender, weekly alcohol consumption (units/week), Body Mass Index (BMI) and Charlson Comorbidity Index. **Results:** There was a progressive decrease in mean EQ5D5L value, indicating a poorer

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

HRQoL, with an increasing fibrosis: 0.83 (SD: 0.23), 0.75 (SD: 0.27), 0.70 (SD: 0.29) and 0.66 (SD: 0.31) for groups 1-4 respectively ($P < 0.0001$) (Figure 1). However, there was no significant difference between HRQoL between individuals with MASLD, MetALD and ALD in each group: Group 1 ($p = 0.07$), 2 ($p = 0.25$), 3 ($p = 0.95$) and 4 ($p = 0.26$). Across the five dimensions each aetiology demonstrated different significant associations in multivariate regression analysis with fibrosis group. For participants with MASLD a significant association was observed between fibrosis group and "mobility" (ß = 0.12; 95% CI, 0.05-0.19; $p = 0.001$), "self-care" (ß = 0.06; 95% CI, 0.01-0.12; $p = 0.02$) and "usual activities" (ß = 0.11; 95% CI, 0.04-0.19; $p = 0.004$). However in participants with MetALD and ALD this was "usual activities" (ß = 0.27; 95% CI, 0.11-0.43; $p = 0.001$) and "anxiety and depression" (ß = 0.16; 95% CI, 0.02-0.29; $p = 0.02$), respectively. **Conclusion:** Across a spectrum of steatotic liver disease, HRQoL declines with increased fibrosis. This is driven by different dimensions of HRQoL dependent upon the underlying chronic liver disease aetiology.

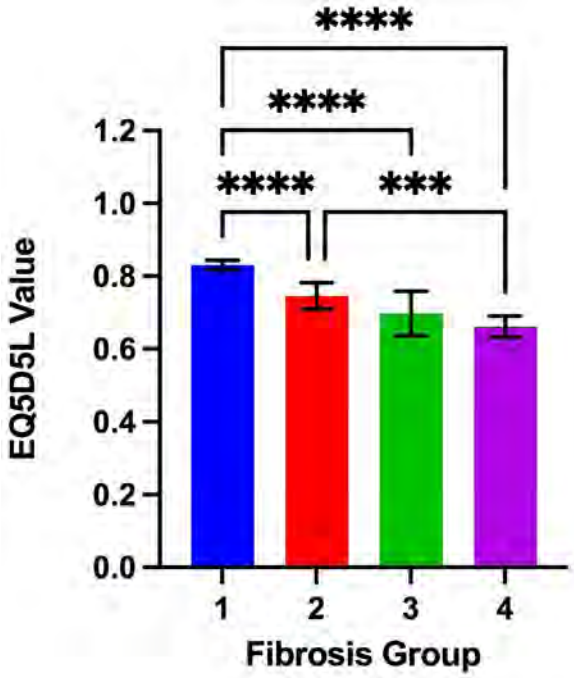

Figure 1: Bar chart showing the mean EQ5D5L value for each liver fibrosis group. Error bars represent the 95% confidence intervals and brackets show comparisons between groups statistically analysed with ANOVA and Tukey's Multiple Comparison test with **** representing P<0.0001 and ***, P<0.001.

◆ 3023 | A HOSPITAL-BASED HCV ELIMINATION MODEL BASED ON MULTIDISCIPLINARY COLLABORATION.

Xuehua Yan[1] Haiyan Wang[1], [1]The No.2 People's Hospital of Lanzhou

Background: The incomplete referral system of HCV in hospitals, and the lack of understanding of the diagnostic process and therapeutic advances of hepatitis C by doctors in non-infectiou disease(NID)/hepatology departments have seriously affected the diagnosis rate and the treatment rate of the patients. In this context, HCV elimination programs in hospitals are particularly important. To improve the diagnosis and treatment rate of HCV patients by establishing a standardized and efficient in-hospital HCV management model. **Methods:** From April 1, 2021, multidisciplinary collaboration was carried out in the No.2 people's hospital of Lanzhou, including various clinical departments, laboratory departments(LD), hospital infection control departments, and hospital information technology departments. Hospital-wide education and training on the importance of HCV screening and treatment were conducted, a hepatitis C management working group was established, and a mechanism for professional supervision and inspection was developed. After detecting anti-HCV positivity or HCV RNA positivity, the LD will immediately notify the relavant supervising physician and medical staff of the Infectious Diseases (ID)/hepatology department to follow up the patient's medical consultation, at the same time, the test report form will indicate the need for further medical diagnosis and treatment as well as a pop-up window reminder for hospitalized patients were also set up. **Results:** A total of 71,696 patients were screened from the database of the infection control department, of which 8,604 patients were screened from March 31, 2019, to March 31, 2021, and 1,291 patients were HCV antibody-positive. 399 HCV antibody-positive patients were from the ID department, accounting for 30.9%, and 892 HCV antibody-positive patients were from the NID department, accounting for 69.1%. Among them, 456 HCV antibody-positive patients underwent HCV RNA testing, 436 patients were HCV RNA positive, 79.8% of ID department HCV RNA testing, and 20.2% of NID department HCV RNA testing. The number of patients receiving DAA treatment was 212, with a treatment rate of 48.6%. From April 1, 2021 to April 1, 2024, a total of

63,092 patients were screened since the start of the hospital HCV elimination program, with 1,201 HCV antibody-positive patients, 322 patients in the ID department were HCV antibody-positive, accounting for 26.8% of the patients, and the proportion of HCV antibody-positive patients in the NID department was 73.2%. Of these, 675 antibody-positive patients underwent HCV RNA testing, and there were 640 HCV RNA positive patients. The number of patients treated was 398, with a treatment rate of 62.2%. **Conclusion:** Since the implementation of the hospital-based HCV elimination program, the number of HCV patients screened, the diagnosis rate of HCV patients, and the treatment rate have increased significantly compared to the previous rates.

◆ 3024 | HOW CAN GEN AI EMPOWER LIVER PATIENTS?

Mustafa Behan[1] Jutta Kurz[1] Valeriia Aksakovska[1] Richard Jaenisch[2] Michael Tunkelrott[3] Lorrinda Gray-Davis[2] David Jaenisch[2] Karen Hoyt[2] Emmanuel Gorospe[4] Tarek Hassanein[5], [1]Amsety, [2]None, [3]Amsety LLC, [4]Burrell College of Osteopathic Medicine, [5]Southern California Liver Centers

Background: Over 67 million people use ChatGPT/week in the US. Among post-liver transplant patients (pts), 37% rely mainly on online tools for health information versus physicians (30%) or support groups (23%). With growing usage of digital tools, we need to understand the implications on the liver health field in general and the diagnosis and treatment context for liver pts. The aim is to develop strategies for pt communication with the help of Gen AI and identify benefits for pt management. **Methods:** The Amsety database consists of 650,000 individuals in the US. These individuals are mainly connected to Amsety through online educational tools. 3 additional surveys were conducted with 177 respondents with cirrhosis, post-transplant status, or recent liver diagnoses. The surveys assessed awareness and use of Gen AI, perceived quality, and comparisons to medical professionals. **Results:** The average age was 42 years old; 70% had metabolic liver. 58% used Gen AI tools in the previous 6 months. Top use cases were for nutrition/meal planning (72%), understanding their pattern of disease (62%) and diagnosis (56%). 58% rated AI responses as good or excellent. Pts perceived advantages of Gen AI over medical providers as constant availability (66%), cost-effectiveness (58%), unlimited question handling (50%). However, their concerns were no access to personal health history (48%), generic advice (34%) and lack of emotional support and privacy concerns (28%). The advantages of medical professionals over Gen AI are viewed as better qualification of providers (66%), access to their full medical history (60%) and legal accountability (52%). The disadvantages of information from a medical professional over Gen AI are viewed as inconsistent availability at the time of need (70%), unclear/difficult-to-understand information (44%) in some occasions, discomfort or time pressure during appointments (44%) and difficulties in getting appointments (42%). Pts sought Gen AI to answer liver-specific questions (68%), suggest medical tests (42%), use medical history for personalized advice (42%) and link to latest research (40%). **Conclusion:** Digital tools are widely accepted by liver patients and serve as key resources for health information, often convinced with the answers they receive. Gen AI has strong potential to support education, lifestyle guidance, and early intervention but must evolve to provide personalized, curated support while deferring critical decisions to physicians.

3025 | CLINICIAN ADHERENCE TO AN ELECTROCARDIOGRAM-ENABLED ARTIFICIAL INTELLIGENCE MODEL FOR DETECTION OF LIVER DISEASE IN PRIMARY CARE: INSIGHTS FROM THE DULCE TRIAL

Alberto Calleri[1] David Rushlow[2] Blake Kassmeyer[3] Kan Liu[4] Ryan Lennon[3] Puru Rattan[1] Matthew Bernard[2] Gagandeep Singh[5] Mark Deyo-Svendsen[2] Graham King[2] Stephen Stacey[2] Amy Olofson[1] Alina Allen[1] Joseph Ahn[1] Paul Friedman[4] Patrick Kamath[1] Zacchi Attia[4] Peter Noseworthy[4] Vijay Shah[1] Douglas Simonetto[1], [1]Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota, [2]Department of Family Medicine, Mayo Clinic Health System, [3]Division of Clinical Trials and Biostatistics, Mayo Clinic, Rochester, Minnesota, [4]Department of Cardiovascular Medicine, Mayo Clinic, Rochester, Minnesota, [5]Department of Family Medicine, Mayo Clinic Health

Background: The expanding use of artificial intelligence (AI) raises questions about clinician trust in AI-generated results, particularly in community settings. The Detection of Undiagnosed Liver Cirrhosis via Electrocardiogram (DULCE) was a pragmatic, randomized clinical trial demonstrating that a machine learning (ML) model applied to routine electrocardiograms (ECG) improves the detection of advanced chronic liver disease in primary care. In this post-hoc analysis, we examine clinician characteristics and adherence to follow-up recommendations prompted by positive ECG-ML results. **Methods:** Ninety-eight Primary Care Teams in Minnesota and Wisconsin were cluster-randomized to either the intervention arm (access to ECG-ML results) or standard care. Adults without known liver disease undergoing ECG between April and October 2023 were included. Clinician demographics were collected via REDCap survey. In the intervention arm, adherence was defined as the proportion of ECG-ML positive results followed by clinical action, such as ordering follow-up diagnostic tests or documenting a reason for not proceeding with further testing. High adopters were defined as providers in the upper quartile of adherence. **Results:** Of 126 clinicians randomized to the intervention arm, 110 were assessed for adherence, as had at least one patient with positive ECG-ML result. Mean age was 45 years; 67% physicians; 55% female; mean 14 years in practice. Most (85%) reported low confidence in managing cirrhosis at baseline. In the intervention arm, 8,034 patients had an ECG of whom 1,385 (17.2%) tested positive. Adherence to the AI alerts ranged from 19.5 to 49% across geographic regions. An adherence rate above 66.7% identified high adopters in our cohort. No differences in adherence were found by age, sex, degree type, or years in practice. The rate of follow-up diagnostic tests ordered was higher among high adopters compared to low adopters (55.1% vs. 9.1%, $p = 0.0001$). Among ECG-ML positive patients, any liver fibrosis was diagnosed in 65/274 cases (23.7%) in the high-adherence group compared to 73/1,111 (6.6%) in the low-adherence group ($p < 0.001$). High adopters were more likely to detect advanced fibrosis (F3–F4; OR 2.12, 95% CI 1.36–3.30, $p = 0.001$) and mild fibrosis (F1–F2; OR 2.08, 95% CI 1.88–4.72, $p < 0.001$) when compared to low adopters. **Conclusion:** In the DULCE trial, overall adherence to AI-based recommendations was moderate. However, providers with high adherence were significantly more likely to diagnose both early and advanced liver disease. Adherence was not linked to clinician demographics, suggesting a broader acceptance of AI across provider groups. Strategies to support clinician engagement may further enhance the real-world impact of AI in primary care.

3026 | HEPATITIS C TREATMENT EXPOSURE IN PREGNANCY: THREE-YEAR EXPERIENCE FROM THE &LDQUO;TIP-HEPC&RDQUO; CLINICAL CASE REGISTRY

Neil Gupta[1] Lindsey Hiebert[1] Jana Manning[1] Saeed Hamid[2] Manal El-Sayed[3] Ravi Jhaveri[4] Ali Judd[5] Tatyana Kushner[6] Mia Biondi[7] Catherine Chappell[8] John Ward[9], [1]Coalition for Global Hepatitis Elimination, The Task Force for Global Health, [2]Department of Medicine, Aga Khan University, Karachi, Pakistan, [3]Pediatric Department, Ain Shams University and Clinical Research Center, Faculty of Medicine, Ain, [4]Department of Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, IL, USA, [5]University College London, London, UK; Fondazione Penta ETS, Padova, Italy, [6]Division of Gastroenterology & Hepatology, Weill Cornell Medicine, New York, USA, [7]School of Nursing, York University Viral Hepatitis Care Network, University Health Network, [8]Department of Obstetrics, Gynecology, and Reproductive Sciences, University of Pittsburgh, PA, [9]Coalition for Global Hepatitis Elimination

Background: About one-fifth of HCV infections worldwide are among women of childbearing age. In countries such as the US, policies for antenatal screening have led to greater identification of pregnant persons with HCV. However, due of a lack of safety data, pregnant persons are not universally recommended to receive antiviral therapy. AASLD-IDSA recommends case-by-case collaborative decision making for considerations of HCV treatment in pregnancy. The TiP-HepC registry was launched in June 2022 to capture, analyze, and routinely publish data regarding safety of HCV antiviral treatment in pregnancy. **Methods:** Standard data elements from cases of exposure to HCV antiviral therapy during pregnancy were reported to the registry through a web-based secure portal. Primary adverse pregnancy outcomes were defined as preterm delivery (< 37 weeks gestational age), stillbirth or fetal demise, and maternal death. Primary adverse birth outcomes were defined as low birth weight (LBW < 2500g), small for gestational age (SGA), neonatal intensive care unit (NICU) admission, and congenital anomalies. Descriptive analysis was conducted for cases submitted from June 1, 2022, to May 29, 2025. **Results:** A total of 37 eligible cases were reported in the registry (see table). Cases were from the US (n = 30), Canada (n = 3), Mexico (n = 2) and Australia (n = 2); 21 cases had been previously published in clinical trials or case series. There was a high prevalence of co-morbid substance use. There was one maternal death attributed to acute respiratory infection. Primary adverse birth outcomes included 10 NICU admissions, one LBW, and one SGA. Among cases with infant follow-up data, there were no infant deaths or congenital anomalies reported. **Conclusion:** The TiP-HepC registry provides valuable real-world data on HCV treatment exposure in pregnancy. To date, the registry has accrued substantial data, including 16 previously unreported cases. Although completeness of case reporting remains a limitation, current data from the registry has not revealed major safety concerns in terms of primary adverse pregnancy outcomes, infant deaths, or congenital anomalies. The Tip-HepC registry continues to solicit case reports to better inform collaborative decision-making, treatment and follow-up of pregnant persons and their newborns.

Table 1. Maternal-Infant characteristics and outcomes of TiP-HepC Registry cases (June 1, 2022 – May 29, 2025)

Exposures during first trimester (≤13 weeks gestation):	
Cumulative registry cases	8
Median age, years (range)	30 (22-35)
Baseline co-morbidities or substance use	IVDU=3, opioid use=3, tobacco=2, marijuana=4, cocaine=1, mental/behavioral disorders related to opioid use disorder=6, methamphetamine=2
Treatment regimen	G/P=3, SOF/VEL=5
Treatment completed	Yes=6, No=2
Median number of days of treatment exposure in pregnancy (range)	56 (32-79)
Maternal HCV outcomes	Cured = 2, No data = 6
Primary adverse pregnancy outcomes	None = 3, Maternal death = 1, No data = 4
Primary adverse birth outcomes	None = 3, NICU admission = 1, No data = 4
Congenital anomaly	Yes = 0, No = 3, No data = 5
Infant HCV outcome	No data = 8
Exposures after first trimester (>13 weeks gestation)	
Cumulative registry cases	29
Median age (range)	30 (18-44)
Baseline co-morbidities or substance use	IVDU=12, opioid use=7, tobacco=7, marijuana=4, cocaine=4, mental/behavioral disorders related to opioid use disorder=6, methamphetamine=2
Treatment regimen	SOF/LDV = 20, SOF/VEL = 9
Treatment completed	Completed=23, Not Completed=0, No data=6
Median number of days of treatment exposure in pregnancy (range)	83 (42-92)
Maternal HCV outcomes	Cured=17, not cured = 2, No data = 10
Primary adverse pregnancy outcomes	No adverse pregnancy outcomes =17, preterm delivery = 6, no data = 6
Primary adverse birth outcomes	NICU admission = 9, low birth weight = 1, small for gestational age = 1, no data = 2
Congenital anomaly	Yes = 0, No = 22, No data = 7
Infant HCV outcome	Positive = 0, Negative = 13, No data = 16

3027 | AVATAR: AI VIRTUAL ASSISTANT FOR TRIAGE AND REFERRALS IN AN ACADEMIC HEPATOLOGY PRACTICE

Anubhav Shankar[1] Hersh Shroff[2] Oren Fix[3], [1]University of North Carolina, [2]UNC Chapel Hill, [3]University of North Carolina at Chapel Hill

Background: In tertiary hepatology care settings, efficient and accurate triage of new outpatient referrals is an important yet burdensome process due to patient complexity, antiquated processes involving faxed paper records from external institutions, and lacking interoperability standards for electronic health records. Artificial intelligence (AI) tools provide an opportunity to improve the review and triage of patient referral records. **Methods:** We used our institution's HIPAA-secure, GPT-4o-powered large language model (LLM), known as AI Virtual Assistant (AVA), to read and extract data from scanned PDF records of new referrals to our academic hepatology practice. In the *development* phase, we analyzed dictated audio recordings made by an advanced practice provider (APP1) while triaging new patient referrals and extracted a comprehensive list of data elements required for triage. An AVA prompt was created using the final list of data elements and iteratively tested on unique patient records to maximize accuracy. In the *testing* phase, structured summaries of 15 unique referral records were generated in AVA using the final prompt. APP1 reviewed all 15 records for triage. After a 3-month delay, APP1 re-reviewed a subset of the AVA summaries, and a second APP (APP2) reviewed a different subset. Outcomes measured included *time to triage* (original records and AVA summaries), *accuracy of data extraction* compared to human review, and *appropriateness of resulting triage decision* judged by a member of our study team. Statistics were conducted using Python 3.11.8. **Results:** In the development phase, we identified 48 unique data elements used for triage (e.g., reason for referral, urgency, demographics including address and insurance, and various clinical details). Upon completion of the development phase, average AVA accuracy in data element extraction was 94.1%. In the testing phase, we observed a significant reduction in average time to triage per referral: *within-provider (APP1)*: 100s with full records vs 25s with AVA summaries, $p = 0.0001$; *between-providers:* 119s for APP1 with full records vs 65s for APP2 with AVA summaries, $p = 0.0128$. Mean $\pm$ SD lengths of AVA summaries were 2 ± 1 pages vs. 30 ± 34 pages with original records. Both APPs reached an appropriate triage decision in 89% ($n = 16/18$) of patients with AVA. The two instances of inappropriate triage decisions occurred due to an inability of AVA to read lab values in the referral records. In both cases, the APPs recognized the need to refer to the original records to verify missing or incorrect information. **Conclusion:** In this pilot study, a HIPAA-secure LLM extracted data from scanned patient records with high accuracy, significantly reducing triage times with minimal compromise of the appropriateness of triage. With further refinement, our model has the potential to significantly reduce the burden on providers of record review, triage, and other administrative tasks.

3028 | INTEGRATING EVIDENCE-BASED STRATEGIES FOR HBSAG TESTING UPTAKE IN VIET NAM: A HYBRID EFFECTIVENESS-IMPLEMENTATION TRIAL ★

Thanh Kim[1] Diem Dao[2] Trang Ngoc Doan Pham[3] Loc Phan[2] Thuy Tran[4] Trang Nguyen[4] Anh Le[2] Khanh Tran[4] Doan Dao[5] Vu Dang[4] Toan Le[6] Cong Ly[4] Hung Vo[4] Tung Do[4], [1]Pham Ngoc Thach University of Medicine, [2]Vietnam Viral Hepatitis Alliance, Reston, VA, USA, [3]University of Illinois at Chicago, Chicago, IL, USA, [4]Le Van Thinh Hospital, Thu Duc City, Ho Chi Minh City, Viet Nam, [5]Johns Hopkins School of Medicine, [6]University of Medicine and Pharmacy at Ho Chi Minh City, Viet Nam

Background: Despite WHO guidelines, hepatitis B surface antigen (HBsAg) screening remains $< 10\%$ in low- and middle-income countries (LMICs), including Viet Nam (HBV prevalence $> 8\%$; baseline HBsAg testing ~0.35%). Our systematic review of 25 trials ($n = 130{,}598$) confirmed that healthcare provider (HCP)-led education combined with point-of-care (POC) rapid testing increases HBsAg uptake (risk difference 62.5%, 95% CI: 53.1–71.9) [1]. Yet, no trials have tested these strategies in LMICs or under a hybrid implementation framework. **Methods:** We conducted a hybrid

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

effectiveness-implementation trial (06/2024–03/2025) in the outpatient department of a general hospital in Ho Chi Minh City. The sequential interventions included: 1) continuous medical education (CME, 06/2024) for providers focused on HBV epidemiology, screening guidelines, and testing procedures, reinforced with quarterly refreshers; (2) best practice alerts (BPAs, 10/2024); and (3) POC HBsAg rapid testing (02/2025). BPAs were real-time EHR prompts alerting providers to order HBsAg testing for eligible patients. The primary outcome: HBsAg testing uptake; secondary outcomes: downstream care linkage and implementation fidelity. We analyzed 201,851 outpatient visits (including preimplementation phase from 01/2023- 05/2024 serving as control) using seasonal ARIMA modeling. ARIMA was chosen to account for significant seasonality and autocorrelation detected in weekly testing rates to evaluate the incremental and combined impact of the bundle on HBsAg testing (interventions 1,2, and 3), with anti-HCV, cholesterol, and glucose screening serving as negative controls. **Results:** Baseline HBsAg testing was 3.41 tests/1000 visits/week. CME alone showed no significant effect on HBsAg testing (immediate: −2 tests/1,000 visits/week, 95% CI: −8.2 to +4.1; gradual: +1.1/1,000/week, 95% CI: −0.2 to +2.6). Adding the BPAs demonstrated modest ramp-up effects (+1.7/1,000/week, 95% CI: +0.04 to +3.4). Notably, the final addition of free POC testing drove dramatic increases (immediate: +9.9/1,000, 95% CI: +5.1 to +14.7; gradual: +8.4/1,000/week, 95% CI: +7.2 to +9.5), translating to a 28-fold testing rate improvement compared to pre-implementation. Qualitative analyses to evaluate for implementation fidelity and downstream metrics (anti-HBs, HBV DNA, referrals, treatment) are underway. **Conclusion:** This trial offers the first LMIC evidence demonstrating that provider education and digital BPAs alone are insufficient, but when combined with free POC-HBsAg, they catalyze transformative increases in HBsAg testing uptake. Our findings present an innovative, scalable, and evidence-backed model for advancing hepatitis B elimination goals.

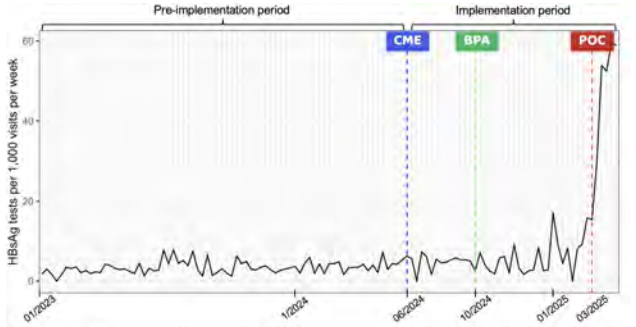

Figure 1. Weekly HBsAg testing rates during the study period. The timing of each intervention is indicated by dashed vertical lines: blue for the introduction of CME (June 2024), green for EHR best practice alerts (October 2024), and red for point-of-care (POC) testing (February 2025).

3029 | EFFECT OF THE COVID-19 PANDEMIC ON OVERALL SURVIVAL AMONG PATIENTS WITH HEPATOCELLULAR CARCINOMA IN THE UNITED STATES

Yi-Te Lee[1] Jasmine Wang[2] Pojsakorn Danpanichkul[3] Hyunseok Kim[4] Alexander Kuo[1] Walid Ayoub[1] Hirsh Trivedi[1] Yun Wang[1] Aarshi Vipani[1] Paul Martin[1] Amit Singal[5] Ju Dong Yang[1], [1]Cedars-Sinai Medical Center, [2]University of Washington, [3]Texas Tech University Health Sciences Center, [4]Cedars Sinai Medical Center, [5]University of Texas Southwestern Medical Center

Background: The COVID-19 pandemic affected diagnosis and management of hepatocellular carcinoma (HCC). However, its impact on survival remains unknown. **Methods:** We conducted a retrospective cohort study using the Surveillance, Epidemiology, and End Results (SEER) Program among patients diagnosed with HCC between 2000 and 2022. Kaplan–Meier analysis was performed to estimate 1-, 2-, and 3-year overall survival (OS) rates. Multivariable Cox regression, adjusting for demographic and clinical factors, was used to identify factors associated with OS, including a comparison of the COVID-19 era (2020-2022) vs. the pre-COVID-19 era (2016-2019). **Results:** Among 107,911 eligible HCC patients with survival data, 16,838 were diagnosed during the COVID-19 pandemic (2020-2022) and 25,131 during the pre-COVID era. The 1- and 2-year OS for patients during the COVID-19 era and pre-COVID-19 era were 57.3% (95% CI: 56.5-58.1%) and 41.9% (95% CI: 40.9-42.8%), compared to 58.6% (95% CI: 58.0-59.2%) and 43.7% (95% CI: 43.1-44.4%), respectively (log-rank test, $p < 0.001$) (Figure 1a). However, in multivariable analysis, the COVID-19 era was not significantly associated with worse survival compared to the pre-COVID era (HR: 1.01, 95% CI: 0.98-1.03, $p = 0.3$). In subgroup analyses, the COVID-19 era was significantly associated with better survival in patients < 50 years old (HR: 0.84, 95% CI: 0.71-0.98, $p = 0.035$, Figure 1b). Conversely, the COVID-19 era was significantly associated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

with worse survival in patients with localized tumors (HR: 1.06, 95% CI: 1.01-1.11, p = 0.01, Figure 1c).
A smaller proportion of HCC patients diagnosed during the COVID-19 era received curative-intent therapies (local ablation, liver resection, liver transplantation) compared to the pre-COVID era (21.7% vs. 23.9%, p < 0.001). This difference in curative treatments was also observed in patients with localized tumors (35.5% vs. 37.5%, p < 0.001), although a higher proportion of younger patients < 50 years old received curative-intent therapies during the COVID era (36.6% vs. 29.9%, p = 0.003). **Conclusion:** The COVID-19 pandemic was associated with worse survival in patients with HCC overall, including subgroup with early-stage HCC, although better survival was observed in younger patients. These differences in survival may reflect variations in access to curative-intent therapies.

3030 | REAL-WORLD ASCITES TREATMENT PATTERNS DIVERGE FROM AASLD RECOMMENDATIONS: AN ANALYSIS OF OVER 200,000 PATIENTS WITH CIRRHOSIS AND ASCITES

Kate Solpari[1] Dominique Gay[1] Emma Leipsner[1] Scarlet Yang[1] Jessica Siguencia[1] Tatyana Kushner[1], [1]Weill Cornell Medical College

Background: The 2021 American Association for the Study of Liver Diseases (AASLD) guidelines recommend a stepwise approach to ascites management beginning with sodium restriction and spironolactone, adding furosemide as needed for refractory ascites, the guidelines advise escalation to large-volume paracentesis (LVP), transjugular intrahepatic portosystemic shunt (TIPS), and ultimately liver transplantation. We sought to evaluate national real-world practices in adherence with these recommendations for ascites management. **Methods:** Patients with cirrhosis and associated ascites were identified using ICD-10 diagnosis codes from 99 healthcare organizations in the TriNetX Research Network. We tracked ascites-related treatments over time, defining a new line of therapy (LOT) when a new medication or procedure was initiated or substituted. We quantified therapy use and identified common treatment sequences across up to six LOTs. **Results:** Of 257,245 adults with cirrhosis-related ascites treated between 2005 and 2025 (68% White, 10% Black or African American, 5% Asian; median follow-up 371 days, IQR 1,140), treatment pathways were reconstructed for 185,128. Across all therapy lines, dual diuretics (furosemide plus spironolactone) were prescribed to 58% of patients, furosemide alone to 56%, and large-volume paracentesis to 36% (see Figure). First-line practice diverged from

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

guidelines: furosemide monotherapy was used in 37% of patients—nearly three times as often as spironolactone alone (14%, $p < 0.001$). The most common escalation sequence was furosemide followed by combination diuretics, seen in 14% of those who started on furosemide. Paracentesis use increased with treatment progression, reaching 21% among patients receiving a sixth line of therapy. Other diuretics appeared in 7.5% of treatment pathways (3% at first line). Advanced interventions were rare: TIPS was used in 0.002% of patients, and liver transplantation in 2.8%. **Conclusion:** Real-world ascites management frequently diverges from AASLD guidelines, with many patients starting treatment on furosemide monotherapy rather than spironolactone. Escalation to guideline-recommended rescue therapies such as TIPS and transplantation was rare. These patterns suggest that clinical decision-making may be influenced by provider preference, institutional norms, or patient factors not captured in guidelines. Findings should be validated in prospective cohorts due to potential misclassification bias inherent in administrative coding data. Efforts to promote guideline-concordant care and address barriers to appropriate escalation are warranted.

3031 | HOSPITAL AT HOME FOR ACUTE CARE PATIENTS WITH DECOMPENSATED CIRRHOSIS PROVIDES COMPARABLE CLINICAL OUTCOMES TO HOSPITAL-BASED CARE WHILE IMPROVING PATIENT-CENTEREDNESS: A PROSPECTIVE STUDY

Miranda Stovall[1] Haleigh Rodgers[2] Qing Tang[1] Bridget Hawryluk[3] Courtney Moore[3] Andrea Kiser[3] Nanditha Kolur[1] Elyse Thorne[2] Blaine Takesue[2] Raj Vuppalanchi[1] Eric Orman[3] Naga Chalasani[4] Archita Desai[1], [1]Indiana University School of Medicine, [2]Indiana University Health, [3]Indiana University, [4]Indiana University Medical Center

Background: Hospital at Home (HaH) is a patient-centered program that delivers hospital-level care at home using telemedicine. This model has been shown to reduce adverse events, readmissions, and costs while improving patient satisfaction. In liver disease, many hospital days after initial stabilization are spent on lower acuity needs like IV medications or lab monitoring, representing an opportunity for HaH to reduce hospital-related adverse events and healthcare utilization. We aim to prospectively explore the clinical and patient-reported outcomes of HaH services. **Methods:** Thirty-four hospitalized liver disease patients received HaH care from 6/2023-4/2025. 17 consented to participate in pre-post qualitative interviews and to complete the Telemedicine Satisfactory Survey (TSQ) after HaH care. Using interactive activities, patients and caregivers were asked to (1) identify perceived risks, benefits, barriers of HaH care, (2) provide expectations of HaH, (3) explore how expectations aligned with experienced outcomes, and (4) provide revisions of the program. Control participants were propensity score matched in a 1:3 ratio using a greedy nearest-neighbor algorithm from a prospective inpatient cirrhosis cohort (7/2020–4/2025), based on age, gender, active alcohol use, liver disease etiology, admission reason, Child-Pugh (CP) class, primary service team, ED visits in the past 30 days, and hospitalizations in the past 6 months. Clinical outcomes were compared between study participants to matched controls using regression models. **Results:** The study cohort ($n = 17$) and matched controls ($n = 51$) are described in Figure. Among HaH participants, 96% were classified as CP class B/C with a median MELD 3.0 score of 22.5 (IQR: 17.0, 28.5). The primary reasons for admission were ascites (41%), hepatic encephalopathy (18%), and AKI (15%). The mean inpatient stay was shorter in the HaH

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

group compared to the control (6.9 ± 7.1 days vs 12.3 ± 10.9 days; p = 0.071). 30-day readmissions were less frequent in the HaH group (6%, n = 1) than in the control group (35%, n = 18; p = 0.043). There were no 30-day deaths in the HaH group vs. 6% (n = 3) in the control group. All TSQ mean scores in HaH exceeded 3, indicating agreement that care was comparable to in person care (Table). In qualitative interview activities (e.g., participants wrote love/breakup letters), participants noted many strengths of the program (Figure). Indications for improvement noted vague discharge instructions, issues with technology, and timeliness of home visits. **Conclusion:** HaH is an emerging model of acute care for patients with decompensated cirrhosis. Our experience indicates similar clinical outcomes to hospital-based care while improving patient-centered care. Future studies are needed to analyze the impact of HaH-based cirrhosis care on inpatient complications, cost of care, and patient/caregiver reported outcomes.

3032 | DIMENSION ANALYSIS OF ENVISION STUDY EQ-5D DATA TO ASSESS RELATIONSHIP BETWEEN ANNUALIZED ATTACK RATE AND CHRONIC SYMPTOMS IN PATIENTS WITH ACUTE HEPATIC PORPHYRIA

Manisha Balwani[1] Manish Thapar[2] Susana Monroy[3] Weiming Du[4] Teresa Kauf[4] Marianne Sweetser[4] Jamie Weiss[4] Paolo Ventura[5] Bruce Wang[6], [1]Icahn School of Medicine at Mount, Sinai, [2]Thomas Jefferson University, Philadelphia, PA, USA, [3]Centro Médico ABC, Mexico City, Mexico, [4]Alnylam Pharmaceuticals, Cambridge, MA, USA, [5]University of Modena and Reggio Emilia, Modena, Italy, [6]UCSF Health, San Francisco, CA, USA

Background: Acute hepatic porphyria (AHP) is a group of rare disorders with acute attacks of pain and neurological symptoms, which may lead to altered mental status. While attack frequency is often used to categorize AHP, data from the phase 3 ENVISION study of givosiran suggest patients may have chronic symptoms that are not necessarily related to acute attacks. Here, we further investigate the relationship between annualized attack rate (AAR) and chronic symptom burden, using a broader classification of attacks than used in ENVISION. **Methods:** ENVISION enrolled patients with AHP aged ≥ 12 years with ≥ 2 attacks requiring hospitalization, urgent care, or intravenous hemin at home in the 6 months before randomization.

In this *post hoc* analysis, patients from the givosiran and placebo groups were categorized into quartiles by an expanded measure of historical AAR (eAAR), also including attacks requiring healthcare facility visit, and attacks without hemin use at home, to account for less severe attacks that may contribute to disease burden. Patients completed the EQ-5D survey at baseline (BL), rating mobility, self-care, usual activities, pain/discomfort, and anxiety/depression on that day. BL EQ-5D scores were thought to reflect chronic disease burden, as patients were not in an acute attack during assessment. The relationship between historical eAAR and BL EQ-5D dimension scores was tested by Spearman correlation coefficients (ρ) and logistic regression. **Results:** Among 94 patients (mean [SD] age 38.8 [11.4] years; 89.4% female), the median (range) historical eAAR was 8 (4-50); 52% of patients reported prior chronic symptoms between attacks. Patients most frequently reported problems in the pain/discomfort dimension (75.5%) and least frequently in the self-care dimension (17.2%). The proportions of patients reporting problems in each dimension were

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

generally similar across eAAR quartiles (Figure). Aside from self-care (weak correlation of $\rho = 0.2$; odds ratio 1.06), no correlations were found between eAAR and individual EQ-5D dimension scores, and odds of reporting a problem in other EQ-5D dimensions did not significantly increase with increased historical eAAR. **Conclusion:** Patients with AHP may experience chronic symptoms not necessarily predicted by historical AAR, including pain/discomfort and anxiety/depression. Broadening the AAR criteria did not meaningfully affect the results. The chronic burden of AHP on health-related quality of life should be assessed regularly to help guide disease management.

3033 | ADOLESCENT LIVED EXPERIENCES WITH HEPATITIS B

Catherine Freeland Suzanne Block[1] Vincent DiLorenz[2] Prutha Tailor[2] Djeneba Fofana[3] Samuel Etien[4] Patricia Brazille[5] Agathe Beauquesne[5] Chari Cohen[1] Manal El-Sayed[6], [1]Hepatitis B Foundation, [2]Thomas Jefferson University, [3]Université des Sciences, des Téchniques et des Téchnologies de Bamako (USTTB), Mali, [4]Youth Health Center (Espace Santé Jeunes), Diagnostic and Therapeutic Center, Hôtel-Dieu Hospital, G, [5]Youth Health Center (Espace Santé Jeunes), Diagnostic and Therapeutic Center, Hôtel-Dieu Hospital, [6]Ain Shams University

Background: Hepatitis B affects over 250 million people globally, yet research rarely considers the lived experiences and treatment preferences of those infected, especially young adults and adolescents. To address this gap, qualitative interviews were conducted with individuals with hepatitis B under the age of 30 to better understand their management experiences, challenges and treatment preferences. **Methods:** The study includes qualitative interviews focused on individuals aged 18–30 living with hepatitis B. Interviews assessed lived experiences, treatment preferences, stigma, and quality of life. Interviews were conducted virtually and in-person, utilizing a semi-structured interview guide with five sections and 26 questions, lasting approximately 30–50 minutes. Data were analyzed using grounded theory and Nvivo software, with interviews transcribed and translated verbatim and double coded by at least two trained researchers. A codebook guided analysis, ensuring intercoder reliability and agreement. **Results:** Participants represented global perspectives from various international settings (including Nigeria, Mali, Egypt, the United States and France). Qualitative interviews of young people with hepatitis B highlight overarching themes such as common experiences of discrimination and stigma, challenges associated with accessing care and affording medication to manage their condition, low knowledge within the community, and fear to disclose their hepatitis B status to others. Experience differences related to accessing treatment and care were commonly reported in upper income countries (France and the United States), while medication access and provider challenges were less reported. Despite varying experiences associated with hepatitis B, young people remain hopeful towards a cure for hepatitis B and are optimistic in the outlook of their health. **Conclusion:** While young people with hepatitis B experience challenges associated with their diagnosis, they maintain an optimistic outlook on current and future developments towards a hepatitis B cure and treatment. Efforts should continue to understand young person's perspectives associated with hepatitis B so interventions can be effectively designed to

3034 | PROSPECTIVE IMPLEMENTATION AND EVALUATION OF A REAL-WORLD FIB-4 SCREENING PATHWAY FOR MASLD WITH SIGNIFICANT FIBROSIS IN PRIMARY CARE PATIENTS WITH DIABETES, OBESITY, OR BOTH

Mohsen Merati[1] Max Goldman[2] Janet Chu[1] Bilal Hameed[1] Nghiem Ha[1] Mandana Khalili[1] Gabrielle Winer[3] Rena Fox[1], [1]University of California, San Francisco, [2]Kaiser Permanente, Northern California, [3]Stanford University

Background: AASLD recommends primary care providers (PCPs) perform FIB-4 screening for MASLD with significant fibrosis (F2-4) in patients with one or more risk factors. However, awareness and adoption of this pathway among PCPs remains low, and few studies have evaluated its real-world implementation. We prospectively assessed a FIB-4-based MASLD screening pathway in primary care (PC) patients with type 2 diabetes mellitus (DM), obesity, or both, focusing on the detection of significant fibrosis, referral drop-offs, and opportunities for education or system improvement. **Methods:** We identified adult patients from a large urban primary care practice using EMR data from 2019-2023. Annual FIB-4 scores were calculated, and the most recent score was categorized by age-based thresholds into low-, indeterminate-, or high-risk for advanced fibrosis. For patients with indeterminate- or high-risk FIB-4, PCPs received an EMR prompt recommending Fibroscan referral. All steps took place within routine care: PCPs chose whether to refer or not, and scheduling followed usual processes. Fibroscan results were classified as significant fibrosis (F2-F4) if median liver stiffness was $\geq$8kPa. **Results:** Among 22,806 PC patients, 7,027 (31%) had DM, obesity, or both. Of these, 5,055 (72%) had at least one FIB-4, and 1,158 (23%) were categorized as indeterminate- or high-risk. To date, the PCPs of 430 indeterminate- and high-risk FIB-4 patients received a prompt recommending Fibroscan. The PCPs referred 223 (52%) thus far, of whom 162 (73%) scheduled Fibroscans. The majority (80%) are completed or pending. Significant fibrosis was detected in 26 of 104 patients (25%) to date (Figure 1). **Conclusion:** We report interim results from our prospective FIB-4 screening in PC patients in three risk-factor cohorts, including real-world uptake by PCPs and Fibroscan results. In over half the patients, PCPs opted to refer for Fibroscan, and most referred patients completed a Fibroscan. Previously unrecognized $\geq$F2 fibrosis was found in 25% of scanned patients with elevated FIB-4. The most significant drop-off in the pathway was the PCP decision to refer for Fibroscan; 48% of patients were not referred, revealing a critical point for improved PCP education. Given the emergence of therapies to treat MASLD fibrosis, optimizing the uptake of the screening pathway will improve delivery of high-quality MASLD care to the large population of patients with unrecognized fibrosis.

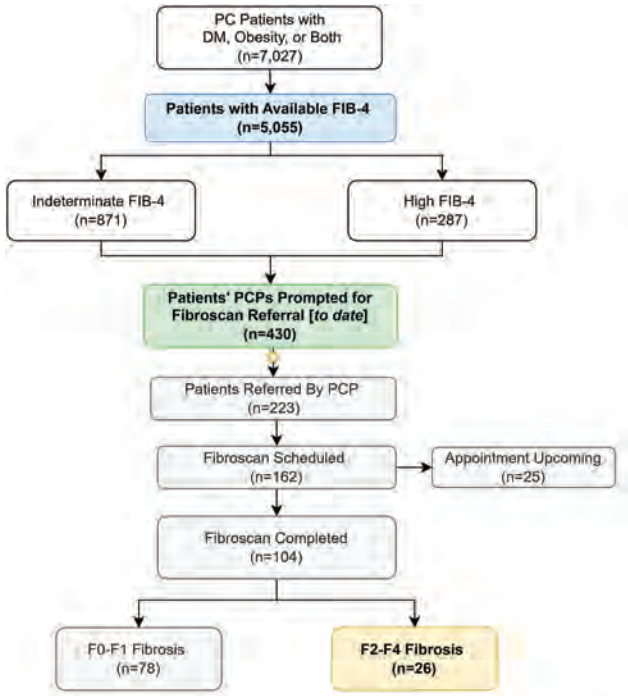

Figure 1 Implementation and interim evaluation of a real-world referral algorithm in primary care for identifying significant fibrosis (F2-4) in MASLD among patients with type 2 diabetes, obesity, or both. The most significant drop off point is indicated by a "*". *Abbreviations: DM, type 2 diabetes mellitus; FIB-4, fibrosis-4 index score; PC, primary care; PCP, primary care provider*

3035 | EPIDEMIOLOGY OF AT-RISK CLINICALLY SIGNIFICANT PORTAL HYPERTENSION IN THE UNITED STATES

Ritik Mahaveer Goyal[1] Apoorva Doshi[2] Sameer Rao[3] Rohan Karkra[3] Imran Qureshi[4] Paul Gaglio[3], [1]Rutgers New Jersey Medical School, [2]University of Alabama at Birmingham, [3]Rutgers NJMS, [4]RUTGERS THE STATE UNIVERSITY OF NEW JERSEY

Background: Clinically significant portal hypertension (CSPH) represents a pivotal stage in the progression of chronic liver disease. According to the Baveno VII guidelines, CSPH can be ruled out in individuals with liver stiffness measurement (LSM) <15 kPa and platelet count $>150{,}000/\mu l^3$. However, patients with compensated advanced chronic liver disease (cACLD) who do not meet these criteria require further evaluation, as they are considered at risk for CSPH. This study aimed to characterize the prevalence and demographic features of individuals at risk for CSPH in the United States. **Methods:** We analyzed data from adults who underwent complete transient elastography (TE) using the National Health and Nutrition Examination Survey (NHANES) from 2017 - March 2020. Patients meeting Baveno VII rule-out criteria (LSM <15 kPa and platelets $>150{,}000/\mu l^3$) were categorized as "rule-out CSPH," while all others (LSM ≥ 15 kPa or LSM <15 kPa with platelets $<150{,}000/\mu l^3$) were defined as "at-risk CSPH." We applied NHANES-recommended sample weights to account for the complex sampling design. Chi-square tests were used for categorical variables and ANOVA for continuous variables. **Results:** A total of 7,847 adult participants had complete TE data, of which 7,479 met criteria for rule-out CSPH, while 368 were classified as at-risk CSPH. The weighted prevalence of at-risk CSPH was 5.78% (95% CI: 4.9%–6.8%). Compared to the rule-out group, at-risk CSPH patients were older (mean age 54.9 vs. 46.9 years, $p<0.001$), had a lower proportion of males (32.2% vs. 52.2%, $p<0.05$), higher mean BMI (33.4 vs. 29.4, $p<0.001$), and waist circumference (110.1 vs. 99.5 cm, $p<0.001$). The at-risk group had a significantly higher prevalence of hypertension (66.2% vs. 45%, $p<0.001$), diabetes mellitus (30.1% vs. 13.8%, $p<0.001$), MASLD (33.8% vs. 23.5%, $p<0.05$), and chronic hepatitis C (6.5% vs. 1.8%, $p<0.001$). No significant differences were observed in the prevalence of chronic hepatitis B, excessive alcohol use, or current smoking. Notably, 88% of those in the at-risk group were unaware of their liver disease. **Conclusion:** In this nationally representative sample, nearly 6% of U.S. adults undergoing transient elastography were at risk for CSPH. This group demonstrated a distinct clinical profile marked by older age, higher BMI, and greater metabolic and viral liver disease burden. Alarmingly, most remained unaware of their liver condition, underscoring the need for enhanced screening and early detection strategies.

Table: Demographic, comorbidity and etiological profile of patients with CSPH ruled out and at-risk CSPH

Participant Factors	LSM<15kPa and Platelet count >150,000/uL (CSPH ruled out) (N=7,479)	LSM>15kPa OR LSM < 15kPa + Platelet count ≤150,000/uL (at-risk CSPH) (N=368)	p-value
Weighted Prevalence	94.2% (93.2%-95.1%)	5.78% (4.9%-6.82%)	
Mean Age in years (SE)	46.91 (± 0.55)	54.91 (±1.04)	<0.001
Males, % (95% CI)	52.2% (50.4-53.9)	32.2% (26.5-38.5)	<0.05
Race, prevalence % (95% CI)			0.72
White	62.8% (57.9-67.4)	63.3% (52.2-73.1)	
Black	10.77% (8.28-13.89)	12.13% (8.37-17.26)	
Asian	5.76% (4.14-7.98)	3.4% (3.34-8.54)	
Mexican American	8.85% (6.64-11.67)	7.6% (4.47-12.86)	
Other Hispanic	7.77% (6.34-9.48)	6.52% (4.29-9.8)	
Multiracial	4.05% (3.39-4.84)	4.97% (2.67-9.09)	
Have been told that they have liver disease, % (95% CI)	4.23% (3.46-5.15)	11.97% (8.01-17.51)	<0.001
Mean BMI (SE)	29.4 (±0.17)	33.43 (±0.71)	<0.001
Waist Circumference (±SE) (in cm)	99.5 (±0.48)	110.14 (±1.41)	<.001
Current Smoker, % (95% CI)	16.67% (14.65-18.92)	15.54% (9.46-24.46)	0.77
Diabetes Mellitus, % (95% CI)	13.8% (12.8-14.7)	30.1% (25.4-35.3)	<0.001
Hypertension, % (95% CI)	45% (42.1-47.8)	66.2% (58.8-73)	<0.001
MASLD, % (95% CI)	23.48% (21.52-25.56)	33.79% (26.25-42.26)	<0.05
Excess Alcohol Intake, % (95% CI)	9.74% (8.44-11.22)	9.24% (5.27-15.7)	0.84
Active Hepatitis B_s % (95% CI)	0.87% (0.56-1.33)	1.14% (0.24-5.16)	0.71
Chronic hepatitis C, % (95% CI)	1.84% (1.13-2.97)	6.32% (4.94-8.58)	<0.001

3036 | TREATMENT DELAYS AND SURVIVAL IN PATIENTS WITH HEPATOCELLULAR CARCINOMA: A MULTICENTER COHORT STUDY

Mohammad Jarrah[1] Mohammed Al-Hasan[1] Gloria Figueroa[2] Stephanie Garces[2] Sruthi Yekkaluri[1] Lisa Quirk[1] Suaiba Syeda[1] Patricia Jones[2] Adam Yopp[1] Nicole Rich[1] Amit Singal[1], [1]University of Texas Southwestern Medical Center, [2]University of Miami

Background: Interruptions in the cancer care continuum, such as treatment delays, can impact survival in patients with hepatocellular carcinoma (HCC). While the impact of such delays have been described in other cancers, data are limited on the prevalence of these delays what factors predict delays, and the impact of delays on survival among patients with HCC. **Methods:** We conducted a retrospective cohort study of patients diagnosed with HCC between 2010 and 2018 across 4 U.S. health systems. Treatment delay was defined as receiving the first treatment >90 days after HCC diagnosis. Patients who remained untreated and those with BCLC stage D were excluded from analyses given limited options for HCC-directed treatment outside of liver transplantation. Univariable and multivariable logistic regression models were performed to identify factors associated with treatment delays. The association between treatment delay and overall survival was evaluated using multivariable Cox regression model; to account for immortal time bias, we established a 6-month landmark in which patients who died before 6 months were excluded. **Results:** Of the 1561 eligible patients (median age 61.7 [IQR 56.7 – 67.7], 75.0% men, 48.0% BCLC stage 0/A), treatment delays occurred in 357 (22.9%) patients. Treatment delays were observed in 31.1% of patients with BCLC stage 0, 24.3% of BCLC stage A, 22.6% of BCLC stage B, and 13.6% of BCLC stage C, including 28.1% of patient within Milan criteria. Men (OR 0.68, 95%CI 0.49 – 0.96) and patients with BCLC stage C HCC (vs BCLC A: OR 0.40, 95%CI 0.25 – 0.63) were less likely to experience delays, while those with BCLC stage 0 (vs BCLC A: OR 1.56, 95%CI 1.06 – 2.29) were more likely to experience delays. Using a 6-month landmark analysis, median overall survival was 19.0 months (IQR: 7.9 – 40.6) in patients who received timely treatment compared to 18.7 months (IQR: 8.5 – 39.6) in those with delayed treatment. Based on this landmark, there was no significant difference in survival between delayed vs. timely treatment (HR 0.94, 95%CI 0.76 – 1.18). **Conclusion:** Treatment delays beyond 90 days occur in nearly one-fourth of patients, with significant associations with sex and tumor burden. Treatment delays did not significantly impact overall survival, suggesting that modest delays may not compromise survival outcomes. Additional studies are needed to better understand the impact of treatment delays.

3037 | SURVEILLANCE FOR HEPATOCELLULAR CARCINOMA IN ALASKA NATIVE PEOPLES WITH CHRONIC HEPATITIS B

LESLEIGH KOWALSKI FRANK, BRIAN J MCMAHON, CHRISS HOMAN, MARY SNOWBALL, LISA TOWNSHEND-BULSON*, Lesleigh Kowalski Frank[1] Brian McMahon[2] Lisa Townshend-Bulson[1] Chriss Homan[1] mary snowball[1]*

[1]Alaska Native Tribal Health Consortium, [2]Alaska Native Medical Center

Background: Hepatitis B virus (HBV) causes the most common acute and chronic serious viral infections globally. Chronic hepatitis B (CHB) is a leading risk factor for developing hepatocellular carcinoma (HCC). HBV is endemic in Western Alaska and Alaska Native (AN) peoples have high prevalence rates of HBV infection, acquired primarily at birth or early in life, and have a higher incidence of HCC compared to other communities. AASLD recommends people at a higher risk for HCC receive bi-annual liver function (LFT)/HBV tests, AFP tests, and liver ultrasound (US). In this study, we aimed to identify the proportion of people who did/did not meet AASLD HCC surveillance guidelines. **Methods:** We established a clinical registry for all HBsAg-positive AN peoples in the 1980s during a HBV screening and vaccination campaign. We send letters to all AN persons with CHB and their providers every 6 months to remind them to obtain liver blood tests and HCC screening with US. For this analysis, we used registry data from a 5-year period from 2017 through 2021 of AN peoples who consented to participle in a long-term hepatitis B cohort study to determine receipt of these surveillance tests. **Results:** Of the 913 AN peoples with CHB, 689 (75.5%) were considered high risk for HCC based on: cirrhosis, a family

history of HCC, age ≥40 years men and ≥50 year women, or HBV genotype F at any age. Of these persons, an average of 38.4% had LFT/HBV and 21.4% had AFP tests at least twice/year; 67.4% obtained LFT/HBV and 54.8% had AFP tests at least once/year. During the pandemic (years 2020-2021), 8.7% had at least two US tests/year while 40.6% had at least one, compared to 9.7% and 41.6% before the pandemic (2017-2019), respectively. US frequency was significantly higher ($p < 0.001$) in all years in urban and hub communities with access to US compared to more rural communities where air travel is required to access US. **Conclusion:** We were one of the first organizations to initiate an HCC surveillance program for those with chronic HBV infection in an endemic region. This study shows that encouraging people with CHB with no symptoms to complete screening tests every 6 months is challenging, especially if they live in remote Alaskan communities. HCC US screening rates lag behind other cancer screening rates among AN peoples, such as colorectal (56.2%) and breast (61.3%), with the exception of lung (9.3%). Further targeted risk stratification may help to prioritize patients at the highest risk of HCC to increase surveillance rates.

3038 | MASLD/MASH CARE PATHWAY ADHERENCE IDENTIFIES PATIENTS WITH ADVANCED FIBROSIS

Anna Mageras[1] Jake DeBroff[2] Jihae Jeon[3] Rama Hussein[4] Tracey Rosa[5] Ilana Ramer Bass[3] Christopher Gold[6] Stephanie Wang[7] Theresa Mack[7] Desiree Chow[3] Nina Priven[3] Heather Viola[3] Xiaotao Zhang[3] Fernando Carnavali[3] Meena Bansal[8], [1]Liver Diseases, Icahn School of Medicine at Mount Sinai, [2]Mount Sinai Beth Israel, [3]Icahn School of Medicine at Mount Sinai, [4]Mount Sinai Morningside-West Hospital, Icahn School of Medicine at Mount Sinai New York, NY, United, [5]Icahn School of Medicine at Mount Sinai New York, [6]Mount Sinai West, New York, NY, [7]Mount Sinai Morningside, New York, NY, [8]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: At baseline in our large, urban healthcare system, <10% of patients with diabetes (PWD) were screened for metabolic dysfunction-associated steatotic liver disease (MASLD) with FIB-4 score per American Association for the Study of Liver Diseases (AASLD) recommendation. Nevertheless, ambulatory leaders were reluctant to add a screening prompt to our electronic medical record (EMR), citing provider alert fatigue. To generate supporting data, a group of primary care providers (PCPs) and endocrinology fellows piloted improved adherence to the care pathway. We evaluated different methods, barriers to care, and health disparities. **Methods:** In two primary care and one endocrinology clinics, providers used a SmartPhrase typed into their encounter note to calculate FIB-4 from existing AST, ALT, and Platelet lab results. The SmartPhrase provided age-adjusted recommendations for VCTE (FIB-4 1.3-2.67 for ages 18-64; 2.0-2.67 for 65+) or hepatology referral (> 2.67). In two additional clinics, backend FIB-4s were calculated from existing labs, and PCPs were given lists of PWD needing referrals. For analysis, we removed PWD seen by oncology or liver and lacking requisite labs. We used chi-square tests to compare arms and univariable and multivariable logistic regression to assess health disparities through the care pathway. **Results:** Among 5,641 PWD eligible for FIB-4 screening, 45% were under age 65; 60% female; 33% Black, and 31% Latino. Of 2,769 (49%) screened, 859 (31%) needed a referral, 367 (13%) received one, and 177 (6%) completed VCTE, identifying 13% F2 (8-10kPa), 6% F3 (10-14kPa), and 7% F4 (>14kPa) cases. Of 190 PWD who received but did not complete referrals, 22 had upcoming appointments, 69 needed outreach, 7 no-showed, 5 declined, 1 was unable to complete, and 72 were pending provider signature in the EMR. Backend FIB-4 calculation resulted in a 100% screening rate, versus a 16% rate via provider-driven screening. But significantly higher rates of referrals were given and completed among PWD screened by providers ($p < .0001$). PWD with higher BMI, non-white, and Medicare- and/or Medicaid-insured had higher odds of being screened; PWD with higher BMI and identifying as Black had higher odds of getting a referral; but Black PWD and those of unknown race had lower odds of completing VCTE (Table 1). **Conclusion:** Forty-nine percent of eligible patients were screened, and 26% of VCTE-evaluated patients had F2-F4, demonstrating the care pathway's utility. Our quality intervention improved adherence to the care pathway, but gaps remain. Placing referrals and engaging patients is labor intensive. Patient navigators would support providers and patients and reduce disparities. Patient anxiety about out-of-pocket expenses was a barrier; VCTE-only appointments may streamline referrals. A provider dashboard that auto-calculates FIB-4 and allows bundled referrals may be a more effective, equitable, and less burdensome implementation.

3039 | LONG-TERM FOLLOW-UP AND FACTORS INFLUENCING FOLLOW-UP ADHERENCE AFTER DAAS THERAPY: A MULTICENTER STUDY OF SVR 3,704 PATIENTS IN NATIONWIDE SURVEY

Masatsugu Ohara[1] Ritsuzo Kozuka[2] Yoshihito Uchida[3] Chikara Iino[4] Ryo Sasaki[5] Hiroki Tojima[6] Satoru Kakizaki[7] Yoshio Tokumoto[8] Hirokazu Takahashi[9] Akira Asai[10] Jun Inoue[11] Mizuki Endo[12] Kazuhito Kawata[13] Kenji Nagata[14] Koji Ogawa[15] Tetsuro Shimakami[16] Masaru Enomoto[2] Tadashi Ikegami[17] Tatsuya Ide[18] Naoya Sakamoto[19] Masaaki Korenaga[20], [1]Hokkaido University Hospital, [2]Osaka Metropolitan University, [3]Saitama Medical University, [4]Hirosaki University, [5]Yamaguchi University, [6]Gunma university, [7]NHO Takasaki General Medical Center, [8]Ehime university, [9]Saga university, [10]Osaka Medical and Pharmaceutical University Hospital, [11]Tohoku university, [12]Oita university, [13]Hamamatsu University School of Medicine, [14]University of Miyazaki, [15]NTT Medical Center Sapporo, [16]Kanazawa university, [17]Tokyo Medical University Ibaraki Medical Center, [18]Kurume university Medical center, [19]Graduate School of Medicine Hokkaido University, [20]Japan Institute for Health Security (JIHS)

Background: Achieving sustained virologic response (SVR) after direct-acting antiviral (DAA) therapy significantly improves the prognosis of hepatitis C virus (HCV) patients. However, the long-term follow-up status for SVR patients, particularly regarding the continuation of care and risk factors for discontinuation, remains underexplored. This study aims to address this gap by evaluating the follow-up outcomes of SVR patients at regional core centers across Japan. To evaluate the long-term follow-up outcomes of patients who achieved SVR after DAA therapy and analyze factors influencing follow-up adherence, transfer, and discontinuation. **Methods:** A retrospective, multicenter study was conducted at 16 regional core centers, analyzing data from 3,704 patients who achieved SVR between 2015 and 2018. We assessed patient demographics, follow-up status, and clinical outcomes, including hepatocellular carcinoma (HCC). Multivariate analyses identified factors associated with discontinuation, transfer, and follow-up continuation. **Results:** At the time of analysis, 41.2% of patients remained under follow-up at regional core centers, 31.3% transferred to other institutions, and 21.3% discontinued follow-up. Serotype 2 (OR 1.61, 95% CI 1.34–1.93, $p < 0.001$) was significantly associated with a higher likelihood of discontinuation. Furthermore, a higher FIB-4 index, HCC, and other malignancies were all significantly associated with a reduced likelihood of discontinuation (FIB-4 index between 1.3 and 3.25: OR 0.628, 95% CI 0.497–0.793; FIB-4 index $\geq$ 3.25: OR 0.701, 95% CI 0.526–0.934; HCC: OR 0.209, 95% CI 0.121–0.362, $p < 0.001$; other malignancies: OR 0.61, 95% CI 0.386–0.963, $p = 0.0338$). In contrast, age $\geq$65 years, serotype 2, and hypertension were significantly associated with a higher likelihood of transfer to other institutions (age: OR 1.59, 95% CI 1.33–1.89, $p < 0.001$; hypertension: OR 1.24, 95% CI 1.04–1.49, $p = 0.0188$). Patients with a higher FIB-4 index (OR 0.755 for 1.3-3.25, OR 0.709 for $\geq$3.25) and HCC (OR 0.27, 95% CI 0.18–0.405, $p < 0.001$) were less likely to transfer. **Conclusion:** This study highlights that serotype 2, higher FIB-4 index, and HCC are key factors related to follow-up adherence. Patients with higher FIB-4 indices and HCC were more likely to remain under follow-up at regional core centers, indicating these centers effectively manage high-risk cases.

3040 | OPTIMIZING WORKFLOWS FOR PROVIDERS USING LARGE LANGUAGE MODELS TO RESPOND TO PATIENT MESSAGES IN THE ELECTRONIC PORTAL

Hersh Shroff[1] Oren Fix[2], [1]UNC Chapel Hill, [2]University of North Carolina at Chapel Hill

Background: Healthcare providers (HCPs) who care for patients with complex, chronic liver disease spend significant time outside of clinic on electronic health record (EHR) tasks. An increasing volume of patient medical advice requests (PMARs) has been linked to clinician burnout. Artificial intelligence (AI) tools offer opportunities to reduce EHR burden on HCPs. We assessed two methods for using a large language model (LLM) to assist HCPs in responding to PMARs. **Methods:** We enrolled a convenience sample of HCPs at an academic center to test two LLM workflows (Models 1 and 2). Model 1 uses Epic's *Automated Response Technology (ART)*, where an EHR-integrated LLM is given a standard prompt and reads the text of a patient message to generate a draft reply. Model 2 uses our institution's HIPAA-secure LLM, accessed separately from the EHR. In this workflow, HCPs provide the LLM with a standard prompt written by the study investigators followed by a shorthand description of the provider's desired response, and the LLM generates a reply. Both models use OpenAI's GPT 4o. HCPs tested 40 unique PMARs (20 per model) and used an online survey (Qualtrics, Provo, UT) to rate AI-generated drafts on quality of information content, communication style, provider's preference of using model vs. self, and cognitive burden. Ratings were compared using the Mann-Whitney U test. All statistics were performed in R (version 4.5.0). **Results:** Of 13 currently-enrolled HCPs, 8 are gastroenterologists and hepatologists, 10 are physicians, and 3 are advanced practice providers. Thus far, 5 HCPs have completed testing of 90 Model 1 and 95 Model 2 messages. On a 5-point Likert scale (0 = significantly disagree; 4 = significant agree), HCPs were significantly more likely to agree that messages from Model 2 (as compared to Model 1) provided high information quality (median [IQR]: 4 [3-4] vs. 1 [0-3], $p < 0.001$) and appropriate communication style (4 [3-4] vs. 2 [1.25-3], $p < 0.001$). HCPs reported lower cognitive burden to use Model 2 (1 [0-2] vs. 2 [1-2.75], $p < 0.001$). When asked if they preferred to use the AI response versus writing the message on their own, HCPs agreed for Model 2 responses (3 [1-4]) but not for Model 1 (1 [0-3]). **Conclusion:** With increasing integration of AI tools into clinical practice, it is important for HCPs and health systems to continuously re-evaluate optimal workflows. In our study, a model allowing HCPs to engage with and instruct an LLM was significantly preferred over an alternative model where providers had little input or control.

Table 1: Example of a top-rated draft message by Model 2 workflow

Patient's Original Message	Thank you! I will continue with the nifedipine and that Miralax bowel prep. I will also add that I was only taking Miralax twice a day for a week before that scan - and I know that likely isn't long enough to move things along. I will continue with the Miralax! I will also add that yesterday evening I had another significant bowel movement (half diarrhea, half solid) yesterday evening - but for a couple seconds I blacked out from the pain during that bowel movement. I wasnt straining, but there was likely a ton of pain within my colon as things were passing through. I felt fine after that. And I feel relatively normal today. Thank you,
Provider Input to Large Language Model (LLM)	[Copied and pasted text of patient's initial message into LLM] * discuss vagal response and constipation, advise to continue to monitor symptoms
LLM Draft Response	Hi XXXX, Thank you for your message. I'm glad to hear that you will continue with the nifedipine and the Miralax bowel prep. It's important to give Miralax some time to work, so continuing it is a good plan. Regarding your recent experience, it sounds like you might have had a vagal response during your bowel movement. This can happen when the vagus nerve is stimulated, leading to a temporary drop in heart rate and blood pressure, causing you to feel faint or briefly black out. This response can sometimes occur during bowel movements, especially if there is significant pain or strain. Constipation can contribute to this issue, as the discomfort and effort to pass stool can trigger the vagal response. It's good to hear you felt fine afterward and feel relatively normal today. Please monitor your symptoms closely and let us know if you experience any more severe pain or other concerning symptoms. If you have any questions or need further assistance, please let us know. Best regards, XXX

3041 | DETERMINANTS OF HEALTH-RELATED QUALITY OF LIFE AMONG CHRONIC HEPATITIS B PATIENTS IN FRANCE

Clotilde Lepers[1] Clovis Lusivika-Nzinga[2] Samuel Nilusmas[2] Jonathan Bellet[2] Paul Burgat[2] Marc Bourliere[3] Maria Patrizia Carrieri[4] Fabrice Carrat[5] Sylvie Deuffic-Burban[6], [1]Université Paris Cité, Inserm, IAME, Hôpital Bichat, AP-HP Nord, Paris, France, [2]Sorbonne Université, Inserm, iPLesp, Paris, France, [3]Aix Marseille Univ, Inserm, IRD, SESSTIM, ISSPAM, Hospital Saint Joseph, Marseille, France, [4]Aix Marseille Univ, Inserm, IRD, SESSTIM, ISSPAM, Marseille, France, [5]Sorbonne Université, Inserm, iPLesp, Hôpital Saint-Antoine, AP-

HP, Paris, France, [6]Université Paris Cité and Université Sorbonne Paris Nord, Inserm, IAME, Paris, France

Background: Health-related quality of life (HRQoL) has been shown to be impaired in patients with chronic hepatitis B (CHB). Beyond the level of disease severity, HRQoL may be affected by socio-demographic and economic conditions. The objective was to evaluate the HRQoL and their determinants among CHB patients included in the French ANRS CO22 HEPATHER cohort. **Methods:** A cross-sectional study was conducted within the prospective multicenter ANRS CO22 HEPATHER cohort between 2012 and 2019. All patients with CHB were invited to complete a questionnaire on HRQoL, at enrolment and at clinical visits. HRQoL was assessed using EQ-5D-5L collected at the first questionnaire, and utility scores were derived using the French value set. Sociodemographic, behavioral, and clinical data were obtained from HEPATHER database. Utility scores were rescaled to the (0,1) interval and modeled using a Beta-inflated GAMLSS approach. Variables were first tested in univariable analyses; those with $p < 0.05$ or clinical relevance (e.g., sex) were included in the multivariable model after multiple imputation. Average association (mean odd-ratios and their 95% confidence interval (95%CI)) was obtained using Rubin's methods. **Results:** A total of 1,715 patients completed at least one questionnaire. Among respondents, 64.4% were men, the median age was 46 years, 63.6% were under current or past treatment, 11.7% had compensated cirrhosis, 5.2% had complications (0.9% < 1 year; 4.3% > 1 year). The mean utility score was 0.94, and the median 0.98. In univariable analyses, mean utility score decreased with older age, female sex, non-sub-Saharan African origin, separated/divorced/widowed status, lower education, unemployment and at-risk alcohol consumption (current or former), and the presence of cirrhosis, complication, hypertension, diabetes and obesity. However, only unemployment and separated/divorced/widowed status decreased significantly HRQoL in the final model (Table). **Conclusion:** In this large cohort of CHB patients, HRQoL was mainly influenced by sociodemographic and behavioral factors rather than CHB-related clinical parameters. Among CHB patients, unemployment and separated/divorced/widowed status significantly alter HRQoL. These results suggest that future therapies to achieve functional cure will not necessarily improve HRQoL in these patients, underlying the importance of considering sociodemographic determinants in CHB patients' healthcare.

Table: Determinants of HRQoL (mean odd-ratios and their 95% confidence interval (95%CI)): Multivariate analysis

Variable	Odd ratio	95% CI Low	95% CI High	p-value
Women	0.93	0.82	1.04	0.23
Age superior or equal to median (46years)	0.95	0.83	1.08	0.45
Sub-Saharan origin	1.08	0.94	1.24	0.3
Lower education	0.96	0.86	1.08	0.52
Separated/divorced/widowed status	**0.82**	**0.7**	**0.96**	**0.04**
Unemployment	**0.82**	**0.73**	**0.92**	**0.01**
Current or former excessive alcohol consumption	0.88	0.71	1.08	0.24
Diabetes	0.92	0.76	1.12	0.41
Hypertension	0.86	0.75	0.99	0.06
Obesity	0.86	0.74	0.99	0.06
Cirrhosis	0.97	0.79	1.19	0.8
Ancient complication	0.96	0.74	1.26	0.78
Recent complication	0.63	0.39	1.02	0.09

3042 | PREDICTORS OF SPECIALTY REFERRAL AMONG RESETTLED REFUGEES LIVING WITH HEPATITIS B

Erin Mann[1] Darin Erickson[1] Jose Debes[1], [1]University of Minnesota

Background: Most refugees resettling to the United States (US) are from regions with intermediate to high hepatitis B virus (HBV) endemicity. Linkage to care is critical to establish proper care and reduce HBV-related complications. However, studies show gaps in chronic HBV management and care linkage after refugee arrival. The domestic medical examination (DME), the initial medical screening for refugees, often marks their first interaction with US healthcare. **Methods:** We conducted a cross-sectional analysis of DME screening data for refugees living with hepatitis B who arrived between 2003–2023, using data from the Colorado Center of Excellence in Newcomer Health, a national surveillance network spanning seven states. We summarized referrals and used multivariate regression to estimate risk ratios (RR) for associations between referral and age, sex, region of origin, hepatitis C, and HIV. Two definitions of specialty referral were used: "hepatitis B" only compared to "hepatitis B" or "gastrointestinal," based on coding review. **Results:** Among 2,449 refugees who tested positive for HBV (median age 29, IQR 21- 39; 62.0% male), most were from Asia (50.0%), the Eastern Mediterranean (27.1%), and Africa

(21.2%). Co-infection rates were low (1.6% for HCV; 1.1% for HIV). During the DME, 16.4% were referred based on “hepatitis B” codes alone, and 23.0% when including both "hepatitis B" or “gastrointestinal.” The broader definition had a higher area under the ROC curve (0.67 vs. 0.59). In this model, adult age (RR 1.44, 95% CI 1.14–1.82) and male gender (RR 1.17, 95% CI 1.03–1.32) were associated with higher referral probability. HCV and HIV were not associated with referral, though analyses may have been underpowered. Predicted referral probabilities were highest for refugees from Asia (26.8%), the Eastern Mediterranean (25.5%), and Africa (22.8%), and lowest for Europe (15.1%) and the Americas (8.0%). **Conclusion:** In this national sample of refugees with HBV (largest to date on this topic), 16.4% were referred to specialty care based on “hepatitis B” coding alone and 23.0% when including both “hepatitis B” and “gastrointestinal” codes. Adult age and male gender were associated with a higher probability of referral. Referral probabilities were highest among refugees from Asia, the Eastern Mediterranean, and Africa. Strengthening early referral pathways may help reduce long-term HBV-related health disparities.

3043 | EARLY DETECTION OF HEPATIC FIBROSIS AND HEPATOCELLULAR CANCER IN VULNERABLE ADULTS IN COMMUNITY SETTINGS: A PILOT SERVICE EVALUATION PROJECT IN SE ENGLAND

James Ryley[1] Vikki Charles[1] Margaret O'Sullivan[1] Jason Howell[1] Duncan Cresswell[1] Jeremy Tibble[1], [1]University Hospitals Sussex

Background: Many patients with chronic liver disease (CLD) present with cirrhosis and its complications including hepatocellular cancer (HCC). Early detection of CLD is the key to prevent liver related morbidity/mortality. CLD screening in the community to enable timely HCC surveillance was commissioned by NHS England as a service evaluation pilot and Sussex (SE England) selected as one of the pilot sites. In addition, screening of the public (without known risk factors) was done as part of a British Liver Trust (BLT) event. **Methods:** The setting was multiple community centres/ events, targeted populations included alcohol and substance misusers, metabolic dysfunction-associated steatotic liver disease, viral hepatitis, people experiencing homelessness (at risk group) and general public (not known risk group). At drop-in and booked clinics, transient elastography (TE) performed and routine clinical data collected. After consultant clinical review, most with liver stiffness measurement of > 11.5 kPa were offered HCC surveillance with ultrasound. Multivariate analysis was performed to determine predictors of advanced hepatic fibrosis. Data were collected between 2022 and 2025. **Results:** Total number of individuals undergoing TE were n = 3054, n = 1783 (58%) being male, majority white British, mean age 54 +/- 12 years. Average weekly alcohol consumption was 44 units. Distribution of hepatic fibrosis was none/mild (< 8.5kPa, n = 2446 (80%)), moderate (8.5 - 11.5 kPa, n = 294 (10%)) and advanced (> 11.5kPa, n = 293 (10%)).[SV1] Of the n = 293 with advanced fibrosis, n = 184/189 (97%) offered, attended for HCC surveillance ultrasound, mean time to surveillance being 87 days +/- 126. Three individuals were diagnosed with HCC (BCLC stages 0/A).
Using a multivariate logistic regression model predictors of advanced fibrosis were, alcohol units per week and at-risk vs BLT group. Each additional unit of alcohol consumed per week, increased odds of advanced fibrosis by 0.6% (OR = 1.006, 95% CI: 1.005–1.008, $p < 0.001$). Those screened at the BLT event (not known risk group) had 86% reduced odds of having advanced fibrosis (OR = 0.139, 95% CI: 0.03-0.37, $p < 0.001$). **Conclusion:** Community screening of at-risk individuals identifies a 20% prevalence of moderate to advanced hepatic fibrosis. Despite the vulnerable nature of the cohort, nearly all patients offered, accepted HCC surveillance which allowed for detection of HCC at early BCLC stage.

3044 | LIVER DISEASE-SPECIFIC LARGE LANGUAGE MODELS (LLMS) DRAFTED HEPATOLOGY "E-CONSULT" RESPONSES ARE NOT EQUIVALENT TO HUMAN RESPONSES

Debra Yen[1] Michelle Li[1] Gabrielle Jutras[1] Lisa Deng[1] Mark Pletcher[1] Jennifer Lai[1] Bilal Hameed[1] Jin Ge[1], [1]University of California, San Francisco

Background: We developed LiVersa, a protected health information (PHI)-compliant liver disease LLM customized with Retrieval Augmented Generation (RAG) on OpenAI’s GPT-4o. Specialty-specific LLMs like LiVersa may be able to address “e-consults,” which answer limited clinical questions without a patient visit using only electronic health record (EHR) data. In this study, we evaluated LiVersa-generated e-consult drafts versus actual human responses. **Methods:** We queried hepatology e-consults answered at UCSF between April-June 2024. We used LiVersa to draft responses

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

using only the question contained in the e-consult request and no additional information to the chart. Three hepatologists who did not write the original responses compared LiVersa drafts with human responses using 12 Likert scale and free-text questions. These questions were specifically developed within UCSF to grade clinical LLMs by clinical equivalence, specificity, accuracy, and safety. We used correlation heatmap analyses to determine associations in responses. **Results:** We evaluated 52 e-consults. Compared to human responses, only 25% of drafts contained all components of human responses without missing information, and 28% of drafts were considered clinically equivalent. 29% of drafts had content with potential for mild or moderate harm, and 3.8% had potential for severe or life-threatening harm. However, 74% of LiVersa-generated drafts were considered "helpful starting points," 69% had no misleading or incorrect information, and 96% were sufficiently specific to the clinical scenario. Correlation heatmaps showed that lack of clinical equivalence in the LiVersa draft had moderate associations with being incorrect (0.46) and potentially harmful (0.5). Of note, evaluators thought most (61%) e-consult requests, as written, did not contain sufficient information. In these cases, the actual human responses contained data from further chart review that was not available to LiVersa. **Conclusion:** While LLMs, in their current form, are unlikely to replace human expertise, this study concerning e-consults showed that disease-specific LLMs like LiVersa have potential to augment human hepatologists. Further work is needed to improve the quality of clinically relevant EHR data passed to LiVersa, as our study suggests LLM drafts were more clinically equivalent and more accurate when the relevant data was available to the LLM.

3045 | HARNESSING THE PATIENT PERSPECTIVES TO IMPROVE EMERGENCY DEPARTMENT UTILIZATION IN CIRRHOSIS

Swetha Parvataneni[1] Nicholas Harrison[1] Bridget Hawryluk[1] Courtney Moore[1] Anurag Harishchandrakar[1] William Bennett[1] Raj Vuppalanchi[1] Eric Orman[1] Naga Chalasani[2] Archita Desai[1], [1]Indiana University, [2]Indiana University Medical Center

Background: Individuals with cirrhosis often visit emergency department (ED) with 20% experiencing high ED use (HEDU) $\geq$2 ED visits within 90-days. We aimed to understand patient and caregiver perspectives on the reasons that contribute to HEDU and identify potential opportunities for reducing unnecessary visits. **Methods:** At a large tertiary care center, we retrospectively identified adult patients with diagnosis of cirrhosis who were HEDU patients in 2024. Eligible patients were invited to participate in a 3-hour semi-structured group-based interactive session facilitated by human-centered design experts. A custom board game modeled on the children's game "Chutes and Ladders" was used to facilitate engagement. This interactive game included questions exploring decision making prior to ED utilization and patient perspective after ED visit (Figure 1). **Results:** Seven participants (three dyads of patients and caregiver, and one patient without a caregiver) attended the session. At baseline, three patient participants had decompensated cirrhosis (2 with ascites, 1 with encephalopathy). Affinity mapping during analysis generated key drivers of HEDU. Some participants described needing to present to the ED because they did not monitor their symptoms until they were severe. Participants valued receiving effective and immediate relief for symptoms in the ED and reported that it reduced patient and caregiver stress. Participants also expressed a lack of trust in available online resources regarding cirrhosis management. Participants typically informed their outpatient doctors only after the ED visit because their prior written instructions directed them to ED for worsening symptoms. Patients believed that correctly taking their medications and monitoring their symptoms play a major role in improving their condition but are also burdensome for patients and caregivers. Conceptual modes were created to explore and explain the relationship between these drivers and relationships between patient, caregiver and provider. **Conclusion:** Our study highlights that uncontrolled symptoms, lack of access to on-demand advice from the outpatient team, and the daily stress of living with cirrhosis as drivers for frequent ED use. Patients viewed the ED as a reliable and quick source of care. These findings reveal the need for improved outpatient support, medication management, symptom monitoring, and trusted educational resources in cirrhosis care. Digital health technologies partnered with

3046 | HEPATOLOGY-LED PATIENT EDUCATION ON ALCOHOL-RELATED LIVER DISEASE DURING CHEMICAL DEPENDENCY TREATMENT: PATIENT PERSPECTIVES

Taylor Bowler[1] Elizabeth Aby[1] Lisa Vollmer[1] Mary Thomson[1], [1]University of Minnesota

Background: Alcohol use disorder (AUD) treatment is traditionally led by licensed alcohol counselors with limited education on medical complications of heavy alcohol use. Patients often only learn about medical consequences of alcohol use after the development of alcohol-related liver disease (ARLD). An earlier multidisciplinary approach would be ideal, but needs to be scalable given the number of people with AUD. To help foster this approach, our institution's inpatient alcohol treatment program added a group session led by hepatology providers to educate patients about ARLD. In this retrospective survey-based study, we aimed to understand patient perspectives on this educational intervention. **Methods:** Residents at an inpatient alcohol treatment program completed a voluntary and anonymous survey after attending a physician-led lecture on medical complications of ARLD. The survey included 14 multiple choice questions and 4 open-ended questions. Data was collected on resident demographics, knowledge of ARLD before and after the lecture, likelihood of following up with a health provider, and likelihood of maintaining sobriety after attending the lecture. Descriptive statistics were used to analyze the data. **Results:** Questionnaires were completed by 83 residents over six sessions (Table 1). The response rate was estimated to be 46% (estimated 180 attendees). Most commonly residents were male (68.7%), who identified as white (68.7%), and were between the ages of 31 and 60 (30.1% aged 31-40 years, 22.9% aged 41-50 years, 24.1% aged 51-60 years). Residents' highest educational level was some college for 33.7% followed by 21.7% with a high school degree. 85.6% of residents were interested in the lecture topic. Most residents (75.9%) had previously engaged in conversation with a health care provider about alcohol impacting their health. Residents reported that their knowledge of ARLD improved after attending the lecture. Furthermore, 74.7% of residents were more likely to follow-up with their health care provider after the lecture, and 83.1% of residents believed that the presentation was helpful in maintaining sobriety from alcohol. **Conclusion:** Overall, the majority of residents reported that the lecture enhanced their understanding of ARLD, positively impacted their sobriety and increased their willingness to follow-up with a health care provider. These results suggest that a group educational lecture on ARLD is an effective intervention to encourage abstinence and potentially reduce alcohol-related morbidity and mortality in patients with AUD.

3047 | HEPATOLOGY CLINICIAN PERCEPTIONS OF ADDICTION TREATMENT IMPORTANCE FOR PATIENTS WITH LIVER DISEASE ACROSS THE CONTINUUM OF TRANSPLANT CARE

Dylan Balter[1] Hye Young Choi[1] Marissa Justen[2] Yanhong Deng[3] E. Jennifer Edelman[4] David Fiellin[4] Lamia Haque[5], [1]Yale School of Medicine, [2]University of California - San Francisco, [3]Yale Center for Analytical Sciences, Yale School of Public Health, [4]Yale School of Medicine, Program in Addiction Medicine, Department of Internal Medicine, [5]Yale New-Haven Hospital

Background: Alcohol (AUD), opioid (OUD), and tobacco use disorder (TUD) are common in patients with liver disease, yet few receive treatment. Patients receive care along a transplant spectrum: non-transplant (NT), listed for transplant (LT), and post-transplant (PT). It is unclear how addiction treatment is prioritized for these groups. We assessed hepatology clinicians' views on the importance of treating AUD, OUD, and TUD for NT, LT, and PT patients. **Methods:** From July-September 2022, we conducted a mixed-methods study of hepatology clinicians at six sites within an academic center as part of a formative evaluation of attitudes toward treating addiction in liver clinics. Clinicians rated the importance of treating AUD, OUD, and TUD for NT, LT, and PT patients on a 5-point Likert scale. To compare perceived treatment importance across patient groups, we used generalized linear mixed-effects models while accounting for repeated measures from the same clinician. Type III test of fixed effects assessed whether transplant status predicted perceived treatment importance. Among a subset of clinicians, we also conducted semi-structured interviews and used thematic analysis to explore clinician views on addiction treatment for NT, LT, and PT patients. **Results:** Of 50 survey respondents (94% response rate; median age 41; 56% female), 35 completed interviews. Most clinicians rated AUD treatment as very important for NT (86%), LT (92%), and PT patients (90%), with no significant differences between groups. For OUD, treatment was rated very important less often for NT vs PT patients (52% vs 80%; $p = 0.002$), but similarly for LT vs PT patients (84% vs 80%; $p = 0.42$). For TUD, treatment was rated very important less often for NT vs PT patients (42% vs 78%; $p < 0.001$) and similarly for LT vs PT patients (86% vs 78%; $p = 0.17$). Overall, transplant status predicted perceived importance of treating OUD ($p = 0.0003$) and TUD ($p < 0.001$), but not AUD ($p = 0.51$). Emergent themes showed that clinicians deemed treatment more crucial for LT and PT patients due to transplant requirements and care investment. Fragmentation of care was a barrier to integrating hepatology and addiction care (Table 1). **Conclusion:** Hepatology clinicians believe AUD treatment is important for all patients, while OUD and TUD treatment is more crucial for LT and PT patients, underscoring varying attitudes toward addiction treatment for different patient groups. Interventions are needed to overcome barriers to integrated addiction treatment across the transplant spectrum.

