Background: Patients with diabetes mellitus (DM) are at an increased risk of developing cardiovascular disease (CVD). Hepatic steatosis is common among patients with DM, but its impact on CVD risk remains unclear. This study aimed to prospectively assess the association between a reduction in hepatic steatosis and a lower risk of CVD in patients with DM. **Methods:** A total of 323 patients with DM were prospectively enrolled from January 2022, after excluding those with viral hepatitis, overt cirrhosis, and cancer. The following parameters and data were assessed: body weight (BW), body mass index (BMI), waist circumference (WC), laboratory data, presence of hypertension (HTN), dyslipidemia, alcohol consumption, smoking status, liver stiffness measurement (LSM), current anti-DM medications, and CVD events. Hepatic steatosis was quantified using the controlled attenuation parameter (CAP) measured by FibroScan® at baseline and after 2 years. CVD was defined as ischemic heart disease or ischemic/hemorrhagic stroke. **Results:** A total of 277 patients completed 2-year follow-up and underwent repeat CAP assessment. The mean age was 57 ± 12 years, and 56.3% were male. The baseline mean CAP was 274 ± 18 dB/m. A history of CVD was present in 86 (31%) patients, while 6 (3.2%) developed new CVD events during follow-up. CAP scores decreased in 176 patients (d-CAP group) and increased in 101 patients (i-CAP group). The mean CAP change was -33 ± 29 dB/m in the d-CAP group and $+24 \pm 18$ dB/m in the i-CAP group. Patients in the d-CAP group were older (58 ± 12 vs. 55 ± 12 years, $p = 0.012$) and had higher baseline CAP (284 ± 50 vs. 255 ± 47 dB/m, $p < 0.001$) than those in the i-CAP group. There were no significant differences in male proportion, BW, BMI, WC, laboratory data, HTN, dyslipidemia, alcohol consumption, smoking status, or baseline LSM between the two groups. The insulin use was lower in the d-CAP group than in the i-CAP group (5.1% vs. 12.9%, $p = 0.022$). When stratified by CAP change, the incidence of new CVD was 0% (0/55) in patients with CAP reduction of $\leq$-40 dB/m, 2% (4/201) in those with changes between -40 and +40 dB/m, and 9.5% (2/21) in those with CAP increases of $\geq$+40 dB/m ($p = 0.037$). **Conclusion:** A marked decrease in CAP score was associated with a lower risk of CVD in patients with DM. Therefore, CAP monitoring may be a valuable tool for assessing CVD risk. Efforts to reduce hepatic steatosis, as reflected by CAP reduction, may contribute to CVD prevention in this population.

Abdelmalek[7] Anna Mae Diehl[3], [1]University of California, San Diego, [2]Hepta Bio, Inc., [3]Duke University, [4]Saarland University Medical Center, [5]Akero Therapeutics, Inc, [6]Saint Louis University, [7]Mayo Clinic Rochester

Background: MASH presents diagnostic challenges due to the invasive nature of liver biopsy. Cell-free DNA (cfDNA) methylation profiling offers a non-invasive alternative, capturing epigenetic alterations associated with disease progression. Intersection of genomics and built-for-purpose AI could enhance diagnostic accuracy and provide insights into underlying biological mechanisms. **Methods:** This international multi-cohort study includes 528 biopsy-confirmed MASLD patients (Control = 59, F0 = 88, F1 = 113, F2 = 106, F3 = 101, F4 = 61) from 3 independent cohorts across US and Europe: (1) Akero Therapeutics's SYNCHRONY Phase 3 program (n = 179), (2) Duke MASLD biobank (n = 276), (3) University Medical Center Mainz biobank (n = 73). Plasma samples were collected at baseline. Deep methylation sequencing of cfDNA was performed generating 33 terabytes of genomic data. We have developed a proprietary liquid biopsy-native AI platform which, using a 20,000 core dynamic compute cluster, enables the training of the model required to capture the molecular-level complexity across hundreds of millions of unique cfDNA molecules per sample. The negative binomial deep neural network model, with 89 million parameters, is trained to detect "at-risk MASH" (i.e. NAS $\geq$ 4 with F $\geq$ 2) and the 5-fold cross-validated performance is reported. Additionally, methylation signatures contributing to the classification algorithm were identified and subjected to pathway enrichment analysis to assess biological plausibility. **Results:** The AI model identified methylation signatures correlating with disease severity with AUC of 0.81 for detecting "at-risk MASH" compared to 0.70 for Fib-4 ($p < 0.01$). ELF score was available on a subset of Akero subjects (n = 172), on which our model had an AUC of 0.80 compared to ELF's AUC of 0.71 ($p < 0.01$). There was no significant difference in the model's performance across cohorts, demonstrating robustness and generalizability. Pathway analysis performed on the genomic features driving classification revealed enrichment in a substantial number of metabolic, fibrosis, and inflammation regulation pathways which align with known MASH pathophysiology and demonstrate the model's biological plausibility. **Conclusion:** By combining state-of-the-art AI with deep methylation profiling we have created and validated a powerful technology to study disease epigenetics, identify relevant methylation signatures, and diagnose "at-risk MASH". This innovative approach for blood-based biomarker provides mechanistic insights into disease pathobiology through pathway analysis and offers a novel promising direction for early detection of MASH and fibrosis, disease monitoring, risk stratification, with potential application in therapy selection based on the mechanistic characterization.

◆ 2006 | VALIDATION OF NEW CLINICAL OBESITY CRITERIA FOR STEATOTIC LIVER DISEASE IN THE UNITED STATES

Luis Antonio Diaz[1] Nikhil Kalita[2] Federica Tavaglione[2] Patrick Corr[3] Chinar Sheth[2] Darryl Contrano[2] Veeral Ajmera[2] Rohit Loomba[2], [1]Pontificia Universidad Católica de Chile, [2]University of California San Diego, [3]Integrative Medicine, George Washington University School of Medicine & Health Sciences

Background: Obesity is highly prevalent in the United States and constitutes a leading cause of steatotic liver disease (SLD). However, the optimal anthropometric measures for identifying patients at risk of liver fibrosis remain uncertain. We aimed to compare body mass index (BMI) and waist circumference (WC) classifications in their association with liver fibrosis stages, applying the new 2025 clinical obesity definition. **Methods:** We performed a cross-sectional analysis of adult participants from the 2017–2023 NHANES cycles who underwent vibration-controlled transient elastography (VCTE). We included participants aged ≥12 years and excluded those with chronic hepatitis B or C infection. WC was classified both by standard (SWC) and metabolic-dysfunction–specific thresholds (MWC). Steatosis was defined by a CAP ≥288 dB/m, and significant fibrosis was defined by liver stiffness measurement ≥7.6 kPa. MASLD was diagnosed according to the 2023 criteria. We used multinomial logistic regression, adjusted for age, sex, race/ethnicity, diabetes, hypertension, hyperlipidemia, and alcohol use to estimate odds ratios (OR) for significant fibrosis across BMI and WC categories. We also incorporated restricted cubic splines (three knots) to model non-linear effects. Subgroup analyses were performed for SLD subtypes. **Results:** We included 27,493 individuals. The prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) was 30.2%. The prevalence of significant fibrosis was 34.0% among individuals with BMI ≥35 kg/m², compared to 5.6% among those with BMI ≤25 kg/m². In adjusted models, participants with BMI ≥35 kg/m² had significantly higher odds of significant fibrosis compared to those with underweight/normal BMI (odds ratio [OR]: 8.29; 95%CI: 6.36–10.81). The very high SWC category (>110/120 cm for women/men) had an OR of 2.99 (95% CI: 2.19–4.09) for significant fibrosis compared to the very low SWC category (<70/80 cm for women/men), while the very high MWC category (>120/130 cm for women/men) had an OR of 13.09 (95%CI: 10.11–16.94) compared to the very low MWC reference (<90/100 cm for women/men). Adjusted non-linear models revealed an inflection point where significant fibrosis risk increases at BMI ≥28.4 kg/m² and WC ≥85 cm (Figure). Similar findings were observed when analyses were restricted to

individuals with MASLD. **Conclusion:** Central adiposity measured by WC thresholds enhances identification of fibrosis risk beyond BMI alone. Routine incorporation of WC into screening algorithms may optimize early detection and referral for fibrosis assessment in clinical practice.

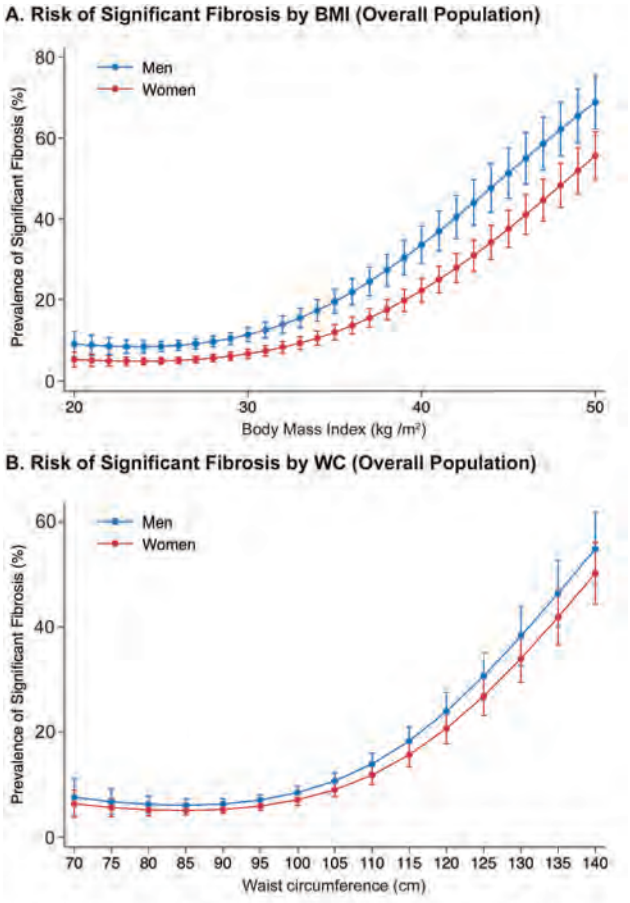

Figure. Nonlinear adjusted models to assess the prevalence of significant fibrosis (liver stiffness ≥7.6 kPa on vibration-controlled transient elastography) according to body mass index (BMI) and waist circumference (WC). Models were adjusted by age, sex, race/ethnicity, diabetes, hypertension, hyperlipidemia, and alcohol use.

◆ 2007 | PATIENTS WITH MASLD DECOMPENSATE AT A LOWER HEPATIC VENOUS PRESSURE GRADIENT THRESHOLD: DATA FROM A MULTICENTRIC RETROSPECTIVE COHORT STUDY

Xiao Yu Xie[1] Myriam Martel[2] Yu Jun Wong[3] Ikram Abow-Mohamed[2] Julien Bissonnette[4] Puneeta Tandon[5] Amine Benmassaoud[2], [1]Université de Montréal, [2]Division of Gastroenterology and Hepatology, Department of Medicine, McGill University Health Centre, [3]Division of Gastroenterology and Hepatology, Department of Medicine, University of Alberta, Edmonton, [4]University of Montreal Hospital Center, [5]University of Alberta

Background: Hepatic venous pressure gradient (HVPG) is the gold standard to predict hepatic decompensation in patients with advanced chronic liver disease (ACLD). However, the ability of clinically significant portal hypertension (CSPH) defined as HVPG ≥ 10 mmHg to predict decompensation in metabolic dysfunction-associated steatotic liver disease (MASLD) patients requires further validation. This study aimed to identify specific HVPG cutoffs to predict hepatic decompensation and liver-related events in MASLD patients. **Methods:** This is a retrospective cohort study from 3 Canadian tertiary centers including patients ≥18 years old with ACLD and portal hypertension diagnosed by HVPG ≥5 mmHg. Patients were identified through a prospective HVPG database from 2013 to 2024. Patients with non-cirrhotic portal hypertension, HVPG measured during acute hepatitis or acute-on-chronic liver failure, prior TIPS or liver transplant before HVPG measurement were excluded. We assessed the discriminatory abilities of HVPG to predict hepatic decompensation and liver-related events using the area under the receiver operating characteristic curve (AUROC) reporting with 95% confidence interval (CI). Cutoff values were derived based on Youden's Index. Hepatic decompensation is defined as new or worsening ascites, hepatic encephalopathy or variceal bleeding and liver-related events are defined as hepatic decompensation, liver transplant or death. **Results:** 409 patients with ACLD were included: 166 (40.6%) were women, mean age was 56.9 ± 13.2 years, mean HVPG was 13.1 ± 5.9 mm Hg, mean MELD Na score was 14.9 ± 8.0, 129 (31.5%) were MASLD patients. 149 (36.4%) patients had new hepatic decompensation, and 225 (55.0%) patients had new liver-related events. The HVPG thresholds to predict new hepatic decompensation in all patients and in MASLD patients were 11.0 mm Hg (AUROC = 0.62 (95%CI 0.56; 0.67)) and 5.9 mm Hg (AUROC = 0.67 (95%CI 0.58; 0.76)), respectively, both with a weak discriminatory ability. The HVPG thresholds to predict new liver-related events in all patients and in MASLD were 11.0 mm Hg with a weak discriminatory ability (AUROC = 0.69 (95%CI 0.64; 0.74)) and 8.5 mmHg with a fair discriminatory ability (AUROC = 0.73 (95%CI 0.65; 0.82)), respectively. **Conclusion:** HVPG demonstrated weak discriminatory ability to predict new hepatic decompensation and fair discriminatory ability to predict liver-related events in MASLD patients. Our

◆ 2008 | HIGH-RESOLUTION COLLAGEN PROFILING REVEALS STAGE-SPECIFIC FIBROSIS PATTERNS IN PEDIATRIC MASLD USING DIGITAL PATHOLOGY AND UMAP

Li Chen Adi Lightstone[1] Mathieu Petitjean[1] Karenina Valdez[2] Cynthia Behling[2] Jeffrey Schwimmer[2], [1]Pharmanest, [2]University of California

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD) is the most common cause of chronic liver disease in children. Despite its rising prevalence and characteristic zone 1–predominant steatosis and fibrosis, conventional histology lacks the resolution to assess fiber-level phenotypes or architectural complexity. To overcome this limitation, we applied FibroNest™, a high-resolution digital pathology platform, to quantify single-fiber collagen remodeling across fibrosis stages (NAS F0–F4) in pediatric MASLD liver biopsies. **Methods:** Liver biopsies from 67 pediatric MASLD patients (F0: 10, F1a: 9, F1b: 6, F1c: 23, F2: 8, F3: 8, F4: 3) were analyzed using FibroNest to quantify collagen quantity, fiber morphometry, and architectural complexity. Collagen fibers were segmented and profiled across three representative domains, selected from over 300 quantifiable fibrosis traits: Fiber Density (collagen quantity), Fiber Class (Fine vs Assembled reticulated collagen, and MFI (measures fiber structural maturity). Dimensionality reduction using Uniform Manifold Approximation and Projection (UMAP) enabled spatial visualization of collagen phenotypes across fibrosis stages. **Results:** UMAP analysis revealed distinct collagen phenotypes across fibrosis stages in pediatric MASLD, showing a clear progression from sparse, fine fibers in F0 to dense, mature, and complex structures in F3–F4. Within early-stage F1, subclassification revealed a gradient: F1a showed low fiber density and complexity; F1b had increased density and maturation; and F1c, with the highest collagen content and MFI, resembled F2, suggesting a transitional fibrotic state. Density UMAPs highlighted dispersed fibers in F0–F1 and dense, aggregated septa-like patterns in F2–F4. MFI increased with stage, with F3–F4 forming bright, compact clusters indicative of mature collagen. Fiber Class UMAPs showed a shift from fine collagen in early stages to assembled collagen in F2–F4, capturing architectural progression and dynamic collagen remodeling not apparent in conventional histology. **Conclusion:** FibroNest enables high-resolution, spatially resolved profiling of fibrosis in pediatric MASLD. UMAP visualization uncovered stage-specific collagen patterns and fibrosis progression. These findings support digital fiber phenotyping as a promising tool for improved disease staging and therapeutic monitoring in children with MASLD.

◆ 2009 | DIFFERENT LIPIDOMIC SIGNATURE IN EXTRACELLULAR VESICLES IN PATIENTS WITH MASLD-HCC: ANALYSIS OF DIFFERENT STAGES OF MASLD

Mario Alvares-da-Silva[1] Melina Keingeski[1] Bruno Basso[1] Larisse Longo[1] José Tadeu Stéfano[2] Claudia Oliveira[2] Juan Pablo Arab[3] Carolina Uribe-Cruz[4], [1]Universidade Federal do Rio Grande do Sul, [2]Universidade de São Paulo, [3]Virginia Commonwealth University, [4]Facultad Católica de Misiones

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) ranges from isolated steatosis (STE) to steatohepatitis (MASH), cirrhosis (CIR) and hepatocellular carcinoma (HCC). Non-invasive markers have limited ability to identify different stages. Extracellular vesicles (EVs) are essential for cellular communication and could be useful as a liquid biopsy tool. This study aims to evaluate the lipid signature of EVs and their usefulness in disease progression. **Methods:** EVs were isolated using silica columns from serum of patients with different MASLD stages: STE (n = 25), MASH without fibrosis (MASH; n = 25), CIR (n = 25) and HCC (n = 18), and compared to controls (CON; n = 25). EVs were characterized by nanoparticle tracking analysis flow cytometry, and Western-Blot. Lipidomics was performed by mass spectrometric analysis of sphingolipids (Cer-20, Cer-22, Cer24-0, Cer24-0, S1P-d18-1, S-d18-1, C16-SM, C17-SM, C18-SM, C20-SM, C22-SM, C261-SM and C24DHC), oxysterols (7aHC, 7KC, 56a-EHC and CH) and bile acids (TaMCA, TbMCA, GbMCA, TCA, GCA, TCDCA, TDCA, CA, GDCA, TLCA, GLCA, LCA and CDCA-3-S). **Results:** Figure 1 shows a heatmap of lipid profiles across the groups. C24DHC was lower in all disease groups vs CON, suggesting early alterations in membrane lipid homeostasis during MASLD. C18-SM, C20-SM, C22-SM and Cer24-0 decreased in CIR and HCC vs CON, STE, and MASH, indicating progressive disruption of sphingolipid metabolism with disease

progression. C17-SM and C261-SM were significantly reduced in HCC vs CON, reflecting extensive lipid remodeling in late-stage disease. 7KC levels were significantly increased in HCC vs CON, STE, MASH, and CIR, consistent with enhanced oxidative stress specifically associated with advanced MASLD and hepatocarcinogenesis. Bile acids TCA and CA were higher in HCC vs other groups, pointing to dysregulation of bile acid pathways in late-stage disease. All differences, $p < 0.05$. **Conclusion:** The lipid composition of EVs may reflect key molecular changes during MASLD progression. The reduction of sphingolipids and accumulation of oxysterols and bile acids in advanced stages suggest disrupted lipid metabolism, oxidative stress, and hepatocellular dysfunction. These findings support the potential of EV lipidomics as a non-invasive tool for disease staging and mechanistic insight.

◆ 2010 | POPULATION SCREENING STRATEGIES FOR SIGNIFICANT FIBROSIS IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE IN THE ERA OF DISEASE-SPECIFIC THERAPY

Winston Dunn[1] Naim Alkhouri[2] Terry Cheuk-Fung Yip[3] Nipun Verma[4] Laurent Castera[5] Ming-Hua Zheng[6] Leon Adams[7] Manal Abdelmalek[8] Ajay Duseja[9] Vincent Chen[10] Grace Lai-Hung Wong[3] Syed-Mohammed Jafri[11] Juan Pablo Arab[12] Vincent Wong[3] Bihui Zhong[13] Ashwani Singal[14], [1]University of Kansas Medical Center, [2]Summit Clinical Research, [3]The Chinese University of Hong Kong, [4]Postgraduate Institute of Medical Education and Research, [5]Hopital Beaujon, [6]The First Affiliated Hospital of Wenzhou Medical University, [7]University of Western Australia, [8]Mayo Clinic Rochester, [9]Postgraduate Institute of Medical Education & Research, [10]University of Michigan Medical Center, [11]Henry Ford Health System, [12]Virginia Commonwealth University, [13]The First Affiliated Hospital, Sun Yat-sen University, [14]University of Louisville

Background: Current clinical practice often employs the Fibrosis-4 (FIB-4) score as an initial screening tool, which is effective in identifying individuals at risk for advanced fibrosis and related complications. However, in the MAESTRO-NASH trial, the median FIB-4 among patients with significant (F2) to advanced (F3) fibrosis was only 1.3. Applying this as a cutoff would exclude nearly half of potentially eligible patients from further vibration-controlled transient elastography (VCTE) evaluation and subsequent resmetirom treatment. In this study, we compared two novel screening strategies—the Steatosis-Associated Fibrosis Estimator (SAFE) score and the mAchine Learning ADvanceD fibrosis and at-risk MASH Novel predictor (ALADDIN)-F2-Lab—against the traditional FIB-4 approach. **Methods:** We analyzed data from the 2017–2020 National Health and Nutrition Examination Survey (NHANES), the only cycle with VCTE data currently available. We included adults ($\geq$18 years) with hepatic steatosis (controlled attenuation parameter $>$248 dB/m), $\geq$1 metabolic risk factor, and alcohol intake consistent with MASLD, excluding those with viral hepatitis. We compared the performance of FIB-4, SAFE score, and ALADDIN-F2-Lab in identifying individuals with liver stiffness measurement (LSM) $\geq$8 kPa, the AASLD-recommended threshold for resmetirom treatment. All analyses incorporated survey design weights, strata, and primary sampling units. **Results:** In NHANES 2017–2020, 4,092 participants—projecting to 114.4 million U.S. adults—met criteria for MASLD, of whom 15.3% had liver stiffness measurement (LSM) $\geq$8 kPa. Using the current guideline of FIB-4 $\geq$1.3 as the initial screen, 28.5 million individuals would undergo VCTE to identify 5.2 million with LSM $\geq$8 kPa. In comparison, the SAFE score–based approach would identify 7.8 million individuals with LSM $\geq$8 kPa—a 51% increase in case detection—while requiring 1.1 million fewer VCTEs (a 4% reduction). The ALADDIN-F2-Lab–based approach would identify 9.4 million with LSM $\geq$8 kPa—an 81% increase in case detection—at the cost of 3.2 million additional VCTEs (an 11% increase). See Figure. **Conclusion:** In the era of disease-specific therapy for MASH, accurate and efficient non-invasive screening is critical for identifying patients with significant fibrosis eligible for treatment. The SAFE score improves upon the current FIB-4–based strategy by increasing case detection while reducing the number of required VCTEs. The ALADDIN-F2-Lab model provides even greater gains in identifying at-risk individuals, with a modest increase in VCTE use. Integrating SAFE or ALADDIN-F2-Lab into clinical workflows may enhance patient selection and expand access to therapy.

Background: Purine metabolites such as ATP, adenosine, inosine are potent immune regulators. The conversion from adenosine to inosine in the extracellular space is catalyzed by adenosine deaminase 2 (ADA2), an ecto-enzyme secreted by monocytes and macrophages. ADA2 deficiency can cause autoimmunity and vasculitis. However, the function of ADA2 remains elusive. We have previously reported that ADA2 promotes fibrogenesis in metabolic dysfunction associated steatotic liver disease (MASLD) by modulating monocyte differentiation. This study aims to interrogate the biology of ADA2 in MASLD leveraging the Trans-Omics for Precision Medicine (TOPMed) multi-omics data in Multi-Ethnic Study of Atherosclerosis (MESA). **Methods:** A total of 427 MASLD patients were identified from MESA based on medical history and the liver-to-spleen density ratio on CT. Among these individuals, ADA2 activity and components of Extended Liver Fibrosis panel were measured in the serum. We analyzed O-link proteomics and LC-MS metabolomics data of 320 MASLD patients and 2020 individuals without MASLD. Proteomics findings were further cross-examined in 110 individuals with RNA sequencing data of PBMC (n = 103), T cell (n = 40), and monocyte (n = 42). **Results:** ADA2 activity in the serum was significantly associated with ELF score ($r = 0.484$; $p < 0.0001$) in patients with MASLD. MASLD patients with high ADA2 activity (1 SD above mean) have elevated CXCL10, a monocyte specific chemokine, along with CXCL9 and CXCL11 in the serum. O-link proteomics analysis also revealed elevation of ADGRE1, CDCP1, LILRA6, CLEC6A, FCAR, and SIGLEC1, signatures of tissue-infiltrating proinflammatory monocytes-derived macrophages. Gene ontology pathway enrichment analysis indicated upregulation of leukocyte cell-cell adhesion, chemotaxis, and proliferation. These findings were supported by the upregulation of interferon (IFN)-induced genes (IFI27, IFIT3, IFI6, IGLV7-46), and cell migration regulators (CXCL10, CCR9, ITGA1, MIF) in PBMC transcriptome. We then performed hypothesis-free clustering analysis of circulating purine metabolites and identified three profiles. Besides the majority with low purine metabolites, individuals with high purine metabolites demonstrate two profiles: Type 1 (elevation in ATP, ADP, AMP, adenosine) and Type 2 (elevation in inosine, hypoxanthine, xanthine), with main differences at the rate of adenosine deaminase activating, potentially catalyzed by ADA2. **Conclusion:** Integrated multi-omics analyses indicate a strong role of ADA2 in shaping circulating purine metabolite profiles. Elevated ADA2 activity is associated with proteomic and transcriptomic signatures of tissue infiltration of monocytes with proinflammatory differentiation.

◆ 2012 | WEIGHT LOSS-INDUCED METABOLIC REMODELING IN MASLD: A COHORT STUDY STRATIFIED BY POLYGENIC RISK

Torre Pietro[1] Jacopo Troisi[1] Luigi Schiavo[1] Benedetta Maria Motta[1] Martina Lombardi[1] Mariano Festa[1] Tommaso Sarcina[1] Mario Masarone[1] Marcello Persico[1], [1]University of Salerno, Italy

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the hepatic expression of systemic metabolic derangement, yet tools for tracking its regression remain limited. Metabolomics can provide dynamic biomarkers that reflect pathophysiological change. The objective of this study is to delineate serum metabolomic adaptations to a weight-loss-oriented Mediterranean diet in obese MASLD patients stratified by genetic risk. **Methods:** In a prospective cohort, 148 adults with ultrasound-confirmed MASLD started a personalized hypocaloric Mediterranean diet. Weight loss was classified as $< 5\%$, 5–10%, or $> 10\%$ of baseline. Single-nucleotide polymorphisms in PNPLA3, TM6SF2, MBOAT7 and GCKR were genotyped and combined into a weighted polygenic risk score. Untargeted gas chromatography–mass spectrometry profiled fasting serum samples at baseline and study end. Data were processed by partial least squares discriminant analysis, variable importance in projection scoring, and pathway enrichment. **Results:** Mean weight decreased by 8% and controlled attenuation parameter declined by 17%, with greatest steatosis reduction in PNPLA3 G-allele carriers. Metabolomic modelling achieved 92% classification accuracy and revealed fourteen key metabolites. Caproic acid, glycerol and hydroxypropanedioic acid increased consistently, whereas palmitic acid and D-galactose decreased. Enriched pathways included galactose, butanoate and glycerolipid metabolism. Metabolic shifts scaled with weight loss intensity and differed by genotype; high responders showed enhanced branched-chain amino acid catabolism. The figure shows a stratified metabolomic analysis by weight loss class after 6 months of dietary intervention; patients were divided into three groups based on the percentage

of body weight loss at 6 months: low (< 5%, panels A1–A3), mid (5–10%, panels B1–B3), and high (> 10%, panels C1–C3). **Conclusion:** Mediterranean diet-induced weight loss triggers rapid, weight-dependent and genotype-modulated metabolomic reprogramming that parallels hepatic fat clearance. Caproic acid, glycerol and hydroxypropanedioic acid constitute biomarkers and, combined with polygenic risk assessment, may support precision nutrition strategies for MASLD.