Table 1: Major Themes and Representative Quotes from Qualitative Interviews Describing Perceived Importance of Addiction Treatment Across Non-Transplant, Listed, and Post-Transplant Patients in Liver Clinics

Theme	Quotes
Due to limited resources, addiction care may be prioritized for patients being considered for liver transplantation.	• "But I think that maybe at least for the ones that are really struggling, decompensated, having alcoholic hepatitis, you're trying to get them maybe potential transplant and they're having multiple readmissions, it might be worthwhile like having a separate clinic for those really high-risk patients so that you have that option. But yeah, I mean you have to prioritize, I don't think it's a very realistic goal that every single patient with alcohol use disorder and cirrhosis gets a mental health visit or addiction care at the same time when they come to your clinic." – Gastroenterology/Hepatology Fellow • "It becomes very, you know, difficult, because we obviously all want patients to get a transplant, but you know our job on the psychosocial team is really to point out the risks of those patients, because obviously we don't have enough livers to go around. So I mean just yeah I mean it's you know a huge issues, because I feel like the bottom line is it is often a life or death situation. Sometimes, you know, we get people very early or very late, you know, in terms of referrals and, you know, we do our best to try and beat the clock so people can be able to get the treatment." – Behavioral Health Provider
Pre-transplant candidates are viewed as more motivated to engage with addiction treatment due to transplant requirements, whereas engaging non-transplant patients can be more challenging.	• "I would land on the side of you know, like incorporating services to treat addiction to reduce the risk of recidivism, and I think that, like part of the opportunity with a transplant-based approach to treating this is that is that patients sort of number one are firsthand already like what alcohol has done, like they're sort of a captive audience, but then also a highly motivated audience in some ways." – Hepatology Attending • "I mean I think that sometimes like the advantage of the transplant hepatologist who says, you just have to do this or else you're not going to be able to get listed." – Hepatology Attending • "Yeah, I mean, I think we definitely hold our pre-transplant, and post, but especially pre-transplant patients to very high standards in terms of them achieving sobriety or cessation." – Gastroenterology/Hepatology Fellow • "And the thing is a little bit different when you're seeing transplant versus non-transplant patients because with transplant patients it's almost easier because you can say this is a prerequisite for your transplant. When it's a non-transplant patient, the person has to be, you know, ready to commit and I think a lot of the people you meet who are non-transplant are like pre-contemplative, like they're not even at that stage. So I don't have as much success with the non-transplant patients." – Hepatology Attending
Post-transplant patients may have greater access to addiction treatment resources due to significant investment in their care.	• "I mean we invested enough to transplant them, we should invest to someone being there, you know, and say well look, now you've seen the surgeon and now you can see your addiction specialist." – Hepatology Attending • "It is a post-transplant setting where everything is available to them to help them stop, because we want our outcomes and everything to be great, and those patients are just supported like probably too much." – Gastroenterology/Hepatology Fellow • "Yeah to me this if you invested all this money to get somebody successfully through transplant, it's kind of silly not to give them ways to succeed long-term, and even, you know, you can make the argument that maybe post-transplant alcohol relapse is not such a big deal from the liver perspective, the liver can take a lot and only a small minority of patients will actually lose the graft because of alcohol, you know. But from a psychological perspective of the medical team, you really feel let down if somebody has alcohol relapse." – Hepatology Attending
Limited time, lack of training, and fragmentation of care are barriers to robust integration of addiction care into hepatology visits.	• "There are both time constraints, and also I think there needs to be a lot of more deeper diving into why that's the problem, and what to do, and that definitely is not going to happen in a hepatology clinic, so it ends up being a referral when someone is in a bad place." – Gastroenterology/Hepatology Fellow • "Well, I have to say, I admit that I completely fell in tobacco addiction, like I don't, unfortunately, I just don't have the bandwidth to address that, but that's like a whole separate thing that I probably don't even address at all like, I would say, because there's so many other things on the table." – Advanced Practice Provider • "There is something that I actually feel probably fairly inadequate in. The current process – I think it's fair to say that there is no formal process at the present – but it's really geared towards the individual patients and existing resources that a patient may have engaged with already, either relapse prevention programs or other addiction services with other community organizations, rather than those that are initiated within our liver clinic." – Hepatology Attending • "I think, part of this challenge has been another one really fragmented access to specialty services that have expertise in the management and potential pharmacotherapy of these addiction disorders, and number two, a relative lack of knowledge and training in the management, specifically in the context of liver disease, and so that has led to a general sense of inadequacy and that we are not meeting the needs to this area for patients and a clear desire for something better." – Hepatology Attending • "So I think even the separation, you know hepatology/transplant hepatology, seems kind of artificial, you know, we basically we work in silos because this is how the health system is created." – Hepatology Attending
Integrating addiction treatment into hepatology care settings may facilitate addiction treatment for patients with liver disease	• "I would love to be able to refer a patient as part of the multi-disciplinary team for alcohol cessation and tobacco cessation and if that provider is also integrated into our system that would make sense." – Advanced Practice Provider • "I see patients who have alcohol use disorder have a concomitant tobacco use disorder and so I would like to have a provider that I know is available for that support ... pretty much all of those patients who are coming in with alcohol use disorder and have been admitted or have issues with their liver, they need that support, they need a formal pathway to assess them and help them achieve abstinence, in knowing that, as a provider my focus would be on that liver, and then the other providers' focus would be on trying to help eliminate those risks in terms of alcohol use and tobacco use that are detrimental to the liver so it would be sort of a collaboration, you know, very close, hands off, and you know those providers also would be familiar with working with patients with liver disease, because not all mental health providers are comfortable familiar doing that." – Hepatology Attending • "But maybe there could be a system where there are two physicians in this clinic, and they take turns taking on the sort of more liver-oriented stuff, and then the other more alcohol, tobacco, or opioid and treatment-related things. I think it's just a time issue." – Trainee

Background: Several immuno-oncology regimens are approved or under consideration for uHCC. With the evolving treatment landscape, understanding how patients' and physicians' make trade-offs among the differing benefit-risk profiles is increasingly important. As part of the AMBER preference study, qualitative research was conducted to explore decision-making, identify attributes of treatment, and understand the outcomes that are important to patients with uHCC and physicians making treatment recommendations in this setting. **Methods:** In-depth semistructured interviews (n = 29) were conducted with 15 physicians (3 hepatologists, 12 oncologists) who treat patients with uHCC and 14 patients diagnosed with uHCC who have received systemic treatment. Interviews were audio-recorded, transcribed, and analyzed to identify themes related to treatment perceptions, preferences, and decision-making. Key agreements and disagreements between patients and physicians also were identified. **Results:** Both patients and physicians prioritized survival while balancing side effects. However, physicians considered conventional clinical trial endpoints (e.g., median overall survival), whereas patients tended to focus on survival in the context of concrete landmarks (i.e., how much extension to their lives they could obtain while maintaining independence and daily functioning). Physicians factored in patient characteristics, including bleeding risk and liver function, and emphasized the need to limit severe adverse events (AEs) to preserve patients' quality of life and avoid hospitalization. Patients tended to assess AEs, such as nausea and fatigue, by the impact these had on their daily functioning. Patients reported not being offered treatment options and consequently physicians reported needing to make treatment decisions on behalf of their patients. **Conclusion:** Despite a shared priority of survival, patients and physicians viewed the outcome through different lenses. The absence of shared decision-making may mean these divergences are not apparent during consultations about treatment. These findings will be used to inform discrete choice experiment survey, which forms part of the wider AMBER preference study.

3049 | ANXIETY AND WORRY AFTER REVIEW OF ABNORMAL HEPATOCELLULAR CARCINOMA IMAGING RESULTS

Beverly Kyalwazi[1] John Deng[2] Laura Salej Duran[2] Dabel Emebo[2] Amit Singal[2] Jeremy Louissaint[2],
[1]University of Texas Southwestern Medical Center,
[2]University of Texas Southwestern

Background: Disclosure of abnormal hepatocellular carcinoma (HCC) imaging results via the patient portal is discordant with delivering bad news protocols. We have demonstrated that patients review their HCC imaging results rapidly and well before result-related patient-provider communication (PPC); however, reactions to receipt of these results on the portal before PPC remain unknown. Herein, we report preliminary survey data measuring anxiety and worry in patients reviewing their abnormal HCC imaging results before PPC. **Methods:** We identified patients with cirrhosis enrolled in the patient portal who had a new LI-RADS (LR) liver lesion seen on ambulatory US or multiphasic CT/MRI. Patients who reviewed the result prior to documented PPC were eligible for inclusion and were contacted to participate in the survey study within 2-4 weeks of result review. Survey scales included 1) PROMIS Anxiety 7a (anxiety): raw scores converted to T-scores with a population mean of 50, 2) Worry: one-item Likert question measuring result-related worry, and 3) Perceived Severity: Likert question with responses ranging from 1 (not severe) to 10 (highly severe). We calculated the mean (SD) anxiety scores between patients reviewing US and CT/MRI results and for patients with low (scores 1-5) and high (score 6-10) perceived severity scores. We also determined the proportion of patients with increased worry after reviewing the result. **Results:** A total of 25 patients were surveyed, with median age 55 years, 52% female, and 68% non-Hispanic White. Imaging results included 5 US-2, 10 US-3, 4 LR-3, 2 LR-4, 3 LR-5, and 1 LR-M. Mean Anxiety score was 52.3 (SD 13.8), and scores ranged from 36.3 to 82.7. Mean anxiety scores were higher in patients reviewing CT/MRI versus US results showing a new liver mass (55.0 [SD 14.5] vs 50.5 [SD 13.5]). Patients who perceived the severity of the result as high (32%) had a mean anxiety score of 61.2 (SD 14.7) compared to 48.1 (SD 11.5) in those who perceived the severity as low. Over one-fourth (28%) of patients reported feeling more or much more worry after result review. For patients with an LR-4 lesion or higher, 50% reported increased worry compared to 21% in patients with lower risk lesions. However, only one patient regretted the decision to view their results before PPC. **Conclusion:** These preliminary findings suggest patients with abnormal HCC surveillance results may experience high anxiety/worry related to imaging type, finding, and perceived severity that require future study.

3050 | MEANINGFUL ENGAGEMENT OF PATIENTS WITH CIRRHOSIS AND THEIR CARE PARTNERS: STRATEGIES FROM THE LIVE-SMART STUDY

Jacqueline Theroux[1] Anvi Sonarikar[1] Tasnuva Tarannum[2] Oma Anaenugwu[1] Mark Alber[3] Geraldine Hynes[3] James Hynes[3] Beanna Martinez[2] Samantha Nikirk[2] Richard Mason[1] Sumeet Asrani[4] Elliot Tapper[2] Marina Serper[1] Donna Evon[5], [1]University of Pennsylvania, [2]University of Michigan, [3]Cirrhosis Patient Engagement Group Member, [4]Baylor University Medical Center, [5]University of North Carolina

Background: The LIVE-SMART trial (NCT#05794555) is a PCORI (Patient-Centered Outcomes Research Institute)-funded multi-center randomized trial aimed at reducing the risk of injurious falls in people with cirrhosis. The investigative team collaborates with a Cirrhosis Patient Engagement Group (CPEG) consistent with PCORI's foundational expectations for patient engagement. We report how the investigative team engaged with the CPEG throughout the design and implementation of the study. **Methods:** During the grant writing phase, we convened a group of seven CPEG members to contribute to the study: 5 patients with cirrhosis and 2 care partners. During the project, CPEG meetings were held every 3-6 months to solicit CPEG feedback on various elements of the study. The CPEG was kept informed through bi-monthly study update emails. Satisfaction with patient engagement is evaluated bi-annually using a brief Qualtrics survey. Engagement was guided by community engagement principles, a detailed patient engagement plan, and specific engagement goals that were approved by the CPEG within the first six months of the project. The investigative team engaged with the CPEG members on information, consultation, and collaboration during LIVE-SMART. **Results:** From 2021 to 2025, 10 meetings were held with CPEG members in which they provided feedback on study measures, patient remuneration, development of a participant newsletter, retention strategies, informed consent form, tailoring patient-facing materials, and suggestions on meaningful outcomes and presentation of study results. CPEG members helped the study team make specific and impactful adjustments to the study, such as shifting from the term "caregivers" to "care partners" to utilize more sensitive language and emphasize the partnership that is needed to manage cirrhosis. The CPEG played a collaborative role in designing quarterly participant e-newsletters to share study updates. Suggestions included using a reader rather than writer focus and limiting the use of cartoons that might downplay the seriousness of cirrhosis. The principal investigators held a special informational session on self-management of cirrhosis to address this pre-specified goal of several members. Meeting attendance has been $>80\%$. Through engagement satisfaction surveys, CPEG members express appreciation for the study team, gaining knowledge about cirrhosis care, and being involved in LIVE-SMART.

Conclusion: The CPEG was engaged primarily as consultants during the LIVE SMART study from design to completion of the primary trial. CPEG engagement led to several meaningful changes to patient-facing materials and how to communicate study updates to study participants. We will continue to engage with the CPEG during the data analysis and dissemination phase of LIVE-SMART to ensure the study findings are patient-centered and meaningful for people living with cirrhosis and their loved ones.

3051 | USING THE INTEGRATED PALLIATIVE CARE OUTCOME SCALE (IPOS) FOR SYMPTOM ASSESSMENT: A PROSPECTIVE STUDY IN A LIVER SUPPORTIVE CARE PROGRAM IN SINGAPORE

Cheryl Huang[1] Danielle Ho[1] QIQI SU[1] Kee Yon Lionel See[1] Yuda Lin[1] Jolyn Tan[1] Guan Hong Koh[1] Charlene Tan Huimin[1] Marianne De Roza[1], [1]Sengkang General Hospital

Background: Patients with decompensated cirrhosis experience a high burden of physical and psychosocial symptoms, yet structured symptom assessment is not routinely integrated into hepatology care. There are currently no dedicated programs in Singapore to streamline multidisciplinary care for this vulnerable population. The Integrated Palliative Care Outcome Scale (IPOS) is a validated patient-reported outcome measure (PROM) widely used in palliative care. This study evaluates the feasibility and utility of IPOS—supplemented with liver-specific symptoms—within PEACE (Palliate End-stage and Advanced Cirrhotics Early), a multidisciplinary liver supportive care program. **Methods:** Patients with decompensated cirrhosis were prospectively recruited from a tertiary public hospital in Singapore. IPOS was administered at enrollment, follow-up visits, during decompensation, and post-intervention. Additional questions on pruritus, abdominal distension, and sleep disturbance were included. Scores were graded on a Likert scale from 0 (not at all) to 4 (overwhelmingly) based on the extent to which symptoms affected patients. Patients seen in hepatology clinics or inpatient wards but not enrolled in PEACE served as the comparison group. **Results:** Fifty patients were recruited, of whom 23 were enrolled in PEACE. When comparing the PEACE to non-PEACE group, mean age was higher in PEACE (73.9 vs 66.1 years); males comprised 47.8% and 58.3% respectively. Most participants were Chinese (87.0% vs 70.8%). The PEACE group had significantly better mean IPOS scores at second and third follow-up visits compared to non-PEACE (0.91 and 0.70 vs 0.92; $p = 0.029$ and $p = 0.01$). Dyspnea scores improved across all PEACE follow-ups ($p < 0.05$). Appetite scores improved at the second follow-up visit, but this was not sustained subsequently. Abdominal distension scores were better in PEACE (median 0 vs 1.5 at first and second follow-ups; $p < 0.05$). PEACE patients also reported better outcomes on addressing practical problems related to illness from second to fourth follow-ups (all $p < 0.05$). **Conclusion:** IPOS, supplemented with liver-specific symptoms, is a feasible and practical PROM for holistic symptom assessment in patients with advanced liver disease. It requires minimal training, can be implemented at pre-clinic nursing triage, and supports longitudinal tracking of symptom burden. PEACE participants demonstrated significantly better patient-reported outcomes, highlighting the value of integrating early palliative care into hepatology.

3052 | DEFEAT MASLD - METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE: A PRECISION DIGITAL THERAPEUTICS PILOT FEASIBILITY RANDOMIZED CONTROLLED TRIAL

Puneet Puri[1] Thuy-duyen Vu[2] Maribeth Capuno[3] Joelle Lemmons[4] HoChong Gilles[5] Michael Fuchs[6], [1]Virginia Commonwealth University, Richmond VA Medical Center, [2]Central Virginia VA Health Care Systems, [3]Richmond VAMC, [4]Central Virginia VA Health Care System, [5]McGuire Veterans Affairs Medical Center, [6]Central Virginia VA Healthcare System

Background: MASLD afflicts ~100 million Americans. Resource constraints limit access to a structured diet and lifestyle intervention, key to managing MASLD. In a randomized controlled pilot feasibility trial (RCT), we studied Aim 1: the acceptance, engagement and adherence of digital therapeutics (DT), and Aim 2: the impact on liver and metabolic health. **Methods:** 38 MASLD subjects (White: 60%, 89.5% males; average age 51 years) were enrolled between 3/2024 to 7/2024

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and randomized to 3 groups: ***Grp1*** DT using *Livvy*® app (n = 13), ***Grp 2*** DT + home delivered planned Mediterranean diet (n = 12), and ***Grp 3*** DT + self-hypnosis eat well *Reveri*® app (n = 13). For Aim 1, number of Bluetooth enabled weight measurements, steps goal, *Livvy*® app related daily logins, % assessments completed, app and device activity were tracked for 1-21 weeks till access to DT license expired. For Aim 2, changes in ALT levels, *Fibroscan*® CAP, weight and visceral fat area up to 24-weeks were evaluated. **Results:** For ***Aim 1*** at 12-weeks (average/week, whole group and Grp 1 vs. Grp 2 vs. Grp 3): number of weight measurements were 6.1/week (6.4 vs. 6.7 vs. 5.5), daily step goals were met 96%/week (113% vs. 75% vs. 102%). Subjects logged in every 2nd day in *Livvy*® app, which was comparable for all groups. Average educational articles read 40% (10-82%) (51.6% vs. 30% vs. 25%). 100% of *Livvy*® app assessments were completed. Only 5.5% had low *Livvy*® app activity (not logged in 10 days) and device activity (not weighed in 7 days). In ***Grp 2***, 92% adhered to ordering 100% of free meals offered as part of study. In ***Grp 3***, 33% opted out of *Reveri*® app with low Eat Well weekly usage averaging 1 day/week compared to 3-4 days/week for *Livvy*® app, which was similar in other groups. The secondary end points assessed for ***Aim 2*** are summarized in the table. **Conclusion:** This *DEFEAT MASLD* RCT demonstrates excellent acceptance and patient engagement. Disease specific educational content, reminders, goal-setting features, ready access to and communication with healthcare providers likely improved patient knowledge, motivation, and long-term adherence. This remote treatment with periodic in person visits also improved liver and metabolic health. Notably, the effects of intervention persisted beyond intervention at 24-weeks. Future studies in larger MASLD population are needed. This can be a transformative, scalable and data-driven management approach of chronic diseases such as MASLD.

% Change at 12-weeks from baseline				
	ALT level	CAP Score	Body Weight	Visceral Fat Area
Whole Group	-10.6%	-3.9%	-1.8%	-6.6%

3053 | OUTREACH CLINICS IMPROVE ACCESS AND REDUCE MORTALITY IN LIVER TRANSPLANT CANDIDATES

Sanad Dawod[1] Mei Lu[1] Qiong Zhang[1] Yichu Wang[1] Kimberly Ann Brown[1], [1]Henry Ford Health System

Background: Geographic disparities in liver transplant access and outcomes persist, especially for rural and underserved patients. Limited proximity to transplant centers reduces rates of evaluation, waitlisting, and transplantation, and increases cirrhosis-related mortality. This study evaluates the impact of outreach clinics on evaluation, waitlisting, pre-transplant mortality, transplantation, and post-transplant outcomes, within 12 months of first evaluation for transplant. **Methods:** We conducted a retrospective cohort study of adults evaluated for liver transplant at Henry Ford Health (2007–2022). This analysis focused on LT evaluations and their outcomes within 12 months of the first evaluation (index date). Distances to transplant and outreach clinics were mapped. Three outcomes were assessed: time to waitlisting, transplant, and pre-transplant mortality, using Fine and Gray competing risks models adjusted for age, race, MELD, albumin, and distance. Patients without transplant indication were excluded. **Results:** Among 3,572 adults evaluated, 804 (22.5%) were waitlisted, 320 (9.1%) received a transplant, and 2,086 (59.4%) died before transplant within 12 months of evaluation. Compared to 2018–2022, patients in 2007–2012 and 2013–2017 had lower waitlisting (aHR 0.58, 0.41) and transplant (aHR 0.028, 0.061) rates, and higher pre-transplant mortality (aHR 1.85, 1.875; all $p < 0.0001$). Black patients had lower odds of waitlisting (aHR 0.615) and transplant (aHR 0.492). Distance to outreach clinics was protective: patients within 14 miles had lower mortality compared to those ≥ 31 miles away (aHR 0.852 for < 7.5 mi; 0.836 for 7.5–14 mi), while proximity to the main center was linked to lower waitlisting. MELD ≥ 30 was linked to reduced waitlisting (aHR 0.577) and a fivefold higher risk of mortality (aHR 5.07). MELD 9–17 and MELD > 17–30 were linked to higher transplant rates (aHR 1.487, 1.836). Age ≥ 60 (aHR 2.694), albumin ≤ 3.5 (aHR 0.734, 0.577), and ALT levels also influenced mortality. Key predictors of outcomes are summarized in figure 1. **Conclusion:** Outreach clinics were associated with improved transplant outcomes and lower pre-transplant mortality within 12 months of evaluation. Proximity to outreach clinics, rather than the main center, conferred a protective effect, suggesting that decentralized care can reduce spatial barriers to transplantation. However, Black patients continued to

3054 | EXPLORING FACTORS ASSOCIATED WITH BEING &LDQUO; TOO EARLY&RDQUO; FOR LIVER TRANSPLANTATION: A CALIFORNIA LIVER NETWORK STUDY

Jasleen Singh[1] Mignote Yilma[2] Kabir Rahal[1] Julia Valenzuela[1] Fatima Zahoui[1] Michaela Evans[1] Hannah Choi[1] Allison Kwong[3] Steven Wisel[4] Hirsh Trivedi[4] Justin Steggerda[4] Alexander Kuo[5] Aarshi Vipani[4] Tiffany Lim[4] Michie Adjei[4] Lana Bridi[6] Veeral Ajmera[6] Monica Tincopa[7] Irine Vodkin[7] Hillary Braun[2] Chris Freise[2] Ryutaro Hirose[8] Neil Mehta[8] Shayana Seneviratne[9] Kali Zhou[10] Arpan Patel[11], [1]UCLA, [2]UCSF, [3]Stanford University Medical Center, [4]Cedars Sinai Medical Center, [5]Cedars-Sinai Medical Center, [6]UCSD, [7]University of California, San Diego, [8]University of California, San Francisco, [9]University of Southern California, [10]USC, [11]University of California, Los Angeles

Background: Optimizing efficiency and value of liver transplant (LT) assessments is an important consideration for centers. Understanding the clinical and demographic factors associated with being “too early for transplant” may help quality improvement efforts to streamline referrals for LT evaluation. **Methods:** The California Liver Network (CLN) is a retrospective cohort of adults referred to six transplant centers for LT between 2018-2020. Demographic, psychosocial, and clinical factors were obtained for evaluated patients. Reasons for denial were assessed by chart review. We used descriptive statistics to assess clinical factors of patients deemed “too early”. We then conducted Pearson’s χ^2 tests to assess differences in socio-demographic factors between patients deemed “too early” and those waitlisted. For this second analysis, we limited comparisons to adults with alcohol-related liver disease (ALD) to reduce heterogeneity. **Results:** Among 6,630 patients evaluated for LT, 3,148 (47.4%) were declined for listing and 3,482 (52.5%) were waitlisted. Among those declined, “too early” (N = 575, 18.3%) was the most commonly cited reason, though the reported rate across centers varied significantly (range: 3.5%-26.0%, median: 16.4%). The most commonly referred conditions were: 1) decompensated cirrhosis, MELD < 15 (N = 165, 28.7%); 2) compensated cirrhosis (N = 136, 23.7%); and 3) decompensated cirrhosis, MELD³15 (N = 101, 17.6%). ALD comprised 40.4% of all evaluations. Compared to patients who were waitlisted, patients deemed “too early” with ALD were more likely to be female, non-Hispanic/Latino, English-speaking, Medicaid-insured, and non-foreign born. A significantly larger portion of patients who were deemed “too early” were reported to have “no social support” at time of initial evaluation, compared to those waitlisted (29.0 vs. 4.3%, $p < 0.001$) (Table). **Conclusion:** Nearly a quarter of adults declined for being “too early” were referred for compensated cirrhosis only, indicating potential over-utilization of transplant resources. Center-level variation in denials for early candidates may reflect differences in the LT referral intake process across institutions. Social support at initial visit may influence determination of being “too early” and should be explored further. Greater efforts to improve screening of referrals and promote education of referring providers are needed.

Sociodemographic Factors Associated with Being Deemed “Too Early” Among Patients with ALD Evaluated for Liver Transplantation.

Variable	Waitlisted, ALD (N=1,303)	“Too Early”, ALD (N=193)	p-value
Socio-demographics			
Age (mean, SD)	54.7 (26.8)	53.7 (10.5)	0.61

3055 | MORTALITY AND HOSPITALIZATION ASSOCIATED WITH HIGH NEIGHBORHOOD DEPRIVATION ONLY AMONG WHITE PATIENTS WITH CIRRHOSIS

Saad Hussain[1] Paola Barrios[1] Suyanpeng Zhang[1] Dominic Vitello[1] Sijia Wei[1] Salva Balbale[1] Oriana Dentici[1] Al'ona Furmanchuck[1] Nikhilesh Mazumder[2] Lisa VanWagner[3] Lihui Zhao[1] Andres Duarte-Rojo[4] Sanjay Mehrotra[1] Daniela Ladner[1], [1]Northwestern University, Chicago, IL, [2]University of Michigan Hospitals and Health Centers, [3]University of Texas Southwestern Medical Center, [4]Northwestern Medicine

Background: Neighborhood deprivation, as measured by the Area Deprivation Index (ADI), has been associated with higher mortality and hospitalizations in cirrhosis. We evaluated the clinical outcomes for patients from different ADIs by race/ethnicity. **Methods:** CAPriCORN, a large EHR data repository across 7 health care systems in a large US metropolitan area, was used to identify adult patients with cirrhosis from 2016-2021. Demographics and clinical factors were collected including age, sex, race/ethnicity, urban/rural, etiology, insurance type, Area Deprivation Index (ADI) [Q1: high resourced, Q5: low resourced), MELD 3.0, Charlson comorbidity index (CCI), decompensation and frailty (HFRS); [Low: HFRS <5, severe: HFRS >15]. The primary outcomes of interest were all-cause mortality and hospitalization. Rates are reported per 100 patient-years (PY). Multivariable Cox proportional hazard models were used to assess mortality and multivariable logistic regression assessed hospitalization within 1 year. Significance $= P<0.05$. **Results:** 18,718 patients with cirrhosis were included. Mean age was 59.8, 43.1% were women, 45% were white, 19% black, 21% Hispanic, and 97% lived in urban areas. Most common etiologies were MASLD (28.6%), MetALD (23.1%), ALD (12.8%). 29.5% had Medicare, 27.8% Private, 22.3% Medicaid, 14.3% other insurance, 6.2% uninsured. ADI (Q1: 5.7%, Q2: 30.8%, Q3: 36.4%, Q4: 23.6%, Q5: 2.4%). Mean MELD was 16.3, CCI 6.79 and 29.7% were decompensated at inclusion. The overall, unadjusted mortality rate was 13.3 deaths per 100 patient-years. This was 16.1, 9.1, and 8.9 for white, black, and Hispanic patients respectively. Among the cohort, there were 57.9 hospitalizations per 100 patient-years. This was 66.28, 66.63, and 46.83 for white, black, and Hispanic patients respectively. On adjusted analyses, among white patients, higher ADI was associated with stepwise increases in mortality (Q5 vs Q1: HR 2.38, 95% CI 1.54–3.70) and hospitalization (Q5 vs Q1: OR 2.80, 95% CI 1.52-5.24). (Figure) This effect was not observed in other racial groups (black: $p=0.686$, Hispanic $=0.561$). **Conclusion:** In white patients with cirrhosis, neighborhood deprivation was associated with higher mortality and hospitalization rates, an effect not observed in any other race/ethnicity. Non-white patients might have mediating factors that make neighborhood deprivation less pertinent.

3056 | PALLIATIVE CARE INVOLVEMENT IN INPATIENT LIVER TRANSPLANT EVALUATIONS: AN OPPORTUNITY FOR GROWTH

Kathy Nguyen[1] Katherine Cooper[1] Navine Nasser-Ghodsi[2] Mary Flynn[2], [1]University of Massachusetts School of Medicine, [2]University of Massachusetts Memorial Health Care

Background: Expedited liver transplant evaluation (eLTE) is a resource intensive process reserved for critically ill patients with advanced liver disease. Palliative care (PC) consultation has been studied in the context of cirrhosis and LT, but the role of PC consult during eLTE remains underexplored. **Methods:** This is a retrospective analysis of eLTEs at our center from 2019-2021. Patients with acute liver failure were excluded. eLTE outcomes were categorized as Favorable (index admission LT, listed at discharge) or Unfavorable (declined, no decision, or deceased). Length of stay (LOS), intensive medical interventions, advanced care planning (ACP) and discharge location were compared in those with and without a PC consult. **Results:** A total of 165 patients were included. Patients with Unfavorable outcomes ($n = 54$) were more likely to be women ($p < 0.01$) and age over 50 years ($p = 0.08$) than those with Favorable outcomes ($n = 111$). Only 15% ($n = 24$) received a PC consult, without differences between groups ($p = 0.59$), most of which occurred at an outside hospital prior to transfer for eLTE ($n = 13$, 54%), and the remainder were for medical decision-making during eLTE ($n = 5$, 21%) or after patient was declined for LT ($n = 6$, 35%). Those who received a PC consult prior to decision ($n = 18$) tended to be White ($p = 0.09$) and to have graduated high school ($p = 0.05$) compared to no PC consult. Receipt of a PC consult prior to hospital transfer or declined for LT was not associated with fewer intensive medical interventions (p-values 0.2-0.9) or reduced length of stay ($p = 0.54$). However, PC consult recipients were more likely to have goals of care conversations (GOCC), though this association was observed in those with Favorable outcomes ($p < 0.01$) but not in the Unfavorable outcomes ($p = 0.90$) on stratified analysis. Of those not listed for LT, PC consult was associated with more intensive interventions following decision. **Conclusion:** In this single center study, PC consultation during eLTE was not associated with reduced care utilization. There were more GOCC for listed patients who had a PC consult than no consult. However, many patients who were not listed had a GOCC regardless of a PC consult or not. Most PC consults occurred prior to transfer for eLTE, potentially indicating patient preference/commitment toward treatment course, and/or the provider's concern the patient might not be an LT candidate. Future steps will assess these relationships in subsequent years of LTEs to assess if the role of PC has changed over time in the context of eLTE.

3057 | TECHNOLOGY UTILIZATION AND (HEALTH) LITERACY ASSESSMENT FOR PATIENTS WITH CHRONIC LIVER DISEASE (TULAP-CLD)

Jonathan Day[1] Zoe Post[2] Ashley Cawthon[2] Sierra Anderson[2] Ana Maria Davila Morales[2] Sujit Janardhan[2], [1]Rush Medical College, [2]Rush University Medical Center

Background: Chronic liver diseases (CLD) affect a considerable part of the population in the United States. Chronic Disease Management (CDM) models allow patients to actively monitor their disease using mobile technology and can improve patient outcomes. For mobile CDM models to be successful, we need to understand CLD patients' health literacy and ability to use technology. Therefore, we aimed to assess technology utilization and health literacy in CLD patients. **Methods:** Single tertiary center prospective study

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

including adult, English-speaking CLD patients. Informed consent was obtained. Demographics such as age, sex, race/ethnicity, level of education, and CLD characteristics were obtained. Health literacy was assessed using the Rapid Estimate of Adult Literacy in Medicine Short Form (REALM-SF). We developed a technology utilization measuring instrument, including device and internet access questions based on Health Survey by Pew Research Centers' Internet and American Life project. **Results:** 100 patients were included. 58% were female. 33% were Caucasian, 29% Hispanic and 27% Black. Highest education level is high school for 23% and bachelor's degree or higher for 40%. Most have metabolic (38%) or alcohol (19%) associated CLD; 44% have cirrhosis, 30% of which have complications. Average REALM-SF score was 6.34, with 24% at 7-8th grade level or less. 95% use the internet, of which 98% through smartphone and 97% report daily internet use. Text messaging, video calling, checking weather/traffic and finding product information online are activities most engaged in ($>90\%$), whereas posting online (e.g. blog or photos) is done by $<60\%$ of patients. 86% of patients use the internet for health-related activities, most commonly looking up personal health information, accessing online chart and learning about medical conditions (both $>85\%$). 71% of patients engage in e-visits with providers. However, sending personal medical information to providers and communicating with support groups is less frequently used (53% and 25% respectively). **Conclusion:** Reassuringly, the majority of CLD patients use the internet and engage in relatively simple activities. However, CDM models often include more advanced tasks, such as posting online or sending medical information, which are not commonly performed by CLD patients. Furthermore, our REALM-SF data suggests that a quarter of patients may not understand provided patient education materials, affecting usability of available and future CDM models.

3058 | REAL-WORLD IMPLICATIONS OF THE NEW AASLD/IDSA HCV "TEST AND TREAT" ALGORITHM: FOCUS ON CARDIOVASCULAR COMEDICATIONS IN HEPATITIS C VIRUS (HCV) PATIENTS RECEIVING DIRECT-ACTING ANTIVIRALS (DAAS)

DILIP MAKHIJA[1] Thomas Debray[2] Candido Hernandez[3], [1]GILEAD SCIENCES, INC., [2]Smart Data Analysis and Statistics, [3]Gilead Sciences Ltd.

Background: The new AASLD/IDSA algorithm for Hepatitis C point-of-care (POC) testing and treatment recommend medication reconciliation via the Liverpool DDI tracker (https://www.hep-druginteractions.org/) to assess drug-drug interaction (DDI) risk. If DDIs exists, specialist consultation is advised, potentially adding complexity to this expedited pathway. We aimed to assess the real-world applicability of this algorithm by evaluating the impact of cardiovascular comedications on DDI risk among US HCV patients receiving pangenotypic direct-acting antivirals (pDAAs). **Methods:** We leveraged the IQVIA PharMetrics Plus claims database (July 2015-June 2023) to evaluate the co-administration of statins and antihypertensive drugs with pDAAs, specifically sofosbuvir/velpatasvir (SOF/VEL) or glecaprevir/pibrentasvir (GLE/PIB), in US patients. DDI risk was assessed using the Liverpool DDI tracker; and reconciled with the AASLD/IDSA algorithm's guidance regarding specialist consultation. We used 1:1 propensity score (PS) matching without replacement to create matched SOF/VEL and GLE/PIB cohorts for comparative analysis. **Results:** Among 11,324 HCV patients receiving pDAAs, 11.6% ($n=1,317$) were on statins and 2.5% ($n=280$) were on antihypertensives. Of those on statins, 867 received SOF/VEL and 450 received GLE/PIB. For anti-hypertensives, 174 received SOF/VEL and 106 received GLE/PIB. After PS matching, cohorts comprised 431 statin patients and 91 antihypertensive patients, with similar baseline characteristics. Based on Liverpool DDI tracker risk assessment, 14.6% (63/431) of SOF/VEL-treated patients on statins and 78.0% (71/91) on antihypertensives could follow the AASLD/IDSA algorithm without requiring specialist consultation. In contrast, all GLE/PIB-treated patients on concomitant statins ($n=431$) or antihypertensives ($n=91$) would require specialist consultation. All 321 contraindications among statin users were associated with GLE/PIB, specifically involving atorvastatin, lovastatin, and simvastatin. For antihypertensives, olmesartan, prazosin, and enalapril were the most common comedications posing a clinically significant DDI risk. **Conclusion:** Applying the new AASLD/IDSA algorithm, especially when statins or antihypertensives are co-administered with pDAAs, would necessitate specialist consultation for a significant number of patients due to DDI risk. This potential barrier to rapid "test and treat" implementation could be substantially reduced by carefully selecting the DAA regimen based on individual patient DDI risk profiles.

3059 | IMPACT OF LIVER-RELATED CLINICAL COMPLICATIONS AT FIRST HOSPITALIZATION ON THE OUTCOME OF PATIENTS WITH LIVER CIRRHOSIS AND HEPATOCELLULAR CARCINOMA: A 13-YEAR NATIONAL STUDY

Claire DELACOTE[1] Xavier Lenne[2] Line-Carolle Ntandja-Wandji[3] Alexandre Louvet[3] Amélie Bruandet[2] Sylvie Deuffic-Burban[4] Philippe Mathurin[3], [1]U1286, [2]CHU Lille, DIM, [3]CHU Lille, service des maladies de l'appareil digestif, [4]IAME

Background: In cirrhotic and/or hepatocellular carcinoma patients (HCC), liver-related deaths are mainly HCC-related in viral and metabolic liver disease and liver failure-related in alcohol. Yet the impact of the presence of these complications at 1st hospitalization on outcome remains to be assessed. **Methods:** Data of patients hospitalized between 2011 and 2023 with ≥ 1 ICD-10 code of cirrhosis and/or HCC were extracted from the French national medicalized information system program. Probabilities of death over the study period and during the 1st hospitalization were estimated according to presence of liver complications (HCC or liver failure) and etiology of liver disease (viral [VIR], alcohol [ALC], metabolic syndrome [MS], others). **Results:** Over 2011-2023, deaths occurred in 219,587/543,208 (40.4%) cirrhotic/HCC patients and were 64.2%-liver-related. At 1st hospitalization, 101,419 (18.7%) patients were admitted with liver-related complications. The probability of being admitted with liver complications was 1.7-1.8 higher in VIR (21.3%) and ALC (20.0%) than in MS (11.8%). Liver-related deaths were more frequent for patients admitted with liver complications at 1st hospitalization (80% vs 60% in absence, $p < 0.01$).

At 1st hospitalization, liver-failure was more frequent than HCC (13.5% vs. 5.2%). Of the 28,144 patients with HCC, 7,767 (27.6%) also had liver failure, more often in ALC patients (34.7% vs 23.5% in VIR and 17.5% in MS, $p = 0.02$). The probability of death during the 1st hospitalization was 2.3% and 17-times higher when admitted for liver complications (10.0% vs. 0.6% in absence, $p < 0.01$), regardless of etiology ($p = 0.81$). Probabilities of death during the 1st hospitalization were 5.6% for HCC patients without liver failure, 9.8% for liver-failure patients and 22.4% for those with HCC and liver failure ($p < 0.01$), regardless of etiology ($p = 0.92$). **Conclusion:** Of the 543,208 patients with cirrhosis and/or HCC, 40% died during the 13-year period, of which 64% were liver-related deaths. At 1st hospitalization, liver event as a cause of hospitalization was around 2-times lower in MS than in VIR and ALC patients. First hospitalization for liver complications was associated with 10%-probability of death after admission, with the highest risk observed in those with liver failure and HCC (23%). Changes in the management pathway of cirrhotic and/or HCC patients are required to improve their outcomes.

3060 | THE IMPACT OF EARLY EVALUATION AFTER REFERRAL FOR LIVER TRANSPLANT ON PATIENT OUTCOMES

Kaushik Puranam[1] Lindsay King[1] April Wall[2] Andrew Muir[2] Jacqueline Henson[2], [1]Duke University School of Medicine, [2]Duke University

Background: Time from referral to liver transplant (LT) evaluation is a proposed AASLD quality measure, though no benchmark exists for the optimal time window. In the Veterans Affairs (VA) system, early LT evaluation within 30 days of referral is associated with lower pretransplant mortality. Whether this applies outside the VA system is not known. We aimed to examine the impact of time from referral to LT evaluation on patient outcomes at a large-volume transplant center. **Methods:** We identified all adult patients referred and evaluated for first-time, single-organ LT at our center from 1/1/2016 to 12/31/2023, with follow up data through 12/31/2024. Patients referred for urgent inpatient LT evaluation were excluded. Patients were categorized as early evaluation (EE, evaluation within 30 days of referral), and late evaluation (LE, >30 days). The Charlson Comorbidity Index was calculated to account for comorbidities outside of liver disease. Logistic regression was performed to evaluate the association between EE and waitlisting. Competing risk analysis was used to examine the relationship between EE and pretransplant mortality, accounting for the competing outcome of transplant. **Results:** A total of 1369 patients met inclusion criteria: 452 underwent EE (33.0%) and 917 LE (67.0%). Median time from referral to evaluation for

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

EE was 21 days (interquartile range [IQR] 17-26), compared to 48 days (IQR 39-73) for LE. The proportion of EE declined over time (40.6% in 2016 vs. 27.6% in 2023, $p_{trend} = 0.01$). EE patients were more likely to be male, have higher MELD-Na scores, and live closer to the transplant center (Table 1). Overall, 709 (51.8%) patients were waitlisted, and 594 (43.3%) underwent LT. EE patients were more likely to be waitlisted (57.7% vs 42.3%, p = 0.002) and transplanted (49.3% vs 40.5%, p = 0.002). The relationship between EE and waitlisting persisted after adjusting for confounders (adjusted odds ratio 1.32, 95% confidence interval [CI] 1.04-1.68). The median time from referral to waitlisting and LT was shorter in the EE group (78 vs. 116 days, p < 0.001;188 vs. 220 days, p = 0.01, respectively). There were 429 pretransplant deaths, 140 (31.0%) in the EE group and 289 (31.5%) in the LE group (p = 0.84). In competing risk analysis, EE was not associated with pretransplant mortality (subhazard ratio 0.99, 95% CI 0.81-1.21). **Conclusion:** At our center, EE for liver transplant was associated with higher rates of waitlisting and transplantation, as well as shorter time to listing and transplant. However, despite these associations, it was not associated with differences in pretransplant mortality. These findings suggest that while timely evaluation improves access and progression through the transplant process, it may not impact pre-transplant survival. Further multicenter studies are needed to define optimal evaluation timelines and assess whether these findings generalize across diverse healthcare settings.

Table 1. **Baseline Characteristics of Referred Patients for Liver Transplant by Time to Evaluation**

	Cohort (n=1369)	Early Evaluation (n=452)	Late Evaluation (n=917)	p-value
Age at referral, years	59 (51–65)	60 (51–65)	59 (51–65)	0.45

3061 | IMPROVING CIRRHOSIS IDENTIFICATION: EVALUATION OF ICD-10 CODES AND DEVELOPMENT OF A HYBRID ALGORITHM FOR ENHANCED ACCURACY IN ALBERTA&RSQUO;S HEALTHCARE SYSTEM

Kinjal Patel[1] Mayur Brahmania[2] Grace Wang[3] Mathew Daniel[4] Samina Khan[4] Mohamed Abdalla[5] Puneeta Tandon[1], [1]Division of Gastroenterology (Liver Unit), Department of Medicine, Faculty of Medicine and Dentistry, [2]University of Calgary Cumming School of Medicine, Calgary, AB, Canada., [3]Alberta Health Services, [4]Department of Medicine, University of Alberta Hospital, [5]Department of Medicine, University of Alberta

Background: Cirrhosis is a global health issue contributing to high morbidity, mortality, and repeated hospitalizations. The Cirrhosis Care Alberta initiative aims to standardize cirrhosis management through order sets and Our Practice Advisories (OPAs) integrated into the Connect Care (CC) electronic medical record system (EMR). However, inconsistent documentation and underutilization of EMR problem lists hinders accurate identification of cirrhosis, leading to missed opportunities for clinical decision support. This study aimed to evaluate published consensus ICD-10 codes and develop an enhanced algorithm integrating administrative and EMR data for improved cirrhosis identification. **Methods:** Firstly, the consensus ICD-10 codes (Shearer et al 2022) were evaluated in a cohort of 719 patients with chart-review confirmed cirrhosis patients based on clinical, biochemical, and imaging criteria. The positive predictive value (PPV) of each ICD-10 code was determined and confirmed to be greater than 90%. Subsequently, a novel cirrhosis identification algorithm was developed using ICD-codes from the consensus code set recorded either in the administrative data (Discharge Abstract Database, DAD) or EMR problem lists (Connect Care) or if a patient was noted to have “cirrhosis” in their Connect care diagnosis. Patients with a history of liver transplant were excluded using transplant-specific codes. Lastly, the algorithm’s performance was evaluated in a cohort of 913 patients admitted to gastroenterology or internal medicine services at four healthcare sites in Alberta over a 12 week period. This included two tertiary centres and two smaller centres. Chart reviews served as the reference standard to assess sensitivity and specificity. **Results:** The validation of consensus codes yielded positive predictive values consistent with previous studies. Sensitivity and specificity of cirrhosis identification using

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

administrative data alone (DAD) were 76.2% and 97.7%, respectively (Table 1). Using EMR data (Connect Care) alone, sensitivity was 85.3%% and specificity was 97.5%. When combining DAD and EMR data, the algorithm achieved sensitivity of 86.2% and specificity of 97%. Site variability was observed, with lower sensitivity at rural sites (70% and 78.6) likely due to differences in coding practices. **Conclusion:** A combined administrative and EMR-based algorithm provides a robust algorithm for identifying cirrhosis patients across diverse healthcare settings. This algorithm holds promise to support more accurate OPA activation, facilitate clinician use of cirrhosis order sets, and enable the development of a comprehensive cirrhosis registry for quality improvement and research. Further optimization, particularly in rural settings, may improve specificity and overall performance.

Population	Algorithm	Specificity (%)	Sensitivity (%)
Overall (n=913)	DAD	97.74	76.15
	CC	97.49	85.32
	DAD or CC	97	86.24
University of Alberta Hospital (n=172)	DAD	97.71	77.14
	CC	99.24	88.57

3062 | ASSESSING NEED FOR HEPATITIS B VACCINATION IN ADULTS AGED 18-59 ACROSS HEALTH SYSTEM ENTERPRISE

Jayati Anand[1] Beatriz Torre[2] Jonathan Fenkel[2], [1]Beth Israel Deaconess Medical Center, [2]Thomas Jefferson University Hospital

Background: In March 2023, the CDC recommended Hepatitis B virus (HBV) triple-screening for all adults, testing surface antigen (sAg), surface antibody (sAb), and total core antibody (cAb), regardless of perceived risk. We designed a quality improvement (QI) project using an EMR-based tool called a Care Gap, a "hard-stop" mechanism of QI, within our academic health system's EPIC-based EMR to increase HBV triple-screening. This intervention aimed to improved triple-screening rates and permitted an opportunity to examine HBV immunity at an enterprise level. We sought to understand the need for HBV vaccination in adults aged 18-59, as this population is recommended to be vaccinated against HBV. **Methods:** The HBV screening Care Gap was enacted from 2/13/24 - 5/2/24 for adult patients at a large non-profit, metropolitan health system encompassing 10 EPIC-based hospitals surrounding an academic tertiary care center. HBV test results were collected at an enterprise level pre-intervention (6 weeks prior) and post-intervention (14 weeks through 5/23/24 to permit completion of tests ordered during intervention period). The pre- and post-intervention groups were compared using descriptive statistics. **Results:** In the pre-Care Gap period, 3,192 patients had some form of HBV testing. Of these patients, only 622 (19.5%) were triple-screened, per CDC guidelines. Of the triple-screened patients, 39.4% were vaccine-immune (sAb+, sAg-, cAb-), and 50.8% were triple-negative. When cohorted by age, 33.3% of the triple-screened patients were 18-59 years old and non-immune, non-exposed to HBV, making them eligible for vaccination. In the post-Care Gap period, 34,519 patients had some form of HBV testing. Of these patients, 28,641 (83%) were triple-screened, a robust increase from the pre-Care Gap period ($p < 0.0001$). Of the triple-screened patients, 33.1% were vaccine-immune (sAb+, sAg-, cAb-), and 61.5% were triple negative (sAb-, sAg-, cAb-) to HBV. When cohorted by age, 41.1% of the of the triple-screened patients were 18-59 years old and non-immune, non-exposed to HBV, making them eligible for vaccination. **Conclusion:** The EMR-based HBV screening Care Gap resulted in a significant increase in HBV triple-screening. The results support CDC guidance on screening and vaccination, as approximately 2 in 5 triple-screened adults in our enterprise are candidates for HBV vaccination. This data supports further use of EMR-based QI tools such as the hard-stop Care Gap to enhance screening and vaccination for HBV.

Table 1: Triple-Screening and Immunity Status in Pre and Post Care Gap Populations

	Triple Screened	Vaccine Immune (sAb+, sAg-, cAb-)	Non-immune, Non-exposed (sAb-, sAg-, cAb-)	Non-immune, Non-exposed AND 18-59 years old
Pre-Care Gap	622	245 (39.4%)	316 (50.8%)	207 (33.3%)
Post-Care Gap	28641	9480 (33.1%)	17625 (61.5%)	11768 (41.1%)

3063 | OOPHORECTOMY IS ASSOCIATED WITH HEPATIC DECOMPENSATION IN WOMEN WITH PRE-EXISTING CIRRHOSIS: A MULTICENTER RETROSPECTIVE COHORT STUDY

Emma Leipsner[1] Kate Johnson[2] Priyanka Gaur[2] Scarlet Yang[2] Tatyana Kushner[2], [1]Weill Cornell Medicine, [2]Weill Cornell Medical College

Background: Estrogen is thought to play a protective role in chronic liver disease progression, but the impact of estrogen withdrawal after oophorectomy in women with pre-existing cirrhosis is less understood. We evaluated whether surgical menopause independently contributes to hepatic decompensation in patients undergoing oophorectomy. **Methods:** This retrospective cohort study used the TriNetX Research Network compared women with cirrhosis who underwent an oophorectomy to those who had not, excluding those with prior decompensation. Propensity score matching was conducted on 22 characteristics, including demographics, comorbidities, and history of hysterectomy. A composite decompensation outcome was defined as the presence of hepatic encephalopathy, variceal bleeding, portal hypertension, ascites, and/or hepatocellular carcinoma (HCC). Kaplan-Meier analysis was used to determine time to decompensation events. **Results:** We identified 1,275 women with cirrhosis who had undergone oophorectomy (mean age at index 62.7 +/- 12.4) and 65,299 female controls with cirrhosis only (mean age at index 61.5 +/- 13.6) from 2005 to 2025. Oophorectomy indications included ovarian cysts (19.2%), ovarian cancer (7.8%), and endometriosis (8.3%). Hormone replacement therapy (HRT) was used more frequently in the oophorectomy group (12.1% vs. 3.8%, $p < 0.001$). After propensity score matching, 1265 women remained in each group with a median follow up time of 843 and 829 days, respectively. Women with cirrhosis who underwent oophorectomy had significantly higher rates of all hepatic decompensation compared to controls (RR 3.15, $p < 0.001$) (Figure 1). Specifically, portal hypertension (RR 3.31, $p < 0.001$) and ascites (RR 4.75, $p < 0.001$) were more common in the oophorectomy group. There was a significantly shorter time to onset of the composite hepatic decompensation outcome post-oophorectomy (HR 3.66, $p < 0.001$). **Conclusion:** Women with cirrhosis who undergo oophorectomy have a significantly higher and accelerated risk of hepatic decompensation, especially ascites and portal hypertension, highlighting the role of endogenous estrogen withdrawal and surgical risk in liver disease progression. These findings highlight the importance of supporting HRT and interdisciplinary care between hepatology and gynecology to optimize management post-oophorectomy.

3064 | EVALUATING SHORT-TERM AND LONG-TERM PATIENT REPORTED SYMPTOMS FOLLOWING COVID-19 EXPOSURE IN CIRRHOSIS: IMPLICATIONS FOR QUALITY PATIENT CARE MANAGEMENT

Dhweeja Dasarathy[1] Jeremy Luk[2] Robert Wong[3] Ramsey Cheung[4] Alexander Monto[5] Amy Shui[6] Michael Ostacher[7] Steven Batki[8] Hannah Snyder[9] Taylor Fakadej[10] Christina Haight[8] Meimei Liao[11] Derek Satre[12] Mandana Khalili[13], [1]Department of Medicine, Stanford University, [2]National Institute on Alcohol Abuse and Alcoholism, [3]VA Palo Alto Healthcare System, [4]Stanford University Medical Center, [5]Veterans Affairs Greater Los Angeles Health Care System, [6]Department of Epidemiology and Biostatistics, University of California, San Francisco, [7]Stanford University School of Medicine, [8]Veterans Affairs San Francisco Health Care System, [9]University of California, San Francisco, CA, [10]Zuckerberg San Francisco General, [11]Veterans Affairs Palo Alto Health Care System, [12]Weill Institute for Neurosciences, University of California, San Francisco, [13]University of California, San Francisco

Background: Patient-reported symptoms can adversely impact quality of life (QOL) in patients with cirrhosis and are an important component of cirrhosis management. To date, a significant proportion of patients have been exposed to coronavirus disease (COVID-19), which may result in both acute or chronic symptoms but data on type and severity of symptoms or impact on QOL has not been assessed in patients with cirrhosis. In this analysis, we

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

evaluated how the severity and number of symptoms post-exposure to COVID-19 affects QOL in patients with cirrhosis. **Methods:** Participants with cirrhosis and a prior COVID-19 diagnosis were identified from hepatology clinic records and administered telephone-based surveys (208 surveys in 156 participants) about COVID-19 diagnosis, symptoms following COVID-19 exposure (a total of 31 symptoms were evaluated), and Liver Disease QOL (LDQoL) instruments. Liver disease etiology and severity were extracted from electronic health records. Multivariable regression models assessed the relationship between QOL and total number of COVID-19 symptoms and symptom severity. **Results:** The study sample had a mean age of 64.5 years, 19% female, 39% had alcohol-related liver disease (ALD), and 39% decompensated cirrhosis. Overall, similar to the general population, the most common symptoms post-COVID-19 were fatigue, cough, and fever. The mean (SD) number of COVID-19 symptoms reported was 7.4 (6.4), with 66% proportion reporting at least one severe/very severe symptom. 16% of patients had long COVID-19 ($\geq$ 3 months of symptoms). When stratified by cirrhosis etiology (ALD versus no-ALD) and severity (decompensation versus compensation), patients had a similar distribution of symptoms reported (Figure 1) and did not have significant differences in severity of symptoms. However, among those with at least one severe symptom, the total number of severe symptoms was inversely associated with QOL. For each additional severe symptom reported, QOL decreased by 1.3 points (95% CI -1.83 to -0.78, $p < 0.001$). This was true even as we controlled for age, sex, decompensation, MELD-Na, and ALD, with QOL decreasing by 1.1 point for each additional severe symptom (95% CI -1.70 to -0.53, $p = 0.001$). **Conclusion:** In patients living with cirrhosis, assessing severity and chronicity of post-COVID-19 exposure symptoms can help clinicians address patient reported QOL concerns in order to improve cirrhosis management.

Figure 1. Most frequently encountered symptoms among patients with a history of COVID-19 and (A) Decompensated cirrhosis; (B) Compensated cirrhosis; (C) Alcoholic liver disease; (D) Non-Alcoholic Liver Disease

3065 | PROSPECTIVE EVALUATION OF A FAST-TRACK TREATMENT PATHWAY FOR INDIVIDUALS WITH CHRONIC HEPATITIS B UNDER PRIMARY CARE

Jimmy Che-To Lai[1] Tiffany Ying-Tung Joeng[1] Vincent Wong[1] Vicki Wing-Ki Hui[1] Yee-Kit Tse[1] Terry Cheuk-Fung Yip[1] Grace Lai-Hung Wong[1], [1]The Chinese University of Hong Kong

Background: Linkage-to-care has been an issue leading to suboptimal engagement of individuals with chronic hepatitis B (CHB) into the hepatology care pathway. We developed a novel fast-track treatment pathway for individuals with CHB under primary care and evaluate its effect on linkage-to-care. **Methods:** From 2021 to 2024, individuals with CHB under two primary care clinics were offered access to transient elastography examination, serum hepatitis B virus (HBV) DNA and liver biochemistry tests at baseline and 3 years later, with an additional HBV DNA and liver biochemistry tests in between. Participants who fulfilled the antiviral treatment criteria (HBV DNA $>$2,000 IU/mL with serum alanine transaminase [ALT] $>$1-2 times upper limit of normal or liver stiffness measurement $>$9.0 kPa) were referred to hepatology specialist clinic by the fast-track treatment pathway, while those not fulfilling the antiviral treatment criteria continued their care at the primary care clinics. The linkage-to-care, including referral and antiviral treatment uptake rate, were analyzed and compared to participants under primary care over 3 years before the commencement of this treatment pathway (i.e., prospective and retrospective groups, respectively). **Results:** 466 and 2,703 participants were recruited in the prospective and retrospective groups, respectively. The mean age was 61.9 vs 59.9 years and female (60.5% vs 71.0%) were predominant, respectively (both $p<0.001$). The mean HBV DNA level was 2.8 ± 1.3 vs 3.5 ± 2.0 $\log_{10}$ IU/mL and serum ALT was 24.0 (18.0-33.0) vs 27.0 (19.0-42.0) IU/L, respectively (all $p<0.001$). In the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

prospective group, 384 participants (82.4%) underwent at least one scheduled assessment and 19.6% out of those who remained in primary care attended all three assessments. Overall, 4.4% and 6.2% of the participants in prospective and retrospective groups, respectively, fulfilled the antiviral treatment criteria ($p = 0.194$). All participants in the prospective group who fulfilled the treatment criteria were referred through the fast-track treatment pathway, while 47.7% in the retrospective group were referred ($p < 0.001$). The mean waiting time to the hepatology specialist clinic was 15.8 vs 42.9 weeks ($p < 0.001$) and the attendance rate to the specialist clinic was 100% vs 88.1% ($p = 0.137$), respectively. Among those who fulfilled antiviral treatment criteria, the treatment uptake rate was 89.5% vs 54.5% ($p < 0.001$), respectively (Figure). **Conclusion:** A fast-track treatment pathway enhances timely referral and antiviral treatment uptake rates for individuals with CHB indicated for antiviral treatment.

3066 | "FIB-4 MORE": IMPROVING MASLD SCREENING AND MANAGEMENT IN PATIENTS WITH TYPE 2 DIABETES IN AN URBAN DIVERSE ENDOCRINOLOGY CLINIC

Melina Manolas[1] Lorena Rasquin Leon[2] Zoe Verzani[3] Brett Fortune[2], [1]Montefiore Medical Center, Weill Cornell Medicine, [2]Montefiore Medical Center, [3]Weill Cornell Medicine

Background: Metabolic dysfunction-associated steatotic liver diseaes (MASLD) affects 65–70% of adults with type 2 diabetes (T2D). Despite major endocrinology society guidelines to screen adults with T2D using Fibrosis-4 (FIB-4) index, screening in endocrinology practices remains low. Before this project, our electronic health record (EHR) lacked standardized screening tools, leading to missed opportunities for early detection and risk stratification. **Methods:** We conducted a pre/post-intervention quality improvement project at a single-center tertiary system for an urban diverse population aimed at increasing MASLD screening in patients with T2D by 15% over six months. Two *Epic* SmartPhrases (".FIB4" and ".FIB4MORE") were developed and implemented to calculate and interpret FIB-4 and initiate appropriate labs, imaging, and referrals (Fig 1). The SmartPhrase was shared with all endocrinology providers, who also received an in-person educational session and email. Data were collected for three months pre- and four months post-intervention. Clinical encounters for adults with T2D were included; those with T1D or pre-existing hepatology care were excluded. **Results:** Primary outcome was the percentage of patients with T2D who received documented MASLD screening using FIB-4. Baseline median MASLD screening rate was 4% in the 3 months pre-intervention (Weeks 1–12). Median screening rates increased to 47% and ultimately 59% in the 4-months post-intervention (Weeks 13–29) and tracked with SmartPhrase use, which was adopted into note templates by 44% of providers. Among patients with intermediate/high FIB-4, a composite of downstream clinical actions (hepatology referral, labs, and imaging orders) increased significantly from 17% to 43% post-intervention ($p = 0.019$), though overall volume of referrals and imaging orders placed were low and follow-through actions were inconsistent across providers. **Conclusion:** EHR-based decision support tools make for a feasible and scalable strategy to improve MASLD screening in patients with T2D. In our endocrinology clinic, these tools led to a 14-fold increase in MASLD screening rates with FIB-4 and improved downstream clinical actions, particularly among patients with intermediate/high-risk scores. SmartPhrase note template integration and provider buy-in were key drivers of adoption. However, follow-through actions

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

such as imaging and referrals were inconsistently applied, underscoring the need to strengthen structured screening pathways that bridge recognition with timely, coordinated management. Future directions include enhanced automation (e.g., lab prompts) and incorporation of the ELF (enhanced liver fibrosis) test.

3067 | USING COMMUNITY PARTNERSHIPS TO ACHIEVE HCV MICRO-ELIMINATION IN VANCOUVER'S INNER-CITY

Christina Wiesmann[1] Shana Yi[1] David Truong[1] Brian Conway[1], [1]Vancouver Infectious Diseases Centre

Background: The individuals living in Vancouver's inner city have some of the highest rates of hepatitis C virus (HCV) Canda, and the Vancouver Infectious Diseases Centre (VIDC) is working towards eliminating HCV in this population. The VIDC does this using an approach involving regular community pop-up clinics, or CPCs, at various inner-city locations. At each event, point-of-care HCV antibody testing is offered to up to 30 individuals. Individuals testing positive for HCV antibodies often have their blood drawn on site and those confirmed to be viremic are followed up with by outreach individuals and engaged in treatment under a multi-disciplinary model of care. We aimed to determine whether VIDC is achieving a reduction in the prevalence of HCV viremia in Vancouver's inner-city through a CPC approach to diagnosis and treatment. **Methods:** As part of a partnership with Atira housing society, since 2022 CPCs have regularly been held in the common spaces of Atira inner-city buildings with the goal of achieving elimination of HCV infection among the individuals living in these spaces. As a preliminary analysis, we determined the proportion of individuals testing positive for HCV antibodies, and those viremic, at CPC events held at 4 different Atira buildings in 2022 and in 2024. We then averaged the proportion of individuals testing positive at each location in 2022 and in 2024. Using these data, we were able to determine if there was a significant reduction in the proportion of individuals residing in these four buildings living with HCV in 2024 relative to 2022. **Results:** We saw that Indigenous ancestry, incarceration history, and history of injection drug use were all significantly associated with HCV seropositivity among the residents of these four buildings who were tested for HCV. We saw a clear reduction in the proportion of viremic individuals tested over time at all four locations. We performed a more detailed analysis of the individuals testing positive at pop-up events at the Luugat and saw that the reduction in viremic individuals over time largely due to the previous treatment of viremic individuals living in that building. Overall, we did not see a reduction in the proportion of individuals with HCV antibodies in these four buildings (32% in 2022 vs. 26% in 2024). However, we saw a clear reduction in the proportion of individuals residing in these residences who were viremic for HCV (14% in 2022 vs. 4% in 2024; $p = 0.1$). **Conclusion:** This study has demonstrated that while PWID may be a particularly difficult demographic to target for HCV treatment, with the help of community partnerships, a multidisciplinary approach to care, and continued testing and follow-up, we are on our way to achieving micro-elimination of HCV among the residents of Vancouver's inner city. By decreasing barriers to care and meeting people where they are at, we can achieve high rates of HCV cure even among unstable and traditionally difficult-to-treat populations.

3068 | APPROPRIATE INTERVENTIONS HELP TO REDUCE 30-DAY HOSPITAL READMISSIONS FOR CIRRHOSIS: A SCOPING REVIEW

Jawaid Shaw[1] John Cyrus[2] Richard Sterling[3], [1]Fellow, Virginia Commonwealth University, Health System, [2]Virginia Commonwealth University, Health Science Libraries, Richmond Virginia, [3]Virginia Commonwealth University

Background: Hospital readmissions (RA) for cirrhosis impose burdensome clinical, psychological and financial implications for the patients (pts), caregivers and the healthcare systems. The aim of our scoping review was to ascertain the burden of 30-day RA, predictors of such readmission and to see if any strategies work in reducing RA. **Methods:** A scoping literature search from 2015-2025 was performed. Studies reporting 30-day RA in cirrhosis pts hospitalized for non-elective reasons were included. Two reviewers independently reviewed and agreed upon a particular study to be included for extraction of detailed data including demographics, admission and predictors of RA. **Results:** We identified 98 studies, out of which 26 (8 retrospective/8 prospective) were selected after applying inclusion and exclusion criteria consisting of 700,764 patients, from heterogenous sources and design. The sample size ranged from 134 to 303,346 (Table 1). The mean age of patients was 60 years (ranged 52-73 years) with MELD Na 13-21. The 30-day RA rates were 10% to 50% with the pooled readmission rate being 25.8% (95% CI 23.8-30.2). Most of the studies had higher rates with 12 studies between 20% to 29.9%; 10 between 30% to 39.9%;3 between 10%-15%; and only 1 study at 50%. Only 6 studies reported 90-day RA, and this ranged from 21% to 41%. Predictors of higher RA found were: broadly grouped as follows, concomitant medical illnesses (COPD, in-patient dialysis use, CVA, etc.), presence of complications of cirrhosis (liver failure, ACLF, HE, Ascites, EVB, HRS, etc.), lab values at index admission (increased MELD Na Score, WBC, CRP >10, etc.), patient characteristic (advanced age, higher BMI, lower patient education, etc.), others (Medicaid or Medicare coverage, early outpatient follow up in <7days, GI attending service). Predictors of decreased RA were: Female sex, Age $\geq$ 45, cancer, infections, interventions (Attendance in transitional liver clinic, application of interruptive alerts for medication adherence, electronic decision support), others (being on hospitalist service, EGD during index admission, DC to SNF & attendance at alcohol rehab facility).

Conclusion: On our updated review the 30-day hospital RA for cirrhosis continues to be high despite focus on this problem from last many decades. While most of the predictors for increased RA are non-modifiable, interventions shown to decrease RA include attendance in transitional liver clinic and using the electronic health record (EHR)interventions.

3069 | DESIGNING FOR ADOPTION: A QUALITATIVE STUDY OF CLINICIAN PERSPECTIVES ON RISK PREDICTION TOOLS IN CIRRHOSIS

Kinza Khan[1] Mackenzie Bolas[2] Nadim Mahmud[3], [1]University of Pennsylvania Health System, [2]PSOM School of Medicine, [3]Hospital of University of Pennsylvania

Background: Although medical risk prediction tools are widely developed and published, few achieve sustained clinical adoption. In hepatology, surgical risk calculators are particularly underutilized in the care of patients with cirrhosis. In this study, we sought to identify key design and implementation factors that influence provider uptake of such tools, using the VOCAL-Penn Score (VPS) as a case example. **Methods:** We conducted a qualitative study of diverse clinicians who care for patients with cirrhosis. Semi-structured interviews were guided by the Consolidated Framework for Implementation Research (CFIR) to explore factors influencing the adoption of medical risk prediction tools, including the VPS. Interviews were transcribed and analyzed using a combined grounded theory and deductive approach. Emergent themes were synthesized into a conceptual framework for future implementation efforts. **Results:** We interviewed 22 clinicians (median age 38 years; 64% male; 45% White) representing a range of specialties and career stages (Table). Five recurrent themes emerged as central to the adoption of risk prediction tools: efficiency, accessibility, transparency, accuracy, and generalizability. Clinicians emphasized the need for tools that are intuitive, require minimal inputs, and integrate seamlessly into existing workflows (e.g., EMRs, web tools, UpToDate). Face validity of input variables — ensuring they were clinically meaningful and readily available — was cited as critical to encouraging use. Transparency in model development, validation, and limitations was essential to building trust. Participants stressed the importance of comparative performance data relative to existing clinical standards, as well as published external validations, to support the tool's credibility in real-world settings. Finally, generalizability was emphasized as key to equitable application across diverse patient populations. **Conclusion:** Using the VPS as a grounding example relevant to hepatology, our findings reveal how clinicians evaluate the utility of risk prediction tools in practice, emphasizing the importance of face-valid inputs, seamless workflow integration, and transparent communication of model performance and limitations. The five domains identified — efficiency, accessibility, transparency, accuracy, and generalizability — provide a practical framework to inform the development and dissemination of future tools. By aligning tool design with real-world clinical needs, this framework may support broader adoption and more equitable implementation of medical risk prediction tools across hepatology and other fields.

Table – Cohort Characteristics

Variable and Category	N=22

3070 | RACE AND ETHNICITY INFLUENCE PREGNANCY OUTCOMES IN WOMEN WITH CHRONIC LIVER DISEASE AND CIRRHOSIS

Katherine Cooper[1] Meera Garriga[2] Deepika Devuni[3] Monika Sarkar[2], [1]Massachusetts General Hospital, [2]University of California, San Francisco, [3]UMass Chan Medical School

Background: Pregnancies with chronic liver disease (CLD) have increased maternal and fetal risks. Racial

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

disparities contribute to pregnancy risks in the general population, though differences in the context of CLD are not known, which is essential to informing equitable care. **Methods:** This study evaluated the association between race/ethnicity and pregnancy outcomes between 2010-2024 in those with pre-pregnancy CLD using the TriNetX Research Network. Racial/ethnic groups included: White, Black, and Hispanic. Pregnancy outcomes were reported as percentages for each group. MELD-3.0 was calculated using mean laboratory values nearest index pregnancy event. Multivariable analyses were performed after 1:1 propensity score matching (PSM) to balance cohorts by age, body mass index (BMI), bilirubin, baseline varices, type 2 diabetes (T2DM) and CLD etiology: alcohol associated (ALD) or metabolic dysfunction-associated steatotic liver disease (MASLD). **Results:** Among 4,380 pregnancies (mean age 33.8 years), 2,672 were White, 833 Black, and 875 Hispanic. The most common CLD etiology was MASLD (26- 52%). Prior to matching, rates of antenatal bleeding (12% vs. 8%), genitourinary infections (GUI, 9% vs. 6%), DM (22% vs. 10-15%), and liver conditions of pregnancy (18% vs. 12-15%) were higher in Hispanic patients compared to White and Black patients. In contrast, liver complications, including bilirubin $\geq$ 3 (11%), ascites (11%), varices (8%) and mortality (3%), were highest in Black patients. After matching, 59% of each group had pre-pregnancy cirrhosis. Compared to Black patients, Hispanic patients had increased adjusted odds of GUI (OR 1.93, 95% CI 1.30-2.87, $p < 0.01$), and antenatal bleeding (OR 1.44, 95% CI 1.00-2.11, $p = 0.05$) and T2DM (OR 1.85, 95% CI 1.33-2.57). Compared to Hispanic patients, White patients had increased adjusted odds of gestational hypertension (OR 1.67, 95% CI 1.14-2.44, $p < 0.01$) and perinatal mood disorders (OR 95% CI 2.17, 95% CI 1.41-3.23, $p < 0.,01$), with similar point estimates when compared to Black patients. Black patients had increased odds of ascites (OR 1.47, 95% CI 1.04-2.08, $p = 0.03$), varices (OR 1.58, 95% CI 1.05-2.40, $p = 0.03$) and bilirubin $\geq$ 3 (OR 1.83, 95% CI 1.27-2.63, $p < 0.01$) as compared to White patients but no increased odds of adverse pregnancy outcomes. However, compared to Hispanics, Black patients had increased odds of labor complications (OR 1.33, 95 CI 1.02-1.75, $p = 0.04$) and fetal stress during labor (OR 1.65, 95% CI 1.04-2.22, $p = 0.03$). **Conclusion:** In this diverse, nationally represented cohort, pregnancy-related risks in CLD differed by race/ethnicity. Many differences were eliminated when adjusted for CLD etiology. However, infection and bleeding risk persisted in Hispanic females and liver-related events remained more common in those of Black race. These patterns underscore the need for individually tailored care to optimize pregnancy outcomes in the growing population with CLD.

3071 | STRATEGIES FOR REDUCING THE TIME FROM HCV DIAGNOSIS TO TREATMENT INITIATION: LESSONS FROM VANCOUVER, BC, CANADA

Christina Wiesmann[1] Shana Yi[1] David Truong[1] Brian Conway[1], [1]Vancouver Infectious Diseases Centre

Background: The eradication of HCV infection as a public health concern requires targeted initiatives. In Canada, approximately 35% of people who use drugs are infected with HCV, representing more than 60,000 individuals. The Vancouver Infectious Diseases Centre (VIDC) runs weekly or twice-weekly pop-up clinics in Vancouver's inner-city to test for HCV antibodies. Anecdotally, we identify numerous individuals who have

documented HCV viremia and who state they have never been offered treatment. There is an urgent need to meaningfully re-engage these indivdiuals in an accessible and timely manner. Reducing the time from HCV antibody diagnosis to treatment initiation is thought to be a key strategy for increasing HCV treatment uptake. **Methods:** Between August of 2023 and June of 2024, many measures were put in place to help reduce the time from point-of-care testing to initiation of treatment. These included on-site medical records look-up and phlebotomy if required, immediate special authority (SA) application, physician appointment with telehealth assistance and/or an appointment at our Downtown East-side (DTES) inner-city clinic, and a partnership with a pharmacy with a ready supply of HCV medication and daily delivery services. We measured the effect of these measures on time from initial contact to treatment initiation. **Results:** The median time from initial contact to treatment initiation was reduced from 6 weeks to approximately 3.5 weeks, with a range from 4 days to 57 days. The time median from initial patient contact to SA application being sent was 2 days (range from 0 to 33 days), and the median number of days for SA approval was 1 day (range from 1 to 22 days). The median number of days from SA approval to prescription being written was 5 days (range from 0 to 40 days), and the median number of days from the prescription being written to the patient receiving their first dose of medication was 7 days (range from 0 to 25 days).
We identified a number of facilitators and barriers to timely treatment initiation. Facilitators included on-site phlebotomy, telehealth assistance for appointments, pharmaceutical delivery, and dispensation with other medications. Barriers included follow-up with individuals without a fixed address, lengthy SA approval times for complex cases, requirement for a fibroscan in some cases, and wait times for HCV medication or pharmaceutical delivery services. **Conclusion:** We have identified many different interventions which have helped to decrease the time between initial contact and treatment start date. We believe that many of these interventions can be implemented in similar communities around the world. Follow-up analysis will investigate whether or not these measure helped to increase the numer of individuals initiating treatment, and reduce rates of loss to follow-up.

3072 | BARRIERS AND PROPOSED INTERVENTIONS TO IMPROVE HEPATOCELLULAR CARCINOMA SURVEILLANCE ADHERENCE IN PATIENTS WITH HEPATITIS C VIRUS POST-SUSTAINED VIROLOGIC RESPONSE: A QUALITATIVE SURVEY ASSESSMENT OF HEPATOLOGY EXPERTS

Seren Gedallovich[1] Sudharshan Achalu[1] Tatyana Kushner[2] Ashwani Singal[3] Robert Brown[2] Neehar Parikh[4] Nancy Reau[5] T.Tara Ghaziani[1] Douglas Dieterich[6] K Rajender Reddy[7] Amit Singal[8] Mindie Nguyen[1] Paul Pockros[9] Stuart Gordon[10] Renumathy Dhanasekaran[1] Paul Kwo[1], [1]Stanford University Medical Center, [2]Weill Cornell Medicine, [3]University of Louisville, [4]University of Michigan Medical Center, [5]Rush University Medical Center, [6]Icahn School of Medicine at Mount Sinai, [7]University of Pennsylvania, [8]University of Texas Southwestern Medical Center, [9]Scripps Clinic and Scripps Translational Science Institute, [10]Henry Ford Health System

Background: Hepatitis C virus (HCV) therapy significantly reduces hepatocellular carcinoma (HCC) risk in patients who achieve sustained virologic response (SVR). However, patients remain at risk of HCC due to persistent oncogenic inflammation and fibrosis, coupled with host genetic susceptibility. HCC surveillance after SVR is widely underused, highlighting need for quality improvement. We aimed to gather expert perspectives on barriers to surveillance adherence and inform strategies for improving uptake through a qualitative analysis. **Methods:** Semi-structured interviews were conducted by teleconferencing with 13 nationwide hepatologists, experienced in managing patients with post-SVR HCV. Interviews focused on perceived barriers to HCC surveillance adherence and strategies for long-term follow-up. Transcripts were coded, and reflexive thematic analysis was completed to identify recurrent patterns and challenges. **Results:** In interviews, four major themes emerged (Figure):
1. Variation in Surveillance Practices:

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Surveillance protocols varied, especially for patients with advanced fibrosis without cirrhosis. For patients with cirrhosis, surveillance was uniformly recommended every 6 months, whereas practices for those with F2-F3 fibrosis were dependent on patient risk factors and provider discretion.

2. Patient-Related Barriers:

Patients may mistakenly believe that achieving SVR eliminates HCC risk. Factors such as asymptomatic status, low health literacy, limited financial resources, and competing life priorities hinder routine follow-up.

3. Provider and System Fragmentation:

Inconsistent recall strategies, unclear messaging, and lack of shared responsibilities between hepatologists and primary care providers (PCPs) result in lapses in care. Many patients are followed by PCPs after SVR, but PCPs may prioritize other health issues over HCC surveillance due to educational gaps and competing concerns.

4. Proposed Solutions and Innovations:

Suggested interventions included embedding patient navigators, establishing digital tracking systems, streamlining EMR prompts, and improving coordination with Radiology for easier access. Enhanced patient and provider education using simple language and teach-back techniques, along with longer imaging intervals and the development of blood biomarker-based surveillance strategies, were also recommended. **Conclusion:** HCC surveillance in post-SVR HCV patients faces challenges due to inconsistent protocols and multiple barriers. Targeted interventions to improve adherence are necessary.

Figure. Overview of barriers to HCC surveillance and proposed solutions.

3073 | THE RISING GLOBAL CLINICAL AND ECONOMIC BURDEN OF METABOLIC DYSFUNCTION–ASSOCIATED STEATOHEPATITIS (MASH) DRIVEN BY TYPE 2 DIABETES (T2D): A 20-YEAR MODELING STUDY ACROSS NINE COUNTRIES

Zobair Younossi[1] James Paik[1] Cyrielle Caussy[2] Amalia Gastaldelli[3] Michael Roden[4] Scott Isaacs[5] Cristiane Villela-Nogueira[6] Jeremy Tomlinson[7] Hussain Abdulrahman Al- Omar[8] Patrizia Burra[9] Yuichiro Eguchi[10] Javier Crespo[11] Elisabetta Bugianesi[12] Jerome Boursier[13] Mario Pessoa[14] Frank Tacke[15] Manuel Romero-Gómez[16] Hirokazu Takahashi[17] Claudia Pinto Oliveira[14] Paul Brennan[18] Takumi Kawaguchi[19] Faisal Abaalkhail[20] Vincent Wai-Sun Wong[21] Philip Newsome[22] Fatema Nader[1] Linda Henry[1] Shira Zelber-Sagi[23] Laurent Castera[24] Saleh Alqahtani[20], [1]The Global NASH Council, Washington DC, United States, [2]Diabete and Nutrition, Hôpital Lyon Sud, Hospices Civils de Lyon Pierr-Bénite, France, [3]Institute of Clinical Physiology, National Research Council (CNR) Pisa, Italy, [4]Institute for Clinical Diabetology, Heinrich Heine University, Düsseldorf, Germany, [5]Division of Endocrinology, Emory University School of Medicine, Atlanta, GA, [6]School of Medicine and Hepatology Division, Universidade Federal do Rio de Janeiro, Brazil, [7]NIHR Oxford Biomedical Research Centre, University of Oxford, Churchill Hospital, Oxford, UK, [8]Department of Clinical Pharmacy, College of Pharmacy, King Saud University, Riyadh, Saudi Arabia, [9]Department of Surgery, Oncology and Gastroenterology, Padua University Hospital, Padua Italy, [10]Loco Medical General Institute, Saga, Japan, [11]Valdecilla Research Institute (IDIVAL), Marqués de Valdecilla University Hospital, Santander, Spain, [12]Department of Medical Sciences University of Turin, Italy, [13]Diabete and Nutrition, Hôpital Lyon Sud, Hospices Civils de Lyon Pierre-Bénite, France, [14]Hospital das Clínicas da Faculdade de Medicina daUniversidade de São Paulo, São Paulo, Brasil, [15]Charité - Universitätsmedizin Berlin, Germany, [16]Department of Medicine, University of Seville, Seville, Spain, [17]Liver Center, Saga University Hospital, Faculty of Medicine, Saga University, Saga City, Japan, [18]Division of Molecular and Clinical Medicine, University of Dundee, Scotland, UK, [19]Kurume University School of Medicine, Kurume, Japan, [20]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia, [21]The Chinese University of Hong Kong, Hong Kong, China, [22]King's College London, Foundation for Liver Research and King's College Hospital, London, [23]University of Haifa, Haifa, Israel, [24]Department of Hepatology, University of Paris-VII, Hopital Beaujon, Clichy, France

Background: T2D is an important risk for MASH. To inform long-term planning and intervention strategies, we projected the clinical and economic burden of MASH among adults with and without T2D across 9 countries (United States [US], Germany [DE], Spain [ESP], France [FR], Italy [IT], United Kingdom [UK], Japan [JPN], Brazil [BR], and Saudi Arabia [SA]) over 2 decades. **Methods:** Country-specific Markov models were developed to estimate 20-year (2021–2040) burden of MASH, stratified by T2D status across 9 health states: MASH without fibrosis (F0), fibrosis stages 1–3 (F1–F3), compensated cirrhosis, decompensated cirrhosis, hepatocellular carcinoma, liver transplantation (LT) year 1, and post-LT survival. Competing mortality risks (liver-related, cardiovascular, and other) were incorporated. Transition probabilities were derived from literature and calibrated using country-level data on T2D, obesity, and advanced liver disease. Direct medical costs, work productivity (WP) losses, and health-related quality-of-life (HRQL) impairments were estimated annually by disease stage and T2D status. All costs were expressed in 2020 USD and adjusted using International Monetary Fund inflation forecasts. **Results:** From 2021 to 2040, MASH prevalence in the general population is projected to rise in all countries: US (6.71% to 7.41%), DE (4.43% to 4.97%), ESP (4.50% to 5.38%), JPN (3.67% to 5.02%), BR (7.19% to 7.52%), SA (7.39% to 7.50%), FR (4.04% to 4.26%), IT (4.57% to 4.92%), and UK (4.74% to 4.86%). Among MASH patients, proportion of MASH with T2D is expected to rise: US (43.6% to 51.7%), DE (31.1% to 37.3%), ESP (49.8% to 60.3%), JPN (68.8% to 84.9%), BR (25.3% to 30.8%), SA (47.0% to 53.2%), FR (27.6% to 33.0%), IT (33.3% to 40.8%), and UK (41.6% to 48.5%). Cirrhosis cases among MASH patients with T2D are estimated to increase in every country (Figure 1A). Direct annual MASH-related medical costs will more than double, with the share attributable to T2D increasing: JPN (79.5% to 93.0%), ESP (67.8% to 79.4%), US (63.5% to 72.4%), FR (56.0% to 67.6%), UK (57.7% to 67.9%), IT (59.2% to 71.0%), DE (44.1% to 54.8%), SA (54.5% to 64.5%), and BR (30.7% to 40.1%,) (Figure 1B). WP losses and HRQL impairments among MASH patients with T2D are also projected to worsen. **Conclusion:** T2D is a major and growing driver of the clinical and economic burden of MASH in most regions. Targeting T2D patients to identify and treat MASH could help reduce future clinical and economic burden.

3074 | RURAL-URBAN TRENDS IN LIVER-RELATED MORTALITY POST-PANDEMIC DIFFER BY ETIOLOGY AND AGE

Tiange Zhang[1] Brian Lee[2] Jennifer Dodge[1] Norah Terrault[1], [1]University of Southern California, [2]Keck School of Medicine

Background: Before the COVID-19 pandemic, liver-related mortality increased in both rural and urban areas with a widening rural-urban disparity. During the pandemic, liver-related deaths surged but trends post-pandemic have been less studied. **Methods:** Using CDC WONDER mortality data for adults aged ≥25 from 2005 to 2023, overall liver-related deaths were identified using validated ICD-10 codes for cirrhosis, ALD, MASLD, viral hepatitis, autoimmune/cholestatic, and hereditary/genetic disorders. Rural-urban status was defined by established definitions (rural: micropolitan/noncore; urban: large central metro/large fringe metro/medium/small metro). We calculated age-adjusted mortality rates (AAMR) overall and by etiology (ALD, MASLD, others), sex, and age. Trends were assessed using Joinpoint regression to estimate annual percentage change (APC) across detected trend segments, comparing rural and urban areas. **Results:** In both rural and urban areas, overall AAMR for liver-related etiologies peaked in 2021 before declining through 2023 (Fig. 1A). Rural areas had a positive APC of +11.38% (95%CI: +6.6 to +16.3) in 2018-2021, followed by a negative APC of −5.76% (-9.6 to -1.8) in 2021-2023. Urban areas had similar trends (2018-2021: +8.1% [+4.9 to +11.3]; 2021-2023: -3.9% [-6.6 to -1.2]). Between 2021-2023, AAMR remained above pre-pandemic levels and higher in rural vs. urban areas. ALD (Fig. 1B), but not MASLD (Fig. 1C), mirrored overall trends with a peak in 2021 followed by a decline in 2021-2023. When ALD and MASLD were excluded, the 2021-2023 segment had a stable APC in rural areas (-2.44% [-7.6 to +3.0]), and no distinct 2021-2023 segment was detected by trend analysis in urban areas. Within the ALD group, the 2021-2023 segment had an APC that declined in both rural and urban areas for females, males, adults age 25-44, and adults age 45-64 but not among adults age ≥65 with ALD, where the 2021-2023 segment had a stable APC in rural areas (+0.35% [-10.7 to +12.8]), and no distinct 2021-2023 segment in urban areas. No trend differences by sex or age were observed for MASLD. **Conclusion:** Overall liver-related mortality remains above pre-pandemic levels, with rural rates consistently exceeding urban rates. ALD clearly drove pandemic increases but has had variable declines across age groups from 2021-2023, with older adults in both rural and urban areas remaining particularly vulnerable. Strategies to curtail liver-related mortality in the post-pandemic era are an

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

urgent priority, with rural populations and older adults with ALD among the highest risk groups.

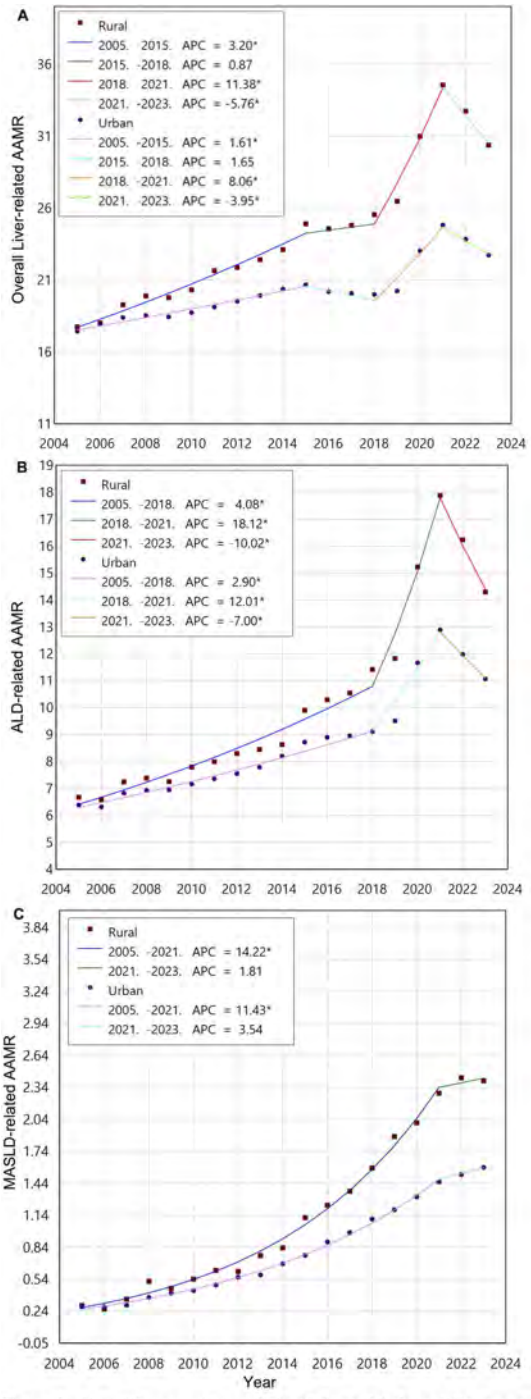

Figure 1. Joinpoint regression analysis of liver-related mortality among adults in rural vs. urban areas, 2005-2023. (A) Overall liver-related mortality. (B) Mortality from ALD. (C) Mortality from MASLD. *Indicates that the Annual Percentage Change (APC) is significantly different from zero at alpha of 0.05. AAMR: age-adjusted mortality rate.