◆ 2013 | CURRENT CARE PATHWAY AND REFERRAL PATTERNS IDENTIFY GAPS IN SCREENING, DIAGNOSIS, AND TREATMENT OF MASLD/MASH IN AMBULATORY CARE SETTING

Rahul Sandella[1] Hee Yeon Kim[2] Andrew Davis[1] Mary Rinella[1], [1]The University of Chicago, [2]Bucheon St Mary's Hospital, The Catholic University of Korea

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is typically asymptomatic even with significant fibrosis, contributing to its under-diagnosis. Despite cross-society alignment in guidelines on the use of FIB-4 to screen at-risk populations, adherence to recommendations remains poor. We aimed to assess care patterns across FIB-4 risk strata in a large ambulatory cohort. **Methods:** We conducted a retrospective cohort study of patients aged 35-70 years seen between 2021 and 2025 across 35 ambulatory care clinics within a large academic health system. Data were extracted from the electronic health record using MDCLONE software. Patients with available ALT, AST, and platelet count were included. FIB-4 was calculated and categorized as low, intermediate, or high risk (table). We examined metabolic risk factors, liver biochemistries, medication use, hepatology referral, and visits across risk strata, using ANOVA and chi-squared testing. **Results:** Of 56,552 patients, 73% were low-risk, 20% intermediate-risk, and 7% high-risk according to FIB-4. Demographic and clinical characteristics differed significantly across FIB-4 strata (table). Use of GLP-1 receptor agonists was more common in low-risk patients, while SGLT-2 inhibitor use increased with fibrosis risk ($p < 0.001$ for both). Hepatology referral rates were low across groups, while actual hepatology visits were more frequent in high-risk patients ($p < 0.001$). High-risk patients were most likely to be referred, seen by hepatology, or undergo liver stiffness assessment when seen by gastroenterology (73%) or endocrinology (39%), and least likely when seen by cardiology, family medicine, or internal medicine (22-24%, $p < 0.001$). Among high-risk patients, Black patients were less likely to be referred or seen by hepatology compared to White patients ($p < 0.001$), and the presence of diabetes or obesity was not associated with higher referral rates. **Conclusion:** Despite 7% of patients meeting high-risk FIB-4 criteria, most were not referred to hepatology, while some low-risk patients were referred unnecessarily. Referral patterns varied significantly by provider specialty and patient demographics, suggesting potential disparities and inefficiencies in triage. System-level interventions are urgently needed to improve adherence to guidelines and ensure timely, risk-based, and equitable hepatology care to prevent major adverse liver outcomes in MASH patients.

Table. Patient characteristics and Hepatology referral across FIB-4 risk categories

Parameters (counts are n (%) or mean (SD))	FIB-4 Category			P-value
	Low-risk FIB-4 < 1.3 if < 65 y FIB-4 < 2.0 if ≥ 65 y N=41,525	Intermediate-risk FIB-4: 1.3 - 2.66 if < 65 y FIB-4: 2.0 - 2.66 if ≥ 65 y N=11,292	High-risk FIB-4 ≥ 2.67 N=3,735	
Female	25,056 (60%)	5,406 (48%)	1,551 (42%)	<0.001

◆ 2014 | MISSED OPPORTUNITIES FOR EARLY MASLD TREATMENT: TRENDS IN FIBROSIS BURDEN AND DISEASE AWARENESS IN THE U.S. POPULATION — RESULTS: FROM THE NATIONAL HEALTH AND NUTRITION EXAMINATION SURVEY 2017–2023

Jameel Alp[1] Giovanni Roldan[2] Jesse Fletcher[1] Amy Gravely[3] Lisa Smith[3] Pimsiri Sripongpun[4] Prowpanga Udompap[5], [1]Department of Medicine, University of Minnesota, Minneapolis, MN, [2]Division of Gastroenterology, Hepatology, and Nutrition, University of Minnesota, Minneapolis, MN, [3]Research Service, Minneapolis Veterans Affairs Health Care System, Minneapolis, MN, [4]Gastroenterology and Hepatology Unit, Prince Songkhla University, Hat Yai, Thailand, [5]Minneapolis VA Medical Center, Minneapolis, MN

Background: Metabolic dysfunction-associated liver disease (MASLD) has become a leading cause of chronic liver disease worldwide. MASLD patients with steatohepatitis (MASH)/moderate fibrosis (F2-F3) are eligible for resmetirom, the FDA-approved treatment for MASH that can potentially improve clinical outcomes. Yet, it remains challenging to capture MASLD population at-risk for disease progression and those eligible for resmetirom since majority of patients are asymptomatic, and the diagnosis required high index of suspicion from the providers. This study aims to evaluate temporal trends in the fibrosis burden as well as the awareness of their liver disease among U.S. adults with MASLD. **Methods:** Using the data from the National Health and Nutrition Examination Survey (NHANES) 2017-March 2020 (pre-pandemic) and August 2021-August 2023 (post-pandemic), adults aged ≥ 18 with valid vibration-controlled transient elastography and body mass index (BMI) were included. Hepatic steatosis (HS) was defined based on the controlled attenuation parameter ≥ 274 dB/m. Individuals with HS were categorized into MASLD, MASLD with increased alcohol intake (MetALD), or alcohol-associated liver disease (ALD) per current nomenclature. Liver fibrosis stage 2-3 (F2-F3) was defined by liver stiffness (LS) 8-15 kPa and compensated advanced chronic liver disease (cACLD) was defined by LS ≥ 15 kPa. **Results:** A total of 13,188 adults were included in the initial analysis which projected to a total of 219 million (M) Americans. Of these, 50.5M pre- and 30.4M post-pandemic had MASLD. 13.4% of MASLD participants in pre- and 15.7% in post-pandemic ($p = 0.15$) had LS of 8-15 kPa or F2-F3 fibrosis and deemed eligible for resmetirom. The prevalence of MASLD-related cACLD increased significantly from 3.7% pre- to 5.4% post-pandemic ($p = 0.02$). Interestingly, the awareness of liver disease remained low among all individuals with MASLD (6.3% pre- vs 6.7% post-pandemic ($p = 0.64$)). While the awareness of the liver disease among individuals with MASLD-related cACLD increased significantly from pre- (8.4%) to post-pandemic (20.4%), ($p = 0.02$), the awareness remained low among MASLD participants eligible for resmetirom (12.6% pre- vs 10.3% post-pandemic, ($p = 0.53$)). Factors associated with awareness included central obesity (OR 3.2; 95%CI [1.1, 9.9]), HTN (OR 1.5, 95%CI [1.1, 2.3]), diabetes (OR 1.7, 95%CI [1.1, 2.6]). **Conclusion:** The awareness of liver disease increased after the pandemic among MASLD individuals with cACLD; however, this group is already

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

at high risk for complications and is no longer eligible for resmetirom. Approximately 13-15% of the MASLD population are eligible for resmetirom but only 1 in 10 individuals in this group are aware of their condition. These findings highlight an urgent need to expand screening efforts, improve risk stratification strategy and access to elastography in order to identify eligible individuals for intervention earlier.

Table 1: Characteristics of U.S. adults with valid vibration-controlled transient elastography and BMI data in NHANES, pre- and post-pandemic

	Pre-pandemic (2017-March 2020)	Post-pandemic (August 2021-August 2023)	p-value
Study Participants			
Number of US residents age ≥18 with valid elastography, and available BMI (in millions, (SE))	133.2 (5.5)	85.8 (4.5)

◆ 2015 | GENETIC CORRELATION AND PHENOME-WIDE ASSOCIATION STUDIES PROVIDE INSIGHTS INTO THE METABOLIC FEATURES AND GENETIC SUBTYPES OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Ci Song[1] Wentao Yao[1], [1]Nanjing Medical University

Background: According to the latest diagnostic criteria, a diagnosis of metabolic dysfunction-associated steatotic liver disease (MASLD) requires individuals to exhibit hepatic steatosis alongside at least one cardiometabolic risk factor (CMRF). However, certain conventional metabolic factors, such as LDL cholesterol, are omitted from these criteria, and the relationship between the included factors and hepatic steatosis remains incompletely elucidated. **Methods:** We conducted a genome-wide association study (GWAS) meta-analysis of imaging-quantified hepatic fat content (HFC) in 34,309 Caucasian participants and 28,318 Han Chinese participants. Leveraging GWAS summary statistics from diverse sources, we estimated the genetic correlations between HFC and nine clinically relevant metabolic biomarkers, including those both within and outside the diagnostic criteria. Subsequently, using the colocalization probabilities from significant loci between HFC and each metabolic biomarker, we performed unsupervised clustering analysis and constructed polygenic risk scores (PRS) for the resulting latent subgroups, which were then used to conduct phenome-wide association studies (PheWAS). **Results:** We identified 18 lead SNPs associated with HFC at $P < 5 \times 10^{-8}$, including two novel signals. Genetic correlation analyses confirmed robust associations between HFC and the seven markers included in the current diagnostic criteria, irrespective of the specific sources of summary statistics. In contrast, two metabolic markers previously reported to be associated with MASLD—LDL cholesterol and total cholesterol—showed no correlation with HFC across any dataset. Colocalization-driven clustering analysis uncovered three distinct genetic subgroups: the first subgroup exhibited strong colocalization with HDL cholesterol, demonstrating robust associations with a broad spectrum of liver diseases while being linked to a reduced risk of cardiovascular disease; the second subgroup primarily colocalized with fasting glucose, showing weaker associations with liver disease but contributing to an elevated risk of cardiovascular disease; and the third subgroup displayed strong colocalization with both glucose markers and triglycerides, maintaining moderate associations with both liver and cardiometabolic diseases. Furthermore, we observed that MASLD patients without evident metabolic dysregulation exhibited a higher overall genetic burden, predominantly concentrated in the SNP subgroup colocalizing with HDL cholesterol. **Conclusion:** Our study supports the selection of CMRFs in the current diagnostic criteria and provides genetic insights into the heterogeneity of MASLD. Furthermore, these findings suggest that genetic factors likely play a significant role in MASLD among patients without metabolic dysregulation, potentially facilitating the diagnosis and management of cryptogenic MASLD cases.

Figure | Genetic correlation and colocalization analyses reveal global and local metabolic features and potential genetic subtypes of MASLD. a, Using LDSC, we analyzed the genetic correlations between HFC-GWAS summary statistics derived from meta-analysis and summary statistics for nine cCMRFs from six sources (four association studies and two meta-analyses). The heatmap colors represent the magnitude of genetic correlation between HFC and the corresponding CMRF from specific sources, with asterisks indicating statistically significant correlations ($P < 0.05$). b, Based on Bayesian colocalization posterior probabilities (PP.H4) with seven CMRFs exhibiting genetic correlations, we performed unsupervised clustering of significant HFC loci. Strong colocalization (dark red) was defined as PP.H4 ≥ 0.8, moderate colocalization (light red) as PP.H4 between 0.4 and 0.8, and PP.H4 < 0.4 as non-colocalization (white). The final number of clusters was set to N = 3 based on the silhouette coefficient. UKB, UK Biobank; BBJ, BioBank Japan; TWB, Taiwan Biobank. H&W, HOPE cohort and WELLSPRING cohort; HDL-C, high-density lipoprotein cholesterol; BMI, body mass index; TG, triglycerides; DBP, diastolic blood pressure; SBP, systolic blood pressure; GLU, fasting glucose; HbA1c, glycated hemoglobin; LDL-C, low-density lipoprotein cholesterol; TC, total cholesterol.

◆ 2016 | LIVERPRO CAN OPTIMIZE TRIAL RECRUITMENT AND LOWER SCREEN FAILURE RATES IN STEATOTIC LIVER DISEASE

Julie Astono[1] Andreas Sand[1] Katrine Thorhauge[1] Georg Semmler[2] Rida Nadeem[3] Aarya Patel[3] Manal Chughtai[3] Sahasraara Hemant[3] Yasmeen Fallouh[3] Himanshi Kapoor[3] Camilla Dalby Hansen[2] Johanne Hansen[2] Stine Johansen[2] Helle Schnefeld[2] Peter Andersen[2] Katrine Bech[2] Nikolaj Torp[2] Søren Overgaard[1] Mads Israelsen[2] Katrine Lindvig[1] Maja Thiele[2] Aleksander Krag[4] Naim Alkhouri[3], [1]Evido Health, [2]Odense University Hospital, [3]Arizona Liver Health, [4]University of Southern Denmark

Background: Recruitment for clinical trials targeting moderate and severe fibrosis in steatotic liver disease (SLD) remains a major challenge due to high screen failure rates. Clinical trials often start by targeting individuals with cardiometabolic risk factors (CMRFs), followed by prescreening tools to enrich recruitment, but their performance varies across populations and disease prevalence. We evaluated LiverPRO, a non-invasive algorithm-based fibrosis tool, to improve recruitment efficiency compared to conventional strategies. **Methods:** We included two clinical cohorts from Denmark and the US, both representing populations at-risk of SLD. All participants underwent blood sampling and transient elastography (TE); liver biopsy was performed if TE ≥8 kPa (Denmark), or universally (US). To assess the impact of prevalence on diagnostic performance, we simulated three additional cohorts (n = 5,000 each) with predefined fibrosis prevalences (TE ≥8 kPa) of 10%, 30%, and 50%. We evaluated three recruitment pathways: no prescreening, FIB-4 ≥1.3, or LiverPRO ≥65%. In all three we considered follow-up Fibroscan-AST (FAST) test in those screening positive, and biopsy if FAST ≥0.35 to confirm significant fibrosis (≥F2). For each pathway and cohort, 500 trial recruitments were simulated to enroll 400 patients with significant fibrosis by sampling from a large population. Mean screen failure rates, number of FAST tests needed, and negative biopsies (F0-1) were compared across pathways and cohorts. **Results:** The Danish cohort included 4,612 individuals (52% male, median age 58 [interquartile range (IQR): 53 - 63] years) at-risk of SLD due to CMRFs, 322 (7%) had TE ≥8 kPa, and 147 (3%) biopsy-verified ≥F2. The US cohort included 495 participants (31% male, median age 58 [IQR: 49 - 65] years) with CMRFs at-risk of metabolic dysfunction-associated steatotic liver disease, 408 (82%) had TE ≥8 kPa and 356 (72%) had biopsy-verified ≥F2. When comparing the pathway simulations leading to 400 enrolled patients with biopsy confirmed significant fibrosis (≥F2), LiverPRO reduced the number of FAST tests by 31-89% compared to no prescreening and by 7-73% compared to FIB-4, with the greatest reductions observed in lower prevalence cohorts. Similarly, the number of negative (unnecessary) biopsies decreased by 53-66% versus no prescreening and by 7-51% versus FIB-4. Screen failure rates declined by 23-46 and 6-28 percentage points when using LiverPRO in prescreening versus no prescreening or FIB-4, respectively.
Conclusion: LiverPRO substantially improved screening efficiency across cohorts. For trial recruitment of SLD patients with ≥F2, employing LiverPRO resulted in lower screen failure rates, fewer FAST tests, and less negative biopsies than using no prescreening or FIB-4.

◆ 2017 | IDENTIFICATION OF SIGNATURE GENES AND PATHWAYS IN THE PROGRESSION OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS: A META-ANALYSIS IN LIVER TRANSCRIPTOMICS

Wei Zhang[1] Xiangwen Ji[2] Yangyang Sun[3] Leyi Wang[3] Xiangsha Kong[4] Lin Zhang[4] Zhengxi Wang[5] Long Zhang[3] Jing Zhou[4], [1]Peking University People's Hospital, Beijing, China, [2]Peking University Third Hospital, Beijing, China, [3]Peking University First Hospital, Beijing, China, [4]Peking University People's Hospital, Beijing, China, [5]Capital Medical University, Beijing, China

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is considered as the progression of steatosis and the primary driver of liver fibrosis. Then, changes of liver gene expression along with the progression of MASH should be not only as a predictor of liver histology but also as a potential target for treatment. By now, the association remains unclear. Therefore, the aim of our study was to explore differentially expressed genes (DEGs) in the progression of MASH patients (steatosis-steatohepatitis-fibrosis 3-4) whose histological features were assessed according to NASH CRN histological scoring systems. **Methods:** The Gene Expression Omnibus database (GEO) and PubMed were searched with key terms and MeSH terms. We combine results of individual studies using a random-effects model. The $\log_2$ fold changes ($\log_2$FC) and 95% confidence interval (CI) of genes between two groups were given and p value < 0.05 was considered as the significance cut-off for differential gene expression. For the gene functional enrichment analysis, we employed the single sample gene set enrichment

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

analysis (ssGSEA) module. **Results:** The nine GEO datasets were included. Among 691 adult patients in these studies, 56% were female, and the ranges of age and BMI (mean) were 43.8 to 54 yrs and 30.2 to 47kg/m2, respectively. For metabolic abnormalities, 44.3% patients (274/618), 53.7% (139/259) and 56.6% (145/256) were diagnosed with diabetes, hyperlipidemia and hypertension, respectively. To identify DGEs and pathways which play important roles in the progress from steatosis to steatohepatitis and further severe fibrosis, we compared and overlapped results from the following meta-analyses: 1) NAS (0-3) versus Controls, 2) NAS (4-8) versus (0-3) and 2) Fibrosis stage (3 or 4) versus (0 or 1) in patients with NAS (4-8). 3,447, 5,639 and 4,474 DEGs were identified in the above comparisons. Among shared genes, 131 up-regulated and 83 down-regulated genes were identified (Fig.1) and the top 3 significant differentially expressed pathways included "low-density lipoprotein receptor particle metabolic process", "Release of apoptotic factors from the mitochondria" and "intracellular sphingolipid homeostasis". **Conclusion:** To the best of our knowledge, this is the first study to provide a comprehensive and robust analysis of DEGs in the progression of MASH patients whose histological features were assessed according to NASH CRN and identify important pathways in the progression.

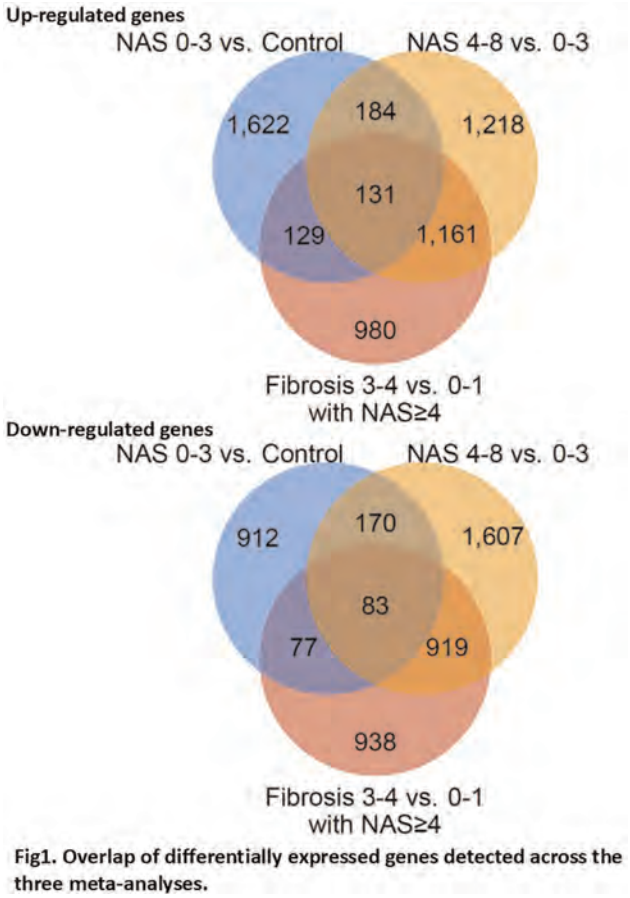

Fig1. Overlap of differentially expressed genes detected across the three meta-analyses.

◆ 2018 | THE SMELL OF MASLD: DISCRIMINATORY BREATH VOC SIGNATURE IN CHILDREN WITH MASLD; A PROSPECTIVE COHORT STUDY

Jennifer Panganiban[1] Amalia Berna[2] Sarah Abu Alreesh[1] Yang Liu[2] Aakanshya Aryal[2] Audrey Odom John[2], [1]Division of Gastroenterology, Hepatology and Nutrition, Children's Hospital of Philadelphia, [2]Division of Infectious Diseases, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, US

Background: Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD) is the most common cause of chronic liver disease in children, defined by hepatic steatosis with at least one cardiometabolic risk factor. Pediatric MASLD is often underrecognized, screening measures are inadequate and non-invasive tests validated in adults lack accuracy in pediatrics. Breath-based volatile organic compounds (VOCs) show promise for noninvasive diagnosis. A pediatric study by Alkhouri et al 2014, identified altered VOCs in presumed MASLD, diagnosed by ultrasound, using targeted analysis of 14 compounds. Our study builds on this by applying untargeted breath VOC analysis to better characterize diagnostic breath signatures in children. **Methods:** This is a prospective IRB-approved cohort study at the Children's Hospital of Philadelphia. Children aged 4–20 years were enrolled into either the MASLD or healthy control group. Inclusion criteria for the MASLD group were either: (1) BMI $\geq 85^{th}$ % for age and sex based on CDC growth charts, hepatic steatosis on imaging, Alanine aminotransferase (ALT) $\geq 2\times$ the upper limit of normal for sex (≥ 52 U/L for males ≥ 44 U/L for females); or (2) biopsy-confirmed MASLD $\leq$ 6 months from consent. Controls had BMI $\geq 85^{th}$% for age and sex based on CDC growth charts, normal hepatic ultrasound and normal ALT. Breath samples were analyzed via two-dimensional gas chromatography-mass spectrometry (GC×GC-MS). Raw data were processed using ChromSpace software (v2.0.1, SepSolve, UK). A Random Forest model was applied to evaluate the predictive capacity of identified VOCs. **Results:** 20 healthy controls and 22 MASLD patients were enrolled: 10 patients had biopsy-confirmed MASLD and 12 patients had non-biopsy MASLD. Breath analysis in children with MASLD had a distinct breath VOC profile than their healthy obese counterparts. Ten discriminatory molecules were found.

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Random Forest applied to the data set indicates that VOCs can predict pediatric MASLD with 73% sensitivity and 65% specificity, with an area under the curve (AUC) of 0.84. Using the VOC with the highest Gini importance, 2,4-Dimethyl-1-heptene had a greater sensitivity of 85% and specificity 77.3% with AUC of 0.81. (Figure 1). **Conclusion:** This study demonstrates a distinct breath VOC signature associated with pediatric MASLD. These findings support the potential utility of breath analysis as an easy, noninvasive screening tool for MASLD in children. Limitations include the small sample size, and further studies are needed to validate these results.

◆ 2019 | COMPARISON OF DIGITAL IMAGES VERSUS GLASS SLIDES FOR THE HISTOPATHOLOGICAL EVALUATION OF LIVER BIOPSY SAMPLES ACCORDING TO THE NASH-CRN SCORING SYSTEM FOR MASH: A VALIDATION PERFORMED AS PART OF THE NATIV3 STUDY

Carolin Lackner[1] Zachary Goodman[2] Dina Tiniakos[3] Prodromos Hytiroglou[4] Arun Sanyal[5] Sven Francque[6] Philippe Huot-Marchand[7] Lucile Dzen[7] Benoit Noel[7] Pierre Broqua[7] Martine Baudin[7] Michael Cooreman[8] Louis Griffel[7], [1]Medical University of Graz, [2]INOVA Fairfax Hospital, [3]Univeristy of Athens, GR & Visiting Professor, Translational & Clinical Res Inst, Newcastle Univ, UK, [4]Aristotle University of Thessaloniki, [5]Virginia Commonwealth University, [6]University of Antwerp, [7]Inventiva Pharma, [8]INVENTIVA

Background: Histopathologic assessment by liver biopsy remains the standard for diagnosis and assessing treatment response in metabolic dysfunction-associated steatohepatitis (MASH) clinical trials. Historically, this has been done by interpretation of glass slides. The development of digital technology has afforded a more efficient option that allows all pathologists to view a consistent digital image. **Methods:** As part of the NATiV3 trial (NCT04849728), we performed validation of histological scoring of digital images compared to glass slides of the same case. Three expert liver pathologists each scored 20 biopsies, each stained with hematoxylin & eosin and Masson trichrome. Glass slides representing the full MASH spectrum were used to generate digital images. Scoring of digital images and then of glass slides were performed at least 2-weeks apart, independently (results from 1st scoring not available at time of 2nd scoring) using both the NASH-CRN and SAF scoring systems. For each component (steatosis, lobular inflammation and ballooning grade, fibrosis stage), agreement rates between digital images and glass slides were calculated and intra-variability between the 2 scorings was measured with linear weighted Cohen's kappas and 95% confidence intervals. Results were pooled using the 3 pathologists' scores. **Results:** Agreement on fibrosis stage between digital images and glass slides was high with Kappa 0.81 [0.71-0.92] (agreement rate of 82%). Agreement on NAS steatosis, inflammation and ballooning were substantial with Kappas 0.68 [0.53-0.83], 0.63 [0.45-0.81] and 0.67 [0.52-0.81], respectively (agreements rates 77%, 83% and 72%). Similarly, agreements on SAF inflammation, ballooning and activity were substantial with Kappas 0.75 [0.57-0.93], 0.70 [0.52-0.88] and 0.72 [0.59-0.85], respectively (agreements rates 90%, 83% and 75%). Other studies that investigated intra-observer agreement on either glass slides or digital images reported ranges from 0.62 to 0.88 for steatosis, 0.21 to 0.76 for inflammation, 0.27 to 0.79 for ballooning, and 0.48 to 0.87 for fibrosis. [Ref 1.Langford 2022, 2.Kleiner 2019, 3.Davison 2020, 4.Iyer 2024, 5. Pulaski 2024] **Conclusion:** Concordance rates observed in our project between digital images and glass slides are comparable to or higher than published NASH CRN concordance estimates. These data support that the use of digital images does not introduce additional variability and is equivalent to glass slides, highlighting their suitability in clinical MASH trials.

◆ 2020 | ZONE-SPECIFIC FIBROSIS REDUCTIONS INDUCED BY PEGOZAFERMIN OVER 24 WEEKS ARE SIMILAR IN NON-CIRRHOTIC (F2/F3) AND CIRRHOTIC (F4) MASH

Quentin Anstee[1] Maya Margalit[2] Arun Sanyal[3] Vlad Ratziu[4] Mildred Gottwald[2] Elaine Chng[5] Yukti Choudhury[5] Harpreet Nagra[2] Cynthia Hartsfield[2] Dean Tai[5] Hank Mansbach[2] Rohit Loomba[6], [1]Newcastle University, UK, [2]89bio, [3]Virginia Commonwealth University, [4]Service D' Hepatogastroenterologie (FR), [5]HistoIndex, [6]University of California, San Diego

Background: In the ENLIVEN trial, pegozafermin (PGZ), a glycoPEGylated FGF21 analog administered at 30mg every week (QW) or 44mg every 2 weeks (Q2W) for 24 weeks significantly improved fibrosis without worsening of MASH in F2-F3 patients. qFibrosis features in the portal, periportal, and zone 2 regions have previously been reported to be predictive of hepatic decompensation and all-cause mortality[1]. In this post-hoc study, qFibrosis zonal analysis was conducted to assess hepatic zone-specific effects of PGZ in non-cirrhotic and cirrhotic MASH. [1] Kendall et al. Liver Int. 2024. **Methods:** Paired, unstained biopsies from baseline (BL) and week 24 for qFibrosis analysis were available for a subset of subjects in ENLIVEN: 1) F2-F3 subjects [n = 122; placebo (PBO, n = 46), 30mg QW (n = 45), 44mg Q2W (n = 31)], and 2) F4 patients at BL (as re-read by a 3-panel consensus, not included in ENLIVEN main results) [n = 7; PBO (n = 1), 30mg QW and 44mg Q2W pooled (n = 6)]. Biopsies were imaged using second harmonic generation/two-photon excitation fluorescence microscopy and fibrosis changes were assessed across 5 hepatic zones: portal zone, periportal (zone 1), peri-sinusoidal (zone 2), central zone, and peri-central (zone 3). Steatosis-correction was applied to account for the effect of large reductions in steatosis by PGZ, on fibrosis quantification. **Results:** By qFibrosis zonal analysis, treatment of pathologist-determined F2-F3 patients with PGZ (30 mg QW and 44 mg Q2W) for 24 weeks led to significant reductions in fibrosis specifically in the portal zone, zone 1, and zone 2, compared to baseline ($p < 0.05$). No reduction was observed in PBO. In pathologist-determined F4 patients, similar pronounced fibrosis regression was seen in zones 1 and 2, with modest reductions in the other zones. Findings were aligned in subjects identified as qFibrosis stage F2/F3 or F4 at baseline. **Conclusion:** PGZ led to consistent patterns of qFibrosis portal zone, peri-portal (zone 1), and peri-sinusoidal (zone 2) regression in non-cirrhotic (F2-F3) and cirrhotic (F4) patients with MASH at 24 weeks. This is the first report of qFibrosis regression in these clinically meaningful zones induced by a therapeutic intervention in MASH cirrhosis. PGZ is currently being studied in Phase 3 studies in non-cirrhotic and cirrhotic MASH.