3075 | MATERNAL AND PERINATAL OUTCOMES IN PREGNANT PATIENTS WITH COMORBID INFLAMMATORY BOWEL DISEASE AND CHRONIC LIVER DISEASE: A NATIONAL INPATIENT SAMPLE STUDY

Jessica Lee[1] Konstantinos Papamichael[2] Lauren Grinspan[3] Adam Cheifetz[2] Melissa Spiel[4] Tatyana Kushner[5] Loren Rabinowitz[2], [1]Department of Medicine, Beth Israel Deaconess Medical Center, [2]Division of Gastroenterology, Department of Medicine, Beth Israel Deaconess Medical Center, [3]Division of Liver Diseases, RMTI, Icahn School of Medicine at Mount Sinai, [4]Department of Obstetrics and Gynecology, Beth Israel Deaconess Medical Center, [5]Division of Gastroenterology and Hepatology, Department of Medicine, Weill Cornell Medical College

Background: Chronic liver disease (CLD) and inflammatory bowel disease (IBD) are each associated with adverse pregnancy outcomes. IBD also increases the risk of liver diseases such as primary sclerosing cholangitis, but the impact of coexisting IBD and CLD on pregnancy is unknown. We compared maternal and perinatal outcomes among patients with both IBD and CLD to those with IBD only, CLD only, or neither. **Methods:** We conducted a retrospective cohort study using the National Inpatient Sample from 2016-2022 to identify delivery hospitalizations among pregnant women aged ≥18 years, excluding nonviable pregnancies and abortions. Deliveries were classified into mutually exclusive groups using ICD-10-CM codes: IBD+CLD, IBD only, CLD only, or neither. CLD etiologies included alcohol, autoimmune, viral hepatitis, metabolic dysfunction-associated steatotic liver disease, alpha-1 antitrypsin deficiency, Budd-Chiari syndrome, Wilson's disease, hemochromatosis, and toxic liver disease. NIS survey discharge weights were applied to generate national estimates. Multivariable logistic regression was adjusted for age, race, insurance status, multiple gestation, obesity, diabetes, hyperlipidemia, hypertension, and cirrhosis. **Results:** Among 21,304,600 weighted deliveries, 680 (0.003%) had IBD+CLD, 47,555 (0.22%) had IBD only, and 178,025 (0.84%) had CLD only. IBD+CLD patients had

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

higher rates of preexisting hypertension and hyperlipidemia compared to all groups and steroid use and autoimmune liver disease compared to CLD only. Regarding maternal outcomes, IBD+CLD had higher odds ($p < 0.001$ for most) of hypertensive complications, perinatal mood disorders, cesarean delivery, postpartum hemorrhage, and severe maternal morbidity (Table 1). In terms of perinatal outcomes, IBD+CLD had increased odds ($p \leq 0.01$ for most) of preterm premature rupture of membranes (PPROM) and PROM, preterm birth, fetal growth restriction and fetal death. IBD and CLD only were each associated with increased adverse outcomes compared to controls, with IBD+CLD showing even higher odds than either condition alone. **Conclusion:** Individuals with coexisting IBD and CLD face substantially higher risk of multiple maternal and perinatal complications than those with either condition alone. These findings suggest a compounding effect of IBD and CLD and support risk-based liver disease screening in prenatal care for patients with IBD to improve pregnancy outcomes.

Table 1. Adjusted multivariable logistic regression analyzing the association of an inflammatory bowel disease and/or chronic liver disease status in pregnancy with each adverse maternal and perinatal outcome.

3076 | TIMING IS EVERYTHING: ECONOMIC IMPLICATIONS OF IMMEDIATE VERSUS DELAYED HEPATITIS C CARE

Mark Sulkowski[1] Nancy Reau[2] Natasha Martin[3] Zach Baldwin[4] Yuri Sanchez Gonzalez[4] Barbra Cave[4] Hélène Parisé[5] Tianzhou Yu[5] Warren Stevens[5], [1]Johns Hopkins Medicine, [2]Rush University Medical Center, [3]University of California, San Diego, [4]AbbVie Inc., North Chicago, IL, USA, [5]Medicus Economics, Boston, MA, USA

Background: Immediate care for hepatitis C virus (HCV) infection by treating at time of diagnosis could reduce the risk of disease progression and onward viral transmission. A recent study demonstrated the efficacy of 8-week glecaprevir/pibrentasvir (G/P) therapy in acute HCV. We evaluated the cost-effectiveness of treating newly diagnosed HCV patients with G/P vs waiting to determine chronicity to treat with sofosbuvir/velpatasvir (SOF/VEL). **Methods:** A health state transition model of HCV natural history and disease progression was developed from the healthcare system perspective over a lifetime horizon. In the strategy to treat at time of diagnosis, all patients were treated with 8-week G/P regardless of chronicity. In the strategy to wait for chronicity, only those who remained viremic after 6 months were treated with 12-week SOF/VEL and assumed to infect an average of 0.4 persons while untreated. Costs included were related to treatment, direct hepatic medical costs, and extra-hepatic manifestations. Re-infection and re-treatment were not considered. Efficacy of G/P was obtained from NCT04903626 and efficacy of SOF/VEL was sourced from its US product insert. Other parameters including drug acquisition costs were derived from published literature. All costs were inflated to 2025 Q1 US dollars. Key outcomes were total healthcare costs, total quality-adjusted life-years (QALYs), and net monetary benefit (NMB) calculated using a willingness-to-pay threshold of $100,000/QALY. To assess the impact of uncertainty in model parameters and structural assumptions, sensitivity analyses were performed. **Results:** In the base case analysis, treatment at time of first diagnosis with G/P regardless of chronicity was a dominant strategy compared to waiting for chronicity to treat with SOF/VEL, providing greater incremental QALYs (difference: 3.456), lower costs (difference: $32,121), and a NMB of $377,699. In the probabilistic sensitivity analyses, immediate treatment with G/P was a dominant strategy in 99.22% of the 10,000 simulations and cost-effective in 99.96% of the simulations. **Conclusion:** Treating HCV at first diagnosis with 8-week G/P therapy regardless of chronicity is projected to be a QALY- and cost-saving strategy compared to delaying treatment with SOF/VEL until confirmed HCV chronicity. This highlights the importance of therapies effective in treating HCV at the time of diagnosis, as it enables a more efficient use of finite healthcare resources, and lowers the transmission risk and time to cure.

3077 | OPTIMIZING TRANSITIONS OF CARE FOR LIVER CIRRHOSIS PATIENTS: A RETROSPECTIVE ANALYSIS OF INPATIENT ENCOUNTER DATA ON 30- DAY READMISSIONS

Sai Patel[1] Ayush Kaushish[1] Michael Moseley[1] Alexis Kim[1] Allison Ladetto[2] Hannah Lee[3] Carolyn Marcelo[1], [1]Virginia Commonwealth University Health System, [2]Virginia Commonwealth University School of Medicine, [3]Virginia Commonwealth University

Background: Liver cirrhosis is a major cause of morbidity and mortality and is associated with high hospital readmission rates. Reducing readmissions, particularly for cirrhosis patients, is a priority at Virginia Commonwealth University Health System (VCUHS). According to FY 2024 Vizient data, VCUHS's General Medicine-Hepatobiliary Sub-Service Line, which includes all patients with a cirrhosis diagnosis-related group, had a readmission rate of 25.3%, compared to a median of 21.7% among academic medical centers. This retrospective cohort study identifies gaps in discharge care coordination by evaluating 30-day readmission data among cirrhosis patients. **Methods:** Cirrhosis patients admitted to a medicine service at VCUHS between January and June 2024 were identified. Data was collected on readmission timing, chief complaints, discharge planning, and follow-up care. Cirrhosis etiology, Model for End-Stage Liver Disease (MELD) 3.0 scores, and transplant status were also analyzed. **Results:** 78 cirrhosis patients who were readmitted within 30 days of discharge were identified. Alcohol-associated (47.4%) and metabolic dysfunction-associated (30.8%) were the most common cirrhosis etiologies. The mean MELD 3.0 score was 23. Hepatic encephalopathy (HE) (43.6%) and hypervolemia (29.4%) were the most common admission symptoms. 41% were listed for transplant during or prior to hospitalization. Only 26.9% had primary care follow-up scheduled within 30 days; of these, 57.1% were scheduled within 7 days. Hepatology follow-up was arranged for 55.1% of patients, with only 32.6% occurring within 7 days. 84.6% received new prescriptions, 63.7% of which were filled at the VCUHS discharge pharmacy. 65.3% of patients received free text written instructions, 28.2% received standard patient education materials, and 25.6% received no cirrhosis- related instructions. 38.4% received home health services, 10.3% received remote patient monitoring services, and 8.9% received a care coordination follow-up call. HE (35.9%) and hypervolemia (17.9%) were the most frequent reasons for readmission. **Conclusion:** Our findings highlight substantial gaps in discharge coordination for cirrhosis patients. Low rates of early follow-up, underutilization of monitoring services, and inconsistent discharge education were prevalent. Enhanced transitional care strategies, including timely follow-up scheduling, standardized patient education, and increased use of remote monitoring, may reduce avoidable readmissions and improve patient outcomes.

3078 | HOSPITALIZATION PATTERNS AND RESOURCE UTILIZATION IN LIVER CIRRHOSIS

Paola Barrios[1] Gil Peled[2] Aditya Jain[3] Saad Hussain[1] Oriana Dentici[1] Lisa VanWagner[4] Andres Duarte-Rojo[5] Laura Kulik[6] Nikhilesh Mazumder[2] Charles Manski[2] Daniela Ladner[1], [1]Northwestern University Comprehensive Transplant Center, [2]Northwestern University, [3]Northwestern Univeristy, [4]University of Texas Southwestern Medical Center, [5]Northwestern Medicine, [6]Northwestern Medical Faculty Foundation

Background: Liver cirrhosis affects 2-5 million adults and is associated with high morbidity, mortality and a reduced quality of life. Patients with chronic diseases in high resourced areas have been found to have better outcomes. We examine hospitalizations, in-hospital resource utilization and cost in a large longitudinal

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

national dataset and compare patients in low vs high-resourced environments using Area Deprivation Index (ADI). **Methods:** This is a retrospective cohort study of privately insured adults with cirrhosis using a large national insurer claims database from 7/2011-12/2022. Hospitalization rates, in-hospital resource utilization and cost were analyzed. ADI categories are reported (D1: least deprived; D5: most deprived). Multivariate analyses were adjusted for age, gender, insurance type, Charleston Comorbidity Index (CCI), and etiology. **Results:** In 393,745 patients (mean age 63.9 years; 45.5% female; Medicare 57.6%), the most common etiology was ALD (38.8%). Average CCI is 5.7, and mean MELD 3.0 is 14.1. Mean hospitalization rate is 65 hospitalizations/100 patient years. Patients in D5 vs DI 1 had 11.1% higher hospitalization rates, lower outpatient-to-inpatient visit ratio by 13.5%, and an increase in acute care visits by 50.8%. D5 patients experienced 2.1% higher LOS. D5 patients were 10.3% more likely to be discharged to hospice and 28% more likely to leave the hospital against medical advice. D5 patients underwent 17.8% fewer cirrhosis related procedures while inpatient. D1 had a higher cost per single hospitalization at $18,251.74 vs $16,194.69 in D5 but overall cost of care/100-patient years was 5.1% higher in D5 vs D1 ($1,332,500 vs $1,268,478) (Figure). All results reached statistical significance ($p < 0.05$). **Conclusion:** Hospitalization rates are high for patients with cirrhosis. Patients living in the most deprived geographic areas have lower cost of hospitalizations, but likely because of higher hospitalization rates and fewer outpatient relative to inpatient visits, patients in more deprived areas incur higher overall costs of inpatient care.

3079 | FRAILTY AND DECOMPENSATED CIRRHOSIS ARE ASSOCIATED WITH SIGNIFICANTLY HIGHER MORTALITY INDEPENDENT OF RACE AND ETHNICITY

Saad Hussain[1] Paola Barrios[1] Suyanpeng Zhang[1] Dominic Vitello[1] Sijia Wei[1] Salva Balbale[1] Oriana Dentici[1] Al'ona Furmanchuck[1] Nikhilesh Mazumder[2] Lisa VanWagner[3] Lihui Zhao[1] Andres Duarte-Rojo[4] Sanjay Mehrotra[1] Daniela Ladner[1], [1]Northwestern University, Chicago, IL, [2]University of Michigan Hospitals and Health Centers, [3]University of Texas Southwestern Medical Center, [4]Northwestern Medicine

Background: Mortality is very high in patients with cirrhosis. We examine if mortality varies across different racial and ethnic groups. **Methods:** A retrospective cohort study was performed to identify adult patients with cirrhosis using CAPriCORN, a large EHR data repository across 7 health care systems in a large US metropolitan area from 2016-2021. Demographics and clinical covariates examined including age, sex, race/ethnicity, urban/rural, etiology, insurance type, Area Deprivation Index (ADI) [Q1: high resourced, Q5: low resourced), MELD 3.0, Charlson comorbidity index (CCI), decompensation and frailty (HFRS); [Low: HFRS < 5, severe: HFRS > 15]. The primary outcome of interest was all-cause mortality rates reported per 100 patient-years (PY). Univariate and multivariate analyses were performed. Significance = $P < 0.05$. **Results:** 18,718 patients with cirrhosis were included. The mean age was 59.8, 43.1% were women, 45% were white, 19% black, 21% Hispanic, and 97% lived in urban areas. Most common etiologies were MASLD (28.6%), MetALD (23.1%), ALD (12.8%). 29.5% had Medicare,

27.8% Private, 22.3% Medicaid, 14.3% other insurance, 6.2% uninsured. ADI (Q1: 5.7%, Q2: 30.8%, Q3: 36.4%, Q4: 23.6%, Q5: 2.4%). Mean MELD was 16.3, CCI 6.79 and 29.7% were decompensated at inclusion. 54.1% patients had low frailty, 28.1% intermediate and 15.7% severe frailty. (Table) Mean mortality per 100 PY was 13.26 (white: 16.13, black: 9.08, Hispanic: 8.86 per 100PY). Severe vs low frailty was associated with increased mortality (25.48 vs 10.22 per 100PY) and was consistently associated with >2.8x higher mortality across races/ethnicity (white: 306%, black: 367%, hispanic: 289% increase, respectively). (Figure) Decompensated vs compensated cirrhosis was associated with increased mortality (21.35 vs 10.35 per 100PY) and decompensation was consistently associated with >1.8x higher mortality across races/ethnicity (white: 233%, black: 251%, Hispanic: 183% increase, respectively). **Conclusion:** Severe frailty and decompensation is race-agnostic, as patients with cirrhosis of any race/ethnicity had 3-fold and 2-fold increase in mortality respectively, independent of race and ethnicity.

3080 | CHARACTERIZING HEALTHCARE COSTS IN MEDICARE BENEFICIARIES WITH A NEW DIAGNOSIS OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS (MASH) WITH COMPENSATED CIRRHOSIS

Nipun Atreja[1] Francis Lobo[1] Yestle Kim[1] Dominic Nunag[2] Andrew Epstein[2], [1]Madrigal Pharmaceuticals, [2]Medicus Economics

Background: Current studies on the economic burden of MASH with compensated cirrhosis are limited by focusing on short-term (annual) costs and only reporting average costs, without examining heterogeneity across the cost distribution. **Methods:** We conducted a cohort study using a full sample of Medicare FFS beneficiaries aged ≥ 65, continuously enrolled for any 4-year span between 01/01/2016 to 12/31/2023 (1-year baseline, 3-year follow-up). Compensated cirrhosis was defined by ≥ 1 inpatient or ≥ 2 outpatient claims (any position) for cirrhosis (ICD-10-CM: K74.4–K74.6, I85.00, I85.10, I85.9, I98.2) and MASH (K75.81), occurring ≤ 90 days apart in either order. Mean total healthcare costs per beneficiary were calculated over the 3-year follow-up and adjusted to 2023 dollars. Beneficiaries were stratified into quartiles (Q) based on total costs. Baseline characteristics were compared using chi-square (categorical) and ANOVA (continuous) tests. **Results:** Among 3,726 beneficiaries (mean age, 72.1 years) with a new diagnosis of compensated cirrhosis, mean (standard deviation [SD]) total 3-year healthcare costs were $95,891 ($108,188) and were highly skewed (mean [SD], Q1: $19,950 [$7,658]; Q2: $47,703 [$9,118]; Q3: $90,025 [$16,707]; Q4: $225,973 [$146,228]; Figure). Beneficiaries in the highest-spending quartile (Q4) were responsible for 59% of total spending, while those in the lowest-spending quartile (Q1) contributed 5%. Beneficiaries in the highest-spending quartile (Q4) were more likely to be dual eligible for Medicare/Medicaid coverage compared to those in the lower-spending quartiles ($P<0.001$). Compared to those in the lower-spending quartiles (Q1–Q3), beneficiaries in the highest-spending quartile (Q4) also had more unique medications, greater prevalence of hospitalization, greater comorbidity, and greater diabetes complications severity index, all measured in the baseline period ($P<0.001$ for all). **Conclusion:** In Medicare FFS, total healthcare costs in the 3 years after a new diagnosis of MASH with compensated cirrhosis are high overall and highly

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

concentrated, with a quarter of beneficiaries accounting for 59% of total spending. Targeting early identification and treatment for compensated cirrhosis in the costliest patients may translate into meaningful savings for payers.

3081 | IMPACT OF A BRIEF VIDEO INTERVENTION ON DISEASE UNDERSTANDING AND ADVANCED CARE PLANNING IN HOSPITALIZED PATIENTS WITH DECOMPENSATED CIRRHOSIS

Helene Bloom[1] Nabeeha Mohy-ud-din[1] Dheera Grover[1], [1]Allegheny Health Network

Background: Cirrhosis has an increasing incidence with over 54,000 new diagnoses/year and is currently the tenth leading cause of death in the US [1]. Despite this, patients historically have limited understanding of disease progression and it's impact on their health and prognosis. This pilot project aimed to increase education regarding progression of cirrhosis and to introduce patients to advanced care planning with the goal of limiting invasive medical interventions at the end of their lives. **Methods:** Inpatients aged 18-89 years with Child-Pugh Class B and C cirrhosis who are not deemed transplant candidates with two prior hospitalizations within 6 months at our tertiary care hospital were included in the study. Participants completed a questionnaire assessing their pre-existing knowledge and were shown a 5-minute informative video designed by our team on progression of cirrhosis and introduction to palliative care services, followed by a post-intervention survey. **Results:** 14 patients were included in the study with one unable to complete the survey due to fatigue. The mean age of patients was 63.4 and 84.6% were male. Pre-intervention, 76.9% (n = 10) patients reported understanding of their liver disease and its progression, with improvement to 92.3% (n = 12) post intervention. Pre-intervention, 69.2% (n = 9) noted an understanding of palliative care services, with an improvement to 76.9% (n = 10) post-intervention. Only 5 patients had been introduced to the term palliative care and 4 had met a palliative care provider previously. 53.8% (n = 7) patients were 'full code' prior to the intervention, and one patient was interested in changing the code status to DNR/okay to intubate from full code. 92.3% (n = 12) patients either agreed or strongly agreed to have a better understanding of cirrhosis and goals of palliative care services/advanced care planning post-intervention and 92.3% (n = 12) were interested in completing a POLST or advanced care directive at the conclusion of the study. **Conclusion:** A brief educational video regarding disease progression and advanced care planning can be beneficial in improving patients' knowledge and aid with decisions regarding end-of-life care.

3082 | MISSED OPPORTUNITIES IN HCV ELIMINATION: INSIGHTS FROM ITALY&RSQUO;S NATIONAL SCREENING AND EQUITY GAPS

Loreta Kondili[1] Maria Giovanna Quaranta[1] Benedetta Mattioli[1], [1]Istituto Superiore Di Sanita (ISS)

Background: IItaly bears one of the highest HCV burdens in Europe, with prevalence and liver-related mortality nearly three times the EU average. Unlike other countries where infection is limited to high-risk groups, Italy's epidemic significantly affects the general population, particularly adults over 55. Italy leads Europe in HCV treatment and remains the only country to fund a national screening program via its Ministry of Health. Launched in 2022, this feasibility project targeted individuals born 1969–1989, people in addiction services (SerD), and inmnates. **Methods:** Ongoing

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

HCV free of charge screening is delivered in Italy via proactive and opportunistic approaches. Screening indicators are validated by the Istituto Superiore di Sanità. Interim evaluations of screening coverage, test uptake, antibody and RNA positivity, and linkage to care, are reported across the three populations' settings. **Results:** A total of 2,605,054 individuals were screened within this nationwide program, identifying 16.866 active infections:

- General population: 2, 384.024 screened; 3,302 infections (0.14%)
- SerD: 135,469 screened; 10.551 infections (7.8%)
- Prisons: 85, 561 screened; 3.013 infections (3.5%)
- Linkage to care is still a challenge variying from 49.5% in SerD to 67% in prisons.

Among SerD invitees, 33% were PWID, with 474 reinfections.The lower prevalence in SerD and prison settings, compared to historical data, likely reflects the positive impact of DAA scale-up. Prisons achieved the highest HCV screening coverage (92.6%) and adherence (82.8%) in Europe, demonstrating success in structured environments.
In contrast, the general population showed low antibody (0.8%) and RNA positivity rates, likely due to participation by previously treated individuals and a poor risk perception of individuals who did not undergo HCV screening. The explanation of a lower chronicity rate in infections acquired via non-classical routes (non-injection exposures), is currently under investigation. Comparative studies show that HCV prevalence in marginalized populations can significantly exceed that of the general population (2,9% vs 0.4%), indicating the national program failed to sufficiently reach those at highest risk, limiting its effectiveness in driving HCV elimination. **Conclusion:** Italy's free of charge screening of over 2.6 million people, mainly from general population,and from people who use drugs and inmates, offers a rare glimpse into population-scale HCV elimination strategies in a European Union country. Successes in SerD and prisons contrast with general population's low engagement and unsustained efforts.The program's closure with unused funds risks political misinterpretation that no further action is needed. Without renewed investment, outreach programs, and effective testing and linkage-to-care strategies for older adults, Italy risks an ongoing disease burden and failure to meet the elimination goals.

3083 | LIVER AND SPLENIC STIFFNESS IN CLINICALLY SIGNIFICANT PORTAL HYPERTENSION.

Sandeep Kaur Toor[1] Himanshu Gupta[1] Amandeep Singh[2] Jahnvi Dhar[1] Nitesh Bassi[1], KABIR KANG[1] Rashmeet Brar[1] MANJYOT[1] Virendra Singh[1] [1]Punjab institute of liver and biliary sciences, [2]PUNJAB INSTITUTE OF LIVER AND BILIARY SCIENES

Background: Non-invasive strategies to determine portal hypertension are crucial to stratify patient care . Elastography in clinical practice has enabled the early identification of patients with clinically significant portal hypertension (CSPH) and consequently, risk of decompensation and liver-related death. The aim of the present study was to reach the highest predictive accuracy using liver stiffness measurement (LSM), and splenic stiffness measurement (SSM) as different parameters for predicting the development of CSPH, without the need for doing invasive procedures such as endoscopy. Endoscopy was taken as a gold standard for the development of CSPH. We evaluated patients who presented to our institute between March, 2024 and April, 2025 with clinical features of chronic liver disease. These patients underwent elastography for measurement of both liver and splenic stiffness; and endoscopy . We calculated the cut off values of LSM and SSM; beyond which diagnosis of CSPH can be reliably made. **Methods:** It is a cross sectional study . 86 selected patients had undergone both endoscopy and had liver and splenic stiffness measurements; **Methods:** The eligibilty criteria included- all adult patients; age more than 18 years; who underwent endoscopy and fibroscan (for hepatic and splenic stiffness within an interval of maximum 15 days. The data was collected irrespective of the aetiology of the cirrhosis, laboratory parameters or clinical presentation of the patient. Patients with IQR more than 30% were excluded. **Results:** Analysis: The presence of the endoscopy findings were categorized into binary variables 0 and 1; depending upon whether portal hypertensive gastropathy(PHG) was present or absent; irrespective of the grading of the PHG and varices .The LSM and SSM were taken as continous variables. **Results:** Binary logistic regression reveals a positive coeffficient of variables (both liver stiffness and splenic stiffness) with the endoscopy findings. P values are less than .01 implying a stastically significant correlation between increasing stiffness measurements(both liver and splenic) and evidence of portal hypertension. This was also corroborated with odd's ratio which is more

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

than 1 in analysing both the variables. Further analysis of the liver stiffness measurement in patients with positive endoscopy findings reveals a median measurement of 42, with 95% confidence interval of liver stiffness varying between 38.08-48.54. The splenic stiffness in these patients had a median value of 50.56 with 95% confidence interval between 43.86-57.26. **Conclusion:** LSM and SSM can be used as independent predictors of CSPH, With increasing LSM and SSM values, the possiblity of portal hypertension increases. Cut off values of 42 KPa and 52 KPa for LSM and SSM can suggest definte portal hypertension; without needing endoscopic correlation. However further studies with larger patient groups would be needed for confirming these findings.

	LIVER STIFFNESS	SPLENIC STIFFNESS
Mean	43.31	50.56
Median	42	52
Mode	75	27.2
Std. Deviation	22.1	25.24
Variance	488.57	637.23

3084 | LONG TERM ANTIBODY RESPONSE FOLLOWING CHADOX1–NCOV (COVISHIELD) VACCINE IN PATIENTS WITH CIRRHOSIS: A CROSS-SECTIONAL OBSERVATIONAL STUDY

Amandeep Singh[1] Rishav Aggarwal[2] Arka De[3] Mini P Singh[4] Rashmeet Kaur Brar[5] Virendra Singh[5] Simrat Kaur Parmar[5] Tanu kundal[6], [1]Punjab Institute of Liver and biliary sciences, SAS Nagar, [2]Department of Medicine, PGIMER, Chandigarh, [3]Department of Hepatology, PGIMER Chandigarh, [4]Department of Virology, PGIMER, Chandigarh, [5]Punjab Institute of Liver and biliary sciences, SAS Nagar, Punjab, India, [6]Adesh Institute of Medical Sciences, Ambala

Background: Patients with cirrhosis have a higher risk of severe COVID-19 and mortality. WHO recommended booster doses of vaccination in view of Global uncertainties around COVID-19 pandemic, waning of Antibody response and variants of concerns. However, data on long term antibody response and timing of vaccination in patients with cirrhosis is scarce. Hence, we aimed to assess the long-term antibody response following ChAdOx1–nCOV (Covishield) vaccine in patients with cirrhosis. **Methods:** Patients with cirrhosis who attended the Liver clinic at our institute in May to June 2022 were screened using a pre-specified questionnaire. Patients who had completed 2 doses of ChAdOx1-nCOV (with the 2nd dose administered at least 6 months back) and without history of documented COVID-19 infection (pre- or post-vaccination) were tested for antibodies against the spike protein. Seropositive patients were divided into high, moderate, and low antibody responses based on the signal/cut-off. **Results:** Total of 139 patients of cirrhosis who were completely vaccinated with COVID-19 vaccines were screened and 86 patients were enrolled in the study as per the inclusion and exclusion criteria with at least 6 months duration between the 2nd dose of ChAdOx1-nCOV vaccine and the date of sampling. Breakthrough infections were seen in 4.4% patients. Local and systemic adverse events were reported by 25 % and 9% patients with first and second dose respectively. None developed serious adverse events requiring hospitalization. Seroconversion was documented in 83 (96.5%) out of 86 patients. Sub-optimal antibody response was seen in 12(13.9%). No difference was observed in level of antibody response between patients with compensated and decompensated cirrhosis. Antibody titre comparison of 35 patients at 40 days and 6 months of receipt of 2nd dose of ChAdOx1-nCOV vaccine showed that titres after 6 months were on lower side but there was no statistical significance ($p = 0.09$). **Conclusion:** The present study concludes that cirrhosis patients have good long term seropositivity with Covishield vaccine, irrespective of age, gender, aetiology of cirrhosis, comorbidities and severity scores, indicating a good vaccine immunogenicity in this population. However, suboptimal antibody titres in a small subgroup, may indicate the need of an early Covishield booster requirement in cirrhosis patients.

3085 | BALANCING QUALITY TRAINING FOR PRIMARY SURGEONS AND IMPROVED PATIENT OUTCOMES: THE ART OF FLUORESCENCE NAVIGATION IN DIFFICULT LAPAROSCOPIC CHOLECYSTECTOMY – RESULTS: FROM AN ONGOING OPEN-LABEL RANDOMIZED CLINICAL TRIAL

Baojia Zou[1] Luyao Zhang[1] Peiping Li[1] Jiafan Chen[1] Jianzhong He[1] Xialei Liu[1] Zhouying Zheng[1] Xiaopeng Hong[1] Genglong Zhu[1] Jian Li[1] Chaonong Cai[1], [1]The Fifth Affiliated Hospital of Sun Yat-sen University

Background: Difficult laparoscopic cholecystectomy (LC) increases the risk of bile duct injury (BDI), especially in patients with obscured biliary anatomy. This presents a dual challenge: safeguarding patient safety while providing meaningful training opportunities for junior surgeons. Near-infrared fluorescence (NIRF) imaging with indocyanine green (ICG) enables real-time visualization of key biliary structures, offering a unique solution that bridges these two needs. **Methods:** As part of a prospective clinical trial (ChiCTR2400088163), 80 patients undergoing complex LC at the Department of Hepatobiliary Surgery, the Fifth Affiliated Hospital of Sun Yat-sen University were analyzed. Patients were grouped based on whether NIRF (ICG-guided) or standard white-light (WL) imaging was used. The study evaluated the rate and time of intraoperative visualization of the cystic duct (CD), common bile duct (CBD), and common hepatic duct (CHD), along with implications for surgical training. **Results:** NIRF significantly enhanced intraoperative biliary visualization compared to WL:

- CD–CBD junction: 98% vs. 73%, $P = 0.003$
- CHD: 88% vs. 63%, $P = 0.010$
- CD visualization time: 2.0 vs. 7.0 min, $P < 0.001$
- CHD visualization time: 5.0 vs. 8.0 min, $P = 0.009$
- CD–CBD junction visualization time: 4.0 vs. 9.0 min, $P < 0.001$

These improvements not only supported more accurate and confident dissections but also created safer conditions for supervised training of primary surgeons. **Conclusion:** NIRF-guided LC facilitates safer navigation of complex biliary anatomy, significantly reducing operation time and enhancing surgical confidence. Importantly, this approach supports high-quality, real-time training for junior surgeons without compromising patient safety. These interim results from our ongoing clinical trial demonstrate NIRF as a promising strategy to balance surgical education and clinical excellence in hepatobiliary surgery.

3086 | A QUALITATIVE STUDY EXPLORING THE EXPERIENCES AND UNMET NEEDS OF PATIENTS LIVING WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS

Ahsan Shoeb[1] Jannie Laursen[1] Nathalie Marcela Eklöf[1], [1]Novo Nordisk A/S

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is a chronic, progressive metabolic disease affecting the liver. This study explored the lived experiences of patients with MASH, identifying unmet needs and focusing on understanding their perspectives regarding their clinical care pathway (CCPs). **Methods:** Qualitative data were collected Oct–Nov 2024. Patients with a MASH diagnosis (n = 80 [US (n = 25), France (n = 11), Italy (n = 12), Germany (n = 15), Canada (n = 8), Japan (n = 9]) were enrolled via social media/healthcare professional (HCP) or patient advocacy group referral. The web-assisted telephone interviews were moderated using a semi-structured discussion guide, utilizing open-ended questions. Thematic analysis was used to analyse the data. **Results:** Clinical patient characteristics are shown in Figures 1A–B, with 56% of patients aged 50–69 years, and 60% identifying as female.

MASH diagnoses are delayed, in part, due to low awareness and misattribution of symptoms (abdominal pain, bloating, fatigue, nausea etc.) to other comorbidities. Delayed diagnosis of a progressive condition was associated with increased levels of anxiety amongst patients. Regardless of severity, few patients associated their symptoms with MASH. Patient interactions with HCPs are negatively impacted by perceived stigma and incorrect assumptions of alcohol intake. Delayed access/HCP buy-in to initiate tests exploring potential diagnoses is a source of frustration for patients. Following diagnosis, patients struggle with unclear treatment options and poor communication about the consequences of MASH, resulting in concern, worry and anxiety; few patients feel satisfied when moving into the initial management stage. A lack of psychological support for managing multiple chronic conditions also contributes to high patient anxiety throughout the CCP (Figure 1C). **Conclusion:** This research demonstrates significant unmet needs across MASH CCPs from a patient perspective, including a need for improved patient information, and guidance and support mechanisms from HCPs and the healthcare system. Engaging HCPs with customised education on presentation, diagnosis and management of MASH to support dialogue with patients is essential to drive clarity and reduce patient anxiety.

3087 | FIB-4 RISK STRATIFICATION MODEL CAN PREDICT LIVER-RELATED OUTCOMES OF MASLD PATIENTS RECEIVING CARE IN NON-SPECIALTY/PRIMARY CARE SETTINGS

Jay Bae[1] Mark Hartman[2] Yuanyuan Tang[1] Arti Mansharamani[3] Belle van Rosmalen[1] Arun Sanyal[4], [1]Eli Lilly and Company, [2]Eli Lilly & Co, [3]Eli Lilly and Company, Indianapolis, IN, USA, [4]Virginia Commonwealth University

Background: The MASLD clinical risk stratification model (Sanyal et al, 2023) represents a simple yet high performing clinical risk stratification tool developed from the TARGET-NASH registry, conducted at hepatology, gastroenterology and endocrinology sites. This study aimed to validate the model in non-specialty/primary care settings. **Methods:** A large electronic health record database linked to claims (Optum Market Clarity, 2003-2020) from all non-long-term care providers was analyzed. MASLD/MASH index diagnosis, overweight/obesity, and liver enzyme tests were required at baseline for inclusion. Patients with a diagnosis of alcoholic liver disease at any time were excluded. Fibrosis-4 (FIB-4) score was calculated using the closest laboratory test results to the index diagnosis, and patients were classified into Class A (FIB-4 < 1.3), Class B (FIB-4 1.3 - 2.6), and Class C (FIB-4 > 2.6).

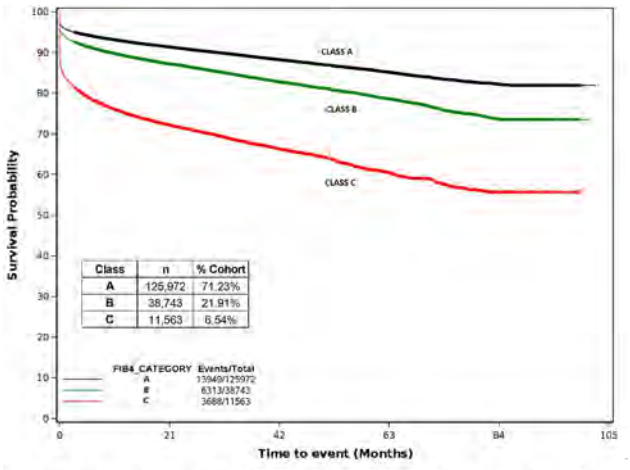
The composite endpoint MASLD progression (defined as occurrence of cirrhosis, hepatic decompensation or liver transplantation by ICD-10 diagnoses) was examined both descriptively and with a Cox proportional hazard model using baseline characteristics (i.e., FIB-4 classes, age, sex, race, body mass index, smoking status, diabetes status, statin use, chronic kidney disease, hypertension, etc.). **Results:** The validation cohort consisted of 176,856 patients with mean follow-up of 3.07 years (total 543,524 patient-years). Mean age was 51.5 years (SD: 14.9), 57% were female, 78% White, 9% African American, 2% Asian, and 10% others/unknown. Distribution of FIB-4 class was A:71.2%; B:21.9%; C:6.5%. Overall, 13.7% experienced one or more liver-related clinical events. The most frequent outcomes were compensated cirrhosis (10.5%) and decompensated cirrhosis (4.7%) with mean times to first occurrence of 18.8 months and 19.7 months, respectively. MASLD progression rate was 11.1% for A, 16.3% for B, and 31.9% for C. The risk of liver outcomes was significantly ($p < 0.001$) increased for both Class B (HR: 1.44, 95% CI: 1.39-1.49) and Class C (HR: 3.16, 95% CI: 3.02-3.30) versus Class A (figure). **Conclusion:** In this non-specialty/primary care database, the FIB-4 based risk classification was a highly significant predictor of progression to liver-related clinical events among patients with MASLD. The model demonstrated consistent performance. The non-invasive risk stratification system is a practical and useful tool for assessing MASLD progression risk in the non-specialty/primary care setting.



Kaplan-Meier curves demonstrating MASLD progression events (occurrence of cirrhosis, hepatic decompensation, or liver transplantation) for patients classified as Class A (FIB-4 <1.3), Class B (FIB-4 1.3 - 2.6), and Class C (FIB-4 >2.6) at index diagnosis.

3088 | TRENDS IN HEPATITIS C VIRUS (HCV) ANTIBODY SCREENING AND POSITIVITY RATES, 2020-2024: ANALYSIS OF >35 MILLION US ADULTS USING REAL-WORLD DATA

Isabelle Winer[1] Monica Silver[1] Alina Bogdanov[1] Natalia Coenen[1] Maryam Ajose[1] Janna Manjelievskaia[1],
[1]Veradigm

Background: With HCV prevalence on the rise in the US, clinical practice guidelines were updated in March 2020 to recommend universal screening, thus marking a change from the former risk-based and birth-cohort screening approaches. Despite updated guidelines, HCV screening rates in the US remain low. We sought to understand the real-world trends in HCV antibody screening in a general US population born on or after 1966 (post 'Baby Boomer' generation) between 2020-2024. **Methods:** Adults (18+), born on or after 01/01/1966, with at least 1 preventive healthcare visit between March 2, 2020-December 31, 2024 were identified in the Veradigm Network EHR database linked to healthcare claims from Komodo Health. Presence of HCV antibody screening and proportion of positive/reactive antibody HCV tests were evaluated by year (2020-2024), overall and by birth cohort (Gen X (1966-1979), Millennials (1980-1996), Gen Z (1997-2012)). Demographic characteristics, including social determinants of health (SDOH), were evaluated during patient history or as of earliest visit date. **Results:** A total of 35,975,646 adult patients were identified as having a preventive healthcare visit. Among them, 1,850,836 had evidence

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

of HCV antibody screening, reflecting an HCV screening rate of 5.1%. The majority of those screened were female (69%). Among 258,461 patients with documented access to care issues, the HCV screening rate was 20.3%. The proportion of adults with HCV screening generally increased from 2020-2024 (Figure 1). Among those screened, a majority were in the Millennial birth cohort (51%), followed by Gen X (32%), and Gen Z (17%). Among HCV tests containing a valid result, 2.6% were positive/reactive overall, with the highest proportion among Millennials (2.9%), followed by Gen X (2.8%), and Gen Z (0.9%). Positivity rates remained fairly stable from 2020-2023 (2.7%-3.0%) with a minor decrease in 2024 (1.5%). **Conclusion:** Our real-world study of adults in a large ambulatory EHR database linked to claims found an overall HCV screening rate of 5.1%. The substantially higher screening rate (20.3%) among those with access to care issues may be reflective of patients perceived to be at higher risk for HCV, or potential confounding between documentation of SDOH factors and likelihood of HCV screening. Continued surveillance of HCV among the general adult population is important in understanding the prevalence of disease over time.

3089 | LIVER DISEASE ELIMINATION: WUWEI MEDICAL CONSORTIUM OF LIVER DISEASE SPECIALISTS MODEL

Fengmei Wang[1] Wenhua Zhang[1] Haitao Tang[1] Wenling Jia[1] Chunhui Liang[1], [1]Wuwei Academy of Medical Sciences

Background: To study the impact of the medical consortium on the level of prevention and treatment of liver disease in Wuwei City and surrounding areas of Gansu Province. **Methods:** Since 2018, the Hepatobiliary Disease Center of Wuwei Academy of Medical Sciences started to establish a medical consortium of liver disease specialists in Wuwei City and surrounding areas of Gansu province and formed a management model for liver disease patients: 1. We helped county-level hospitals to establish hepatology departments and we appointed a liver disease specialist from a tertiary hospital as the director of the hepatology department for these hospitals. 2. Liaison specialists were selected by the rural health centers to conduct follow-up work for chronic liver disease patients. 3. A network platform for remote consultation has been established. 4. Hepatology department of tertiary hospitals organized academic activities, training, and patient education activities every year. 5. Established a green referral channel for two-way communication and referral between superior and subordinate medical institutions. **Results:** Through the medical consortia, we have set up hepatology departments in 9 county-level hospitals in Wuwei and surrounding areas. We have also trained 27 liver disease specialists and 54 liver disease specialist nurses to provide specialized diagnosis and treatment for liver disease patients. At the same time, 14 rural health centers were included in the medical consortium. In the past 5 years, a total of 10 academic meetings and training sessions on liver disease were held with 2,324 participants. A total of 22,280 chronic liver disease patients have been followed up. The number of outpatients at the Hepatobiliary Disease Center,Wuwei Academy of Medical Sciences has increased from 11,544 in 2017 to 21,373 in 2023, and the number of hospitalized patients has increased from 1,987 in 2017 to 3,337 in 2023. **Conclusion:** The medical consortium of liver disease specialists was first established and operated in Wuwei City, Gansu Province. The management mode of liver disease patients has been gradually formed under the situation of the medical consortium.The prevention and treatment network of liver disease specialists has been gradually formed there, laying the foundation for achieving the goal of eliminating viral hepatitis by 2030.

Neil Shah[5] Lindsay Yoxheimer[3] Hersh Shroff[4], [1]UNC Healthcare, [2]University of North Carolina, [3]University of North Carolina Health, [4]UNC Chapel Hill, [5]University of North Carolina at Chapel Hill

Background: Peroxisome proliferator-activated receptor (PPAR) agonists, elafibranor and seladelpar, were recently approved as second-line agents for primary biliary cholangitis (PBC) in ursodeoxycholic acid (UDCA) non-responders. This study provides real-world data on medication accessibility and efficacy at a tertiary academic medical center hepatology clinic. **Methods:** A 10-month, single-center retrospective chart review was conducted for patients with PBC who were prescribed elafibranor or seladelpar from 6/2024-3/2025. We defined access as successful initiation of treatment, and we assessed the steps required to attain access, including insurance prior authorizations (PAs), denials and appeals. Effectiveness was measured by changes in relevant biochemical markers. **Results:** A total of 37 patients were prescribed elafibranor (n = 14) or seladelpar (n = 23). 89% were female and the median age was 61 years. Payor types included commercial (n = 14), Medicare (n = 16), Medicaid (n = 3), and manufacturer patient assistance program (n = 4). All 37 patients were on UDCA. 30% of patients (n = 11) were on other second-line PBC therapies at the time PPAR agonist therapy was considered. A majority of these (n = 8) discontinued the second-line agent upon starting the PPAR agonist. Treatment was approved in 90% (n = 33) of patients, of whom 27 (73%) required PA, 5 (14%) did not require PA, and 1 (3%) was denied but successfully overturned after appeal. Among the four patients who did not access treatment, two were denied for not being on UDCA for ≥ 1 year and two had insurance plans where PPAR agonists were excluded from coverage. At the time of chart review, 32 patients (86.5%) had started PPAR agonist treatment, with a median time from prescription date to treatment initiation of 16 days. Median (IQR) baseline lab values included: AST 37 (27-43) U/L, ALT 27 (17-57) U/L, total bilirubin (TB) 0.6 (0.4-1.1) mg/dL, and alkaline phosphatase (ALP) 229 (193-296) U/L. In 25 patients with follow-up labs (obtained an average of 71 days after treatment initiation), median (IQR) follow-up ALP was 149 (120-183) U/L. The median change in ALP per 30 days of PPAR agonist treatment was –42.6 U/L. **Conclusion:** In our cohort, despite their novelty and specialty medication status, PPAR agonists were highly accessible with relatively low administrative burden. Consistent with clinical trials, treatment was associated with rapid improvements in relevant biochemical markers.

Table 1. Baseline characteristics and follow-up results

	Total (n=37)
Age, median (IQR) – years	61 (54 –67)
Gender, # (%)	
Female	33 (89%)
Prescriptions, # (%)	
Elafibranor	14 (38%)
Seladelpar	23 (62%)
Patients on UDCA, # (%)	37 (100%)
Second-line treatments*	11 (30%)
Obeticholic acid (OCA)†	7 (n=5 discontinued)
Fenofibrate†	5 (n=4 discontinued)

3091 | CHATGPT FOR CLINICAL DATA EXTRACTION: A COMPARISON WITH MANUAL REVIEW OF HEPATOLOGY REFERRAL PACKETS

Vinathi Polamraju[1] Jason Pan[2], [1]Washington University School of Medicine, [2]Washington University in St. Louis

Background: Large language models (LLMs) such as ChatGPT are increasingly being evaluated for their potential to automate clinical data extraction. This retrospective study from a high-volume hepatology referral center aimed to compare manual versus institutional ChatGPT-based extraction across structured and unstructured clinical fields in referral packets. **Methods:** Twenty-nine consecutive referral packets were reviewed. Manual data extraction was performed and compared to ChatGPT-based extraction using a uniform prompt. All extractions were conducted using a secured sandbox version of ChatGPT-4o that is HIPAA-compliant. Variables included numeric fields (e.g., age, sex, lab values) and string fields (e.g., past medical history, alcohol use history, imaging findings). A mismatch was defined as a significant discrepancy between manual and ChatGPT-extracted data. For numeric values, mismatches were defined as deviations >0.5 units. String fields were first preprocessed via lowercasing, punctuation/stopword removal, de-duplication, and alphabetic sorting. A tuning experiment identified 0.25 as the optimal threshold. As such, for string fields, a normalized Levenshtein distance >0.25 indicated mismatch. Mismatch rates were calculated per variable as mismatches divided by total entries (29). **Results:** Referral packets ranged 6–242 pages (mean = 63.86). Mismatch rates ranged 0–0.482 (mean = 0.150). Structured fields (e.g., age, name, Cr) showed near-perfect agreement. Highest mismatch rates were in semi-structured fields: past medical history (0.448), alcohol use history (0.379), ALT (0.276) (Figure 1). When ChatGPT was asked to extract only these variables individually, mismatch rates dropped: past medical history (0.207), alcohol use (0.138), ALT (0.138), indicating improved accuracy with focused prompts. Referral packet length correlated with mismatch rate ($r = 0.673$, $p < 0.001$). Linear regression revealed each 1-page increase in referral length was associated with a 0.0016 increase in mismatch rate ($R^2 = 0.453$). Formatting inconsistencies, data redundancy, and fragmented information contributed to mismatches. **Conclusion:** ChatGPT performs well with structured data and improves on unstructured fields when queried individually. Longer, more complex documents are associated with higher mismatch rates. Hybrid methods combining targeted LLM queries with preprocessing may enhance automation in clinical data workflows.

3092 | CHARACTERIZING HEALTHCARE COSTS IN MEDICARE BENEFICIARIES WITH A NEW DIAGNOSIS OF NON-CIRRHOTIC METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS

Nipun Atreja[1] Francis Lobo[1] Yestle Kim[1] Dominic Nunag[2] Andrew Epstein[2] Zachary Marcum[2], [1]Madrigal Pharmaceuticals, [2]Medicus Economics

Background: Current studies on the economic burden of non-cirrhotic metabolic dysfunction-associated steatohepatitis (MASH) are limited by reporting average costs, without examining variation across the cost distribution, and have focused on short-term (annual) costs. **Methods:** We conducted a retrospective cohort study using a full sample of Medicare FFS beneficiaries aged ≥ 65, continuously enrolled for any 4-year period between 01/01/2016–12/31/2023 (1-year baseline, 3-year follow-up). MASH (ICD-10-CM: K75.81) was identified by ≥ 1 inpatient or ≥ 2 outpatient claims (any position); those with cirrhosis codes 360 days before or 90 days after the index date were excluded. Mean total healthcare costs per beneficiary were calculated over the 3-year follow-up and adjusted to 2023 dollars. Beneficiaries were stratified into quartiles (Q) based on total costs. Baseline characteristics were compared across quartiles using chi-square tests for categorical variables and ANOVA tests for continuous variables. **Results:** Among 26,927 beneficiaries (mean age, 71.8 years) with a new diagnosis of non-cirrhotic MASH, mean (standard deviation [SD]) total 3-year healthcare costs were $67,094 ($88,775) and were highly skewed (mean [SD], Q1: $10,951 [$4,410]; Q2:

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

$28,275 [$5,891]; Q3: $56,730 [$11,559]; Q4: $172,437 [$124,406]; Figure). Beneficiaries in the highest-spending quartile (Q4) were responsible for 64% of total spending, while those in the lowest-spending quartile (Q1) contributed 4%. Beneficiaries in the highest-spending quartile (Q4) were more likely to be dual eligible for Medicare/Medicaid coverage compared to those in the lower-spending quartiles ($P < 0.001$). Compared to those in the lower-spending quartiles (Q1–Q3), beneficiaries in the highest-spending quartile (Q4) also had more medications, more GLP-1 agonist use (Q4: 11.2% vs. Q1: 0.5%), greater prevalence of hospitalization, and greater comorbidity, all measured in the baseline period ($P < 0.001$ for all). **Conclusion:** In Medicare FFS, total healthcare costs in the 3 years after a new diagnosis of non-cirrhotic MASH are high overall and highly concentrated, with a quarter of beneficiaries accounting for 64% of total spending. Baseline characteristics, including dual-eligibility status and comorbidity, differed across cost quartiles. Early identification and treatment of MASH in the highest-cost patients stand to generate substantial cost savings for healthcare payers.

3093 | SHIFTING PATTERNS IN LIVER BIOPSY INDICATIONS AND DIAGNOSES: A RETROSPECTIVE COMPARISON BETWEEN TWO TIME PERIODS

Fani Karapanagiotidi[1] Emmanouil Sinakos[1] Anastasia Fotiadou[2] Spiros Papadopoulos[3] Evangelos Akriviadis[1] Ioannis Goulis[1] Prodromos Hytiroglou[2], [1]Aristotle University of Thessaloniki, Hippokratio General Hospital, [2]Aristotle University of Thessaloniki, [3]Hippokratio General Hospital

Background: The role of liver biopsy is perceived to have lost part of its central role in the diagnostic evaluation of liver diseases. Advances in antiviral treatments, the increasing prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD), and the widespread use of non-invasive fibrosis assessment tools may have contributed to this shift. This study aimed to assess potential changes in the use of liver biopsy across two distinct time periods. **Methods:** This was an observational, single-center, retrospective study. We reviewed liver biopsy indications and outcomes in patients, who underwent a liver biopsy during two 5-year periods: 2010–2014 (Group A) and 2020–2024 (Group B). Patients with malignant neoplasms were excluded. Data recorded included age (> 16 years), sex, liver enzyme levels, prior liver transplant, referral indication, histological diagnosis and fibrosis stage. Statistical analysis was performed using R software, with Mann-Whitney U, Student's t-test, chi-square, and logistic regression applied as appropriate. **Results:** A total of 725 liver biopsies were analyzed—465 in Group A (50.5% male, median age 51 years) and 260 in Group B (48.5% male, median age 54 years). A prior biopsy was noted in 150 cases (127 in Group A vs. 23 in Group B, $p < 0.05$), while liver transplantation was reported in 51 patients (35 vs. 16, $p > 0.05$). A significant decrease in the mean annual number of biopsies was observed in Group B (93 vs. 52, $p < 0.05$), especially for biopsies performed solely for disease staging (204 vs. 30, $p < 0.05$). Histological diagnoses in Group A included: chronic hepatitis B (25.2%), MASLD (17.4%), non-specific histological changes (11%), primary biliary cholangitis (10.7%), chronic hepatitis C (8.8%), autoimmune hepatitis (5.4%), drug-induced liver injury (4.7%), chronic cholangiopathies (4.3%) and others (12.3%). In Group B: MASLD (32.4%), non-specific histological changes (15.9%), autoimmune hepatitis (13.1%), chronic cholangiopathies (6.6%), drug-induced liver injury (5.4%), primary biliary cholangitis (5.4%), and others (21.2%). A significant reduction in biopsies for viral hepatitis was observed in Group B ($OR = 0.06$, 95% CI: 0.03–0.12, $p < 0.001$), alongside an increase in MASLD-related biopsies ($OR = 1.91$, 95% CI: 1.35–2.70, $p < 0.001$). Advanced fibrosis (F3–F4) was more common in Group B ($OR = 1.48$, 95% CI: 1.07–2.06, $p = 0.019$), although significance was lost after adjustment for age, sex, and diagnosis ($p = 0.10$). **Conclusion:** This study highlights a significant reduction in the total number of liver biopsies between the two time periods, with a marked decline in biopsies for viral hepatitis and a notable increase in those related to MASLD in the more recent period. Biopsies conducted solely for fibrosis staging also significantly decreased. The role of liver biopsy seems to gradually change mainly due to shifts in disease epidemiology and advances in non-invasive diagnostics.

3094 | AVOIDING THE IMPACT OF INACTION: HOW TO MAXIMIZE PROGRESS TO HCV ELIMINATION IN THE UNITED STATES

Nancy Reau[1] Zach Baldwin[2] Barbra Cave[2] Yuri Sanchez-Gonzalez[2] Mark Sulkowski[3], [1]Rush University Medical Center, [2]AbbVie Inc., North Chicago, IL, USA, [3]Johns Hopkins Medicine

Background: Only twelve countries — ten of them high-income — are on track toward the World Health Organization (WHO) global targets for eliminating hepatitis C virus (HCV). With the current diagnosis and treatment levels, the U.S. is not expected to achieve elimination targets before 2050. We explore clinical, economic, and societal benefits associated with alternative strategies for HCV elimination in the U.S. using a model populated with real-life data. **Methods:** A previously published disease burden and economic impact model was populated with data from published literature. Clinical outcomes included end-stage liver disease (ESLD) and deaths; economic outcomes included healthcare costs from HCV screening, treatment, and liver-related and extrahepatic complications; societal outcomes included new infections, net present value (value of quality-adjusted life-years gained net of screening and treatment costs), and return on investment (ROI, incremental medical savings over screening and treatment costs). Three scenarios were projected over 2025-2034: (1) Base Case following the status quo of current treatment and diagnosis levels in the U.S., (2) Elimination scenario defined by the minimum level of annually diagnosed and treated chronic viremic cases needed to reach the WHO's 2030 elimination goals (starting in 2026), and (3) Optimized Elimination scenario augmenting the latter Elimination scenario by diagnosing 90% of incident acute cases of HCV and treating 80% of those diagnosed. **Results:** The Base Case scenario would incur $160.6 billion in total costs and lead to 1.2 million new infections and 9,735 deaths over 2025–2034. The Elimination scenario would require annually diagnosing 557,000 and treating 593,000 chronic cases starting in 2026 to save $41.3 billion in total costs compared to the Base Case. This would avoid 668,000 new infections and 6,924 deaths for a net present value of $27 billion. The Optimized Elimination scenario would achieve the highest total cost savings of $46 billion and lead to the greatest reduction in new infections (704,000) and deaths (6,991) for a net present value of $29.5 billion. **Conclusion:** An optimized HCV elimination strategy requiring treatment at first diagnosis regardless of HCV chronicity can maximize clinical, economic, and societal benefits. The implementation of test-and-treat models of care is needed to achieve these required levels of diagnosis and treatment and meet 2030 elimination goals.

Table 1. Clinical, Economic, and Societal Outcomes of HCV Elimination Scenarios

	Base case	Elimination	Optimized Elimination
Cumulative new cases (2025–2034)			
Decompensated cirrhosis	6,861	1,879	1,835
HCC	13,074	3,778	3,686
Liver transplant	1,141	363	359

Background: The European Union faces a growing rise in MASLD and MASH, conditions characterised by the accumulation of excess fat in liver cells. They are at a heightened risk of liver cancer. This project aimed to raise awareness of early liver disease detection using portable transient elastography (TE) in community settings. **Methods:** In October 2024, ELPA Members Liver4Life and SOS Hépatite testing vans offered TE scans to European Parliament staff and the public over 5 days. ELPA representatives engaged MEPs and sent invitations to promote the event. The vans were outside the main entrance with specific messaging placed on the vans. The TE devices were managed by trained operators, including some Belgian HCPs. A brief intervention on lifestyle was used when a high Controlled Attenuation Parameter (CAP) reading was identified. The same was used if a high stiffness reading was identified paired with a self-referral letter for medical follow-up. Participants also completed an anonymous questionnaire assessing iver health. **Results:** The total number of completed and recorded TE examinations over the 5 days was 309 paired with the same number of questionnaires. These were all adults: 165 men and 144 women. Of the total examinations, 30 people (9.7%) had stiffness readings in excess of 7.1Kpa, and these people were given self-referral letters after brief intervention advice. The highest stiffness reading over the 5 days was 12.4 Kpa. The study also identified 67 people (22%) with a CAP reading of 275 or higher (UK criteria) and 181 people (59%) with a CAP reading of 225 or higher (Belgium criteria). Everyone with a CAP score of 225 or greater was given brief intervention lifestyle advice.The average age of people who completed the examinations was 44.8 years old. The average weight was 74.8 kg, height was 169.2 cm, and BMI was 26.1. 40 people had a BMI higher than 30 (9.7%).99 people (32%) stated that they were worried their liver could be damaged, and the main reasons given were: 55 (17.7%)overweight, 50 (16.1%) thought they drank too much, and 23 (7.4%) thought they may have an auto-immune condition. There was no option to select more than a single primary reason.38 people (12.3%) stated that they drank alcohol on 4 or more days per week, 47 people (15.2%) reported high bloodpressure, and 75 people (24.2%) reported a stress level of 7 out of 10 or higher, and 77 people (24.9%) had relied onsubstances (alcohol, caffeine or medication) to manage their stress level. **Conclusion:** This year's larger cohort showed similar results to last year, with more people than expected having raised CAP readings under both criteria. The lack of agreement on criteria may lead to differing care for similar patients. Most with high CAP readings were unaware they had fat in the liver, though many suspected it due to their lifestyles but hesitated to see the results. These findings highlight the urgent need for public health action to raise awareness.

3096 | ASSOCIATION BETWEEN PRURITUS AND HEALTHCARE UTILIZATION AND COSTS AMONG INDIVIDUALS WITH PRIMARY BILIARY CHOLANGITIS IN THE UNITED STATES

Robert Gish[1] Michel Mendler[2] Edward Mena[3] Chong Hoon Kim[4] C. Fiorella Murillo Perez[4] Yi Pan[5] Mihail Samnaliev[5] Diane Ito[5] Maria Agapova[4], [1]Robert G Gish Consultants LLC, [2]California Liver Research Institute, [3]California Liver Reasearch Institiute, [4]Gilead Sciences, [5]Stratevi

Background: Pruritus is a prevalent, debilitating but under-prioritized symptom of primary biliary cholangitis (PBC). This study assessed the impact of pruritus on healthcare resource utilization (HCRU) and costs among individuals with PBC in the US. **Methods:** A retrospective cohort study was conducted using US claims and laboratory data from Komodo's Healthcare Map between September 1, 2017 and September 30, 2023. Cases (PBC with pruritus) were indexed on a random medical encounter with a pruritus diagnosis code; controls (PBC only) were indexed on a random encounter without pruritus. Subgroup analyses required pruritus treatment (sertraline, naltrexone, cholestyramine, cholestipol, rifampin, colesevelam, hydroxyzine or diphenhydramine) within ± 90 days of the index date. Eligibility included age $>=18$, continuous enrollment for $>=12$ months pre- and post-index date, excluding patients receiving obeticholic acid during baseline. Negative binomial models estimated HCRU rate ratios, and linear regression models estimated incremental all-cause total costs (2024 USD) associated with pruritus over the 12-month post-index period, adjusting for baseline demographics and clinical characteristics. **Results:** 10,077 patients with PBC and pruritus and 41,957 controls (PBC only) were identified. Most were female (85.9%), over 65 years old (54.3%) and enrolled in Medicare (57.2%). At baseline, 16.0% had depression, 8.6% had sleep disorders and 2.3% had dementia. Adjusted HCRU rates were significantly higher in the pruritus compared to the control group, with rate ratios of 1.69 (inpatient), 1.36 (outpatient), 1.65 (emergency room), and 1.44 (prescription counts), all $p < 0.001$. Total regression-adjusted average 1-year healthcare costs were $39,949 and $25,695 in the pruritus and control group, respectively with an incremental cost of

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

$14,254 ($p < 0.001$) associated with pruritus. In the subgroup analysis, 3,043 cases and 21,957 controls were identified. Estimates associated with pruritus were more pronounced in the subgroup analysis, with rate ratios of 2.38 (inpatient), 1.50 (outpatient), 2.06 (emergency room), and 2.04 (prescription counts), and incremental regression-adjusted costs of $27,669 (all $p < 0.001$). **Conclusion:** In a real-world study of patients with PBC, pruritus was a significant contributor to HCRU and costs. These findings highlight the need for effective management and novel therapies to alleviate pruritus and reduce its associated clinical burden and costs.

3097 | COST-EFFECTIVENESS OF EMERGENCY DEPARTMENT OPT-OUT BBV TESTING TO ADVANCE ELIMINATION TARGETS FOR VIRAL HEPATITIS AND HIV TRANSMISSION: TALES FROM OPPOSITE CORNERS OF THE WORLD

Joseph Doyle[1] Jürgen Rockstroh[2] Phillip Keen[3] Valerie Delpech[4] Louise Evans[5] Hartmut Stocker[6] Laurel Bates[7] Yixuan Ma[7] Andrea Polokaova[7] Elisabeth Adams[7] James Jarrett[8] Murad Ruf[9], [1]Department of Infectious Diseases, Alfred Health and Monash University, Australia, [2]Department of Internal Medicine, University Hospital Bonn, Bonn, Germany, [3]The Kirby Institute, UNSW Sydney, Australia, [4]North Coast Population and Public Health Directorate, Coffs Harbour, New South Wales, Australia, [5]Department of Clinical Immunology, Liverpool Hospital, NSW and the University of New South Wales, [6]Department of Infectious Diseases, St. Joseph Krankenhaus, Berlin, Germany, [7]Aquarius Population Health, London, United Kingdom, [8]Global Health Economics and Outcomes Research, Gilead Sciences Europe, London, United Kingdom, [9]Public Health, Medical Affairs, Gilead Sciences Europe, London, United Kingdom

Background: In Germany and Australia, despite advances in meeting national viral hepatitis elimination targets, an estimated 80% and 31% of Hepatitis B (HBV) and 63% and 16% of Hepatitis C (HCV) infections, respectively, remain undiagnosed. Additionally, 10% and 8% of HIV infections are undiagnosed. European and US study results demonstrate the impact of opt-out blood-borne virus (BBV) testing in emergency departments (ED) in high-prevalence areas. While Australia has piloted testing in EDs, the approach has not been widely adopted. In Germany, there is no systematic BBV testing in EDs. Our study assessed the potential health and economic value of opt-out combined BBV (HBV, HCV, HIV) testing in high-prevalence areas. **Methods:** We developed a hybrid cost-effectiveness model based on defined published clinical pathways to compare projected outcomes of opt-out BBV testing with current testing in ED as standard of care (SoC). A decision tree simulated testing and linkage to care (LTC) for ED attendees requiring blood tests who do not opt out; a Markov model estimated long-term outcomes. Publicly available country-specific parameters informed the model and were supplemented with international literature and national expert opinion. We used a national health service perspective over a lifetime. Primary outcomes were the number of new diagnoses, LTC, quality-adjusted life years (QALYs) and healthcare costs, converted to USD. **Results:** ED opt-out testing resulted in 82 incremental new BBV diagnoses per 10,000 attendees in Germany and 32 in Australia compared to SoC, of which over 85% were active chronic viral hepatitis cases. Additionally, an incremental 39 (Germany) and 17 (Australia) BBV patients per 10,000 were linked to care. Combined testing for all three BBVs was highly cost-effective over a lifetime, with an incremental cost per QALY gained of $6,613 in Germany and $2,260 in Australia (Figure 1). While individual cost-effectiveness varied by virus, HCV testing was estimated to be cost-saving in both countries, driven by disease progression when left undiagnosed and the high effectiveness of treatment among those linked to care. **Conclusion:** Our findings suggest targeted high-prevalence area opt-out BBV ED testing could prove highly cost-effective, enhance earlier viral hepatitis and HIV infection diagnosis, and facilitate engagement in care in both countries.

3098 | TRENDS IN 1-YEAR POST-LIVER TRANSPLANT OVER TWO DECADES: A NATIONAL COHORT STUDY USING THE UNOS REGISTRY

Sangmin Lee[1] Mohammad Qasim Khan[2], [1]Department of Medicine, Schulich School of Medicine & Dentistry, Western University, London, Ontario, [2]Department of Medicine, Division of Gastroenterology, Western University, London, Ontario

Background: Employment is a key indicator of recovery and quality of life after liver transplant (LT), reflecting not only medical stability, but also functional and social integration. Prior studies have shown persistently low post-LT employment rates (17-24%), but the transplant landscape has changed significantly over the past two decades. Whether these clinical advances have improved return-to-work outcomes remains unknown. **Methods:** We conducted a retrospective cohort study of adult LT recipients (age 18-60 years) in the United States using the UNOS/OPTN registry (2002-2022). Included patients survived 1 year post-LT without re-transplant or death. The transplant year was examined as a categorical (2002-2012 vs. 2013-2022) and a continuous variable. Employment status at 1 year was modelled using Poisson regression with robust standard errors. The multivariable model was adjusted for sex, race/ethnicity, education, insurance, pre-LT employment, diabetes, liver disease etiology, post-LT functional status and hospitalization. **Results:** Among 65,692 event-free 1-year survivors, employment rose from 32.2% in the first decade (2002-2012) to 34.2% in the second (2013-2022), while event-free survival improved from 71.2% to 84.4%. Over time, the transplant population included more patients with private insurance, higher education, and etiology of ALD or MASH vs. fewer HCV. Transplant year was associated with a 0.8% annual employment increase (RR: 1.008, 95% CI: 1.006-1.010); this remained significant after adjustment (aRR: 1.003, 95% CI: 1.001-1.005), confirming a modest but consistent upward trend. Strong positive predictors of employment included private insurance (aRR: 2.34), pre-LT employment (aRR: 2.25), male sex, college education, and autoimmune/cholestatic liver disease. Negative predictors included post-LT mobility limitations (aRR: 0.47), hospitalization (aRR: 0.87), hepatitis C virus, diabetes, and Hispanic ethnicity. **Conclusion:** Employment at 1-year post-LT has modestly improved alongside greater post-transplant survival. Yet, most recipients remain unemployed, revealing a persistent gap between clinical success and functional reintegration. These findings suggest that transplant programs should go beyond medical care and proactively address social and functional recovery. Integrating employment-focused rehabilitation and navigation into multidisciplinary care could help more patients reclaim their independence and quality of life after transplant.

3099 | ASSESSING GOALS OF CARE PRACTICES AMONG INTERNAL MEDICINE RESIDENTS DURING A DEDICATED INPATIENT LIVER SERVICE ROTATION

Charles Marvil[1] Ramya Sampath[1] Stephen Possick[2] Vandana Khungar[3] Alex Choi[4] Laura Morrison[5], [1]Yale University School of Medicine, Department of Internal Medicine, [2]Yale School of Medicine, Section of Cardiovascular Medicine, [3]Yale School of Medicine, Section of Digestive Diseases, [4]Yale University School of Medicine, Department of Internal Medicine Yale Palliative Care Program, [5]Yale University School of Medicine, Department of Internal Medicine Yale Palliative Care Program

Background: Inpatient liver teaching services care for medically complex patients with advanced liver disease and high mortality. These rotations provide internal medicine residents with a key opportunity to engage in goals of care (GOC) communication. However, the frequency of these discussions, the extent of resident leadership, and alignment with palliative care (PC) practices remain poorly understood. **Methods:** Internal medicine residents who completed an inpatient liver teaching service rotation between June 2023 and March 2025 completed a 10-question survey assessing their experiences delivering care in this setting. The survey included items on training year, participation and leadership in GOC conversations, alignment with attendings on treatment planning, follow-through on palliative care (PC) consultations when indicated, and the perceived impact of knowing patients' baseline functional status. Responses were summarized descriptively. **Results:** Twenty-seven residents who had rotated on inpatient liver service completed the survey. Most respondents (22, 81%) completed the rotation during PGY-1. Nearly half (11 of 25, 44%) reported participating in goals of care conversations

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

less than once per week. Only 4 residents (16%) participated in GOC conversations more than weekly. When goals of care conversations occurred, most residents (20 of 25, 80%) reported that they led them only sometimes, rarely, or never.
Over half of respondents (13 of 25, 52%) reported that their treatment plans differed from those of their attendings either "sometimes" or "often," while the remaining 12 (48%) reported disagreement "rarely" or "never." When a PC consult was clinically indicated, only 12 residents (48%) reported it was obtained often or always; 13 residents (52%) reported follow-through occurred "sometimes," "rarely," or "never." Among 23 respondents, 14 residents (61%) reported that a better understanding of patients' baseline functional status would have improved care "quite a bit" or "a great deal." **Conclusion:** Despite frequent exposure to seriously ill patients, residents reported infrequent GOC participation and rarely led discussions on the inpatient liver teaching service. Discrepancies with attendings and inconsistent PC consultation suggest missed opportunities for goal-concordant care. Most felt that understanding baseline functional status would improve decision-making. These findings highlight the need for educational and systems-level changes to support serious illness communication.

3100 | RE-LIVE STUDY (RE-LINKAGE TO PAN-VIRAL HEPATITIS): INTERIM RESULTS: FROM A MULTICENTER OBSERVATIONAL STUDY ON CARE ENGAGEMENT IN CHRONIC VIRAL HEPATITIS

Jae hyun Yoon[1] Young-Sun Lee[2] Yang Jae Yoo[2] Yu Rim Lee[3] Seul Ki Han[4], [1]Chonnam National University Hospital, College of Medicine, [2]Department of Gastroenterology and Hepatology, Korea University Hospital, School of Medicine, Seoul, [3]Department of Gastroenterology and Hepatology, Kyungpook National University Hospital, School of Me, [4]Department of Gastroenterology and Hepatology, Wonju Yonsei University Hospital, School of Medicine

Background: Despite the availability of effective antiviral therapies, linkage to care remains a key barrier to the global elimination of viral hepatitis. A considerable proportion of individuals with chronic hepatitis B, C, and D remain undiagnosed, untreated, or lost to follow-up, sustaining the burden of disease and transmission. In Korea, reimbursement criteria for HBV treatment were expanded in 2023; however, a substantial number of eligible patients remain untreated. This study aimed to evaluate systematic re-linkage strategies to re-engage these individuals in the continuum of care, with the goal of improving clinical outcomes and contributing to public health objectives. **Methods:** A retrospective chart review was conducted at four tertiary hospitals in Korea. HBV treatment eligibility included: (i) non-cirrhotic patients with HBV DNA $>2{,}000$ IU/mL and fibrosis stage ≥ 2, and (ii) cirrhotic patients with any detectable HBV DNA. For HCV, partially diagnosed-but-untreated (DBU) cases were defined as anti-HCV positive without HCV RNA data; completely DBU cases were HCV RNA positive without prior antiviral therapy. Eligible HBV patients were screened for HDV via RT-PCR. Identified patients were re-contacted via phone or text for evaluation and potential linkage to care. **Results:** Among 2,192 patient charts reviewed, 33 HBV and 127 HCV patients were enrolled in the call-back program. Among HBV patients, 21.2% (7) responded and agreed to further evaluation; 6.1% (2) initiated antiviral therapy, while 78.8% (26) did not respond to call-back. Of 92 partial HCV DBU cases, 13.0% (12) agreed to evaluation, 3.3% (3) had prior treatment, 3.3% (3) sought care elsewhere, 2.2% (2) refused, and 78.3% (72) did not respond. Among them, 2.2% (2) initiated treatment. Among 35 complete DBU cases, 2.9% (1) agreed to evaluation, 2.9% (1) sought care elsewhere, 5.7% (2) refused, and 88.6% (31) did not respond; only 2.9% (1) initiated treatment. HDV RT-PCR was performed in 618 chronic HBV patients; 0.1% (1) tested positive but declined further management. In total, 3.1% (5) of 160 patients identified through the call-back program initiated antiviral therapy. **Conclusion:** Although effective antiviral treatments and expanded eligibility criteria are now available, many patients with viral hepatitis remain disconnected from care. Our re-linkage efforts showed limited success in bringing patients back into the treatment pathway. These findings emphasize the need for continued, practical strategies to improve access to care and support national and global goals for viral hepatitis elimination.

3101 | EVALUATING THE AGREEMENT BETWEEN PATIENT SELF-ADMINISTERED QUESTIONNAIRES VS. TRANSPLANT TEAM PSYCHOSOCIAL ASSESSMENTS IN LIVER TRANSPLANT CANDIDACY SCREENING

Hyundam (Dami) Gu[1] Marie Diener-West[1] FNU Baimaji[2] Jason Wheatley[3] Andrew Cameron[2] Ahmet Gurakar[2] Po-Hung (Victor) Chen[2], [1]Johns Hopkins Bloomberg School of Public Health, [2]Johns Hopkins University School of Medicine, [3]Johns Hopkins Hospital

Background: Psychosocial evaluations are a key part of determining liver transplant candidacy. These assessments can be supported by self-administered, web-based questionnaires, which offer scalable and standardized data collection that may be less susceptible to social desirability bias. However, it remains unclear how closely such self-reported data align with clinical assessments conducted by transplant clinicians. We hypothesized that discrepancies would be more common for variables perceived as stigmatizing, due to differences in disclosure behaviors between private, web-based questionnaires and real-time, face-to-face clinical interviews. **Methods:** In this single-center, observational study, we compared data from liver transplant candidates who finished a web-based psychosocial questionnaire with corresponding clinical assessments conducted by social workers and documented in electronic medical records (EMR). We evaluated categorical variables using kappa statistics to assess agreement. For continuous variables, Lin's concordance correlation coefficients (CCC) and Bland-Altman plots were used to assess agreement and visualize systematic biases. Demographic and socioeconomic factors associated with discordant responses were also identified. **Results:** Among the 140 participants, the median age was 55.8 $\pm$ 8.6 years, with 56.4% male and 84.2% identifying as White. Alcohol-associated liver disease was the most common diagnosis (34.3%). Agreement between the questionnaire and EMR data varied across domains (Table). Very good or good agreement was observed for smoking history, education level, and marriage/partnered living status. Moderate agreement was found for psychiatric history and employment status, while drug use history showed fair agreement. Discordance in drug use history was significantly associated with younger age, marriage/partnered living status, increased proximity of support, and cohabitation. For continuous variables, abstinence duration showed high concordance (CCC = 0.969), whereas age at first drink showed low concordance (CCC = 0.235). **Conclusion:** This study highlights the potential for discrepancies between self-administered questionnaires and clinical interview data in psychosocial assessment. While certain variables showed higher concordance, variables perceived as potentially stigmatizing, like drug use history, were more prone to discordance. These findings underscore the complexity of psychosocial evaluation and suggest that data source and reporting context can influence the information obtained. Further investigation is needed to understand how specific characteristics of assessment modalities or settings may influence reporting behaviors in transplant evaluations.

Table: Agreement Level Between Self-Administered Questionnaire and Electronic Medical Record Data Across Psychosocial Binary and Categorical Variables

Variable	Kappa (95% CI)	Agreement Level*
Binary Variables		
Psychiatric History	0.573 (0.426 – 0.708)	Moderate
Smoking History	0.885 (0.786 – 0.995)	Very good
Drug Use History	0.344 (0.179 – 0.488)	Fair
Employment Status	0.553 (0.388 – 0.678)	Moderate
Categorical Variables**		
Marriage/Partnered Living Status	0.786 (0.678 – 0.872)	Good
Education Level	0.803 (0.730 – 0.877)	Good

Agreement Level*
0.00-0.20: Poor agreement
0.21-0.40: Fair agreement
0.41-0.60: Moderate agreement
0.61-0.80: Good agreement
0.81-1.00: Very good agreement

Levels for Categorical Variables**
Marriage/Partnered Living Status: Married or living with partner; Widowed; Divorced; Separated or single. In cases with mixed information (e.g., "divorced/cohabitate"), partnered living status was prioritized over legal marital status to better reflect the individual's social support structure. Education Level: No high school or some high school (no diploma); High school diploma or equivalent; Some college, no degree; Associate's degree; Bachelor's degree; Master's or doctorate or post-graduate.

3102 | IMPACT OF COVID-19 INFECTION ON OUTCOMES IN HOSPITALIZED PATIENTS WITH LIVER CIRRHOSIS: A NATIONWIDE ANALYSIS

Ritik Mahaveer Goyal[1] Vraj Shah[2] Sameer Rao[2] Rohan Karkra[2] Imran Qureshi[3] Paul Gaglio[2], [1]Rutgers New Jersey Medical School, [2]Rutgers NJMS, [3]RUTGERS THE STATE UNIVERSITY OF NEW JERSEY

Background: Liver cirrhosis is a major public health concern and is associated with high morbidity and mortality. Currently, a significant number of cirrhotic patients are found to have a COVID-19 infection in clinical settings. Given the immune dysfunction and hepatic reserve limitations in cirrhosis, concurrent COVID-19 infection may significantly worsen outcomes. This study aimed to evaluate the impact of COVID-19 on clinical outcomes in hospitalized patients with liver cirrhosis. **Methods:** We utilized the 2020 National Inpatient Sample (NIS) to identify adult hospitalizations with a diagnosis of liver cirrhosis. Patients were stratified based on the co-diagnosis of COVID-19 infection. We assessed differences in in-hospital mortality, major adverse liver outcomes (MALOs), length of stay (LOS), and total hospital charges between the two groups. Multivariable logistic and linear regression analyses were conducted, adjusting for age, sex, race, income, insurance status, and comorbidities. Statistical analyses were performed using SPSS, with $p < 0.05$ considered statistically significant. **Results:** A total of 842,625 hospitalizations with liver cirrhosis were identified, of which 29,305 (3.5%) had concurrent COVID-19 infection. Compared to cirrhosis patients without COVID-19, those with COVID-19 had significantly higher in-hospital mortality (OR 3.57; 95% CI: 3.46–3.69; $p < 0.001$), higher total hospital charges (β = \$5,496.04; 95% CI: \$3,980–\$7,012; $p < 0.001$), and longer LOS (β = 0.777; 95% CI: 0.690–0.864; $p < 0.001$). They had lower odds of MALOs including ascites (OR 0.48; $p < 0.001$), hepatic encephalopathy (OR 0.53; $p < 0.001$), variceal bleeding (OR 0.47; $p < 0.001$), portal hypertension (OR 0.45; $p < 0.001$), hepatorenal syndrome (OR 0.36; $p < 0.001$), spontaneous bacterial peritonitis (OR 0.39; $p < 0.001$), and liver transplantation (OR 0.13; $p < 0.001$). There was no significant difference in rates of septic shock (OR 0.98; $p = 0.24$). Patients with COVID-19 had higher odds of requiring mechanical ventilation (OR 1.22; $p < 0.001$) but lower odds of acute kidney injury (OR 0.64; $p < 0.001$). **Conclusion:** Hospitalized cirrhosis patients with COVID-19 infection experienced significantly higher mortality and hospital charges, despite lower rates of MALOs. These findings highlight the profound systemic impact of COVID-19 and the need for targeted preventive and management strategies in this vulnerable population.

Table: Impact of COVID-19 on Clinical Outcomes in Hospitalized Cirrhosis Patients: Multivariable Regression Analysis Adjusted for Demographics and Illness Severity

	Adjusted Odds	95% CI	p-value
Marginal Values			
Length of Stay	0.777	0.690 to 0.864	<0.001
Hospitalization Charges	5,496.04	3980 to 7012	<0.001
Odds Ratios			
Mortality	3.569	3.457 to 3.686	<0.001
Ascites	0.483	0.465 to 0.501	<0.001
Hepatic Encephalopathy	0.528	0.450 to 0.619	<0.001
Variceal Bleeding	0.467	0.450 to 0.484	<0.001
Portal HTN	0.447	0.434 to 0.461	<0.001
Hepatorenal syndrome	0.359	0.336 to 0.384	<0.001
SBP	0.386	0.354 to 0.422	<0.001
Intubation	1.215	1.166 to 1.267	<0.001
Septic Shock	0.976	0.936 to 1.017	0.244
AKI	0.641	0.624 to 0.659	<0.001
Liver Transplant	0.125	0.094 to 0.165	<0.001

3103 | PREVENTIVE HEPATOLOGY TO TACKLE THE GROWING BURDEN OF LIVER DISEASE AND HEPATOCELLULAR CARCINOMA IN AUSTRALIA.

Neeraj Bhala[1] Nicholas Hannah[2] James Haridy[2] Aparna Morgan[2] Ashok Raj[2], [1]Melbourne Digestive Diseases Centre, University of Melbourne, [2]Royal Melbourne Hospital

Background: Liver disease is a rising cause of premature mortality in Australia, with increasing burden driven by alcohol-related liver disease (ALD), metabolic-associated steatotic liver disease (MASLD), chronic hepatitis B virus (HBV) and hepatocellular carcinoma (HCC). Liver disease remains under-recognized in the National Prevention Health Strategy, prompting our evaluation of critical gaps in preventive hepatology. **Methods:** We analyzed data from the Australian Institute of Health and Welfare (AIHW), national hospital admissions, mortality data, and burden of disease estimates (DALYs) from 2013 to 2023. Subgroup analyses were performed by liver disease etiology, age, sex, Aboriginal and Torres Strait Islander peoples (ATSI), and geography (urban vs rural/remote). We reviewed national preventive strategies related to alcohol use, obesity, and viral hepatitis control. **Results:** Liver disease is now the 5th leading cause of death in Australia when combined with HCC mortality. There was a 41% increase in cirrhosis mortality over the past decade. MASLD accounts for

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

over 30% of all liver-related hospital admissions, while ALD-related cirrhosis rose by 38%, particularly among younger adults aged 25–44. Indigenous Australian face liver disease mortality rates up to 3-4 times higher than non-Indigenous populations, with lower access to liver health services. Despite available treatments, only ~20% of people with HBV are engaged in care.
HCC incidence increased by 38% over the past decade, with mortality rising in parallel. Over 60% of cases were diagnosed at late stage, with only 20–30% of patients receiving curative-intent therapy. The leading underlying etiologies were HBV (30%), MASLD (28%), and ALD (22%). **Conclusion:** Adverse liver disease and HCC outcomes in Australia continue to increase yet national strategies have not adequately addressed these preventive chronic hepatology conditions. Emphasising early detection, risk factor modification, and equitable access to care for ALD, MASLD, viral hepatitis and HCC is urgently needed in Australia by embedding liver health in national non-communicable disease and cancer strategies.

3104 | ESTABLISHING BASELINE QUALITY METRICS FOR PARACENTESIS IN PATIENTS WITH CIRRHOSIS IN ALBERTA, CANADA

Leona Chan[1] Swapan Mahal[2] Christopher Fung[1] Puneeta Tandon[1] Mayur Brahmania[3], [1]University of Alberta, [2]Alberta Health Services, [3]University of Calgary

Background: Decompensated cirrhosis is associated with high health care utilization, with ascites recognized as the most common complication requiring frequent therapeutic paracentesis. Given the high volumes of paracenteses performed and its vital role in reducing admissions and emergency department (ED) visits, it is important to ensure that best practices are met. Connect Care (CC) is Alberta's province-wide clinical information system, containing electronic medical records for inpatient and outpatient encounters. In this project, we aim to quantify paracentesis volume and burden across the province, identify quality gaps, and inform targeted quality improvement initiatives to optimize patient care. **Methods:** This is a retrospective population study examining adult patients with cirrhosis who underwent paracentesis in Alberta, Canada between January 1, 2020 and December 31, 2024. In collaboration with the Strategic Clinical Network (DHSCN), patients were identified using CC grouper codes (123346, 34674, 110482) corresponding to procedures performed under Interventional Radiology. Paracenteses performed using point-of-care ultrasound (POCUS) were excluded in this study. To ensure data quality, chart audits were conducted to validate the accuracy of ICD coding for cirrhosis and ascites. **Results:** A total of 25,172 paracenteses were performed in Alberta between 2020 and 2024, with an average year-to-year increase of 9.9%. Among the procedures with documented output volumes (60%), the average volume removed was 5.53L; 54.2% were large-volume paracenteses ($\geq$5L drained) with albumin administered in 89% of cases. Overall, there has been a steady increase in the number of paracenteses performed across all care settings (outpatient, inpatient, ED), with a growing proportion conducted in the inpatient setting and a relatively stable proportion performed in the ED with subsequent discharge. Specifically, despite a 373% increase in ED presentations over the study period, the percentage of ED patients discharged after paracentesis has steadily declined from 19% in 2020 to 7% in 2024. **Conclusion:** In this large retrospective population-based study, we have observed increasing provincial demands for paracentesis alongside rising hospital presentations. Notably, a substantial proportion of patients underwent small-volume paracentesis, many of whom received albumin replacement. These findings highlight opportunities for targeted interventions, especially if small-volume paracenteses were performed for therapeutic purposes. Ongoing work will focus on further data validation and inclusion of additional quality metrics, such as wait times and appropriateness of referrals for Transjugular Intrahepatic Portosystemic Shunt (TIPS) or liver transplant among patients requiring frequent paracentesis.

3105 | IMPROVING TOBACCO CESSATION IN LIVER TRANSPLANT CANDIDATES THROUGH A MULTIDISCIPLINARY QUALITY IMPROVEMENT INITIATIVE

BRANDON SHORE, SUSAN TROUT, KIM SHOENBILL, HERSH SHROFF, Brandon Shore[1] Susan Trout[1] Kimberly Shoenbill[2] Hersh Shroff[1] [1]UNC Chapel Hill, [2]Moffitt Cancer Center

Background: Nicotine use is prevalent among liver transplant (LT) candidates and negatively impacts post-LT outcomes. Though nicotine policies vary by LT center, there is opportunity for cross-institutional multidisciplinary partnerships to improve smoking cessation In LT candidates. **Methods:** We conducted a multifaceted QI intervention to improve diagnosis and treatment of nicotine use in LT candidates, including an educational session for our LT team, a standardized note template for documenting smoking status during LT evaluation (LTE), and a streamlined pathway for early referral to our institution's Tobacco Treatment Program (TTP). Eligible patients included those who began LTE and had active or "recent" (quit within previous 6 months) nicotine use. We surveyed our LT team via Qualtrics (Provo, UT) to assess baseline level of comfort with smoking cessation practices. We collected the following data on pre- and post-intervention cohorts: baseline demographics, clinical characteristics, and process and outcome metrics that occurred between 6 months before LTE start until LTE completion. **Results:** Over 24 months pre-intervention, 371 patients were referred for LTE. 17% were active or recent ($n = 62$) smokers, of whom 63% quit during the defined time period. 4 patients were referred to the TTP and 18 were prescribed pharmacotherapy. We surveyed 24 multidisciplinary LT team members (5 physicians or advanced practice providers, 10 nurses, 3 pharmacists, and 6 social workers/psychologists/dieticians). A majority reported *always* or *often* asking about nicotine use (75%), assessing readiness to quit (75%), counseling patients (83%), and providing resources (58%). Top barriers to screening for nicotine use were competing health concerns, low patient motivation, and other clinical priorities. Treatment barriers included patient refusal, limited educational materials, time constraints, and competing priorities. Over 10 months post-intervention, 184 patients were referred for LT and 15% ($n = 28$) were active/recent smokers. We excluded 8 who either never started LTE or underwent fully inpatient LTEs. Of the remaining 20 patients, 12 had smoking status appropriately documented by a nurse coordinator at LTE start, 12 were referred to TTP, and 10 attended ≥ 1 visit. Nine patients received smoking cessation medications. At the 3-month follow-up with the TTP, 4 out of 6 patients had either reduced, quit, or maintained abstinence from tobacco use. **Conclusion:** Active smoking remains common among LT candidates, yet referral to tobacco cessation programs is low despite available resources. Early identification, improved patient education, and streamlined referral pathways may improve quit rates and post-transplant outcomes.

3106 | CAN CHANGING LIVER TRANSPLANT SURGICAL LEADERSHIP INCREASE TRANSPLANT VOLUME?

Jonah Ladetsky[1] David Goldberg[2], [1]Millburn High School, [2]University of Miami

Background: Liver transplant centers, like professional sports teams, change leadership in hopes of improving production (i.e., increasing transplant volume). There is however little empirical data to determine whether leadership change is associated with increases in transplant volumes. **Methods:** We used publicly available OPTN transplant data to quantify annual liver transplant volume from 2010-2019 to evaluate the association between leadership change and change in transplant volume. We only included centers that performed an average of at least 50 liver transplants per year during this period to focus on higher-volume centers and to reduce bias in relative annual changes due to small sample sizes. Surgical leadership data were collected by identifying each center's primary liver transplant surgeon from another OPTN database. Data on the surgeon's start date were found from various sources, including transplant center websites and publicly available profiles such as LinkedIn. We fit mixed effect linear regression models to evaluate the interaction of leadership change and calendar year. **Results:** Independent of leadership changes, the average transplant center volume increased annually. There was a significant interaction between transplant volume, calendar year, and leadership change ($p < 0.001$), signifying an overall relationship between leadership change and increases in transplant volume. However, when compared on a year-to-year basis, there were only two years where there was a significant increase from one year to the next, and both occurred in the absence of a leadership change (Table). Yet when centers were compared over a longer period of time, the changes became more apparent. For example, when

2010 was the reference for all comparisons, centers in 2015 with the same leadership as 2010 performed an average of 12 more liver transplants than they did in 2010, while centers in the first or second year of a leadership change performed an average of 29 more transplants ($p = 0.003$). **Conclusion:** Our study demonstrates that there is an overall association between leadership change and increase in transplant volume among liver transplant centers. However, this association was not uniform and did not occur with all leadership changes, suggesting that changing leadership does not guarantee improvement. Future work needs to investigate practices associated with growth in transplant volume with new leadership.

3107 | ENHANCING THE PRESCRIPTION FREQUENCY OF COST-EFFECTIVE PHARMACOTHERAPY IN METABOLIC ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) AND OBESITY: A QUALITY IMPROVEMENT INITIATIVE

Chusila Lee[1] Cody Ashcroft[1] Christina Awad[1] Raphael John Sabado[1], [1]Brooke Army Medical Center

Background: Metabolic associated steatotic liver disease (MASLD) affects over 30% of US adults and is the most common chronic liver disease in Western nations. Obesity, a significant comorbidity, drives MASLD progression to cirrhosis, ultimately drastically increasing healthcare costs. Modeling studies suggest that effective therapies for MASLD, particularly those halting fibrosis progression, could avert $7.6 billion in healthcare costs. Glucagon-like peptide-1 receptor agonists and glucose-dependent insulinotropic polypeptide receptor agonists (GLP1) have demonstrated efficacy in MASLD reversal. Data gathered from 1108 patients seen in the gastroenterology clinic over the past two years showed a baseline GLP1 prescription rate of 22.9% in patients with comorbid obesity and MASLD/MASH. Based on this data, we conducted a preliminary quality improvement (QI) project to increase GLP1 prescription rates to reduce MASLD cirrhosis-related financial healthcare burden. **Methods:** An online provider survey (35% response from 150 internal medicine and GI providers) identified the prior authorization (PA) as the primary barrier to prescription. In response, we delivered an educational lecture to Gastroenterology and Internal Medicine trainees and staff that included a flowchart on the qualifying criteria for a GLP1. Prescription rate was reassessed after 2 months in 100 patients. As a process measure, the rate of GLP1 prescription in the Hepatology clinic was also assessed during this time. While the sample size and time frame are limited, this was intended as an initial gap analysis and test of intervention impact. **Results:** After the intervention, the prescription rate increased to 29%. Though still below our goal of $>75\%$, this early improvement supports expanding the project. However, amongst patients seen in the Hepatology clinic, only 5% of eligible patients evaluated during this time frame were prescribed a GLP1. **Conclusion:** This preliminary study suggests that education alone is insufficient to substantially improve GLP1 prescription rates. A multi-faceted approach addressing broader systemic issues, such as policy change or system-level interventions, is necessary to enhance prescription rates and ultimately make an impact on the cost associated with the complications of progression to cirrhosis. Our future efforts will involve larger sample

3108 | DOES THE PAY-FOR-PERFORMANCE PROGRAM (P4P) FOR TYPE 2 DIABETES PATIENTS REDUCE THE INCIDENCE OF PRIMARY LIVER CANCER?

Chao-Yi Lai[1] CHENG-LI LIN[1] Hsueh-Chou Lai[1], [1]China Medical University Hospital, Taichung, Taiwan

Background: Patients with type 2 diabetes mellitus (T2DM) face an elevated risk of developing primary liver cancer, particularly hepatocellular carcinoma (HCC). Improved glycemic control, has been linked to reduced cancer risk. To improve diabetes outcomes, Taiwan's National Health Insurance Administration launched the Pay-for-Performance (P4P) program in 2001. However, its impact on HCC incidence remains uncertain. **Methods:** We conducted a retrospective cohort study using National Health Insurance Research Database (NHIRD) from 2008 to 2021. A total of 1,952,586 T2DM patients were included, with 976,293 enrolled in the P4P program and 976,293 matched controls. The risk of HCC was evaluated using Cox proportional hazards models, Fine and Gray competing risk regression, and inverse probability of treatment weighting (IPTW) based on propensity scores. All models were adjusted for age, sex, liver-related comorbidities (e.g., HBV, HCV, cirrhosis), and use of antidiabetic and lipid-lowering medications. **Results:** P4P participation was significantly associated with a reduced risk of HCC. The adjusted hazard ratio (aHR) was 0.71 (95% CI: 0.69–0.73, $p < 0.001$) in Cox proportional hazards model, and the adjusted subhazard ratio (aSHR) was 0.72 (95% CI: 0.70–0.74, $p < 0.001$) in Fine and Gray competing risk regression. Inverse probability of treatment weighting (IPTW) based on propensity scores further confirmed this protective effect (aHR = 0.71). The benefit was consistent across all age groups, both sexes, and patients with high-risk comorbidities. Use of SGLT2 inhibitors (aHR = 0.50), GLP-1 receptor agonists (aHR = 0.53), and statins (aHR = 0.70) were independently associated with lower HCC risk. Conversely, insulin (aHR = 4.83) and sulfonylureas (aHR = 1.32) were associated with increased HCC risk. Although among non-P4P participants, metformin users had a borderline significant risk of HCC compared to non-users, P4P participants using metformin showed a reduced risk of HCC. Regardless of metformin use, P4P enrollment consistently conferred protection. Subgroup analyses confirmed the benefits of P4P, even in patients with hepatitis B, hepatitis C, or liver cirrhosis. **Conclusion:** This large nationwide cohort study demonstrates that participation in Taiwan's diabetes P4P program significantly lowers the risk of HCC in patients with T2DM. The protective effect remains robust across subgroups and after adjustment for key clinical variables. These findings support structured, performance-based diabetes care as an effective strategy for reducing cancer risk.

3109 | EARLY LIFE BODY SIZE AND RISK OF DEVELOPING BILIARY TRACT CANCERS

Prema Bhattacharjee[1], [1]National Cancer Institute

Background: Biliary tract cancers (BTCs) are rare, aggressive, and vary by sex and subsite. Early-life body size may play a role in BTC risk. We investigated childhood body mass index (BMI) trajectories, BMI and height at individual ages and birthweight in relation to BTC risk, including subsites, in a large Danish cohort. **Methods:** The study included 172,113 males and 168,503 females born from 1930-1996 from the Copenhagen School Health Records Register. Heights and weights were measured at ages 6-15 years. Five sex-specific trajectories were identified using latent

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

class trajectory models. At individual ages, BMI was categorized as normal weight or overweight using Centers for Disease Control age- and sex-specific criteria. BMI and height were further analyzed continuously as z-scores based upon an internal reference. We estimated hazard ratios using sex- and birth-cohort-stratified Cox regressions. **Results:** During a median follow-up of 34.5 years, 635 individuals developed BTCs (314 males, 321 females). The overweight (HR: 1.58; 95% confidence interval [CI]: 1.06–2.34) and obesity (HR: 3.22; 95% CI: 1.61–6.44) trajectories in males and the obesity trajectory in females (HR: 2.88; 95% CI: 1.62–5.15) were associated with increased BTC risk. Childhood overweight/obese at age 7 was strongly associated with intrahepatic bile duct cancer risk in males (HR: 2.66; 95% CI: 1.48–4.75) and extrahepatic bile duct cancer risk in females (HR: 3.83; 95% CI: 1.94–7.56). Taller childhood height was linked to higher BTC risk in males only; birthweight showed no associations. We found no sex interaction. **Conclusion:** Our study provides evidence that being overweight or obese in childhood increases BTC risk in adulthood.

3110 | DEVELOPMENT OF THE PALLIATE END-STAGE AND ADVANCED CIRRHOTICS EARLY (PEACE) LIVER SUPPORTIVE CARE PROGRAMME: LESSONS AND EARLY OUTCOMES FROM A MULTIDISCIPLINARY APPROACH TO PROVIDING PALLIATION FOR LIVER CIRRHOSIS PATIENTS IN SINGAPORE

Marianne De Roza[1] Danielle Ho[1] Qiqi Su[2] Charlene Tan[1] Aiden Lin Yuda[1] Guan Hong Koh[1] Jolyn Tan[1] Kee Yon Lionel See[1], [1]Sengkang General Hospital, [2]Sengkang Genral Hospital

Background: Liver cirrhosis patients have a high symptom burden with frequent hospitalizations and reduced quality of life. There is an unmet need for these patients to receive palliative care but this is often provided late in their disease. **Methods:** PEACE is a multidisciplinary team led by hepatologists with palliative care training and comprises nurses, physiotherapists, social workers, pharmacists, dietitians, and palliative medicine doctors. PEACE holistically delivers specialty liver disease management together with physical symptom control, addressing caregiver and psychosocial needs, advanced care planning, preventive health through vaccinations and frailty screenings, anticipatory planning with patient and family, direct support hotline service, seamless transitions to community and hospice teams and bereavement support. The programme referral criteria used was adapted from SPICT (*Supportive and Palliative Care Indicators Tool)* and includes decompensated liver cirrhosis with any of the following: >1 complication in the past year for refractory ascites, hepatic encephalopathy, hepatorenal syndrome, spontaneous bacterial peritonitis, recurrent variceal bleed, inoperable hepatocellular carcinoma and/or indicators of deteriorating health or frailty: >2 unplanned admissions in 1 year, deteriorating performance status with limited reversibility, progressive weight loss/sarcopenia, frequent falls, recurrent infections or complex psychosocial issues not fitting clinical criteria. **Results:** Patients were enrolled prospectively at a tertiary public hospital in Singapore from September 2024 to current. Despite an estimated 100 patients who fulfilled criteria from an internal audit (between jul-dec 2024), only 30 were referred and 25 enrolled, the remaining 5 passed away within a week of referral. 52% were female and 87% of patients were Chinese with mean age of 74. Serious illness conversations were conducted for all patients with attending caregivers and advanced care planning (ACP) completed for 44%. Barriers to ACP discussions were lack of readiness, denial and family-centredness. 29 hospital admissions were prevented via the hotline service. Physical and psychosocial symptom assessment scores were tracked using the Integrated Palliative care Outcome Scale. PEACE patients had better outcomes for both physical and psychosocial symptoms ($p<0.05$) compared to a control group of liver cirrhosis patients. **Conclusion:** Earlier integration of palliation through a structured programme improves quality of life and fosters better communication to help align shared preferences and values. More support is needed to expand and further develop similar programmes.

3111 | CONFLICTING EXPERT OPINIONS ON HOSPITAL READMISSION PREVENTION IN ADVANCED LIVER DISEASE

Eric Orman[1] Elliot Tapper[2] Richard Kalman[3] Mary Rinella[4] Nicole Bendin[4] Jake McCarty[1] Francis Pike[1] Pavani Jyothi Kavuri[1] Lindsay Yoder[1], [1]Indiana University, [2]University of Michigan Medical Center, [3]Jefferson Einstein Philadelphia Hospital, [4]University of Chicago

Background: Following hospital discharge, patients with cirrhosis frequently experience early readmission, but preventability of these readmissions has been understudied, and methods to reliably define

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

preventability are lacking. **Methods:** We performed a multicenter prospective observational study of patients with decompensated cirrhosis or alcohol associated hepatitis enrolled in the "usual care" control arm of an ongoing clinical trial at 4 centers. We included 47 readmissions (within 30 days), up to the first 12 patients who were enrolled during their index hospitalization at each center. 4 hepatologists (1 from each center) independently reviewed preventability of all readmissions using a 5-point Likert scale ranging from "unlikely ($<25\%$ likelihood)" to "definite ($>95\%$)." Those with $\geq 50\%$ likelihood of preventability were considered preventable. We assessed inter-reviewer agreement using Gwet's AC2 and compared preventable to non-preventable readmissions. **Results:** The 4 reviewers assessed the following proportions of events as preventable: 11%, 15%, 40%, 45%. All 4 agreed on "unlikely" preventability ($<25\%$ likelihood) for 7 events (15%). No other preventability rating had unanimity. 3/4 reviewers agreed on "unlikely" for 8 events and "possible" preventability (25-49%) for 1 event. When scores were collapsed into preventable ($\geq 50\%$ likelihood) vs. non-preventable, reviewers had unanimous agreement on 15 cases (2 preventable, 13 non-preventable), and 3/4 agreed in 22 cases (1 preventable, 21 non-preventable), leaving 10 cases with disagreement (21%) (Figure). Overall, agreement was moderate (0.46, 95% CI 0.28-0.63). All 4 reviewers discussed the 10 with disagreement, and the consensus was that 6 of these were preventable, for a total of 9 preventable readmissions (19%). In those with preventable readmission, the index hospitalization was most often for hepatic encephalopathy (33%), and in those with non-preventable, the index hospitalization was most often for ascites (34%). Non-preventable readmissions were most often for laboratory abnormalities (24%), abdominal pain (16%), and GI bleeding (16%); and preventable readmissions were most often for dyspnea (22%) and abdominal distention (22%). **Conclusion:** In a multicenter prospective study of patients with advanced liver disease, agreement between expert reviewers on readmission preventability was moderate, and most readmissions were not preventable. Harmonization of preventability criteria may enhance the reliability of this outcome and facilitate interventions to prevent readmission.

3112 | LONGITUDINAL MONITORING WITH COMMERCIAL WEARABLE TECHNOLOGY IS FEASIBLE ACROSS SOCIODEMOGRAPHIC AND DISEASE SEVERITY SPECTRUM IN CIRRHOSIS

Adam Buckholz[1] Kamaryn Tanner[2] Avesh Thuluvath[3] Olivia Blocker[4] Jessica Siguencia[4] Brian McSteen[4] Ziyu Liu[4] Jialin Gao[4] Elizabeth Verna[5] Alan Cohen[2] Robert Brown[6], [1]New York Presbyterian Hospital Program, [2]NewYork-Presbyterian/Columbia University Medical Center, [3]Columbia University Irving Medical Center, [4]NewYork-Presbyterian/Weill Cornell Medical Center, [5]Columbia University Medical Center, [6]Weill Cornell Medicine

Background: Cirrhosis is a highly morbid, progressive condition. Commercial wearable technology could enable development of digital biomarkers which would enable novel monitoring and intervention strategies, to improve clinical outcomes. While most research in wearable technology has been conducted in healthy volunteers, people with cirrhosis may experience more healthcare barriers. Thus, the feasibility of longitudinal monitoring in this population is unclear. **Methods:** We enrolled a large pragmatic cohort of patients with cirrhosis from 8/2023-5/2025 at two academic medical centers. English- or Spanish-speaking patients with a smart phone were eligible. Clinical, cognitive and survey data was collected at baseline and participants were given an Oura fitness tracker, which they were instructed to wear continuously for 6 months. Participants received assistance with downloading the app, connecting the ring, and troubleshooting. Wear time (% of possible) of the ring was used to assess adherence. Our primary endpoint was percentage of days with full adherence, defined as at least 90% data available (< 10% non-wear time). The final day of "possible wear" was the first of 180 days after enrollment or 5/11/25. Beta regression was used to estimate the association between proportion of days with full adherence and hepatic encephalopathy [HE], impaired cognition (by PHES), Child-Turcotte-Pugh Score [CTP], decompensation, and history of ascites. We hypothesized that adherence would be higher in younger patients with earlier, compensated cirrhosis, but that all groups would have significant overall usage. **Results:** Of 117 participants who provided consent, 6 were lost to follow up without collecting any sleep data. In total, 11,788/13,949 (84.5%) potential days had non-zero data collection, with a median 115 days of collection (92% of potential) per participant, and 9484 (68%) and 8453 (61%) of the potential days had 80 or 90% "wear time," respectively. Demographic factors (gender, education, race/ethnicity) were not significantly associated with adherence, but power was limited and age > 60 trended to lower adherence (OR 0.76, 95%CI: 0.51, 1.14). Adjusted for age and other demographics, participants with higher CTP [OR = 0.66, 95% CI: 0.43, 1.0], HE [OR = 0.63, 95% CI: 0.41, 0.96] and impaired cognition [OR = 0.60, 95% CI: 0.38, 0.94] had lower odds of having a higher proportion of fully adherent days. Prior decompensation status was not associated with lower adherence. **Conclusion:** Results from a large diverse cohort provide the strongest evidence to date for the feasibility of commercial wearables for longitudinal monitoring in cirrhosis, with high frequency of days with both non-zero (84.5%) and > 90% (61%) data collection, and all examined groups had more than half of days with full (> 90%) wear. Though more advanced disease, especially HE, had lower adherence, wearables can still be used in these groups for digital biomarker development.

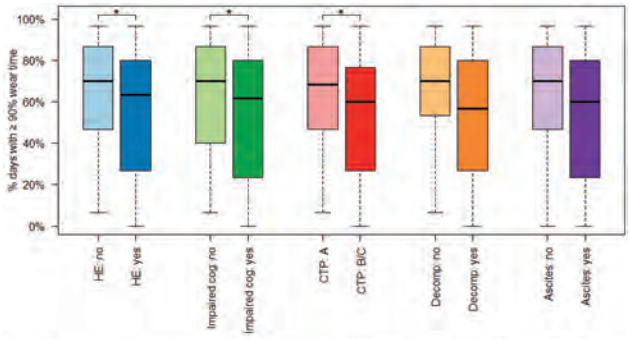

Figure. Bar plots of the percentage of days with at least 90% wear time, stratified by severity of liver disease. * Indicates a significant association in a beta regression adjusted for age, gender, years of education and race/ethnicity at $p<0.01$.

3113 | GLOBAL BURDEN OF LIVER CANCER FROM 1990 TO 2021 AND 20-YEAR PROJECTIONS: FINDINGS FROM THE GLOBAL BURDEN OF DISEASE STUDY 2021

Yikai Wang Yaping Li[1] Liu Yang[1] Meng Zhang[1] Zihan Liu[1] Juanjuan Shi[1] Shuangsuo Dang[1], [1]The Second Affiliated Hospital of Xi 'an Jiaotong University

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Liver cancer poses a significant global health burden, characterized by substantial regional disparities. We analyzed liver cancer incidence and mortality across 204 countries and territories from 1990 to 2021 and projected trends from 2021 to 2041. **Methods:** Data from the Global Burden of Disease (GBD) Study 2021 were used to calculate age-standardized rates (ASRs), average annual percentage change (AAPC), and estimated annual percentage change (EAPC). Risk factors, human development index (HDI), and sociodemographic index (SDI) were evaluated. The Nordpred and BAPC models projected future trends. **Results:** Globally, the ASR of liver cancer incidence rose by 0.03% annually, while mortality ASR declined by 0.21%. Viral hepatitis B and C remained primary causes, but non-alcoholic steatohepatitis (NASH) contributions increased. Drug-use-associated liver cancer rose by 12%, notably in North America. High-HDI/SDI countries exhibited higher ASRs due to aging and metabolic diseases. Projections indicated rising cases but declining ASRs by 2041. **Conclusion:** Tailored prevention strategies are needed to address region-specific risk factors and mitigate the growing burden of liver cancer.

Background: Novel therapies and treatment strategies that aim to achieve a functional cure (FC) for chronic hepatitis B (CHB) are in development. Such strategies are likely to require changes to treatment and care pathways. This study evaluated the level of consensus within an expert panel regarding the recommended clinical pathway for CHB FC, and implementation priorities. **Methods:** A modified nominal group technique (NGT) meeting took place in May 2025. The panel included members from Europe, North America, and the Asia-Pacific region, and included patient advocates, hepatologists, gastroenterologists, infectious disease specialists, and public health specialists. NGT was modified to support participation from panelists who could not attend in person (allowing advance comments and conducting final voting online). Voting used a 7-point Likert scale. Clinical pathway steps were subject to a $\geq$75% agree/strongly agree consensus threshold. Implementation priorities were ranked by mean score. **Results:** In total, 18 panelists participated (3 participated remotely). After round-robin idea sharing and follow-up discussion, the clinical pathway put forward for voting included nine steps: 1) Screening, diagnosis, and preparing the person with CHB for FC; 2) Supporting people receiving nucleos(t)ide analogs (NA) across settings; 3) Discussing the use of FC treatments with individuals living with CHB; 4) Shared decision to attempt FC treatment based on eligibility, risk / benefit profile, patient preference and predictors for treatment response; 5) Initiation of FC treatment; 6) Management and response-guided milestones, and patient support during FC treatment; 7) Treatment completion; 8) Follow-up after FC treatment; and 9) Rescue therapy and retreatment (if applicable). Steps 1, 2, 4, 5, 7, and 9 reached the consensus threshold, while steps 3, 6, and 8 did not. Comments indicated that lack of consensus was due to regional and national variations in care systems. In total, 19 implementation areas were identified and prioritised during the NGT process (Table). **Conclusion:** Care pathways for CHB FC will vary between regions and countries, but should be evidence-based and patient-centered. This study identifies themes and priorities that regional and national healthcare stakeholders should consider in CHB care and planning to implement functional cure strategies.

Table: Mean priority scores for priority implementation areas identified by panellists. Higher scores indicate higher priority.

Implementation area	Mean priority score (0–7)
Access to and use of quantitative hepatitis B surface antigen testing	6.78
Simple, evidence-based, algorithmic pathway design	6.67
Effective screening and diagnosis	6.56
Access to treatment targeting functional cure	6.56
Education tools for healthcare professionals, particularly on functional cure and alanine aminotransferase flares (e.g. extension for community healthcare outcomes [ECHO])	6.50
Risk / benefit analysis (including assessment of co-morbidities and predicting individual response to treatment)	6.50
Education tools for people with chronic hepatitis B	6.44
Engagement with policymakers	6.39
Early specialist involvement	6.17
Support tools/systems – patient adherence	6.11
Implementation of digital management / telehealth / remote support	5.94
Increase the number of patients eligible for treatment (via expanded and simple guidelines)	5.94
Understanding patient experience using patient-reported experience measures / patient-reported outcome measures	5.89
Incentives for HCPs to target functional cure	5.83
Provision of peer engagement / peer navigators	5.78
Support tools/systems – patient information networks	5.67
Learning from care models in other therapy areas	5.50
Prioritising care at home	5.44
Support tools/systems – mental health support	5.33

3115 | US HEALTH CARE SPENDING ON CIRRHOSIS AND OTHER CHRONIC LIVER DISEASES

Xiaomeng Cui[1] Wenjun Wang[1] Yan Tian[2] Ting Li[1] Shuangsuo Dang[1] Xiaoli Jia[1], [1]Second Affiliated Hospital of Xi'an Jiaotong University, [2]Second Affiliated Hospital of Xi'an Jiaotong University

Background: Chronic liver diseases (CLD), including cirrhosis, represent a significant burden on the US health care system. This study aims to quantify health care spending on CLD from 2010 to 2019, examining variation by sex, age, type of care, and geographic

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

location to inform policy and resource allocation. **Methods:** Using data from a comprehensive analysis of US health care spending by health condition, we extracted spending estimates for CLD. Spending was stratified by sex, age group, type of care, and state. All estimates were adjusted for inflation (2019 USD). **Results:** Health care spending on CLD increased from $9.8 billion in 2010 (95% CI, $9.6 billion-$10.0 billion) to $13.6 billion (95% CI, $13.3 billion-$13.9 billion) in 2019. The proportion of health care spending attributed to CLD increased from 0.51% (95% CI, 0.50%-0.52%) in 2010 to 0.57% (95% CI, 0.56%-0.58%) in 2019. Males accounted for $7.5 billion (95% CI, $7.3 billion-$7.7 billion), while female accounted for $6.1 billion (95% CI, $5.9 billion-$6.2 billion). By age group, individuals aged 45-64 years had the highest spending (49.3%), followed by those aged ≥65 years (30.1%), 20-44 years (17.6%), and <20 years (3.0%). Hospital inpatient care accounted for the largest share of spending (49.8%), followed by ambulatory care (35.8%), prescribed retail pharmaceuticals (6.4%), emergency department care (3.8%), nursing facility care (2.2%), and home health care (2.1%). At the state level, age- and sex-standardized spending per capita ranged from $29.2 (95% CI, $27.2-$37.1) in Utah, to $55.2 (95% CI, $50.7-$57.9) in New Mexico. **Conclusion:** Health care spending on CLD has increased significantly from 2010 to 2019, with substantial variation by sex, age, type of care, and geographic location. These findings highlight the growing economic burden of CLD and underscore the need for targeted interventions to reduce disparities and improve the efficiency of care delivery.

3116 | TEMPORAL CHANGES IN SCREENING FOR ESOPHAGEAL VARICES IN PATIENTS WITH CIRRHOSIS

Ethan Weinberg[1] *Tanvi Goyal*[1] *Hemza Tarawneh*[1], [1]*University of Pennsylvania*

Background: Endoscopic screening for esophageal varices (EV) in patients with cirrhosis is invasive, costly, and can usually be avoided in patients who meet the low-risk Baveno criteria (Vibration-controlled transient elastography (VCTE) liver stiffness < 20 kPa and platelets > 150×10^9/L). Our goal was to evaluate the temporal trends in EV screening in the context of evolving portal hypertension guidelines at a large American liver clinic. **Methods:** We performed a single-center retrospective cohort study of adults with compensated advanced chronic liver disease seen in January to March of the following years: 2014, 2018, and 2022. We used descriptive statistics to characterize the study population. We calculated the proportion of patients who were low risk for portal hypertension yet still underwent screening endoscopy, patients that received primary treatment with non-selective beta-blocker (NSBB, patients that met criteria for treatment with non-selective beta-blocker, but did not receive one, and patients that underwent endoscopy despite being on a non-selective beta-blocker. Secondary analyses examined compliance by NSBB status, as well as excess procedures and complications. **Results:** We found no difference in endoscopy screening and NSBB prescription practices across the three time points evaluated (ANOVA). We found that about 50%, 64%, and 46% of the endoscopies done in 2014, 2018, and 2022 respectively were unnecessary based on low risk for large varices. There was little change in referral pattern for upper endoscopy across these three time-points despite the recommendations in 2016 from Baveno VI conference that patients withVCTE liver stiffness of <20 kPa and platelet >150,000 do not warrant varices screening. However, some individual providers cited the Baveno criteria, patient preference for non-invasive management and platelets >150,000 as reasons for deferring endoscopies. Baveno VII, published in 2022, recommended initiation of NSBB if patients met criteria for clinically significant portal hypertension. We did not find a change in NSBB prescribing patterns in our early 2022 cohort. **Conclusion:** We assessed practice gaps and their clinical consequences to show that our health system can benefit from improved targeted implementation strategies to reduce unnecessary endoscopies. This study will inform resource utilization and beta blocker use for patients with cirrhosis to improve outcomes.

3117 | HBV SCREENING AND LINKAGE TO CARE PROJECT IN THE FIRST AFFILIATED HOSPITAL OF XINJIANG MEDICAL UNIVERSITY

Ziyi Zhang[1] tongtong shao[1] Rongjiong Zheng[1] Rongjiong Zheng[1] Xiaobo Lu[1], [1]The First Affiliated Hospital of Xinjiang Medical University

Background: China has the world's heaviest burden of HBV infection and is crucial to achieving the WHO's goal of eliminating hepatitis worldwide by 2030. Previous studies have shown that the effective screening and referral strategies can improve the diagnosis and treatment rates of HBV in the hospital and optimize the management of HBV in the hospital. This study is to explore an optimized HBV screening and linkage to care model to improve HBV diagnosis and treatment rates in the hospital setting. **Methods:** This HBV screening and linkage to care project in the First Affiliated Hospital of Xinjiang Medical University was initiated by the Center for Infectious Disease and Hepatology(CIDH) in February 2024, in collaboration with the Information Department (ID), Clinical Laboratory Department, Internal Medicine Departments and Surgery Departments. HBsAg testing is recommended for all patients visiting the hospital. It is recommended that HBsAg-positive patients be referred to the CIDH clinics or be seen by an infectious disease and hepatology specialist for further examination and treatment. Additionally, the ID collects data and sends message reminders to the doctors overseeing patients to prevent missed follow-ups. Interdisciplinary academic exchanges are actively carried out within the hospital to raise awareness among HCPs of non-infectious and liver diseases regarding the diagnosis and treatment of HBV. We incorporate relevant work into the assessment of the Xinjiang Center for Quality Control of Infectious Diseases, and periodically have assessment and feedback exchange. **Results:** From February 2024 to February 2025, a total of 17,005 HBsAg positive patients were identified in the hospital compared to 16,912 from 2023 to 2024, the rate of HBV DNA testing increased from 91.0% (15,405/16,912) to 92.2%(15,685/17,005), and the antiviral treatment rate according to the 2022 China HBV guideline increased from 77.1% to 82.5% respectively before and after the project started. The top ten departments with HBsAg positive rate were 2nd CIDH (13.2%, 2,244/17,005), 1st CIDH(9.5%, 1,615/17,005), 3rd CIDH(7.2%, 1,224/17,005), Interventional Radiology department(5.7%, 969/17,005), 2nd Gastroenterology department(5.3%, 901/17,005), Hepatobiliary surgery department(3.4%, 578/17,005), Hepatobiliary Echinococcosis surgery department(2.7%, 459/17,005), 1st Coronary Heart Disease department(2.6%, 442/17,005), Hypertension department(2.5%, 425/17,005) and 2nd Coronary Heart Disease department(2.4%, 408/17,005). **Conclusion:** This project can be replicated because it effectively improved the screening, diagnosis, and treatment rates for HBV patients in the hospital, as well as supporting the optimization of HBV management.

◆ 3118 | AI DRIVEN CT DECIPHERING OF INTRATUMORAL HETEROGENEITY TO PREDICT RESPONSE TO TACE PLUS IMMUNOTHERAPY AND MOLECULAR TARGETED THERAPY IN HCC ★

Zhi-Cheng Jin[1] Jian-Jian Chen[1] Hai-Dong Zhu[1] Gao-Jun Teng[1], [1]Zhongda Hospital, Southeast University

Background: The efficacy of combining transarterial chemoembolization (TACE) with immune checkpoint inhibitors (ICIs) and molecular targeted therapies (TACE-ICI-MTT) has been validated by two prospective randomized controlled trials—EMERALD-1 and LEAP-012—as well as several real-world studies. However, the ability to identify HCC patients who could benefit from combination therapy is an important unmet clinical need. This study aims to quantify intratumor heterogeneity (ITH) and identify prognostic imaging biomarkers in patients with HCC treated with TACE-ICI-MTT. **Methods:** This multicenter cohort study included 742 patients with unresectable HCC who received first-line TACE-ICI-MTT from Jan. 2018 to Dec. 2022 (323 patients in the training set, 139 in internal validation set, 228 in external test set, and 52 in TCIA-TCGA set). Primary endpoint was objective response rate. Three-dimensional tumoral regions of interest (ROIs) were delineated on pretreatment computed tomography (CT) scans using deep learning method, followed by manual calibration. A simple linear iterative clustering algorithm was used to segment super-pixel regions. Radiomics features were extracted

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

from global tumor region (GTR) and intratumoral subregions. Unsupervised clustering was applied to subregions using a Gaussian mixture model to identify similar features, and an ITH feature vector was established. Ensemble learning was employed to integrate multiple machine learning algorithms for predicting patient outcomes. The principal component analysis was used to generate a unified composite (GTR-ITH) score. Model discrimination was evaluated using receiver operating characteristic curves with area under the curve (AUC) values. Bulk RNA-seq from TCGA-LIHC set explored immune-infiltration patterns. **Results:** After feature dimension reduction, 27 ITH features and 17 GTR radiomics features were retained for model construction. For predicting treatment response, the GTR-ITH model achieved AUC values of 0.94 (95%CI: 0.92−0.97) in the training set, 0.82 (95%CI: 0.74-0.89) in the internal validation set, and 0.83 (95%CI: 0.78-0.88) in the test set. After adjustment, the GTR-ITH score strongly associated with treatment response (OR 34.39; $P < 0.001$) and independently associated with overall survival (HR 0.63; $P = 0.004$). The GTR-ITH low-risk group consistently demonstrated longer median OS across all datasets. In the TCIA cohort, GTR-ITH low-risk patients showed higher effector cell infiltration (plasma cells, M1 macrophages), elevated ESTIMATE immune/stromal scores, and lower tumor purity, whereas high-risk patients were characterized by increased suppressive populations (M2 macrophages). **Conclusion:** A CT-based imaging biomarker that integrates global tumor features and intratumoral heterogeneity accurately predicts response to TACE-ICI-MTT in HCC and correlates with immune microenvironment status.

◆ 3119 | GLOBAL BURDEN OF PRIMARY LIVER CANCER: A POPULATION-BASED ANALYSIS FROM 1990 TO 2021 WITH PROJECTIONS TO 2050

Xinrong Zhang[1] Charles Levesley[1] Sovann Linden[1] Tyler Wong[1] Scott Barnett[1] Ramsey Cheung[2] Fanpu Ji[3], [1]Division of Gastroenterology and Hepatology, School of Medicine, Stanford University Medical Center, [2]Stanford University Medical Center, [3]Xi'an Jiaotong University

Background: The etiologies of primary liver cancer (PLC) have changed in recent years, but its impact on the global PLC burden and future forecast data are limited. We presented temporal trends between 1990 and 2021 and future forecasted to 2050 for PLC-related incidence, mortality, and disability-adjusted life-years (DALYs) by age, sex, regions and etiologies. **Methods:** We analyzed data from the Global Burden of Disease study between 1990 and 2021 to assess the age-standardized incidence rates (ASIRs), mortality rates (ASMRs), and disability-adjusted life years (ASDALYs) of PLC by age, sex, regions and etiologies. DALYs were calculated as the sum of years of life lost and years lived with disability. The estimated frequency of incidences, deaths, and DALYs are accompanied by 95% uncertainty intervals (UIs). Trends were evaluated by annual percentage change (APC) with 95% confidence intervals (CIs) using joinpoint regression analysis and forecasted to 2050 using prediction models. **Results:** Globally in 2021, there were 529,202 incident cases, 483,875 deaths, and 12.9 million DALYs related to PLC. The estimated ASIR, ASMR, and ASDALYs of PLC were 6.15 (95% UI 5.58-6.90), 5.65 (95% UI 5.13-6.30), and 149.29 (95% UI 135.24-167.48) per 100,000 population, respectively. During the forecasted period between 2021 and 2050 (Table 1), there was a predicted global decline in PLC-related ASIR (APC: -1.12%, 95% CI -1.13 to -1.12), ASMR (APC: -0.91%, 95% CI -0.92 to -0.89) and ASDALYs (APC: -1.05%, 95% CI -1.08 to -1.03). The ASIRs, ASMRs and ASDALYs of PLC were higher among males and the elderly. The greatest decrease of ASIR and ASMR were observed in the Western Pacific (APC: -1.60% and -1.65%) and the Africa regions (APC: -1.25% and -1.60%), whereas the greatest increase were observed in the Americas (APC: 0.67% and 0.77%) and Southeast Asia (APC: 0.62% and 0.61%), respectively. For etiologies, the ASIRs, ASMRs and ASDALYs showed the largest decrease for hepatitis B and C-related PLC, remained stable for alcohol-related PLC, and increased for metabolic dysfunction-associated steatotic liver disease (MASLD)-related PLC. **Conclusion:** The global burden of PLC was predicted to decrease over the next three decades, mostly in the

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

Western Pacific and Africa regions and in hepatitis B or C-related PLC, while the burden increased for MASLD-related PLC and for other regions including the Americas. Future targeted prevention measures and region-specific interventions are needed.

Table 1. Forecast age-standardized incidence and mortality rates from 2021 to 2050 of primary liver cancer stratified by age, sex, regions and etiologies

	Age-standardized incidence rate, per 100,000 (95% UI)		APC of incidence rate (95% CI)	Age-standardized mortality rate, per 100,000 (95% UI)		APC of mortality rate (95% CI)
	2021	2050		2021	2050	
Overall	6.15 (5.58-6.90)	4.42 (0.97-8.10)	-1.12* (-1.13 to -1.12)	5.65 (5.13-6.30)	4.35 (1.81-7.01)	-0.91* (-0.92 to -0.89)

◆ 3120 | VISUALIZATION QUALITY AND EFFECTIVENESS OF NONCONTRAST-ABBREVIATED MAGNETIC RESONANCE IMAGING FOR HEPATOCELLULAR CARCINOMA SURVEILLANCE IN CIRRHOTIC PATIENTS WITH PRIOR ULTRASOUND VISUALIZATION SCORE C

Sunyoung Lee[1] Hyun Kyung Yang[1] Min Young Lee[2], [1]Severance Hospital, Yonsei University College of Medicine, [2]Yonsei University

Background: The recently updated Liver Imaging Reporting and Data System (LI-RADS) version 2024 surveillance ultrasound (US) algorithm introduced alternative strategies, including abbreviated magnetic resonance imaging (AMRI), for patients with repeat or at high risk for repeat US visualization score C (VIS-C) examinations. We investigated the adequacy of the liver visualization and effectiveness of noncontrast-abbreviated magnetic resonance imaging (NC-AMRI) for hepatocellular carcinoma (HCC) surveillance in cirrhotic patients with VIS-C on prior US. **Methods:** This retrospective study included Child–Pugh class A or B cirrhotic patients with prior US VIS-C and underwent NC-AMRI for HCC surveillance between December 2018 and August 2022. Two radiologists reviewed the visualization quality of the NC-AMRI, assessing three parameters: the degree of liver parenchymal heterogeneity (1 = homogeneous or mildly heterogeneous; 2 = moderate parenchymal heterogeneity; or 3 = severely heterogeneous), artifacts (1 = no or minimal; 2 = moderate; or 3 = severe), and liver visualization (1 = liver visualized in near entirety; 2 = some portions of the liver or diaphragm not visualized; or 3 = majority of the right or left lobe or diaphragm not visualized) on each T2-weighted image (T2WI) and diffusion-weighted image (DWI). Early- and very early-stage detection, receipt of curative treatment, and false referral were evaluated. **Results:** A total of 264 patients (mean age, 60.1 years; 169 men) were included. On 264 prior VIS-C, the frequencies of severely heterogeneous liver parenchyma, severe beam attenuation or shadowing, and majority (> 50%) of right or left lobe or diaphragm not visualized were 51.5% (136/264), 19.3% (51/264), and 41.7% (110/264), respectively, according to the LI-RADS surveillance US algorithm. On NC-AMRI, the mean values for the degree of liver parenchymal heterogeneity, artifacts, and liver visualization were 1.23, 1.02, and 1.03 on T2WI, respectively, and 1.36, 1.08, and 1.07 on DWI, respectively. Among the 264 patients, 23 HCCs developed in 18 (18/264, 6.8%) patients. The proportions of early- and very early-stage detection were 94.4% (17/18) and 55.6% (10/18); receipt of curative treatment, 55.6% (10/18); and proportion of false referral, 22.2% (4/18). **Conclusion:** NC-AMRI provided adequate visualization of the liver in cirrhotic patients with prior US VIS-C. NC-AMRI may be an effective surveillance modality for early-stage HCC detection and may serve as an alternative surveillance strategy for cirrhotic patients following US VIS-C.

N-acetylcysteine for efficacy and safety in preventing PES after transcatheter arterial chemoembolisation (TACE).

This study primary aimed to evaluate an outcome was a negative result of PES at 48 h after TACE, which was defined as temperature ≥ 38.5 °C and 3-fold higher alanine transaminase level from baseline to evaluated. The secondary outcome included liver decompensation at 48 hours, duration of admission, and safety outcomes (e.g., blood sugar changes and adverse reactions). Additionally, progression-free survival at one month was evaluated in both the DEX and NAC groups. **Methods:** In this phase 3, randomized (1:1), double-blind, double-dummy, parallel-group, non-inferiority study, patients with early to intermediate stage HCC (BCLC stage A-B) without macrovascular invasion who had eligible indication for TACE were randomly assigned to either an intravenous single dose of dexamethasone 8 mg (DEX) or N-acetylcysteine - initial dose 150 mg/kg IV 1 hour, followed by 12.5 mg/kg IV 4 hours then 6.25 mg/kg IV up to 48 hours after TACE (NAC). **Results:** A total of 90 patients were initially enrolled in the study. However, outcome analysis was conducted on 85 patients, seventy-five patients (88%) were male, mean age over 60 years in both groups. HBV cirrhosis was the most common cause, found 46 participants (55%). Most participants had liver cirrhosis, Child-Pugh A, and BCLC stage B, approximately 70% and 87%, respectively. PES incidence was non-inferior between groups (difference proportion DEX-NAC 0.02, (95%CI: -0.13-0.17), $p = 0.002$). However, subgroup symptoms analysis showed significantly greater reduction in abdominal pain (87.5% vs. 55.3%, $p = 0.002$) and fever (52.5% vs. 28.9%, $p = 0.035$) in DEX group compared to NAC group. Liver decompensation was significantly greater reduction in DEX group than NAC group (90% vs. 52.6%, $p = < 0.001$). Anaphylactoid reactions, presenting as dermatologic manifestations (18.4%), and other adverse events (10.4%) were observed exclusively in the NAC group. There was no significant difference in the incidence of hyperglycemia between the two groups. The median length of hospital stay was 4 days in both groups. Additionally, a one-month follow-up for progression-free survival revealed no significant difference between the groups in terms of disease progression or stable disease. **Conclusion:** PES incidence was non-inferior between groups. However, at 48 hours post-TACE, the DEX regimen was associated with a significant reduction in fever, pain, and liver decompensation. Additionally, anaphylactoid reactions and other adverse events occurred exclusively in the NAC group, while the median length of hospital stay did not differ significantly between the groups.

◆ 3122 | ADVANCING HCC DIAGNOSTICS: OUTPERFORMANCE OF NOVEL BIOMARKER LC-SPIK IN DETECTION OF HCC IN EARLY-STAGE, AFP-NEGATIVE AND NON-VIRAL CIRRHOSIS CASES

karteek kadimisetty[1] Felix Lu[1] Connor Ott[1] Prabha Bista[1] Lanla Conteh[2] Anne Noonan[3] Daryl Lau[4] Xuanyong Lu[1], [1]ImCare Biotech, [2]Ohio State University, Wexner Medical Center, [3]The Ohio State University, Comprehensive Cancer Center, [4]Beth Israel Deaconess Medical Center

Background: Hepatocellular carcinoma (HCC) is the most prevalent and lethal form of liver cancer with an estimated 905,677 new cases in 2020 worldwide. Unfortunately, most cases are diagnosed late, where curative options are limited with a 5-year survival rate below 15%. Early detection of HCC significantly improves clinical outcomes, yet existing screening tests like ultrasound and α-fetoprotein (AFP) fall short in accuracy, especially in early-stage disease. Ultrasound is operator-dependent, considered suboptimal in patients with obesity and MASLD. AFP shows poor sensitivity ($< 40\%$) for detecting HCC in early stage and cirrhosis patients, particularly in non-viral cirrhosis. **Methods:** ***Novel Biomarker.*** ImCare Biotech discovered and developed liver cancer-secreted serine protease inhibitor Kazal (LC-SPIK), a protein that is uniquely secreted by liver cancer cells but not by normal hepatocytes or inflamed tissues. LC-SPIK retains an extra 23-amino-acid N-terminal fragment which is usually removed during protein secretion. We have developed proprietary monoclonal antibodies that specifically detects LC-SPIK and built a robust ELISA platform *Seravue*® that enables sensitive and specific detection of HCC across diverse population,

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

including those with AFP-negative disease cases or complex cirrhotic etiologies. **Results:** In one case-control study, which included 164 HCC patients and 324 controls, LC-SPIK had an AUC of 0.87 compared to only 0.70 for AFP in distinguishing HCC from other liver disease (cirrhosis, HBV/HCV). LC-SPIK also performed significantly better than AFP for the 81 patients with early-stage HCC (BCLC stage 0 and A), with an AUC of 0.85 compared to only 0.61 for AFP. Notably, LC-SPIK identified HCC in over 70% of patients both with early and late HCC who were AFP-negative. LC-SPIK's clinical performance was also studied in HCC patients with cirrhosis, which is the major risk factor for HCC, including viral and non-viral cirrhosis caused by MASLD and ALD. In total 163 viral cirrhosis patients with 93 HCC patients (50 early-stage), LC-SPIK had an AUC of 0.85, while AFP had an AUC of 0.70. For 120 patients with nonviral cirrhosis, including 62 HCC (23 early-stage) patients, LC-SPIK had an AUC of 0.84, while AFP had an AUC of only 0.72. **Conclusion:** Serum levels of LC-SPIK have shown significant improvement in HCC detection, especially in early-stage and AFP-negative HCC cases as well as in patients with viral and non-viral cirrhosis. All these results suggest its potential for disease stratification and monitoring the development of HCC.

◆ 3123 | DIAGNOSTIC PERFORMANCE OF GALAD AND GAAD VS. ULTRASOUND FOR HCC DETECTION IN PATIENTS WITH NON-VIRAL LIVER DISEASE

Mohammad Jarrah[1] Sneha Deodhar[1] Lisa Quirk[1] Mohammed Al-Hasan[1] Eunice Amador[1] Hannah Pitts[1] Nicole Rich[1] Neehar Parikh[2] Jorge Marrero[3] Fasiha Kanwal[4] Amit Singal[1], [1]University of Texas Southwestern Medical Center, [2]University of Michigan Medical Center, [3]University of Pennsylvania, [4]Michael E. DeBakey VA Medical Center

Background: Ultrasound (US) is operator dependent and is prone to hepatocellular carcinoma (HCC) surveillance failure, particularly in metabolic dysfunction–associated steatotic liver disease (MASLD) and alcohol-associated liver disease (ALD). As the predominant etiology of HCC shifts from viral to non-viral, there is growing interest in blood-based biomarkers. **Methods:** We conducted a case-control study evaluating the performance of blood-based biomarkers GALAD and GAAD vs. US for detection of early-stage HCC (BCLC stage 0 or A) in patients with MASLD or ALD cirrhosis. Blood specimens were collected within 6 months following HCC diagnosis (cases) and during routine visits for cirrhosis (controls). GALAD and GAAD scores were measured using the Roche Elecsys platform and established cutoffs of 2.47 and 2.57, respectively. A positive US was defined as a liver lesion ≥ 1 cm within 6 months of blood collection. Diagnostic accuracy, using AUROC, was compared using DeLong's test, and sensitivity and specificity were compared using Wald test. **Results:** Among 152 patients (56.6% men), 46.7% had HCC (54.9% BCLC 0/A) and 53.3% had cirrhosis. Liver disease etiologies were MASLD (53.5%) and ALD (46.5%). For any-stage HCC, US had 67.5% sensitivity and 89.9% specificity (AUROC 0.79); GALAD 91.5% sensitivity and 67.9% specificity (AUROC 0.92); GAAD 91.5% sensitivity and 69.1% specificity (AUROC 0.92). Compared to US, GALAD and GAAD had higher sensitivity (both $p = 0.01$), lower specificity (both $p < 0.001$), and higher AUROC (both $p = 0.01$); they had comparable performance to each other ($p = 0.96$). For early-stage HCC, US had a sensitivity of 57.1% and specificity of 89.9% (AUROC 0.73). GALAD sensitivity of 87.2% and specificity of 67.9% (AUROC 0.90), GAAD sensitivity of 88.0% and specificity of 69.1% (AUROC 0.90). Compared to US, GALAD and GAAD had higher sensitivity (both $p = 0.12$), lower specificity (both $p < 0.001$), and higher AUROC (both $p = 0.01$); they had comparable performance to each other ($p = 0.39$). Combining GALAD and GAAD with US improved sensitivity for early-stage HCC to 90.5% for both, albeit with lower specificities (63.8% and 65.2%, respectively). **Conclusion:** In a pilot study, blood-based biomarkers had high performance, competitive to ultrasound, in patients with non-viral cirrhosis. These results support ongoing prospective studies validating biomarkers for HCC surveillance in patients with cirrhosis.

◆ 3124 | "COMPARISON OF DEXAMETHASONE AND N-ACETYLCYSTEINE VERSUS N-ACETYLCYSTEINE ALONE IN PREVENTION OF POST-EMBOLIZATION SYNDROME IN PATIENTS WITH HEPATOCELLULAR CARCINOMA FOLLOWING TRANSARTERIAL CHEMOEMBOLIZATION – RANDOMIZED CONTROLLED TRIAL."

Phool Chand[1] VINOD ARORA[1] Rakhi Maiwall[2] Amar Mukund[1] YASHWANT PATIDAR[1] Nirupma Trehanpati[3] Sukriti Baweja[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences (ILBS), New Delhi, [2]Institute of Liver and Biliary Sciences, New Delhi, [3]Institute of Liver and Biliary Sciences (ILBS),New Delhi

Background: Post-embolization syndrome (PES), characterized by fever, nausea vomiting and abdominal pain, is a frequent complication following transarterial chemoembolization (TACE) for hepatocellular carcinoma (HCC), contributing to increased morbidity and hospitalization. While N-acetylcysteine (NAC) and corticosteroids have shown individual benefit, no randomized controlled trial (RCT) has evaluated their combined efficacy. This study addresses this clinical gap by assessing whether adjunctive dexamethasone with NAC reduces the incidence of PES more effectively than NAC alone. **Methods:** Adults (18–75 years) TACE eligible patients for unresectable HCC were enrolled and randomized 12 hours prior to TACE into two arms: Arm A (NAC + dexamethasone) and Arm B (NAC alone). Patients with Child-Pugh C, curative intent therapies, uncontrolled diabetes or hypertension, recent surgery, or viral activity (HBV DNA >100 IU/mL, detectable HCV RNA) were excluded. The primary endpoint was incidence of PES within 72 hours, defined by SWOG toxicity score ≥ 2. Secondary endpoints included post-TACE hepatic decompensation at 4 weeks, hospital stay duration, and adverse events (CTCAE 5.0). **Results:** Of 208 screened, 134 patients were randomized (Arm A: $n=68$; Arm B: $n=66$). PES at day 3 was noted in 11.8% (8/68) in Arm A vs 43.9% (29/66) in Arm B ($p<0.001$). PES prevention was achieved in 88.2% (60/68) of patients in Arm A compared to 56.1% (37/66) in Arm B ($p<0.001$).Mean hospital stay was shorter in Arm A (3.13 ± 0.38 days) vs Arm B (3.58 ± 1.07; $p<0.001$). Post-TACE decompensation was observed in 4.6% (Arm A) vs 7.8% (Arm B) ($p=0.452$). Adverse events were similar (9 vs 8 patients), with no serious events requiring discontinuation. On multivariate analysis, higher baseline AST (OR 1.035, CI 1.013–1.057, $p=0.001$), baseline serum creatinine (OR 17.82, CI 2.072–153.25, $p=0.008$), and baseline CRP (OR 1.066, CI 1.004–1.131, $p=0.039$) independently predicted PES. **Conclusion:** Dexamethasone plus NAC significantly reduced PES incidence and hospitalization following TACE in HCC patients, with a favourable safety profile. These findings support combined prophylaxis as an effective strategy to improve post-TACE outcomes.

◆ 3125 | OUTCOMES OF US LI-RADS VISUALIZATION SCORE B IN HEPATOCELLULAR CARCINOMA SURVEILLANCE

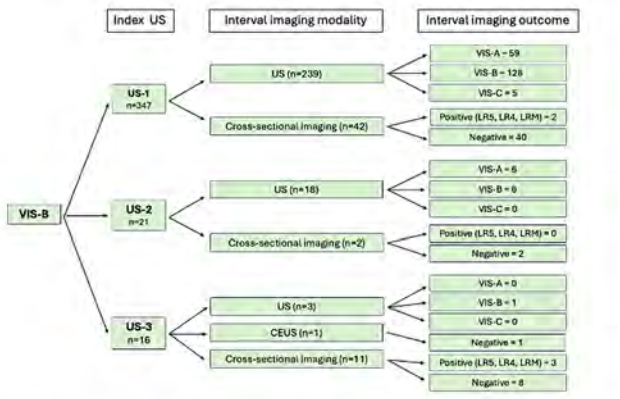
Sanjna Shelukar[1] Caroline Conlon[1] Jashanveer Johal[1] Shuchi Rodgers[2] Andrej Lyshchik[1] Jesse Civan[1], [1]Thomas Jefferson University Hospital, [2]University of Pennsylvania, Perelman School of Medicine

Background: Surveillance for hepatocellular carcinoma (HCC) with 6-monthly ultrasound (US) and alpha fetoprotein (AFP) is recommended for high-risk individuals. The US LI-RADS system was created to standardize reporting of liver lesions detected on US (US-1: negative, US-2: subthreshold [lesion <10mm], US-3: positive [lesion >10mm]) and the US quality (VIS-A [no or minimal limitations], VIS-B [moderate limitations], VIS-C [severe limitations]). There is a paucity of literature on the expected false negative and false positive rates for VIS-B US. There is no specific guideline regarding optimal recall strategy for the VIS-B cohort. This study aims to assess the patient factors and clinical outcomes associated with US LI-RADS VIS-B. **Methods:** A retrospective chart review of electronic health records at our institution was conducted. Patients aged 18 years and older at high-risk for HCC with an US with a VIS-B score between March 2020 and August 2022 were included in the study. Descriptive analysis of patient demographics and disease characteristics was performed. **Results:** 384 patients with an index US result of VIS-B were identified. 63% were male. The median age at index scan was 59 years. The main etiologies of liver disease were chronic hepatitis B (HBV) (60%), MASLD (20%) and

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

chronic hepatitis C (13%). 60% were non-cirrhotic, of which 91% had chronic HBV. At index scan, the median BMI was 28.7, median AFP was 2.70ng/mL and median MELD 3.0 for patients with cirrhosis was 8. The results of the index scans were as follows; 90% US-1, 5.5% US-2 and 4.5% US-3.
316 patients proceeded to further imaging: 260 US (VIS-A = 65, VIS-B = 135, VIS-C = 5), 46 multiphase MRI, 9 multiphase CT and 1 contrast-enhanced US. The median time to interval scan was 7 months. The incidence of HCC on interval imaging was 0.9% (n = 3). Graph 1 outlines the interval imaging modalities and outcomes per index scan results. **Conclusion:** Our data shows that patients with negative or sub-threshold findings on HCC surveillance US, even with US LI-RADS VIS-B score, are unlikely to have HCC identified on subsequent imaging. For our cohort with US-1 and VIS-B findings on index US, about one quarter improved to VIS-A on subsequent US. Our findings suggest that following US-1 VIS-B surveillance US with multiphase, contrast-enhanced CT or MRI is unlikely to have higher yield than repeating the US. One limitation of our study was the high proportion of non-cirrhotic patients, which may limit generalizability of our findings.



Graph 1. Interval imaging modalities and outcomes per index scan US LI-RADS result. Cross-sectional imaging included multiphase, contrast-enhanced CT or MRI. Visualization score was not recorded in 55 interval ultrasounds. CEUS = contrast-enhanced ultrasound; CT = computed tomography; LR5 = LI-RADS 5 lesion (HCC); LR4 = LI-RADS 4 lesion (probable HCC); LRM = LI-RADS M lesion (likely malignant, but not definite HCC); MRI = magnetic resonance imaging; US = ultrasound; VIS-B = visualization score B.

◆ 3126 | GLYCOLYTIC REWIRING OF MONOCYTE-DERIVED MACROPHAGES PROMOTES IMMUNOSUPPRESSION IN HEPATOCELLULAR CARCINOMA

Hengdong Qu[1] Di Zhang[1] Junli Liu[1] Peixin Zhao[1] Yihui Yu[1] Ziwei Kang[1] Yiming Cui[1] Jinyu Lv[1] Hao Bai[1] Ping Tao[1] Nan Yao[1] Wencai Ye[1] Jian Hong[1], [1]State Key Laboratory of Bioactive Molecules and Druggability Assessment, Jinan University

Background: While glycolysis is generally considered to fuel pro-inflammatory activation and anti-tumoral immunity of macrophages, emerging evidence highlights its paradoxical role in tumor-associated macrophages (TAMs) through upregulation of immune checkpoints, including programmed cell death protein 1 (PD-1) and programmed cell death ligand 1 (PD-L1). This study is aimed at deciphering the role of glycolysis in TAMs and at investigating its impact on tumor immunity of hepatocellular carcinoma (HCC). **Methods:** Glycolytic landscape and immunomodulatory signatures of hepatic TAMs, including Kupffer cells and monocytes-derived macrophages (MDMs), were assessed by multi-dimensional approaches. To interrogate the function and mechanism of glycolytic MDMs in HCC progression, we established diethylnitrosamine/carbon tetrachloride (DEN/CCl_4)-induced and orthotopically implanted HCC models using mice with myeloid-specific deletion of pyruvate kinase M2 (PKM2), the rate-limiting enzyme of glycolysis. **Results:** Bioinformatic screening and flow cytometry analysis identified that $PKM2^+$ MDMs, which constructively represent the major cellular source of glycolytic macrophages in HCC tumors, displayed an immunosuppressive phenotype. Macrophage-specific PKM2 knockout profoundly mitigated tumor progression (24-week: number of surface tumor, $P < 0.001$; largest tumor diameter, $P < 0.001$) but not tumor formation (19-week: number of surface tumor, $P = 0.977$; largest tumor diameter, $P = 0.940$) in DEN/CCl_4-induced spontaneous HCC model. The protective effect of macrophage PKM2 ablation was verified in orthotopic HCC model. Functional studies illustrated that macrophage PKM2 deficiency reduced conventional M1 macrophages but enhanced the anti-tumoral activities of $CD8^+$T cells through downregulation of macrophage PD-L1 expression. Furthermore, PKM2-dependent glycolysis promotes histone lactylation and the transcription of immunosuppressive molecules (PD-L1, IL-10, TGF-β, etc.) in macrophages, which thereby facilitates $CD8^+$T cell exhaustion and HCC progression. Interestingly, compared to non-steatotic liver conditions, the abundance of $PKM2^+$ MDMs was markedly enriched in metabolic dysfunction-associated steatotic liver disease (MASLD), whilst depletion of macrophage PKM2 efficiently reversed immunosuppression and boosted the efficacy of anti-PD-1 therapy in MASLD-HCC mice. **Conclusion:** This study demonstrates that PKM2-dependent glycolytic reprogramming of MDMs promotes immunosuppression and HCC progression. Targeting PKM2/glycolysis/lactylation axis in macrophage may potentiate the therapeutic effect of immune checkpoint blockades in MASLD-HCC.

◆ 3127 | WATCH OR TREAT? OUTCOMES FOLLOWING MANAGEMENT OF VERY SMALL HEPATOCELLULAR CARCINOMA (LESS THAN 2 CM)

Varun Rohatgi[1] Andrea Kierans[1] Jeffrey Sung[1] Robert Brown[1] Resmi Charalel[1], [1]Weill Cornell Medicine

Background: Current OPTN liver transplant guidelines provide HCC exception points for stage T2 disease (single HCC $\geq$2 cm or multifocal HCC). For patients with T1 disease ($<$ 2 cm), clinicians may consider deferring treatment until T2 progression to gain exception points and potentially expedite transplant. However, the risks/benefits and resultant outcomes of this strategy are poorly understood. With the recent alignment of OPTN guidelines with LI-RADS, there is a growing need to understand the progression of these smaller lesions to inform decision-making. **Methods:** Retrospective, single-center cohort study of treatment-naïve patients presenting with LR-4 or LR-5 lesions less than 2 cm on triple-phasic liver protocol CT or MR between January 2010-June 2024. Patient records were evaluated for demographics, treatment history, staging, transplant outcomes (wait-time, evaluation/listing metrics, receipt/timing of exception points, MELDs) and pathology correlation. Subjects presenting with T1 disease were compared based on cancer stage (T1 or T2) at time of treatment. Separate analysis was performed for patients who presented with pre-2023 criteria OPTN 5a lesions vs those presenting with T1-compatible LR-4 or LR-5 disease. Overall survival (OS) and post-therapeutic progression free survival (PFS) were evaluated via Kaplan-Meier. **Results:** Eighty-eight subjects with 110 lesions (40 LR-4 and 70 LR-5) met inclusion criteria. Of these, 70 subjects presented with T1-stage LR-4/LR-5 lesions (34 treated at stage T2 vs 36 treated at T1) with 47 classified as pre-2023 OPTN 5a. Reviewing the pooled LR-4/LR-5 group, the median delay associated with deferring treatment to T2 was 105 days (169 days T2-treated vs 64 days T1-treated, p = 0.001). Median wait-time between presentation and transplant was greater for T2-treated subjects (416 vs 204.5 days, p = 0.0461). While T2-treated subjects more often underwent transplant evaluation (79.4% vs 55.6%, p = 0.0434), they weren't more likely to be listed (61.8% vs 41.7%, p = 0.102) nor receive transplant (52.9% vs 38.9%, p = 0.337). Among those with available pathology, all 17 T2-treated subjects demonstrated malignancy compared to 18/23 T1-treated subjects (p = 0.060). OS was 70.25% and PFS was 57.8%, with no significant difference between T2-treated and T1-treated patients (OS 76.5% T2-treated vs 82.8% T1-treated, p = 0.60; PFS 50.3% T2-treated vs 70.2% T1-treated, p = 0.24). **Conclusion:** For patients presenting with single LR-4 and LR-5 lesions less than 2 cm, while those with T2 progression were more likely to undergo transplant evaluation, they experienced similar transplant rates and slower total wait-times than those treated at T1. There was no impact on survival outcomes. Therefore, despite delays in transplant receipt, this study suggests no negative long-term impact of delaying treatment decision, which already minimizes the risk of potential transplant for non-malignant disease.

◆ 3128 | MORPHOLOGICAL SIGNATURES AND SPATIAL BIOLOGY IN HCC: FOCUS ON MACROTRABECULAR AND VESSELS-ENCAPSULATING TUMOR CLUSTERS PATTERNS

Jun Akiba[1] Reiichiro Kondo[2] Hironori Kusano[2] Masamichi Nakayama[2] Taro Shioga[2], [1]Department of Pathlogy, Kurume University, [2]Kurume University

Background: Hepatocellular carcinoma (HCC) is a histologically heterogeneous tumor, with macrotrabecular massive (MTM) and vessels-encapsulating tumor clusters (VETC) types recognized as aggressive subtypes associated with poor prognosis. Our previous studies demonstrated that even a 5% presence of MT or VETC pattern is a poor prognostic factor, and these patterns often coexist within the same nodule. To elucidate the spatial diversity and biological significance of these patterns, we conducted a spatial transcriptomic analysis using surgical specimens and performed a detailed histopathological investigation using autopsy cases. **Methods:** Two surgically resected HCC cases exhibiting MT and/or VETC components within the same tumor nodule were analyzed. Formalin-fixed paraffin-embedded (FFPE) tissues were processed using the tissue microarray method to selectively sample characteristic regions. Spatial transcriptomics was performed using the Visium HD platform (10X Genomics). In parallel, 254 autopsy-confirmed HCC cases were histologically reviewed to evaluate the frequency of MT and VETC patterns in both primary tumors and metastatic lesions. A 5% cut-off was used to define pattern positivity. **Results:** Spatial transcriptomic analysis revealed that conventional HCC and VETC-HCC from the same tumor had relatively similar gene expression profiles; however, endothelial cell–dominant clusters were observed specifically in VETC-HCC. MT-HCC exhibited clearly distinct expression patterns. In another case, AFP expression was confined to MT-HCC, and multiple transcriptionally distinct clusters were identified among AFP-positive cells. Clusters characterized by tumor cells with large nuclei also exhibited unique gene signatures, distinct from surrounding populations.
Histological analysis of autopsy cases showed significantly higher frequencies of MT-HCC (44.2%) and VETC-HCC (38.5%) compared to surgically resected cases (24.6% and 23.8%, respectively). Cases with MT or VETC patterns had significantly higher rates of distant metastasis, especially pulmonary, but lymph node involvement was unaffected. Macroscopically, these subtypes were more likely to present as diffuse or massive forms and less frequently as nodular types. No consistent pattern concordance was found between primary and metastatic lesions. **Conclusion:** MT and VETC subtypes display distinct spatial transcriptomic profiles, even within a single tumor, reflecting the intratumoral heterogeneity of HCC. These patterns were more frequently observed in autopsy cases and were associated with aggressive metastatic behavior. Ongoing bioinformatic analyses and case expansion aim to further clarify their roles in HCC progression and tumor evolution.

◆ 3129 | ARID1A IS DECISIVE FOR INITIATING HEPATOCYTE-DERIVED INTRAHEPATIC CHOLANGIOCARCINOMA VIA NOTCH PATHWAY ACTIVATION

Jinqiang Zhang[1] Weina Chen[2] Tong Wu[3], [1]Tulane University, [2]Tulane, [3]Tulane Medical Center

Background: ARID1A, a DNA-binding subunit of the SWI/SNF chromatin remodeling complex, has context-dependent roles in cancer as both a tumor suppressor and oncogene. In intrahepatic cholangiocarcinoma (iCCA), high-throughput sequencing studies have identified ARID1A mutations as among the most common genetic alterations. However, the functional relevance of ARID1A in iCCA initiation and progression remains unclear. **Methods:** We analyzed ARID1A mutations and expression across multiple iCCA patient cohorts. To investigate ARID1A's functional role, we employed two genetically engineered mouse models of hepatocyte-derived iCCA: TAZ^S89A/myr-AKT and NICD/myr-AKT. We evaluated tumor burden following ARID1A deletion and performed chromatin accessibility (ATAC-seq) and transcriptomic (RNA-seq) analyses to explore downstream molecular effects. **Results:** Patient cohort analyses showed that ARID1A mutations were frequent and marginally correlated with better survival, whereas high ARID1A expression was associated with poorer prognosis. In both mouse models, ARID1A deletion significantly reduced liver tumor burden in mice iCCA induced by hydrodynamic tail vein injection, suggesting its oncogenic role in hepatocyte-derived iCCA. Mechanistically, ARID1A loss reduced chromatin accessibility at Notch target loci, leading to suppression of Notch pathway gene expression essential for cholangiocyte differentiation and iCCA development. We identified that RBP-J, a core Notch transcription factor, recruits ARID1A-containing SWI/SNF complexes to activate target genes. These findings were corroborated by similar tumor suppression upon ARID1A loss in the NICD/myr-AKT model. Additional analyses indicated ARID1A mutations are rare in hepatocyte-origin human iCCA, consistent with its tumor-promoting function in this context. Moreover, patients with intact ARID1A showed gene expression profiles suggestive of greater responsiveness to immunotherapy. While the functional loss of ARID1A is associated with poor prognosis in numerous types of cancers, our data suggest

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

that its loss in iCCA inhibits tumorigenesis, highlighting the complex and context-dependent role of ARID1A across different tissues. **Conclusion:** Our study identifies ARID1A as a key oncogenic driver in hepatocyte-derived iCCA by maintaining chromatin accessibility and Notch signaling. These findings highlight its context-specific function and suggest that targeting ARID1A or its downstream pathways may represent a novel therapeutic approach for iCCA, a cancer with few effective treatment options.

◆ 3130 | THE STAGE-DEPENDENT, DIVERGENT, AND CONTRASTING EFFECT OF CONCURRENT MASLD ON THE PROGNOSIS OF PATIENTS WITH HEPATOCELLULAR CARCINOMA (HCC): A NATIONWIDE COHORT STUDY

Chun-Ting Ho[1] Elise Chia-Hui Tan[2] Wei-Yu Kao[3] Yi-Hsiang Huang[4] Ming-Chih Hou[4] Jaw-Ching Wu[5] Chien-Wei Su[4], [1]Taipei Veterans General Hospital/NYCU, [2]China Medical University, [3]Taipei Medical University, [4]Taipei Veterans General Hospital, [5]National Yang Ming Chiao Tung University

Background: The prognostic impact of cardiometabolic risk factors (CMRF), steatotic liver disease (SLD), and Metabolic dysfunction-associated steatotic liver disease (MASLD) on patients with hepatocellular carcinoma (HCC) remains inconclusive. Besides, further risk stratification and subgroup analysis across stages are still lacking. This study aims to evaluate the prognostic influence of SLD, CMRF, and MASLD on HCC patients across different stages. **Methods:** This retrospective study included 30,857 treatment-naïve patients diagnosed with HCC in Taiwan between 2017 and 2021 from the National Health Research Database in Taiwan. Patients were classified into MASLD and non-MASLD groups utilizing ICD-10 codes and demographic data. Further stratification divided patients into four subgroups: patients without SLD or CMRF, patients with SLD but without CMRF, patients with CMRF but without SLD, and MASLD. The primary outcome was overall survival (OS). Cox proportional hazards models (COX PH) and Fine and Gray's sub-distribution hazard model were used to evaluate the prognostic impact of SLD, CMRF, and MASLD on OS. Kaplan-Meier (KM) survival analyses were performed to compare the outcomes between subgroups. **Results:** Among all patients, 4747 (15.4%) HCC patients have concurrent MASLD. Patients with MASLD are older, more female, have smaller tumor sizes, early tumor stages, and lower serum alpha-fetoprotein. After a median follow-up of 26.3 months, 13460 patients died. 5-year OS of MASLD and non-MASLD groups were 43.5% and 47.1%, respectively. The OS in the two groups was comparable. COX PH model identified MASLD as an independent risk factor for poor OS, while the sole presence of SLD or CMRF was not prognostically significant. Further analysis revealed a stage-dependent effect of SLD, CMRF, and MASLD: In earlier stages, the presence of SLD, CMRF, or MASLD was all associated with poor OS, while in advanced stages, the presence of SLD or MASLD became protective, and CMRF remained hazardous. Stage-stratified COX PH models also identified SLD and MASLD as independent risk factors in early stages. While stratified into four groups, patients without SLD and CMRF had the best OS in early stages, and patients with SLD but without CMRF had the best OS in advanced stages. **Conclusion:** The prognostic effects of SLD, CMRF, and MASLD on HCC patients are divergent and contrasting across different stages. SLD and MASLD were hazardous in early stages but became protective in advanced stages, while CMRF remains hazardous across all stages.

◆ 3131 | HEALTHCARE UTILITY AND DISEASE BURDEN IN ADVANCED HEPATOCELLULAR CARCINOMA PATIENTS RECEIVING SYSTEMIC THERAPY

Rex Wan-Hin Hui[1] Matthew Shing Hin Chung[1] Lu Li[1] Xianhua Mao[1] Chi-Leung Chiang[2] Carlos King-Ho Wong[3] Ian Chi-Kei Wong[3] Ka-Shing Cheung[1] Man-Fung Yuen[1] Wai-Kay Seto[1] Lung-Yi Mak[1], [1]Department of Medicine, The University of Hong Kong, [2]Department of Clinical Oncology, The University of Hong Kong, [3]Department of Pharmacology and Pharmacy, The University of Hong Kong

Background: While cancer survivorship for hepatocellular carcinoma (HCC) improves, associated disease time burden in HCC patients on systemic therapies has not been well studied. We utilized days at home (DAH), a patient-centered metric, to compare the disease time burden between patients on immunotherapies and tyrosine kinase inhibitors (TKIs). **Methods:** Advanced HCC patients receiving systemic therapy from 2008 – 2023 were identified from a population-based cohort in Hong Kong. Patients were classified based on the use of immunotherapy (nivolumab, pembrolizumab, atezolizumab, durvalumab, tremelimumab, and ipilimumab; including monotherapies or combinations) or TKI (lenvatinib, sorafenib, cabozantinib, and regorafenib). The primary outcome was DAH – defined as days alive and not requiring healthcare utilization within the first year of systemic therapy. **Results:** This study included 3,988 patients (578 on immunotherapy and 3,410 on TKI), with the immunotherapy group having significantly higher 1-year overall survival (58.1% vs 34.2% respectively, $p < 0.001$). Mean DAH was significantly higher in the immunotherapy group than in the TKI group (223.1 +/- 134.7 vs 183.3 +/- 129.4 days respectively, $p < 0.001$), and these results remained robust in multivariate and subgroup analyses. Immunotherapy was associated with fewer days spent on inpatient stay and emergency department attendance, but was associated with more days spent on day procedures and investigations (all $p < 0.01$). Immune-related adverse events (irAEs) occurred in 12.3% of immunotherapy patients, and had a negative impact on DAH (32.5 fewer days, $p = 0.056$). Immunotherapy patients with irAEs had comparable DAH with TKI patients ($p = 0.469$). **Conclusion:** Immunotherapy, when compared with TKI, was associated with significantly reduced disease time burden in advanced HCC patients in this real-world cohort. However, this difference was mitigated with the occurrence of irAEs. Our data has important quality of life implications, and may influence patients' decisions for therapy.

◆ 3132 | A MARKOV MODEL FOR COST-EFFECTIVENESS ANALYSIS COMPARING THE NOVEL BLOOD-BASED HELIOLIVER® TEST VS LIVER ULTRASOUND SEMIANNUALLY FOR EARLY DETECTION OF HEPATOCELLULAR CARCINOMA

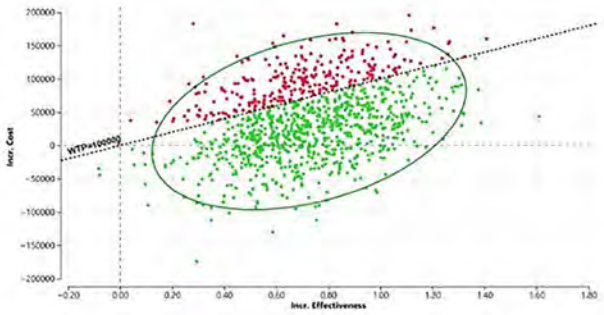
Jim C. Huang[1] Xinrong Zhang[2] Guan-Wei Huang[1] Chieh-Ying Chang[1] Rui Huang[2] Taotao Yan[2] Sovann Linden[2] Ramsey Cheung[2] Mindie Nguyen[2], [1]National Sun-Yat Sen University, Kaohsiung, Taiwan, [2]Stanford University Medical Center, Stanford, California, USA

Background: While significant progress has been made in detecting hepatocellular carcinoma (HCC) at earlier stages using serum biomarkers, the economic value of such strategies remains insufficiently evaluated. **Methods:** This study assessed the cost-effectiveness of semiannual HCC surveillance using the HelioLiver Test compared to

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

conventional abdominal ultrasound in patients with compensated cirrhosis. A Markov model with 9 health states and a 6-month cycle length was constructed. The model incorporated surveillance sensitivity, specificity, compliance rates, and costs associated with surveillance and treatment across liver disease stages, from a payer's perspective. Health outcomes were measured in quality-adjusted life years (QALYs). Model parameters were informed by data from published literature and expert opinions. Both costs and QALYs were discounted at an annual rate of 3% over a lifetime horizon. The primary outcome was the incremental cost-effectiveness ratio (ICER), with a willingness-to-pay threshold set at $100,000 per QALY gained. A microsimulation with 100,000 iterations was conducted for the base-case analysis. Deterministic and probabilistic sensitivity analyses were performed to evaluate the robustness of the results against parameter uncertainty. All costs were reported in 2024 US dollars. **Results:** The HelioLiver Test strategy demonstrated an incremental cost of $39, 154 with an incremental effectiveness of 0.705 QALYs compared to the ultrasound-based surveillance strategy, yielding an ICER of $55,574 per QALY gained. The one-way sensitivity analysis identified the utility, treatment cost, and mortality rate associated with decompensated cirrhosis as the most influential parameters for the estimated ICER. The conclusion remains robust even when the market price of the HelioLiver Test is set as high as $1,000, where the ICER is $67,502 per QALY gained. Probabilistic sensitivity analysis with 1,000 trials of 1,000 resamples using Monte Carlo simulation further indicated that 75.1% of simulations favored the HelioLiver Test as the more cost-effective option (Figure). **Conclusion:** Semiannual HCC surveillance using the HelioLiver Test is more cost-effective than the ultrasound-based surveillance strategy for patients with compensated cirrhosis. This study addresses a critical knowledge gap in the economic evaluation of blood-based biomarker screening and provides valuable insights for healthcare policy and reimbursement decisions.



Scatterplot of Incremental Effectiveness (QALYs) and Incremental Cost (in 2024 USD) based on Probabilistic Sensitivity Analysis

Note: The dots in the scatter plot indicate the result of incremental cost and effectiveness for each simulation run from the probabilistic sensitivity analysis, where green dots are the runs indicating a more cost-effective option for semiannual HelioLiver Test and red ones indicate the runs preferring regular sonography screening.

◆ 3133 | SOCIAL DETERMINANTS OF HEALTH ARE ASSOCIATED WITH TREATMENT RECEIPT AND SURVIVAL IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

Mohammed Al-Hasan[1] Nicole Rich[1] Gloria Figueroa[2] Stephanie Garces[2] Sruthi Yekkaluri[1] Lisa Quirk[1] Mohammad Jarrah[1] Gi Giamarqo[1] Mariadelcarmen Yanez[1] Adam Yopp[1] Amit Singal[1] Patricia Jones[3], [1]University of Texas Southwestern Medical Center, [2]University of Miami, [3]University of North Carolina at Chapel Hill

Background: The association between social determinants of health and hepatocellular carcinoma (HCC) remains unclear. **Methods:** We leveraged the Multi-Ethnic HCC (ME-HCC) Cohort comprised of adults diagnosed with HCC between September 2018 and July 2023 across four U.S. health systems. Patients completed baseline and follow-up surveys assessing various domains, including health literacy, medical mistrust, experienced discrimination, patient-provider communication, and barriers to treatment. We used multivariable logistic regression models to identify factors associated with treatment receipt, and Fine-Gray subdistribution hazard models to identify factors associated with risk of death, with liver transplantation as a competing event. **Results:** Among 1,245 eligible patients, 833 (66.9%) completed the baseline survey and 495 (59.4%) completed the follow-up survey. Median age was 64.2 years, 75.8% were men, and 55.4% had Child Pugh A cirrhosis. HCC-directed treatment was completed in 69.9% of patients, of whom 45.5% received curative therapy. Median survival was 29.0 months (IQR 9.0–57.6). In multivariable analysis excluding BCLC stage D patients, ALD etiology (OR 0.52, 95%CI 0.28–0.98), Child Pugh class B (OR 0.45, 95%CI 0.27–0.75), higher medical mistrust (OR 0.61, 95%CI 0.38–0.98), and higher experienced discrimination (OR 0.80, 95%CI 0.76–0.83) were negatively associated with treatment receipt. Among patients who completed the follow-up survey, barriers to treatment were also negatively associated with treatment receipt (OR 0.79, 95%CI 0.65–0.93). In multivariable analysis adjusting for tumor stage and type of HCC treatment, patients with Child Pugh class B had a higher risk of death (sHR 1.44, 95%CI 1.08–1.91), while patients with higher experienced discrimination had lower risk of death (sHR 0.96, 95%CI 0.93–0.98). Among patients who completed the follow-up survey,

patients with better patient-provider communication had lower risk of death (sHR 0.95, 95% CI 0.92–0.98). **Conclusion:** Medical mistrust, experienced discrimination, and barriers to treatment are inversely associated with treatment receipt, while better patient-provider communication is associated with improved survival. These findings underscore the importance of addressing social determinants of health and health beliefs and enhancing patient-provider communication to improve equitable treatment delivery and HCC survival.

◆ 3134 | DISPARITIES IN OUTCOMES IN PATIENTS WITH HEPATOCELLULAR CARCINOMA TREATED WITH LIVER TRANSPLANTATION

Imran Qureshi[1] Muhammad Ali Ibrahim Kazi[2] Muhammad Hassaan Arif Maan[3] Rohan Karkra[3] Ritik Mahaveer Goyal[4] Wajiha Khan[3] Siddharth Verma[5] Ahmed Al-Khazraji[3] Paul Gaglio[3], [1]RUTGERS THE STATE UNIVERSITY OF NEW JERSEY, [2]Luminis Health Anne Arundel Medical Centre, Annapolis, Maryland, United States, [3]Rutgers New Jersey Medical School, Newark, New Jersey, United States, [4]Rutgers New Jersey Medical School, [5]Veterans Affairs Medical Center, East Orange, USA

Background: Hepatocellular carcinoma (HCC) is on the rise globally and is the fastest-growing cause of cancer deaths in the U.S. In select patients with HCC, Liver transplant (LT) offers a potentially curative modality. However, there is data to suggest racial and socioeconomic disparities related to receipt of LT. In this study, we look at disparities in outcomes in patients who have received LT. **Methods:** We queried the National Cancer Database from 2004 to 2022 for patients with HCC who had received LT. We fit a multivariate Cox proportional hazards model using sociodemographic factors as predictors of overall survival (OS) in patients. We reported adjusted hazard ratios (HR) of OS, along with their 95% confidence intervals (CI) and p-values. **Results:** We identified 16,893 patients with HCC who received LT between 2004 and 2022. Compared to males, females had a lower risk of mortality after LT (HR: 0.92, 95% CI 0.86–0.99, $p = 0.02$). In terms of race, Black patients had a higher mortality after LT compared to White patients (HR: 1.11, 95% CI 1.01–1.23, $p = 0.03$), while Asian patients had a lower mortality (HR: 0.73, 95% CI 0.63–0.84, $p < 0.01$). Hispanics had higher OS than non-Hispanic patients (HR: 0.82, 95% CI 0.74–0.91, $p < 0.01$). Patients with public insurance (HR: 1.28, 95% CI 1.20–1.36, $p < 0.01$) and those uninsured (HR: 1.30, 95% CI 1.01–1.67, $p = 0.04$) had higher mortality than those with private insurance. Interestingly, higher Charlson-Deyo Comorbidity scores were associated with lower odds of mortality compared to a score of 0: score 1 (HR: 0.89, 95% CI 0.82–0.96, $p < 0.01$), score 2 (HR: 0.90, 95% CI 0.81–0.99, $p = 0.04$), and score ≥ 3 (HR: 0.87, 95% CI 0.81–0.94, $p < 0.01$). Median household income between $46,277 and $57,856 was also associated with lower OS (HR: 1.10, 95% CI 1.00–1.21, $p = 0.04$). Compared to the Northeast region, residing in the West was associated with lower mortality (HR: 0.84, 95% CI 0.76–0.93, $p < 0.01$). Finally, patients aged under 50 years had a higher OS compared to those over 50 years (HR: 0.80, 95% CI 0.72–0.89, $p < 0.01$). No significant disparities were noted in terms of the education status of the area, hospital type, or region (Table 1). **Conclusion:** Our study demonstrated significant socioeconomic disparities related to mortality in patients who receive LT for HCC. This may be due to multiple factors, including disparities in post-transplant care or differences in tumor biology associated with higher recurrence rates or poor response to therapy. This underscores the need for studies to further assess the cause of these poor outcomes and targeted public health interventions to address them.

◆ 3135 | A REAL-WORLD STUDY OF HEPATOCELLULAR CARCINOMA SURVEILLANCE OVER 4 DECADES – IS THE CURRENT SURVEILLANCE STRATEGY ADEQUATE?

Wei-Lun Liou[1] Yi-Xuan Lee[1] Kaina Chen[2] George Boon-Bee Goh[1] Jason Pik Eu Chang[1] Chee-Kiat Tan[1], *[1]Singapore General Hospital, [2]SingHealth*

Background: Hepatocellular carcinoma (HCC) is the third leading cause of cancer mortality worldwide and in Singapore. The poor prognosis is partly due to barriers to effective HCC surveillance, leading to HCC presenting at advanced stages. HCC surveillance was first recommended by major liver societies in 2000, with further refinement of the recommendations in 2011. The aim of the current study is to examine the trend of HCC surveillance and its impact on HCC characteristics in Singapore over the last 4 decades. **Methods:** Study cohort comprised HCC patients seen in the Department of Gastroenterology and Hepatology, Singapore General Hospital between 1990 and 2024. Baseline demographics and HCC clinical characteristics were compared across 4 decades (1990-1999, 2000-2009, 2010-2019, 2020-2024). **Results:** There were 1,963 patients of which 79.1% were males. The median age was 64.6 (IQR 15.9) years. The most common etiologies of HCC were hepatitis B (HBV), with 1,236 (63%) cases, followed by metabolic dysfunction-associated steatotic liver disease (MASLD), with 445 (22.6%) cases. Overall, 697 (35.5%) were diagnosed via surveillance. The number of HCC diagnosed by surveillance improved from 221 (18.7%) cases in pre-2010, to 476 (61%) cases in post-2010 ($p < 0.001$). In line with the increase in HCC surveillance post-2010, more patients presented with early-stage HCC (BCLC stage 0/A), 460 (59%), compared with pre-2010, 226 (19.1%) ($p < 0.001$). The proportion of HCC diagnosed by surveillance stagnated after the initial rise in 2010-2019, 60.2% versus 62.2% in 2020-2024. This may be due to increasing prevalence of MASLD contributing to cases of HCC in patients who were not identified for surveillance, as evidenced by lower proportion of HCC diagnosed on surveillance in MASLD patients post-2010 in comparison to HBV (53.9% versus 66.8%, $p < 0.001$). In patients on surveillance, there was still a proportion of HCC who presented with intermediate or advanced stage (BCLC stages B/C/D) - 72 (26.1%) cases in 2010-2019 and 44 (21.9%) in 2020-2024 period. This suggests that our current surveillance strategy is inadequate in patients with higher risk of HCC development and progression. **Conclusion:** Current HCC surveillance strategy may have reached its maximum capability in diagnosing early-stage HCC in our population. This study highlights the need for better identification algorithms and personalised surveillance strategy in particular for patients with MASLD, as well as validated risk stratification HCC biomarkers to improve detection of early stage HCC.