◆ ★ 2021 | VALIDATION OF AGILE-3+ AND AGILE-4 SCORES FOR NONINVASIVE DETECTION OF FIBROSIS AND CIRRHOSIS IN METABOLIC DYSFUNCTION–ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) IN LATIN AMERICA

Luis Antonio Diaz[1] Carlos Esteban Coronel-Castillo[2] Natalia Baeza[1] Francisco Idalsoaga[1] Daniel Cabrera[3] Fernando Barreyro[4] Sebastián Marciano[5] Jorge Martinez[5] Cristiane Villela-Nogueira[6] nATHALIE Carvalho Leite[6] Gil Salles[6] Claudia Cardoso[6] Claudia Couto[7] Rafael Theodoro[8] Misia Joyner de Sousa Dias Monteiro[8] Mario Pessoa[9] Mario Alvares-da-Silva[10] Bruno Basso[10] Gabriella Jonko[10] Fatima Higuera de la Tijera[2] Constanza Sabate[11] Manuel Mendizabal[11] Mazen Noureddin[12] Naim Alkhouri[13] Winston Dunn[14] Rohit Loomba[15] Claudia Oliveira[16] Adrián Gadano[5] Marco Arrese[1] Juan Pablo Arab[17], [1]Pontificia Universidad Católica de Chile, [2]Hospital General de México "Dr. Eduardo Liceaga", [3]Universidad de los Andes, [4]Universidad Nacional de Misiones, [5]Hospital Italiano de Buenos Aires, [6]Hospital Universitário Clementino Fraga Filho, [7]Federal University of Minas Gerais, [8]Hospital das Clínicas da Universidade Federal de Minas Gerais, [9]Universidade de São Paulo, [10]Hospital de Clínicas de Porto Alegre, [11]Hospital Universitario Austral, [12]Houston Methodist Hospital, [13]Summit Clinical Research, [14]University of Kansas Medical Center, [15]University of California San Diego, [16]University of Sao Paulo School of Medicine, [17]Virginia Commonwealth University

Background: Early detection of liver fibrosis in MASLD is crucial for preventing progression to cirrhosis. The Agile-3+ and Agile-4 scores are designed to identify advanced fibrosis and cirrhosis, respectively, but their performance in Latin American populations is unknown. This study aimed to validate Agile-3+ and Agile-4 scores in predicting advanced fibrosis and cirrhosis in a well-characterized cohort of Latin American patients with MASLD. **Methods:** We conducted a multicenter cross-sectional study with patients from 10 centers across Brazil, Argentina, Chile, and Mexico, all diagnosed with MASLD according to the 2023 definition. Liver fibrosis was assessed using liver biopsy and liver stiffness measurements (LSMs) by vibration-controlled transient elastography (VCTE) and liver biopsy was used as the standard for grading fibrosis. Biochemical and clinical studies were obtained to calculate FIB-4, Agile-3+, and Agile-4 scores. The diagnostic efficacy of non-invasive indices in detecting advanced fibrosis ($\geq$F3) and cirrhosis (F4) was evaluated using receiver operating characteristic (ROC) curve analysis and Youden index. **Results:** We included 770 adults with MASLD, with a median age of 59 years [51–66], 60% were men, and 64.5% were Hispanic. The median body mass index (BMI) was 33.3 $\pm$ 8.2 kg/m² and 69.6% had type 2 diabetes mellitus. The median liver stiffness on VCTE was 9.1 kPa [IQR 6.9–12.6]; 29.9% of participants had advanced fibrosis and 10.5% had cirrhosis. When comparing performance in predicting advanced fibrosis, Agile-4 had the highest performance (AUROC 0.765, 95%CI: 0.725–0.805; p = 0.037) compared to LSM by VCTE alone, while Agile-3+ did not show significant differences (AUROC 0.754, 95%CI:

0.715–0.793; p = 0.213) (Figure A). Accuracy improved for cirrhosis, where Agile-4 achieved an AUROC of 0.875 (95% CI: 0.836–0.914, p = 0.003), outperforming Agile-3+ (AUROC 0.856, 95% CI: 0.813–0.899, p = 0.100) (Figure B). For Agile-4, the optimal cut-off to rule out cirrhosis (90% sensitivity) was ≥ 0.159, and the optimal cut-off to rule in cirrhosis (90% specificity) was ≥ 0.366. **Conclusion:** In this Latin American MASLD cohort, the Agile-4 score demonstrated superior noninvasive rule-out performance for advanced fibrosis and cirrhosis. Incorporating these Agile-4 thresholds into VCTE-based algorithms could reduce unnecessary biopsies and streamline MASLD care pathways across resource-variable settings (FONDECYT 1241450).

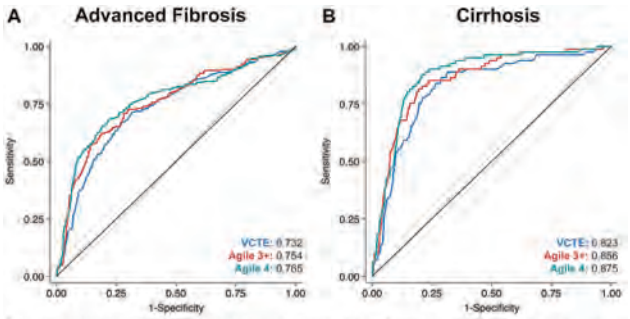

Figure. Receiver-operating characteristic curves comparing the performance of vibration-controlled transient elastography (VCTE) liver stiffness measurements with Agile-3+ and Agile-4 scores in predicting (A) advanced fibrosis and (B) cirrhosis.

◆ 2022 | SINGLE CIRCULATING BIOMARKERS SVCAM-1 AND TSP2 ACHIEVED EFFECTIVE PROGNOSTIC PERFORMANCES FOR THE DETECTION OF FIBROSIS PROGRESSION TO CIRRHOSIS

Vlad Ratziu[1] Sven Francque[2] Bérénice Alard[3] Jérémy Magnanensi[3] Zouher Majd[3] Dean Hum[4] Bart Staels[5] Quentin Anstee[6] Arun Sanyal[7], [1]Service D' Hepatogastroenterologie (FR), [2]Gastroenterology and Hepatology, Antwerp University Hospital, University of Antwerp, Belgium, [3]GENFIT SA, [4]GENFIT CORP, [5]University Lille 2, [6]Newcastle University, UK, [7]Virginia Commonwealth University

Background: Cirrhosis (F4) is the main source of complications and mortality for patients (pts) with chronic liver diseases. An early detection of pts at high risk of progression to F4 could optimize clinical management and reduce related health-care burden. We compared the prognostic performance of 40 single circulating biomarkers (BMs) vs ELF™ and VCTE-based tests for progression to cirrhosis in pts with MASH and fibrosis (F). **Methods:** Pts with non-cirrhotic MASH enrolled in the RESOLVE-IT Phase 3 trial (NCT02704403), with paired liver biopsies (baseline and end of study [EOS]) and available data at baseline for ELF, VCTE, Agile3+, Agile4 and 40 circulating BMs, were selected (N = 739). Placebo and treated arms were included as the evaluated agent did not significantly impact fibrosis evolution. AUC and associated Delong tests were used to compare the overall performance of the BMs vs ELF, VCTE, Agile3+ and Agile4 for the detection of fibrosis progression towards

F4. For BMs with AUC not significantly lower than ELF, a single cutoff was derived to achieve same sensitivity (sen) as ELF at its threshold indicative of increased risk of progression to cirrhosis (9.8). Corresponding specificity (spe), PPV and NPV were computed. A subpopulation matched for baseline histology and clinical characteristics between progressors and non-progressors to F4 was also extracted using a propensity score matching (PSM) algorithm. **Results:** Mean follow-up was 19 months. All pts had MASH with F1-3 at baseline, mean age was 55 y and 54% were male. 5.4% of pts (n = 40) progressed to F4 at EOS; 40% of progressors were male, mean age was 59 y and all had F3 at baseline. ELF at baseline achieved an AUC of 0.778 for the detection of pts who progressed to F4 and had a spe of 0.61 and a sen of 0.78 at a cutoff of 9.8. Among the 40 BMs evaluated, 6 achieved similar AUC to ELF and were kept for further analyses: TSP2 (0.785, p = 0.86), sVCAM-1 (0.782, p = 0.90), YKL40 (0.739, p = 0.44), TIMP1 (0.736, p = 0.24), GGT (0.733, p = 0.37) and P3NP (0.725, p = 0.11). Among these BMs, only sVCAM-1 at a cutoff of 896 ng/mL and TSP2 at a cutoff of 63 ng/mL achieved significantly higher spe than ELF (resp: 0.69 vs 0.61, p < 0.001; 0.68 vs 0.61, p = 0.002) for the same sen. Among VCTE-based tests, Agile4 achieved the highest AUC (0.835). TSP2 and sVCAM-1 were the only BMs with AUC not significantly lower than Agile4. The PSM algorithm resulted in a cohort of n = 117 pts (39 progressors and 78 non-progressors to F4) with F3 at baseline, well-balanced for clinical characteristics. Within this population, a similar overall ranking was observed with VCTE-based tests performing best, followed by sVCAM-1, TSP2 and ELF. **Conclusion:** Single biomarkers sVCAM-1 and TSP2 predicted progression to cirrhosis with similar performance as VCTE-based tests (Agile4, Agile3+ and VCTE) and the composite marker ELF™, an FDA-approved tool for this indication. These two circulating BMs could represent valuable tools to predict progression to cirrhosis.

Hospital Padre Hurtado, Santiago, Chile., [5]Norfolk and Norwich University Hospital NHS Trust, Norwich, UK., [6]Peterborough City Hospital, Peterborough, UK., [7]Summit Clinica Research, San Antonio, TX, USA.

Background: Current methods for evaluating chronic liver disease primarily focus on structural alterations, markers of hepatic injury, or general biochemical indicators, providing limited information on the hepatic functional reserve. LIBRA is a novel non-invasive breath test designed to assess liver impairment by quantifying the metabolism of orally administered Exogenous Volatile Organic Compounds (EVOCs), which are processed by the liver and detected in exhaled breath. This study evaluates the diagnostic performance of LIBRA in identifying liver dysfunction associated with cirrhosis among individuals with relevant risk factors and clinical symptoms. **Methods:** This case-control multicentre study enrolled 171 participants with chronic liver disease of different aetiologies. Of these, 83 had cirrhosis confirmed through clinical and imaging assessments. Breath was sampled before, 15, and 30 minutes after EVOCs ingestion. Samples were analysed using thermal desorption-gas chromatography-mass spectrometry (TD-GC-MS), and classification models were refined using lasso logistic regression with bootstrap resampling **Results:** Presence of cirrhosis alters EVOCs breath levels at 15 min with higher limonene (Median: cirrhosis 862 ng, control = 326 ng ($p = 3.1e-7$)), and reduced conversion of 2-butanol (Median: cirrhosis 33.2 ng, control = 15.5 ng ($p = 2.2e-4$)) into its metabolite 2-butanone (Median: cirrhosis 491.7 ng, control = 995.4 ng ($p = 1.5e-4$)). LIBRA identified subjects with cirrhosis with an AUC of 0.82 (95% CI: 0.73-0.90) a sensitivity of 68% (95% CI: 47-86%), and a specificity of 79% (95% CI: 61-94%) at Youden index (Fig.1a). Across the cohort, EVOCs were associated with fibrosis stage estimated using FibroScan® ($p < 0.05$). In the cirrhosis group, breath limonene at 15 minutes correlated with FIB-4 ($r = 0.55$) and platelet count ($r = 0.65$). Analysis of Covariance (ANCOVA) showed a significant effect of platelet count on breath limonene levels in relation to cirrhosis status ($p = 0.04$). Within the cirrhosis group, subjects with thrombocytopenia showed higher limonene levels compared to those with normal platelets count ($p = 0.001$) (Fig.1B). **Conclusion:** The presented data demonstrates LIBRA clinical utility in assessing liver dysfunction associated with cirrhosis. Correlations between exhaled EVOCs and fibrosis staging support breath analysis to assess liver disease severity. Moreover, limonene association with thrombocytopenia, a well-established marker of portal hypertension, indicates its potential utility in monitoring this cirrhosis-related complication.

◆ 2024 | LIVER IRON CONCENTRATION CHARACTERISES PROGRESSION OF MASLD TO METALD

Edward Jackson[1] Anneli Andersson[1] Helena Thomaides Brears[1] Jacqueline O'Leary[2] Niharika Samala[3] Rohit Loomba[4] Vinod Rustgi[5] Carlos Duncker[6] Andrea Dennis[1] Rajarshi Banerjee[1], [1]Perspectum, Oxford, UK, [2]University of Texas Southwestern, Dallas, TX, USA, [3]Indiana University School of Medicine, Bloomington, IN, USA, [4]University of California at San Diego, CA, USA, [5]Rutgers Robert Wood Johnson Medical School, NJ, USA, [6]Pinnacle Clinical Research, San Antonio, TX, USA

Background: MetALD describes individuals whose liver pathology is in a continuum between metabolic dysfunction-associated steatotic liver disease (MASLD) and alcohol-associated liver disease (ALD), depending on alcohol consumption. Diagnosis of MetALD poses challenges due to the limited reliability of self-reported alcohol consumption. Quantitative multiparametric MRI is increasingly used to diagnose and monitor chronic liver disease, with biomarkers of liver fat, iron and fibro-inflammation. Using population data from the UK biobank, this study aimed to identify how MRI biomarkers of liver health discern MASLD from MetALD and to risk stratify major liver related events (LRE) and new-onset diabetes. **Methods:** Multiparametric MRI (LiverMultiScan) was used to measure iron-corrected T1 (cT1, ms), liver fat content (LFC, %) and liver iron content (LIC, mg Fe/g) in 60,595 UK biobank participants. Self-reported daily/almost daily alcohol consumption stratified MetALD from MASLD in individuals with LFC >5% and at least one cardiometabolic risk factor. Associations between biomarkers and new onset diabetes and LRE were investigated using Cox proportional hazard models adjusted for age, sex and BMI. Adjusted hazard ratios (HR) are reported. **Results:** MASLD was diagnosed in 11,818 participants (aged 65 years, 57% male, 96% White) and MetALD in 2,720 (aged 67 years, 71% male, 98% White). After matching for age, sex, BMI and metabolic risk factors, patients with MetALD had small but statistically significant differences, a higher LFC (11.5 vs. 10.7%) and lower cT1 (740 vs. 748ms), higher LIC (1.36 vs 1.29 mg Fe/g), with a higher proportion of patients with hepatic iron above the 1.3 mg Fe/g threshold (49% vs 36%) (Figure 1). Higher cT1 was associated with LRE in MetALD (HR 2.4 (1.3, 4.4)) and in MASLD (HR 2.4 (1.3, 4.4)), LFC and cT1 were both associated with new onset diabetes (HR per SD increase, LFC 1.3 (1.1, 1.5) cT1: 1.5 (1.2, 1.9)). Increased LIC however was not associated with any outcome. **Conclusion:** In a large-scale population study, we find individuals with MetALD have significantly higher levels of LIC compared to MASLD. cT1 predicted LREs and both cT1 and LFC predicted new onset diabetes, similarly in both MASLD and MetALD. Liver iron content may accelerate disease, so should be measured in people with suspected MetALD.

2025 | FAST AND CAP SCORES AS EARLY BIOMARKERS OF TREATMENT RESPONSE IN MASLD PATIENTS RECEIVING RESMETIROM: A REAL-WORLD STUDY

Winston Dunn[1] Ashwani Singal[2] Imad Asaad[3] Edward Mena[4] Amreen Dinani[5] Savannah Nelson[6] Karthikeya Kodali[6] Rayan Ahmed[6] Phuong Nguyen[6] Wamda Ahmed[1] Sheel Patel[2] Sonal Kumar[7] Madhavi Rudraraju[8] Mazen Noureddin[9] Naim Alkhouri[10], [1]University of Kansas Medical Center, [2]University of Louisville, [3]Fireland Health, [4]California Liver Reasearch Instituite, [5]Duke University School of Medicine, [6]Arizona Liver Health, [7]Cornell University, [8]Pinnacle Clinical Research, [9]Houston Methodist Hospital, [10]Summit Clinical Research

Background: Resmetirom is the first FDA-approved medication for non-cirrhotic metabolic dysfunction-

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

associated steatohepatitis (MASH) patients with significant (F2) to advanced (F3) fibrosis. Current AASLD guidance recommends assessing response at one year; however, reliable biomarkers indicating earlier clinical improvement are critically needed. This study evaluated the sensitivity of biomarkers, including liver enzymes (ALT, AST), fibrosis indicators (FIB4, Agile3, FAST), controlled attenuation parameter (CAP), and liver stiffness measurements (LSM) at 3 and 6 months post-treatment initiation in a real-world cohort. **Methods:** This observational study enrolled MASLD patients treated at six U.S. tertiary hepatology clinics (March–November 2024). Demographic data, laboratory values, LSM, CAP, and medications were collected at baseline, 3, and 6 months. Inclusion required meeting at least one AASLD criterion: (1) LSM 8–20 kPa, (2) ELF 9.2–11.3, or (3) biopsy fibrosis stage F2–F3. Paired t-tests assessed changes from baseline. Cohen's d (mean change divided by standard deviation) quantified standardized response magnitude independently of sample size. Treatment discontinuations were documented. **Results:** 485 patients initiated Resmetirom; 9 discontinued treatment. Baseline means were: ALT 53.9 U/L (SD 41.2), AST 43.7 U/L (SD 30.3), CAP 324 dB/m (SD 41.2), FAST 0.52 (SD 0.19), Agile3 0.56 (SD 0.22), and LSM 13 kPa (SD 9.6). At 3 months, FAST was the most responsive biomarker, demonstrating the largest standardized improvement (Cohen's d -0.64, $p = 0.0002$), followed by CAP score (Cohen's d -0.42, $p = 0.0008$). At 6 months, CAP emerged as the top-performing biomarker with even greater improvement (Cohen's d -0.94, $p < 0.0001$), followed by FAST (Cohen's d -0.63, $p < 0.0001$). ALT also improved at both 3 months (Cohen's d -0.19, $p = 0.008$) and 6 months (Cohen's d -0.42, $p < 0.0001$). Fibrosis-related biomarkers (LSM, Agile3, FIB4) showed minimal responsiveness within 6 months (Table 1). **Conclusion:** FAST was the most responsive biomarker at 3 months, while CAP provided the greatest standardized response at 6 months, highlighting their potential utility as early indicators of Resmetirom treatment effectiveness. Fibrosis markers showed minimal short-term changes, suggesting that fibrosis improvement may require longer treatment duration. Incorporating FAST and CAP into clinical practice could facilitate earlier assessment and optimization of therapy.

Month	Biomarker	N	Cohen's d	p-value	Interpretation
3	**FAST**	71	-0.64	0.0002	Largest early improvement
3	CAP Score	71	-0.42	0.0008	Moderate early improvement
6	**CAP Score**	74	-0.94	<0.0001	Largest overall improvement
6	FAST	74	-0.63	<0.0001	Continued large improvement
6	ALT	96	-0.42	<0.0001	Moderate delayed improvement

Note:

- Cohen's d indicates the magnitude of standardized improvement. Larger negative values represent greater treatment response.

2026 | ALLYL NONANOATE: A BILE METABOLITE AND POTENTIAL BIOMARKER FOR HEPATIC FIBROSIS IN MASLD

Dae Won Jun[1] Hyo Young Lee[2] Hyun Woo Oh[3] Eileen Yoon[2] Sang Bong Ahn[4] HA IL KIM[2], [1]Hanyang University, [2]Department of Internal Medicine, Hanyang University, Seoul, Korea, Rep. of South, [3]Department of Internal Medicine, Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicin, [4]Department of Internal Medicine, Nowon Eulji Medical Center, Eulji University, College of Medicine,

Background: Metabolic dysfunction-associated steatosis (MASLD) is a prevalent chronic liver disease with limited treatment options due to unclear pathophysiology. Bile acids play a critical role in MASLD progression; however, we hypothesized that serum or fecal bile acids may not directly reflect hepatic bile acid signaling due to their multi-step metabolic processing. To address this, we conducted metabolomic analysis to investigate distinguishing bile metabolites obtained from gallbladder samples of biopsy-proven MASLD patients compared to healthy controls. **Methods:** Primary bile samples and liver biopsies were collected from 68 patients undergoing cholecystectomy, including 19 healthy controls and 49 MASLD patients with varying degrees of hepatic fibrosis. Metabolomic profiling of bile acids was conducted using mass spectrometry to identify metabolites associated with hepatic fibrosis. RNA sequencing was performed on HT29 cells treated with the identified metabolite, and its fibrotic effects were further investigated using the human hepatic stellate cell line LX-2. **Results:** Among the metabolites increased in patients with fibrosis (139 in mild fibrosis and 173 in significant fibrosis) compared to controls, eight bile metabolites showed a positive dose-dependent correlation with fibrosis severity. Allyl nonanoate was ultimately identified as an elevated metabolite in fibrosis patients. Gene set enrichment analysis revealed downregulation of pathways related to cell cycle progression, including the G2/M checkpoint. In vitro, allyl nonanoate demonstrated a dose-dependent reduction in the mRNA expression of fibrosis markers FN1 and Col1A1. **Conclusion:** This study identified allyl nonanoate as a bile metabolite associated with hepatic fibrosis in MASLD patients. These findings highlight the

potential of primary bile samples as a valuable resource for identifying novel biomarkers and therapeutic targets. **Disclosures:** Dae Won Jun: Nothing to Disclose, Hyo Young Lee: Nothing to Disclose, Hyun Woo Oh: Nothing to Disclose, Eileen Yoon: Nothing to Disclose, Sang Bong Ahn: Nothing to Disclose, HA IL KIM: Nothing to Disclose

2027 | DEVELOPMENT AND VALIDATION OF QINFLAMMATION: AN AI-DRIVEN DIGITAL PATHOLOGY ALGORITHM FOR DIFFERENTIATING PORTAL AND LOBULAR INFLAMMATION IN METABOLIC-ASSOCIATED STEATOHEPATITIS

Yayun Ren[1] Kutbuddin Akbary[1] Karoline Lackner[2] Daniela Allende[3] Feng Liu[4] David Kleiner[5] Dean Tai[6], [1]HistoIndex Pte Ltd, [2]Medical University of Graz, [3]Cleveland Clinic, [4]Peking University People's Hospital, [5]National Cancer Institute, Bethesda, [6]HistoIndex

Background: Accurate histopathological assessment is critical for evaluating treatment response in metabolic-associated steatohepatitis (MASH), yet differentiating lobular and portal inflammation—key markers of disease progression—remains challenging with traditional microscopy. AI-driven digital pathology enables standardized, reproducible quantification of histological features. This study describes the first-round development and performance of the qInflammation (qI) algorithm, with two additional optimization rounds planned. **Methods:** The qI algorithm was developed to detect portal and lobular inflammation in H&E-stained liver tissue digital images (3–5 mm tissue length, cropped from whole slides). Three rounds of iterative optimization were planned; the first round included 30 unrotated and 8 90°-rotated images. Three expert pathologists (DK, CL, DA) independently labeled labeled each algorithm-identified inflammation foci as "YES" (correct identification of portal/lobular inflammation focus), "NO" (algorithm-identified region not representing inflammation focus), or "Misclassification" (algorithm misassigned portal focus as lobular or vice versa). Performance metrics—true positive ratio (TPR), false positive ratio (FPR), misclassification ratio (MR)—were validated against pathological consensus, with algorithm updates applied in subsequent planned rounds. **Results:** In Round 1, unrotated images (n = 30) showed portal inflammation grades: I0 (33%), I1 (37%), I2 (30%); lobular grades: I0 (20%), I1 (30%), I2 (27%), I3 (23%). qI detected 155 portal and 614 lobular foci, with strong Spearman correlations between histological grades and focus counts (portal: $\rho = 0.87$; lobular: $\rho = 0.86$). Rotated images (n = 8) retained 87% focus detection, confirming rotational invariance. Pathologist-specific metrics for portal inflammation: TPRs 61% (DK), 73% (CL), 84% (DA); FPRs 26%, 10%, 5%; MRs 14%, 17%, 11%. For lobular inflammation: TPRs 45% (DK), 64% (CL), 68% (DA); FPRs 40%, 28%, 23%; MRs 15%, 8%, 10%. Consensus agreement (≥ 2 pathologists) yielded portal metrics: TPR = 77%, FPR = 8%, MR = 12%; lobular: TPR = 60%, FPR = 28%, MR = 9%. **Conclusion:** The first-round evaluation demonstrates qI's robust potential for automated quantification of portal/lobular inflammation in MASH. Planned subsequent optimization rounds will focus on enhancing lobular inflammation detection accuracy to further improve algorithm performance.

Table: True positive ratio (TPR), false positive ratio (FPR) and misclassification ration (MR) for portal inflammation and lobular inflammation were determined by the pathologists (DK – David Kleiner; CL - Carolin Lackner; DA - Daniela S. Allende).

Determined by	Portal Inflammation			Lobular Inflammation		
	TPR	FPR	MR	TPR	FPR	MR
DK	61%	26%	14%	45%	40%	15%
CL	73%	10%	17%	64%	28%	8%
DA	84%	5%	11%	68%	23%	10%
At least 1 pathologist	89%	31%	23%	77%	46%	19%
At least 2 pathologists	77%	8%	12%	60%	28%	9%
All 3 pathologists	51%	2%	6%	39%	16%	5%

2028 | IMPROVING THE PREDICTION OF MASLD WITH ADVANCED FIBROSIS AMONG PRIMARY CARE PATIENTS WITH OBESITY, DIABETES, OR BOTH: A PROSPECTIVE COHORT STUDY IMPLEMENTING SCREENING WITH FIB-4 AND SAFE SCORES

Max Goldman[1] Nghiem Ha[2] Rena Fox[2] Bilal Hameed[2] Mandana Khalili[2] Mohsen Merati[2] Gabrielle Winer[3] Janet Chu[2], [1]Kaiser Permanente, Northern California, [2]University of California, San Francisco, [3]Stanford University

Background: FIB-4 is recommended for screening primary care (PC) patients at risk for MASLD-related fibrosis, but its performance in general versus specialty populations is suboptimal. The steatosis-associated fibrosis estimator (SAFE) score adds BMI, type 2 diabetes mellitus (DM), and globulins to FIB-4, and may improve risk stratification. We aimed to evaluate the utility of SAFE compared to FIB-4 in a PC setting. **Methods:** We used EMR data from 2019-2023 to identify PC adults with three risk factor profiles: (1) obesity only, (2) DM only, or (3)

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

obesity + DM. Annual FIB-4 and SAFE scores were calculated. The most recent scores were used to categorize by age-based cutoffs into low-, indeterminate-, or high-risk for advanced fibrosis. Patients with indeterminate/high-risk FIB-4 and available SAFE were included; their primary care provider (PCP) was prompted in the EMR to refer for Fibroscan. The primary outcome was significant fibrosis (F2-4), defined as median liver stiffness $\geq$8kPa. We calculated descriptive statistics and conducted two multivariable logistic regressions to analyze F2-4 association with (1) risk factor profile, adjusting for age and sex, and (2) FIB4/SAFE category, adjusting for sex. **Results:** Of 22,806 PC patients, 7,027 (31%) met inclusion for one of three risk factor groups: obesity (n = 3,644), DM (n = 1,896), or both (n = 1,474). The majority had data for at least one FIB-4 (72%) and SAFE (63%). To date, n = 430 met the FIB-4/SAFE cohort inclusion criteria, prompting their PCP to order Fibroscan. The cohort mean age was 62 years; 43% had obesity, 31% DM, and 26% both. Most had indeterminate FIB-4 (85%) and high SAFE (77%). Among 104 who underwent Fibroscan, 25% had F2-4, including 40% of those with high FIB-4 (Figure 1). Compared to F0-1, F2-4 patients had higher FIB-4 (2.5 vs 2.0, p = 0.01) and higher SAFE (242 vs 156, p < 0.001). Obesity + DM but not DM alone was independently associated with F2–4, which remained significant in multivariable analysis adjusting for age and sex (OR 7.97, 95% CI 2.25–28.21), compared to obese only. The addition of high SAFE to indeterminate FIB-4 did not increase the odds of F2-4 fibrosis (OR 4.60, 95% CI 0.56–37.69), but the combination of high FIB-4 + high SAFE did (OR 10.29, 95% CI 1.10–95.99). **Conclusion:** In PC patients, those with obesity + DM were significantly more likely to have F2-4 fibrosis relative to DM or obesity alone. High FIB-4 yielded a higher percent of F2-4 fibrosis relative to high SAFE. Applying both scores, the detection of significant fibrosis by indeterminate FIB-4 did not improve when combined with high SAFE, but high FIB-4 may be improved when combined with high SAFE in the PC setting.

2029 NEW SUBMISSION | A MACHINE LEARNING-VALIDATED MODEL CAN DIFFERENTIATE THREE SUBTYPES OF STEATOTIC LIVER DISEASE BASED ON SELF-REPORTED ALCOHOL USE: ANALYSIS OF NHANES DATABASE

Talal Bhatti Nicholas Dunn[1] Wanyu Zhang[2] Maiying Kong[3] Craig McClain[3] Winston Dunn[4] Ashwani Singal[3], [1]KUMC,KS, [2]University of Louisville School of Medicine, [3]University of Louisville, [4]University of Kansas Medical Center

Background: The new nomenclature of steatotic liver disease (SLD) based on self-reported alcohol use identified a new entity of metabolic dysfunction and alcohol associated liver disease (MetALD). There are challenges on accurately identifying MetALD given inaccurate reporting and changing alcohol use. ASH-NASH index (ANI) [PMID 17030176] can accurately distinguish patients with metabolic dysfunction associated liver disease (MASLD) and alcohol-associated liver disease (ALD). We analyzed NHANES database to develop a machine learning model (ANI 2.0) to differentiate three subtypes of SLD (MASLD, MetALD, and ALD). **Methods:** A random forest model was fitted on subjects with steatotic liver disease (SLD) in the NHANES database (1999–2006 and 2017–2020) using an iron panel (UIBC, TIBC, iron, ferritin, and transferrin), AST, ALT, MCV, demographics, GGT, folate, globulin, and CMRF. SLD was defined in presence of $\geq$1 cardiometabolic risk factor (CMRF), negative for hepatitis B or C virus, and with elevated ALT. We examined the model to distinguish SLD subtypes based on self-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

reported alcohol use, utilizing the new 2023 nomenclature. The dataset was randomly divided into 70% training and 30% test sets. We applied the synthetic minority over-sampling technique (SMOTE) on the training set to balance the sample sizes across groups. Performance was summarized with confusion matrices and one-versus-all ROC curves (with corresponding AUCs) for both the training and test datasets. **Results:** 7637 participants were stratified SLD subtypes: metabolic-dysfunction associated liver disease (MASLD, n = 7084), metabolic dysfunction and alcohol-associated liver disease (MetALD, n = 418), and alcohol-associated liver disease (ALD, n = 135). Three subtypes differed on baseline characteristics (Table). The model on the training dataset yielded a c-statistics of 0.98 for MASLD and 0.99 for both MetALD and ALD. In the test data, the model resulted in c-statistics of 0.79 for MASLD, 0.76 for MetALD, and 0.80 for ALD. Overall c-statistics (average of all pairwise AUCs) was 0.99 and 0.73 in training and test data respectively. The most important variables were five iron panel markers, age, AST, ALT, and MCV. **Conclusion: Conclusion:** A validated machine learning model (ANI 2.0) can accurately differentiate three subtypes of SLD. If confirmed in other prospective and retrospective cohorts, this could be clinically useful for clinical care pathway and for recruitment in research trials.