◆ 3136 | ASSOCIATION OF CONCOMITANT MASLD AND HEPATITIS B VIRUS WITH CLINICAL OUTCOMES IN HEPATOCELLULAR CARCINOMA FOLLOWING CURATIVE RESECTION

Chih Wen Lin[1] Yaw-Sen Chen[1] Yao-Chun Hsu[1] Wen-Lung Wang[1] Chih-Jan Ko[2] Shang-Chen Tseng[1] Ming-Lung Yu[3], [1]E-Da Hospital, I-Shou University, [2]China Medical University Hsinchu Hospital, [3]Kaohsiung Medical University

Background: In 2023, a multisociety Delphi consensus redefined that the term "metabolic dysfunction–associated steatotic liver disease" (MASLD) was introduced to replace the term "nonalcoholic fatty liver disease." The prevalence of MASLD is increasing worldwide. The prevalence of concomitant MASLD and hepatitis B virus (HBV)-related hepatocellular carcinoma (HCC) is also increasing. In Taiwan, where HBV is endemic, the prevalence of concurrent MASLD in HBV-related HCC is expected to increase. Only one study has explored the effect of MASLD on the clinical prognosis of HBV-related HCC after curative hepatectomy. The new definitions emphasize MASLD as a critical condition that can coexist with HBV, highlighting the need for further research in this area. Accordingly, the present study investigated the effect of MASLD and HBV coexistence on the clinicopathological features and long-term clinical outcomes of MASLD and/or HBV-related HCC after curative hepatectomy. The study focused on HBV-endemic countries with a high prevalence of HCC. **Methods:** The study retrospectively collected the data of 653 patients with HCC who had undergone curative hepatectomy between 2011 and 2022 from E-Da health group. Patients were included if they were diagnosed as having HBV infection, were diagnosed as having MASLD, underwent curative hepatectomy between 2011 and 2022, and had a pathology report of liver steatosis. Patients were excluded if they lacked a report of liver steatosis, were diagnosed as having HCV infection, consumed a substantial amount of alcohol (>210 g/week for men, >140 g/week for women), or had less than 6 months of follow-up data. We assessed the association of histologically confirmed MASLD with HCC recurrence and mortality. **Results:** Of 653 patients, 320 (49.0%), 103 (15.8%), and 230 (35.2%) had concomitant MASLD and HBV, MASLD only, andHBV only, respectively. The median follow-up period was 5.1 years. Patients with concomitant MASLD and HBV were at a significantly increased risk of HCC recurrence ($P = 0.013$ and $P = 0.041$) and mortality ($P = 0.044$ and $P = 0.026$) than those with MASLD or HBV alone in Figure 1. Multivariable analysis results indicated that male sex (hazard ratio [HR]: 1.66; 95% confidence interval [CI]: 1.15–2.42, $P = 0.008$), tumor size ≥ 5 cm (HR: 1.35; 95% CI, 1.06–1.72, $P = 0.022$), and concomitant MASLD and HBV (HR: 1.62; 95% CI, 1.13–2.33, $P = 0.007$) were also significant risk factors for HCC recurrence. However, BMI ≥ 23 (HR: 0.56; 95% CI, 0.41–0.76, $P < 0.001$) and antiviral therapy (HR: 0.74; 95% CI, 0.56–0.95, $P = 0.021$) were significantly associated with lower HCC recurrence rates. Furthermore, multivariable analysis results revealed that male sex (HR: 1.66; 95% CI: 1.09–2.52, $P = 0.019$), type 2 diabetes mellitus (HR: 1.54; 95% CI, 1.13–2.09, $P = 0.006$), serum aspartate aminotransferase ≥ 40 U/L (HR: 1.34; 95% CI, 1.02–1.76, $P = 0.033$), tumor size ≥ 5 cm (HR: 1.56; 95% CI, 1.19–2.05, $P < 0.001$), tumor cell differentiation II–III (HR: 3.63; 95% CI, 1.89–6.95, $P < 0.001$), microvascular invasion (HR: 1.51; 95% CI, 1.21–2.05, $P = 0.007$), lymph node invasion (HR: 2.29; 95% CI, 1.28–4.09, $P = 0.005$), tumor recurrence (HR: 2.79; 95% CI, 2.14–3.66, $P < 0.001$), and concomitant MASLD and HBV (HR: 1.45; 95% CI, 1.01–2.08, $P = 0.046$) were significant risk factors for mortality. **Conclusion:** Patients with concomitant MASLD and HBV are at a significantly greater risk of HCC recurrence and mortality after curative hepatectomy than those with MASLD or HBV alone.

◆ 3137 | CHILD-PUGH SCORE 7 WITH MILD ASCITES AND HYPOALBUMINEMIA DEMONSTRATES COMPARABLE OUTCOMES TO CHILD-PUGH SCORE 6 IN HCC PATIENTS TREATED WITH ATEZOLIZUMAB/BEVACIZUMAB

Soon Kyu Lee[1] Jaejun Lee[1] Keungmo Yang[1] Ji Won Han[1] Pil Soo Sung[1] Jeong Won Jang[1] Hee Sun Cho[1] Hyun Yang[2] SI HYUN BAE[1] Heechul Nam[1] Chang Wook Kim[3] Hae Lim Lee[1] Hee Yeon Kim[1] Sung Won Lee[1] Ahlim Lee[1] Do Seon Song[1] Myeong Jun Song[1] SOON WOO NAM[1] Jung Hyun Kwon[4], [1]College of Medicine, The Catholic University of Korea, [2]Seoul St. Mary's Hospital, [3]Uijeongbu St. Mary's Hospital, [4]The Catholic University of Korea

Background: Atezolizumab plus bevacizumab (Ate/Bev) has demonstrated remarkable outcomes and is now approved as a first-line treatment for patients with advanced hepatocellular carcinoma (HCC), particularly those with a Child-Pugh score (CPS) of 5 or 6. However, as limited data exist regarding its efficacy in patients with CPS 7, this study aims to evaluate the effectiveness of Ate/Bev in CPS 7 patients and to identify specific subgroups within CPS 7 that may benefit from this treatment. **Methods:** This study included patients with advanced HCC who received Ate/Bev as first-line therapy between September 2020 and December 2023 at six university hospitals. The primary outcome was overall survival (OS), while secondary outcomes included progression-free survival (PFS) and treatment response. Within the CPS 7 group, patients were further subdivided into two groups based on the survival risk distribution of CPS variables. **Results:** Among the 374 included patients, those with CPS 5 (n = 169) demonstrated the highest OS and PFS, followed by patients with CPS 6 (n = 105) and CPS 7 (n = 100) ($P < 0.05$). For the variables comprising CPS, the hazard ratio (HR) for OS increased with elevated total bilirubin (TB) levels and was lower in patients with moderate or severe ascites ($P < 0.05$). Regarding albumin levels, the HR for OS tended to decrease as albumin levels dropped to 2.8 g/dL. Based on these findings, CPS 7 patients were further classified into two subgroups: favorable (TB < 2 mg/dL, $3.5 >$ Alb ≥ 2.8 g/dL, mild ascites, and absence of hepatic encephalopathy) and unfavorable (other CPS 7). Compared to patients with CPS 6, those in the favorable CPS 7 group exhibited similar OS and PFS, while unfavorable CPS 7 patients had significantly lower OS and PFS ($P < 0.05$, Figure A and B). Moreover, the favorable CPS7 group demonstrated higher treatment response compared to the unfavorable CPS7 group. Multivariate analysis identified unfavorable CPS 7 as a significant risk factor for both OS and PFS ($P < 0.01$). **Conclusion:** This study suggests that Ate/Bev treatment can be effective in favorable CPS 7 patients, highlighting the potential to broaden treatment eligibility for this population.

3138 | DEVELOPMENT AND VALIDATION OF A RISK PREDICTION MODEL FOR PATIENTS WITH HEPATOCELLULAR CARCINOMA RECEIVING ATEZOLIZUMAB-BEVACIZUMAB

Heechul Nam[1] Dong Yun Kim[2] Sung Won Lee[1] Do Young Kim[3] Jeong Won Jang[1], [1]The Catholic University of Korea, [2]Yonsei University, [3]Yonsei University College of Medicine

Background: Atezolizumab plus bevacizumab (AB) has become the standard first-line treatment for advanced hepatocellular carcinoma (HCC). However, identifying reliable prognostic biomarkers remains a critical challenge. We aimed to develop a comprehensive scoring system to predict overall survival (OS) in advanced HCC patients receiving first-line AB. **Methods:** We established inception cohorts consisting of consecutive HCC patients who were undergoing AB treatment. The derivation cohort was constructed in a retrospective multicenter manner, including patients from seven academic hospitals of the Catholic University of Korea between September 2020 and July 2024. For validation, we used a retrospective single-center cohort from Severance Hospital, Korea, spanning October 2020 to December 2023. **Results:** We included patients with advanced HCC receiving first-line (AB) from multiple centers in Korea, forming a derivation cohort (n = 456) and a validation cohort (n = 205). Multivariable analysis identified five independent prognostic factors: C-reactive protein ≥ 1.0 mg/dL (hazard ratio [HR] 2.06; p < 0.001), albumin < 3.5 g/dL (HR 1.60; p = 0.002), protein induced by vitamin K absence or antagonist-II ≥ 1,500 mAU/mL (HR 1.60; p = 0.002), total bilirubin ≥ 1.0 mg/dL (HR 1.50; p = 0.006), and macrovascular invasion (HR 1.48; p = 0.009). We developed the CRAPT-M model named after these factors' initial letters. Patients were categorized into low (≤ 4), intermediate (5-12), and high (≥ 13) risk groups by CRAPT-M score. Median OS differed significantly: 22.4 (95% CI, 18.6-25.0), 12.9 (95% CI, 8.7–14.8), and 6.7 (95% CI, 5.1–7.7) months for low-, intermediate-, and high-risk groups, respectively (p < 0.001). Time-dependent area under the receiver operating characteristic for CRAPT-M demonstrated consistently higher predictive accuracy than the CRAFITY model, with values of 0.785, 0.737, and 0.742 at 12, 24, and 36 months, respectively. The model demonstrated robust predictive performance in external validation cohort, with excellent calibration and consistent discrimination across sensitivity analyses. **Conclusion:** The CRAPT-M model demonstrated robust OS prediction, offering a valuable tool for prognosis estimation and clinical decision-making in advanced HCC patients receiving AB.

3139 | POLY(I:C) COULD BE AN EFFICIENT CANCER ADJUVANT FOR IMMUNOTHERAPY IN HEPATOCELLULAR CARCINOMA BY ACTIVATING CYTOTOXIC CD8+ T CELLS

yichun ji[1] Yanting Wang[2] Nicholas Webster[3] Gensheng Feng[3], [1]Department of Medicine, University of California San Diego, [2]the Second Affiliated Hospital of Zhejiang University School of Medicine, [3]University of California, San Diego

Background: Immune checkpoint inhibitors combined with antiangiogenic therapy has become the standard of care for advanced hepatocellular carcinoma, albeit with limited therapeutic benefit. Our previous studies demonstrated the immunomodulatory and antitumor effects of polyIC, a synthetic double-stranded RNA. Here, we compared the efficacy of anti-programmed death ligand 1 (αPD-L1) plus polyIC versus αPD-L1 plus anti-vascular endothelial growth factor (αVEGF) in primary and metastasized liver tumor models. **Methods:** We established a primary liver tumor model using hydrodynamic tail vein injection of Ras/Myc oncogenes and metastasized model via intrasplenic injection of colon cancer cells. Flow cytometry and gene expression analysis were performed to assess immune profiles across treatment groups. Key factors contributing to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

antitumor efficacy were explored. **Results:** In both models, αPD-L1 plus polyIC demonstrated superior antitumor effects relative to αPD-L1 plus αVEGF. Unlike αVEGF, polyIC enhanced the immune response to αPD-L1 by increasing T cell infiltration, T effector memory CD8+ T cells, CD8+ to CD4+ T cell ratios, and CD8+ T cell function. This combination also promoted apoptosis in tumors and accumulation of conventional dendritic cells and invariant Natural Killer T cells. Additionally, αPD-L1 plus polyIC treatment led to upregulation of cytokines and chemokines, with CCL5 blockade partially reducing CD8+ to CD4+ T cell ratios and attenuating polyIC-driven antitumor effects. **Conclusion:** This preclinical study identifies polyIC as a better enhancer of αPD-L1 efficacy than αVEGF in liver cancer, providing a novel strategy for improving immunotherapy outcomes. Further clinical investigation is warranted.

3140 | NON-ADHERENCE TO SURVEILLANCE PROTOCOL OF HEPATOCELLULAR CANCER IN PATIENTS WITH LIVER CIRRHOSIS: PREVALENCE AND REASONS

Vaibhav Padole[1] Arun Vaidya[1] Akash Shukla[1], [1]Seth GS Medical College & KEM Hospital

Background: Surveillance for hepatocellular carcinoma (HCC) in cirrhosis is recommended. There is paucity of data regarding adherence to the surveillance protocols. We conducted this study to assess the adherence to HCC surveillance protocol (6monthly alfa-feta protein [AFP] and ultrasound [USG]) and determine factors responsible for non-adherence. **Methods:** We collected data of 3 year follow-up of consecutive adult patients with liver cirrhosis from a prospectively maintained database with regards to adherence to the HCC . Patients with pre-existing liver lesions and incomplete medical records were excluded. Factors leading to non-adherence were enquired during each visit. **Results:** Out of 945 patients screened, 800 patients (649 males; mean age 47.7 years) were included. The etiology of cirrhosis was alcohol- related liver disease[380(47.6 %)], chronic hepatitis B seen [139(17.4%)], metabolic dysfunction associated steatotic liver disease [98 (12.3%)] and chronic hepatitis C [92(11.5%)] . Only 73/800(9.1%) patients were completely adherent to protocol. Additionally, 346 (47.5%) patients were compliant to six- monthly ultrasound abdomen but not with serum AFP testing. The factors leading to non-adherence are enumerated in Table 1. Lack of advice by the treating doctor was the commonest cause for non-adherence to HCC surveillance (almost one-fourth of patients). **Conclusion:** Only a small minority adhere to the HCC surveillance protocol. The most common cause for non-adherence to HCC surveillance was lack of advice by treating doctor for surveillance, followed by lack of access to surveillance tools.

Table 1: Factors leading to non-adherence to HCC surveillance protocol

Factors	Number and proportion of patients with non-adherence (total 727 patients)
Serum AFP or ultrasound not advised by treating doctor	189 (26%)
Living in remote area with no nearby access	115 (15.8%)
Was unwell at the time of visit for the HCC surveillance	70 (9.6%)
Financial constraints	128 (17.6%)
Felt that they were better and need not follow-up	90 (12.3 %)
Radiology appointment delay	56 (7.7%)
Could not specify the reason	42 (5.7%)
More than one risk factor	37 (5.1%)

3141 | COMBINED TEAD AND RAS INHIBITOR THERAPY ACHIEVES LONG-TERM SURVIVAL IN KRAS-MUTANT CHOLANGIOCARCINOMA

Qiuyan Sun[1] Dhruv Goyal[1] Sheila Gonzalez Ramos[1] Robert Schwabe[1], [1]Columbia University

Background: Despite an expanding arsenal of FDA-approved therapies for the treatment of cholangiocarcinoma (CCA), including chemotherapy +/- immunotherapy and targeted therapies, 5-year survival remains below 7-20%. Here, we sought to uncover novel therapeutic vulnerabilities in CCA and synergistic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

combination treatments. **Methods:** Expression of transcriptional regulators and druggable targets was analyzed by bulk RNA-seq in mouse models of CCA and the TCGA and Fu-iCCA cohorts, and validated by scRNA-seq in 14 patients. *In vivo* CRISPR interference (CRISPRi) and pharmacologic panTEAD inhibitors (panTEADi) VT104 and IAG933 were used to functionally study the role of TEADs in CCA growth in the $KRAS^{G12D}$+$p19^{CRISPR}$, FBXW7delF+AKT and NICD +AKT models. RAS inhibition (RASi) was achieved using $KRAS^{G12D}$ inhibitor MRTX1133 and panRAS inhibitors RMC-7977 and RMC-6236. Drug synergies were evaluated in primary CCA cell lines and in $KRAS^{G12D}$+$p19^{CRISPR}$ model. **Results:** Bulk and scRNA-seq analysis in mouse CCA models, the TCGA and Fu-iCCA cohorts and human scRNA-seq data revealed a consistent upregulation of YAP/TAZ/TEAD pathway members. Tumor cell-specific CRISPRi of each of the four TEAD paralogs significantly reduced tumor burden and extended survival in mouse models of CCA, suggesting YAP/TAZ/TEAD as a novel therapeutic target. Pharmacologic panTEADi suppressed YAP target gene expression, altered tumor transcriptomic profiles, impaired proliferation, and improved survival across three distinct mouse models, including KRAS-driven CCA. Based on the high prevalence of KRAS mutations in CCA, we next evaluated the therapeutic potential of combined panTEADi and RASi treatment. VT104 or IAG933 plus $KRAS^{G12D}$-specific inhibitor MTRX1133 or panRAS inhibitors RMC-7977 and RMC-6236 blocked compensatory YAP/TAZ pathway activation, achieved strong synergies *in vitro* and extended median survival from 2.3 weeks to 9.7 weeks (VT104 + MRTX1133, $p < 0.0001$) and 14.4 weeks (VT104 + RMC7977, $p < 0.0001$) in $KRAS^{G12D}$-driven CCA. However, prolonged dual therapy induced resistance and the emergence of drug-tolerant persister cells, stromal remodeling, and treatment failure. Mechanistic analysis implicated the contribution of epithelial-mesenchymal transition (EMT) in tumor cells and enhanced fibroblast activation and extracellular matrix deposition in the TME in the development of resistance, which can be partially reversed by targeting cancer-associated fibroblasts (CAFs). **Conclusion:** Collectively, our study identified TEAD and RAS signaling as convergent and druggable vulnerabilities that can be targeted to prolong CCA survival and delay the development of resistance.

3142 | HORMONE-REPLACEMENT THERAPY REDUCES THE RISK OF HEPATOCELLULAR CARCINOMA AND SLOWS CHRONIC LIVER-DISEASE PROGRESSION IN POST-MENOPAUSAL WOMEN: A PROPENSITY-MATCHED TRINETX ANALYSIS

Prabhat Kumar[1] Archana Kharel[2] Michael Eiswerth[1] Vinay Jahagirdar[1] Hasan Alroobi[1] umesh bhagat[2] Gowthami Kanagalingam[1] Scott Matherly[1], [1]Virginia Commonwealth University, [2]Cleveland Clinic Foundation

Background: Estrogen has antifibrotic and antitumor properties in experimental liver models, yet population-level data on its clinical impact remain limited. We assessed whether hormone-replacement therapy (HRT) has a role in reducing the risk of development of hepatocellular carcinoma (HCC) and the development of chronic liver disease (CLD) in women without pre-existing liver disorders. **Methods:** We queried the cloud-based TriNetX Research Network (> 100 U.S. and international health-care systems) for women ≥ 50 years without chronic liver disease ICD-10 codes K70–K76 (database inception–May 2025). Exposure was systemic hormone-replacement therapy (HRT: estradiol or conjugated estrogens). Women with prior hepatocellular carcinoma (HCC; C22.0), liver transplantation (Z94.4), or unspecified primary malignancy (C80.1) before index were excluded. Greedy 1:1 propensity-score matching (caliper 0.01) balanced age, race, body-mass index, digestive-system disorders, and endocrine/metabolic comorbidities, yielding two cohorts of 203,726 each (standardized differences < 0.01). Follow-up began one day post-index and continued until outcome, death, or end of data. Primary outcomes were (i) incident HCC and (ii) incident/progressive chronic liver disease (fatty liver, NASH, or cirrhosis newly coded). Absolute risk, risk difference (RD), risk ratio (RR), Kaplan–Meier curves, and Cox hazard ratios (HR) were calculated. **Results:** After matching, the median age was 63 years with identical racial and BMI distributions. HCC developed in 2,632 non-HRT women (1.29 %) versus 1,853 HRT users (0.91 %), yielding an RD = -0.38 %, RR 1.42 (non-HRT vs. HRT; 95 % CI 1.34-1.51), and HR 1.48 (1.40-1.57; log-rank $p < 0.001$). Chronic liver disease progression occurred in 68,796 non-HRT patients (33.8 %) vs. 62,570 HRT patients (30.7 %): RD = -3.1 %, RR 1.10 (1.09-1.11), and HR 1.19 (1.18-1.20; log-rank $p < 0.001$). Median time to CLD was delayed by > 2,500 days with HRT (6,646 vs. 4,114). Survival

probabilities at study end were consistently higher among estrogen users for both endpoints. **Conclusion:** In a large real-world cohort of women without underlying liver disease, estrogen therapy was associated with a 40 % relative reduction in HCC incidence and a 10 % relative reduction—and marked delay—in CLD progression after rigorous confounder adjustment. These findings suggest a hepatoprotective role for HRT and support prospective trials to clarify causality and inform clinical decision-making for post-menopausal women at risk for liver malignancy and fibrosis.

Table 1. Outcomes for incidence of hepatocellular carcinoma (HCC) in post-menopausal women after 1:1 propensity-score matching.

Cohort	Patients in Cohort	Patients with Outcome	Risk	
Without HRT	203,726	2,632	0.013	
With HRT	203,726	1,853	0.009	
Statistical Analysis:				
Measure	Value	95% Confidence Interval	z-value	p-value
Risk Difference	0.004	(0.003, 0.004)	11.697	<0.001
Risk Ratio	1.42	(1.339, 1.507)	N/A	N/A
Odds Ratio	1.426	(1.343, 1.514)	N/A	N/A

Table 2. Survival analysis for incidence of chronic liver disease (CLD) in post-menopausal women after 1:1 propensity-score matching.

Cohort	Patients in Cohort	Patients with Outcome	Median Survival (days)	Survival Probability (%)	
Without HRT	203,726	68,796	4,114	42.71%	
With HRT	203,726	62,570	6,646	49.70%	
Statistical Analysis:					
Test	HR	CI	Chi-square (χ^2)	df	p-value
Log-Rank Test			968.913	1	<0.001
Hazard Ratio	1.187	95% CI (1.175 - 1.200)	χ^2 = 12.401	1	<0.001

3143 | EXTRATUMORAL HSC-DERIVED CXCL12 PROMOTES LIVER METASTASIS IN MASLD THROUGH THE CXCR4/YAP AXIS AND IMMUNE-FIBROTIC REMODELING

Jieun Kim[1] So Yeon Kim[1] Mustafa Karabicici[1] Ekihiro Seki[1], [1]Cedars-Sinai Medical Center

Background: Liver metastasis is a major determinant of poor prognosis in patients with colorectal cancer (CRC) and pancreatic ductal adenocarcinoma (PDAC). MASLD significantly increases the risk of liver metastasis, yet the underlying mechanisms are not fully understood. We previously showed that intratumoral hepatic stellate cells (HSCs) or cancer-associated fibroblasts (CAFs) in steatotic livers promote metastasis in metabolic dysfunction-associated steatotic liver disease (MASLD) by mediating intercellular communication within the tumor microenvironment (TME). However, the role of extratumoral HSCs in MASLD-related liver metastasis remains unclear. Here, we hypothesized that CXCL12 secreted by extratumoral HSCs recruits and activates cancer cells, CAFs, and immune cells through the CXCL12/CXCR4/YAP axis, establishing a pro-metastatic niche. **Methods:** To model MASLD-associated liver metastasis, mice were fed either a low-fat or high-fat diet (HFD) for 6 weeks, followed by splenic injection of MC38 CRC or Pan02 PDAC cells, and monitored for two additional weeks. **Results:** HFD-fed mice developed more liver metastases and higher CXCL12 expression in HSCs. CXCL12+ HSCs were primarily found in extratumoral, non-tumor liver areas and did not produce collagen, whereas intratumoral HSCs produced collagen but expressed little CXCL12. This spatial distinction suggests that extratumoral HSCs initiate a chemotactic niche via CXCL12, while intratumoral HSCs contribute to fibrosis. In HSC-specific CXCL12-deleted mice, metastatic tumor growth, CAF activation, and collagen deposition were reduced. Mechanistically, we identified HIF-1α as a transcriptional regulator of CXCL12 in HSCs. Deleting HIF-1α in HSCs downregulated CXCL12 and suppressed metastasis in MASLD. Steatotic liver also enhanced collagen deposition and CXCR4, YAP, CD44, and osteopontin (OPN) expression in tumor areas. In 3D spheroid cultures, collagen-rich matrices induced CXCR4 and YAP expression in cancer cells, but this effect was abolished by CXCR4 deletion, indicating that CXCR4/YAP axis is critical for tumor growth in the fibrotic TME. Our scRNA-seq analysis further revealed that M2 macrophages in steatotic livers highly express CXCR4, CD44, and PD-L1, and interact with PD1+ exhausted CD8 T cells. In addition, activated CAFs express OPN and interact with CD44+ M2 macrophages and cancer cells in the fibrotic TME. These interactions are enriched in steatotic livers and contribute to an immunosuppressive TME in steatotic livers. **Conclusion:** In conclusion, CXCL12 from extratumoral HSCs orchestrates the recruitment and activation of cancer cells, CAFs, and immune cells, thereby reshaping the TME through CXCR4/YAP axis in MASLD-associated liver metastasis.

3144 | ACCURATE DIAGNOSIS OF HEPATOCELLULAR CARCINOMA WITH A HIGH-THROUGHPUT TEST FOR PLASMA DNA METHYLATION SIGNATURES

Rex Wan-Hin Hui[1] Ho-Ming Cheng[1] Sharon Luk[2] Kai Yeung Martin Leung[1] Lung Yi Mak[1] Man-Fung Yuen[1] Moshe Szyf[2] Tan-To Cheung[1] Wai-Kay Seto[1], [1]The University of Hong Kong, [2]HKG Epitherapeutics Limited

Background: Early diagnosis of hepatocellular carcinoma (HCC) is often challenging due to the limited accuracy of current biomarkers. DNA methylation signatures may enable differentiation of HCC and non-HCC DNA in plasma, which in turn facilitates noninvasive and accurate HCC detection. **Methods:** Consecutive patients with HCC referred to a tertiary surgical unit for management were prospectively recruited. Healthy controls were also recruited for comparison. Plasma samples were taken from all subjects and analyzed with the epiLiver test, which is a validated high-throughput test for detection of DNA methylation signatures. The epiLiver test assesses four CpG markers in cg02012576, cg03768777, cg05739190, and cg24804544 of the CHFR, VASH2, CCNJ, and GRID2IP gene respectively. **Results:** This exploratory analysis included 86 patients (61 HCC patients and 25 healthy controls, mean age 57.5 +/- 17.9, 72.1% male). Among the HCC patients, 56 patients (91.8%) had chronic hepatitis B and 32 patients (52.5%) had cirrhosis. The Barcelona Clinic Liver Cancer (BCLC) staging was BCLC-0, BCLC-A, BCLC-B, and BCLC-C in 15 (24.6%), 39 (63.9%), 3 (4.9%), and 4 (6.6%) of patients respectively. The epiLiver test achieved area under curve of 0.861 for diagnosing HCC (Specificity 100%, sensitivity 72.1%, positive predictive value 100%, negative predictive value 59.5%). All healthy controls had negative results. The epiLiver test had excellent performance in patients with higher HCC and liver disease burden, as it accurately identified HCC in 87.5% of patients with cirrhosis, 85.7% of patients with BCLC-B or BCLC-C staging, 84.2% of patients with alpha fetoprotein $\geq$ 20 ng/ml, and 80.6% of patients with dominant HCC lesion $\geq$ 3 cm respectively. **Conclusion:** Our high-throughput test for plasma DNA methylation signatures accurately diagnosed HCC with high specificity. This technology has potential as a confirmatory test, and its role in HCC prognostication should be further explored.

Background: Antiviral treatment is associated with improved survival and cancer recurrence in viral HCC patients, but treatment rate data is limited. We aimed to assess the utilization rates of antiviral treatment in HBV patients with either HBV or HCV. **Methods:** We conducted a multicenter real-world study of adult HCC patients with either HBV or HCV from 16 centers across

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

7 countries/regions. The primary study outcomes were the treatment rates with either nucleos(t)ide analogs (NAs) at any time in HBV-HCC patients or direct acting antivirals (DAAs) at/or after HCC diagnosis in HCV-HCC patients. **Results:** We analyzed 3883 HCC patients: 3186 with HBV and 647 with HCV. Overall, half (49.7%) of HCC patients with HBV and two-third (63.2%) of those with HCV received antiviral treatment, with marked variations among the subgroups for both the HBV and HCV groups **(Figure 1)**. For HBV patients, NA treatment rates were lower in those who were female (41.7 vs. 51.8%), older than 60 (45.3 vs. 54.5%), without cirrhosis (41.2 vs. 56.8%) and from Asia (37.9 vs. 85.0%), all $P < 0.001$, while among HCV patients, DAA treatment rates were lower in patients who were male (59.0 vs. 72.4%), without cirrhosis (60.5 vs. 73.2%) and from non-Asia regions (58.2 vs. 69.9%), all $P < 0.005$. Child C (vs. A and B) cirrhosis also patients had lower antiviral treatment rates for both NA (78.6 vs. 48.3 vs. 43.8%) and DAA (68.2 vs. 53.3 vs. 38.6%), while early BCLC stage (0/A vs. B vs. C vs. D) patients had higher rates for both NA (59.9 vs. 50.9 vs. 36.7 vs. 41.0%) and DAA (72.5 vs. 53.3 vs. 51.9 vs. 30.2%), respectively, all $P < 0.001$. In multivariable regressions, factors associated with lower NA treatment rate were female sex [adjusted odds ratio (aOR) = 1.59 for male vs. female], age > 60 (aOR = 0.63), Asia (vs the U.S) such as Taiwan (aOR 0.11) and Japan (aOR 0.49), and noncirrhosis (aOR = 1.62 for Child A and 1.36 for Child B vs. noncirrhosis) for HBV (all $P < 0.05$), and included male sex (aOR 0.62), age > 65 (aOR 0.65), and Child B (aOR = 0.46) or C (aOR 0.35) for HCV (all $P < 0.05$). BCLC stage B or C (vs. 0/A) were associated with lower treatment rate in both HBV (aOR = 0.76, 0.58) and HCV (aOR = 0.57, 0.53), respectively (all $P < 0.05$). **Conclusion:** In this global study of HCC patients, only 50% of HBV and 60% of HCV patients received antiviral treatment, with multiple age, sex, and region-specific disparities, often in opposite directions between HBV and HCV patients. Treatment rates were especially poor in those who may benefit the most such as those with more advanced liver disease or HCC stage.

3146 | A PROSPECTIVE STUDY OF CYTOLOGY, FISH, AND METHYLATED DNA MARKERS IN BILE AND BILIARY LAVAGE FOR PANCREATOBILIARY CANCER DETECTION

Shuji Mitsuhashi[1] Chinmay Guralwar[1] Qiliang Ding[1] Emily Barr Fritcher[1] Manik Aggarwal[1] Khushboo Gala[1] Rishad Khan[1] Eric Vargas[1] Ryan Law[1] John Martin[1] Bret Petersen[1] Samuel Han[1] Jad AbiMansour[1] Andrew Storm[1] Gregory Gores[1] Lewis Roberts[1] Benjamin Kipp[1] Vinay Chandrasekhara[1], [1]Mayo Clinic Rochester

Background: Early diagnosis of pancreatobiliary (PB) malignancies remains challenging due to the limited sensitivity of current methods. While ERCP-based brush cytology and fluorescence *in situ* hybridization (FISH) improve diagnostic yield in biliary strictures, overall performance remains suboptimal. Post-brushing biliary lavage may enhance detection by capturing residual tumor material dislodged during diagnostic maneuvers. This study evaluated whether methylated DNA markers (MDMs) in bile and/or post-brushing lavage fluid improve diagnostic accuracy. **Methods:** This prospective single-center study included patients undergoing ERCP-guided sampling for biliary strictures between 2023 and 2024. Samples were obtained via bile aspiration before brushing (Bile-MDMs), brush cytology with FISH, and post-brushing biliary lavage and aspiration (Lavage-MDMs) (Figure 1). Positive cytology was defined as “suspicious” or “malignancy”. Previously identified MDM panel (TWIST1, HOXA1, CLEC11A, VSTM2B) was analyzed using methylation-specific droplet digital PCR. Malignancy was defined by histopathology or by meeting institutional clinical criteria. Benign cases were confirmed by negative surgical pathology and $\geq$6 months of follow-up. **Results:** Of 51 patients, 16 (31.0%) were diagnosed with malignancy: 10 cholangiocarcinoma (CCA), 2 pancreatic adenocarcinoma, 3 periampullary adenocarcinoma, and 1 gallbladder adenocarcinoma. 22 (43.1%) had primary sclerosing cholangitis, of whom 19 had benign disease and 3 were diagnosed with CCA. The diagnostic sensitivities of individual tests were as follows: brush cytology 50.0%, polysomy FISH 68.8%, Bile-MDMs 46.7%, and Lavage-MDMs 66.7%. Combining brush cytology and/or polysomy FISH improved sensitivity to 81.3%. While Lavage-MDMs demonstrated higher standalone sensitivity compared to Bile-MDMs, both assays provided comparable additive diagnostic value when used alongside cytology and FISH. The highest diagnostic performance was achieved when all modalities were combined, yielding a sensitivity 93.8%, specificity 77.1%, positive predictive value 65.2%, and negative predictive value 96.6%. Sample acquisition was successful in all patients, and no adverse events were observed. **Conclusion:** Post-brushing biliary lavage enhances MDM sensitivity compared to pre-brushing bile samples. When combined with cytology and FISH, both contribute similarly to a safe, and high-yield strategy for enhancing the diagnosis of PB malignancy during ERCP.

	Sensitivity	(95% CI)	Specificity	(95% CI)	PPV (95% CI)		NPV (95% CI)	
Cytology	50.0%	(36.3-63.7%)	100.0%	(100.0-100.0%)	100.0%	(100.0-100.0%)	81.4%	(70.7-92.1%)

3147 | REAL-WORLD INSIGHTS INTO THE TREATMENT LANDSCAPE OF HEPATOCELLULAR CARCINOMA AND ITS ADHERENCE WITH GUIDELINE RECOMMENDATIONS: A 5-YEAR NATIONWIDE PROSPECTIVE STUDY IN THE NETHERLANDS

Coosje Verhagen[1] Jochem Grossouw[1] Danny van der Helm[1] Jose Willemse[2] Jeffrey Braak[1] Sorina de Jonge[1] M. Kater[3] Simeon Ruiter[3] F van Vilsteren[3] Judith de Vos-Geelen[4] Matthijs Kramer[4] Christiaan van der Leij[5] Ijsbrand Zijlstra[6] Otto van Delden[6] Bart Takkenberg[7] Dewkoemar Ramsoekh[6] Heinz Josef Klumpen[6] J de Bruijne[8] Maarten Smits[8] Merve Rousian[9] Pam van der Meeren[9] Kevin Wiese[9] Dave Sprengers[9] Bas Groot Koerkamp[9] Roeland de Wilde[9] Mark Burgmans[10] Minneke Coenraad[11], [1]Leiden Univeristy Medical Centre (LUMC), [2]Nederlandse Leverpatienten Vereniging, [3]University Medical Centre Groningen (UMCG), [4]Maastricht University Medical Centre, [5]Maastricht University Medical Centre (MUMC), [6]Amsterdam University Medical Centre (AUMC), [7]Amsterdam University Medical Centers, location AMC, [8]Utrecht University Medical Centre (UMCU), [9]Erasmus University Medical Centre (EMC), [10]m.c.burgmans@lumc.nl, [11]Leiden University Medical Center

Background: Dutch guidelines for hepatocellular carcinoma (HCC) are based on the European Association for the Study of the Liver (EASL) guidelines, with the version of 2018 as the leading reference during this study period. As new treatment options have emerged, the therapeutic landscape has evolved. This study aimed to assess the extent to which first-line treatments aligned with the EASL guidelines in a real-world national patient cohort. Secondary aim was to provide insight into underlying liver diseases. **Methods:** This prospective nationwide cohort study enrolled treatment-naïve HCC patients ($\geq$18 years) from 2019–2024 across six Dutch tertiary centers, with a 12-month follow-up. Staging was in accordance to the Barcelona Clinic Liver Cancer (BCLC) classification system. Data on patient demographics, tumor stage, presence of cirrhosis, treatments provided and outcome were systematically collected. **Results:** 621 patients (79.0% male, median age 71 years) received 775 oncological treatments. BCLC stage distribution at diagnosis was: 11.3% BCLC-0, 51.7% BCLC-A, 13.7% BCLC-B, 18.4% BCLC-C, 3.9% BCLC-D, and 1.1% missing data. 59.4% received a single treatment, 28.3% two treatments, and 12.5% underwent more than two treatments. First line treatment guidelines adherence was 44.1%, with the greatest treatment heterogeneity in BCLC-C patients. The highest therapeutic stage migration rate was in BCLC-D patients, with 45.8% treated according to left-sided stage migration. For comparative analysis, adherence was also assessed based on the updated 2025 EASL guidelines. An increase in adherence and a concurrent decline in the use of treatment techniques not endorsed by the guidelines were observed across all stages, except for BCLC-D. In this context, the average guideline adherence rate would have been 63.9%. Cirrhosis was present in 65% of the patients, alcoholic liver disease was the main etiology for this (31.1%). Among patients without cirrhosis, metabolic dysfunction-associated steatotic liver disease was the main etiology (37.9%). One-year transplantation-free overall survival rates were 95.6% (BCLC-0), 91.2% (BCLC-A), 81.6% (BCLC-B), 70.1% (BCLC-C), and 66.8% (BCLC-D). Sensitivity analysis, accounting for patients censored due to best supportive care, showed one-year overall survival rates of 94.8% (BCLC-0), 84.5% (BCLC-A), 72.5% (BCLC-B), 43.9% (BCLC-C), and 31.9% (BCLC-D). **Conclusion:** In this real-world national cohort, first line treatment adhered to guidelines in less than half of the newly diagnosed patients with HCC, with particularly low adherence in patients with BCLC-C HCC. The wide range of therapies across all BCLC stages at initial and subsequent treatment sessions, resulted in favorable short-term outcomes, highlighting a shift towards personalized treatment strategies. Over half of the patients was diagnosed at an early disease stage, indicating a shift towards earlier diagnosis.

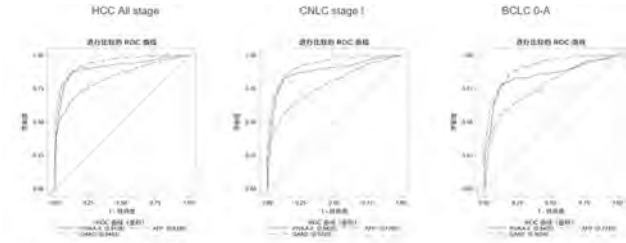
3148 | MULTI-CENTER VALIDATION OF ELECSYS GAAD DIGITAL ALGORITHM PERFORMANCE IN CHINESE POPULATION

Yujuan Guan[1] Ao Zhang[2] Changmin Wang[3] Yifan Han[4] Qi Zhang[5] Yihua Sun[6] Aiqi Lu[1] Shuli Guo[3] Cheng Chen[3] Yuemeng Li[5] Danni Mu[5] Song Gao[7] Wanli Liu[2] Xiaoyuan Xu[4], [1]Guangzhou Eighth People's Hospital, Guangzhou Medical University, Guangzho, [2]Guangdong Provincial Clinical Research Center for Cancer, Sun Yat-sen University Cancer Center, [3]People's Hospital of Xinjiang Uygur Autonomous Region, China, [4]Peking University First Hospital, Beijing, China, [5]Peking Union Medical College Hospital, Peking Union Medical College, [6]Affiliated Cancer Hospital of Harbin Medical University, China, [7]Affiliated Cancer Hospital of Harbin Medical University, Harbin, China

Background: The Elecsys GAAD algorithm digitally integrates age, gender, AFP, and DCP to yield a semi-quantitative result for hepatocellular carcinoma (HCC) diagnosis. While the performance of GAAD has been documented in Caucasian and Asian populations, its effectiveness in the Chinese population is yet to be determined. This study intends to assess the Elecsys GAAD algorithm's performance specifically within the Chinese population. **Methods:** This retrospective study included patients with clinically confirmed chronic liver disease (CLD) or hepatocellular carcinoma (HCC) who underwent the Elecsys AFP/PIVKA-II test across research sites. Data collected for all participants included their Child-Pugh level. For HCC patients, the number and size of tumors were recorded to confirm their Barcelona Clinic Liver Cancer (BCLC) and China Liver Cancer (CNLC) stages. The Elecsys GAAD score was calculated using patients' baseline data. The study aims to validate the diagnostic performance of AFP/PIVKA-II and the Elecsys GAAD algorithm for HCC. **Results:** A multi-center study from June 2023 to March 2025 involving 1616 patients (779 with hepatocellular carcinoma [HCC] and 837 with chronic liver disease [CLD], of whom 76.05% were HBV-positive and 7.12% were HCV-positive, 4.27% ALD, 7.12% MAFLD and 11.94% other cause of CLD/HCC validated the performance of the Elecsys GAAD digital algorithm in a Chinese population. Using a cut-off of 2.57, the GAAD test achieved 82.93% sensitivity, 90.32% specificity, and 86.76% accuracy, with an area under the curve (AUC) of 94.43%. In comparison, AFP (at a 20ng/ml cut-off) showed 57.51% sensitivity, 92.23% specificity, 75.50% accuracy, and an AUC of 83.36%. PIVKA-II (at a 21.29ng/ml cut-off) demonstrated 88.45% sensitivity, 82.08% specificity, 85.15% accuracy, and an AUC of 91.08%. The Delong test indicated that GAAD had a statistically significant performance advantage ($p < 0.001$) of 3.35% over PIVKA-II and 11.08% over AFP. In CNLC HCC stage I and BCLC 0-A populations, GAAD achieved AUCs of 92.59% and 90.56%, respectively, also showing statistically significant performance advantages over individual tumor markers. **Conclusion:** This study indicates that Elecsys GAAD demonstrates superior analytical performance compared to using tumor markers independently.



AUCs comparison Delong test

3149 | PATIENTS WITH CIRRHOSIS LIVING IN RURAL AREAS ARE LESS LIKELY TO RECEIVE HEPATOCELLULAR CARCINOMA SURVEILLANCE: A POPULATION-BASED STUDY INVOLVING 43,207 PATIENTS WITH CIRRHOSIS

Paul Karre[1] Christine Hsu[2] Louise Henderson[1] Bradford Jackson[1] Christopher Baggett[1] Michele Jonsson-Funk[1] Andrew Olshan[1] Parul Gupta[1] A. Sidney Barritt[1] Hanna Sanoff[1] Stephanie Wheeler[1] Jennifer Lund[1] Andrew Moon[1], [1]University of North Carolina, [2]University of Texas Medical Branch

Background: Cirrhosis is the leading risk factor for hepatocellular carcinoma (HCC), and semi-annual

surveillance improves stage at diagnosis and overall survival. HCC mortality rates are increasing at a higher rate for rural populations, suggesting disparities in screening access and utilization. **Methods:** We conducted a retrospective cohort study of patients with cirrhosis using claims data from NC Medicare, NC Medicaid, and private insurers. Patients were included if they were >17 years of age, had 12 months of continuous insurance coverage prior to diagnosis, and had at least two corresponding cirrhosis ICD-9/10 codes between 2004 and 2017. Rural versus urban residence was based on county-level Rural-Urban Continuum Codes. Our primary outcome was HCC surveillance (abdominal ultrasound, CT, or MRI) after cirrhosis diagnosis. Index date was defined as date of first cirrhosis diagnosis. We calculated the 2-year cumulative incidence of first HCC surveillance, with HCC diagnosis, liver transplant, and death as competing events, and stratified by level of rurality. We estimated unadjusted and adjusted subdistribution hazard ratios (sdHRs) using the Fine and Gray competing risks regression model. **Results:** Baseline characteristics for the patients included in this study are provided in Table 1. Among 43,207 patients with cirrhosis eligible for screening, 70% of patients lived in urban areas, 26% in rural adjacent to urban (RAU), and 4% in rural non-adjacent to urban (RNAU). The overall 2-year cumulative incidence of HCC surveillance was 54.7% (95% CI: 54.3-55.1%). When stratified by rurality level, the 2-year cumulative incidence was 55.2% (95% CI: 54.7-55.7%) for patients in urban areas, 54.0% (95% CI: 53.2-54.7%) for those in RAU, and 52.5% (95% CI: 50.6-54.4%) for those in RNAU. Univariable Fine and Gray regression results also showed that patients residing in rural areas were less likely to receive HCC surveillance within 2 years of cirrhosis diagnosis compared to their urban counterparts (sdHR: 0.97, 95% CI 0.94-0.99 for RAU; sdHR: 0.93, 95% CI 0.87-0.98 for RNAU). Moreover, rural patients remain less likely to receiving appropriate HCC surveillance compared to their urban counterparts after adjusting for age group, sex, etiology of liver disease, decompensated status, and Charlson Comorbidity Score (sdHR: 0.97, 95% CI 0.95-0.99 for RAU; sdHR: 0.94, 95% CI 0.88-0.99 for RNAU). **Conclusion:** In this statewide, population-based study, patients with cirrhosis living in rural areas were less likely to receive guideline-concordant HCC surveillance compared to those in urban areas. Disparities in surveillance access, in addition to other rural-health barriers, could be contributing to disproportionately increasing HCC mortality rates. Further research is necessary to elucidate which contributors most significantly impact rising mortality in rural populations.

Table 1: Baseline patient characteristics

	Overall	Urban	Rural Adjacent to Urban	Rural Non-Adjacent to Urban
Age (mean, std)	64.1 (13.44)	63.95 (13.33)	64.28 (13.2)	65.27 (13.33)

Tetsuo Takehara[3], [1]Osaka University, [2]Osaka University Graduate School of Medicine, [3]Kansai Rosai Hospital

Background: Combination therapy with atezolizumab and bevacizumab (Atez/Bev) has improved outcomes in unresectable hepatocellular carcinoma (uHCC), but significant responses are limited to a subset of patients. This study aimed to identify predictive biomarkers for Atez/Bev efficacy and explore the novel therapeutic targets, focusing on carbonic anhydrase 9 (CA9). **Methods:** Pre-treatment plasma samples were collected from 167 uHCC patients receiving Atez/Bev and divided into discovery (n = 78) and validation (n = 89) cohorts. In the discovery cohort, 92 cancer immunity-related proteins were profiled using high-sensitivity proteomics. Proteins significantly elevated in non-responders were identified as candidate markers. In the validation cohort, patients were stratified by candidate protein levels and evaluated for clinical outcomes. A CA9-overexpressing mouse HCC cell line was established and subcutaneously implanted in immunocompetent mice to assess the tumor immune microenvironment (TIME) using single-cell RNA sequencing. Functional assays using CA9 inhibitors were performed in vitro and in vivo. **Results:** Proteomic analysis revealed elevated CA9, IL-6, and IL-8 in non-responders. High CA9 levels were associated with significantly shorter progression-free survival (PFS) and overall survival (OS), supporting CA9 as a predictive biomarker. In the validation cohort, using a CA9 cutoff of 187.7 pg/mL from ROC curve, the high CA9 group showed a lower response rate (47.8% vs 74.4%, $p < 0.05$), shorter median PFS (3.0 vs 8.2 months, $p < 0.05$), and OS (11.3 vs 25.0 months, $p < 0.05$) compared to the low CA9 group. In the TIME analysis, CA9-overexpressing tumors displayed enhanced angiogenesis, increased M2 macrophages, and reduced cytotoxic T cells, indicating an immune-excluded phenotype. These tumors were less responsive to PD-L1 and VEGF antibodies. CA9 expression was induced under hypoxia in vitro, and CA9 inhibition suppressed tumor cell proliferation. In vivo, combining CA9 inhibition with PD-L1/VEGF therapy improved anti-tumor efficacy. **Conclusion:** CA9 is a predictive biomarker for Atez/Bev resistance in HCC and a potential therapeutic target contributing to an immune-suppressive tumor microenvironment.

3151 | BILE-DERIVED EXOSOMAL MIR-196A/-196B AS DIAGNOSTIC BIOMARKERS ASSOCIATED WITH TUMOR PROGRESSION IN BILIARY TRACT CANCE

Naotaka Kugiyama[1] Katsuya Nagaoka[1] Yasuhito Tanaka[1], [1]Kumamoto University

Background: Bile-based liquid biopsy presents a promising approach for identifying novel biomarkers for biliary tract cancer (BTC) given its proximity to tumor sites. The aim of this study was to identify bile-derived exosomal microRNAs (miRNAs) with diagnostic potential for BTC. **Methods:** Exosomal RNA was extracted from the bile samples of 10 BTC patients and 10 controls. The candidate miRNAs were screened by RNA sequencing, and validated in an independent cohort of 50 BTC patients and 53 controls using TaqMan PCR. The serum levels of miRNAs were analyzed in 64 BTC patients and 79 controls. Functional assays were performed to determine the effects of the miRNAs on cholangiocarcinoma cells. **Results:** MiR-196a, miR-196b, and miR-424 were identified as candidate biomarkers of BTC. Validation assays confirmed that miR-196a and miR-196b were significantly elevated in the bile samples of BTC patients, and miR-196a was also elevated in early-stage BTC patients. MiR-196a achieved an area under the receiver operating characteristic curve (AUROC) of 0.79 for the diagnosis of BTC. The combination of miR-196a and CA19-9 increased the AUROC to 0.86, and further improvement to 0.88 was observed upon the addition of CEA. Furthermore, serum miR-196a levels were significantly elevated in patients with metastatic BTC (3.0E-6 vs. limit of detection (LOD), $p = 0.02$). Functional assays demonstrated that miR-196a/-196b promoted the proliferation and invasion of cholangiocarcinoma cells ($p < 0.05$). **Conclusion:** Bile-derived exosomal miR-196a/-196b are novel BTC-specific biomarkers. MiR-196a may contribute to early BTC detection, enhance diagnostic accuracy in combination with serum markers, and detect metastasis.

3152 | NEXT-GENERATION PLASMONIC IMAGING PLATFORM FOR HEPATOCELLULAR CARCINOMA DETECTION

Mohammad Sadman Mallick[1] Kshipra Kapoor[1] Giovanni Duca[1] Guadalupe Cisneros[1] Saswat Mohapatra[2] Prasun Jalal[3] Matthew Clayton[1] Steven Lin[4] Wei-Chuan Shih[5], [1]Seek Diagnostics Inc., [2]University of Houston, [3]Baylor College of Medicine, [4]The University of Texas MD Anderson Cancer Center, [5]Seek Diagnostics Inc. & University of Houston

Background: Hepatocellular carcinoma (HCC), the most common primary liver cancer, remains a major health burden due to late diagnosis and limited screening tools. Current methods like ultrasound and Alpha-Fetoprotein (AFP) testing suffer from poor sensitivity and specificity, while advanced imaging and biopsies are invasive, costly, and prone to false negatives. This has led to growing interest in small extracellular vesicles (sEVs) as blood-based biomarkers. sEVs carry molecular cargo reflective of disease states, making them valuable for early cancer detection. However, their clinical utility is limited by challenges in detecting and characterizing them at the single-particle level. To address this, we developed PANORAMA (PlAsmonic NanO-apeRture lAbel-free iMAging), a label-free plasmonic imaging system using antibody-functionalized arrayed gold nanodisks on invisible substrate (AGNIS). The platform quantifies and sizes individual sEVs from just 20 μL of plasma. Previously, PANORAMA achieved 99.5% sensitivity and 97.3% specificity in distinguishing cancer patients (n = 205) from healthy controls (n = 106). In this study, we further enhanced the system with a molecular profiling module using 11 fluorescently labeled molecular beacons (MBs) and a protein probe for multiplexed detection of miRNAs and surface markers. **Methods:** PANORAMA is built on an Olympus IX83 inverted microscope with bandpass-filtered illumination. The AGNIS surface is functionalized with biotin-PEG-thiol, neutravidin, and antibodies (CD9, CD63, CD81) to capture sEVs. Fluorescence imaging detects target miRNAs via hybridization with MBs, triggering a conformational change that emits fluorescence. The overview of our technology is shown in Figure 1a. **Results:** Plasma from 76 participants (13 healthy, 21 liver disease, 42 cancer) was analyzed. PANORAMA sEV counts varied: healthy (156 ± 55), liver disease (370 ± 130), and cancer (458 ± 100) (Figure 1b). Using a 280 sEV cutoff, PANORAMA achieved 100% sensitivity but only 55% specificity due to elevated sEVs in non-cancer liver disease. To improve specificity, we profiled sEVs using 11 MBs and 1 surface protein, Annexin V. A five-miRNA panel (miR-126-3p, miR-222-3p, miR-31, miR-21, miR-221) showed no signal in healthy samples and selected liver disease cases, but positive in cancer samples with 90.8% sensitivity and 100% specificity (Figure 1c-f). Validation in 10 additional plasma samples showed 100% sensitivity and 83% specificity. A larger prospectively collected set of samples will be evaluated blinded, and these results will be reported at the meeting. **Conclusion:** In conclusion, our plasmonic imaging platform enables sensitive, specific, and minimally invasive molecular profiling of sEVs, supporting its potential as a clinical tool for early HCC detection.

3153 | IMPACT OF SOCIAL DETERMINANTS OF HEALTH ON HEPATOCELLULAR CARCINOMA SURVEILLANCE RECEIPT AND EARLY DETECTION

Mohammed Al-Hasan[1] Nicole Rich[1] Gloria Figueroa[2] Stephanie Garces[2] Lisa Quirk[3] Sruthi Yekkaluri[3] Thomas Kerr[1] Patricia Jones[4] Adam Yopp[5] Amit Singal[3], [1]University of Texas Southwestern Medical Center, [2]Division of Digestive Health and Liver Diseases, Department of Internal Medicine, U Miami, Miami, FL, [3]Department of Internal Medicine, UT Southwestern Medical Center, Dallas, TX, [4]University of North Carolina at Chapel Hill, [5]Department of Surgery, UT Southwestern Medical Center, Dallas, TX

Background: The association between social determinants of health (SDOH) and hepatocellular carcinoma (HCC) surveillance receipt and early tumor detection remains unclear. **Methods:** We leveraged the Multi-Ethnic HCC (ME-HCC) Cohort comprised of adults diagnosed with HCC between September 2018 and July 2023 across four U.S. health systems in Texas and Florida. Patients completed surveys assessing demographics, health literacy (using Chew health literacy assessment), medical mistrust (using the group-based medical mistrust score), experienced discrimination (using the shortened everyday discrimination scale), patient-doctor communication, health locus of control, and barriers to treatment. We used multivariable logistic regression models to identify factors associated with surveillance imaging in the 3-9 months prior to HCC diagnosis and early-stage detection, defined as BCLC stage 0/A or tumor within Milan criteria. **Results:** Among 1,245 eligible patients, 833 (66.9%) completed the baseline survey and 495 (59.4%) completed the follow-up survey. Median age was 64.2 years, 75.8% were men, and 55.4% had Child Pugh A cirrhosis. Surveillance was only completed in 40.5% of patients, and HCC was detected at an early stage in 50.9% of patients per BCLC and in 47.8% per Milan criteria. Surveillance receipt was positively associated with ALD etiology (vs: hepatitis C: OR 1.61, 95% CI 1.04-2.61) and negatively associated with lack of insurance (vs: Medicare: OR 0.36, 95% CI 0.14-0.94). Early-stage HCC detection per BCLC was positively associated with surveillance receipt (OR 2.70, 95% CI 1.87-3.91) and Hispanic ethnicity (OR 1.87, 95% CI 1.20-2.94), while it was negatively associated with male gender (OR 0.54, 95% CI 0.35-0.84) and Child Pugh class B (OR 0.45, 95% CI 0.31-0.66). Survey measures failed to have a significant association with surveillance receipt nor BCLC early-stage detection. Detection within Milan Criteria was positively associated with surveillance receipt (OR 3.13, 95% CI 2.23-4.39), while it was negatively associated with Black race (OR 0.50, 95% CI 0.28-0.91), Child Pugh Class B (OR 0.63, 95% CI 0.43-0.92), and age > 65 years (OR 0.65, 95% CI 0.42-0.98). Among patients who completed the follow-up survey, better patient-doctor communication was associated with detection within Milan (OR 1.08, 95% CI 1.02-1.13). **Conclusion:** HCC surveillance receipt is the strongest correlate of early-stage tumor detection but remains underused in clinical practice.

3154 | A SIMPLE LIVER-STIFFNESS AND FIB-4 ALGORITHM IDENTIFIES PATIENTS WITH NON-CIRRHOTIC MASLD WHO ARE AT HIGHER RISK FOR HCC

Philip Vutien[1] Nicole Kim[1] Trang VoPham[2] Abbey Barnard Giustini[3] Kristin Berry[3] Bret Mecham[3] Vyshnika Sriskantharajah[3] George Ioannou[1], [1]University of Washington Medical Center, [2]Fred Hutchinson Cancer Center, [3]Veterans Affairs Puget Sound Healthcare System

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD) is a rising cause of hepatocellular carcinoma (HCC). HCC surveillance focuses almost exclusively on patients with established cirrhosis (> 1% per year risk of HCC). However, up to one-third of MASLD-related HCC cases occur without a diagnosis of cirrhosis. Simple methods of identifying patients with non-cirrhotic MASLD who have sufficiently high risk of HCC to merit screening are lacking. To bridge this gap, we sought to develop a pragmatic, two-parameter classification that leverages two widely available non-invasive tests—FibroScan-derived liver stiffness (LS) and the serum fibrosis-4 (FIB-4) index—to identify non-cirrhotic MASLD patients at high enough HCC risk to merit HCC surveillance, using a risk threshold of > 0.2 per 100 person-years (P-Ys).

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Methods: We identified 21,747 patients with MASLD who underwent a valid LS measurement between 5/2014 to 5/2023. Patients were required to have a FIB-4 score within 6 months of LS, and no HCC or cirrhosis diagnosis prior to or within 90 days after LS. Patients were followed from the LS date until the earliest of death, HCC, or last follow-up. We created risk categories according to incremental LS cut-offs: 5, 10, 15, 20, 25 kPa, and FIB-4 cut-offs of either 2.67 or 3.25. We calculated HCC incidence rates per 100 P-Ys. **Results:** In this cohort of patients with non-cirrhotic MASLD, 90.8% were male and the mean age was 58.2 ± 13.2 years. Over a median follow-up of 3.25 years, 91 patients were diagnosed with incident HCC. HCC incidence was very low (0.04 per 100 P-Ys) for those with LS <5 kPa (Table, Figure). HCC incidence was substantial when LS was ≥ 15 kPa (0.44 per 100 P-Ys), when LS 5-9.9 kPa & FIB-4 ≥ 3.25 (0.32 per 100 P-Ys), and LS 10-14.9 kPa & FIB-4 ≥ 2.67 (0.49 per 100 P-Ys). **Conclusion:** In this national non-cirrhotic MASLD cohort, a simple algorithm consisting of LS and FIB-4 scores identified patients at high enough HCC risk to warrant HCC surveillance. These data suggest HCC surveillance should be considered in individuals with LS ≥ 15 kPa, LS 5-9.9 kPa with FIB-4 ≥ 3.25 and LS 10-14.9 kPa and FIB-4 ≥ 2.67.

Table. HCC incidence for U.S. veterans with non-cirrhotic MASLD according to LS and FIB-4 risk category

LS and FIB-4 risk categories	Number of patients	Follow-up time (Years)	Number with HCC (%)	HCC incidence (per 100 patient-years)
LS 2.5-4.9 kPa	4997	18,514	8 (0.2%)	0.04
LS 5-9.9 kPa & FIB-4 <3.25	11,984	45,030	34 (0.3%)	0.08
LS 10-14.9 kPa & FIB-4 <2.67	2373	8802	13 (0.5%)	0.15
LS 5-9.9 kPa & FIB-4 ≥3.25	526	1848	6 (1.1%)	0.32
LS 10-14.9 kPa & FIB-4 ≥2.67	411	1433	7 (1.7%)	0.49
LS ≥15 kPa	1456	5210	23 (1.6%)	0.44

3155 | SMYD2 INHIBITION REDUCES TUMOR GROWTH AND SYNERGIZES WITH ANTI-PD1 THERAPY IN MURINE HCC ★

Barbara Bueloni[1] Mariel Fusco[2] Esteban Fiore[2] María Jose Cantero[2] Lucia Lameroli Mauriz[2] Brian Martinez Ruiz[2] Nicolas Marcolini[2] Catalina Atorrasagasti[2] Mariana Malvicini[2] Guillermo Mazzolini[2] Juan Bayo[2], [1]IIMT-Universidad Austral, CONICET, [2]IIMT-Universidad Austral, CONICET

Background: Immune checkpoint inhibitors have improved treatment options for advanced hepatocellular carcinoma (HCC), yet outcomes and response rates remain limited. Epigenetic alterations in HCC highlight epigenetic modifiers as potential therapeutic targets. Among them, the methyltransferase SMYD2 has emerged as an oncogenic factor overexpressed in several tumors, targeting histones and various non-epigenetic substrates mutated in HCC, such as p53, β-catenin and PTEN. However, its role in hepatocarcinogenesis remains poorly understood. Our goal was to study the effect of SMYD2 inhibition in HCC and assess its therapeutic potential. **Methods:** SMYD2 expression was analyzed in public and spatial transcriptomic datasets from HCC patients. Its correlation with key pathways was assessed by Gene Ontology analysis and immune deconvolution. RNA-seq was performed on HuH7 cells after SMYD2 inhibition. To study the effect of the SMYD2 inhibitor AZ505 on Wnt signaling, we used PM299L cells, which harbor hyperactive β-catenin. In vitro assays with Wnt pathway modulators were performed in J774 macrophages to assess tumor–macrophage interactions. In vivo, AZ505 was tested in orthotopic Hepa129 and PM299L murine HCC models, as well as in combination with anti-PD-1 in PM299L tumors. Immune infiltrate was assessed by flow cytometry and gene expression by qPCR. **Results:** SMYD2 is upregulated in HCC and linked to oncogenic transcriptional programs. RNA-seq showed that its inhibition in HCC cells normalizes these programs. AZ505 selectively reduced HCC cell viability without affecting primary hepatocytes. In vivo, AZ505 reduced Hepa129 tumor growth, while shifting gene expression toward an inflammatory profile. Immune deconvolution revealed a negative correlation between SMYD2 and immune effector infiltration in patients, supporting a role in immune exclusion. Mechanistically, SMYD2 inhibition downregulated Wnt/β-catenin signaling targets in vivo and in vitro, accompanied by a reduction of Wnt ligand expression in PM299L cells. Conditioned media from AZ505-treated tumor cells induced lower TGF-β expression in J774 cells, indicating impaired tumor-driven immunosuppressive signaling. Finally, AZ505 synergized with anti-PD-1 to reduce PM299L tumor growth and enhance immune response, increasing

$CD8^+CD107a^+$ activated T cells. **Conclusion:** SMYD2 inhibition disrupts oncogenic transcriptional programs and macrophage-mediated immunosuppression, leading to improved response to anti-PD-1. These findings highlight SMYD2 as a promising therapeutic target in HCC, especially in Wnt/β-catenin -active tumors.

3156 | PRE-DIAGNOSTIC PLASMA METABOLITES AND RISK OF HEPATOCELLULAR CARCINOMA IN A MULTIETHNIC COHORT

Sihao Han[1] Jesse Goodrich[2] Hongxu Wang[1] Douglas Walker[3] Lida Chatzi[1] David Conti[2] Veronica Setiawan[2], [1]Keck School of Medicine, USC, [2]Keck School of Medicine; Norris Comprehensive Cancer Center, USC, [3]Gangarosa Department of Environmental Health, Rollins School of Public Health, Emory University

Background: Hepatocellular Carcinoma (HCC) is the most common liver cancer and closely associated with cirrhosis, which accounts for 80-90% of HCC cases. Metabolomics emerges as a promising tool in cancer research and may offer insights into disease mechanisms. While prior studies have explored associations between metabolites profiles and HCC, gaps remain in our understanding of metabolic alterations specific to disease progression, particularly from cirrhosis to HCC. This study aimed to identify key metabolic biomarkers and pathways and to develop a metabolite-based prediction model for early HCC detection. **Methods:** This study included 151 cirrhosis and 240 incident HCC cases from the Multiethnic Cohort Study, individually matched to controls on sex, race/ethnicity, study area, birth year, blood draw date, and fasting status. Pre-diagnostic plasma metabolites were measured using an untargeted high-resolution approach^6 . Metabolome-wide association study (MWAS) and pathway enrichment analysis were performed to identify metabolites and pathways associated with HCC risk. In the cirrhosis samples, least absolute shrinkage and selection operator (LASSO) regression with 5,000 iterations was used to identify robust predictive metabolites. The prediction model was developed in cirrhosis patients and predictive performance of known HCC risk factors (age, sex, race/ethnicity, study area, BMI, smoking, alcohol intake, diabetes), metabolites, and polygenic risk score (PRS) was evaluated in the HCC cases using logistic regression. **Results:** 53 of 294 annotated metabolites were significantly associated with HCC risk, most of which were involved in lipid and amino acid metabolism. Glutamate and glycochenodeoxycholate, selected from the cirrhosis samples, were identified as key predictors of HCC risk. Using coefficients from the cirrhosis cohort to test prediction in the HCC cohort, the model including metabolites and risk factors showed the highest area under the receiver operator characteristics curve (AUC) of 0.73 (95%CI 0.68–0.78), outperforming the model with risk factors alone (AUC = 0.64, 95%CI 0.59–0.69) and with risk factors and PRS (AUC = 0.65, 95%CI 0.60-0.70). A similar improvement was observed using coefficients from the HCC samples, where the model including metabolites and risk factors achieved an AUC of 0.76 (95%CI 0.71–0.80). **Conclusion:** Our findings highlight the potential of metabolomics to enhance early detection of HCC. Higher pre-diagnostic levels of glutamate and glycochenodeoxycholate were significantly associated with increased HCC risk, supporting their potential role as early biomarkers of disease progression. When combined with established risk factors, these metabolites notably improved predictive accuracy. These results underscore the value of metabolite profiling as a complementary tool for conventional and genetic risk assessment strategies in liver cancer prevention.

3157 | EFFICACY AND SAFETY OF SBRT COMBINED WITH ATEZOLIZUMAB PLUS BEVACIZUMAB VS ATEZOLIZUMAB PLUS BEVACIZUMAB IN TREATING UNRESECTABLE ADVANCED HEPATOCELLULAR CARCINOMA (SAB –AN OBSERVATIONAL STUDY)

Phool Chand[1] VINOD ARORA[1] Deepti Sharma[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences (ILBS), New Delhi

Background: Hepatocellular carcinoma (HCC) with portal vein tumor thrombosis (PVTT) is associated with poor prognosis and limited treatment options. Although atezolizumab combined with bevacizumab (AB) is the current first-line standard of care, real-world outcomes remain suboptimal. Stereotactic body radiotherapy (SBRT) has been proposed to enhance immunogenicity and synergize with immunotherapy and may also help in recanalizing PVT. However, clinical data comparing

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

SBRT+AB with AB alone are scarce. **Methods:** We conducted an ambi-spective, single-centre observational study between November 2023- November 2024. 388 patients with cirrhosis with unresectable advanced HCC and PVTT were screened, and patients with CTP score > B7, prior systemic therapy, high-risk varices, or fewer than two cycles of AB were excluded. 76 (68 males and 8 females) patients met inclusion criteria. 35 received SBRT+AB and 41 AB alone. The primary endpoint was objective response rate (ORR) at 6 months per mRECIST. Secondary endpoints included overall survival (OS), progression-free survival (PFS), disease control rate (DCR), biomarker trends (AFP, PIVKA-II), and treatment-related adverse events (TRAEs). **Results:** Despite significantly more aggressive tumor biology in the SBRT+AB group, including higher median AFP {1230.4 () vs 96.1 () ng/mL; $P = 0.013$}, higher tumor volume (320.5 vs 105.1 cm³; $p = 0.015$), and largest tumor diameter (8.3 ± 2.55 vs 6.48 ± 2.08 cm; $P = 0.001$), outcomes were notably superior. ORR at 3, 6, and 12 months was 88.6%, 74.3%, and 66.7% in the SBRT+AB group, compared to 61%, 40%, and 29.4% in the AB group ($p = 0.006$, 0.003, 0.03, respectively). DCR at 6 and 12 months was also higher in the SBRT+AB group (80% and 66.7% vs 55% and 29.4%; $p = 0.022$ and 0.027). Median overall survival was 15 {95% CI: (6.07-23.92) } months in the SBRT+AB group versus 12 {95%CI: (9.26 -14.74) } months with AB alone (p = 0.01), while median progression-free survival was 12 vs 9 months (p = 0.001) (Figure). Grade ≥3 treatment-related adverse events (TRAEs) were infrequent and comparable between groups (8.6% in the SBRT+AB group vs 9.7% in the AB group). The most frequent adverse events were hypertension and fatigue, with no treatment-related deaths reported. **Conclusion:** SBRT in combination with atezolizumab and bevacizumab significantly improved tumor response, disease control and survival, and in patients with unresectable advanced HCC and PVTT, even in the presence of more aggressive disease features. These findings support the incorporation of SBRT into systemic treatment strategies in unresectable advanced HCC and PVTT.

3158 | HEPATOCELLULAR CARCINOMA RISK IN METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE WITH INCREASED ALCOHOL INTAKE (METALD)

Binu John[1] Dustin Bastaich[2] Elizabeth Paulus[1] Seth Spector[1] Bassam Dahman[2], [1]University of Miami and Miami VA, [2]Virginia Commonwealth University

Background: Limited data exist on HCC risk in patients with MetALD (Metabolic Dysfunction Associated Steatotic Liver Disease [MASLD] with increased alcohol consumption) and how it compares to other steatotic liver diseases. The primary aim of this study was to examine annual incidence rates of HCC in patients with MetALD, with and without cirrhosis. The secondary aim was to compare HCC rates in patients with MetALD with those in MASLD, Alcohol-associated liver disease (ALD), and non-SLD controls. **Methods:** We conducted a retrospective cohort study of veterans with MetALD, MASLD, ALD, or no SLD. We identified patients with SLD using natural language processing that has been validated to identify steatosis from abdominal imaging reports with a high degree of accuracy. The baseline was defined as the date of imaging documenting the presence (SLD) or absence (controls) of steatosis. We used Poisson regression to estimate incidence rates within stratifications of patient characteristics and a multivariable time-updated Fine and Gray competing risk model with death as a competing risk to examine HCC risks, adjusted for sex, race, age, cirrhosis, diabetes, BMI, tobacco use, ALT and AST levels, and platelet counts.

Results: We included 666,428 participants (392,286 MASLD, 104,065 MetALD, 40,230 ALD, and 129,847 controls) between 1/1/2011 and 12/31/2022, with a follow-up period to 5/31/2023. In patients without cirrhosis, adjusted HCC rates per 100,000 person-years (PY) were lowest for MASLD (71.64, 95% CI 68.14-75.32), higher for MetALD (80.24, 73.23-87.94), and highest for ALD (104.83, 91.59-119.98). The cumulative incidence of HCC per 100,000 at 5 years was highest with ALD (663.79, 581.77-754.83), followed by MASLD (450.71, 428.46-473.89), and MetALD (449.89, 407.56-495.74) vs. controls (76.03, 61.47-93.46). Similarly, the cumulative rates of HCC per 100,000 at 10 years was highest with ALD (1176.65, 1033.78-1334.36), followed by MetALD (814.16, 739.33-894.10), and MASLD (762.86, 725.86-801.35) vs. controls (89.67, 72.67-110.06).

The rates of HCC were significantly higher in patients with cirrhosis. HCC rates per 100,000 PY in cirrhosis were highest with MetALD (1078.13, 95% CI 950.05-1223.48) and MASLD (1061.91, 95% CI 992.76-

1135.88), followed by ALD (887.92, 95% CI 769.66-1024.34, p = 0.03 vs. MASLD).
Compared to the non-SLD groups (reference), the hazard of HCC increased 2.9-fold in patients with MetALD (aHR 2.90, 95% CI 2.71-3.10). The above HCC risk among MetALD was intermediate between that of MASLD (aHR vs. controls 2.64, 95% CI 2.46-2.82) and ALD (aHR 3.11, 95% CI 2.91-3.33).
Conclusion: The risk of HCC associated with MetALD is higher than MASLD and significantly lower than ALD. These differences may be attributable to the carcinogenic potential of alcohol. This data is useful for counselling patients with MetALD.

3159 | PIVKA-II MONITORING TO PREDICT RESPONSE OF THE FIRST TRANSARTERIAL CHEMOEMBOLIZATION (TACE) IN INTERMEDIATE STAGE OF HEPATOCELLULAR CARCINOMA ★

Napapong Nitiwaranggoon[1] Anucha Ahooja[1] Tanita Suttichaimongkol[1] Chitchai Rattananukrom[1],
[1]Srinagarind hospital, Khon Kaen university

Background: Hepatocellular carcinoma (HCC) is a major cause of cancer-related mortality, with transarterial chemoembolization (TACE) being the standard treatment for intermediate-stage disease. Early prediction of treatment response is crucial for optimizing patient management and critically guiding therapeutic decisions. Protein induced by vitamin K absence-II (PIVKA-II) has emerged as a potential biomarker for monitoring HCC treatment. However, the utility of PIVKA-II in predicting a complete radiologic response (CR) after the first TACE is not well established. This study aims to determine the optimal cutoff and diagnostic performance of the percentage reduction in PIVKA-II levels (PIVKA-II response) at 2 weeks post-TACE in predicting CR at 8 weeks as assessed by imaging. Additionally, the study evaluates the predictive accuracy of the PIVKA-II response at both 2 and 8 weeks following the initial TACE. **Methods:** We performed a prospective diagnostic accuracy study involving 57 patients with intermediate-stage HCC undergoing their first TACE at Srinagarind Hospital, Khon Kaen University, Thailand. Serum levels of PIVKA-II were measured at baseline and subsequently at 2 and 8 weeks following TACE. The radiologic response at 8 weeks was evaluated using the modified Response Evaluation Criteria in Solid Tumors (mRECIST). The predictive value of changes in PIVKA-II levels at 2 and 8 weeks post-TACE was assessed using the area under the receiver operating characteristic (AUROC) curve. **Results:** At 8 weeks following TACE, 26% of patients achieved a complete radiological response. The median reduction in PIVKA-II levels at 2 weeks was not significantly different in the CR group (97.8%) compared to those with partial response (PR) (79.3%), stable disease (SD) (70.6%), and progressive disease (PD) (64.7%) (p = 0.40). The area under the AUROC curve for PIVKA-II response at 2 weeks was 0.74 for predicting CR, 0.65 for the objective response rate (ORR), and 0.63 for the disease control rate (DCR). At 8 weeks, the AUROC curve improved slightly, with values of 0.79 for CR, 0.72 for ORR, and 0.71 for DCR. AUROC analysis revealed that a reduction in PIVKA-II of ≥83.8% at 2 weeks predicted CR with 80.0% sensitivity, 64.3% specificity, a positive predictive value of 44.4%, a negative predictive value of 90.0%, and an overall accuracy of 68.4%. At 8 weeks, a reduction of ≥87.7% in PIVKA-II predicted CR with an accuracy of 75.4%. **Conclusion:** An early reduction in serum PIVKA-II levels following the first TACE is associated with radiologic responses, notably CR. This suggests its potential as a valuable biomarker for treatment monitoring. With an AUROC of 0.74 for predicting CR, the PIVKA-II response at 2 weeks offers promise as an early surrogate marker. This may facilitate timely therapeutic decisions and improve clinical outcomes.

3160 | RISK FACTORS FOR INCIDENTAL HEPATOCELLULAR CARCINOMA AT TIME OF LIVER TRANSPLANTATION

Mahip Grewal[1] Yuan Zhang[2] Elizabeth Verna[1] Meaghan Phipps[1], [1]Columbia University Irving Medical Center, [2]Columbia University

Background: Despite routine hepatocellular carcinoma (HCC) screening for patients listed for liver transplant (LT), incidental hepatocellular carcinoma (iHCC) on explant is a persistent phenomenon. Rates of iHCC and risk factors for iHCC remain poorly characterized. The purpose of this investigation is to elucidate differences in pre-LT patient characteristics and imaging patterns between known HCC (kHCC) and iHCC cases to identify risk factors for iHCC and avenues for improving pre-LT HCC screening. **Methods:** This was a retrospective study of LT patients with HCC from 1998-2025 at a large academic medical center. iHCC cases were defined by the absence of HCC identification on pre-LT imaging. Patient characteristics, pre-LT imaging, tumor characteristics on explant, and post-LT outcomes were extracted via manual chart review. **Results:** Among 746 LT patients with HCC on explant, there were 673 kHCC cases and 73 iHCC cases. There were no significant differences in age, sex, race/ethnicity, BMI, or liver disease etiology between groups. In univariable analysis, as compared to kHCC cases, iHCC cases exhibited significantly higher laboratory model for end-stage liver disease (MELD) at time of LT but significantly lower pre-LT maximum alpha-fetoprotein (AFP) and days on the waitlist (all $p < 0.01$). iHCC cases had smaller maximum tumor size ($p < 0.01$) and lower rates of moderate and poor differentiation ($p < 0.01$). There were no iHCC cases with macrovascular invasion; however, 11 had microvascular invasion and 21 were multifocal. In multivariable analysis controlling for patient and tumor characteristics, laboratory MELD at LT, presence of ascites, number of tumors, and maximum tumor size were associated with iHCC. Notably, overall survival (OS) was longer in iHCC cases as compared to kHCC cases (93.3 months v. 70 months, $p < 0.01$). Pre-LT imaging patterns also differed significantly between groups, with magnetic resonance imaging (MRI) performed in 83% of kHCC cases versus 65% of iHCC cases ($p < 0.01$). **Conclusion:** In this large cohort of LT patients spanning >25 years, 9.8% of HCC cases were incidentally identified on explant. Though iHCC cases overall exhibited less aggressive disease, 29% were multifocal and 15% had microvascular invasion. kHCC patients had significantly less ascites and higher rates of pre-LT MRI, suggesting suboptimal performance of non-MRI based imaging, especially in patients with ascites. Despite higher MELD at LT, patients with iHCC had better OS than their kHCC counterparts.

Background: Due to the infrequent occurrence of HCC-HVTT/IVCTT, comprehensive studies on its clinical outcomes are lacking, with existing data limited to small case series. There still is no evidence to support a standardized first-line therapy for these patients. Therefore, this study aimed to evaluate the effectiveness and safety of tyrosine kinase inhibitors (TKIs)/anti-vascular endothelial growth factor (anti-VEGF) antibody plus immune checkpoint inhibitors (ICIs) with or without transarterial chemoembolization (TACE) as first-line therapy for hepatocellular carcinoma (HCC) with hepatic vein and/or inferior vena cava tumor thrombus (HCC-HVTT/IVCTT). **Methods:** This multi-center retrospective cohort study included HCC-HVTT/IVCTT treated with either TKIs/anti-VEGF antibody with ICIs plus TACE (TKIs/VEGF-ICIs-TACE) or TKIs/anti-VEGF antibody plus ICIs (TKIs/VEGF-ICIs) between June 2018 and March 2024. Propensity score matching (PSM) was utilized to balance baseline characteristics. The primary outcomes were OS and PFS. The second outcomes were objective response rate (ORR), disease control rate (DCR) and treatment-related adverse events (TRAEs). **Results:** Among 746 patients with HCC-HVTT/IVCTT included: 479 in TKIs/VEGF-ICIs-TACE group and 267 in TKIs/VEGF-ICIs group. The median follow-up time was 32.1 months. TKIs/VEGF-ICIs-TACE group demonstrated a significantly longer median OS compared to TKIs/VEGF-ICIs group (20.9, 95% CI: 19.1–22.4 months vs. 14.3, 95% CI: 12.0–16.8 months; HR = 0.65, 95% CI: 0.54–0.77, $p < 0.0001$). According to RECIST v1.1, TKIs/VEGF-ICIs-TACE group achieved a significantly longer median PFS compared to TKIs/VEGF-ICIs group (10.7, 95% CI: 9.8–11.7 months vs. 7.3 95% CI: 6.4–8.5 months; HR = 0.67, 95% CI: 0.57–0.79, $p < 0.0001$); TKIs/VEGF-ICIs-TACE group exhibited a significantly higher ORR and DCR using either RECIST v1.1 (ORR: 45.3% vs. 28.8%, $p < 0.001$; DCR: 81.2% vs. 64.8%, $p < 0.001$) or mRECIST criteria (ORR: 53.6% vs. 36.3%, $p < 0.001$; DCR: 81.6% vs. 64.4%, $p < 0.001$). 238 patients (34.2%) in TKIs/VEGF-ICIs-TACE group and 87 patients (31.5%) in TKIs/VEGF-ICIs group experienced grade ≥ 3 TRAEs. **Conclusion:** TKIs/VEGF-ICIs-TACE has shown improved survival benefit as first-line therapy for HCC-HVTT/IVCTT, with manageable safety profiles.

3162 | DISTINCT MOLECULAR PATHWAYS REGULATED BY ACTIVATED AKT AND YAP SIGNALING DURING INTRAHEPATIC CHOLANGIOCARCINOMA PROGRESSION

Jinqiu Zhao[1] xin chen[2], [1]The First Affiliated Hospital of Chongqing Medical Universit, [2]university of hawaii

Background: Activated AKT and YAP signaling cascades have key roles in intrahepatic cholangiocarcinoma (iCCA) pathogenesis. However, how these pathways modulate iCCA progression, especially how they regulate tumor microenvironment remains unclear. **Methods:** We engineered two doxycycline (doxy) conditional iCCA murine models using hydrodynamic injection to deliver transposon plasmids encoding inducible activated *YAP* or *Akt* into the mouse liver, *Akt/TRE-YAP* or *TRE-Akt/YAP*, respectively. *YAP* or *Akt* was inhibited in established *Akt/YAP* iCCA tumor cells by withdrawing doxycycline. Histological and molecular analyses were used to investigate the phenotypes, especially tumor microenvironment, as well as genes and pathways that are regulated by *Akt* and/or *YAP* during iCCA progression. **Results:** We found that suppression of YAP in *Akt/TRE-Yap* iCCA model led to tumor regression initially. However, livers eventually progress in the liver, leading to HCC-like lesions in mice due to the activated AKT signaling. In contrast, suppression of AKT in *TRE-Akt/Yap* iCCA model lead to a more profound regression of iCCA lesions with limited tumor burden over long term AKT suppression. Histologically, we found that YAP inhibition led to the elimination of the neutrophils in iCCAs with the infiltration of CD4+ and CD8+ T cells, whereas AKT suppression has limited impacts on immune cells. The data suggest that YAP, but not AKT, is the major driver of tumor immune microenvironment in iCCA. The activation of YAP/TAZ and the immune suppressive phenotypes were consistently observed in human iCCAs. Using gene expression analysis, we discovered that AKT and YAP largely modulated distinct pathways during iCCA pathogenesis with limited overlapping genes. Furthermore, we identified RNF125 as a tumor suppressor whose expression is inhibited by YAP in iCCA cells. Overexpression of RNF125 inhibited iCCA tumor and cell growth both *in vivo* and *in vitro*. Finally, while YAP-OFF leads to increased T-cell infiltration, these T cells express PD1. Combined YAP-OFF with anti-PDL1 treatment resulted in increased tumor regression. **Conclusion:** Our studies systematically analyzed the molecular signatures of AKT and YAP during iCCA progression. We identified novel YAP targets and revealed activated YAP as a key regulator of the suppressive tumor immune microenvironment in iCCA. The data support the therapeutic potential of combining YAP inhibitors with immune checkpoint inhibitors for iCCA treatment.

3163 | UBE2D3 FUNCTIONS AS A NOVEL TUMOR SUPPRESSOR IN HEPATOCARCINOGENESIS BY MODULATING THE P62–SHP2–STAT3 SIGNALING AXIS

Hideharu Nagasawa[1], [1]Department of Gastroenterology and hepatol, Osaka University

Background: Pharmacological treatment for hepatocellular carcinoma (HCC) has advanced significantly in recent years, with an increasing number of therapeutic agents becoming available. However, the prognosis for HCC remains poor, underscoring the need for a deeper understanding of the mechanisms underlying hepatocarcinogenesis. Through a cancer gene screen using transposon insertional mutagenesis, we identified UBE2D3 as a candidate tumor suppressor gene in the liver. This study aimed to elucidate the role of UBE2D3 in HCC.
. **Methods:** We assessed the clinical significance of UBE2D3 alterations in human HCC across multiple patient cohorts. Functional studies were conducted by either silencing or overexpressing UBE2D3 using shRNA transfection in murine immortalized liver progenitor cells (LPCs) or cDNA transfection in the human HCC cell line SNU-387. Effects on cell proliferation, apoptosis (Caspase-3/7 activity), sphere formation, and tumorigenicity were evaluated, alongside analyses of associated signaling pathways. To assess in vivo relevance, we generated liver-specific Ube2d3 knockout mice and examined hepatocarcinogenesis in models of steatohepatitis induced by a CDAA-HFD diet or liver-specific Pten deletion. **Results:** Human HCC samples exhibited significant copy number loss at the UBE2D3 locus, accompanied by markedly reduced UBE2D3 mRNA expression compared to adjacent nontumorous liver tissues. Lower UBE2D3 expression levels were significantly associated with poorer patient survival. UBE2D3 suppression in LPCs inhibited apoptosis, promoted cell proliferation and sphere formation, and significantly increased allograft tumor formation. Conversely, forced expression of UBE2D3 in SNU-387 cells enhanced apoptosis, reduced proliferation and sphere formation, and suppressed xenograft tumor growth. Mechanistically, UBE2D3 negatively regulated STAT3 phosphorylation, and pharmacological inhibition of STAT3 attenuated the oncogenic phenotypes induced by UBE2D3 knockdown in LPCs. UBE2D3-deficient cells also showed increased levels of p62 and SHP2 proteins, and STAT3 hyperactivation induced by UBE2D3 knockdown was reversed upon SHP2 co-silencing. In vivo, hepatic deletion of Ube2d3 promoted liver tumorigenesis by increasing hepatic levels of p62, SHP2, and phosphorylated STAT3, accompanied by activation of downstream effectors NRF2 and mTOR. **Conclusion:** UBE2D3 functions as a novel tumor suppressor in hepatocarcinogenesis by modulating the p62–SHP2–STAT3 signaling axis.