Table Demographic table across alcohol groups, for cycles with all iron variables available - All NA values are removed, for model fitting

2030 | CIRCULAR RNA PROFILING REVEALS IGF2BP-LINKED REGULATORY NETWORKS IN HUMAN METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS

Sareh Bayatpour[1] Hui Li[1] Grayson Way[2] NAN WU[1] Yunling Tai[1] Derrick Zhao[1] Meiyi Song[1] Lianyong Su[1] Emily Gurley[1] Xuan Wang[1] Phillip Hylemon[1] Arun Sanyal[2] Huiping Zhou[2], [1]VCU, [2]Virginia Commonwealth University

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is the progressive, inflammatory form of metabolic dysfunction-associated steatotic liver disease (MASLD), characterized by hepatic steatosis and lobular inflammation, with or without fibrosis. MASH has emerged as one of the most prevalent causes of chronic liver disease globally and is a leading indication for liver transplantation. Recent studies have reported altered circular RNA (circRNA) expression profiles in MASH mouse models; however, the circRNA landscape in human MASH remains largely unexplored. This study aims to identify circRNAs associated with MASH pathogenesis and to investigate their potential cellular and molecular mechanisms. **Methods:** Frozen liver tissues from MASH patients and healthy controls (HCs) were obtained through the Liver Tissue Cell Distribution System (Minneapolis, Minnesota), funded by NIH Contract# HSN276201200017C. Hepatic circRNA profiles were analyzed using the Arraystar Human circRNA Array V2 platform (n = 8, both male and female). Differentially expressed circRNAs were identified using circRNA-specific bioinformatics algorithms. Publicly available RNA-binding protein (RBP) databases (ENCORI and POSTAR3) were used to identify RBPs predicted to interact with the circRNA sequences. **Results:** The majority of detected circRNAs were exonic (75%). A total of 358 upregulated and 141 downregulated circRNAs were identified in MASH patients compared to HCs (fold change ≥ 2.5, $p < 0.05$). The top 10 upregulated circRNAs showed expression increases ranging from 25- to 193-fold. Bioinformatic analysis revealed that several of the most significantly upregulated circRNAs—circCNOT6L, circAHCY, circKIAA0319, circPOLR2A, and circPTPRF—are predicted targets of a shared group of RBPs: the IGF2BP family. IGF2BPs are known to regulate key oncofetal proteins such as MYC, IGF2, and β-catenin, and also act as readers of N6-methyladenosine (m^6A) RNA modifications, which are involved in cancer-related signaling pathways including PI3K/AKT, Wnt/β-catenin,

and MAPK/ERK. **Conclusion:** These findings suggest that IGF2BPs may contribute to MASH pathogenesis by binding to and regulating key circRNAs, thereby altering hepatic metabolic and inflammatory responses. Future studies are warranted to validate the functional impact of these circRNA–IGF2BP interactions in vitro and in vivo, and assess their potential as diagnostic biomarkers or therapeutic targets in MASH.

2031 | PREDICTORS OF LONGITUDINAL CHANGES IN LIVER CORRECTED T1 VALUE BASED ON UK BIOBANK COHORT

Ju Dong Yang[1] Minsun Kwak[2] Hyunseok Kim[3] Yufeng Wang[3] Lixia Wang[1] Walid Ayoub[1] Alexander Kuo[1] Paul Martin[1] Hirsh Trivedi[1] Aarshi Vipani[3] Yun Wang[1] Stephen Pandol[1] Debiao Li[1] Shelly Lu[1] Mohammad Saeid Rezaee-Zavareh[4] Abdelrahman Attia[1], [1]Cedars-Sinai Medical Center, [2]Seoul National University Hospital Gangnam Center, Seoul, South Korea, [3]Cedars Sinai Medical Center, [4]Middle East Liver Diseases (MELD) center, Tehran, Iran

Background: Corrected T1 (cT1), measured by liver MRI, is a non-invasive biomarker reflecting hepatic fibro-inflammation. Our recent study showed that a cT1 with a lower cut-off value (≥700ms) was associated with increased all-cause mortality, cardiovascular mortality and liver-related events. However, little is known about factors influencing longitudinal changes in liver cT1. The aim of this study was to investigate predictors of cT1 trajectory in individuals who underwent at least two liver MRI scans. **Methods:** Participants who performed two consecutive liver MRI were included among UK Biobank cohort. Participants were categorized into four groups based on serial cT1 measurements as follows; Group 1 (cT1 <700ms at both exam), Group 2 (cT1 <700ms at baseline, ≥700ms at follow-up), Group 3 (cT1 ≥700ms at baseline, <700ms at follow-up), Group 4 (cT1 ≥700 ms at both). Multinomial logistic regression adjusted by age, sex, number of cardiometabolic risk factors, smoking, alcohol, diet, physical activity, and PNPLA3 genotype was performed to compare Group 2 vs. Group 1 (worsening), and Group 3 vs. Group 4 (improved). **Results:** Among total of 2,467 participants with longitudinal MRI measurement, 1,132 (45.9%) were in Group 1, 312 (12.7%) in Group 2, 210 (8.5%) in group3, and 813 (33.0%) in Group 4. Median follow-up duration between the first and the follow-up MRI was 26.7 months (interquartile range 26.2-27.7 months). Compared to individuals with stable cT1 values below 700ms (Group 1), those whose cT1 values worsened to 700ms or higher at follow-up (Group 2) were more likely to be male (Relative Risk Ratio, 1.40, [95% confidence interval, 1.03–1.91]), have three or more cardiometabolic risk factors (1.67, [1.20–2.34]), and more likely to carry the PNPLA3 GG genotype (2.18, [1.07–4.43]). Conversely, compared to individuals who maintained high cT1 values ≥700ms (Group 4), those whose cT1 improved to below 700ms at follow-up (Group 3) were less likely to have three or more cardiometabolic risk factors (0.37, [0.25–0.54]), more likely to engage in moderate-to-vigorous physical activity (2.61, [1.21–5.62]). **Conclusion:** In summary, cardiometabolic burden and genetics (PNPLA3 GG genotype) were important predictors of worsening liver cT1, while physical activity and lower cardiometabolic risk were associated with cT1 improvement. These findings suggest that lifestyle interventions and cardiometabolic risk factor control may influence hepatic fibro-inflammation progression or resolution.

2032 | GENETIC CONTRIBUTIONS TO FATTY LIVER DISEASE–RELATED LIVER CANCER

Ching-Wen Chang[1], [1]GIMOS, Taipei Medical University

Background: Obesity has emerged as a major global health burden, markedly increasing the prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) and its progressive form, metabolic dysfunction-associated steatohepatitis (MASH). These conditions are now recognized as key drivers of hepatocellular carcinoma (HCC), particularly in populations with rising obesity rates. Notably, liver cancer exhibits the strongest association with obesity among all cancer types, emphasizing the pivotal role of metabolic dysfunction in hepatic carcinogenesis. The growing incidence of MASH-related HCC, especially in Western countries, underscores the urgent public health challenge posed by obesity-linked liver diseases. Genetic susceptibility plays a critical role in determining MASLD and MASH outcomes. Among known variants, the PNPLA3 I148M allele is the most robustly associated with hepatic steatosis, inflammation, and fibrosis. However, interindividual differences in disease severity among carriers point to additional genetic modifiers. **Methods:** We searched genetic alleles among the 24 most significant alleles associated with body fat distribution from a genome-wide association study of 344,369 individuals and validated the top allele in 3 independent cohorts of American and European patients (N = 1380) with NAFLD/NASH/HCC. **Results:** Our research highlights DNAJA3, particularly the rs3747579-TT variant, as a novel contributor to MASH and MASH-related HCC. DNAJA3 encodes a mitochondrial chaperone that preserves mitochondrial integrity and cellular homeostasis. Its deficiency disrupts mitochondrial biogenesis, shifts energy metabolism toward glycolysis, and promotes lipid accumulation and cholesterol synthesis. We further observed a positive global correlation between MASH-related HCC prevalence and the frequency of the DNAJA3 eQTL variant, reinforcing its pathogenic relevance. Interaction analyses of DNAJA3 and PNPLA3 variants indicate that the convergence of mitochondrial and lipid dysregulation amplifies liver cancer risk. **Conclusion:** Together, our findings emphasize the importance of integrating genetic and metabolic insights in assessing liver cancer susceptibility in obesity. This work advances precision medicine by identifying actionable biomarkers for early detection and therapeutic targeting in MASH-related liver cancer.

Background: Fibrotic metabolic dysfunction-associated steatohepatitis (MASH) is the leading cause of all-cause and liver-related mortality. Radiomics could predict disease progression. We developed a diagnostic model for identifying fibrotic MASH using radiomics analysis based on hepatic vibration-controlled transient elastography (VCTE). **Methods:** A total of 163 patients with biopsy-proven metabolic dysfunction-associated steatotic liver disease (MASLD) were enrolled and divided into training (50%) and validation (50%) cohorts. The outcome was defined as Fibrotic MASH (NAS $\geq$4 and fibrosis stage $\geq$2). VCTE images were obtained and extracted 1209 radiomics feature, where 7 features were selected using Least absoluteshrinkage and selection operator regression. R Score was established using support vector machines based on selected features. The diagnostic model was constructed using multiple logistic regression based on R Score and clinical data, which performance was compared with previous models (Agile 3+, Agile 4, FAST, FIB-4, FNI, NFS). **Results:** Fibrotic MASH patients presented elder ages, higher AST, and higher liver stiffness measurement (LSM) than Non-Fibrotic MASH patients. The AST, R Score, LSM and age were combined to construct diagnostic model (ARLA). The ARLA model yielded best accuracy with AUROC of 0.86 (95% CI = 0.78-0.94) and 0.87 (95%CI = 0.78-0.95) in training and validation cohorts, respectively (Figure1 A-B). The decision curve analysis showed the ARLA model offered more benefit than other models in both cohorts. The calibration curves showed the ARLA model demonstrated acceptable consistency between predictive and actual outcomes in both cohorts. Moreover, the ARLA model exhibited highest correct classified proportion of 69% and 70% with the smallest grey zone of 16% in both cohorts (Figure 1C). Furthermore, the two-step approach based on FIB4 and ARLA exhibited smaller grey zone (4.9%) and higher correct classified proportion (70.4%) than traditional two-step approach based on FIB-4 and LSM (grey zone = 6.2% and correct classified proportion = 63.0%) (Figure 1D-E). The nomogram based on ARLA model was developed for clinical practice. **Conclusion:** The ARLA model satisfactorily identified the Fibrotic MASH patients with high accuracy, cost-effectiveness, and acceptability, which could be an effective and noninvasive tool for optimal management of MASLD patients.

Background: Current clinical guidelines recommend hepatocellular carcinoma (HCC) surveillance in patients with metabolic dysfunction-associated steatotic liver disease (MASLD) and cirrhosis when annual incidence exceeds 1%, but the role of noninvasive tests (NITs) in identifying suitable candidates remains unclear. In our previous study, fibrosis-related NITs showed good accuracy for predicting cirrhotic complications, but limited value in forecasting HCC. **Methods:** This cohort study utilized data from a natural history cohort of patients with MASLD who underwent vibration-controlled transient elastography (VCTE) at 16 tertiary referral centers across the United States, Europe, and Asia. Patients were stratified according to liver stiffness measurement (LSM) thresholds of 8 and 12 kPa into three groups: advanced fibrosis (AF), gray-zone, and non-AF. We evaluated the performance of LSM-based HCC risk scores, such as PLEASE score, as well as etiology-agnostic scores such as aMAP. These scores were compared with fibrosis-related NITs. Sensitivity analyses were performed using alternative LSM thresholds (10 and 15 kPa), as well as a two-step pathway incorporating Fibrosis-4 index followed by LSM. The primary outcome of interest was the development of HCC. **Results:** A total of 16,603 MASLD patients with available LSM data were included. Over a median follow-up of 51.7 months (interquartile range, 25.2–85.2), 139 patients (0.8%) developed HCC. Among those with AF or in the gray-zone, the aMAP score consistently showed the best discrimination for 3-, 5-, and 8-year HCC risk, with the highest area under the receiver operating characteristic curve and C-index values. Toronto HCC Risk Index (THRI) also performed well, with all metrics above 0.75. These results held across different LSM cutoffs (8/12, 10/15 kPa) and with the two-step stratification. We used established score cutoffs to stratify HCC risk in AF patients. Regardless of the LSM threshold or two step method, patients classified as high-risk by aMAP or THRI had 5-year HCC rates above 7%, exceeding the 1% annual threshold for surveillance. Conversely, 5-year incidence in low-risk groups remained below 0.8% for both scores. Notably, THRI classified nearly 50% of patients as intermediate-risk, while this proportion was much lower for aMAP. **Conclusion:** Among AF patients, LSM-based HCC risk scores performed worse than aMAP and THRI. Although THRI classified nearly 50% of MASLD patients as intermediate-risk, it only requires age, sex, and platelet count, making it practical in real-world settings, especially when lab data are limited. When additional parameters like bilirubin and albumin are available, aMAP is preferred for risk stratification.

Table 1. HCC risk stratification by aMAP and Toronto HCC risk index.