3164 | HEPATOCELLULAR CARCINOMA (HCC): GANKYRIN AND MIRNA EXPRESSION PROFILING AS POTENTIAL MARKERS FOR DIAGNOSIS AND MONITORING

Levan Gogichaishvili[1] Mikheil Jangavadze[2] Zanda Bedinashvili[3], [1]Geohospitals Medical Corporation, [2]Ivane Javakhishvili Tbilisi State University, Aleqsandre Natishvili Institute of Morphology., [3]Alexander Natishvili Institute of Morphology

Background: Early diagnosis of (HCC) and detection of disease recurrence are vital for improving patient survival. This study investigated plasma gankyrin/PSMD10 mRNA expression and tissue microRNA profiles as potential biomarkers for HCC diagnosis and monitoring, particularly focusing on their utility in differentiating HCC from cirrhotic liver. **Methods:** The study included 64 participants: HCC ($n = 32$), metastatic HCC ($n = 5$), cirrhosis ($n = 7$), HCV+ ($n = 5$), and healthy individuals ($n = 5$). Blood plasma was evaluated for gankyrin expression, while gankyrin/PSMD10 mRNA and key microRNAs (miR-122, miR-152, miR-200A, miR-200B, miR-21, miR-15, miR-130, miR-9) were analyzed in tissue samples from HCC tumors, adjacent tissues, cirrhotic liver, and normal liver using RT-qPCR. Expression levels were calculated using the 2^-ΔΔCq method with 18S rRNA as reference for gankyrin and miR-26 as reference for microRNAs. **Results:** Importantly, gankyrin mRNA was undetectable in plasma of patients with cirrhosis, HCV+, or healthy individuals, but present in all HCC patients (mean ΔCq: 11.69 ± 1.6 in HCC vs. 10.16 ± 0.4 in metastatic HCC, $p < 0.0002$). Tissue analysis showed significant gankyrin upregulation in HCC (418.5 ± 220.6) compared to adjacent tissue (78.68 ± 49.40), cirrhosis (20.62 ± 11.32), and normal liver (1.02 ± 0.23) ($p < 0.001$). MicroRNA analysis revealed upregulation of miR-200A, miR-200B, miR-21, miR-15, miR-130, and miR-9 in HCC tissues. Most notably, we identified a distinctive pattern of miR-122 and miR-152: miR-122 showed decreased expression in HCC (0.598-fold) and adjacent tissues but increased in cirrhotic liver (1.093-fold), while miR-152 exhibited an opposite pattern with upregulation (1.508-fold) in HCC tissues but downregulation in adjacent (0.471-fold) and cirrhotic tissues (0.258-fold). These miR-122/miR-152 signatures create distinct tissue-specific phenotypes for diagnostic use. **Conclusion:** This study demonstrates that gankyrin RNA is significantly increased in HCC tissues and, crucially, is detectable in plasma of HCC patients but completely

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

absent in all non-HCC individuals. The discovery of distinct miR-122/miR-152 expression signatures enables differential diagnosis between HCC, adjacent tissue, and cirrhotic liver through unique molecular phenotypes: miR-122↓/miR-152↓ in adjacent tissue, miR-122↓/miR-152↑ in HCC, and miR-122↑/miR-152↓ in cirrhosis without HCC. These findings could have particular clinical value for patients with LiRads-3 lesions, where conventional imaging cannot definitively diagnose malignancy. Combining gankyrin RNA detection in liquid biopsy with tissue microRNA profiling presents a promising approach for early detection, differential diagnosis, and monitoring of HCC in high-risk patients, potentially enabling earlier intervention and improved clinical outcomes.

3165 | RE-EVALUATION OF SERUM AMYLOID A-POSITIVE HEPATOCELLULAR NEOPLASM/ INFLAMMATORY HEPATOCELLULAR ADENOMA (HCA) BY EXPRESSION PATTERN OF GLUTAMINE SYNTHETASE FOR DETECTION OF ASSOCIATED β-CATENIN ACTIVATED HCA

Motoko Sasaki[1], [1]Kanazawa University

Background: Serum amyloid A-positive hepatocellular neoplasm (SAA-HN) is a unique hypervascular hepatocellular lesion resembling hepatocellular carcinoma on the image in patients with alcoholic cirrhosis and shares genetic and histological features with inflammatory hepatocellular adenoma (IHCA). SAA-HN is now regarded as a specific type of IHCA associated with advanced liver disease in metabolic dysfunction–associated steatotic liver disease (MASLD). Recent studies reported that the immunostaining for glutamine synthetase (GS), which is useful for a diagnosis of beta-catenin activated HCA (b-HCA), shows various patterns (pattern 1 [P1], diffuse homogeneous pattern suggesting exon 3-non-S45 mutation; P2, diffuse-heterogeneous, suggesting exon 3-S45 mutation; P3, rim and focal heterogeneous, suggesting exon 7/8 mutations). Previous evaluation of the immunostaining for GS may overlook b-HCA other than P1. The aim of this study is to examine a frequency and clinicopathological features of SAA-HN/b-IHCA by re-evaluating the expression pattern of GS. **Methods:** Twenty-three patients with SAA-HN/IHCA (31 tumors, 4 women and 19 men, mean age, 50yrs) and 14 patients (15 tumors, 2 women and 12 men, mean age, 45yrs) were retrieved from our pathological files (1997-2025). An immunostaining for GS was performed and the expression patterns were classified into P1-P3 and P4 (negative). In addition, hotspot genetic mutations in βcatenin/*CTNNB1*, exon3 and exon7/8 were examined by direct sequencing. **Results:** Expression pattern of GS was classified into 2 of P1, one P2, one P3 and 27 P4 in 31 SAA-HN/IHCAs and 2 of P1, 2 P2, 3 P3 and 8 P4 in 15 IHCAs, suggesting 3 SAA-HN/b-IHCAs, exon3-mutated (10%) and one SAA-HN/b-IHCA, exon7/8-mutated (5%). Furthermore, four IHCAs (27%) may be b-IHCA, exon3-mutated and 3 (20%) may be b-IHCA, exon7/8-mutated. Genetic analysis disclosed one SAA-HN/b-IHCA, exon7-mutated (4%) and 2 SAA-HN/b-IHCAs, exon8-mutated (9%). The SAA-HN/b-IHCA, exon 7-mutated, showed P3 in GS immunostaining, whereas the immunostaining for GS in the rim of tumor nodule was obscure in 2 SAA-HN/b-IHCA, exon 8-mutated (both needle biopsied specimen). **Conclusion:** A part of SAA-HN/IHCA and IHCA may be b-IHCAs, exon3-mutated or exon7/8-mutated. Since a risk of malignant transformation is higher in b-IHCA, exon 3-mutated, than usual IHCA, careful evaluation of immunoreactivity for GS and genetic analysis is mandatory to detect SAA-HN/b-IHCA arising in advanced MASLD.

3166 | ADVANCED BLOOD PLASMA SPECTROSCOPY IMPROVES DIAGNOSTIC ACCURACY FOR LIVER CANCER ACCORDING TO BCLC STAGE

Petr Hříbek[1] Ondřej Vrtělka[2] Lucie Habartová[2] Vladimír Setni?ka[2] Petr Urbánek[3], [1]Military University Hospital Prague, [2]University of Chemistry and Technology, [3]Charles University in Prague, 1st Faculty of Medicine

Background: The overall survival of hepatocellular carcinoma (HCC) significantly declines with delayed diagnosis making early detection essential for improving therapeutic outcomes. In at-risk populations, surveillance is typically performed using liver

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

ultrasonography (USG), which has limited sensitivity of 60% in early stages (BCLC 0+A). Currently, alpha-fetoprotein is the only widely used biomarker for screening, although its clinical utility remains controversial. We hypothesized that a combination of spectroscopic techniques could reveal distinct plasma spectral patterns identifying patients with and without HCC, offering superior diagnostic accuracy – even in early stages – compared to current standards. **Methods:** We employed a combination of conventional and chiroptical spectroscopic techniques – infrared (IR) and Raman spectroscopy (RS), electronic circular dichroism (ECD), and Raman optical activity (ROA) – to differentiate between cirrhotic patients with and without HCC. We enrolled a total of 152 patients with liver cirhosis, including 64 subjects with HCC and 88 subjects without HCC. The BCLC stage distribution among HCC patients was stage 0+A (n = 24; 37%), stage B (n = 19; 30%), and stage C (n = 21; 33%). Spectral data from each technique were analyzed using partial least squares discriminant analysis (PLS-DA) with 10-times repeated 5-fold cross-validation to calculate the area under the receiver operating characteristic curve (AUROC) in distinguishing between HCC and non-HCC samples. **Results:** Conformational changes in plasma proteins were observed, particularly in the infrared and Raman spectra within the amide I, II, and III regions (bands at 1648, 1637, 1546, 1285, and 1270 cm^{-1}). Additional spectral changes were noted in the intensity of signals corresponding to aliphatic lipid chains (~1450 cm^{-1}) and aromatic amino acids (1192 and 1006 cm^{-1}). The most significant difference between spectra of patients with hepatocellular carcinoma (HCC) and healthy controls was found in the intensity of carotenoid signals (1519, 1158, and 1006 cm^{-1}).

Diagnostic performance by BCLC stage was as follows (sensitivity, specificity, and AUROC):

Stage 0+A: IR 0.735, 0.696, and 0.776; ECD 0.589, 0.704, and 0.706; RS 0.745, 0.483, and 0.690; ROA 0.655, 0.700, and 0.752; combination 0.744, 0.743, and 0.814

Stage B: IR 0.712, 0.769, and 0.815,; ECD 0.602, 0.771, and 0.755; RS 0.758, 0.568, and 0.740; ROA 0.735, 0.670, and 0.779; combination 0.745, 0.792, and 0.852

Stage C: IR 0.756, 0.799, and 0.857; ECD 0.780, 0.845, and 0.876; RS 0.954, 0.695, and 0.878; ROA 0.788, 0. 786, and 0.872; combination 0.819, 0.917, and 0.913

Conclusion: Our findings suggest that spectroscopic methods are capable of distinguishing liver cancer even at early stages with promising accuracy, particularly when combined. These techniques could potentially enhance current screening strategies in at-risk populations.

3167 | US HEALTH CARE SPENDING ON LIVER CANCER

Yan Tian[1] Wenjun Wang[1] Xiaomeng Cui[1] Ting Li[1] Shuangsuo Dang[1] Xiaoli Jia[1], [1]Second Affiliated Hospital of Xi'an Jiaotong University

Background: Liver cancer imposes a substantial and growing burden on the US health care system. This study aims to quantify health care spending on liver cancer from 2010 to 2019, examining variation by sex, age, type of care, and geographic location to inform policy and resource allocation. **Methods:** Using data from the US Health Care Spending by Condition database, we analyzed inflation-adjusted (2019 USD) spending estimates for liver cancer. Spendings were stratified by sex, age groups, care categories, and state-level distribution. **Results:** Health care spending on liver cancer increased from $3.5 billion in 2010 (95% CI, $3.4 billion–$3.6 billion) to $5.6 billion (95% CI, $5.4 billion-$5.8 billion) in 2019. The proportion of health care spending attributed to liver cancer increased from 0.18% (95% CI, 0.17%–0.19%) in 2010 to 0.23% (95% CI, 0.22%–0.24%) in 2019. In 2019, males accounted for $3.3 billion (95% CI, $3.1 billion-$3.4 billion), while female accounted for $2.4 billion (95% CI, $2.3 billion–$2.5 billion). By age group, individuals aged $\geq$65 years had the highest spending (54.3%), followed by those aged 45–64 years (37.2%), 20–44 years (6.7%), and $<$20 years (1.8%). Ambulatory care accounted for the largest share of spending (56.3%), followed by hospital inpatient care (25.9%), prescribed retail pharmaceuticals (14.6%), home health care (1.4%), nursing facility care (0.8%), and emergency department care (0.7%). At the state level, age- and sex-standardized spending per capita ranged from $9.9 (95% CI, $8.6–$11.3) in Wyoming, to $23.5 (95% CI, $22.0–$24.8) in California. **Conclusion:** Health care spending on liver cancer has increased significantly from 2010 to 2019, with substantial variation by sex, age, type of care, and geographic location. These findings highlight the growing economic burden of liver cancer and underscore the need for targeted interventions to reduce disparities and improve the efficiency of care delivery.

3168 | TUMOR BIOMARKERS ADDED TO BCLC SCORE AMELIORATE SIGNIFICANTLY HEPATOCELLULAR CARCINOMA STAGING

Francesco Damone[1] Gian Paolo Caviglia[2] Piero Colombatto[1] Filippo Oliveri[1] Gabriele Ricco[1] Silvia Gaia[3] Veronica Romagnoli[1] Daniela Cavallone[1] Marta Guariglia[4] Emanuela Rolle[3] Patrizia Carucci[3] Francesco Faita[5] Ferruccio Bonino[5] Maurizia Rossana Brunetto[1], [1]Hepatology Unit, Pisa University Hospital, Italy, [2]Department of Medical Sciences, University of Turin, Turin, Italy, [3]Unit of Gastroenterology, Città della Salute e della Scienza - Molinette Hospital, Turin, Italy, [4]Department of Medical Sciences, University of Turin, Turin, Italy;, [5]Biostructure and Bio-imaging Institute of National Research Council of Italy

Background: The promising results of new combinations of hepatocellular carcinoma (HCC) targeted therapies prompt the improvement of treatment decision based only on tumor and liver function burdens without staging of tumor biology. The combined prognostic value of Alpha-fetoprotein (AFP), Prothrombin Induced by Vitamin K Absence-II (PIVKA-II), and Glypican-3 (GPC-3) for overall survival (OS) remains unclear. **Methods:** We retrospectively analyzed 605 consecutive HCC patients (pts) from two tertiary centers (Pisa n = 279 and Turin n = 326). The cohort was split in training (n = 483) and validation (n = 122) subsets by stratified random sampling based on key clinical and tumor features. In the training set, univariate Cox regression identified variables associated with OS. Statistically significant variables ($p < 0.05$) were included in a multivariate Cox regression model to determine independent prognostic factors. AFP, PIVKA-II, and GPC-3 were combined in a bio-score: 0 = none > cut-off; 1 = one/two > cut-off; 2 = all > cut-off (cut-offs: AFP = 10ng/ml, PIVKA-II = 200mAu/ml, GPC-3 = 100pg/ml). Statistically significant variables in multivariate analysis ($p < 0.05$) were used to build a prognostic score, weighted by their hazard ratios (HR). The score prognostic ability was tested in the validation cohort and compared with the BCLC score by log-rank test. **Results:** Multivariate analysis (Table1) of the training set showed that bio-score, BCLC stage, and ascites were independently associated with OS. Final HRs weighted scores (range 0–7) were: BCLC (0 = 0, A = 1, B = 2, C = 3), ascites (no = 0, yes = 2), and bioscore (0–2). Pts were classified into four groups based on survival distribution: low (0–1), intermediate (2–3), high (4–5), and very high risk (6–7). Median OS significantly decreased across groups ($p < 0.001$): 40.8, 19.3, 12.2, and 5.2 months, respectively. Kaplan–Meier curves confirmed a clear separation between groups, highlighting the reproducibility and prognostic utility of the model, both in training and validation sets (Figure1A-B). The new prognostic score showed a significant stratification of OS (log-rank $p < 0.001$, $\chi^2 = 153.7$), outperforming BCLC staging alone (log-rank $p < 0.001$, $\chi^2 = 108.1$). **Conclusion:** A new prognostic score combining HCC biomarkers, BCLC stage, and ascites offers a simple and effective tool for risk stratification in HCC outperforming BCLC staging alone

3169 | CLINICAL OUTCOMES IN PATIENTS WITH ADVANCED/ UNRESECTABLE HEPATOCELLULAR CARCINOMA TREATED WITH STRIDE VERSUS ATEZOLIZUMAB-BEVACIZUMAB

Michael Li[1] Huat Lim[1] John Gordan[1] Jocelin Chen[1] Quincy Harris[1] Jennifer Lai[1] Lawrence Fong[2] Robin Kelley[1], [1]University of California, San Francisco, [2]Fred Hutchinson Cancer Center

Background: Single tremelimumab regular interval durvalumab (STRIDE) and atezolizumab-bevacizumab (atezo/bev) are first-line systemic therapy options which improve survival in advanced hepatocellular carcinoma (HCC) but have not been directly compared. We sought to evaluate the impact of regimen on outcomes. **Methods:** We performed a single-center retrospective cohort study of HCC patients who received STRIDE or atezo/bev. Primary outcomes were overall survival (OS) and real-world progression-free survival (rwPFS), defined as clinically-assessed PFS. The secondary outcome was time on treatment (TOT) as a surrogate measure of PFS. To account for confounding by indication, a propensity score model predicting STRIDE treatment (vs atezo/bev) was developed and then used in inverse probability of treatment weighting (IPTW) to create balanced groups for Cox regression. Sensitivity analyses were performed using standard Cox regression adjusting for the same confounders included in the propensity score. **Results:** Of 203 patients, 76 (37%) received STRIDE and 127 (63%) received atezo/bev. There were no differences in liver function, HCC stage, liver disease etiology, or bleeding history between the two groups. STRIDE patients were less likely to be receiving first-line systemic therapy (67% vs 89%, $p < 0.001$) and more likely to have prior extrahepatic thromboembolism (12% vs 3%, $p = 0.014$). STRIDE was associated with a lower disease control rate (56% vs 72%, $p = 0.051$) compared to atezo/bev. After IPTW, key baseline characteristics were balanced, including line of therapy and prior thromboembolism (Love plot, Fig A). On IPTW-Cox regression, there were no differences in OS (HR 0.7, $p = 0.147$) or rwPFS (HR 0.9, $p = 0.662$) when comparing STRIDE vs atezo/bev. However, in the subgroup of patients who achieved disease control ($n = 122$, 60%), STRIDE was associated with longer OS (HR 0.5, 95% CI 0.2-0.9, $p = 0.034$), rwPFS (HR 0.4, 95% CI 0.2-0.9, $p = 0.018$), and TOT (HR 0.4, 95% CI 0.2-0.8, $p = 0.013$ compared to atezo/bev. Sensitivity analyses in the disease control subgroup using standard Cox regression resulted in similar hazard ratios, with STRIDE remaining associated with longer OS (aHR 0.4, 95% CI 0.2-0.8, $p = 0.011$), rwPFS (aHR 0.3, 95% CI 0.2-0.7, $p = 0.004$), and TOT (aHR 0.3, 95% CI 0.2-0.7, $p = 0.002$). In the first-line subgroup of patients with disease control, unadjusted OS (median not reached vs 1.8 years, Fig B) and rwPFS (median not reached vs 0.8 years; Fig C) favored STRIDE. **Conclusion:** STRIDE may be associated with a lower disease control rate compared to atezo/bev, which could reflect that some atezo/bev-treated patients respond to the antiangiogenic component (bev). However, in patients who do achieve disease control, STRIDE treatment was associated with longer OS, rwPFS, and TOT. Our findings support the hypothesis that dual checkpoint inhibition may be associated with more durable immune response.

3170 | ARTIFICIAL INTELLIGENCE FOR HCC RISK PREDICTION IN MASLD: DEVELOPMENT AND VALIDATION OF A PREDICTIVE MODEL IN 306 PATIENTS

Giovane Viola Carvalho[1] Rodolfo Viola Carvalho[1] Regiane Alencar[1] Claudia Tani[1] Mario Pessoa[1] Lisa Saud[1] Aline Chagas[1] Renato Altikes[1] Claudia Oliveira[1], [1]HCFMUSP

Background: The global incidence of hepatocellular carcinoma (HCC) associated with Metabolic Dysfunction–Associated Steatotic Liver Disease (MASLD) is increasing.
However, there are no specific, accurate, and validated tools to predict HCC risk in this population. **Methods:** We conducted a retrospective cohort study including 306 patients with MASLD. Clinical and laboratory variables were used to train a machine learning
model (XGBoost) to predict the development of HCC, confirmed by imaging or histology. The model's performance was evaluated using the area under the
ROC curve (AUC), sensitivity, and specificity. Results were compared with existing scores such as AFP, GALAD, and aMAP. **Results:** The MASLD-HCC Score achieved an AUC-ROC of 0.90, with sensitivity of 90.9% and specificity of 84.3%. Compared to other tools, GALAD had an AUC
of 0.92 (sens. 82%, spec. 89%), aMAP had an AUC of 0.85 (sens. 96%, spec. 64%), and AFP alone performed worse (AUC 0.83; sens. 61%, spec. 86%). Our
model showed superior overall balance between discrimination and clinical utility, especially in MASLD patients without cirrhosis. The most relevant
features included FIB-4, neutrophil-to-lymphocyte ratio (NLR), AST, ALT, albumin, platelets, and age. The model was deployed into an interactive digital
interface for clinical use. **Conclusion:** We developed and validated an artificial intelligence–based model to predict HCC risk in MASLD. The MASLD-HCC Score outperformed existing tools and
may support individualized surveillance strategies in the growing MASLD population.

Model	AUC-ROC	Sensitivity (%)	Specificity (%)
MASLD-HCC Score (Our Model)	0.9	90.9	84.3
GALAD	0.92	82.0	89.0
AFP	0.83	61.0	86.0
Ultrasound (US)	0.81	63.0	97.0
AFP + US	0.83	69.0	95.0
HCC Risk Score	0.89	89.4	71.4
aMAP	0.85	96.0	64.0

3171 | INDUCTION OF CUPROPTOSIS AND IMMUNOGENIC CELL DEATH BY A NOVEL COPPER CARRIER A3 IN HEPATOCELLULAR CARCINOMA: SYNERGISTIC ENHANCEMENT WITH PX-478

yuntao bao[1] Yu-Lan Li[1] wei gao[1], [1]The First Affiliated Hospital of Guangxi Medical University

Background: Cuproptosis is a copper-dependent form of programmed cell death driven by copper binding to mitochondrial lipoylated proteins, leading to protein aggregation and mitochondrial dysfunction. We synthesized a quinoline-derived thiosemicarbazone compound (A3) as a copper ionophore and investigated its ability, alone and with the HIF-1α inhibitor PX-478, to induce cuproptosis and immunogenic cell death (ICD) in hepatocellular carcinoma. **Methods:** Huh-7 cells were treated with A3/Cu (IC_{50} = 1.3 μM) ± PX-478. We measured intracellular copper, FDX1 and DLAT (Western blot), ROS, autophagy markers (LC3-II, p62), and mitochondrial ultrastructure (TEM). ICD was assessed via CRT exposure, HMGB1 release, and ATP secretion. Specificity for cuproptosis was tested using TTM, Ferrostatin-1, Necrostatin-1, and Z-VAD-FMK. In vivo, C57BL/6 mice bearing H22 xenografts received A3/Cu ± PX-478 for 21 days; tumor growth, histology (H&E, Ki-67), DLAT/FDX1 immunofluorescence, and organ toxicity (H&E, serum biochemistry) were evaluated. **Results:** A3/Cu inhibited Huh-7 proliferation, elevated intracellular copper, upregulated FDX1, and altered DLAT; only TTM reversed cytotoxicity, confirming cuproptosis. Treatment increased ROS, autophagy, and mitochondrial damage. ICD markers rose and were further enhanced by PX-478. In vivo, A3/Cu reduced tumor growth, with greater suppression upon PX-478 co-treatment; tumors exhibited necrosis, reduced Ki-67, and DLAT/FDX1 changes consistent with cuproptosis. No organ toxicity was observed. **Conclusion:** A3 induces cuproptosis and ICD in liver cancer cells. Combined with PX-478, it enhances antitumor efficacy with minimal toxicity, offering a promising immunotherapeutic strategy.

3172 | PREOPERATIVE PREDICTION OF MICROVASCULAR INVASION IN INTRAHEPATIC CHOLANGIOCARCINOMA AND ITS PROGNOSTIC IMPLICATIONS: A MULTICENTER STUDY

Dong Hwan Kim[1] Sang Hyun Choi[1], [1]Asan Medical Center

Background: Microvascular invasion (MVI) is a well-established adverse prognostic factor in intrahepatic cholangiocarcinoma (ICCA). However, previous studies on preoperative predictors of MVI in ICCA have yielded inconsistent results. This study aimed to identify preoperative clinical and magnetic resonance imaging (MRI) factors that can predict MVI in ICCA and to evaluate their prognostic utility using a multicenter cohort. **Methods:** A multicenter cohort of 446 patients who underwent preoperative MRI and curative-intent resection for ICCA at six tertiary referral centers between 2009 and 2018 was analyzed. Clinical, pathological, and MRI features were evaluated. Univariable and multivariable logistic regression analyses were performed to identify significant predictors of pathologically confirmed MVI, which were subsequently used to stratify patients into low-, intermediate-, and high-risk groups based on the number of predictors identified. Kaplan–Meier survival analysis and log-rank tests were performed to assess overall survival and early recurrence (defined as recurrence within one year postoperatively) across risk groups. **Results:** Among the 446 patients (mean age, 63.0 ± 9.9 years; 277 men), 234 (52.5%) had MVI on pathology. Independent predictors of MVI included serum carbohydrate antigen 19-9 levels (≥ 80 U/mL; odds ratio [OR]: 2.68, 95% confidence interval [CI]: 1.64–4.37, $p < 0.001$), tumor size (≥ 4 cm; OR: 1.60, 95% CI: 1.01–2.54, $p = 0.046$), tumor multiplicity (OR: 2.84, 95% CI: 1.58–5.12, $p < 0.001$), and arterial-phase peritumoral enhancement (OR: 2.83, 95% CI: 1.81–4.42, $p < 0.001$). Stratifying patients by MVI risk—low (no predictors), intermediate (1–3 predictors), and high (4 predictors)— revealed a significant decrease in both recurrence-free and overall survival rates ($p < 0.001$), along with a corresponding increase in early recurrence rates ($p < 0.001$) as the risk level increased. **Conclusion:** Risk stratification utilizing four key predictors can effectively assess the risk of MVI in ICCA and is associated with postoperative outcomes.

3173 | INVESTIGATION OF TUMOR HETEROGENEITY IN LIVER USING HISTOLOGICAL ANALYSIS AND SPATIAL LIPIDOMICS IN MYRISTOYLATED AKT-TAZ (MYRAKT-TAZ S89A)-DRIVEN MURINE MODEL

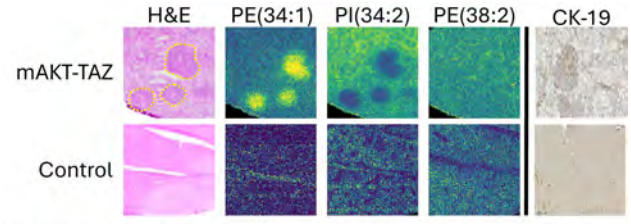
Jee Won Jennifer Shin[1] Seul Kee Byeon[1] Olajide Olaleye[1] Chady Meroueh[1] Pandey Akhilesh[1] Kirk Wangensteen[1], [1]Mayo Clinic

Background: While TAZ overexpression alone is insufficient to drive tumorigenesis (leading to cancer only in a minority of cells after prolonged latency), co-expression of AKT and TAZ significantly accelerates liver tumor development, effectively recapitulating human intrahepatic cholangiocarcinoma (iCCA) more effectively. We have used the myristoylated AKT-TAZ (myrAKT-TAZ S89A) driven murine model that recapitulates human iCCA and have studied its histological spatial distribution of lipids using imaging mass spectrometry(IMS) to study tumor heterogeneity. This study can help correlate specific oncogenic pathways with unique lipid and metabolic fingerprints, which can help

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

identify and validate biomarkers for early detection of liver cancer. **Methods:** 5 Mice were hydrodynamically injected with plasmids co-expressing myrAKT and TAZ S89A. We monitored tumor development and confirmed tumor formation by histological analysis. After 7 weeks, livers were cryosectioned, and spatial lipidomics was performed to map lipid distributions within the tumor environment. We also performed immunohistochemical staining for cytokeratin 19 (CK19) as an aid for tumor morphological assessment. **Results:** All mice (n = 5) receiving the oncogenic plasmids (myrAKT-TAZ S89A) developed liver tumors. Histological analysis of mouse liver sections showed tumors that exhibited cholangiocarcinoma-like features, such as marked nuclear pleomorphism, glandular formation, dense fibrotic stroma, and a tendency to grow near portal tracts. We examined the spatial distribution of various specific lipids. Control liver tissue demonstrated uniform distribution of lipids, reflecting normal liver histology. The myrAKT-TAZ S89A-treated mouse livers had spatially distinguished phosphatidylinositol (PI)-enriched tumors that were spatially distinguished from the tumors that were enriched with ceramide phosphate. Within the ceramide phosphate-enriched tumors, PE(34:1) was enriched, PI(34:2) was depleted, and phosphatidylethanolamine PE(38:2) was unchanged in tumors. CK19 staining was positive but was not uniform, with high nuclear pleomorphism and some gland formation. Some of the neoplastic cells show some eosinophilic cytoplasm, which might represent mixed hepatocellular carcinoma (HCC)- CCA components. We are applying additional markers (e.g., MOC31, arginase1, glypican3) to further characterize the HCC and CCA components of these tumors. **Conclusion:** myrAKT-TAZ S89A -driven murine liver tumors display marked histological and lipidomic heterogeneity reminiscent of human HCC and CCA. Distinct spatial lipid signatures correlate with tumor subtypes, offering insights into tumor biology and pointing to potential metabolic vulnerabilities. Ongoing work is examining the mechanisms underlying these lipidomic differences and aims to identify novel therapeutic targets associated with dysregulated lipid metabolism.



3D Lipidomics: Tumors in mouse livers repopulated with oncogenic plasmids (mAKT-TAZ) showed spatial distribution in which PE(34:1) is enriched, PI(34:2) is depleted, and PE(38:2) is unchanged compared to the control. CK-19 staining shown on the left for both oncogenic liver and control.

3174 | INTERIM SHORT-TERM FEASIBILITY AND SAFETY ANALYSIS OF SINGLE-SESSION YTTRIUM-90 TRANSARTERIAL RADIOEMBOLIZATION FOR SMALL HEPATOCELLULAR CARCINOMA: ONE & DONE TRIAL

Nima Kokabi[1] Sandra Gad[1] Andrew Moon[1] Hanna Sanoff[1] Jingquan jia[2] Neil Shah[3] Michael Mohnasky[1] David Mauro[2] Alex Villalobos[1] Hyeon Yu[1], [1]University of North Carolina, [2]Univeristy of North Carolina, [3]University of North Carolina at Chapel Hill

Background: The One and Done prospective single-arm phase II clinical trial [NCT06618300] aims to evaluate the efficacy and safety of a streamlined single-session treatment protocol in patients with small hepatocellular carcinoma (HCC) receiving resin-based Yttrium-90 (Y90) transarterial radioembolization (TARE). **Methods:** This prospective, currently ongoing study enrolls patients with small HCC lesions with no evidence of macrovascular invasion (Organ Procurement and Transplantation Network (OPTN) Stage T2). The study is designed to enroll a total of 30 patients, and this analysis represents the preplanned interim safety assessment at the halfway point. Enrolled patients have a focal HCC (a single lesion $\leq$5 cm or $\leq$ 3 nodules, $\leq$ 3 cm) confined to one or two anatomical liver segments. Additional inclusion criteria include total serum bilirubin $<$3.0 mg/dL, serum albumin $>$2.5 g/dL, and an Eastern Cooperative Oncology Group (ECOG) performance status $\leq$ 2. Patients undergo a single-session Y90 TARE. During angiography, 3D Cone Beam Computed Tomography (3D-CBCT) is used to confirm complete tumor perfusion. Personalized curative Y90 dose is calculated intraprocedurally, and the corresponding prescribed activity of Y90 microspheres is administered during the same session. Post-procedural imaging includes a single photon emission computed tomography (SPECT)/CT scan to confirm adequate dose delivery and retrospectively calculate lung shunt fraction (LSF). Follow-up includes clinical and biochemical toxicity assessments at 1, 3, 6, and 12 months and imaging to assess response according to modified Response Evaluation Criteria in Solid Tumors (mRECIST) at 3, 6, and 12 months. The study's primary endpoint is time to treatment, with secondary endpoints assessing safety and efficacy. **Results:** Thus far, among recruited patients (n = 15), 14 patients have successfully undergone streamlined single-session Y90 TARE with at least 1 month of postprocedural follow-ups. In one

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

patient, the treatment was aborted due to visualization of early enhancement of hepatic veins on 3D-CBCT, which suggested high LSF. The cohort was predominantly male (86%), with an average age of 66.4+ 7.5 years old. The most common underlying etiologies for HCC were viral hepatitis. Most patients had Child-Pugh Class A liver function (86%). Overall, 15 tumors were treated in the 14 patients with a median tumor size of 2.2 cm (IQR-2). The median time to treatment was 28 days (IQR-18). Mean LSF was 6.7% (SD: 2.6%). The mean delivered dose to the tumor was 465 Gy (SD: 363 Gy). No patients developed $\geq$ Grade 3 AEs post-TARE. Specifically, no patient developed any signs of radiation pneumonitis. Of these patients, 7 had follow-up imaging at 3 months, with all (100%) demonstrating objective response in the treated tumors. **Conclusion:** The interim analysis of this study suggests that streamlined single-session resin-based Y90-TARE in patients with small HCC is feasible and safe

3175 | COMBINED TEAD AND TYROSINE KINASE INHIBITOR THERAPY STRONGLY EXTENDS SURVIVAL IN HEPATOCELLULAR CARCINOMA

Marcella Steffani[1] Yoshinobu Saito[2] Vera Garcia-Outeiral[3] Qiuyan Sun[3] Kirk Wangensteen[4] Robert Schwabe[5], [1]Department of Medicine, Columbia University, [2]The University of Osaka, Graduate School of Medicine, Osaka, Japan, [3]Department of Medicine, Columbia University, New York, NY, USA, [4]Mayo Clinic, [5]Columbia University

Background: Despite recent therapeutic advances such as the combination of immune checkpoint inhibitors with anti-VEGF, the majority of patients with advanced hepatocellular carcinoma (HCC) die within 2 years. Current combination therapies selectively target the tumor microenvironment (TME), leaving tumor cell-targeted therapies a therapeutic gap. Here, we used tumor-selective CRISPR interference (CRISPRi), followed by pharmacologic inhibition of candidates, to uncover novel tumor cell-intrinsic vulnerabilities and extend survival in HCC. **Methods:** Druggable targets were identified using tumor cell-specific *in vivo* CRISPRi screens in models of TAZ-, MET+CCNTB1- or AKT+NRas-driven HCC, induced by hydrodynamic tail vein injection in dCas9 transgenic mice. The impact on tumor growth and survival was evaluated by single-gene CRISPRi and pharmacologic inhibitors, followed by mechanistic evaluation. Synergies between candidates were assessed by high-throughput drug screens. **Results:** CRISPRi screens identified TEAD family members as druggable therapeutic vulnerabilities in HCC. *In vitro* silencing revealed unique transcriptional targets in tumor cells for each of the 4 TEAD members. Accordingly, tumor cell-specific *in vivo* CRISPRi significantly prolonged the median overall survival (OS) in mouse models of HCC for each TEAD. Notably, pharmacological panTEAD inhibitors (panTEADi) recently entered trials for various tumor entities but not for HCC. panTEADi VT104 and IAG933 exerted strong anti-tumor effects in 3 mouse models of HCC, with nearly doubled median OS in MET +CCNTB1-driven HCC (11.9 vs. 5.3 wks, $p = 0.0015$). A complementary high-throughput synergy screen of 372 anti-cancer drugs uncovered strong and significant ($p < 0.001$) synergies between panTEADi and four tyrosine kinase inhibitors (TKI) in murine and human HCC. The combination of TKI lenvatinib and panTEADi IAG933 significantly extended median OS ($>$ 18 wks/ ongoing IAG933+lenvatinib vs 10.5 wks IAG933, 9.9 wks lenvatinib, 5.9 wks vehicle) in MET+CCNTB1-driven HCC. Mechanistically, panTEADi+TKI therapy led to a strong induction of tumor cell death *in vitro* and *in vivo*. **Conclusion:** The unique HCC-promoting functions of each TEAD family member provide the basis for potent anti-tumor effects of panTEADi in HCC. Owing to strong synergies, the combination of panTEADi and TKI may represent a potent and clinically applicable tumor cell-targeted therapy for HCC that could be combined with current TME-directed therapies.

Background: The aggressiveness of intrahepatic cholangiocarcinoma (iCCA) relies on key tumor features such as cellular plasticity, self-renewal capacity, and metastatic potential, collectively described as tumor stemness. Molecular mechanisms driving the maintenance and evolution of stemness features during iCCA progression remain poorly understood. This study aims to characterize the dynamics of stemness-related traits in primary and metastatic iCCA, identify key molecular pathways that sustain tumor cell plasticity, and explore their role in disease dissemination. By elucidating these features in vivo, we seek to uncover novel targets to disrupt tumor stemness and hinder disease progression. **Methods:** Taking advantage of a 3D sphere culture system (SPH) as a model for cancer stem cells, an orthotopic mouse model was developed through intrahepatic injection of Luciferase-GFP-transfected SPH cells obtained by both established and primary iCCA cells. Disseminated GFP+ tumor cells in target organs (lungs, spleen, peritoneum, mesenteric lymph nodes) and blood were analyzed via FACS. GFP+ cells from primary and metastatic lung tumors were isolated by FACS for molecular profiling using pathway-focused qRT-PCR arrays. These findings were validated in human metastatic and non-metastatic iCCA samples through immunohistochemistry and correlated with clinical and pathological data. **Results:** SPH cells were responsible for a great tumor spread in all secondary organs analyzed, especially those derived from MTCHC-01 primary cells. The absence of CD45-/GFP + tumor cells in the blood of animals suggested that lymphatic circle is the preferential via to iCCA dissemination. Notably, lung SPH-disseminated cells showed up-regulation of many tested stem-like, epithelial-to-mesenchymal transition, angiogenesis and drug resistance related genes compared to SPH-primary tumor cells. A panel of 34 genes commonly up-regulated was found in all SPH-disseminated cells. High expression of some of these genes were correlated with a significantly lower 5-years and disease-free survival of 289 iCCA patients. Among these, *TSPAN13* and *WNT5A* are of particular importance. Expression levels of these 2 genes-derived proteins were significantly up-regulated metastatic CCA specimens compared to non-metastatic ones. **Conclusion:** Our data indicate that a core stemness program is maintained during iCCA progression, with *TSPAN13* and *WNT5A* emerging as key markers of stemness and metastasis.

3177 | OUTCOME PREDICTION IN HCC AFTER LIVER TRANSPLANT: HOW MUCH CAN WE TRUST IMAGING?

Natalia Marcos Carrasco[1] Cristina Martinez Cuevas[1] Alicia San Jose Crespo[1] Elena Velasco Martinez[1] Carolina Almohalla Alvarez[1] FELIX GARCIA PAJARES[1] Maria Jordan de la Fuente[1] Laura Jimenez Gonzalez[2] Gloria Sanchez Antolín[1], [1]Hepatology and Liver Transplant Unit. Hospital Universitario Rio Hortega, [2]Hepatology and Liver Transplant Unit. Hospital Universitaria Rio Hortega

Background: Hepatocellular carcinoma (HCC) accounts for 35% of liver transplant (LT) indications. Its diagnosis primarily relies on imaging studies, which often underestimate tumor size. Additionally, vascular invasion in the explant is a significant risk factor for post-transplant recurrence.

The aim of this study was to evaluate the correlation between radiological and pathological findings of HCC in liver explants and their influence on post-transplant survival and recurrence. **Methods:** A retrospective, observational, single-center study was conducted at Hospital Universitario Río Hortega, including patients transplanted for HCC between 2010 and 2022. Radiological findings were compared with histopathological data from liver explants. Survival and associated risk factors were analyzed. **Results:** A total of 147 liver transplant recipients were included, 85.03% male, with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

a median age of 60 years (55-64). The most common etiologies were alcohol-related liver disease (52.4%), hepatitis C virus (19%), and combined etiologies (15.6%). Pre-transplant assessments showed that 66% of patients were Child-Pugh A, with a median MELD score of 10 (8-13). Imaging revealed that 88.4% met Milan criteria, while the remainder met expanded criteria.

In imaging studies, 51% of patients had 1 nodule, 27.2% had 2, 14.3% had 3, and the remainder had ≥ 4 nodules, with a median size of 2.5 cm (1.8-3 cm). Pathological findings revealed that 70.75% of patients met Milan criteria, with 46.2% showing 1 nodule, 21.1% showing 2, 12.9% showing 3, and the remainder ≥ 4 nodules, with a median size of 2.5 cm (1.7-3.5 cm). The correlation between radiological and pathological findings was moderate, 0.45 for nodule number ($p < 0.001$) and 0.41 for size ($p < 0.001$). Median survival was 8.6 years (3,155 days), with 42.2% mortality at the end of follow-up. Neither nodule count nor adherence to Milan criteria (radiological) significantly influenced mortality. However, histological factors associated with poor prognosis were significantly linked to survival ($p < 0.001$). **Conclusion:** Pre-transplant radiological evaluation of HCC is crucial for staging and achieving high post-transplant survival rates. However, survival is not influenced by adherence to Milan or expanded criteria but rather by the presence of histopathological poor prognostic factors, which significantly impact recurrence and post-transplant survival. Strategies to enhance pre-transplant evaluation and address adverse histological features may improve outcomes.

3178 | ADDITION OF COMPUTED-TOMOGRAPHY-DERIVED RADIOMICS FEATURES DID NOT IMPROVE MORTALITY PREDICTION AFTER TRANSARTERIAL CHEMOEMBOLIZATION FOR HEPATOCELLULAR CARCINOMA

Philip Vutien[1] George Ioannou[1] Amilcare Gentili[2] Chunnan Hsu[2], [1]University of Washington Medical Center, [2]Veterans Affairs San Diego Healthcare System

Background: Prior work has shown that a model that includes abdominal computer-tomography (CT)-based radiomics features can predict progression-free survival following transarterial chemoembolization (TACE) for hepatocellular carcinoma (HCC). We examined whether the addition of CT-based radiomics adds predictive value to a clinical model for 1-year mortality after TACE. **Methods:** From the WAW-TACE dataset, we analyzed 229 patients with hepatocellular carcinoma (HCC) with multiphase CT imaging ≤ 90 days before initial TACE, excluding those with metastatic disease, vascular invasion, or Child-Pugh class C. Data were split into 80/20 training/testing sets. Radiomics features were extracted previously using PyRadiomics, which yielded selected features based on abdominal structures that were clinically associated with portal hypertension and liver function (e.g. liver, liver vessels, spleen, and tumor characteristics). From this pool of 53 radiomics features, rank-sum testing ($p < 0.05$) was used to select 7 features associated with 1-year mortality and for eventual model development. Three XGBoost models were built to predict 1-year mortality after initial TACE: 1) Clinical model – liver disease etiology, BCLC stage, Child-Pugh score, INR, AFP, bilirubin, creatinine, albumin, age, sex, and largest tumor characteristics (size, number, location); 2) Radiomics model – 7 features derived from liver, liver vessels, spleen, and tumor characteristics; 3) Combined clinical and radiomics model. Model performance was evaluated on the test dataset and the DeLong test was used to compare differences in C-statistic (e.g. discrimination) between models. **Results:** Among 229 patients, median age was 66 years, 21% were women, 48% had viral hepatitis, and 89% had Child-Pugh A cirrhosis, and 62 died within 1 year following TACE. 63% had unifocal HCC, and median tumor size was 4.5 cm (IQR 3 to 6.2 cm). Model discrimination (Table, Figure) was highest for the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

clinical model (AUC 0.70), lower for the clinical + radiomics model (AUC 0.68), and lowest for the radiomics-only model (AUC 0.57). The performance of the clinical + radiomics model was not significantly different from that for the clinical model (DeLong *p:* 0.72). **Conclusion:** In this cohort with relatively few deaths, adding liver- and spleen-focused radiomics did not improve 1-year mortality prediction over clinical variables, alone. Larger studies and optimized feature extraction are warranted.

Table. Model characteristics ascertained on the test set.

	AUC	Accuracy	Sensitivity	Specificity	PPV	NPV
Clinical*-only Model	0.70	0.76	0.62	0.81	0.57	0.84
Radiomics**-only Model	0.57	0.67	0.15	0.88	0.33	0.72
Clinical + radiomics model	0.68	0.71	0.54	0.78	0.50	0.81

*Clinical model predictors included: etiology of liver disease, BCLC class, Child Pugh score, INR, AFP, biltrubin, creatinine, albumin, age, sex, largest lesion diameter, number of lesions, location (right or left lobe) of the largest lesion. **Radiomics model includes features derived from CT imaging of the spleen, liver, and liver vessels.

Figure. AUC of the three models developed using (1) clinical, (2) radiomics predictors, and (3) clinical + radiomics predictors.

3179 | HEPATOCELLULAR ADENOMA (HCA): GROWTH AND OUTCOMES IN PREGNANCY

Gowthami Kanagalingam[1] Mallika John[2] Jasmine Gamez[3] Liina Poder[4] Richard Sterling[1] Monika Sarkar[5], [1]Virginia Commonwealth University, [2]Wellesley College, [3]UCSF Hepatology/Liver Transplant, [4]UCSF Radiology, [5]University of California, San Francisco

Background: HCAs are typically estrogen-responsive benign liver lesions with risk for growth and rupture during pregnancy. However, granular data on HCA behavior during pregnancy, particularly for lesions larger than 5 cm, are limited. **Methods:** This two-center retrospective study utilized chart-validation and imaging review to evaluate growth and clinical outcomes of HCAs (abdominal pain, hemorrhage, rupture, and/or HCA interventions). HCAs identified prior to or during pregnancy from 2013 to 2024 were included. A change in size from pre-conception to postpartum was reported. **Results:** The cohort included 29 patients, with 37 pregnancies reflecting 20 and 17 pregnancies at each tertiary care center. Median age was 34.5 years and median pre-pregnancy BMI was 27.3kg/??2; 59.3% (16/27) used prior combined hormonal contraception. Median gestation was 38 weeks with 6/37 (16.2%) pre-term births and 13/37 (35%) c-sections. There were 3 (8%) abortions, two induced and one spontaneous. The largest hepatic adenoma lesion pre-pregnancy measured 16.4 cm and the largest lesion during pregnancy was 20 cm. Twenty one percent (4/19) of the hepatic adenomas prior to pregnancy were > 5 cm in size and during pregnancy 6/17 (35.3%) were > 5 cm in size. Among patients with pre-conception and/or multiple gestational scans (n = 18), 55.5% had growth, 16.6% stability, and 27.7% regression during pregnancy. Among patients with post-partum scans (n = 22), the median size was 2.3 cm (IQR 4.9) with 11.8% growth, 23.5% stability, and 64.7% regression at 7 median months postpartum. Abdominal pain was reported in 59.4% (22/37). 5.4% (2/37) had hemorrhage, 5.4% (2/37) had embolization and 2.7% (1/37) resection during pregnancy for lesions with a median size of 9.9 cm (IQR 2.95). **Conclusion:** In this cohort of well-characterized HCA outcomes in pregnancy, growth was observed in over 50% of cases, with the majority showing regression postpartum. Hemorrhage occurred only in lesions > 5.9 cm, with no maternal or neonatal mortality.

3180 | RURAL RESIDENCE IS ASSOCIATED WITH HIGHER ODDS OF ABSENT OR INCOMPLETE LI-RADS CLASSIFICATION ON CROSS-SECTIONAL IMAGING IN PATIENTS REFERRED TO A MULTIDISCIPLINARY HEPATOCELLULAR CARCINOMA CLINIC

Parsa Pazooki[1] Gabriel Lupu[1] Lauren Burke[1] A. Sidney Barritt[1] Sasha Deutsch-Link[2] Oren Fix[1] Neil Shah[1] Hersh Shroff[2] Andrew Moon[3], [1]University of North Carolina at Chapel Hill, [2]UNC Chapel Hill, [3]University of North Carolina

Background: Hepatocellular carcinoma (HCC) prognosis is closely tied to timely diagnosis, and HCC mortality is increasing disproportionately in rural populations. The Liver Imaging Reporting and Data System (LI-RADS) aims to standardize radiologic reporting and diagnosis of HCC for patients with cirrhosis. Rural residence may be associated with barriers to care, delayed diagnosis, and distance from liver transplant centers with expert radiologists. This study evaluated whether rural residence is associated with the absence of proper LI-RADS classification on referral imaging among patients with cirrhosis referred to a multidisciplinary HCC clinic. **Methods:** We performed a single-center, retrospective analysis of patients with cirrhosis who were referred for evaluation of liver masses between 9/30/2016 and 12/6/2024 with CT or MRI imaging. Rural-urban classification was determined using the North Carolina Department of Health and Human Services designations. The primary outcome was incomplete LI-RADS classification on referral imaging. A multivariable logistic regression model was used to assess the association between rurality and incomplete or absent LI-RADS classification, adjusting for serum alpha-fetoprotein (AFP) levels, BMI, imaging modality, and liver disease etiology. **Results:** Of the 89 identified patients, 76 had cirrhosis with CT or MRI imaging, and most referrals (99%) occurred after 2019. 96.3% of rural patients and 85.7% of urban patients were referred from gastroenterology or other subspecialty clinics. Missing LI-RADS was noted in 44.4% of patients with rural residence as compared to 34.7% of urban patients (Table 1). After adjustment for potential confounders, rural residence was associated with increased odds of incomplete LI-RADS classification (OR 2.31; 95% CI: 0.77–6.91). Higher serum AFP levels were associated with incomplete or absent LI-RADS classification, although this finding was not statistically significant. **Conclusion:** Among rural patients with cirrhosis referred for evaluation of liver masses there were increased odds of incomplete LI-RADS classification on initial referral imaging in both unadjusted and adjusted models, although this was not statistically significant. These findings highlight a potential disparity in diagnostic imaging quality or reporting that may impact the timely management of HCC among rural residents. Further work is needed to develop solutions to address this potential contributor to rural–urban disparities.

Table 1. Patient characteristics and multivariable logistic regression analysis of the association between rural residence and the application of LI-RADS criteria on initial CT/MRI imaging among patients with cirrhosis referred to an HCC clinic

	LI-RADS Present on Referral Imaging

Ahmed Kaseb[1], [1]The University of Texas MD Anderson Cancer Center

Background: Hepatocellular carcinoma (HCC) has a high recurrence rate after resection, 70% at 5 years. However, no effective adjuvant or neoadjuvant therapies currently exist. Given the efficacy of anti-VEGF (bevacizumab (Bev)) and anti-PD-L1 (atezolizumab (Atezo)) against HCC, we initiated a pilot trial of pre-operative dual VEGF/PD-L1 blockade in patients with resectable HCC. **Methods:** Patients enrolled in this trial during 2021-2024 received atezolizumab 1200 mg IV and bevacizumab 15 mg/kg IV on day 1 of a 21-day cycle. Patients received 3 cycles before undergoing curative-intent resection during week 12. Co-primary endpoints were safety and tolerability of the Atezo/Bev combination in the pre-operative setting and the rate of major pathologic response (MPR) or pathologic complete response (pCR), identified as occurrence of $\geq$ 70% and 100% necrosis, respectively. Secondary endpoints included overall response rate (ORR) at time of surgery per RECIST 1.1 criteria, duration of response, and overall survival. **Results:** Sixteen patients were enrolled. Median (IQR) age was 72 (67-76) years, and 75% of patients were male. Out of 16 patients enrolled, 13 completed therapy and resection, one patient received all 3 cycles of Atezo/Bev but was not resected due to advanced cirrhosis, and 2 patients dropped out before treatment began. At the time of surgery, pCR was observed in 1/13 patients (7.7% pCR). Another patient had 50% necrosis, and the rest $<$50%. Per RECIST 1.1, 2/13 (15.4%) patients, including the patient who achieved pCR, had partial response ($>$30% radiologic response). No grade 4 or higher toxicity were observed. Immunohistochemical staining of the resection specimens exhibited upregulation of the expression of the growth hormone receptor (GHR) and its downstream oncogenic targets including pERK, pSTAT3, and pIGF-IR, specifically in the viable tumor areas in the patients who did not achieve pCR. After a median follow-up of 23 months, all the patients are alive, and of the 13 patients who received Atezo/Bev and were resected, 2 patients had recurrence. **Conclusion:** Despite the low pCR rate, our study remains significant as it allows to assess resistance biomarkers and identify druggable targets. Further analysis of the GHR pathway and downstream cascade will be our next focus, which may lead to a clinical study to investigate the effects of Atezo/Bev with or without GHR inhibitors in HCC patients.

3182 | PATIENT CHARACTERISTICS AND TREATMENT PATTERNS AMONG PATIENTS WITH INTRAHEPATIC CHOLANGIOCARCINOMA WITH AND WITHOUT AUTOIMMUNE COMORBIDITIES: A RETROSPECTIVE STUDY

Sumera Ilyas[1] Nilofer Azad[2] Shishir Maithel[3] Rachna Shroff[4] Milind Javle[5] Mitesh Borad[6] Nehemiah Kebede[7] Young Jung[8] Sheena Dupuy[9] Stephen Valerio[10] Juan Valle[11], [1]Division of Gastroenterology and Hepatology, Mayo Clinic; Department of Immunology, Mayo Clinic, [2]The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, [3]Robert H. Lurie Comprehensive Cancer Center, Northwestern University, [4]Division of Hematology and Oncology, University of Arizona Cancer Center, [5]Division of Cancer Medicine, The University of Texas MD Anderson Cancer Center, [6]Division of Hematology and Oncology, Department of Medicine, Mayo Clinic, [7]Oncology Data and Statistics, AstraZeneca, [8]AstraZeneca Canada, [9]GI Oncology, AstraZeneca, [10]US Medical Affairs, AstraZeneca, [11]Cholangiocarcinoma Foundation; Division of Cancer Sciences, University of Manchester

Background: Findings from TOPAZ-1 support durvalumab and gemcitabine + cisplatin (GemCis) as a standard-of-care treatment for advanced biliary tract cancer. However, patients (pts) with intrahepatic cholangiocarcinoma (iCCA) often have autoimmune comorbidities that could restrict immunotherapy use. Treatment patterns in pts with iCCA with and without autoimmune comorbidities are reported. **Methods:** This study is a retrospective observational analysis of adult pts diagnosed with iCCA in the United States who were enrolled in registries between 2019 and 2023, with datasets enriched for pts treated with durvalumab. The study used data from the International Cholangiocarcinoma Patient Registry, a collaboration between The Cholangiocarcinoma Foundation and Citizen Health®. The registry contains de-identified data from medical records obtained directly from consenting pts and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

caregivers. Pts were followed from the index date (initial date of CCA diagnosis) until the last activity in the database or death, whichever occurred first. We report pt demographics, clinical characteristics, biomarkers, and treatment patterns (line of therapy) for pts with iCCA with and without autoimmune comorbidities. **Results:** The median (quartile [Q]1–Q3) age of pts with iCCA (N = 335) was 59.0 (48.0–66.0) years, 66.6% were female, and pts had a mean of 9.9 comorbidities. The most common genetic alterations occurring in pts with iCCA were in *FGFR2* (20.3%), *IDH1* (20.3%), *PD-L1* (15.8%), and *HER2* (any method, 5.7%). Autoimmune comorbidities were present in 77 (23.0%) pts with iCCA; colitis (26.0%), rheumatoid arthritis (18.2%), and ulcerative colitis (16.9%) were the most common autoimmune comorbidities recorded. Durvalumab + GemCis was received by 20.5% (60.8% [n/N = 45/74] post-March 2022) and GemCis alone by 35.1% (13.5% [n/N = 10/74] post-March 2022) of pts with iCCA at first-line (1L) (Figure). In pts with iCCA, durvalumab + GemCis was received by 19.0% (60.0% [n/N = 9/15] post-March 2022) of pts with autoimmune comorbidities, and 20.9% (61.0% [n/N = 36/59] post-March 2022) without, at 1L. The use of other immunotherapy regimens at 1L was generally similar across both populations. **Conclusion:** Treatment patterns for immunotherapy regimens were generally similar for the iCCA cohort with and without autoimmune comorbidities, suggesting that autoimmune comorbidities do not restrict durvalumab use. Future research will focus on clinical outcomes and toxicities in these populations, which could inform clinical decision-making.

Figure. Treatment modalities in each line of therapy among patients diagnosed with iCCA

3183 | HEAD-TO-HEAD COMPARISON OF SCORING SYSTEMS TO ASSESS LIVER FUNCTION IN HEPATOCELLULAR CARCINOMA: A MULTICENTRE STUDY

Kai Yi Benjamin Nah[1] N Apoorva Sasikumar[2] Beom Kyung Kim[3] Mark Muthiah[4] Daniel Huang[4] Karn Wijarnpreecha[5] Sung Won Lee[6] Ken Liu[7] Takumi Kawaguchi[8] Gang Chen[9] Hirokazu Takahashi[10], [1]National University Hospital, [2]National University Singapore, [3]Yonsei University College of Medicine, [4]National University Hospital, Singapore, [5]University of Arizona College of Medicine-Phoenix, [6]The Catholic University of Korea, [7]University of Sydney, [8]Kurume University School of Medicine, [9]The First Affiliated Hospital of Wenzhou Medical University, [10]Saga University

Background: Hepatocellular carcinoma (HCC) remains the third leading cause of cancer-related deaths globally, with a 5-year survival rate of less than 20%. Liver function is a key determinant of treatment eligibility and prognosis in HCC. Several scoring systems, including Child-Turcotte-Pugh (CTP), MELD, APRI, FIB-4, and the ALBI grade, are used to assess liver function, but their effectiveness in predicting outcomes specifically in HCC patients is unclear. This study aims to compare the clinical utility of these scores in predicting survival in HCC. **Methods:** This retrospective, multicentre cohort study analysed data from 2,685 adults diagnosed with HCC across seven international centres from January 2003 to July 2021. We compared the prognostic performance of five liver function scores: ALBI grade, CTP score, APRI, MELD, and FIB-4. Discrimination and calibration were assessed using statistical methods such as Harrell's C-index, Brier score, and Kaplan-Meier survival analysis. **Results:** The ALBI grade showed superior discrimination with the highest Harrell's C statistic (0.6724) and AUC values (0.663–0.716), outperforming CTP, MELD, APRI, and FIB-4. Calibration analysis demonstrated that the ALBI grade had the closest alignment to observed survival outcomes, as shown by calibration curves and residual plots. All scoring systems displayed satisfactory calibration, but ALBI consistently showed the best fit. **Conclusion:** The ALBI grade is the most reliable score for assessing liver function in HCC patients, offering superior prognostic accuracy compared to other commonly used scores. While all scores demonstrated acceptable calibration, the ALBI grade's consistent performance suggests it should be prioritized in clinical

practice. Future studies should focus on integrating liver function scores with other biomarkers and clinical parameters to further enhance prognostic accuracy in HCC.

3184 | PROGNOSTIC IMPACT OF DIABETES AND HYPERTENSION ON HEPATOCELLULAR CARCINOMA SURVIVAL: A 15-YEAR REGISTRY-BASED ANALYSIS

Jonggi Choi[1] Ji won Yang[2] Hyeyeon Hong[2] Songgyung Kim[2] Jina Park[2] Chaeyeon Lim[2] Won-Mook Choi[2] Danbi Lee[2] Ju Hyun Shim[2] Kang Mo Kim[2] YOUNG-SUK LIM[2] Han Chu Lee[2], [1]University of Ulsan, Asan Medical Center, [2]Asan Medical Center, University of Ulsan College of Medicine, Seoul, Republic of Korea

Background: In Korea, hepatocellular carcinoma (HCC) is a major cause of cancer-related mortality, and its incidence is rising in the elderly population. Given this trend, the influence of comorbidities, such as diabetes mellitus (DM) and hypertension (HTN), on survival warrants further investigation. This study investigated the prognostic implications of these comorbidities using a 15-year, large-scale registry. **Methods:** A total of 21,699 treatment-naïve HCC patients from the Asan Medical Center HCC registry (2009–2023) were analyzed. The influence of DM and HTN on overall survival (OS) was assessed according to the Barcelona Clinic Liver Cancer (BCLC) staging system. Patients were stratified into four groups based on comorbidity status: none, HTN only, DM only, and both HTN and DM. OS was estimated using the Kaplan–Meier method, with comparisons via log-rank tests. Cox proportional hazards models were used to evaluate the association between comorbidities and survival, with hazard ratios (HRs) calculated for each group. **Results:** The median age of the cohort was 59 years, 80.6% were male, and hepatitis B virus infection was the most common etiology of HCC. Among all patients, 5,476 (26.5%) had DM, and 7,541 (34.8%) had HTN. When stratified by comorbidity status, the median OS was 6.0 years in patients with no comorbidities, 6.8 years in those with HTN only, 5.6 years in those with DM only, and 4.9 years in those with both DM and HTN. Patients with both DM and HTN had significantly worse survival compared to those without comorbidities (HR 1.12, $p < 0.001$).

In patients with BCLC stage 0, OS was significantly lower in those with comorbidities. The HR for OS was 1.20 in patients with HTN, 2.02 in those with DM, and 2.17 in those with both DM and HTN (all $p < 0.001$). A similar pattern was observed in BCLC stage A, where the HR for OS was 1.09 in patients with HTN, 1.33 in those with DM, and 1.49 in those with both comorbidities (all $p < 0.001$). However, in BCLC stages B, C, and D, OS did not show significant differences based on comorbidity status. **Conclusion:** Our findings suggest that DM is associated with poorer prognosis in HCC patients, and the presence of both DM and HTN further worsens survival outcomes, particularly in very early (BCLC 0) and early-stage (BCLC A) disease. These results highlight the need for tailored surveillance and management strategies for HCC patients with metabolic comorbidities.

Namrata Venkatesan[1] Matteo Pellegrini[1] Samuel French[1] Joseph Pisegna[4] Vatche Agopian[5] Enrique Rozengurt[1] Rajat Singh[1] Jihane Benhammou[1], [1]University of California, Los Angeles, [2]Chidren's National Research Institute, Washington DC, [3]Columbia University, [4]University of California, Los Angles, [5]David Geffen School of Medicine at UCLA

Background: Hepatic stellate cells (HSC) are central to cirrhosis and hepatocellular carcinoma (HCC) development. Statin use is associated with decreased incidence of cirrhosis and HCC; however, the mechanisms for their chemoprotective effects remains elusive. We aimed to identify novel pathways in MASLD-related HCC as part of our hypothesis that statins regulate HSC function by lowering the levels of the mevalonate pathway metabolite geranylgeranyl pyrophosphate (GGPP). **Methods:** We integrated single nucleus RNA sequencing (snRNA-seq) of 13 MASLD-HCC patients (n = 12 adj non-tumor, 12 HCC) and spatial transcriptomics of human MASLD-HCC livers (n = 6) using CosMx to identify novel pathways of interest. We used bulk RNA sequencing of statin-treated primary human HSCs (pHSCs) (n = 4) to examine the effects of statins. pHSCs and LX2 cells were used to validate proteins and genes of interest. To investigate the role of GGPP, we used pharmacogenetic inhibition of key pathway targets and reciprocal exogenous GGPP repletion to assess YAP protein localization and effector gene regulation. Intracellular GGPP levels were then assessed via LC-MS/MS. **Results:** Reference cell-types and their proportions were generated from snRNAseq (334,803 cells). We identified 762,287 cells in our spatial transcriptomic analyses and observed cell-type heterogeneity across cell-types including HSCs. Spatial imaging revealed HSCs are predominantly localized with immune cells in HCCs. We identified that statin-treated pHSCs have a significant downregulation of Yes-associated protein (YAP) genes and Rho-dependent pathways ($p < 0.001$). We showed that pHSCs exposed to statin led to cytoplasmic retention of YAP, reduced expression of YAP effector genes, and cytoskeleton restructuring. These effects were restored to baseline with GGPP repletion. Knockdown of GGPP synthase 1, inhibition of GGTAse I (GGPP transferase), and inhibition of Rho each recapitulated the statin effects in HSCs. LC-MS/MS measurements revealed a 10-fold reduction in intracellular GGPP levels in response to statins, confirming our findings that statins downregulate HSC function by lowering GGPP levels. **Conclusion:** We present the largest integrated transcriptomic studies of MASLD-HCCs revealing subsets of HSCs that are spatially localized with immune cells. Our data are the first to directly measure GGPP levels, confirming statins regulate YAP and Rho GTPases in HSCs via GGPP. Further studies will investigate the HSC-immune cross-talk in MASLD/MASH and its relevance to HCC.

3186 | TARGET-SPECIFIC LOCKED NUCLEIC ACID GAPMER DECREASES GROWTH OF HEPATOCELLULAR CARCINOMA

Keyue ZHANG[1] Hong Cao[1] Wenqiang Chen[1] Jill Smith[1], [1]Georgetown University

Background: Hepatocellular carcinoma (HCC) is the fastest growing cause of cancer-related deaths worldwide. The CCK-B receptor (CCKBR) is absent in normal liver tissue but is upregulated with inflammation, cirrhosis, and in HCC. Gastrin promotes tumor cell growth via autocrine signaling at the CCKBR. LNA Gapmers are antisense oligonucleotides that are 16-20 nucleotides in length. They contain a central stretch ("gap") of DNA monomers flanked by 'locked nucleic acid, i.e., (LNA)" modified nucleotides. **Methods:** In this study, we developed a specific LNA Gapmer (Gapmer-90) targeting gastrin. This Gapmer was modified by click chemistry to conjugate an amino acid ligand for selective binding to CCKBR, aiming to disrupt the CCKBR-Gastrin signaling axis. In vitro, human HepG2 and Hep3B HCC cells were characterized for CCKBRs and gastrin expression by qRT-PCR and flow cytometry. In vitro HCC cells were transfected with Gapmer-90 and gastrin expression was evaluated by PCR and immunohistochemistry. Effects on growth were evaluated by MTT assay and viable cell counting assays. Hep3B tumors were developed in Athymic nude mice subcutaneously and mice were treated with PBS (control), untargeted Gapmer-90 (120μM), and targeted Gapmer-90 (120μM). Survival analysis was performed. **Results:** Hep3B cells expressed more gastrin and had more CCKBRs than HepG2 cells by qRT-PCR. Flow cytometry revealed Hep3B expressed more CCK-BRs than HepG2 cells. HCC cells transfected in vitro with Gapmer-90 revealed a significant reduction of gastrin mRNA expression by PCR in Hep3B cells only ($P < 0.01$). Gapmer-90-treated Hep3B cells showed decreased growth by MTT and trypan blue assays by 74% compared to controls ($P < 0.0001$).

Immunocytochemistry showed decreased gastrin peptide in Gapmer#90-treated HCC cells compared to controls. In vivo, mice bearing Hep3B tumors treated with the targeted Gapmer-90 had a 50% greater survival than PBS-controls and also 50% greater survival than mice treated with the untargeted Gapmer-90. **Conclusion:** Gastrin peptide is expressed in human HCC and regulates growth via the CCK-BR in an autocrine fashion. CCK-BR targeted Gapmer-90 effectively down regulates gastrin to inhibit growth of HCC in vitro and improve survival of HCC-tumor bearing mice in vivo. Selective targeting of the CCK-BR- gastrin axis by LNA Gapmers offers a novel strategy for precision medicine by inhibiting growth of HCC and improving survival.

3187 | PLASMA TWEAK LEVELS AS A PREDICTIVE BIOMARKER FOR TREMELIMUMAB PLUS DURVALUMAB IN PATIENTS WITH ADVANCED HEPATOCELLULAR CARCINOMA

Takeru Hirao[1] Takahiro Kodama[1] Yu Sato[1] Yuta Myojin[1] Kazuma Daiku[1] Ryo Takahashi[1] Shuhei Yamamoto[1] Kazuki Maesaka[1] Kumiko Shirai[1] Kazuhiro Murai[1] Yuki Tahata[1] Yuki Makino[1] Yoshinobu Saito[1] Hayato Hikita[1] Tomohide Tatsumi[1] Tetsuo Takehara[2], [1]The University of Osaka, [2]Kansai Rosai Hospital

Background: Immunotherapy has transformed the therapeutic landscape of hepatocellular carcinoma (HCC). However, survival benefits for patients are still limited. This study aimed to identify novel blood-based biomarkers predictive of treatment response to tremelimumab plus durvalumab (Dur/Tre) in advanced HCC patients. **Methods:** We used Proximity Extension Assay (PEA) technology from Olink® to simultaneously profile 92 plasma proteins in pre-treatment samples from 50 patients with unresectable HCC who received Dur/Tre therapy, aiming to identify proteins predictive of progression-free survival (PFS), over-all survival (OS) and response rate. Next, pre-treatment plasma protein levels of tumor necrosis factor-like weak inducer of apoptosis (TWEAK) were evaluated by Enzyme-Linked Immunosorbent Assay (ELISA) in 64 patients with unresectable HCC who received Dur/Tre, and their association with clinical outcomes was investigated. Similarly, plasma TWEAK levels were also measured by ELISA in 66 patients treated with atezolizmab plus bevacizumab (Atez/Bev). **Results:** Using Normalized Protein eXpression (NPX) values generated by Olink®, patients were divided into high and low groups for each circulating protein. Stratification by TWEAK levels enabled clear separation of both PFS and OS. Comparison between NPX values and concentrations measured by ELISA for TWEAK showed a Pearson correlation coefficient greater than 0.85, indicating a strong positive correlation. In 45 patients with unresectable HCC treated with Dur/Tre, high TWEAK levels were associated with a significantly higher overall response rate (ORR: 30.4% vs. 4.8%, $p = 0.0481$) compared to low TWEAK levels. Both PFS (109 days vs. 55 days, $p < 0.05$) and OS (578 days vs. 313 days, $p < 0.05$) were significantly longer in the high TWEAK group. In the validation cohort of 19 HCC patients, similar findings to those in the initial 45 patient cohort were observed. Multivariate Cox proportional hazard analysis identified a high plasma TWEAK level as an independent predictor of prolonged OS. Comparison between the Dur/Tre group ($n = 64$) and the Atez/Bev group ($n = 66$) revealed no significant differences in pre-treatment plasma TWEAK concentrations or OS. Among patients with high plasma TWEAK levels, those treated with Dur/Tre tended to have better OS compared to those who received Atez/Bev. Conversely, among patients with low plasma TWEAK levels, OS was significantly longer in those treated with Atez/Bev than in those who received Dur/Tre. **Conclusion:** Plasma TWEAK levels predicted clinical outcomes in advanced HCC patients treated with Dur/Tre therapy. Furthermore, pre-treatment plasma TWEAK concentrations may serve as a decision-making biomarker for choosing between Dur/Tre and Atez/Bev therapies.

3188 | SYNERGISTIC TUMOR IMMUNOTHERAPY VIA CUPROPTOSIS, APOPTOSIS AND CHEMODYNAMIC THERAPY: FUNCTIONAL COPPER(II) COMPLEXES COMBINED WITH HIF-1α INHIBITION

Yu-Lan Li[1] yuntao bao[1] Songqing He[1], [1]The First Affiliated Hospital of Guangxi Medical University

Background: Hepatocellular carcinoma (HCC) is a highly malignant tumor with limited treatment efficacy

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

due to the immunosuppressive tumor microenvironment (TME). Although immunotherapy has made significant progress, overcoming this barrier remains a major challenge. Cuproptosis, a novel mitochondria-dependent form of regulated cell death driven by protein lipoylation, can synergize with apoptosis and chemodynamic therapy to induce immunogenic cell death (ICD) and promote antitumor immune responses. **Methods:** MTT assay, western blotting, electron paramagnetic resonance (EPR) spectroscopy, flow cytometry, ELISA and transmission electron microscopy (TEM) . **Results:** A series of copper(II) complexes based on pyridine hydrazone ligands were synthesized and evaluated. Among them, Cu4B exhibited the most potent cytotoxicity against Huh-7 cells, with an IC_{50} of 0.46 $\pm$ 0.07 μM. Western blot analysis revealed that Cu4B upregulated DLAT while downregulating LISA, and FDX1, indicating activation of the cuproptosis pathway. EPR results demonstrated that these copper complexes could deplete intracellular glutathione (GSH) and catalyze the conversion of hydrogen peroxide (H_2O_2) into hydroxyl radicals (•OH). This led to decreased GSH levels, increased oxidized glutathione (GSSG), and elevated reactive oxygen species (ROS), suggesting a Fenton-like reaction and resulting in oxidative stress. TEM revealed mitochondrial damage, and apoptosis assays confirmed that Cu4B significantly increased apoptotic cell rates (28.8%) compared to control (2.84%) and cisplatin-treated groups (3.93%), indicating mitochondrial pathway–mediated apoptosis. Furthermore, Cu4B treatment triggered the release of damage-associated molecular patterns (DAMPs) such as calreticulin (CRT), HMGB1, and ATP, demonstrating ICD induction. In a subcutaneous HCC mouse model, Cu4B elicited a potent antitumor immune response, as demonstrated by dendritic cell maturation and T cell proliferation. Cu4B treatment significantly inhibited tumor growth in both single and bilateral HCC-bearing mouse models. Notably, the combination of Cu4B with the HIF-1α inhibitor PX-478 significantly enhanced therapeutic efficacy by promoting cuproptosis, apoptosis, chemodynamic therapy, and immune activation, leading to marked tumor growth inhibition. **Conclusion:** Cu4B induces ICD in HCC by simultaneously activating cuproptosis, apoptosis, and chemodynamic therapy. Co-administration of PX-478 further amplifies these effects. This work providing a promising strategy for enhancing the efficacy of HCC immunotherapy.

3189 | DIAGNOSTIC ACCURACY OF THE GAAD SCORE IN NON-CIRRHOTIC PATIENTS WITH FOCAL LIVER LESIONS

Mohamed Moussa[1] Dave Sprengers[1] Vera Ketting[1] Christian Ramakers[1] Robert De Man[1] Roy Dwarkasing[1] Harry Janssen[2] Antonius van Herwaarden[3] Eric Tjwa[4] Milan Sonneveld[5], [1]Erasmus University Medical Center, Rotterdam, The Netherlands., [2]Erasmus University Medical Centre, Toronto Centre for Liver Disease, Toronto General Hospital, [3]Radboud University Medical Center, Nijmegen, The Netherlands, [4]Radboud University Medical Center, Nijmegen, Netherlands., [5]Erasmus University Medical Center, Rotterdam, The Netehrlands

Background: Focal liver lesions are frequently encountered, often as incidentalomas, in patients without cirrhosis. There is an urgent unmet need for non-invasive tests to distinguish hepatocellular carcinoma (HCC) from other lesions. We studied the diagnostic accuracy of the GAAD score, which is based on patient age, sex and serum values of AFP and PIVKA-II, in non-cirrhotic patients with focal liver lesions. **Methods:** In a multi-center prospective study, all consecutive patients presenting with focal liver lesions in a non-cirrhotic liver were enrolled from two tertiary referral clinics in the Netherlands. The diagnostic accuracy of the GAAD score was assessed at its predefined cutoff score of 2.57 and compared to AFP and PIVKA-II alone in the overall study population and after stratification by lesions size and presence of underlying liver disease. **Results:** A total of 583 patients were included. The median age was 50 years (IQR: 39–65), with 69% females, and the majority were Caucasian (84%). Liver disease was present in 37% of this cohort, with SLD as the most common etiology (28%), followed by viral hepatitis (10%). HCC was diagnosed in 74 (12.7%) cases. Patients with HCC were significantly older (median age 72 vs. 48, $p < 0.001$), and more often male (77% vs. 24%, $p < 0.001$). The GAAD score offered superior discrimination over AFP (AUC 0.96 vs 0.75, $p < 0.001$) and PIVKA-II (AUC 0.96 vs 0.91, $p < 0.011$). At a GAAD cut-off of 2.57, the sensitivity, specificity, PPV and NPV were 85%, 96%, 76% and 98%, with GAAD offering superior specificity over PIVKA-II and superior sensitivity over AFP. The performance of GAAD was consistent regardless of the presence of an underlying chronic liver disease (AUC 0.93 vs 0.97, $p = 0.228$), and regardless of the presence of viral hepatitis (AUC 0.99 vs 0.96, $p = 0.048$) or steatotic liver disease (AUC 0.92 vs 0.98, $p =$

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

0.189). The GAAD score had superior discriminatory performance over AFP in small (AUC; 0.92 vs 0.67, $p = 0.030$), intermediate (AUC; 0.93 vs 0.61, $p < 0.001$) and large (AUC; 0.98 vs 0.80, $p < 0.001$) lesions. GAAD also outperformed PIVKA-II in small (AUC; 0.92 vs 0.81, $p = 0.331$), intermediate (AUC; 0.93 vs 0.89, $p = 0.219$), and large (0.98 vs 0.93, $p = 0.011$) lesions and offered NPVs $> 95\%$ regardless of lesion size. **Conclusion:** In this cohort of non-cirrhotic patients with focal liver lesions, the GAAD score was highly predictive of HCC and offered superior diagnostic accuracy over AFP and PIVKA-II alone. These findings support the use of the GAAD score to guide management decisions in these patients.

3190 | DYNAMICS OF ALPHA-FETOPROTEIN LEVELS DURING TREATMENT WITH ATEZOLIZUMAB COMBINED WITH BEVACIZUMAB IN PATIENTS WITH ADVANCED HEPATOCELLULAR CARCINOMA

Rania Lithy[1] Bavly Daoud[2] Hany William[3] Yasser Elesnawy[3] Nouran Roby[3] Marwa Abdelghany[3] Mohamed Abdelwahed[3] Ashraf Omar[4] Ahmed Abdelmaksoud[5] Tamer Elbaz[6], [1]Faculty of Medicine, Cairo University, ESLC member, Cairo, Egypt, [2]Faculty of Medicine, Cairo University, [3]Ahmed Maher teaching hospital, Cairo, Egypt, [4]Faculty of Medicine, Cairo University, Egypt, ESLC founder, [5]Faculty of Medicine, Cairo University, Egypt, [6]Faculty of Medicine, Cairo University, Egypt, New giza University

Background: Atezolizumab plus bevacizumab is the current first-line standard for advanced unresectable hepatocellular carcinoma (HCC), with improved survival outcomes. However, the biological mechanisms underlying these outcomes, particularly the role of AFP dynamics, remain unclear. This study evaluates changes in Alpha-Fetoprotein (AFP) levels in advanced HCC patients treated with this regimen to assess AFP as a potential biomarker for treatment response and prognosis. **Methods:** This longitudinal study included 34 patients with advanced HCC treated with Atezolizumab and Bevacizumab every three weeks. Baseline characteristics, AFP levels, liver biochemical profile, tumor characteristics, and treatment response by the modified RECIST were assessed at three-month intervals over one year. Additionally, changes in AFP levels were analyzed in relation to total tumor volume (TTV). **Results:** Among the 34 patients, male were predominant (82.4%) with a mean age of 63 years, and 94% had chronic hepatitis C. All patients had an ECOG score of 0 and Child-Pugh class A; 33 were classified as BCLC stage C and one as stage B. The median baseline AFP level was 209.5 ng/mL (range: 6.9–5617.0 ng/mL), which declined significantly to 6.7 ng/mL after one year of treatment. Elevated AFP levels (> 10 ng/mL) were observed in 23 patients, of whom 78% showed an early AFP response ($\geq 30\%$ reduction within 3–6 months) and 21.7% showed a delayed response (6–12 months). Overall, 55.9% were AFP responders, 17.6% were non-responders, and 26.5% had stable AFP levels. Multivariate analysis identified baseline AFP and treatment-related side effects as potential predictors of AFP response. According to mRECIST, 11.7% achieved complete response, 47% partial response, and 8.8% had

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

progressive disease (P = 0.021). Progression-free survival was 58%, and overall survival reached 100%. A significant correlation was observed between reduced total tumor volume (TTV) and decreased AFP levels, with AFP declining from a mean of 11,741 ng/mL at baseline to 62 ng/mL at one year in patients exhibiting a favorable TTV response (p = 0.042). **Conclusion:** AFP dynamics can serve as a promising biomarker for evaluating treatment response in advanced HCC, especially in patients receiving Atezolizumab and Bevacizumab. These findings suggest that AFP monitoring could aid in predicting clinical outcomes and adjusting therapeutic strategies

3191 | LOSS OF PHOSPHOLIPASE CΓ1 SUPPRESSES HEPATOCELLULAR CARCINOGENESIS THROUGH BLOCKADE OF STAT3-MEDIATED CANCER DEVELOPMENT

Eun-Bi Seo[1], [1]Seoul National University College of Medicine

Background: Phospholipase C gamma 1 (PLCγ1) plays an oncogenic role in several cancers, alongside its usual physiological roles. Despite studies aimed at identifying the effect of PLCγ1 on tumors, the pathogenic role of PLCγ1 in the tumorigenesis and development of hepatocellular carcinoma (HCC) remains unknown. **Methods:** To investigate the function of PLCγ1 in HCC, we generated hepatocyte-specific PLCγ1 conditional knockout ($PLC\gamma1^{f/f}$; Alb-Cre) mice and induced HCC with diethylnitrosamine (DEN). **Results:** Here, we identified that hepatocyte-specific PLCγ1 deletion effectively prevented DEN-induced HCC in mice. $PLC\gamma1^{f/f}$; Alb-Cre mice showed reduced tumor burden and tumor progression, as well as a decreased incidence of HCC and less marked proliferative and inflammatory responses. We also showed that oncogenic phenotypes such as repressed apoptosis, and promoted proliferation, cell cycle progression and migration, were induced by PLCγ1. In terms of molecular mechanism, PLCγ1 regulated the activation of signal transducer and activator of transcription 3 (STAT3) signaling. Moreover, PLCγ1 expression is elevated in human HCC and correlates with a poor prognosis in patients with HCC. **Conclusion:** Our results suggest that PLCγ1 promotes the pathogenic progression of HCC, and PLCγ1/STAT3 axis was identified as a potential therapeutic target pathway for HCC.

3192 | PROGNOSTIC AND FUNCTIONAL STUDY OF SLC27A2 IN HEPATOCELLULAR CARCINOMA

Zhan Zeng Yifan Han[1] Ning Lin[1] yanyan yu[1] Xiaoyuan Xu[1], [1]Peking university first hospital

Background: Hepatocellular carcinoma (HCC) is a severe disease with poor prognosis. Solute carrier family 27 member 2 (SLC27A2), a fatty acid transport protein, has been reported to suppress tumor progression in renal cell carcinoma, lung cancer, and ovarian cancer. However, its role in HCC remains unclear. **Methods:** mRNA expression profiles and clinical data were extracted from the TCGA-LIHC cohort. Kaplan-Meier curves were generated to compare the survival difference in two groups. Plasmid-mediated overexpression of SLC27A2 was established in Huh7 hepatoma cells, with transfection efficiency confirmed by quantitative PCR (qPCR) and western blotting (WB). Functional assays, including Transwell migration, wound healing, Cell Counting Kit-8 (CCK-8) proliferation, and Annexin V-APC/PI apoptosis assays by flow cytometry, were conducted to assess phenotypic alterations following SLC27A2 overexpression. Differences between groups were compared by unpaired t-tests. **Results:** Analysis results of TCGA-LIHC dataset showed that SLC27A2 expression was significantly

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

decreased in HCC tissues compared to adjacent tissues ($p < 0.001$). And higher SLC27A2 expression correlated with improved overall survival and progression-free survival ($p < 0.001$). In vitro, SLC27A2 overexpression was successfully validated by qPCR ($p < 0.001$) and WB. Functionally, overexpression of SLC27A2 led to: (1) reduced cell migration in Transwell assays at 48 hours; (2) delayed wound closure in wound healing assays ($p = 0.001$); (3) suppressed proliferation, evidenced by lower CCK-8 optical density values from day 3 onward (($p < 0.001$); and (4) increased apoptosis rates compared to control cells ($p = 0.031$). **Conclusion:** SLC27A2 is downregulated in HCC and may associated with worse prognosis. Its overexpression suppresses proliferation and migration while promoting apoptosis in hepatoma cells, indicating a potential tumor-suppressive role in HCC pathogenesis.

3193 | PREDICTORS OF CURATIVE TREATMENT IN PATIENTS WITH EARLY-STAGE HEPATOCELLULAR CARCINOMA

Ashwini Arvind[1] Samuel Phen[2] Sneha Deodhar[1] Lisa Quirk[1] Gi Giamarqo[1] Amit Singal[1] Nicole Rich[3], [1]UT Southwestern Medical Center, [2]University of California, Riverside, [3]University of Texas Southwestern Medical Center

Background: Curative treatments are available for patients with early-stage hepatocellular carcinoma (HCC) but is underutilized in clinical practice. We aimed to identify predictors of curative treatment receipt and describe reasons for non-receipt in patients with early-stage HCC. **Methods:** We conducted a retrospective cohort study of patients with treatment-naïve, early-stage HCC (within Milan Criteria) seen between 2010 and 2021 at two US medical centers. Curative treatment included liver transplantation, surgical resection and ablation. Recommended primary treatment was determined per AASLD guidelines, and we recorded any barriers to treatment per clinical notes. We also used multivariable logistic regression analysis to identify predictors of curative treatment receipt. **Results:** Of 629 eligible patients, 396 (63.0%) received curative treatment (median age 60 years, 72.3% male). The cohort was racially and ethnically diverse (39.3% White, 25.8% Black, 28.8% Hispanic, 6.2% other). Per AASLD guidelines, liver transplant, surgical resection, and ablation were recommended in 204 (87.6%), 25 (10.7%), and 78 (33.5%) patients, respectively. The most common barriers to liver transplant were lack of funding (35.3%), comorbidities (25.0%) and psychosocial issues (19.6%). The most common barrier to resection was medical comorbidities (56.0%), whereas the most common barrier to ablation was proximity to major vessels or other technical challenges to a percutaneous approach (47.4%). Aggressive tumor biology and patient non-adherence were uncommon barriers to curative treatment (Figure 1). In multivariable analyses, curative treatment receipt was associated with care at the tertiary care transplant center (vs. safety-net system: OR 3.0, 95%CI 2.0-4.5), multifocal disease (OR 0.5, 95%CI 0.3-0.8), tumor size (continuous) (OR 0.7, 95%CI 0.6-0.9) and liver dysfunction (Child Pugh B vs. A: OR 0.3, 95%CI 0.2-0.4; Child Pugh C vs. A: OR 0.1, 95%CI 0.1-0.2). Compared to private insurance, those with Medicaid (OR 0.3, 95%CI 0.1-0.5), county-based financial assistance (OR 0.3, 95%CI 0.2-0.6) or no insurance (OR 0.2, 95%CI 0.1-0.5) were also less likely to receive curative treatment. **Conclusion:** Curative treatment is underused in early-stage HCC due to clinical, tumor-related and health system factors. Targeted strategies are needed to address specific barriers to improve overall treatment receipt.

3194 | ASSOCIATION OF TGF-β MOLECULES IN CIRCULATING TUMOR CELLS WITH DRUG RESISTANCE IN SYSTEMIC THERAPY FOR UNRESECTABLE HEPATOCELLULAR CARCINOMA

Yosuke Murata[1] Takuto Nosaka[1] Yu Akazawa[1] Tomoko Tanaka[1] Tatsushi Naito[1] Kazuto Takahashi[1] Masahiro Ohtani[1] Yasunari Nakamoto[1], [1]University of Fukui

Background: Systemic therapy for patients with advanced, unresectable hepatocellular carcinoma (HCC) has significantly changed with the introduction of combined immunotherapy. However, the mechanisms of drug resistance remain unclear, and there is no reliable biomarker for predicting disease progression. Circulating tumor cells (CTCs) derived from peripheral blood offer a noninvasive, real-time approach to assess tumor biology and treatment response, and have attracted attentions to reveal mechanisms of disease progression. In this study, CTCs were serially collected from patients with HCC undergoing systemic therapy: Atezolizumab plus Bevacizumab (Atezo+Bev), Tremelimumab plus Durvalumab (STRIDE) and Lenvatinib (LEN). Changes in molecular profiles of CTCs were analyzed to elucidate the mechanisms of drug resistance. **Methods:** We obtained 5mL of peripheral blood from 48 patients with HCC treated by systemic therapy (Atezo+Bev/STRIDE/LEN:29/8/11). Treatment response was assessed by RECIST ver.1.1. CTCs were isolated with RosetteSep Human CD45 Depletion Cocktail and enriched cells were stained with monoclonal antibodies targeting the cell surface antigens including Pan-CK and CD45. CD45 negative and Pan-CK positive cells were defined as CTCs by flow cytometry using a FACSAria II. CTC-derived RNA of patients with HCC (Atezo+Bev/STRIDE/LEN:14/5/9) underwent targeted RNA sequencing of 373 genes with next-generation sequencing (NGS) on Illumina Miseq. Gene set enrichment analysis (GSEA) was also performed. **Results:** CTC counts significantly increased correlating with Barcelona clinic liver cancer stages. In PR/SD group, CTC counts decreased at response evaluation, compared to baseline (Atezo+Bev, 193 ± 21 vs. 120 ± 16; STRIDE, 291 ± 91 vs. 85 ± 52; LEN, 185 ± 23 vs. 111 ± 16, $p < 0.05$, respectively) and increased at PD responses, reflecting changes in tumor burden. In NGS analysis, unsupervised hierarchical clustering classified into two clusters, A: responder group and B: non-responder group, in all three treatment groups. Notably, in Atezo+Bev and LEN, the median PFS was significantly longer in cluster A than in cluster B, with a tendency for improved OS in cluster A. GSEA in Atezo+Bev group revealed significant enrichment of TGF-β and MET signaling molecules such as ITGB1 and TGF-β1 in cluster B, and immune-related signaling pathways were enriched in cluster A in clinical course ($p < 0.05$). Furthermore, in LEN group, TGF-β signaling pathway was also elevated in cluster B ($p < 0.05$). **Conclusion:** In systemic therapy for HCC, CTC counts accurately reflect changes in tumor burden during clinical course. NGS analysis revealed that patients with elevated expression of TGF-β molecules in CTCs showed poorer responses to Atezo+Bev and LEN. This suggests TGF-β molecules may promote drug resistance and molecular profiling of CTCs may offer an effective biomarker to elucidate mechanisms of drug resistance in systemic therapy for HCC.

3195 | IMPACT OF PRIOR ONCOLOGICAL TREATMENT ON IMMUNOTHERAPY RESPONSES IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

SHING HIN CHUNG[1] Rex Wan-Hin Hui[1] Lu Li[1] Xianhua Mao[1] Chi Leung Chiang[1] Carlos King-Ho Wong[1] Ian Chi-Kei Wong[1] Man-Fung Yuen[1] Wai-Kay Seto[1] Lung Yi Mak[1], [1]The University of Hong Kong

Background: In recent years, immunotherapy has revolutionized the treatment of hepatocellular carcinoma (HCC). Our study aimed to investigate whether prior oncological treatment impacts HCC immunotherapy response. **Methods:** Patients with HCC treated with immunotherapy (nivolumab, pembrolizumab, atezolizumab, durvalumab, tremelimumab, ipilimumab) in January 2008 – June 2024 were identified from an electronic database in Hong Kong. Patients with other types of cancer diagnosis were excluded. Primary outcomes were overall survival (OS) and hospitalization

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

stratified by prior oncological treatment (curative: surgical resection, liver transplant, radiofrequency ablation, microwave ablation; non-curative: tyrosine kinase inhibitors (TKIs), transcatheter arterial chemoembolization and radiotherapy). Secondary outcomes included OS and hospitalization stratified by age (>60 vs ≤ 60 years), sex, virus-related HCC (hepatitis B virus or hepatitis C virus infection vs non-viral HCC), type 2 diabetes, cirrhosis, albumin-bilirubin (ALBI) grades (grades 2 & 3 vs grade 1), Model for End-Stage Liver Disease (MELD) scores (≥ 10 vs <10), and AFP levels (≥ 400 vs <400 ng/mL). Sensitivity analysis of excluding patients who received TKIs were also performed. The OS was evaluated using Kaplan–Meier method and hazard ratios (HRs) were calculated using Cox regression models. **Results:** We identified 1363 patients who received immunotherapy (15.1% with atezolizumab +bevacizumab, 37.8% with nivolumab monotherapy, 2.2% with durvalumab+tremelimumab). Among them, 314 (23.0%) received curative therapy and 470 (34.5%) received non-curative therapy prior to immunotherapy. The median time from curative and non-curative therapies to immunotherapy were 22.8 (IQR 7.3 – 77.2) and 13.5 (IQR 4.7 – 33.7) months, respectively. Kaplan-Meier analysis showed that patients with prior curative treatment had better OS [median 10.3 vs 7.5 months; HR 1.24 (95%CI 1.05-1.46), $p=0.011$], compared to those without. Conversely, patients with prior non-curative treatment were associated with worse OS [median 7.9 vs 8.1 months; HR 0.61 (95%CI 0.52-0.71), $p<0.001$] and higher risk of hospitalization [43.6% vs 29.5%; HR 1.63 (95%CI 1.37-1.94), $p<0.001$], compared to those without. Cirrhosis, higher ALBI grades, and higher AFP were associated with worse OS (all $p<0.001$) and higher risks of hospitalization (cirrhosis: $p=0.024$; ALBI: $p=0.044$; AFP: $p=0.026$), respectively. Higher MELD score was associated with worse OS ($p<0.001$). The results remained robust in sensitivity and subgroup analyses. **Conclusion:** HCC patients with history of curative therapy had better OS after immunotherapy treatment. Conversely, history of non-curative therapy was associated with poorer outcomes. Treatment history, HCC disease burden, and baseline liver function are important factors that influence the prognosis of HCC patients on immunotherapy.

	Overall survival			Hospitalization		
	HR	95% CI	P-value	HR	95% CI	P-value
Viral-HCC	1.16	(0.94, 1.42)	0.169	1.10	(0.85, 1.44)	0.459
Age (>60 vs ≤60 years)	1.09	(0.94, 1.27)	0.238	1.00	(0.84, 1.19)	0.979

3196 | IMMUNE CHECKPOINT INHIBITOR-INDUCED RAPID DECLINE IN HBV MARKERS IMPROVES THE PROGNOSIS OF HBV-RELATED HEPATOCELLULAR CARCINOMA PATIENTS

Yujie Ran[1] Minghui Zhu[1] Kunyuan Wang[1] Ying Xia[1] Yun Zhu[1] Mengya Zang[1] Shuai Kang[1] Qi Li[1] Xiaoyun Hu[1] Ying Wang[1] Fang Liu[1] Xiaowei Chen[1] Qian Zhao[1] Hongyan Liu[1] Dingli Liu[1] Huaiyu Chen[1] Jinzhang Chen[1] Yabing Guo[1] Rong Fan[1], [1]Nanfang Hospital, Southern Medical University, China

Background: There has been limited investigation regarding the antiviral efficacy of immune checkpoint inhibitors (ICIs) in HBV-related hepatocellular carcinoma (HCC) patients. We aimed to determine the antiviral effects of ICIs in patients with HBV-related HCC and investigate the correlation between declines in HBV markers and HCC prognosis. **Methods:** A retrospective cohort study was performed on 318 HBV-related HCC patients, including 268 who received ICIs (with or without targeted therapy; ICI group) and 50 who received targeted therapy alone (non-ICI group). During follow-up, the levels of quantitative HBsAg (qHBsAg), HBV DNA, HBV RNA, and HBcrAg were measured. Tumor response was evaluated according to RECIST 1.1. **Results:** Patients in the ICI group exhibited greater declines in the levels of qHBsAg, HBV DNA, HBV RNA, and HBcrAg than those in the non-ICI group after multiple imputation (Figure 1). At week 96, patients receiving ICIs demonstrated significantly higher cumulative incidences of HBsAg loss or decline ≥ 0.5 Log_{10} IU/mL (41.6% vs. 14.9%; HR: 5.74, 95% CI: 1.40-23.60, $p = 0.006$), HBV RNA negativity or decline ≥ 0.5 Log_{10} copies/mL (94.1% vs. 100%; HR: 1.80, 95% CI: 1.08-2.99, $p = 0.021$), and HBcrAg negativity or decline ≥ 1 Log_{10} U/mL (46.3% vs. 18.1%; HR: 4.29, 95% CI: 1.34-13.72, $p = 0.007$) compared with those receiving targeted therapy alone. Notably, lower baseline levels of HBV markers were significantly associated with improved overall survival (OS). Multivariate Cox analysis identified baseline HBcrAg levels as an independent prognostic factor for OS (HR: 2.75, 95% CI: 1.26-6.02, $p = 0.011$). Additionally, patients achieving HBsAg loss or a ≥ 0.5 Log_{10} decline, HBV DNA negativity, or HBV RNA negativity or a ≥ 0.5 Log_{10} decline had significantly improved OS than non-responders (HBsAg: 77.8% vs. 61.9%, $p = 0.046$; HBV DNA: 78.2% vs. 26.7%, $p < 0.001$; HBV RNA:

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

70.3% vs. 46.0%, p = 0.001), while HBcrAg negativity or a ≥1 Log_{10} decline trended toward improved OS (74.5% vs. 59.5%, p = 0.137). These virological responders also showed significantly improved progression-free survival (HBsAg: 44.0% vs. 24.2%, p = 0.023; HBV DNA: 43.0% vs. 13.2%, p < 0.001; HBV RNA: 34.9% vs. 12.3%, p < 0.001; HBcrAg: 35.1% vs. 24.0%, p = 0.032) and better objective response rate and disease control rate. **Conclusion:** ICIs may serve as an effective strategy for managing or eliminating HBV infection. The effective suppression of HBV markers is crucial for improving the prognosis of HCC patients.

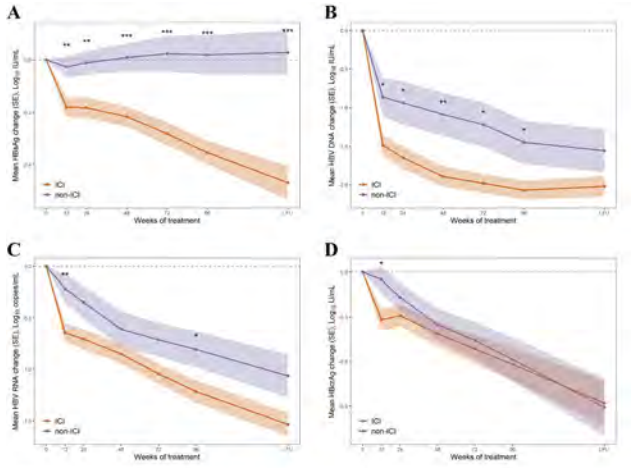

Figure. 1. The decline in the levels of qHBsAg (A), HBV DNA (B), HBV RNA (C) and HBcrAg (D) among the ICI and non-ICI groups after multiple imputation. Statistical significance between groups at each time point is indicated (*p<0.05, **p<0.01, ***p<0.001). qHBsAg, quantitative hepatitis B surface antigen; HBV, hepatitis B virus; HBcrAg, hepatitis B virus core-related antigen.

3197 | TUMOR RESPONSE PATTERNS OF SECOND-LINE TYROSINE KINASE INHIBITORS FOLLOWING ATEZOLIZUMAB/BEVACIZUMAB IN ADVANCED HEPATOCELLULAR CARCINOMA: A PROPORTIONAL META-ANALYSIS

Nehemias Guevara Rodriguez[1] Ronald Blanco Montecino[2] Noemy Coreas[3] Yassine Kilani[4] Syeda Fatima Kamal[5] Daniel Mendoza Quispe[2] Iqra Arshad[4] Kamran Qureshi[6] John Richart[1], [1]Division of Hematology-Oncology and BMT, Saint Louis University, St. Louis, MO, [2]Department of Internal Medicine, St Barnabas Hospital, Bronx, NY., [3]National University of El Salvador, Social Security System, Division of OBGYN-Oncology, [4]Division of General Internal Medicine, Saint Louis University School of Medicine, St. Louis, MO, [5]Division of Hospice and Palliative Medicine, Saint Louis University School of Medicine, St. Louis, MO, [6]Division of Gastroenterology and Hepatology, Saint Louis University School of Medicine, St. Louis,MO

Background: The introduction of Atezolizumab/Bevacizumab has redefined first-line therapy for advanced hepatocellular carcinoma (HCC). However, the optimal second-line strategy remains unclear, especially regarding expected tumor responses. While survival outcomes have been reported, tumor control metrics such as objective response rate (ORR) and disease control rate (DCR) have not been comprehensively evaluated across second-line tyrosine kinase inhibitors (TKIs). This proportional meta-analysis aimed to define radiologic tumor response patterns with TKIs following immune checkpoint inhibitor (ICI) failure. **Methods:** We conducted a systematic proportional meta-analysis of studies reporting RECIST 1.1-based tumor responses to second-line TKIs—including Lenvatinib, Regorafenib, Sorafenib, and Cabozantinib—following progression on Atezolizumab/Bevacizumab. Outcomes of interest included absolute CR, PR, SD, ORR, DCR. Extracted data from 9 retrospective studies were pooled using a random-effects model and TKI-stratified proportions. All statistical analyses, including pooled proportions and heterogeneity estimates, were performed using Stata version 18 (StataCorp, College Station, TX). **Results:** Across 907 patients, ORR remained modest overall, with a pooled rate of 7%. Stratified analysis demonstrated an ORR of 12% for Lenvatinib, 11% for Regorafenib, 5% for Cabozantinib, and 4% for Sorafenib. DCR was notably higher, with a pooled estimate of 53%, mainly driven by stable disease. Regorafenib had the highest DCR at 67%, followed by Lenvatinib (50%), Cabozantinib (66%), and Sorafenib (35%). Complete responses were exceedingly rare (< 1%). Study heterogeneity was moderate to high (I^2 ranging from 41% to 85%), which could be attributed to differences in sample size, patient populations, and study design across the included retrospective studies. **Conclusion:** Although objective responses to second-line TKIs are limited, their ability to achieve substantial disease stabilization underscores their continued clinical utility following immune checkpoint inhibitor (ICI) failure in advanced HCC. This study found that while the overall objective response rate (ORR) remained modest at 7%, disease control rates (DCR) were notably higher, with Regorafenib and Lenvatinib showing the most favorable

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

profiles. The findings emphasize the importance of TKIs as second-line agents for HCC, particularly in the evolving post-immunotherapy landscape where DCR may be a relevant surrogate for clinical benefit. Notably, moderate to high heterogeneity (I^2 ranging from 41% to 85%) was observed, likely due to differences in sample size, patient populations, and study designs. Despite these limitations, the ability of second-line TKIs to stabilize disease in over half of patients progressing on Atezolizumab/Bevacizumab highlights their potential as viable second-line options.

Table 1. Summary of all included studies.

Author (Year)	Intervention(s)	Study Design	Study Period	Sample Size (N)	Location	Placebo-Controlled

3198 | PHARMACOLOGICAL ACTIVATION OF PPARα REVERSES ANTI-PD-1 RESISTANCE IN HCC BY RESTORING GSDME-MEDIATED PYROPTOSIS WITHIN FIBROINFLAMMATORY LIVER MICROENVIRONMENT

peng chen[1] Zheyu Dong[1] Kai Xiong[2] Zhili Wen[2] Huajin Pang[1] Yuchuan Jiang[2], [1]Nanfang Hospital Southern Medical University, [2]The Second Affiliated Hospital of Nanchang University

Background: Resistance to anti-Programmed cell death protein 1 (anti-PD-1) remains a major clinical obstacle in hepatocellular carcinoma (HCC). The fibroinflammatory liver microenvironment (FILM), characterized by excessive extracellular matrix deposition and immunosuppressive inflammatory cell infiltration, has been implicated in anti–PD-1 resistance; however, the underlying mechanisms remain poorly understood. **Methods:** Clinical HCC cohorts and syngeneic HCC mouse models were used to investigate the role of FILM in reducing immune activation and attenuating the efficacy of anti–PD-1 therapy through pyroptosis suppression. Multi-omic analyses and in vivo assays were conducted to determine the role of peroxisome proliferator-activated receptor alpha (PPARα) in FILM mediated inhibition of pyroptosis. Mechanistic studies were conducted using ChIP-PCR, flow cytometer, co-culture assays. The therapeutic synergy between PPARα activation and anti–PD-1 therapy was evaluated in murine models and a retrospective HCC patient cohort. **Results:** Clinically, we stratified HCC patients based on the degree of inflammation and fibrosis in para-tumor liver tissues using the METAVIR scoring system. Patients characterized by significant inflammation and advanced fibrosis—referred to as the representative FILM group—exhibited the poorest prognosis compared to other subgroups and demonstrated resistance to anti-PD-1 therapy. Functionally, FILM suppressed GSDME-dependent pyroptosis in HCC cells, leading to reduced infiltration immune cells and anti-PD-1 resistance. Mechanistically, with in the FILM, cancer-associated fibroblasts recruited $NOS2^+$ macrophages, which down-regulated PPARα transcription and activation in HCC via nitric oxide signaling. This reduced PPARα binding to the PDK4 promoter, decreased mitochondrial ROS production, and ultimately impaired the canonical ROS/Caspase-3/GSDME pyroptotic pathway. Therapeutically, pharmacological activation of PPARα using the agonist GW7647 promoted GSDME-mediated pyroptosis and reprogrammed the immunosuppressive microenvironment, suppressing tumor growth. Notably, combination therapy with PPARα agonists (GW7647 or the clinically approved fenofibrate) and anti-PD-1 achieved superior anti-tumor effects compared to monotherapy in both mouse models and retrospective patient analyses. **Conclusion:** This study identifies PPARα activation as a promising strategy to overcome FILM-induced anti-PD-1 resistance in HCC by restoring GSDME-mediated pyroptosis. Combining PPARα agonists with immune checkpoint inhibitors represents a potential therapeutic approach for HCC patients, particularly those with FILM.

3199 | AGE-DEPENDENT DEVELOPMENT OF HEPATOCELLULAR CARCINOMA IN LIVER-SPECIFIC BETAINE HOMOCYSTEINE METHYLTRANSFERASE (BHMT) KNOCKOUT MICE

Sathish kumar Perumal[1] Ramachandran Rajamanickam[1] Ramesh Bellamkonda[2] Sundararajan Mahalingam[2] Natalia Osna[3] Kurt Fisher[3] Benita McVicker[3] Karuna Rasineni[3] Kusum Kharbanda[1], [1]Research Service, Veterans Affairs Nebraska-Western Iowa Health Care System, Omaha, Nebraska, USA, [2]University of Nebraska Medical Center, Omaha, Nebraska, USA, [3]University of Nebraska Medical Center, Omaha, NE, USA

Background: Hepatocellular carcinoma (HCC) is a major form of liver cancer, often associated with chronic liver diseases and genetic predispositions. Betaine homocysteine methyltransferase (BHMT) is an enzyme critical for one-carbon metabolism and liver health. There is a loss of BHMT in liver cancer cell lines. To understand whether this loss is a cause or a consequence of HCC development, we investigated the role of liver-specific deletion of BHMT in hepatocarcinogenesis development. **Methods:** We generated liver-specific BHMT knockout (BHMT LKO) mice using Cre-loxP recombination under the control of the albumin promoter. Both male and female mice were monitored and aged up to 2 years. Liver tissues were harvested at various time points for histopathological examination, immunohistochemistry, and gene expression analyses. **Results:** Liver-specific BHMT deletion resulted in progressive liver pathology in aging mice. Starting at 6 months of age, BHMT LKO mice began to develop steatosis, which progressed to severe steatohepatitis and fibrosis with aging. At 2 years of age, a 3-fold increase in the liver to body weight ratio and HCC development identified by reticulin staining in all BHMT LKO mice compared to the floxed mice. Further analysis revealed increase in IL-6 with a concomitant decrease in PTEN that correlated with the severity of liver damage and tumor burden in BHMT LKO mice compared with age-matched floxed mice. **Conclusion:** Liver-specific deletion of BHMT in mice results in an age-dependent progression of liver disease, ranging from steatosis to steatohepatitis and fibrosis, ultimately leading to HCC development in 100% of BHMT LKO mice. These findings highlight the critical role of BHMT in preserving liver homeostasis and suggests that individuals carrying loss-of-function BHMT polymorphisms may be at increased risk for developing advanced liver disease with age. The BHMT LKO mouse model could serve as a valuable tool for investigating the molecular mechanisms that connect one-carbon metabolism to HCC development.

Unit Healthy Metabolism, Medical Faculty Mannheim of Heidelberg University, Germany

Background: Hepatocellular carcinoma (HCC) is a leading cause of tumor-related mortality worldwide, with increasing incidence in Europe and the United States. Early diagnosis remains a major challenge but is critical for improving patient outcomes. Artificial intelligence (AI) applications, particularly radiomics, offer new opportunities for enhanced imaging-based detection. However, high-quality standardized datasets for AI training are lacking. **Methods:** All patient data were extracted from the Mannheim University Hospital´s clinical information system and securely stored in a REDCap database. The project was reported to the Ethics Committee II of the University of Heidelberg (application number 2023-873). Data quality was ensured through rigorous validation processes, including SOPs and structured data flow mappings. Imaging data were fully segmented and radiomics features were extracted. **Results:** Clinical, imaging, and laboratory data from 100 HCC patients were systematically collected, annotated, and integrated into a secure Digital Research Environment (DRE). Validation demonstrated high data consistency and integrity. A use case applying multi-modal classification for TNM staging achieved a prediction accuracy of 0.89 $\pm$ 0.05 and an AUC of 0.93 $\pm$ 0.03 using an XGBoost classifier. Data packages were made publicly available via the heiDATA platform (https://doi.org/10.11588/DATA/IKFTTQ), accompanied by the development of a user-friendly access interface. A synthetic data generation approach based on diffusion models was also developed to enhance patient data privacy. **Conclusion:** Q-HCC successfully established a high-quality, privacy-compliant dataset for HCC, demonstrating the critical value of combining clinical, imaging, and laboratory data for AI applications. This initiative provides a strong foundation for future research in precision oncology and AI-supported diagnostics. Free Online access: https://doi.org/10.11588/DATA/IKFTTQ

3201 | PHYSIOLOGIC AND SOCIAL STRESS PREDICT MORTALITY IN HEPATOCELLULAR CARCINOMA: INDEPENDENT CONTRIBUTIONS OF ALLOSTATIC LOAD AND HEALTH LITERACY

Sebastian Abad[1] Allie Carter[2] Nicole Garcia[3] Lauren Nephew[4], [1]Indiana University School of Medicine, [2]Department of Biostatistics & Health Data Science, IUSM, [3]Division of Hepatology and Gastroenterology, Indiana University School of Medicine, [4]Indiana University

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related death, disproportionately affecting socially vulnerable populations. Chronic social adversity may influence outcomes through physiologic stress pathways. Allostatic load (AL), a composite biomarker of stress-related physiologic dysregulation, has not been well studied in liver cancer. **Methods:** We conducted a retrospective cohort study of 139 adults with HCC from two hospitals in Indianapolis. AL was calculated using six biomarkers (blood pressure, BMI, glucose, albumin, creatinine/eGFR, and heart rate); scores ≥ 3 indicated high AL. Relationships between AL and 14 social determinants of health (SDOH) indicators were examined using correlation and regression. Cox proportional hazards models assessed associations with mortality, adjusting for clinical variables. **Results:** The cohort was 73% male, 83% White, with a median age of 64. AL was not significantly correlated with individual or cumulative SDOH indicators ($r = -0.11$; $p = 0.21$). High AL was associated with increased mortality (HR 1.25; 95% CI 1.01–1.55; $p = 0.045$). Low health literacy was also associated with mortality (HR 1.83; 95% CI 1.10–3.05; $p = 0.021$). When both were modeled together, the hazard ratio for AL was attenuated. In stratified models, AL predicted mortality only among patients with high health literacy (HR 1.29; 95% CI 1.03–1.61; $p = 0.028$), but not among those with low literacy (HR 1.11; 95% CI 0.71–1.72; $p = 0.65$). The interaction term in combined models was not statistically significant ($p = 0.727$). **Conclusion:** Physiologic stress (AL) and low health literacy are each associated with mortality in HCC. The effect of AL may be attenuated in patients with low health literacy, suggesting that social and biological risks interact in complex ways. Future studies should

examine whether interventions that address both biologic stress and communication barriers can improve liver cancer outcomes.

Table 1. Associations Between Allostatic Load, Health Literacy, and Mortality

Model Description	HR (95% CI)	p-value
Allostatic Load (univariable)	1.27 (1.05–1.55)	0.016
Health Literacy (univariable)	1.83 (1.10–3.05)	0.021
Allostatic Load + Health Literacy (multivariable)*	1.20 (0.96–1.50); 1.84 (1.09–3.12)	0.107; 0.023
Allostatic Load: High Health Literacy (stratified)	1.29 (1.03–1.61)	0.028
Allostatic Load: Low Health Literacy (stratified)	1.11 (0.71–1.72)	0.650
Interaction Term (AL × Health Literacy)	—	0.727

*Models adjusted for age, MELD-Na, BCLC stage, and Charlson comorbidity index.

3202 | PREDICTING MORTALITY IN PATIENTS WITH HEPATOCELLULAR CARCINOMA: INSIGHTS FROM A MULTICENTER COHORT

JIHYE LIM[1] Seok-Hwan Kim[2] Myeong Jun Song[3], [1]Yeouido St. Mary's Hospital, [2]Daejeon St. Mary's Hospital, The Catholic University of Korea, [3]The Catholic University of Korea

Background: Renal function is a known prognostic factor in patients with end-stage liver disease, yet its impact in hepatocellular carcinoma (HCC) remains underexplored. This study aimed to evaluate the effect of renal function on overall survival in patients with HCC and to compare the prognostic performance of commonly used liver-specific risk models stratified by renal function. **Methods:** We analyzed a nationwide, multicenter cohort comprising 12,665 treatment-naïve patients newly diagnosed with HCC, including 11,464 with preserved renal function and 1,201 with reduced renal function. Overall survival was compared between the two groups. Prognostic performance of the Child–Pugh score, MELD, MELD-Na, MELD 3.0, ALBI, and PALBI grades was assessed using Cox proportional hazards models and time-dependent area under the receiver operating characteristic curve (AUROC) analysis. **Results:** The mean age of the cohort was 61.5 ± 11.7 years, and 78.9% were male. Over a mean follow-up of 51.0 ± 46.9 months, 7,766 deaths occurred in the preserved renal function group and 1,017 in the reduced renal function group. Reduced renal function was independently associated with increased mortality (hazard ratio: 1.58; 95% CI: 1.48–1.69). Despite lacking renal parameters, the PALBI grade consistently demonstrated the highest prognostic accuracy across both renal function strata (time-dependent AUROC at 1 years: 0.828 in reduced renal function group, 0.866 in preserved group), outperforming other models (Figure). **Conclusion:** Renal function significantly impacts survival in patients with HCC and should be routinely monitored and managed. PALBI grade, though lacking direct renal parameters, serves as a reliable risk stratification. Combined use of PALBI and renal function assessments may enhance prognostication and guide clinical management in HCC.

3203 | SETDB1 PROMOTES INTRAHEPATIC CHOLANGIOCARCINOMA PROGRESSION THROUGH METABOLIC REPROGRAMMING AND IMMUNOSUPPRESSIVE MICROENVIRONMENT REMODELING

Xiuqin Huang[1] Xinhua Song[1] Jiabo Wang[1] Zherui Liu[2] Qidi Cui[1] Enxiang Zhang[1], [1]School of Traditional Chinese Medicine, Capital Medical University, Beijing 100069, China, [2]Peking University 302 Clinical Medical School, Beijing, China

Background: Intrahepatic cholangiocarcinoma (ICC), the second most prevalent primary liver malignancy with limited therapeutic options. SETDB1 has been reported to promote the development of multiple tumors. However, the role of SETDB1 in ICC remains unclear. **Methods:** Immunohistochemical staining was performed to detect SETDB1 expression in ICC tumor tissues. SETDB1-knockout sgp19-KRas-induced and AKT-YAP-induced orthotopic ICC models were established using hydrodynamic tail vein transfection. Seahorse glycolysis rate assays were used to determine the glycolytic levels of ICC cells. Flow cytometry and immunohistochemical staining were used to detect the infiltration of immune cells in the ICC tumor microenvironment. ATAC-seq and RNA-seq were used to identify potential functional targets of SETDB1 in ICC, while CUT-RUN assays were employed to validate the interaction pattern and binding regions between SETDB1 and P53. **Results:** Immunohistochemical staining revealed high expression of SETDB1 in ICC tumor tissues, and its expression was correlated with patient prognosis. The deficiency of SETDB1 can inhibit the progression of intrahepatic cholangiocarcinoma and prolong the survival time of model mice. SETDB1-

deficient tumor cells exhibited significantly reduced glycolytic activity. Furthermore, flow cytometry and immunohistochemical analysis showed that SETDB1 depletion inhibited the distribution of vimentin$^+$ cancer-associated fibroblasts, and promoted the infiltration of CD8$^+$ T cells and M1-type macrophages in the ICC tumor microenvironment. Mechanistically, SETDB1 deficiency relieved transcriptional repression of the TP53 promoter, upregulated P53 expression, suppressed GLUT1 expression in the glycolytic pathway, and consequently inhibited tumor glycolysis. **Conclusion:** This study highlights the role of SETDB1 in tumor glycolysis and tumor microenvironment in ICC. As an oncogenic factor, SETDB1 promotes ICC progression through dual mechanisms: 1. Enhancing tumor glycolysis via the SETDB1-P53-GLUT1 axis; 2. Regulating the tumor microenvironment to facilitate immune evasion. Targeting SETDB1 may represent a promising therapeutic strategy for ICC.

3204 | NRF2–COX2–PGE$_2$ AXIS DRIVES IMMUNE COLD TUMORS AND PREDICTS RESISTANCE TO ATEZOLIZUMAB AND BEVACIZUMAB THERAPY IN HEPATOCELLULAR CARCINOMA

Shuhei Yamamoto[1] Takahiro Kodama[1] Kazuki Maesaka[1] Akifumi Kuwano[2] Kenta Motomura[2] Tomomi Yoshida-Hashidate[3] Hideo Shindo[4] Haruhiko Takeda[5] Kumiko Shirai[1] Yuta Myojin[1] Kazuhiro Murai[1] Yuki Makino[1] Yuki Tahata[1] Yoshinobu Saito[1] Hayato Hikita[1] Tomohide Tatsumi[1] Tetsuo Takehara[6], [1]Osaka University Graduate School of Medicine, [2]Iizuka Hospital, [3]Japan Institute for Health Security, National Center for Global Health and Medicine, [4]Japan Institute for Health Security, National Institute of Global Health and Medicine, [5]Kyoto University Graduate School of Medicine, [6]Kansai Rosai Hospital

Background: Atezolizumab plus bevacizumab (Atez/Bev) is a first-line therapy for advanced hepatocellular carcinoma (HCC), but many patients show limited or no response. To elucidate resistance mechanisms, we analyzed the tumor immune microenvironment (TIME) in mouse models and human HCC tissues. **Methods:** Two immunocompetent mouse HCC models were used: a genetically heterogeneous model generated by hydrodynamic tail vein injection (HTVi) of 10 oncogenes, and a syngeneic model using Hep55.1c cells. TIME was assessed using RNA sequencing and spatial transcriptomics (ST). Human samples included 199 resected HCC tissues, 33 pre-treatment biopsies from Atez/Bev-treated patients, and 247 biopsies from the IMbrave150 clinical trial. ST was also performed on paired pre- and post-progression biopsies from two patients. Outcomes related to COX2 inhibitor use were analyzed in 220 Atez/Bev-treated HCC patients. **Results:** In mice, Atez/Bev therapy inhibited angiogenesis, increased tumor-infiltrating lymphocytes (TILs), and prolonged survival. Responding tumors were enriched for effector CD8$^+$ and cytotoxic CD4$^+$ T cells with active antigen presentation via CCL5 and MHC signaling. Resistant tumors exhibited Treg accumulation, exhausted CD8$^+$ T cells, reduced MHC expression, and NRF2 pathway activation. In human HCC tissues, an immune “HOT” TIME with partial exhaustion and close spatial proximity between tumor and immune cells correlated with favorable responses. Non-responders and tumors at progression showed immune “COLD” features, TIL reduction, and NRF2 activation. NRF2-overexpressing tumors also showed increased COX2 expression and an immunosuppressive TIME. In the syngeneic model, NRF2 overexpression induced COX2/PGE2 signaling and conferred resistance to Atez/Bev. Inhibition of NRF2 or COX2 restored therapeutic response. In human samples, NRF2-high tumors showed TIL exclusion and high COX2 expression. Patients treated with COX2 inhibitors had prolonged progression-free survival during Atez/Bev therapy. Notably, in the IMbrave150 trial cohort, patients with poor response also exhibited immune COLD TIME with elevated NRF2 and COX2 signatures. Additionally, plasma PGE2 levels stratified patients according to treatment response. **Conclusion:** NRF2/COX2-driven immune COLD TIME underlies resistance to Atez/Bev

3205 | COMPARATIVE EVALUATION OF FIRST-LINE IMMUNOTHERAPY REGIMENS IN ADVANCED HCC: A NNT- (NUMBER NEEDED TO TREAT) AND NNH- (NUMBER NEEDED TO HARM) BASED ANALYSIS

Luca Galbato Muscio[1] Giorgia Pezzola[1] Emanuela Di Giacomo[1] Andrea Falcomatà[2] Claudia Fulgenzi[3] Giovanni Galati[4] Paolo Gallo[4] Giuseppina Pacella[5] Gianluca Mascianà[6] Rebecca Casati[5] Gabriele D'Ercole[7] Michele Fiore[7] Giuseppe Tonini[1] Antonio Picardi[4] Rosario Francesco Grasso[5] Marianna Silletta[1], *[1]Medical Oncology, Fondazione Policlinico Universitario Campus Bio-Medico, Rome, Italy, [2]Hepatology, Fondazione Policlinico Universitario Campus Bio-Medico, Rome, Italy, [3]Department of Surgery and Cancer, Imperial College London, London, UK, [4]Hepatology, Department of Medicine and Surgery, Università Campus Bio-Medico, Rome, Italy, [5]Interventional Radiology, Fondazione Policlinico Universitario Campus Bio-Medico, Roma, Italy, [6]Colorectal Surgery, Fondazione Policlinico Universitario Campus Bio-Medico, Roma, Italy, [7]Radiation Oncology, Fondazione Policlinico Universitario Campus Bio-Medico, Roma, Italy*

Background: In the past decade, the treatment landscape of advanced hepatocellular carcinoma (HCC) has evolved significantly with the introduction of several effective immunotherapy-based regimens. However, no direct head-to-head comparisons exist between these therapies. In this context, network meta-analyses have been employed to indirectly compare six immune checkpoint inhibitor (ICI) combinations. **Methods:** The aim of our study is to assess and compare the selected regimens using two clinically relevant parameters: Number Needed to Treat (NNT) and Number Needed to Harm (NNH); which reflect the risk reduction in mortality and the increase in treatment-related toxicities, respectively. We included first-line positive phase III clinical trials that reported or allowed extraction of 18- and 24-month overall survival (OS) rates. The trials analyzed were: REFLECT, IMbrave150 (including updates), HIMALAYA, CAREs-310, RATIONALE-301, and CheckMate 9DW. NNT and NNH were calculated using the following formulas: NNT = 1 / (Risk in control arm – Risk in experimental arm) and NNH = 1 / (Risk in experimental arm – Risk in control arm). A lower NNT indicates a more effective treatment, while a higher NNH indicates better safety. Negative NNH values, due to the comparison with an active treatment instead of placebo, suggest that ICI-based therapies appear less toxic. OS rates were taken from published data or extracted from Kaplan–Meier curves using WebPlotDigitizer v10 when not directly reported. For NNH, we analyzed rates of grade 3–4 treatment-related adverse events (TRAEs). **Results:** At 18 and 24 months, the most favorable regimens in terms of NNT were: camrelizumab/rivoceranib: NNT = 6.4 (18 months), 8.1 (24 months); atezolizumab/bevacizumab: NNT = 8.3 (18 months), 9.0 (24 months) and durvalumab/tremelimumab: NNT = 13.9 (18 months), 12.7 (24 months). Based on NNH, the regimens with the most favorable safety profiles were: tislelizumab: NNH = –3.21; durvalumab/tremelimumab: NNH = –9.1 and atezolizumab/bevacizumab: NNH = –33.3. These findings highlight both efficacy and differential safety profiles among the first-line immunotherapy options for advanced HCC. **Conclusion:** In the absence of direct comparisons between first-line treatments for unresectable HCC, NNT and NNH offer valuable quantitative tools to support clinical decision-making. According to the selected metrics, Atezolizumab/Bevacizumab and Durvalumab/Tremelimumab appeared to have the best risk/benefit ratio.

STUDY	OS 18MO ICK	OS 18MO EXP	OS 24MO CR	OS 24MO EXP	NNT 18MO	NNT 24MO	NNH

3206 | A NOVEL ROLE OF SECRETED METHIONINE ADESNOSYLTRANSFERASE α2 IN THE DEVELOPMENT OF COLORECTAL LIVER METASTASES

Monica Justo[1] Heping Yang[1] Andrea Floris[1] Youngyi Lim[1] Swati Chandla[1] Manisha Dagar[1] Alexandra Gangi[1] Maria Lauda Tomasi[1] Shelly Lu[1], [1]Cedars Sinai Medical Center

Background: Colorectal liver metastasis (CRLM) occurs in 50% of patients with colorectal cancer (CRC). Methionine adenosyltransferase (MAT) catalyzes the formation of S-adenosylmethionine (SAMe), the principal methyl donor. *MAT1A* (encodes MATα1) is expressed mainly in normal adult liver, whereas *MAT2A* (encodes MATα2) is expressed in all extrahepatic tissues. We reported MAT1A is a major defense against CRLM as loss of *Mat1a* sensitizes the liver to CRLM. In contrast, MAT2A is overexpressed in CRC and promotes oncogenicity. We found that human hepatocytes co-cultured with RKO (human CRC) cells, had lower MAT1A expression. Here, we sought to determine if MATα2 is secreted and if it affects hepatocytes' MAT1A expression.

. **Methods:** Our study included human hepatocytes, RKO cells, extracellular vesicle (EV) isolation, chromatin immunoprecipitation (ChIP), ChIP-seq, promoter activity assays, proliferation, migration, and invasion assays, western blotting, immunohistochemistry and immunofluorescence. We confirmed some of the findings using human CRLM and normal liver tissue array and human plasma. **Results:** CRCs secrete MATα2 in free but truncated form (MATα2-t) and intact within EVs. EV-MATα2 can be internalized by human hepatocytes and found within the nucleus, which then binds to *MAT1A* and *MAT2A* promoters on ChIP to lower and increase *MAT1A* and *MAT2A* promoter activities, respectively. In human CRLM samples, hepatocytes in nontumor regions express lower MATα1 but higher MATα2 as compared to normal liver. Treating RKO cells with EVs released from RKO cells overexpressing MAT2A promoted cell proliferation, migration, and invasion. MATα2-t was detected at a higher level in media from colon, pancreatic, and prostate cancer cell lines than corresponding normal epithelial cells as well as CRC patients' plasma than healthy controls. RKO cells treated with MATα2-t activated focal adhesion kinase (FAK), an important kinase for cancer cell evasion of apoptosis. Conversely, treatment with MATα2 neutralizing antibody inhibited FAK and induced apoptosis. **Conclusion:** CRC cells secrete both MATα2 within EVs and free MATα2-t. EV-MATα2 can be internalized and act as a transcription factor to lower hepatocytes' MAT1A, the major defense against CRLM, while promoting CRC oncogenicity. Freely released MATα2-t acts as a ligand in an autocrine fashion to activate FAK, which is essential for CRC survival. Taken together, secreted MATα2 plays an essential role in promoting CRLM.

3207 | RECENT TRENDS IN SURVEILLANCE-DETECTED HCC IN THE UNITED STATES

Naomy Kim[1] Abdelrahman Attia[1] Emily Truong[1] Hasmik Adetyan[1] Rami Hemadeh[1] Manaf Alsudaney[1] Jaeho Park[2] Aarshi Vipani[1] Hirsh Trivedi[1] Yun Wang[1] Walid Ayoub[1] Alexander Kuo[1] Paul Martin[1] Hyunseok Kim[1] Ju Dong Yang[1], [1]Cedars-Sinai Medical Center, [2]University of Arkansas Medical Sciences

Background: Hepatocellular carcinoma (HCC) remains a leading cause of cancer-related mortality. Surveillance programs aim to detect HCC at an early stage, potentially improving survival through curative treatments. Despite increased public awareness, recent trends in surveillance-detected HCC and its associated outcomes require further investigation. **Methods:** We analyzed data from 1,801 HCC patients diagnosed between 2009 and 2025 at a tertiary referral center in the U.S., categorized by detection method: symptomatic ($n = 486$), incidental ($n = 614$), and surveillance ($n = 701$). Tumor characteristics (size and number of lesions) and staging (BCLC) were compared across groups. Survival was assessed using Cox regression, with median overall survival (OS) and hazard ratios (HR) calculated. **Results:** Surveillance-detected HCC rates have not increased recently, with detection rates remaining stable at 23.4% (2021–2025), comparable to 23.0% (2009–2012) and 22.7% (2017–2020. Surveillance-detected cases were associated with smaller tumors (≤ 2 cm: 36.2% vs. 4.0% symptomatic, 19.4% incidental and > 5 cm: 11.1% vs. 70.1% symptomatic, 30.5% incidental, $p < 0.001$) and earlier BCLC stages (0–A: 78.8% vs. 24.0% symptomatic, 64.2% incidental, $p < 0.001$). Single lesions were more common in surveillance cases (70.3% vs. 49.5% symptomatic, 62.4% incidental, $p < 0.001$). Surveillance cases had a

higher chance of curative treatment (52.2% vs. 17.2% symptomatic, 43.3% incidental, $p < 0.001$). Median OS was significantly higher for surveillance (75 months) and incidental (65 months) cases compared to symptomatic (21 months, $p < 0.001$) cases. Cox regression analysis adjusted for maximum tumor diameter, number of lesions, age, gender, and race showed improved survival for incidental (HR 0.73, 95% CI 0.60–0.88, $p < 0.001$) and surveillance (HR 0.76, 95% CI 0.62–0.93, $p = 0.007$) versus symptomatic cases, with no significant survival difference between incidental and surveillance groups. **Conclusion:** Despite increased awareness, surveillance-detected HCC has not risen recently, suggesting potential gaps in implementation, which could be in part attributable to COVID 19 pandemic in the most recent years. Surveillance is strongly associated with early-stage disease, smaller tumors, and fewer lesions, offering a higher chance of curative treatment and improved survival compared to symptomatic detection, though outcomes are similar to incidental cases. Enhanced surveillance strategies are needed to improve early detection rates.

3208 | QUALITY OF LIFE AND BEHAVIORAL RISK PROFILES IN PATIENTS WITH CHOLANGIOCARCINOMA AND HEPATOCELLULAR CARCINOMA

Fowsiyo Ahmed[1] Joseph Larson[1] Qian Shi[1] Lewis Roberts[1], [1]Mayo Clinic Rochester

Background: Cholangiocarcinoma (CCA) and hepatocellular carcinoma (HCC) are distinct liver cancers with limited comparative data on quality of life (QoL) and behavioral risk factors. We analyzed baseline QoL and self-reported smoking and alcohol use at diagnosis using self-administered FACT-Hep and lifestyle questionnaires to identify factors influencing patient well-being and guide personalized supportive care strategies. **Methods:** We identified 6,332 patients with CCA or HCC from a single-institution prospective registry who were consented from 2000-2025. The cohort represented patients with diverse demographics and clinical backgrounds. Only those who completed the FACT-Hep and lifestyle questionnaires within one year of diagnosis ($n = 609$) were included. Patients were excluded if key data were missing, or surveys were completed beyond one year. Descriptive statistics summarized patient responses. **Results:** Of the 609 patients included, 320 had CCA and 289 had HCC. Among them, 477 (CCA $n = 264$; HCC $n = 213$) completed smoking and alcohol surveys. The cohort was predominantly male (69%) and Caucasian decent (87%). Median FACT-Hep total scores, where higher values indicate better overall quality of life, were similar between CCA and HCC patients (135.0 vs. 136.0; $p = 0.47$). CCA patients reported significantly lower physical well-being scores (21.0 vs. 23.0; $p = 0.04$), while emotional (17.0 vs. 18.0; $p = 0.18$), functional (18.0 vs. 18.0; $p = 0.65$), and hepatobiliary cancer subscale scores (54.0 vs. 55.0; $p = 0.35$) were not significantly different. Fatigue and lack of energy were the most reported symptoms in both groups: fatigue was reported by 88.3% of CCA and 83.3% of HCC patients, and lack of energy by 87.9% vs. 85.2%, respectively. Other frequent symptoms included pain (63% vs. 62%), feeling ill (56% vs. 45%), and difficulty meeting family needs (52% vs. 46%). HCC patients more often reported a history of smoking (65% vs. 41%), while current alcohol use was higher among CCA patients (44% vs. 23%), who more frequently described social or occasional drinking patterns. **Conclusion:** Despite similar overall QoL scores, CCA patients reported lower physical well-being, and a slightly higher symptom burden compared to those with HCC. Differences in

behavioral risk profiles, such as smoking and alcohol use, highlight the importance of incorporating lifestyle assessments into baseline evaluations. These findings support the importance of tailored supportive care strategies based on tumor type and individual patient factors.

3209 | FRAILTY IS ASSOCIATED WITH ADVERSE INPATIENT OUTCOMES IN HEPATOCELLULAR CARCINOMA: A NATIONWIDE STUDY FROM 2018 TO 2022

Daniel Gonzalez Mosquera[1] Maria Mateo Chavez[2] Mariana Nunes Ferreira[1] Sakina Paracha[1] Juan Martinez-Ortega[1] Carolina Gonzalez Mosquera[3] Yassine Kilani[4] Victor Victor-Prophete[1], [1]New York Health + Hospitals | Lincoln–Weill Cornell Medical College Affiliate, New York, USA, [2]Knowledge and Research Evaluation Unit, Mayo Clinic, Rochester, Minnesota, USA, [3]Universidad Catolica Santiago de Guayaquil, [4]Washington University in St. Louis, Saint Louis, Missouri, USA

Background: Frailty has emerged as a critical determinant of adverse outcomes in chronic liver disease, yet its impact on hepatocellular carcinoma (HCC)-related hospitalizations remains insufficiently explored in recent large-scale datasets. This study aimed to assess the relationship between frailty and clinical outcomes in HCC hospitalizations using the National Inpatient Sample (NIS). **Methods:** We performed a retrospective cohort study identifying adult hospitalizations with diagnosis of HCC from the NIS database (2018–2022). Frailty was measured using the Hospital Frailty Risk Score (HFRS) and categorized as low (<5), intermediate (5–15), and high (>15) for descriptive analyses. Due to a small sample size in the high frailty group, multivariable regression models were constructed using a binary frailty variable (no frailty: HFRS <5 vs. frailty: HFRS ≥ 5). Descriptive statistics were used to report unadjusted incidence of mortality, ICU admission, length of stay (LOS), charges, organ dysfunction, vascular events, and procedures. Adjusted odds ratios (aOR) were estimated through logistic regression controlling for age, race, comorbidity index, and hospital characteristics. **Results:** We identified 59,345 HCC hospitalizations, with 66.8% classified as low frailty, 32.5% intermediate, and 0.6% high frailty. Descriptive analysis showed a consistent increase in adverse outcomes with higher frailty. Mortality rose from 5.1% in the low frailty group to 8.1% in the high frailty group. ICU admission rates increased from 1.9% to 13.2%, and sepsis-related complications from 0.4% to 7.9%. Additionally, mean LOS rose from 4.8 to 14.5 days, and total hospital charges were higher in patients with greater frailty.

In adjusted regression analysis comparing patients with frailty (HFRS ≥ 5) to those without (HFRS <5), frailty was independently associated with higher odds of mortality (aOR: 3.12 [2.68–3.63], $p<0.001$), ICU admission (aOR: 4.29 [3.45–5.35], $p<0.001$), respiratory failure (aOR: 5.52 [3.67–5.56], $p<0.001$), and sepsis-related complications (aOR: 12.06 [8.06–18.03], $p<0.001$). Frailty was also significantly associated with increased risk of cerebrovascular events, acute renal failure, and thrombotic complications. Notably, frail patients were less likely to undergo locoregional therapies including TACE (aOR: 0.71 [0.59–0.87], $p=0.001$) and ablation (aOR: 0.31 [0.20–0.47], $p<0.001$). **Conclusion:** Our study reveals a strong association between frailty and adverse outcomes in HCC hospitalizations. Even after adjustment, frailty correlated with significantly higher mortality, organ dysfunction, and reduced use of TACE and ablation. These findings highlight the need for routine frailty assessment and targeted interventions to improve outcomes and optimize resource use. Incorporating frailty into clinical pathways may enhance risk stratification and guide management in this vulnerable population.

3210 | ASSOCIATION BETWEEN STATIN USE AND HEPATOCELLULAR CARCINOMA RECURRENCE AFTER CURATIVE TREATMENT: A META-ANALYSIS OF ADJUSTED HAZARD RATIOS

Madia Ahad[1] Anwar Uddin[1] Aisha Elamin[1] Rahat Uddin[1], [1]Suny Downstate Medical Center

Background: Hepatocellular carcinoma (HCC) remains a major cause of cancer-related death worldwide. Although curative treatments such as surgical resection and ablation have improved outcomes, recurrence rates remain high, often surpassing 50% within five years. Statins, widely used for cardiovascular disease, have demonstrated potential anticancer effects, including antiproliferative and immunomodulatory properties. However, their impact on recurrence-free survival (RFS) after curative treatment for HCC remains unclear. This meta-analysis assessed whether statin use is associated with reduced recurrence following definitive HCC therapy. **Methods:** We conducted a meta-analysis of observational studies reporting multivariable-adjusted hazard ratios (HRs) for HCC recurrence after curative therapy (resection or ablation). PubMed, EMBASE, and Scopus were searched through April 2025. Studies included adult HCC patients, compared recurrence between statin users and non-users, and reported adjusted HRs with 95% CIs. Eight studies (n = 3,625) met inclusion. Extracted data included study design, statin type, treatment, follow-up, adjustment covariates, and HRs. A DerSimonian–Laird random-effects model pooled log-transformed HRs. Heterogeneity was assessed via I^2 and τ^2; publication bias via funnel plot and Egger's test. **Results:** Eight observational studies involving 3,625 patients with HCC were included. All reported multivariable adjusted hazard ratios for recurrence free survival following curative treatment, comparing statin users to nonusers. Covariates commonly included tumor size, liver function (Child Pugh or MELD), antiviral therapy, age, and comorbid conditions. Pooled analysis using a random effects model showed statin use was associated with a significantly lower risk of recurrence. The pooled adjusted HR was 0.61 (95% CI 0.54 to 0.70), reflecting a 39% relative reduction. Individual adjusted HRs ranged from 0.48 to 0.70, consistently favoring statin use. The direction and magnitude of association were similar across studies despite variation in statin class, treatment modality, and patient population. No statistical heterogeneity was observed ($I^2 = 0\%$ $\tau^2 = 0$ Q = 3.55 df = 7), though clinical differences such as follow up duration, statin intensity, and cointerventions may exist. Funnel plot inspection revealed no asymmetry, and Egger's test (p = 0.58) indicated no evidence of publication bias, although the limited number of included studies may reduce power to detect subtle bias. **Conclusion:** Statin use was associated with a significantly lower risk of hepatocellular carcinoma recurrence after curative treatment. The results were consistent across studies with no statistical heterogeneity observed. Future studies, preferably prospective in design and stratified by statin class and dose, are needed to confirm these findings and evaluate causality.

3211 | COMPARATIVE OUTCOMES OF TRANSRADIAL (TRA) VERSUS TRANSFEMORAL (TFA) ACCESS IN LOCOREGIONAL THERAPIES FOR HEPATOCELLULAR CARCINOMA: SYSTEMATIC REVIEW AND META-ANALYSIS IN TARE, TACE, AND HAIC

Renan Prado[1] Julia TIrelli Rocha[2] Gustavo Jose Silva Sanchez[3] Maria Julia Godoy Siqueira[4] Milena Zadra Prestes[5] Mariana Leticia de Bastos Maximiano[6] Melissa Lou Silva[7], [1]Cleveland Clinic Foundation, [2]Jundiai Medical School, Brazil, [3]University of Connecticut, [4]Anhembi Morumbi University, Brazil, [5]State University of Ponta Grossa, [6]Federal Fluminense University, Brazil, [7]University of California San Diego

Background: Transradial access (TRA) is increasingly adopted as an alternative to the conventional transfemoral approach (TFA) in various endovascular procedures. In hepatocellular carcinoma (HCC), locoregional therapies such as transarterial radioembolization (TARE), transarterial chemoembolization (TACE), and hepatic arterial infusion chemotherapy (HAIC) rely heavily on arterial access. Emerging evidence suggests potential advantages of TRA in terms of safety, efficiency, and patient satisfaction. However, comparative data across modalities have not been systematically evaluated. **Methods:** We conducted a systematic meta-analysis of studies comparing outcomes of TRA versus TFA in TARE, TACE, and HAIC for HCC. PubMed, Embase, and the Cochrane Library were searched through December 31, 2024, yielding 358 records. After removing screening, 19 studies (2 for HAIC, 6 for TARE, and 11 for TACE) were included. Key outcomes analyzed included access failure, arterial occlusion, hematoma, bruising, procedural metrics, radiation exposure, pain scores, and patient preference. Pooled risk ratios (RRs), mean differences (MDs), and standardized mean differences (SMDs) were calculated with 95% confidence intervals (CIs). (PROSPERO ID: CRD420251013220). **Results:** In HAIC procedures, TRA was associated with a significantly lower risk of hematoma (RR 0.16; 95% CI: 0.04–0.58) and arterial occlusion (RR 0.10; 95% CI: 0.02–0.47), with comparable procedural success (RR 1.00; 95% CI: 0.99–1.01). Procedure time was significantly reduced in the TRA group (SMD −0.87; 95% CI: −1.17 to −0.58).

In TARE procedures, TRA led to shorter fluoroscopy (MD −6.59 min; 95% CI: −9.20 to −3.99), procedure time (MD −12.13 min; 95% CI: −16.49 to −7.77), and radiation time (MD −5.17 min; 95% CI: −6.94 to −3.40). Pain was significantly lower both during the procedure (MD −1.01; 95% CI: −1.41 to −0.60) and in the recovery room (MD −1.20; 95% CI: −1.63 to −0.76). Conversion from TRA to TFA was uncommon.

In TACE interventions, TRA was associated with fewer access site complications, including a lower rate of access failure (RR 0.41; 95% CI: 0.22–0.78), hematoma (RR 0.55; 95% CI: 0.33–0.92), and bruising/ecchymosis (RR 0.58; 95% CI: 0.34–0.99). Moreover, 84% of patients preferred TRA over TFA, citing less discomfort and improved mobility post-procedure. **Conclusion:** TRA demonstrates a superior safety and efficiency profile compared to TFA across locoregional therapies for HCC. TRA offers reduced complication rates, shorter procedure and fluoroscopy times, lower radiation exposure, and greater patient comfort and preference. These findings support wider adoption of TRA in interventional oncology for HCC, particularly in appropriately selected patients. Further high-quality randomized trials are warranted to validate these benefits.

3212 | RISK FACTORS AND OUTCOMES ASSOCIATED WITH HEPATOCELLULAR CARCINOMA IN NONCIRRHOTIC METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Claudio Salinas[1] Jacob Lizak[1] Craig Rosenstengle[2] Shivang Mehta[2] Saleh Elwir[3] Niluka Wickramaratne[2] Marc Najjar[2], [1]Burnett School of Medicine at TCU, [2]Baylor Scott and White All Saints Medical Center Fort Worth, [3]Baylor University Medical Center

Background: Individuals with Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) and cirrhosis are at increased risk of hepatocellular carcinoma (HCC) and require surveillance. Although HCC can occur with MASLD in the absence of cirrhosis, this is infrequent and risk factors for HCC in this population are poorly defined. **Methods:** Retrospective review of consecutive patients with HCC and a diagnosis of MASLD or cryptogenic liver disease with coexisting metabolic comorbidities who presented to a multidisciplinary liver tumor clinic between 2007 and 2023. Patients with a history of alcohol use or other liver disease were excluded. Noncirrhotic patients were identified by liver biopsy review or a combination of imaging, laboratory, and clinical parameters indicating absence of cirrhosis or portal hypertension. Multivariate logistic regression and competing risks survival regression were performed to evaluate risk factors and cumulative incidence of death, respectively. **Results:** Among 277 patients identified with MASLD and HCC, 28 (10%) were found to be noncirrhotic. Patient characteristics included median age 68 (range 32-91), BMI 31.5 kg/m^2 (16.7-65.7), 62% obese, 70% diabetes, 74% hypertension, and 47% hyperlipidemia. Overall, the majority (75%) had a solitary tumor at time of presentation, 96% received treatment for HCC, and 27% were listed for liver transplantation (LT). Median follow up was 1.5 years (range 3 days to 9.5 years). All 28 noncirrhotic patients received HCC treatment. Compared with cirrhotics, noncirrhotic patients were more likely to have hyperlipidemia (64% vs. 45%; $p = 0.05$) and less likely to have diabetes (50% vs. 72%; $p = 0.02$). Hyperlipidemia was an independent predictor of noncirrhotic HCC (OR 2.98, 95% CI 1.22-7.24) vs. other metabolic syndrome risk factors, while diabetes predicted HCC with cirrhosis (OR 3.39, 1.46-7.88). None of the noncirrhotic patients underwent HCC surveillance prior to presentation, at which time tumor size was greater in noncirrhotics with median size 7.5 cm (2.5-21.2) vs. 2.8 cm (1.0-22.1; $p < 0.001$) and noncirrhotic patients were more likely to exceed Milan Criteria; only 4/28 (14%) of noncirrhotics presented within Milan criteria vs. 180/249 (72%) of cirrhotics ($p < 0.001$). Exceeding Milan criteria was strongly associated with decreased survival overall (SHR 2.80, 2.03-3.85) and noncirrhotic status predicted LT ineligibility (OR 0.02, 0.001-0.28) independent of increasing age and obesity class. **Conclusion:** HCC may occur in a small but significant proportion of noncirrhotic patients with MASLD. In the absence of surveillance, HCC presented at an advanced stage among our noncirrhotic cohort, leading to LT ineligibility and poor survival. Identifying factors associated with an increased risk of noncirrhotic HCC among those with MASLD may guide surveillance strategies in selected patients.

Simioni[5] [1]Department of Medicine (DIMED), University of Padua, [2]Clinical Medicine 1 and Thrombotic and Haemorrhagic Disease Unit, Padua University, [3]School of Medicine and Surgery, University of Milan-Bicocca, Milan, [4]Department of Pathology, Ca' Foncello Hospital, ULSS2 Marca Trevigiana, [5]Department of Medicine (DIMED), Padua University, [6]Pathology Unit, Padua University-Hospital, Italy, [7]Department of Surgery, Oncology and Gastroenterology (DISCOG), Padua University, [8]Yale University

Background: Cholangiocarcinoma (CCA) is an aggressive malignancy with a steadily increasing incidence worldwide, particularly of the intrahepatic variant (iCCA). Consequently, identifying factors that may modify the natural history of this disease has become the focus of interest in multiple studies. While the relationship between hepatic fibrosis and the development of CCA has been previously explored, the contribution of fibrosis-induced coagulation imbalance to disease progression remains unclear. This study aimed at investigating the relationship between advanced liver fibrosis, hemostasis activation, and occurrence of cancer-associated thrombosis (CAT) in patients with iCCA. **Methods:** Fifty iCCA patients who underwent curative liver surgery were studied. Graft wedge biopsies served as controls (n = 10). Histological evaluation was performed on archival formalin-fixed, paraffin-embedded samples using the Ishak Fibrosis Score (IFS, 0-6). Immunohistochemical staining was performed to assess tissue factor (TF), FX, fibrinogen and von Willebrand factor (vWF). Portal vein microthrombosis highlighted by fibrin deposition within the vessel lumen was quantified using Martius Scarlet Blue (MSB) staining. Immunofluorescence (IF) analysis for TF and FX was performed on patient-derived organoids (PDOs, n = 10). Extracellular vesicles (EVs) isolated from iCCA-PDO media were analyzed by flow cytometry (FACS) using Calcein-AM, EpCAM-PE, and Annexin V markers. EV-induced platelet activation was evaluated by FACS using CD41, CD62P, and Annexin V markers. **Results:** iCCA patients showed a procoagulant profile with increased coagulation activation and impaired fibrinolysis compared to controls. In iCCA, patients with advanced fibrosis (IFS 4–5, n = 16) showed a more prominent expression of TF, FX, vWF, and fibrinogen than patients with fibrosis stages ≤ 3 (n = 34). Furthermore, the degree of fibrosis correlated with either TF expression by malignant bile ducts or the number of portal vein microthrombosis ($p < 0.05$). IF analysis in iCCA-PDOs confirmed a marked TF and FX upregulation, whereas EVs from iCCA-PDO media promoted platelet activation. **Conclusion:** Hepatic fibrosis is closely linked to CAT occurrence in iCCA patients, and associated with increased expression of TF and platelet activation by malignant cholangiocytes. This fibrosis-coagulation interplay underscores the need to unravel the mechanisms promoting CAT development in CCA progression.

3214 | PREDICTORS OF OUTCOMES FOLLOWING TRANSARTERIAL EMBOLIZATION THERAPIES IN UNRESECTABLE HEPATOCELLULAR CARCINOMA: A MULTICENTER ANALYSIS

Faisal Sanai[1] *Saad Aldosari*[1] *Adnan Alzanbagi*[2] *Mohammed Arabi*[3] *Khalid Bzeizi*[4] *Jameel Bardesi*[5] *Sarah Alfawaz*[6] *Fatimah Albenmousa*[4] *Mohamed Shawkat*[4] *Ali Albenmousa*[4] *Hamdan Alghamdi*[7] *Majed Almaghrabi*[1] *Saleh Alqahtani*[4], *[1]King Abdulaziz Medical City, KAIMRC, Jeddah, Saudi Arabia, [2]King Abdallah Medical City, Makkah, Saudi Arabia, [3]King Abdulaziz Medical City, Ministry of National Guard - Health Affairs, Riyadh, Saudi Arabia, [4]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [5]University of Jeddah, Jeddah, Saudi Arabia, [6]King Abdulaziz Medical City, KAIMRC, Saudi Arabia, [7]King Abdulaziz Medical City, Ministry of National Guard Health Affairs, Riyadh, Saudi Arabia*

Background: Transarterial radioembolization (TARE) with Yttrium-90 resin microspheres and transarterial chemoembolization (TACE) are widely recognized locoregional treatments for patients with unresectable hepatocellular carcinoma (uHCC). However, uHCC is a heterogeneous group of patients, with varying safety and efficacy outcomes influenced by both tumor burden and host-related factors. In this study, we aimed to identify clinical and biochemical predictors of response and survival outcomes in patients with uHCC undergoing TACE and TARE. **Methods:** We retrospectively analyzed consecutive, unselected patients treated with TARE or TACE at four academic institutions. Exclusion

criteria included extrahepatic metastases, Child-Pugh (CP) class C disease, or receipt of non-selective TARE or TACE. Baseline demographics, liver function parameters, and treatment-related variables were collected; adverse events, median overall survival (mOS), and objective response (per mRECIST) were assessed using multivariable modeling to determine independent predictors of efficacy and prognosis. Median follow-up was 24 (interquartile range 11-42) months. **Results:** The cohort comprised 312 patients, predominantly male (73.9%), with a mean age of 66.8 ± 10.5 years. Most patients had intermediate-stage disease (BCLC 'B', 54.5%), followed by early-stage (BCLC '0/A' 34.0%) and locally advanced-stage disease (BCLC 'C', 11.5%). Of the total cohort, 177 patients received TACE (56.7%) and 135 received TARE (43.3%). The mOS of the overall cohort was 32 months (95% CI: 27.0-37.0), and was significantly longer in patients with BCLC stage '0/A' (47 months [95% CI: 33.0-67.0]) than BCLC stage 'B' (30 months [HR, 1.58; 95% CI: 1.17-2.13]) and BCLC stage 'C' (22 months [HR, 2.63; 95% CI: 1.46-4.73]). Multivariable analyses revealed ECOG '0' (OR 2.61, 95% CI: 1.05-6.46), AFP < 400 ng/mL (OR 2.24, 95% CI: 1.31-3.82), complete tumoral response (OR 4.40, 95% CI: 1.99-9.71) and lower ALBI scores (OR 1.69, 95% CI: 1.14-2.51) as independent predictors of survival. The TACE group showed higher complete response rates (33.5%) compared to TARE (23.2%; P = 0.049). Independent predictors of disease control included alkaline phosphatase (OR 0.99, 95% CI: 0.993-0.999), AFP < 400 ng/mL (OR 0.31, 95% CI: 0.16-0.63), and BCLC stage '0/A' (OR 4.92, 95% CI: 1.88-12.92). **Conclusion:** Despite enhanced complete response rates, TACE did not confer a survival advantage over TARE in patients with uHCC. Patient-related factors, rather than the type of intervention, were the primary determinants of treatment outcomes. Given their prognostic significance, a thorough evaluation of these factors is crucial for optimal patient selection for embolization therapies.

3215 | CHARACTERISTICS AND POTENTIAL ROLES OF PROLIFERATIVE CD8$^+$ T CELLS IN HBV-RELATED HCC PATIENTS

Ruoyu Gao[1] Hong Li[1] Wen Zhang[1] Wenyue Wu[1] Ziyan Pan[1] Haodong Ma[1] Caihong Wang[1] Hong You[1] Wei Chen[1], [1]Beijing Friendship Hospital, Capital Medical University

Background: While different CD8$^+$ T cell subsets within the hepatocellular carcinoma (HCC) tumor microenvironment (TME) are critically important and extensively studied, research on proliferative CD8$^+$ T cells (Tpro) remains limited. We aimed to characterize Tpro cells and elucidate their potential roles in hepatitis B virus (HBV)-related HCC patients. **Methods:** We integrated 114,539 liver tissue-derived immune cells from 26 patients across three GEO datasets, including 8 with HBV infection, 6 with HBV and liver fibrosis, and 12 with HBV-related HCC. Bulk RNA-seq data from GEO and TCGA were analyzed using deconvolution, survival analysis, and ssGSEA to investigate Tpro cells. **Results:** We identified Tpro cells exhibiting hyperproliferative capacity (overexpression of 18 cell cycle genes), tissue-resident properties (CD69$^+$ ITGAEhigh), an exhausted state (LAG3$^+$ CTLA4$^+$), cytotoxicity (GZMBhigh IFNG$^+$), and distinct from TCF7-high precursor exhausted T cells (Tpex) (TCF7low). The proportion of Tpro cells significantly increased in HBV-related HCC and demonstrated inter-patient heterogeneity. Tpro enrichment correlated with advanced BCLC and TNM stages and elevated AFP levels. Furthermore, Tpro cells were subdivided into PDCD1$^+$Tpro and PDCD1-Tpro subsets, with PDCD1$^+$Tpro predominating in HBV-related HCC. Patients with higher PDCD1$^+$Tpro proportions exhibited significantly shorter overall survival (OS) and progression-free survival (PFS). HCC TMEs enriched for PDCD1$^+$Tpro displayed increased immunosuppressive CD4$^+$ T cell subsets (Th2, Treg) and decreased immunostimulatory subsets (Th1, Th17). Moreover, patients responding to anti-PD1 therapy showed an upregulated PDCD1$^+$Tpro to PDCD1-Tpro ratio. **Conclusion:** PDCD1$^+$Tpro cells are increased in HBV-related HCC and are strongly associated with disease progression and poor prognosis. They may also serve as predictive biomarkers for immune checkpoint blockade therapy response.

3216 | ENHANCED ANTITUMOR ACTIVITY OF PROGRAMMED CELL DEATH-1 ANTIBODY/REGORAFENIB COMBINED WITH DIPEPTIDYL PEPTIDASE-4 INHIBITION IN HEPATOCELLULAR CARCINOMA ORGANOID MODEL

Heejoon Jang[1] Yookyoung Lim[2] Su Jong Yu[3] Jung-Hwan Yoon[4], [1]SMG-SNU Boramae Medical Center, [2]Boramae Medical Center, [3]Seoul National University Hospital, [4]Seoul National University

Background: Hepatocellular carcinoma (HCC) remains one of the leading causes of cancer mortality globally. While immune checkpoint inhibitors show promise in HCC treatment, their efficacy remains limited. Dipeptidyl peptidase-4 (DPP4) inhibitors are known to enhance immune cell chemotaxis through CXCL10 preservation. This study investigates the potential synergistic effects of combining programmed cell death-1 antibody/regorafenib with DPP4 inhibition using murine-derived organotypic tumor spheroids, which better simulate the tumor microenvironment than conventional models,. **Methods:** Tumor tissues were harvested from mice bearing RIL-175 hepatocellular carcinoma, mechanically minced, and filtered through 70-100 μm cell strainers. The resulting cell suspensions were embedded in collagen hydrogel and cultured in 3D microfluidic devices to generate murine-derived organotypic tumor spheroids (MDOTS). During MDOTS formation, specimens were divided into four treatment groups: control (IgG + DMSO), anti- programmed cell death-1 (PD-1) antibody plus regorafenib, sitagliptin, and anti-PD-1 antibody/regorafenib plus sitagliptin. After MDOTS formation, cultures were maintained for 4-6 days with respective treatments. The proportion of live/dead cells was assessed using confocal microscopy, while DPP-4 activity and CXCL10 concentrations were measured in culture supernatants. **Results:** Confocal microscopy findings of cell viability revealed varying proportions of dead cells across treatment groups: control (14.5%), anti-PD-1 antibody plus regorafenib (25%), sitagliptin (25%), and triple combination therapy (36%). Notably, only the triple combination therapy group (anti-PD-1 antibody/regorafenib plus sitagliptin) demonstrated a significantly higher proportion of dead cells compared to the control group. Furthermore, CXCL10 concentrations in culture supernatants were significantly elevated in the triple therapy group compared to other treatment groups, suggesting enhanced immune cell recruitment potential. **Conclusion:** In this MDOTS platform, triple combination therapy with anti-PD-1 antibody/regorafenib and DPP4 inhibition demonstrated superior cytotoxic effects compared to anti-PD-1 antibody/regorafenib therapy. This improved antitumor activity may be mediated through enhanced immune cell recruitment via CXCL10 preservation, suggesting a potential mechanism for improved therapeutic efficacy in hepatocellular carcinoma.

3217 | THE EFFECT OF CIRCULATING INFLAMMATORY BIOMARKERS ON THE RISK OF NON-VIRAL RELATED HEPATOCELLULAR CARCINOMA DEVELOPMENT

Mazen Elsheikh[1] Rikita Hatia[2] Sherry Fares[1] Mohamad Ali Ibrahim[1] Karim Adhem[1] Megha Bhongade[1] Donghui Li[2] Ximena Ramirez-Morales[1] Ping Chang[2] Yun Shin Chun[2] Asif Rashid[2] Ahmed Kaseb[2] Prasun Jalal[1] Manal Hassan[2], [1]Baylor College of Medicine, [2]The University of Texas MD Anderson Cancer Center

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Inflammatory pathway is a complex biological process triggered by several factors associated with chronic liver diseases. Independent of chronic viral infection, alcohol abuse and chronic metabolic disorders are the major causes of nonviral related hepatocellular carcinoma (NVRHCC). However, there is a paucity in data examining the role of inflammatory-related biomarkers on the risk of NVRHCC. We aimed to assess the associations of blood-based biomarkers involved in the inflammatory pathway and HCC diagnosis in the absence of viral hepatitis. **Methods:** Between 2001 and 2014, all newly diagnosed HCC patients were enrolled in an IRB-approved study at The University of Texas MD Anderson Cancer Center. Controls were healthy spouses of patients who were diagnosed with non-liver/GI cancers. Only cases and controls who were negative for hepatitis B and C markers were included in this study. Blood samples collected at diagnosis/enrollment were tested for 28 inflammatory biomarkers by Myriad RBM, Inc. Using the tertiles of the biomarkers among the controls as a cutoff point, all participants were categorized into subjects with low, moderate, and high levels of the biomarkers. Odds ratio (OR) and 95% confidence interval (CI) values were estimated using multivariable unconditional logistic regression analysis adjusted for relevant confounders. The *P* value is adjusted for multiple testing using the Benjamini-Hochberg with the false discovery rate at 0.25. **Results:** The study analyzed 378 NVR HCC cases and 200 healthy controls, with mean ages of 64.96 ± 12.78 and 60.17 ± 9.53 years, respectively; 76.8% were white. Table 1 shows adjusted ORs and 95% CIs for the top significant five inflammatory biomarkers most strongly linked to NVRHCC risk. Comparing moderate and high levels (2nd and 3rd tertiles) to low levels (1st tertile), Tissue Inhibitor of Metalloproteinases-1 (TIMP-1) showed the strongest HCC risk link (OR = 38.45, *P* = 0.01, highest vs. lowest tertile), followed by Vascular Cell Adhesion Molecule (VCAM-1) (OR = 15.06, *P* = 0.02). Interleukin 8 (IL-8) (OR = 6.16) and Intercellular Adhesion Molecule-1 (ICAM-1) (OR = 4.42) also had positive associations. In contrast, Interleukin 18 (OR = 0.17) and Interleukin 23 (OR = 0.24) were inversely linked to risk. **Conclusion:** TIMP-1, VCAM, IL-8 and ICAM-1 showed significant and independent associations with increased risk of HCC. These observations suggest a potential value of these plasma biomarkers in predicting the risk of HCC in the absence of viral hepatitis infection. This should enhance our knowledge about the role of these markers in the diagnosis of NVRHCC and their potential implication in identifying high risk population for early detection.

Table 1: ORs and 95% Confidence Interval (CI) for the association of each inflammatory-related biomarker with the risk of hepatocellular carcinoma in 378 non-viral HCC cases and 200 controls

	Tertile 1		Tertile 2		Tertile 3		P_{trend}
Inflammatory Biomarker	Case/Control	OR (95% CI)	Case/Control	OR (95% CI)	Case/Control	OR (95% CI)	
Tissue Inhibitor of Metalloproteinases-1	5/66	1	20/73	5.78(1.22- 27.52)	347/61	38.45 (9.48- 228.03)	0.01
Vascular Cell Adhesion Molecule	14/66	1	33/65	5.84(1.36- 23.33)	331/66	15.06 (3.20- 70.81)	0.02
Interleukin 18	80/66	1	91/68	0.39 (0.13- 1.18)	207/66	0.17 (.051- 0.54)	0.03
Interleukin 8	18/69	1	14/65	0.79 (0.21- 2.91)	348/66	6.16 (1.75- 21.70)	0.04
Intercellular Adhesion Molecule-1	23/66	1	32/67	0.95 (0.26- 3.49)	323/67	4.42 (1.36- 14.51)	0.04
Interleukin 23	200/71	1	88/65	0.45 (0.15- 1.36)	73/64	0.24 (0.07- 0.83)	0.05

3218 | NOVEL APPROACHES FOR THE EARLY DETECTION OF HEPATOCELLULAR CARCINOMA: A SYSTEMATIC REVIEW OF DIAGNOSTIC ACCURACY STUDIES

Melissa Barlow[1] Sarah Bailey[1] Badr Albawardy[2] Sadeem Aldarwesh[2] Rowaedh Bawaked[3] Ahmed Allehebi[4] Heba Alharith[2] Asrar Alaklabi[2] Aldanah Althwanay[5] Nora Althumiri[6] Saleh Alabbad[2] Mohamed Mawardi[4] Khalid Bzeizi[2] Saleh Alessy[2] Bandar Aljudaibi[2] Saleh Alqahtani[2], [1]University of Exeter, Exeter, United Kingdom, [2]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [3]Saudi Electronic University, Riyadh, Saudi Arabia, [4]King Faisal Specialist Hospital & Research Center, Jeddah, Saudi Arabia, [5]Washington University in St. Louis, St. Louis, MO, USA, [6]Informed Decision Making, Riyadh, Saudi Arabia

Background: Hepatocellular carcinoma (HCC) remains a major global health burden, with rising incidence and mortality. Novel diagnostic approaches may improve early detection and streamline diagnostic pathways, crucial for improving survival. We aimed to systematically review novel HCC detection approaches reporting diagnostic accuracy measures. **Methods:** A systematic review was conducted using PRISMA guidelines by searching PubMed, EMBASE, Scopus, and the Cochrane Library on Dec 11, 2024. Eligible studies were cohort or randomized controlled trials in design, in English or Arabic, reported a novel diagnostic approach for

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

HCC in any clinical setting, enrolled ≥300 participants, and reported diagnostic accuracy measures. Studies identifying incident HCC were included. Two reviewers independently screened studies and assessed risk of bias using the QUADAS-2 tool. Due to heterogeneity in index tests, populations, and outcome measures, meta-analysis was not performed. **Results:** Four studies (n = 50,363) met the inclusion criteria, each evaluating a distinct approach (Table). Three studies focused on patients with existing liver conditions (hepatitis B and cirrhosis); two studies in hepatitis B cohorts reported predictive algorithms aimed at improving HCC detection above usual care. The methylation, mutation, and protein-HCC (M2P-HCC) clinical prediction model for patients with hepatitis B had an AUC of 0.88 (95% CI 0.81-0.95), outperforming standard care (0.76 [0.69-0.84]), with low risk of bias. Another model for patients with hepatitis B that included circulating tumor DNA had an AUC of 0.93 (0.90-0.97); however, CIs overlapped with those of standard care, limiting the strength of the comparative claim. The ALARM model, based on radiomics and deep learning techniques, achieved an AUC of 0.92 (0.90-0.96) in a cohort of patients with cirrhosis. The fourth study identified novel hepatitis B-specific AFP cut-off for screening in a high-prevalence area, reporting an AUC of 0.999 at a pre-specified cut-off of ≥8.1ng/ml, though concerns remain about overfitting and generalizability. **Conclusion:** This review highlights four novel approaches to HCC diagnosis, encouraging diagnostic performance, particularly in the M2P-HCC and ALARM models. Prospective validation in broader populations is crucial to assess clinical and health economic impacts, alongside regulatory, interpretability, and implementation challenges. The limited number of eligible studies highlights the need for further high-quality, real-world evaluations.

3219 | SERUM TYROSINE LEVEL IS AN INDEPENDENT FACTOR FOR HEPATOCELLULAR CARCINOMA DEVELOPMENT AND MORTALITY IN PATIENTS WITH CHRONIC LIVER DISEASE

Mikita Oi[1] Takao Miwa[1] Yuki Utakata[2] Masashi Aiba[1] Shinji Unome[1] Tatsunori Hanai[1] Makoto Shiraki[2] Naoki Katsumura[2] Yasuhiro Kawashima[3] Masahito Shimizu[1],
[1]Department of Gastroenterology/Internal Medicine, Graduate School of Medicine, Gifu University, [2]Department of Internal Medicine, Chuno Kosei Hospital, [3]Department of Gastroenterology, Nagoya Central Hospital

Background: Amino acid imbalance, with decreased branched-chain amino acids (BCAAs) and increased aromatic amino acids (AAAs) is observed in approximately 30–50% of patients with CLD. Independent contributions of serum BCAA and AAA levels to complications of chronic liver disease (CLD) have been noticed. However, very few studies have focused on their impact on hepatocellular carcinoma (HCC) development. The primary aim of this study is to investigate the effect of amino acid imbalance, including decreased BCAAs and increased AAAs, on HCC development in patients with CLD. The secondary aim is to elucidate the effect of both aspects of amino acid imbalance on mortality in these patients. **Methods:** This multicenter retrospective study included patients with CLD at two institutions in Japan. Amino acid imbalance was assessed by serum BCAA and tyrosine levels. Factors associated with HCC development was analyzed using the Fine–Gray competing risk regression model. Given HCC and overt hepatic encephalopathy as time-dependent covariates, independent determinants of mortality was evaluated using Cox proportional hazards regression model. **Results:** Among 563 patients without HCC at baseline, the median age was 67 years and 51% were male. The median Child–Pugh and MELD scores were 6 and 8, respectively. The underlying etiology of CLD was viral hepatitis (40%), followed by alcohol-associated/related liver disease (24%), metabolic dysfunction-associated steatotic liver disease (10%), and other causes (26%). During a median follow-up period of 3.5 years, 14% (n = 80) developed HCC and 23% (n = 130) died. The cumulative incidence of HCC at 1, 3, and 5 years was 4%, 11%, and 15%, respectively. Patients with high tyrosine levels (>99 μmol/L) had a significantly higher incidence of HCC than those within normal levels (1, 3, and 5 years: 4%, 16%, and 20% vs. 3%, 8%, and 11%; p = 0.002). Given mortality as a competing risk, multivariable analysis showed that serum tyrosine level (subdistribution hazard ratio [HR] 1.01; 95% CI [confidence interval] 1.00–1.02; p = 0.002) was an independent factor for HCC development. Similarly, using HCC development as a time-dependent covariate, serum tyrosine level (HR 1.01; 95% CI 1.01–1.02; p < 0.001) and HCC development (HR 2.84; 95% CI 1.72–4.69; p < 0.001) were independent factors for mortality. **Conclusion:** Serum tyrosine level is an independent factor for HCC development and mortality in patients with CLD. As HCC development affects mortality, amino acid imbalance, especially serum tyrosine levels, should be evaluated to identify high-risk populations and to improve outcomes.

3220 | NOVEL RISK PREDICTION SCORE FOR ACUTE CARE UTILIZATION AFTER LOCOREGIONAL THERAPY FOR HEPATOCELLULAR CARCINOMA

Andrew Moon[1] Chidi Iloabachie[1] Merete Lund[1] Arjun Juneja[1] Patrick Hazelrigg[1] Parsa Pazooki[1] Sydney Power[1] Gabriel Lupu[1] Joyce Badal[1] Yue Jiang[2] David Seligson[1] Hanna Sanoff[1] David Mauro[1] David Gerber[3] Theodore Yanagihara[1] Alfred Barritt IV[1], [1]University of North Carolina, [2]Duke University, [3]University of Cincinnati

Background: Locoregional therapies (LRTs) for hepatocellular carcinoma (HCC) slow tumor growth and improve survival but may cause post-treatment symptoms and decompensation events, resulting in emergency room (ER) visits and hospitalizations. Remote monitoring systems reduce acute care utilization for patients with cancer but it is unclear which HCC patients would benefit most from such resource-intensive interventions. To identify HCC patients most likely to benefit, we aimed to develop a predictive model of post-treatment acute care utilization within 90 days of LRT. **Methods:** We identified all patients with HCC treated with LRT from 4/4/2014 to 12/31/2021 in a large health system including academic and community hospitals. We extracted pre-LRT baseline characteristics and ER visits or hospitalizations (excluding planned post-LRT observation) within 90 days after LRT. We randomly divided the analytic cohort into derivation (80%) and validation (20%) cohorts. In the derivation cohort, group logistic LASSO was used to select variables for a reduced model, with the penalty term identified as that which maximized concordance (AUROC) in 5-fold cross-validation. Adjusted odds ratios are provided for (non-regularized) multivariable logistic regression models containing all predictors and those selected by the group logistic LASSO in the validation set. We compared the AUROC of our model to Child Pugh (CP), Albumin-Bilirubin (ALBI) grade (1,2, 3), and ALBI score (continuous). **Results:** This study included 819 unique patients with 1,412 separate procedures (42% bland- or chemoembolization, 35% laparoscopic or percutaneous thermal ablation, 13% radioembolization, 9% external beam radiotherapy and 1% combination/other). On a procedure-level basis, 7% of procedures were performed in patients with BCLC-0 stage HCC, 30% BCLC-A, 14% BCLC-B, 42% BCLC-C (81% based on ECOG ≥ 1 alone), 7% BCLC-D. ER visits or hospitalizations occurred within 90 days for 18% of procedures. Results of the bivariate analyses are shown in Table 1. The variables selected by the group logistic LASSO were ER visit in the prior year, hospitalization in the prior year, Charlson Comorbidity Index (based on ICD codes from the EMR), and CP Score. The multivariable logistic regression model using only these variables had an AUROC of 0.706 in the validation set compared to 0.694 using the full model, which was superior to CP score (0.611), ALBI grade (0.598) or ALBI score (0.628) only. **Conclusion:** In our cohort, acute care utilization with 90 days occurred after nearly one-fifth of LRTs. This novel predictive model of post-LRT acute care utilization had fair accuracy and outperformed CP score, ALBI grade and ALBI score. This model could help identify patients at greatest risk of post-LRT acute care utilization who may benefit from remote monitoring or enhanced patient navigation, which have been shown to reduce acute care utilization in patients with cancer.

3221 | THE MECHANISM OF M5C METHYLATION REGULATED ENERGY METABOLIC REPROGRAMMING OF HEPATOCELLULAR CARCINOMA MEDIATED BY ALYREF/UGP2 SIGNALING AXIS INVOLVED IN TUMOR PROGRESSION

JUAN LU[1] LanJuan Li[2], [1]Zhejiang University, [2]The First Affiliated Hospital, College of Medicine, Zhejiang University

Background: The molecular mechanism of hepatocellular carcinoma (HCC) development has been the focus of research, due to the low early diagnosis rate of HCC and poor clinical prognosis. RNA methylation modification plays an important regulatory role in tumor progression, whereas, the mechanism of m5C methylation "reader" protein ALYREF in HCC progression has not been reported.We found that ALYREF was highly expressed in HCC tissues and correlated with clinical prognosis.ALYREF can affect the proliferation of tumor cells by targeting UGP2 expression in the m5C methylation-dependent manner. **Methods:** Based on public database, we explored the expression level of ALYREF in pan-tumor and, liver cancer tissues and liver cancer cell lines, separately, furthering searching for the influence of ALYREF expression on the prognosis of HCC and the characteristics of the mutation sites of ALYREF. We explored the effect of knockdown ALYREF on the biological behavior of tumor cells through lentivirus transfection technique, screened ALYREF targets by m5C methylated RNA immunoprecipitation sequencing (m5C MeRIP-seq). The binding effect of UGP2 and ALYREF protein through RNA pulldown technology. **Results:** The results showed that the expression of ALYREF was significantly increased in HCC tissues, and the up-regulated ALYREF was closely related to the poor prognosis of HCC patients based on public database. The proliferation ability of HCC cells was significantly inhibited after the expression of knockdown ALYREF, and the proportion of apoptosis was significantly increased. Further in vivo experiments confirmed that knockdown ALYREF expression could significantly reduce the tumor size and tumor weight of subcutaneous liver cancer in nude mice. The results of m5C MeRIP-seq revealed the change of m5C modification level in cells of the knockout ALYREF group, and screened a number of genes with decreased m5C methylation level after

knockout ALYREF. The binding effect of UGP2 and ALYREF protein through RNA pulldown technology, confirmed that UGP2 is the downstream target of ALYREF. The change of m5C methylation level of UGP2 after the knockout of ALYREF, confirmed that ALYREF regulated UGP2 expression by m5C methylation mode. The differentially expressed genes were screened in the knockdown ALYREF cells group. GSEA enrichment analysis was performed on differential genes, found that more than 20 genes that play key roles in the WNT pathway are significantly enriched. **Conclusion:** We found that WNT pathway regulates the m5C methylation modification level of UGP2 by mediating ALYREF, and is involved in the process of cellular glycolysis metabolism to affect the progression of HCC, which has certain theoretical significance and application value and can provide potentially effective drug targets for the treatment of HCC.

3222 | SERUM METABOLOMIC SIGNATURES PREDICT TUMOR RECURRENCE AFTER RESECTION OR ABLATION IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

Ashwini Arvind[1] Hiroaki Kanzaki[1] Sneha Deodhar[1] Kevin Bass[1] Julia Terrell[1] Courtney Katz[1] Naoto Kubota[2] Naoto Fujiwara[3] Yujin Hoshida[4] Amit Singal[1], [1]UT Southwestern Medical Center, [2]Keio University, [3]Mie University, [4]University of Texas Southwestern Medical Center

Background: Hepatocellular carcinoma (HCC) recurrence occurs in over half of patients who achieve complete response to treatment, potentially reflecting aggressive tumor biology. Serum metabolites reflect cellular metabolic activity and may serve as noninvasive surrogates of tumor behavior. Prior studies have suggested fatty acid-related and microbial-derived metabolites may be linked to poor prognosis. Herein, we aimed to conduct external validation of previously reported metabolite signatures[1,2] for association with HCC recurrence after resection or local ablation. **Methods:** We collected serum samples from patients diagnosed with HCC between 2015 and 2023 at UT Southwestern Medical Center and Parkland Health. All eligible patients had Barcelona Clinic Liver Cancer stage 0/A disease and achieved complete response on imaging after resection or local ablation. Serum metabolite concentrations were quantified by Metabolon, Inc. using liquid chromatography and untargeted mass spectrometry, and data were normalized to the sample median. We applied previously reported 6- and 13-metabolite signatures to stratify the patients into prognostic risk groups. We used univariable and multivariable Cox regression to evaluate the association between the metabolite signatures and overall recurrence, early recurrence (i.e. within two years of treatment), late recurrence, and overall death. **Results:** Of 78 eligible patients, recurrence occurred in 40 (51.3%). Early recurrence occurred in 35 (44.9%) patients, and 32 (41.0%) patients died during a median follow-up of 5.0 years. Median age at diagnosis was 62 years, and 70.5% of the cohort was male. The most common liver disease etiologies were hepatitis C (61.5%) and alcohol (12.8%). In multivariable models, the 13-metabolite signature was associated with overall recurrence (HR: 2.3, 95%CI 1.0-5.4) after adjusting for tumor-related factors. The 6-metabolite signature was associated with early recurrence (HR: 2.1, 95%CI 1.0-4.5) but not late recurrence (HR 0.5, 95%CI 0.1-2.2) after adjusting for tumor-related factors, age, and sex. **Conclusion:** Fatty acid- and microbial-derived metabolite signatures are associated with early and overall recurrence in patients with early-stage HCC and may aid prognostication.

3223 | TEMPORAL TRENDS AND REGIONAL VARIATIONS IN HEPATOCELLULAR CARCINOMA ETIOLOGY AND ASSOCIATED CLINICAL FEATURES: A MULTINATIONAL-APASL HEPATOLOGY/ONCOLOGY CONSORTIUM (A-HOC)- STUDY ACROSS ASIA

YASUTO TAKEUCHI[1] Ryosuke Tateishi[2] shuntaro obi[3] Motoyuki Otsuka[1] Hitoshi Mochizuki[4] Amarsanaa Jazag[5] Osamu Yokosuka[6] Sadahisa Ogasawara[7] Naoya Kanogawa[7] Erdenebayar Gonchig[5] Yuki Matsushita[2] Murat Kekilli[8] Gulden Bilican[8] Yoon Jun Kim[9] Moon Haeng Hur[9] Ming-Lung Yu[10] Chung-Feng Huang[10] Asahiro Morishita[11] Kyoko Oura[11] Atsumasa Komori[12] Yasuhide Motoyoshi[12] Lianda Siregar[13] Imelda Loho[13] Ming Yang[14] Shuichirou Okabe[6] Yoshiyuki Ueno[15] Tomohiro Katsumi[15] Takahisa Sato[3] Cosmas Rinaldi Adithya Lesmana[16] Saut Horas Hatoguan Nababan[16] Yi-Hsiang Huang[17] Hiroaki Nagamatsu[18] Han-Chieh Lin[17] Shuichiro Shiina[18] George Lau[19] Masao Omata[4], [1]Okayama University, [2]The University of Tokyo, [3]Teikyo University Chiba Medical Center, [4]Yamanashi Central Hospital, [5]Happy Veritas Hospital, [6]Matsudo City General Hospital, [7]Chiba University School of Medicine, [8]Gazi University, [9]Seoul National University Hospital, [10]Kaohsiung Medical University Hospital, [11]Kagawa University School of Medicine, [12]Nagasaki Medical Center, [13]Dharmais National Cancer Center, [14]Beijing Tsinghua Changgung Hospital, [15]Yamagata University School of Medicine, [16]Mochtar Riady Comprehensive Cancer Center Siloam Hospitals Semanggi, [17]Taipei Veterans General Hospital, [18]Juntendo University School of Medicine, [19]Humanity & Health Medical Group

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related death in Asia, where over 70% of global cases occur. While recent advances in hepatitis B vaccination and antiviral therapy have reduced the burden of viral hepatitis, lifestyle-related liver diseases are increasingly recognized. This study investigated regional and temporal changes in HCC etiology and associated clinical features across Asia. **Methods:** This multinational, retrospective study included 6,261 patients with newly diagnosed HCC from 19 institutions across seven Asian countries and regions, between 2013 and 2023, as part of the APASL Hepatology/Oncology Consortium (A-HOC). Data on demographics, tumor characteristics, underlying liver disease, and initial treatments for HCC were analyzed. HCC etiologies included hepatitis B virus (HBV), hepatitis C virus (HCV), alcoholic liver disease (ALD), metabolic dysfunction-associated fatty liver disease (MAFLD), MAFLD with excess alcoholic (a daily alcohol consumption of $\geq$30 g and $<$60 g for men, and $\geq$20 g and $<$60 g for women) intake (MAFLD+AL), autoimmune disease, and cryptogenic causes. **Results:** Tumor size and Barcelona Clinic Liver Cancer (BCLC) stage varied by etiology and region. HBV remained dominant (43.3%–69.5%) and stable in most countries and regions. While HCV was the leading cause of HCC in Japan (33.1%) with a marked decline over time probably due to the anti-HCV therapy ($p < 0.01$). The prevalence of MAFLD-related HCC increased in Japan and Turkey, whereas ALD-related HCC rose in South Korea. The tumor size at presentation is smaller in Japan and Taiwan, in contrast, China and Indonesia exhibited more advanced-stage presentations and larger tumors, reflecting the timing of the detection. Treatment patterns reflected these differences; curative treatments were more common in Japan and Taiwan, while systemic therapy and no treatment were more frequent in Indonesia. **Conclusion:** This large-scale study highlights clear regional disparities and evolving etiological trends of HCC in Asia. While viral hepatitis remains the major cause overall, the rising impact of MAFLD and ALD requires region-specific surveillance and prevention strategies. Moreover, differences in tumor burden and treatment selection may contribute to regional variations in prognosis. Strengthening early detection programs and addressing gaps in access to care—particularly for viral hepatitis and metabolic liver disease—are essential to improve outcomes in Asia.

3224 | HEPATOCELLULAR CARCINOMA SCREENING ADHERENCE IS ASSOCIATED WITH HIGHER CURATIVE INTENT SURGICAL RESECTION RATE

Rachel McNulty[1] Ayushi Jain[2] Jessica Zangmeister[3] Huijin Xiao[3] Omar Sims[4] Dian Chiang[3], [1]Cleveland Clinic Akron General, [2]Department of Gastroenterology, Hepatology and Nutrition, Cleveland Clinic, [3]Cleveland Clinic, [4]Cleveland Clinic Foundation

Background: Hepatocellular carcinoma (HCC) is the fifth most common cause of cancer worldwide. Surgical resection is an effective local-regional therapy for early-stage HCC. International guidelines recommend HCC screening be performed every 6 months for at-risk populations, though screening remains underutilized and there is limited data on whether adherence to screening guidelines affect surgical resection candidacy. Our study aims to determine if HCC screening adherence impacts the likelihood of receiving curative intent surgical resection. **Methods:** A retrospective study of adults with cirrhosis was performed, including only those with at least two visits with a hepatologist at our institution between 2018-2022. HCC screening compliance was defined as completion of abdominal imaging within one year of their first hepatology appointment and second abdominal imaging within one year after their second appointment. A sub-group of patients who had undergone resection of primary intrahepatic malignancy at our institution was also identified. Statistical analysis was performed using Wilcoxon rank sum, Pearson's Chi-squared, Mann-Whitney U and Fisher's exact tests. **Results:** There were 1,992 patients with at least 2 visits with a hepatologist in our institution during our study period. Of those, 625 patients were compliant with screening and 1,367 patients were non-compliant. In total, 14 patients had undergone resection of primary intrahepatic malignancy; 9 (1.4%) patients were in the screening compliant group and 5 (0.4%) patients were in the non-compliant group ($p = 0.016$). Subgroup analysis demonstrated 33% 5-year transplant free survival rate after surgical resection in the screening compliant group, as compared to 0% in the non-compliant group ($p = 0.417$). There were no statistically significant differences in tumor burden, BCLC or TNM staging, cirrhosis etiology, MELD or age at diagnosis between the screening compliant and non-compliant patients with surgical resection. **Conclusion:** Compliance with HCC screening is associated with a higher rate of curative intent surgical resection in our retrospective study. The likelihood of surgical resection is not associated with other patient or disease characteristics, which further demonstrates the importance of screening at-risk individuals. Early diagnosis of HCC through screening may improve the candidacy for curative intent surgical resection.

3225 | CLINICO-PATHOLOGICAL DIFFERENCES AND KEY GENOMIC ALTERATIONS IN MASLD-RELATED HEPATOCELLULAR CARCINOMA WITH AND WITHOUT CIRRHOSIS: INTEGRATING WHOLE-EXOME AND SANGER SEQUENCING

Ajay Duseja[1] Priya Singh[2] Muhammad Uwais Ashraf[2] Suvradeep Mitra[2] Amanjit Bal[2] Arka De[2] Divya Khosla[2] Sunil Taneja[2] Harish Bhujade[2] Naveen Kalra[2], [1]Postgraduate Institute of Medical Education & Research, [2]POST GRADUATE INSTITUTE OF MEDICAL EDUCATION AND RESEARCH

Background: In addition to clinico-pathological differences, genetic alterations may influence the occurrence of HCC in the presence or absence of cirrhosis in metabolic dysfunction-associated steatotic liver disease (MASLD). Aim of the present study was to analyse the clinico-pathological-radiological differences and compare and validate the genomic alterations identified by whole exome sequencing (WES) by next-generation sequencing (NGS) and Sanger sequencing in patients with MASLD-HCC with and without cirrhosis. **Methods:** Of 400 patients screened during the study period (January 2022 to March 2025), 322 HCC patients were enrolled, and clinicopathological and radiological differences were studied in 68 MASLD-HCC patients (53 with and 15 without cirrhosis). Fourteen gene variants identified on WES/NGS in 10 patients with MASLD-HCC (with and without cirrhosis) were further validated by Sanger sequencing in a new cohort of 10 MASLD-HCC patients and 10 patients each with Hepatitis B and C related HCC and MASLD patients without cirrhosis and HCC. **Results:** MASLD-HCC patients without cirrhosis were younger, presented with larger tumors, single lesions, less portal vein thrombosis, and more extrahepatic spread. MASLD-HCC without cirrhosis exhibited greater poorly differentiated and macrotrabecular-massive patterns on histopathology; more disease progression on treatment with no survival difference from the cirrhotic group. On WES/NGS, MASLD-HCC patients with cirrhosis had more frequent USF3, CCDC150, HNF1A, BAP1, NBN, CTNNB1, MAPK1, and MED15 gene alterations. In contrast, GNAS, TSC2 and TBP mutations were seen exclusively in non-cirrhotic MASLD-HCC. MED15 was present in 8.3% of cirrhosis vs. 1.6% in those without cirrhosis amongst the MASLD HCC. Shared mutations across both groups included UBXN11, MUC4, MAP2K3, MADCAM1, and DSPP. Sanger sequencing confirmed MED15 mutation as the most frequently altered gene, seen in (60%) MASLD-HCC, (30%) CHB-HCC, (50%) CHC-HCC, and (50%) MASLD samples. **Conclusion:** In addition to clinico-pathological-radiological differences, there are distinct differences in gene alterations among MASLD-HCC patients with and without cirrhosis demonstrated both on whole exome sequencing by NGS and Sanger sequencing. MED15 emerged as the most frequently altered gene across MASLD-HCC and demonstrated a higher frequency in HCC patients with cirrhosis.

3226 | THE PROGNOSTIC METAL SCORE IN HEPATOCELLULAR CARCINOMA TREATED WITH TRANSARTERIAL CHEMOEMBOLIZATION PLUS MOLECULAR TARGETED AGENTS AND IMMUNOTHERAPY

Qian Chen[1] long-wang lin[1] Zhi-Cheng Jin[1] Hai-Dong Zhu[1] Gao-Jun Teng[1], [1]Zhongda Hospital, Medical School, Southeast University

Background: Transarterial chemoembolization combined with molecular targeted agents and immunotherapy represents a promising treatment strategy for unresectable hepatocellular carcinoma (uHCC). However, concerns remain regarding the increased hepatic toxicity associated with this combination regimen, which may counterbalance its survival benefit. We aimed to develop a prognostic tool to identify ideal candidates for this triple therapy. **Methods:** We retrospectively included uHCC patients with preserved liver function (Child-Pugh A/B7) who received first-line triple therapy across 13 tertiary hospitals. A prognostic score was developed in a derivation cohort (n = 378) using multivariable Cox regression and validated in an external cohort (n = 148). Restricted cubic spline analyses were used to determine optimal cut-offs for stratification of survival and radiological response. Survival outcomes across risk strata were assessed using the Kaplan-Meier curves and compared via log-rank test. Score applicability was further evaluated in a separate cohort treated with systemic therapy alone (n = 149). **Results:** A three-variable score incorporating metastatic burden, alpha-fetoprotein, and albumin-bilirubin grade (METAL score) was constructed and showed a linear association with mortality risk (overall $p < 0.001$; nonlinear $p = 0.556$). Median overall survival

for low- (≤0.5 points), intermediate- (0.5-1.5 points), and high-risk (>1.5 points) patients was 30.8 (95% confidence interval, 27.1—42.3), 25.2 (22.5—28.8), and 11.6 (10.7—13.3) months in the derivation cohort, and 34.6 (30.5—NE), 23.0 (21.1—27.9), 14.8 (11.4—21.0) months in the external validation cohort, respectively (all log-rank $p < 0.001$). Additionally, according to either the Response Evaluation Criteria in Solid Tumors (RECIST) version 1.1 or the modified RECIST criteria, confirmed objective response rates decreased progressively across risk groups in both cohorts (all $p < 0.001$). Among high-risk (>1.5 points) patients, receiving systemic therapy alone yielded longer survival than triple therapy (15.6 *vs.* 12.0 months; $p = 0.024$). **Conclusion:** The proposed METAL score allows for early prediction of survival and radiological response, and may help optimize participant selection strategy for triple therapy in future clinical trials.

3227 | PRESERVING LIVER FUNCTION: IMMUNE-CHECKPOINT INHIBITORS VS. TYROSINE KINASE INHIBITORS FOR ADVANCED HEPATOCELLULAR CARCINOMA

Avi Toiv[1] Allison Malick[1] Hayley Justus[1] Hope O'Brien[2] Gokturk Tepe[2] Hwasoo Shin[1] Sunita Ghosh[1] Reena Salgia[1], [1]Henry Ford Hospital, [2]Wayne State University School of Medicine

Background: In the era of improved systemic therapy for hepatocellular carcinoma (HCC), progressive hepatic decompensation often drive mortality rather than tumor burden alone. Over the past 5 years, immune-checkpoint inhibitors (ICI) have been supplanting tyrosine-kinase inhibitors (TKI) as first-line systemic therapy; however, studies comparing the impact of these 2 drugs on liver reserve and overall survival (OS) are limited. We examined OS and longitudinal changes in Model for End-Stage Liver Disease-3.0 (MELD-3), Child-Pugh score (CPS), and Albumin–Bilirubin (ALBI) grade in patients treated with ICI versus TKI. **Methods:** Retrospective comparative cohort study of patients with HCC initiated on ICI or TKI therapy from January 2018 to March 2025. Liver function test results at baseline and at 1, 3, 6, and 12 months of treatment were compared. OS was evaluated with Kaplan-Meier analysis. **Results:** Of 339 patients with HCC, 136 (40%) were in the ICI group; 203 (60%) were in the TKI group. Initially, TKI use was higher than ICI use. Since 2021, ICI use surpassed that of TKI (Figure 1A). No significant differences between the ICI and TKI groups were seen in age (66.7 ± 9.1 vs 64.8 ± 8.7 y), sex, or medical comorbidities, including cirrhosis. A significantly higher number of patients with BCLC stage C HCC were treated with TKI (97 vs 38; $p = 0.01$), other BCLC stages were not significantly different. At baseline, the ICI group had significantly higher median liver function scores (MELD-3.0 median: 10 vs 11; CPS: 5 vs 6; ALBI: –2.5 vs –2; $p < 0.01$). At 3 months, the ICI group continued to have superior hepatic preservation (MELD-3.0: 11 vs 13, $p = 0.02$; CPS: 6 vs 7, $p < 0.01$; ALBI: –2.2 vs –1.8; $p < 0.01$). By 6 months, significant differences between groups in all indices diminished numerically (MELD-3.0: 11 vs 12; CPS 6 vs 7; and ALBI –2.3 vs –2.0; $p > 0.05$), which persisted at 1 year. Median OS did not differ significantly between ICI and TKI groups (14.2 vs 10.5 months; Figure 1B). **Conclusion:** Patients with HCC treated with ICI showed superior preservation of liver function across all metrics during the initial 3 months of therapy compared to those treated with TKI; but this advantage was diminished by 6 months. The early improved hepatic function stability from ICI was not accompanied by a significant benefit in OS. However, this early hepatic stability suggests that ICI may have a benefit for patients at the highest risk of rapid decompensation due to aggressive tumor burden.

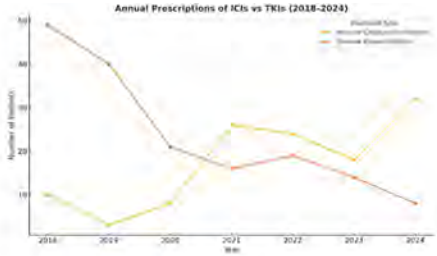

Figure 1A: Number of patients prescribed Immune-Checkpoint Inhibitors (ICIs) and Tyrosine Kinase Inhibitors (TKIs) each year from 2018 to 2024. ICIs show a rising trajectory over time, surpassing TKI use in 2021 and continuing to increase thereafter, indicating a shift in treatment patterns favoring immunotherapy.

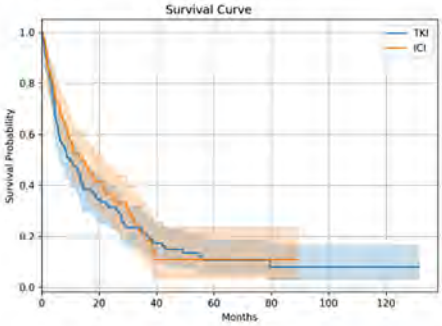

Figure 1B: Kaplan-Meier survival analysis of patients treated with immune checkpoint inhibitors (ICIs) versus tyrosine kinase inhibitors (TKIs). Median overall survival was 14.2 months in the ICI group and 10.5 months in the TKI group. There was no statistically significant difference in survival between groups (log-rank p = 0.30).

3228 | THE IMPACT OF LONG-TERM PREDNISONE USE ON HEPATOCELLULAR CARCINOMA RISK IN AUTOIMMUNE HEPATITIS AND CIRRHOSIS: A RETROSPECTIVE COHORT STUDY WITH LITERATURE REVIEW

Jessica Liu[1] Rami Hemadeh[2] Abdelrahman Attia[2] Pojsakorn Danpanichkul[3] Hasmik Adetyan[2] Naomy Kim[2] Tamar Yalda[2] Manaf Alsudaney[2] Walid Ayoub[2] Ju Dong Yang[2], [1]Chicago Medical School at Rosalind Franklin University of Medicine and Science, [2]Karsh Division of Gastroenterology and Hepatology, Cedars-Sinai Medical Center, [3]Department of Internal Medicine, Texas Tech University Health Sciences Center

Background: Autoimmune hepatitis (AIH) is an immune-mediated liver condition marked by progressive inflammation, piecemeal necrosis, and eventual cirrhosis. Prednisone has long served as a foundational therapy for AIH. However, its prolonged use warrants closer evaluation regarding long-term outcomes. Among cirrhotic patients, the combination of chronic inflammatory and tumor-promoting changes may synergize to compromise immune surveillance and increase susceptibility to hepatocellular carcinoma (HCC). In this context, the additional immunosuppressive burden of corticosteroids may influence cancer risk in ways not yet well investigated. We evaluated whether sustained, dose-defined prednisone use after cirrhosis onset increases HCC incidence in AIH-cirrhosis, aiming to refine risk stratification and inform future therapeutic strategies while recognizing prednisone's essential role in disease control. **Methods:** We conducted a retrospective cohort analysis of 121 adults with AIH-cirrhosis evaluated at Cedars-Sinai between 2001 and 2023. Patients were categorized based on prednisone exposure: those exposed ($\geq$7.5 mg/day for $\geq$6 months following cirrhosis diagnosis) vs. subthreshold exposure (with prednisone $<$7.5 mg/d or without alternative therapies). The primary outcome was HCC incidence and annual incidence rates and hazard ratios derived from Cox proportional hazards models. Secondary outcomes included estimation of HCC incidence by treatment group and evaluation of risk factors using multivariable models adjusted per demographics and liver disease severity. **Results:** In unadjusted time-to-event analysis, prednisone use shortened HCC-free survival. HCC developed in 25.4 % of the prednisone group vs. 9.7 % of controls (p = 0.030). The annual HCC incidence was higher in the prednisone group 3.31% vs. 0.90% (p 0.0182; HR 3.31; 95% CI 1.22-8.96; p = 0.0180). Multivariable analysis adjusted per age, gender, race/ethnicity, Child-Turcotte-Pugh, and alpha-fetoprotein confirmed prednisone as an independent risk factor (adjusted HR 3.36; CI 1.06-10.66; p = 0.040). **Conclusion:** Our cohort study findings suggest that prolonged prednisone exposure in patients with established AIH-cirrhosis may independently contribute to HCC development. This association appears to be supported by mechanistic pathways, driven by prednisone's dose-dependent immunosuppressive and metabolic effects, which disrupt immune surveillance, promote hepatic fibrosis, and activate oncogenic pathways.

3229 | INCREASED LIVER-RELATED MORBIDITY IN AUTOIMMUNE HEPATITIS–PRIMARY SCLEROSING CHOLANGITIS OVERLAP SYNDROME COMPARED TO AUTOIMMUNE HEPATITIS ALONE: A RETROSPECTIVE MULTICENTER ANALYSIS

Muhammad Hassaan Arif Maan[1] Soban Maan[2] Muhammad Mursaleen Ahmad[3] Ritik Mahaveer Goyal[4] Imran Qureshi[5] Menna-Allah Elaskandrany[6] Rohan Karkra[1] Ethan Shamsian[1] Sunnia Khan[7] Ahmed Al-Khazraji[1], [1]Rutgers-New Jersey Medical School, [2]West Virginia University, [3]Pakistan Institute of Medical Sciences, [4]Rutgers New Jersey Medical School, [5]RUTGERS THE STATE UNIVERSITY OF NEW JERSEY, [6]Lennox Hill Hospital, [7]Punjab Medical College

Background: Autoimmune Hepatitis (AIH) is a chronic inflammatory disease driven by immune-mediated hepatocyte injury. Primary Sclerosing Cholangitis (PSC) is a progressive cholestatic disorder characterized by intra- and extrahepatic biliary fibrosis. AIH-PSC overlap syndrome is a rare condition combining features of both diseases. While prior studies have compared AIH-PSC to PSC, data directly comparing AIH-PSC to AIH alone remains limited. **Methods:** We conducted a retrospective cohort study using TriNetX, a multicenter electronic health record network. Patients from January 2000 to December 2024 were categorized into two cohorts: AIH-PSC and AIH. Individuals with a prior history of cirrhosis, hepatocellular carcinoma (HCC), cholangiocarcinoma, or liver transplant were excluded. Propensity score matching (1:1) was employed to balance demographics and comorbidities, including tobacco use, alcohol-related disorders, primary biliary cholangitis, chronic kidney disease, inflammatory bowel disease, obesity, hemochromatosis, Wilson's disease, and viral hepatitis [Table 1]. Primary outcomes included incidence of cirrhosis and HCC; secondary outcomes included cholangiocarcinoma, liver transplant, hospitalization, viral hepatitis, and steroid use. **Results:** Before matching, AIH-PSC patients had significantly higher risks of cirrhosis, HCC, cholangiocarcinoma, liver transplant, viral hepatitis, and steroid use ($p < 0.05$). No difference was observed in hospitalizations. After matching, follow-up durations were comparable (1919 vs. 1715 days). Adequate balancing of all confounding covariates was achieved. Cirrhosis occurred in 53.7% of the AIH-PSC cohort vs. 33.2% in AIH (RR: 1.62, 95% CI: 1.45–1.81). HCC incidence was 2.4% vs. 1.1% (RR: 2.18, 95% CI: 1.08–4.43). Cholangiocarcinoma was seen in 1.0% of both cohorts (RR: 1.00, 95% CI: 0.42–2.39). Liver transplant occurred in 11.2% vs. 5.8% (RR: 1.95, 95% CI: 1.43–2.66). Hospitalization occurred in 34.7% vs. 29.5% (RR: 1.18, 95% CI: 1.04–1.34). Viral hepatitis was similar (6.7% vs. 6.0%, RR: 1.12, 95% CI: 0.80–1.59). Steroid use was higher in AIH-PSC (20.4% vs. 13.8%, RR: 1.48, 95% CI: 1.20–1.82). **Conclusion:** In this novel multicenter cohort study, patients with AIH-PSC overlap syndrome demonstrated a significantly higher risk of several liver-related outcomes, including cirrhosis and HCC, highlighting its more aggressive nature and greater clinical burden.

3230 | TRENDS IN HEPATOCELLULAR CARCINOMA INCIDENCE BY UNDERLYING ETIOLOGY: A RETROSPECTIVE TRINETX ANALYSIS, 2010–2024

Abdallah Hussein[1] Nyan Latt[2] Islam Rajab[3] Ahmed Salem[4] Abdallatif Hussein[5], [1]Virtua Our Lady Of Lourdes Hopspital, Camden, NJ, [2]Virtua our Lady of Lourdes Hospital, [3]St Joseph University medical center hospital, Paterosn, NJ, [4]Maimonides Medical Center Brooklyn, NY, [5]Al-Najah Universirty

Background: Hepatocellular carcinoma (HCC) incidence is rising worldwide, driven by shifts in underlying liver disease etiologies. We sought to characterize temporal trends in HCC incidence attributable to nonalcoholic fatty liver disease (NAFLD), hepatitis B virus (HBV), and hepatitis C virus (HCV) from 2010 through 2024, and to examine demographic patterns across sex, race, ethnicity, and age. **Methods:** We performed a retrospective cohort study using data from the TriNetX US database between January 1, 2010, and December 31, 2024. Annual trends in HCC incidence attributable to NAFLD, HBV, and HCV were extracted and reported as incidence proportions among the corresponding at-risk populations. Stratified analyses by sex, race (American Indian/Alaska Native, Asian, Black/African American, Native Hawaiian/Pacific Islander, White, Other, Unknown), ethnicity (Hispanic/Latino vs. non-Hispanic), and 10-year age bands were conducted to evaluate demographic patterns. **Results:** A total of 42,144 new HCC cases were identified between 2010 and 2024—21,914 (52.0%) NAFLD-related, 3,129 (7.4%) HBV-related, and 17,101 (40.6%) HCV-related. NAFLD-related HCC incidence rose from 0.072% in 2010 to 0.197% in 2024 ($p < 0.01$), HBV-related from 0.122% to 0.645% ($p < 0.01$), and HCV-related from 0.139% to 0.631% ($p < 0.01$). Incidence was higher in males than females for all etiologies (NAFLD 1.568% vs 0.841%; HBV 4.255% vs 1.402%; HCV 4.842% vs 1.823%; all $p < 0.01$). By race, Asian patients had the highest etiology-specific rates (NAFLD 1.066%; HBV 4.547%; HCV 8.738%), whereas White patients had intermediate rates (NAFLD 1.210%; HBV 1.696%; HCV 3.239%). Hispanic/Latino individuals experienced higher HCC incidence for HCV (5.192% vs 3.704% non-Hispanic; $p < 0.01$). Incidence increased with age, peaking in the 75–79 year group (NAFLD 3.223%; HBV 4.377%; HCV 8.166%). **Conclusion:** From 2010 to 2024, HCC incidence increased markedly across all major etiologies, with the greatest relative rise in HBV-related cases, while HCV-related HCC remained the most common. Male sex, Asian race, Hispanic ethnicity, and older age were consistently associated with higher incidence. These findings highlight evolving epidemiology and underscore the need for tailored surveillance and preventive interventions in high-risk subgroups.

	NAFLD (%)	HBV (%)	HCV (%)
Overall incidence	1.133% (21914)	2.827% (3129)	3.569% (17101)
2010	0.072%	0.122%	0.139%
2024	0.197%	0.645%	0.631%
Female	0.841%	1.402%	1.823%
Male	1.568%	4.255%	4.842%

3231 | PLATELETS FROM PATIENTS WITH HEPATOCELLULAR CARCINOMA PROMOTE DISEASE PROGRESSION BY ENHANCING TUMOR CELL MIGRATION AND INVASION

Meng Zhang[1] Muqi Wang[1] Yikai Wang[1] Chenrui Liu[1] Wenhao Wang[1] Guoe Gou[1] Yaping Li[1] Shuangsuo Dang[1], [1]The Second Affiliated Hospital of Xi 'an Jiaotong University

Background: The regulatory role of platelets in the tumor microenvironment has garnered increasing

attention, yet their functional differences and mechanisms in hepatocellular carcinoma (HCC) progression remain unclear. We aimed to investigate platelet activation in HCC patients and examines how platelets influence HCC cell proliferation, migration, and invasion. **Methods:** Peripheral blood samples were collected from 30 HCC patients and 30 healthy volunteers. Platelets were labeled using APC anti-human CD62P (P-Selectin) and PE anti-human CD41 antibodies, and their activation levels were assessed via flow cytometry. Additionally, peripheral blood was collected from three primary HCC patients and three healthy volunteers, from which platelets were isolated and co-cultured with HepG2 and Hep3B HCC cells at a ratio of 100:1. The interactions between platelets and tumor cells were traced using CellTracker CM-DiI fluorescence labeling. After 48 hours of co-culture, platelets were removed, and HCC cell proliferation was evaluated using the CCK-8 assay. Transwell assays (with or without Matrigel coating) were performed to quantitatively assess tumor cell migration and invasion. **Results:** Flow cytometry analysis revealed that the platelet activation marker (CD62P%) was significantly elevated in HCC patients compared to healthy controls (16.39 ± 1.07 vs. 3.21 ± 0.52, $p < 0.001$). Confocal laser microscopy demonstrated prominent fusion and internalization of platelets by tumor cells in HCC patients. The CCK-8 assay indicated that tumor cells co-cultured with either HCC patient-derived or healthy donor-derived platelets exhibited significantly higher proliferation rates compared to the non-co-cultured group ($p < 0.01$), though no significant difference was observed between the HCC and healthy control platelet groups. Transwell migration assays demonstrated that tumor cells co-cultured with healthy donor platelets (359.00 ± 11.53 vs. 246.67 ± 15.04, $p < 0.001$) or HCC patient platelets (519.00 ± 31.51 vs. 246.67 ± 15.04, $p < 0.001$) exhibited significantly enhanced migration compared to non-co-cultured tumor cells. Notably, HCC patient-derived platelets exhibited a stronger promotive effect on tumor cell migration than healthy donor-derived platelets ($p = 0.001$). Similarly, invasion assays revealed that both healthy donor platelets (107.00 ± 9.17 vs. 76.47 ± 18.45, $p = 0.05$) and HCC patient platelets (152.33 ± 19.14 vs. 74.67 ± 18.45, $p = 0.007$) significantly enhanced tumor cell invasion, with HCC patient-derived platelets exhibiting a more pronounced effect ($p = 0.021$). **Conclusion:** Platelet activation levels were significantly elevated in HCC patients compared to healthy individuals. Furthermore, HCC patient-derived platelets exerted a greater promotive effect on tumor cell migration and invasion than healthy donor-derived platelets, suggesting that platelets may play a crucial role in HCC metastasis.

3232 | PROGNOSTIC VALUE OF TERT PROMOTER–MUTATED CFDNA AFTER CURATIVE ABLATION IN EARLY-STAGE HEPATOCELLULAR CARCINOMA

Masaru Muraoka[1] Shinya Maekawa[1] Leona Osawa[1] Shuya Matsuda[1] Yuichiro Suzuki[1] Mitsuaki Sato[1] Atsunori Tsuchiya[1], [1]University of Yamanashi

Background: *TERT* promoter mutations are frequently observed not only in advanced hepatocellular carcinoma (HCC) but also in early-stage disease. Although cell-free DNA (cfDNA) harboring this mutation is a potential target for liquid biopsy, its detection in serum remains challenging. We developed an ultra-sensitive detection method combining PNA clamping and digital PCR (referred to as the MGB-PNA clamp method), and investigated its utility in detecting *TERT* promoter–mutated cfDNA after curative treatment of HCC and its association with early recurrence. **Methods:** We enrolled 41 patients with BCLC stage 0 or A HCC who underwent curative treatment with radiofrequency ablation (RFA) or microwave ablation (MWA) in 2023. Serum samples were collected before treatment and 2 to 3 weeks after treatment. cfDNA was extracted and quantified for *TERT* promoter mutations using the MGB-PNA clamp method. The association between post-treatment mutant DNA detection and recurrence within six months was assessed. **Results:** *TERT* promoter mutations were detected in 20 of 41 patients (48.8%). Among these mutation-positive cases, the median mutant DNA concentration was 9.6 (6.5–17.0) copies/ml serum before treatment and 6.5 (0–12.0) copies/ml serum 2–3 weeks after treatment. Early recurrence within six months occurred in 10 patients overall, including 6 among the 20 mutation-positive cases. In this subgroup, we compared recurrence and non-recurrence groups. Median pre-treatment AFP levels were 4.1 (2.3–19.6) ng/ml in the recurrence group and 4.3 (2.6–5.5) ng/ml in the non-recurrence group ($P = 0.97$). A $\geq 20\%$ decrease in AFP was observed in 50% of the recurrence group and 46.2% of the non-recurrence group ($P = 1.00$), showing no significant association with early recurrence. In contrast, mutant DNA was detectable 2–3 weeks post-treatment in 100% of the recurrence group and 41.7% of the non-recurrence group ($P = 0.038$), suggesting that persistent post-ablation mutant DNA may be associated with early recurrence. **Conclusion:** Persistent detection of *TERT* promoter–mutated cfDNA after curative ablation for

3233 | RADIATION AS AN IMMUNOLOGIC PRIMER: SCOPING THE EMERGING LANDSCAPE OF MULTIMODAL STRATEGIES IN HEPATOCELLULAR CARCINOMA

Eric Welwin[1] Viren Sehgal[1] Ibrahim Qadri[1] Samin Faiaz[1] Taseen Tanzil[1] Colin Hill[2] Brock Hewitt[2], [1]CUNY School of Medicine, [2]The NYU Grossman School of Medicine and NYU Langone Health

Background: Advanced hepatocellular carcinoma (HCC) carries a dismal prognosis, with many patients ineligible for curative resection or transplantation. While radiotherapy has historically been limited by toxicity concerns, advances in techniques like stereotactic body radiation therapy (SBRT), volumetric modulated arc therapy (VMAT), and non-ionizing modalities (such as histotripsy) have renewed interest as a means to overcome treatment resistance. Importantly, emerging data suggest that combining radiotherapy with systemic therapies (immunotherapy, targeted agents, gene modulation) can yield synergistic antitumor effects exceeding monotherapy. This review synthesizes the evolving landscape of radiation-based combination therapies in HCC, exploring mechanisms of synergy, outcomes, and persistent challenges. **Methods:** A scoping review was conducted across clinical trials, preclinical studies, and translational research. Eligible studies involved combinations of SBRT or other radiotherapy modalities with immune checkpoint inhibitors, anti-angiogenic therapies, gene-modulating agents (e.g., microRNAs), or physical techniques such as VMAT or histotripsy. Data was extracted and organized to characterize efficacy outcomes, mechanistic interactions, and toxicity profiles. **Results:** We found that multiple combination strategies demonstrated consistent therapeutic synergy. SBRT combined with PD-1 inhibitors (e.g., sintilimab) showed objective response rates up to 96% and favorable safety in second-line settings. SABR-ipilimumab regimens elicited systemic immune responses, including potential abscopal effects. Triplet therapies with SBRT, lenvatinib, and PD-1 blockade extended median overall survival beyond 30 months. Co-therapies with miR-22-3p and miR-29a-3p sensitized tumors to sorafenib by downregulating pathways such as STK26 and AKT3. VMAT improved precision in treating tumors near radiosensitive structures, while histotripsy combined with local heat enhanced cytotoxicity and immune priming in preclinical models. **Conclusion:** Radiation-based combination strategies are reshaping the therapeutic landscape of hepatocellular carcinoma, offering synergistic gains in both locoregional control and systemic antitumor response. The integration of immunotherapy, anti-angiogenic agents, and gene-targeting modalities with precision radiotherapy holds substantial promise for patients with limited treatment options. However, optimizing therapeutic sequencing, identifying precise biomarkers, and addressing disparities in access to radiation platforms remain critical challenges. These findings strongly advocate for a paradigm shift in HCC treatment, with radiation-based combination therapies poised to become a cornerstone of future clinical practice. Large-scale trials are imperative to validate these results and define optimal implementation strategies.

3234 | ASSOCIATION BETWEEN TUMOR BURDEN AND FRAILTY IN LIVER TRANSPLANT CANDIDATES WITH HEPATOCELLULAR CARCINOMA

Gabrielle Jutras[1] Melinda Wang[2] Aryana Far[1] Michael Li[1] Jin Ge[1] Jennifer Lai[1], [1]University of California, San Francisco, [2]Yale University

Background: Frailty studies in liver transplantation (LT) candidates have largely focused on patients with cirrhosis *without* hepatocellular carcinoma (HCC). However, HCC patients represent a distinct subgroup of LT candidates who are older with better compensated liver disease and more non-hepatic comorbidities. These factors, in addition to HCC tumor burden may influence both the prevalence and underlying contributors to frailty. We aimed to characterize and compare frailty in HCC versus non-HCC LT candidates. **Methods:** We included adults with cirrhosis listed for LT at a single U.S. transplant center (2012-2024) who underwent ambulatory frailty assessment using the Liver Frailty Index (LFI; "frail" = LFI $\geq$ 4.4). HCC tumor characteristics at diagnosis—including number of lesions, tumor size, AFP levels, and initial treatment—were extracted using validated automated data capture. Logistic regression was used to evaluate associations between tumor characteristics and frailty. **Results:** Of 2,420 LT candidates, 801 (33%) had HCC. Frailty was observed in only 9% of HCC candidates, compared to 21% of non-HCC candidates. Among those who were frail, HCC candidates were older, had lower laboratory MELDNa scores, and lower rates of ascites, hepatic encephalopathy and dialysis compared to non-HCC candidates (Table). Rates of hypertension and diabetes were similar between groups, though HCC candidates trended toward more coronary artery disease. Among frail vs. non-frail HCC LT candidates, tumor burden, total tumor diameter, and AFP were comparable ($p > 0.21$). These tumor characteristics were not associated with frailty in uni- and multi-variable analyses. **Conclusion:** In this large cohort of HCC LT candidates, frailty was associated with established hepatic (e.g., MELD, ascites, HE) and non-hepatic (e.g., gender, comorbidities) factors but not associated with tumor characteristics. This differs from patients with non-HCC malignancy, in whom cancer-related frailty is common. In LT candidates with HCC, who generally have well-compensated liver disease, the presence of frailty more likely reflects advanced non-hepatic co-morbidities that are less likely to resolve with LT. This highlights the need for studies specifically investigating the contributors to frailty unique to patients with HCC.

Endocrinology, Faculty of Medicine, Saga University, Saga, Japan, [14]National University Hospital, Singapore

Background: Alpha-fetoprotein (AFP) remains the most widely used biomarker for hepatocellular carcinoma (HCC), yet its clinical utility is hindered by wide inter-individual variability. Traditional linear regression methods may oversimplify these complex patterns, masking important insights. To address this, we employed quantile regression—a powerful technique that captures differential predictor effects across the AFP distribution—to better elucidate the nuanced influence of demographic and clinical factors. **Methods:** This international multicentre retrospective cohort study analysed data from adult HCC patients across nine tertiary institutions between 1 January 2003 and 27 December 2021. Quantile regression was applied at the 0.10, 0.50, and 0.90 quantiles of AFP to characterise how predictor effects vary across its distribution. Logistic regression was also performed, stratifying AFP into <20 ng/mL and ≥ 20 ng/mL groups, to enable direct comparison with conventional analytical approaches. **Results:** A total of 2,298 HCC patients were included, with a median AFP of 13.70 ng/mL (IQR: 4.10–182.85). Multivariable quantile regression revealed striking heterogeneity: Asian ethnicity, elevated AST/ALT, advancing BCLC stage, and HBV or HCV aetiologies were associated with higher AFP levels, particularly in upper quantiles. In contrast, male sex, older age, and elevated creatinine predicted lower AFP levels. Compared to MASLD, HBV ($\beta = 0.44$, 95% CI: 0.05–0.83) and HCV ($\beta = 0.30$ at Q10; $\beta = 0.40$ at Q50) were consistently associated with higher AFP. Logistic regression identified similar predictors but failed to detect the distribution-specific effects captured by quantile regression. **Conclusion:** This study highlights the substantial heterogeneity in how clinical factors shape AFP levels across its distribution. These findings challenge the oversimplified reliance on fixed AFP thresholds and advocate for a more nuanced, distribution-aware interpretation of this widely used biomarker in HCC.

3236 | TRANSARTERIAL CHEMOEMBOLIZATION COMBINED WITH SORAFENIB VERSUS MONOTHERAPY FOR UNRESECTABLE HEPATOCELLULAR CARCINOMA: AN UMBRELLA REVIEW OF META-ANALYSES

Ruchir Paladiya[1] Vikash Karmani[2] Krishan Joshi[3] Vikash Kumar[4] Aalam Sohal[4] Neil Parikh[5], [1]University of Connecticut health center, [2]Jinnah Sindh Medical University, [3]California Health Sciences University, College of Osteopathic Medicine, [4]Creighton University, [5]Hartford Hospital

Background: This umbrella review aimed to synthesize evidence from previously conducted meta-analyses and review articles to compare transarterial chemoembolization combined with sorafenib versus monotherapy for unresectable hepatocellular carcinoma. **Methods:** While adhering to the PRIOR guidelines, PubMed, Google Scholar, Web of Science, and Scopus were searched from database inception to December 2024 to identify relevant articles. The outcomes of interest included (1) Overall, (2) Time to Progression, (3) Disease Control Rate, and (4) Objective Response Rate. A Corrected Covered Area (CCA) assessment was performed to determine the overlap between reviews. The quality and rigor of each included review were assessed using the AMSTAR-2 tool. **Results:**

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Nine meta-analyses were included from the 13,821 articles identified during the literature search; 9 meta-analyses were included. A significant overlap was noted across studies, with a corrected coverage area of 49%. Eight reviews assessed overall survival, with five reporting a significant survival benefit (HR range: 0.62–0.74, $P < 0.001$), while two found no significant effect (HR range: 0.75–0.97, $P > 0.05$). Similarly, eight reviews examined the time to progression, with six showing a significant risk reduction (HR range: 0.61–0.75, $P < 0.05$), whereas two reported non-significant findings (HR: 0.74–0.77, $P > 0.05$). Four reviews evaluated the disease control rate, with two reporting a significant benefit (OR range: 0.52–4.72, $P < 0.01$), one showing a non-significant trend (OR: 1.57, $P = 0.059$), and one finding no effect (RR: 1.04, $P = 0.568$). Six reviews assessed the objective response rate, with three reporting a significant increase in risk (OR range: 2.19–3.59, $P < 0.01$) and one showing a potential reduction in risk (OR: 0.85, $P = 0.0006$). One review found no significant effect (RR: 1.20, $P = 0.257$), while another reported a protective effect (OR: 0.39, $P = 0.008$). **Conclusion:** This umbrella review highlights the efficacy of TACE plus sorafenib in improving the time to progression, objective response rate, and overall survival in patients with unresectable HCC. This underscores the need for personalized treatment and further research to refine protocols.

3237 | PROTEINURIA AND ITS CLINICAL IMPLICATIONS IN HCC PATIENTS TREATED WITH ATEZOLIZUMAB/BEVACIZUMAB: A MULTICENTER REAL-WORLD STUDY

Yu Rim Lee[1] Sung Bum Cho[2] Hyun Young Woo[3] Jae Hyun Yoon[4] Jun Sik Yoon[5] yeowool kang[6] Jeong Eun Song[7] Young Mi Hong[8] Sang Youn Hwang[9] Joonho Jeong[10] Jeong Heo[3] Young Oh Kweon[11] Yang Hyun Baek[6] Soo Young Park[11] Won Young Tak[12], [1]Kyungpook National University, Kyungpook National University Chilgok Hospital, [2]Chonnam National University Hwasun Hospital and Chonnam National University Medical School, [3]Pusan National University and Medical Research Institute, Pusan National University Hospital, [4]Chonnam National University Hospital, [5]Busan Paik Hospital, Inje University College of Medicine, [6]Dong-A University Hospital, [7]Daegu Catholic University School of Medicine, [8]Pusan National University School of Medicine, Pusan National University Yangsan Hospital, [9]Dongnam Institute of Radiologic & Medical Sciences, [10]University of Ulsan College of Medicine, Ulsan University Hospital, [11]Kyungpook National University, Kyungpook National University Hospital, [12]School of Medicine, Kyungpook National University

Background: Atezolizumab/bevacizumab (atezo/bev) has been demonstrated as an effective first-line treatment for hepatocellular carcinoma (HCC). Proteinuria is one of the common adverse events of atezo/bev therapy. Therefore, we evaluated the Prevalance and risk factors for proteinuria in patients treated with atezo/bev for unresectable HCC in a large, multicenter real-world population. **Methods:** From July 2020 to October 2024, this retrospective cohort study included 869 patients with HCC from 9 tertiary hospitals who were treated with atezo/bev. The level of proteinuria was evaluated based on the Common Terminology Criteria for Adverse Events version 5.0. **Results:** After excluding 242 patients due to unavailable baseline urinalysis results or confirmed proteinuria, a total of 627 patients were included in the analysis. During a median follow-up of 8.1 months, 127 (20.3%) patients developed proteinuria at a median of 3.6 months. Three patients permanently discontinued atezo/bev due to proteinuria, and 12 patients temporarily discontinued or reduced the dose of atezo/bev. Treatment duration of atezo/bev was not significantly different between the proteinuria and non- proteinuria groups.

However, both overall survival and progression-free survival were significantly higher in patients with proteinuria compared with patients without proteinuria (log-rank test: $P < 0.001$, $P < 0.001$, respectively). In the multivariate analysis, proteinuria was significantly associated with the presence of hypertension and serum creatinine level (all $P < 0.05$). **Conclusion:** The occurrence of proteinuria during atezo/bev treatment in patients with advanced HCC is not associated with a poor prognosis if treated appropriately.

3238 | BLEEDING COMPLICATIONS AND SURVIVAL OUTCOMES IN HCC PATIENTS TREATED WITH ATEZOLIZUMAB/BEVACIZUMAB: MULTICENTER REAL-WORLD STUDY

Yu Rim Lee[1] Sung Bum Cho[2] Hyun Young Woo[3] Jae Hyun Yoon[4] Jun Sik Yoon[5] yeowool kang[6] Jeong Eun Song[7] Young Mi Hong[8] Sang Youn Hwang[9] Joonho Jeong[10] Jeong Heo[3] Young Oh Kweon[11] Yang Hyun Baek[6] Soo Young Park[11] Won Young Tak[11], [1]Kyungpook National University, [2]Chonnam National University Hwasun Hospital and Chonnam National University Medical School, [3]Pusan National University and Medical Research Institute, Pusan National University Hospital, [4]Chonnam National University Hospital, [5]Busan Paik Hospital, Inje University College of Medicine, [6]Dong-A University Hospital, [7]Daegu Catholic University School of Medicine, [8]Pusan National University School of Medicine, Pusan National University Yangsan Hospital, [9]Dongnam Institute of Radiologic & Medical Sciences, [10]University of Ulsan College of Medicine, Ulsan University Hospital, [11]Kyungpook National University, Kyungpook National University Hospital

Background: Atezolizumab/bevacizumab (atezo/bev) have been demonstrated as an effective first-line treatment for hepatocellular carcinoma (HCC). However, the risk of bleeding complications is a major concern in atezo/bev treatment. Therefore, we evaluated the efficacy and safety with a focus on bleeding events of atezo/bev in a large, multicenter real-world population. **Methods:** From July 2020 to October 2024, this retrospective cohort study included 869 patients with HCC from 9 tertiary hospitals who were treated with atezo/bev. **Results:** During a median follow-up of 8.4 months, 112 (12.9%) patients developed bleeding episodes at a median of 3.9 months. Of these, variceal hemorrhage occurred in 62 (7.1%) patients treated with atezo/bev at a median of 5.5 months (8 cycle). Grade III or IV bleeding occurred in 35 (5.1%) patients of patients, with grade V bleeding observed in 4 (0.6%) patients. At the time of variceal bleeding, 72.9% of the patients were receiving atezo/bev. Progression-free survival was not significantly different between the variceal hemorrhage and non-variceal hemorrhage groups. However, overall survival was significantly lower in patients with variceal hemorrhage (log-rank test: $P = 0.007$). In the multivariate analysis, variceal hemorrhage was significantly associated with the presence of varices, history of variceal bleeding, and macrovascular invasion (all $P < 0.05$). **Conclusion:** Patients with advanced HCC who develop variceal bleeding during atezo/bev treatment may have a poor prognosis. It is necessary to identify high-risk group of variceal bleeding and monitor them carefully.

3239 | CIRCULATING SERUM PROTEINS AS PREDICTIVE BIOMARKERS FOR IMMUNOTHERAPY EFFICACY IN ADVANCED HC

Young-Sun Lee[1] Eunho Choi[1] IN HEE KIM[2] Jin Woo Lee[3] Jung Hwan Yu[3] Sung Bum Cho[4] Ha Seok Lee[1] Youngwoo Lee[1] Yang Jae Yoo[1] Seong Hee Kang[1] Taehyung Kim[1] Yim Sun Young[1] Young Kul Jung[1] Ji Hoon Kim[1] Yeon Seok Seo[1] Hyung Joon Yim[1] Jong eun Yeon[1] Kwan Soo Byun[1], [1]Korea University College of Medicine, [2]Jeonbuk National University Hospital, [3]Inha University School of Medicine, [4]Chonnam National University Hwasun Hospital

Background: Combination immunotherapies like atezolizumab with bevacizumab and durvalumab with tremelimumab are first-line standards for advanced hepatocellular carcinoma (HCC). However, predicting which patients will respond remains challenging due to the absence of validated biomarkers. This study investigates circulating serum proteins to identify predictive biomarkers for immunotherapy efficacy in advanced HCC. **Methods:** Pre-treatment serum samples from advanced HCC patients receiving atezolizumab-bevacizumab were collected across 4 academic centers. Participants were stratified into responders (stable disease, partial/complete response) and non-responders (progressive disease after three cycles). Differential protein expression between groups was analyzed via mass spectrometry-based proteomics. **Results:** The study analyzed samples from a total of 44 patients, of whom 32 were classified as responders and 12 as non-responders. The results showed that non-responders had higher serum levels of C-reactive protein (CRP) and protein S100-A9 (S100A9). In contrast, non-responders had lower levels of several other proteins, including transferrin (TF), transthyretin (TTR), apolipoprotein C-III (APOC3), clusterin (CLU), retinol-binding protein 4 (RBP4), inter-alpha-trypsin inhibitor heavy chain H2 (ITIH2), insulin-like growth factor-binding protein complex acid labile subunit (IGFALS), and antithrombin-III (SERPINC1). The analysis also revealed that proteins such as APOC3 and CLU were highly interconnected within the serum protein interaction network, indicating that they may play important roles as central hubs related to treatment response. **Conclusion:** The findings suggest that circulating serum proteins could serve as useful biomarkers for predicting how patients with advanced HCC will respond to atezolizumab and bevacizumab therapy. Identifying such biomarkers may help guide treatment decisions and improve outcomes for these patients.

3240 | SINGLE-CELL ANALYSIS REVEALS DISTINCT IMMUNE CHARACTERISTICS OF TWO INTERACTING T CELL SUBSETS IN IMMUNOTHERAPY-RESPONSIVE HBV-ASSOCIATED HEPATOCELLULAR CARCINOMA

Wenli Xu[1] Tingfeng Xu[1] Jie Zhang[1] Mingjiang Liu[1] Pengzhan Deng[1] Qiuli Xie[1] Lijuan Liao[1] Songqing He[1], [1]The First Affiliated Hospital of Guangxi Medical University

Background: The prognosis for hepatocellular carcinoma (HCC) remains poor, with 55%-80% of cases linked to hepatitis B virus (HBV) infection. While immunotherapy has demonstrated potential in improving clinical outcomes, its benefits are limited to a small subset of patients. By systematically analyzing the tumor immune microenvironment in responders to immunotherapy, we can obtain critical insights into the underlying immune response mechanisms. **Methods:** To identify cell subsets involved in the immune response to immunotherapy in HBV-HCC, we collected tumor and adjacent liver tissues and PBMCs from two responding HBV-HCC patients. We used scRNA-seq and scTCR-seq to characterize cell clusters with distinct functions. These clusters were analyzed using univariate, multivariate, and survival analyses based on TCGA and GSE14520 data. Differences between responders and non-responders were validated using GSE206325. Spatial distribution was elucidated using skrxzf279n. Finally, findings were confirmed in an independent cohort of 28 HBV-HCC patients. **Results:** Here, we identified two interacting T cell subsets using scRNA-seq. CD8-Pro-T cells, characterized by high expression of proliferation-associated markers such as MKI67, exhibit dysregulated cell cycle control. The other subset, CD8-CXCL13-T cells, displays elevated expression levels of the chemokine CXCL13 and co-expression of PD-1. This subset demonstrates strong exhaustion scores and represents the predominant localization of high-frequency clones within tumor tissues. Furthermore, a robust correlation and interaction were observed between these two T cell subsets. By integrating our single-cell data with external datasets, we found that these cells are predominantly localized in tumor tissues and closely distributed at the tumor periphery, which is associated with poor prognosis. Notably, CD8-Pro-T cells constitute a smaller proportion in responders compared to non-responders. Finally, we validated the expression of CXCL13, PD-1, MKI67, and other markers primarily in tumor tissues from an independent cohort of 28 HBV-HCC patients. **Conclusion:** This study identified and validated two distinct interacting T-cell subsets that exhibit responsiveness to immunotherapy in HBV-HCC, providing a novel therapeutic strategy for the management of HCC.

3241 | PROGNOSIS OF LOW FIB-4 IN A MULTINATIONAL LONGITUDINAL HEPATOCELLULAR CARCINOMA COHORT

Yong Chuan Tan[1] Zhenning Yu[2] Nicole Shu Ying Tang[2] Ken Liu[3] Karn Wijarnpreecha[4] Beom Kyung Kim[3] Sung Won Lee[3] Gang Chen[3] Takumi Kawaguchi[5] Hirokazu Takahashi[6] Daniel Q Huang[1] Mark Muthiah[1], [1]Division of Gastroenterology and Hepatology, National University Hospital, Singapore, [2]Yong Loo Lin School of Medicine, National University of Singapore, Singapore, [3]., [4]University of Arizona College of Medicine-Phoenix, [5]Kurume University School of Medicine, [6]Saga University

Background: The fibrosis-4 index (FIB-4) is recommended as one method to risk stratify people with chronic liver disease. However, it is unclear what proportion of people with hepatocellular carcinoma (HCC) have a low FIB-4. We aimed to assess the proportion of people with HCC of various etiologies who have a low FIB-4. **Methods:** This multicenter, multinational cohort study included 1,778 adults (26% female) with hepatocellular carcinoma (HCC) from seven international centers in Australia, India, Japan, South Korea, Singapore, and the United States. The primary objective was to determine the proportion of patients with a low FIB-4 for each etiology, defined according to established standards for each etiology. **Results:** The median (IQR) age and body mass index were 73 (66-82) and 25.6 (22.3 – 28.0) kg/m^2 with 55% having known cirrhosis. The median FIB-4 was 5.09 (2.60 – 9.96) with a total of 138 patients (8%) who had a low FIB-4. However, the proportion of patients with a low FIB-4 varied by etiology: 11% in HBV, 2% in HCV, 3% in ALD, and 11% in MASLD. Low FIB-4 group presented with fewer tumor nodules (1.22 vs 1.65, $p < 0.001$), lower AFP levels (5.3 vs 13.3 ng/mL, $p < 0.001$), and was associated with better survival outcomes (adjusted HR: 0.54, 95% CI: 0.38–0.76, $p < 0.001$). The odds of receiving curative treatment were significantly higher in those with a low FIB-4 (70% vs 52%, $p < 0.001$). Male sex, HBV, and MASLD were associated with a low FIB-4 (adjusted OR: 5.03, 95% CI: 2.00–15.44), while cirrhosis and advanced BCLC stage were inversely associated (adjusted OR: 0.34, 95% CI: 0.19–0.58, $p < 0.001$). **Conclusion:** Most people with alcohol- and HCV-related HCC have an elevated FIB-4, however, one in ten with HBV- and MASLD-related HCC have a low FIB-4. Hence, while FIB-4 is commonly used in risk stratification for HCC, its ability to accurately predict prognosis may be limited. The reliance on FIB-4 as a stratification tool could potentially misclassify certain patients, particularly those with HBV

3242 | SMART-HCC OUTPERFORMS PLEASE SCORE IN STRATIFYING HCC AND LIVER-RELATED EVENTS RISK IN ADVANCED CHRONIC LIVER DISEASE PATIENTS

Kessarin Thanapirom[1] Kanteera Sriyudthsak[1] Sirinporn Suksawatamnuay[1] Panarat Thaimai[1] Nipaporn Siripon[1] Wanwisar Makhasen[1] Tassanan Jaihan[1] Sombat Treeprasertsuk[2] Piyawat Komolmit[1], [1]Division of Gastroenterology and Hepatology, Chulalongkorn University, [2]Chulalongkorn University

Background: Patients with advanced chronic liver disease (ACLD) are at increased risk of hepatocellular carcinoma (HCC). Effective risk stratification is essential to enhance surveillance and facilitate early detection. The PLEASE and SMART-HCC scores, both based on liver stiffness measurement (LSM), have been developed to identify high-risk individuals. However, comparative data between both scores remained limited. This study aims to compare the performance of both scores in identifying high-risk patients for HCC development and in predicting liver-related events (LRE). **Methods:** This retrospective cohort study included 703 patients with ACLD due to MASLD and HBV infection receiving anti-viral therapy, who underwent LSM using transient elastography (TE) at Chulalongkorn University Hospital between 2017 and 2022, were screened. ACLD was defined as TE $\geq$ 10 kilopascals. Based on the original study, PLEASE score $\geq$ 4 and SMART-HCC score $\geq$ 0.08 were used to identify patients at a high risk for HCC. LRE was defined as the development of one of the following complications: ascites, hepatic encephalopathy and variceal bleeding. **Results:** A total of 461 patients with ACLD (296 with MASLD and 165 with HBV) met inclusion criteria. During the 5-year follow-up, HCC developed in 46 (10%) patients. Among those identified as high-risk, HCC occurred in 19 patients (22.6%) by the PLEASE score and in 31 (27.0%) by the SMART-HCC score. The SMART-HCC score demonstrated superior performance in predicting HCC than the PLEASE score (AUC 0.74 vs 0.63, $p = 0.03$). PLEASE score had a sensitivity of 41.4% and a negative predictive value (NPV) of 92.8%, whereas the SMART-HCC score showed a sensitivity of 67.4% and an NPV of 95.7%. Seventeen patients (3.7%) developed LRE during the follow-up. Those who experienced LRE had significantly higher baseline SMART-HCC scores than those who did not. SMART-HCC score demonstrated fair predictive ability for LRE (AUC = 0.69, 95%CI 0.59-0.80), whereas PLEASE score did not (AUC = 0.54, 95%CI: 0.39-0.68). A SMART-HCC cut-off $\geq$ 0.033 was identified as optimal for predicting LRE risk. In multivariate analysis, a SMART-HCC $\geq$ 0.033 (AUC = 3.81, 95%CI: 1.18-12.17, $p = 0.03$) was independently associated with LRE development. **Conclusion:** The SMART-HCC score outperformed the PLEASE score in identifying high-risk patients for HCC development and predicting LRE in ACLD. These findings support its utility as a risk stratification tool. Future studies are warranted to validate its role in optimizing HCC surveillance strategies.

Louis University, St. Louis, MO, [3]Division of General Internal Medicine, Saint Louis University School of Medicine, St. Louis, MO, [4]National University of El Salvador, Social Security System, Division of OBGYN-Oncology, [5]Division of Gastroenterology and Hepatology, Saint Louis University School of Medicine, St. Louis,MO

Background: Atezolizumab, in combination with Bevacizumab, is currently established as one of the standard first-line regimens for patients with advanced hepatocellular carcinoma (HCC). However, the therapeutic landscape following the progression of this regimen is evolving, particularly regarding the role and relative efficacy of various second-line tyrosine kinase inhibitors (TKIs). To clarify the optimal second-line option, we conducted a systematic review and meta-analysis to evaluate the experience with various TKIs as second-line therapy in patients with advanced HCC who experienced disease progression on Atezolizumab/Bevacizumab. **Methods:** A systematic search of PubMed, Scopus, Embase, and the Cochrane Central Register of Controlled Trials was performed from inception to October 2024. Eligible studies reported median overall survival (OS) and/or progression-free survival (PFS) for patients receiving second-line TKIs. Mean and standard deviation estimates were derived from medians and interquartile ranges using an Excel-based tool for estimating sample mean and standard deviation (SD) (Data Estimation and Conversion for Meta-Analysis [DECoMA]). A random-effects model was applied to pool median OS and PFS across studies. Statistical analyses were conducted using Stata version 18. **Results:** Nine retrospective studies were included, with 907 patients with advanced HCC who progressed on Atezolizumab/Bevacizumab. All patients received a TKI as second-line therapy: Lenvatinib (n = 442), Sorafenib (n = 365), Regorafenib (n = 65), or Cabozantinib (n = 35). Across all studies, overall survival (OS) was 11.0 months (95% CI: 7.99–14.00). When stratified by treatment, the median OS was 12.99 months with Lenvatinib (95% CI: 7.76–18.23), 10.28 months with Sorafenib (95% CI: 2.71–17.86), and 8.79 months with Cabozantinib (95% CI: 5.74–11.85), and data were limited for Regorafenib. No statistically significant differences in OS were observed between the agents. The pooled mean progression-free survival (PFS) was 3.46 months (95% CI: 2.99–3.92). Among the evaluated TKIs, Lenvatinib showed the longest PFS at 3.95 months (95% CI: 3.63–4.27). Sorafenib had a PFS of 2.46 months (95% CI: 2.07–2.85). Cabozantinib and Regorafenib demonstrated mean PFS of 3.41 months (95% CI: 1.26–5.56) and 3.27 months (95% CI: 2.22–4.33), respectively. No statistically significant differences in PFS were observed among Cabozantinib, Sorafenib, and Regorafenib. **Conclusion:** Tyrosine kinase inhibitors showed modest clinical benefits as second-line options for advanced HCC after progression on Atezolizumab/Bevacizumab. While overall survival did not differ significantly among agents, Lenvatinib showed a longer PFS, with no significant differences seen with Cabozantinib or Regorafenib. Further large-scale prospective studies are needed to validate these findings and refine treatment sequencing in this setting.

3244 | N-ACETYLCYSTEINE SLOWS DOWN LIVER CARCINOGENESIS: MECHANISTIC INSIGHTS FROM A PRECLINICAL HEPATOCELLULAR CARCINOMA MODEL

Fernando Caloca-Camarena[1] Scarlet Arceo-Orozco[2] Alondra Martinez-Lara[2] Jorge Salto-Sevilla[3] Roberto Flores-Peña[2] Hugo Monroy-Ramírez[2] Marina Galicia-Moreno[2] Juan Armendariz-Borunda[4], [1]IBMMyTG, CUCS, Universidad de Guadalajara, México., [2]IBMMyTG, CUCS, Universidad de Guadalajara, México, [3]IBMMyTG, CUCS, Universidad de Guadalajara, Méxic, [4]IBMMyTG, CUCS, Universidad de Guadalajara, México/ Tecnologico de Monterrey, EMCS, México.

Background: Hepatocellular carcinoma (HCC) is the most common primary liver cancer and the third leading cause of cancer-related deaths. Its development involves the dysregulation of cellular processes, such as fibrosis, proliferation, and oxidative stress. Given limited treatment options, preventive strategies and a better understanding of their molecular basis are crucial. N-acetylcysteine (NAC), widely used for acetaminophen overdose and as a mucolytic, remains understudied in HCC. This study aims to investigate the effects and mechanisms of NAC in HCC models. **Methods:** Male Fischer-344 rats (180–200 g) were randomly assigned to three groups (n = 4): 1) Control (carboxymethylcellulose), 2) Damage (diethylnitrosamine [50 mg/kg/week, i.p.] + 2-acetylaminofluorene [25 mg/kg/week, p.o.]), and 3) Treatment (Damage + NAC [300 mg/kg/day, p.o.]). Interventions lasted 16 weeks. Serum and liver samples were collected to assess liver injury, oxidative stress, fibrosis, and proliferation. Biochemical, molecular, histological, and immunostaining analyses were performed. Data were analyzed using one-way ANOVA with Tukey's post hoc test. All procedures were approved by the institutional committee (CI-01723). **Results:** NAC prevented weight loss and reduced serum markers of liver injury. The HCC group showed neoplastic changes and dysplastic nodules, which NAC attenuated. Furthermore, fibrosis was reduced, with lower extracellular matrix and collagen deposition, supported by decreased α-SMA and TGF-β expression. Tumor proliferation was also limited, as indicated by low levels of Ki-67, PCNA, and Glypican-3. NAC modulated the Nrf2/Keap1 pathway, enhancing antioxidant enzymes such as catalase, superoxide dismutase, heme oxygenase, and glutathione reductase. Additionally, NAC protected against oxidative DNA damage by upregulating the enzyme OGG1 and decreasing 8-oxoguanine. **Conclusion:** NAC's efficacy in preventing HCC appears to stem from its modulation of oxidative stress, fibrogenesis, cellular proliferation, and tumor progression. Our findings underscore the potential of this approach as an adjuvant therapy in HCC. However, further preclinical and clinical studies are crucial to fully elucidate its mechanisms, confirm its therapeutic benefits, and establish its safety before clinical repositioning in this setting.

3245 | N6-METHYLADENOSINE–MEDIATED UP-REGULATION OF ARRB2 REGULATES INTRAHEPATIC CHOLANGIOCARCINOMA MALIGNANT PROGRESSION AND PEMIGATINIB RESISTANCE THROUGH MAPK AND HIPPO SIGNALING PATHWAYS

qiwei yang[1] Haoqi Chen[2] Genshu Wang[1], [1]Guangdong Provincial Hospital of Traditional Chinese Medicine, [2]The Third Affiliated Hospital of Sun Yat-Sen University

Background: Intrahepatic cholangiocarcinoma (ICC) is a major contributor to cancer-related mortality on a global scale, yet it suffers from a lack of reliable early diagnostic biomarkers and effective therapeutic targets. Pemigatinib has been identified as a therapeutic option for advanced ICC; however, its long-term clinical efficacy is significantly hindered by the development of drug resistance. **Methods:** Pemigatinib resistant ICC cells were established by culturing with increasing drug treatment. 98 pairs of ICC tissue samples were collected and analyzed to assess the association between β-arrestin 2 (ARRB2) and ICC progression. The role and mechanism of ARRB2 in the malignant progression of ICC and resistance to pemigatinib were explored *in vitro* and *in vivo* experiments. **Results:** ARRB2 expression is markedly upregulated in pemigatinib-resistant ICC cells compared to their parental counterparts. Suppression of ARRB2 expression markedly attenuated ICC chemoresistance to pemigatinib. Clinical data further verified that ARRB2 is correlated with poorer pathological classification and prognosis in ICC patients. Mechanistic studies revealed that ARRB2

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

activation in ICC is mediated by METTL3-dependent m6A methylation. Functional analyses demonstrated that ARRB2 promotes the malignant progression of ICC by facilitating YAP1 nuclear translocation while also modulates the sensitivity of ICC to pemigatinib through the Raf-MEK-ERK signaling axis. **Conclusion:** This study identifies the tumor-suppressing activities of ABBR2 and elucidates the regulatory mechanism of the METTL3-ARRB2-YAP1/Raf axis in ICC, which may provide novel prognostic biomarker and potential therapeutic target for human ICC.

3246 | INTRATUMORAL FIBROSIS AND AGGRESSIVE FEATURES IN TREATMENT-NAÏVE ADVANCED HEPATOCELLULAR CARCINOMA

Makoto Fujiya[1] Sadahisa Ogasawara[1] Haruka Anzai[1] Kazuo Tsubura[1] Taro Watabe[1] Midori Sawada[1] Takahiro Tsuchiya[1] Ryohei Yoshino[1] Teppei Akatsuka[1] Ryo Izai[1] Keiichi Katayama[1] Chihiro Miwa[1] Takuya Yonemoto[1] Sae Yumita[1] Kanzaki Hiroaki[1] Keisuke Koroki[1] Masanori Inoue[1] Masato Nakamura[1] Naoya Kanogawa[1] Shingo Nakamoto[1] Jun Kato[1] Mina Komuta[2], [1]Department of Gastroenterology, Graduate School of Medicine, Chiba University, [2]Department of Pathology, International University of Health and Welfare, School of Medicine

Background: Hepatocellular carcinoma (HCC) undergoes continuous morphological transformation during progression. While early-stage, resectable HCC is well characterized, the histology of advanced HCC remains poorly defined. Intratumoral fibrosis is common in advanced cases, but its timing and associations with tumor size, vascular invasion, metastasis, and histological subtypes such as macrotrabecular-massive (MTM) and vessels encapsulating tumor clusters (VETC), which are linked to poor prognosis in early-stage disease, remain unclear. We previously found that spatial patterns of $CD8^+$ T cells, such as parenchymal localization and diffuse distribution, were associated with response to immune checkpoint inhibitors in advanced HCC. This study aimed to clarify when and how intratumoral fibrosis and immune architecture develop in advanced HCC and how they relate to histological subtypes and clinical features. **Methods:** We analyzed 104 biopsy-confirmed, treatment-naive advanced HCC cases ineligible for locoregional therapy. MTM, VETC, and fibrosis were assessed and correlated with imaging-based necrosis, tumor size, MVI, and EHM. **Results:** All patients had intrahepatic lesions confirmed by imaging and biopsy. MVI and EHM were present in 47.1% and 29.8% of cases, respectively; 38.5% had neither. Histologically, 26.9% of tumors were moderately and 64.4% poorly differentiated. Intratumoral fibrosis was seen in 62.5%, more frequent than in early-stage HCC. It was also found in 65.0% of patients without MVI or EHM, showed no association with tumor size, and occurred independently of MTM or VETC. Among 51 patients evaluated for immune features, $CD8^+$ T cells localized mainly within the parenchyma in 78.0%, with diffuse distribution in 58.0%. These patterns were unrelated to MTM/VETC, tumor size, or MVI/EHM, suggesting early establishment. MTM was identified in 50.0%, significantly associated with necrosis ($p < 0.05$) and showed a trend with larger size ($p = 0.078$). VETC was found in 29.9% and showed a non-significant trend toward necrosis ($p = 0.096$). Neither correlated with MVI or EHM, indicating a localized histological role. **Conclusion:** Intratumoral fibrosis and $CD8^+$ T-cell spatial patterns appear to emerge before established morphological and clinical features of tumor progression. MTM and VETC were linked to necrosis and tumor size but not to dissemination. Fibrosis and immune architecture may represent preceding histological changes and warrant further investigation.

3247 | CHEMOPREVENTIVE EFFECT OF FIBRATE AS AN ADD-ON TO STATIN ON THE RISK OF HEPATOCELLULAR CARCINOMA: A NATIONWIDE-POPULATION BASED STUDY

Won Sohn[1] Hyun Woo Oh[2] Cheol-Young Park[2] Kyoung A Ko[3], [1]Kangbuk Samsung Hospital, Sungkyunkwan University School of, [2]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, [3]Kangbuk Samsung Hospital

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: This study aimed to investigate the chemopreventive effects of fibrates as an add-on to statins on the risk of hepatocellular carcinoma (HCC). **Methods:** This population-based cohort study was conducted from the Korean National Health Insurance Service from 2010 to 2019 in Korea. We compared the incidence of HCC between the users of statin and those with fibrate and statin for dyslipidemia, matched using age, sex, and hypertriglyceridemia. **Results:** We analyzed 789,958 individuals, including 394,979 statin users and 394,979 matched fibrate-statin users. During the 1,644,037.6 person-years of follow-up, 791 HCC cases were observed in the statin group, whereas 703 HCC cases were observed in the fibrate-statin group during 1,646,939.6 person-years of follow-up. The HCC incidence rates per 1,000 person-years were 0.48 and 0.43 in the statin and fibrate-statin groups, respectively. The risk of HCC development was lower in the fibrate-statin group compared to the statin group in the unadjusted and adjusted models (hazard ratio [HR] 0.89 with 95% confidence interval [CI]: 0.80–0.98 and adjusted HR [aHR] 0.74 with 95% CI: 0.67–0.83). The chemopreventive effects of fibrate-statin on HCC development increased as the duration of fibrate administration lengthened (aHR 0.76 with 95% CI: 0.68–0.86 in statin and fibrate use for <1 year; and aHR 0.71 with 95% CI: 0.61–0.82 for >1 year). **Conclusion:** The fibrate as an add-on to statin was associated with a reduced risk of HCC compared to statin. The findings of this study may suggest the chemopreventive role of fibrate on HCC.

3248 | EFFICACY OF SYSTEMIC THERAPY FOR PATIENTS WITH INFILTRATIVE TYPE UNRESECTABLE HEPATOCELLULAR CARCINOM

Ming Chieh Hsieh[1] Yi-Hsiang Huang[2], [1]Taipei Veterans General Hospital, Taipei, Taiwan, [2]Taipei Veterans General Hospital

Background: Infiltrative hepatocellular carcinoma (HCC) is a radiologically aggressive subtype frequently associated with vascular invasion and poor prognosis. However, data on its efficacy on treatment outcomes with contemporary first-line systemic therapies, including Lenvatinib and immunotherapy-based regimens, remain unclear. This study aimed to compare clinical characteristics, treatment response, and survival outcomes between infiltrative and non-infiltrative HCC. **Methods:** We retrospectively analyzed 270 patients with unresectable HCC who received first-line systemic therapy (Lenvatinib: $n=103$; immunotherapy: $n=167$) at Taipei Veterans General Hospital between May 2017 and October 2023. Infiltrative HCC was defined by radiologic pattern assessed by two radiologists. Baseline demographics, tumor burden, and liver function parameters were recorded. Treatment response was evaluated using RECIST 1.1 criteria. Multivariate Cox regression analyses were performed to identify factors associated with progression-free survival (PFS) and overall survival (OS). **Results:** Among the 270 patients, 39 (14.4%) had infiltrative HCC. These patients showed significantly higher rates of portal vein invasion (Lenvatinib: 76.9%; Immunotherapy: 92.3%) compared to non-infiltrative HCC (47.8% and 49.6%, respectively; $p<0.001$). Infiltrative HCC was also associated with poorer ALBI grades, elevated ALT levels, and more advanced tumor burden (Up-to-11 criteria). Although the treatment results show that the objective response rate (ORR) of infiltrative HCC is lower than that of non-infiltrative HCC (17.9% vs. 29.9%, $p=0.126$), the disease control rates (DCR) were similar (58.9% vs. 67.1%, $p=0.322$). Infiltrative HCC was associated with significantly shorter median OS (10.9 vs. 24.1 months, $p=0.04$). In the subgroup of infiltrative HCC, no significant difference in survival was observed between patients receiving Lenvatinib versus immunotherapy (median OS: 6.1 vs. 10.8 months, $p=0.492$; median PFS: 5.0 vs. 8.3 months, $p=0.827$). Independent predictors of OS included ALBI grade 2–3 (HR: 1.822), elevated AST (HR: 2.202), and viral etiology (HR: 0.588, protective). Independent factors associated with shorter PFS included ALBI grade 2–3 (HR: 1.551), AFP >100 ng/mL (HR: 1.338), and BMI >27.5 kg/m² (HR: 0.657, protective). **Conclusion:** Infiltrative HCC responds similarly to systemic treatment with lenvatinib or immunotherapy but has poorer survival than non-infiltrative HCC. Lenvatinib or immunotherapy did not result in significant differences in OS or PFS in infiltrative HCC.

Takuma Nakatsuka[1] Tatsuya Minami[1] Masaya Sato[1] Yotaro Kudo[1] Yoshinari Asaoka[2] Mitsuhiro Fujishiro[1] Yuichiro Eguchi[3] Kiyoshi Hasegawa[1] Masayuki Kurosaki[4] Hitoshi Yoshiji[5] Tatsuya Kanto[6] Masatoshi Kudo[7] Norihiro Kokudo[2] Kazuhiko Koike[8], [1]The University of Tokyo, [2]Japan Institute for Health Security, [3]Saga University, [4]Musashino Red Cross Hospital, [5]Nara Medical University, [6]National Center for Global Health and Medicine, [7]Kindai University Faculty of Medicine, [8]Kanto Central Hospital

Background: Chronic viral hepatitis is considered a risk factor for intrahepatic cholangiocarcinoma (ICC), but its impact on prognosis remains controversial. **Methods:** Patients initially diagnosed with ICC between 2018 and 2023 were enrolled from a nationwide registry in Japan. Patients were classified as HBV-related, HCV-related, or non-B, non-C based on the presence of hepatitis B surface antigen or hepatitis C antibody. The primary endpoint was overall survival. Inverse probability of treatment weighting (IPTW) was applied to generate adjusted Kaplan–Meier survival curves. **Results:** Among 1,906 eligible patients (62.7% male), 99 (5.2%), 147 (7.7%), and 1,584 (83.1%) were classified as HBV-related, HCV-related, or non-B, non-C, respectively. Patients with HBV were younger with median age of 73.0 years (interquartile range [IQR], 61.0–73.0) in HBV, than HCV (74.0 years [68.0–79.0]) in HCV and non-B, non-C (73.0 years [67.0–79.0]) in non-B, non-C). A solitary tumor was more frequently observed in HCV patients (80.3%) compared to HBV (73.7%) and non-B, non-C (74.5%). Tumor size was significantly smaller in HCV cases (median 3.50 cm [2.50–5.00]) than in HBV (4.30 cm [3.00–6.00]) and non-B, non-C (4.30 cm [2.95–6.60]). Bile duct invasion was more common in the non-B, non-C group (34.1%) than in HBV (18.2%) and HCV (25.9%). Distant metastases were less frequent in HCV patients (23.8%) than in HBV (26.3%) and non-B, non-C (27.0%). The distribution of Child–Pugh class was similar across all etiologies (Child–Pugh A: 77.6% in HBV, 73.7% in HCV, and 74.0% in non-B, non-C). Surgical resection was performed at comparable rates (61.6% for HBV, 61.2% for HCV, and 59.1% for non-B, non-C). The overall median survival time was 13.0 months (IQR: 4.8–26.5). Unadjusted survival curves did not significantly differ by etiology ($p = 0.11$ for HBV vs. non-B, non-C; $p = 0.74$ for HCV vs. non-B, non-C). IPTW-adjusted analyses confirmed no significant difference in overall survival ($p = 0.90$ for HBV vs. non-B, non-C; $p = 0.30$ for HCV vs. non-B, non-C). **Conclusion:** Although HBV patients tended to be younger and HCV patients were more likely to be diagnosed at earlier stages due to surveillance, the prognosis of ICC patients was similar across etiologies after adjusting for confounding factors including tumor stage and liver function.

3250 | PREDICTING AND MANAGING HEPATOCELLULAR CARCINOMA RECURRENCE AFTER LIVER TRANSPLANT: A SINGLE CENTER EXPERIENCE 2012-2024

Jesse Civan[1] Madison Force[1] Adam Bodzin[1] Daniel Lin[1], [1]Thomas Jefferson University Hospital

Background: Although orthotopic liver transplantation (OLT) is a curative option for selected patients with hepatocellular carcinoma (HCC), post-transplant recurrence can occur. Despite advances in therapy for HCC, management of post-transplant recurrence remains challenging. **Methods:** This single-center retrospective study included all patients undergoing OLT at our center from 1/1/12 to 12/31/24. Clinical data were manually extracted. Patients transplanted for HCC underwent a 5-year protocol of surveillance for recurrence, with mean radiographic follow-up of 40 months. Explant pathology, as well as other clinical data, was reviewed and RETREAT scores were calculated. Statistical analyses were performed using IBM SPSS Version 29. Survival analysis was conducted by Meier-Kaplan log-rank method. **Results:** A total of 923 patients underwent OLT with mean follow-up of 58 months. Of these, 329 (35.6%) underwent OLT for HCC. Overall survival (OS) was similar for patients with HCC (89% 1-year, 82% 3-year) compared to those without HCC (87% 1-year, 82% 3-year). Post-OLT HCC recurred in 36 patients (11%). Mean time from transplant to recurrence was 22 months (range 0 to 55 months). Sites of recurrence were liver (22%), lung (17%), bone (11%), other abdominal/pelvic site (25%), or multiple (25%). Post-OLT OS was worse for patients with recurrence (1-year 78%, 3-year 29%) compared with those without recurrence (1-year 94%, 3-year 89%). Recurrence was more likely in patients with viable tumor beyond Milan on explant, microvascular invasion on explant, and with higher RETREAT scores. Treatment of post-OLT recurrence included sorafenib (36%), lenvatinib (33%), cabozantinib (17%), cytotoxic chemotherapy (8%), locoregional therapy (33%), surgery (14%), and external radiation (47%), with some patients undergoing multiple modalities of treatment. For those with post-OLT HCC recurrence, median survival from transplant was 46 months, and median survival time from diagnosis of recurrence was 9 months. **Conclusion:** In our dataset post-OLT HCC recurrence rate was 11%. Our experience validates previously reported risk factors for post-OLT recurrence including viable tumor beyond Milan Criteria, presence of microvascular invasion, and RETREAT score. However, fully a third of patients who recurred post-OLT were “low risk” by these criteria. Further investigation is needed to identify other criteria to guide post-OLT surveillance.

RETREAT Score	Patients without Recurrence N = 290	Patients with Recurrence N = 36
0	110 (37.8%)	6 (16.7%)
1	114 (39.3%)	6 (16.7%)
2	38 (13.1%)	10 (27.8%)
3	18 (6.2%)	4 (11.1%)
4	4 (1.4%)	3 (8.3%)
5	4 (1.4%)	7 (19.4%)
6	2 (0.7%)	0 (0%)

3251 | INCIDENCE AND SURVIVAL OUTCOMES OF LIVER CANCER: ANALYSIS OF THE SEER DATABASE

Chawin Lopimpisuth[1] Pojsakorn Danpanichkul[2] Amit Singal[3] Ju Dong Yang[4], [1]University of Miami/Jackson Health System, [2]Texas Tech University Health Sciences Center, [3]UT Southwestern Medical Center, [4]Cedars-Sinai Medical Center

Background: The global incidence of adult primary liver cancer is declining, although recent GBD study showed continued increases in North America. We aim to investigate trends, clinical features, and survival outcomes of hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (iCCA). **Methods:** The National Cancer Institute Surveillance Epidemiology and End Results (SEER) Program, including the SEER-21 and SEER-17 registries, was used to extract data on adult (aged 20 years or older) patients with HCC and iCCA. Using the SEER-21 registry, we calculated age-standardized incidence rates (ASIRs), age-standardized mortality rates (ASMRs), and annual percentage changes (APCs) from 2004 to 2022 with SEER*Stat and Joinpoint. Using the SEER-17 registry, we compared demographic and clinical features between patients with HCC and iCCA. We calculated overall survival (OS) using Stata. Multivariable Cox proportional hazard regression models were performed to examine differences in OS between the two groups. **Results:** Of 269,835 adult patients in SEER-21, there

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

were 232,212 HCCs and 37,623 iCCAs. In 2022, HCC had higher ASIR (9.7 vs. 2.7 per 100,000 population) and ASMR (6.3 vs. 2.8 per 100,000 population) than iCCA. From 2004 to 2022, ASIRs increased for HCC (APC: 0.58, 95%CI 0.27 – 0.92) and iCCA (APC: 6.65, 95%CI 6.34 – 7.14); however, we noted variation over the study period. Between 2015-2022, there were declines in ASIR (APC: -2.53, 95%CI -3.22 to -1.58) and ASMR (APC: -1.38, 95%CI -1.68 to -1.20). for HCC. Conversely over this same period, continued increases were noted for ASIR (APC: 5.36, 95% CI 4.64 – 5.96) and ASMR (APC: 2.72, 95%CI 1.88 – 3.36) for iCCA. Of 114,281 patients in SEER-17, 99,898 had HCC and 14,383 had iCCA. Median (IQR) age was 65 (58–73) years, 72.3% were men, and 51.2% were White. The baseline characteristics of the HCC and iCCA groups are compared in Table 1. Median overall survival in patients with HCC and iCCA was 13 vs. 8 months, with 1-, 3-, and 5-year OS survival rates of 54.9%, 31.2%, and 22.1%, vs. 43.2%, 17.3%, and 11.0%, respectively. In multivariable analysis, survival was higher in patients with HCC than those with iCCA (adjusted HR = 0.82, 95%CI 0.79 – 0.84). **Conclusion:** In this large cohort study, the ASIR and ASMR of adult primary liver cancer increased over the last 2 decades, with a recent decline noted for HCC but not for iCCA. Patients with HCC were more likely to be younger, male, Black/Asian/Pacific Islander, not married, and have a lower median household income compared to patients with iCCA. Although HCC continues to have higher incidence and mortality rates, iCCA is associated with worse overall survival.

Variables	HCC (n = 99,898)	CCA (n = 14,383)	P value
Age, median, IQR	64 (58 – 72)	68 (59 – 76)	<0.001