Non-invasive tests	Risk groups	HCCs (N)	Percentage in total HCCs	5-year HCC (%)	HCC incidence per 1 000 PY (95% CI)
LSM ≥12 kPa					
aMAP	<50	7	8.4	0.8 (0.3-1.9)	2.2 (2.1-2.3)
	50-60	24	28.9	2.8 (1.6-4.6)	6.6 (6.5-6.7)
	≥60	52	62.7	11.5 (8.1-15.4)	26.4 (26.2-26.6)
Toronto HCC risk index	<120	2	2.4	0.4 (0.3-2.2)	1.3 (1.2-1.4)
	120-240	43	51.2	3.1 (2.0-4.5)	7.1 (6.9-7.2)
	>240	39	46.4	11.2 (7.6-15.6)	25.9 (25.6-26.2)
LSM ≥15 kPa					
aMAP	<50	4	5.9	0.5 (0.1-2.3)	2.3 (2.2-2.4)
	50-60	19	27.9	3.2 (1.7-5.6)	7.7 (7.6-7.9)
	≥60	45	66.2	13.6 (9.4-18.3)	31.1 (30.8-31.4)
Toronto HCC risk index	<120	1	1.5	-	1.3 (1.1-1.4)
	120-240	33	47.8	3.6 (2.2-5.4)	8.4 (8.3-8.5)
	>240	35	50.7	14.1 (9.4-19.7)	33.2 (32.8-33.5)
Two step pathway for AF					
aMAP	<50	2	2.4	0.2 (0.1-1.1)	0.9 (0.8-0.9)
	50-60	27	32.9	2.2 (1.4-3.5)	4.6 (4.5-4.7)
	≥60	53	64.6	8.6 (6.2-11.4)	17.4 (17.2-17.5)
Toronto HCC risk index	<120	1	1.2	-	0.9 (0.8-0.9)
	120-240	40	48.2	2.6 (1.7-3.8)	5.2 (5.1-5.3)
	>240	42	50.6	7.6 (5.2-10.6)	16.1 (15.9-16.3)

Notes: AF: advanced fibrosis; CI: confidence interval; HCC: hepatocellular carcinoma; LSM: liver stiffness measurement; PY: person-years.

Background: There is a need for accurate high throughput blood based non-invasive tests (NITs) for assessing fibrosis severity within Metabolic dysfunction-Associated Steatotic Liver Disease (MASLD). The ADAPT algorithm has previously been calculated using a PRO-C3 ELISA technology with platelets, age, and diabetes status, however now transitioned to the Roche Cobas® e801 high throughput IVD analyzer. This study aimed to validate the diagnostic performance of the ADAPT algorithm using the Roche Elecsys® PRO-C3, within a well characterized European multicentre study cohort. **Methods:** This prospective, multicentre study included MASLD patients from the LITMUS study cohort with central read biopsy-confirmed fibrosis staging. In the current analysis a total of 1134 patients were included. ADAPT cut-offs were identified in a derivation cohort (n = 451) and tested in a validation cohort (n = 683) including all fibrosis stages: F0 (n = 84), F1 (n = 140), F2 (n = 207), F3 (n = 179), and F4 (n = 73) all originating from the LITMUS study cohort. PRO-C3 was assessed by the Cobas® e801 analyzer. The area under the receiver operating characteristic curve (AUROC) as well as sensitivity at given specificity was used to evaluate the performance in assessing fibrosis severity for significant- ($F \geq 2$), and advanced ($F \geq 3$), liver fibrosis and cirrhosis (F4). **Results:** Elecsys® PRO-C3 as part of the ADAPT algorithm demonstrated strong diagnostic accuracy for detecting fibrosis severity, with AUROC values of 74% (95% CI: 70%-78%) for significant fibrosis (F2-F4) with a cutoff of $\geq$ 10.03; 80% (95% CI: 77%-84%) for advanced fibrosis (F3-F4) with a cutoff of $\geq$ 10.18; and 85% (95% CI: 81%-89%) for cirrhosis (F4) with a cutoff of $\geq$ 11.07. The diagnostic performance at different ADAPT cutoffs were as follows: for significant fibrosis (F2-F4), specificity was 93% (95% CI: 89%-96%) and sensitivity was 34% (95% CI: 29%-38%); for advanced fibrosis (F3-F4), specificity was 90% (95% CI: 87%-93%) and sensitivity was 46% (95% CI: 40%-52%); for cirrhosis (F4), specificity was 91% (95% CI: 88%-93%) and sensitivity was 51% (95% CI: 40%-62%). **Conclusion:** Three potential ADAPT cut-offs were identified for clinically relevant target conditions in MASLD. It was shown, that the ADAPT algorithm is a tractable non-invasive tool for assessing the severity of fibrosis in MASLD, and that a

comparison to other NITs is warranted. Its integration into clinical pathways could improve early detection of disease, fibrosis risk stratification and guide appropriate patient management.

2037 | DOES SUBCUTANEOUS FIBROSIS PREDICT THE SEVERITY OF LIVER FIBROSIS?

Alina Iuliana Onoiu[1] Li Chen[2] Adi Lightstone[2] David Parada[3] Jorge Joven[4], [1]Unitat de Recerca Biomèdica, Hosital Universitari Sant Joan, Universitat Rovira i Virgili, 43204 Reu, [2]PharmaNest Inc., Princeton, New Jersey, USA, [3]Department of Pathology, Hospital Universitari Sant Joan, 43204, Reus, Spain, [4]The Campus of International Excellence Southern Catalonia, 43003, Tarragona, Spain

Background: Metabolic dysfunction-associated steatohepatitis (MASH) in patients with severe obesity often progresses to advanced liver fibrosis or cirrhosis. Given the systemic nature of fibrotic processes in obesity, subcutaneous fibrosis may reflect hepatic disease severity. This study uses quantitative digital pathology image analysis to evaluate whether subcutaneous fibrosis can serve as a minimally-invasive predictor of liver fibrosis in patients with severe obesity, biopsy-confirmed MASH and F2-3 fibrosis. **Methods:** This retrospective cohort study included 40 patients with histologically confirmed MASH, diagnosed via liver biopsy and evaluated according to the NASH CRN criteria by expert pathologists. The cohort consisted of 20 patients with stage F2 fibrosis and 20 with stage F3 fibrosis. FFPE sections (~4 microns) of liver and subcutaneous adipose tissue biopsies were stained with Picrosirius Red. The slides were digitized (Ventana DP200 at 40X) and analyzed using FibroNest™ for quantitative image analysis. For each etiology, the fibrosis phenotype was described for its collagen content (12 traits), the morphometric traits of the collagen fibers (12), and fibrosis architecture traits (7). Each trait was quantified with 7 quantitative fibrosis traits parameters (qFTs) to account for severity, distortion, and variance, resulting in a total of 448 qFTs. As reported elsewhere (doi; 10.1111/liv.15768), the FibroNest Phenotypic Fibrosis composite score (Ph-FCS, established from a selection of qFT that best classify early from advanced liver fibrosis in patients with MASH). Similarly, qFTs that would exhibit a significant ($p < 0.05$) and meaningful ($> 20\%$) relative difference (group average) between the F2 and F3 groups of adipose tissue (AT) samples we selected and assembled in a equi-weighted phenotypic composite score Ph-PCS(AT). **Results:** Contrary to the Ph-FCS values that were well aligned with

NASH-CRN fibrosis stages, the correspondence of the Ph-FCS(AT) with NASH-CRN fibrosis stages was moderate ($p = 0.047$. Ph-FCS(AT) showed a modest performance (AUROC = 0.652 [95%CI: 0.480 – 0.825] to help diagnose F2 from F3 patients from adipose tissue biopsies. **Conclusion:** Sophisticated quantitative Digital Pathology Image analysis found moderate associations between the histological fibrosis phenotypes of subcutaneous tissue and liver biopsies. Subcutaneous biopsies cannot be used to predict the associated Liver NASH-CRN stage with a performance that is acceptable in the context of clinical care.

2038 | SERUM HISTAMINE N-METHYLTRANSFERASE AS A POTENTIAL BIOMARKER FOR LIVER HISTOLOGIC SEVERITY IN MASLD: INSIGHTS FROM IMMUNE-RELATED PROTEOMIC SIGNATURES

Rui-Xu Yang[1] Yi-Wen Shi[1] Qin Li[1] Jian-Gao Fan[1], [1]Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medicine

Background: Metabolic inflammation are believed to play important role in the development of metabolic-dysfunction associated steatotic liver disease (MASLD), the changes in peripheral immune proteomics might provide insights to pathogenesis of MASH and fibrosis. This study explored serum immune proteome panel in the patients of MASLD diagnosed by liver biopsy and aimed to evaluate the immune features associated with liver histological feature. **Methods:** In a MASLD cohort, which prospectively included healthy check-up subjects (n = 43), subjects diagnosed with MASLD (n = 221) by liver biopsy, in which 83.26% were metabolic-dysfunction associated steatohepatitis (MASH). Serum immune protein profiles using the Olink Proximity Extension Assay platform was assessed for association of histologic severities in MASLD and with other biomarkers as follows: anthropometric and inflammation biochemical indicators, and transient resonance elastography. **Results:** We identified 92 serum immune proteins in the MASLD cohort. There were distinct serum immune features between healthy control and MASLD subjects. In the subgroup analysis of histology features of steatosis, inflammation and fibrosis, we identified the top differentiated immune protein: histamine N-methyltransferase (HNMT), which showed the most prominent association with the histological severities of steatosis, steatohepatitis and fibrosis and the correlation analysis with serum inflammatory markers including aminotransferase, C-reactive protein and cytokeratin 18. **Conclusion:** The increased serum HNMT, which used to be associated hypersensitivity disease, might reflects the chronic low-grade inflammation status of MASLD. HNMT showed the prominent association with the histological severities especially in MASH in patients of MASLD, which might provide new targets for potential pathogenesis exploration and non-invasive marker.

2039 | PROSPECTIVE COHORT STUDY IDENTIFIES DIETARY AND ORAL MICROBIAL SIGNATURES ASSOCIATED WITH SIGNIFICANT MASLD FIBROSIS

Xiaotao Zhang[1] Yulu He[1] Ruoxi Yang[1] Maryfe Coronel Novoa[1] Jiangyuan Zhu[1] Yuqing Liu[1] Kamileh Rivera[1] Ziyan Ma[1] Mark Miller[1] Asher Leviton[1] Frances Lee[1] Ilaria Mogno[1] Jeremiah Faith[1] Mirela Berisa[1] Daniel Puleston[1] Kai Nie[1] Seunghee Kim-schulze[1] Augusto Villanueva[2] Ryan Walker[1] Emanuela Taioli[1] Scott Friedman[3] Meena Bansal[3], [1]Icahn School of Medicine at Mount Sinai, [2]NYU Langone Health, [3]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: While gut microbiome has been extensively studied, the role of oral microbiome in liver fibrosis remains less explored. This prospective cohort study investigated associations between dietary intake, oral microbiome, host metabolites and proteins profiles and their collective relationship to MASLD fibrosis. **Methods:** Forty-four MASLD adults were prospectively enrolled, excluding those with viral hepatitis, excessive alcohol use, dental issues, other chronic liver diseases, or recent antibiotics/

probiotics. Liver stiffness (kPa) was used as a fibrosis surrogate; ≥8 kPa indicated significant fibrosis, and >30% increase between sequential LSM assessments in previous year defined rapid progression. Dietary intake was assessed using NCI Dietary Screener Questionnaire. Oral microbiome (metagenomics), serum metabolomics (LC-MS), and plasma proteomics (Olink) were profiled. α-diversity (Shannon) was compared using Mann-Whitney U test. Differentially abundant microbial taxa associated with fibrosis progression were identified using MaAsLin2, while key metabolomic and proteomic signatures linked to significant MASLD fibrosis were visualized using volcano plots. Relationships among diet, key oral microbiota, metabolites and proteins were assessed via Spearman correlations. **Results:** At baseline, 44% of patients had significant MASLD fibrosis, and lower α-diversity (Shannon) was significantly associated with higher LSM ($\beta = -6.8$, $p = 0.035$). Patients with rapid fibrosis progression had higher relative abundances of *Streptococcus*, *Lautropia* and *Atopobium*, with lower relative abundances of *Prevotella*, *Veillonella* and *Alloprevotella*. Significant MASLD fibrosis was associated with higher levels of oxidative stress (e.g., 7-methylguanine, N-acetylputrescine), immune activation (e.g., IL-17C, CD8A, PD-L1), and matrix remodeling markers (e.g., MMP-10, uPA), and lower levels of antioxidants (e.g., taurine, piperine) and immune-regulatory markers (e.g., MCP-2, TRANCE) (Figure 1). No nutrients were associated with significant MASLD fibrosis, but added sugar intake correlated with pro-fibrotic taxa (e.g., *Atopobium*, $r = 0.44$, $p = 0.005$) and immune markers (e.g., IL-17C, $r = 0.38$, $p = 0.049$). **Conclusion:** Higher liver stiffness was associated with lower oral microbial α-diversity. Significant MASLD fibrosis was associated with elevated circulating markers of oxidative stress and immune activation, and lower levels of antioxidant and immune-regulatory markers. Fibrosis progression was linked to increased abundance of pro-fibrotic oral taxa. Added sugar intake was positively associated with pro-fibrotic microbes and immune activation. Given increased accessibility of oral microbiome samples at point of care, these findings may lead to novel approaches for tracking impact of interventions on oral-liver axis and understanding their mechanistic roles in driving fibrosis progression.

2040 | LARGE LANGUAGE MODELS (LLMS) ACCURATELY EXTRACT VCTE MEASUREMENTS FROM UNSTRUCTURED DOCUMENTATION AND ENABLE AT-SCALE PREDICTIVE MODELING IN REAL-WORLD COHORTS

Aryana Far[1] Aryan Ayati[1] Jordan Guillot[1] Shadera Azzam[1] Vivek Rudrapatna[1] Jin Ge[1], [1]University of California, San Francisco

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is a leading cause of cirrhosis. Vibration Controlled Transient Elastography (VCTE) measurements are commonly used to stratify disease severity, but they are often only available in unstructured documentation and therefore poorly available for clinical research. Recent advances in LLMs enable accurate extraction of clinical variables and measurements from unstructured notes, offering new opportunities for large-scale analyses in real-world cohorts of patients with compensated MASH cirrhosis. **Methods:** We used an established cohort of 493 patients with compensated MASH cirrhosis from the University of California, San Francisco (UCSF). We selected 1,670 de-identified clinical notes referencing VCTE and evaluated the accuracy of GPT-4o and Claude 3.5 Sonnet in extracting FibroScan stiffness and Controlled Attenuation Parameter (CAP) measurements. We used multivariate LASSO-Cox regressions to assess the association of these LLM-extracted measurements with the composite outcome of death or decompensation. **Results:** LLM-extraction identified 148 patients with stiffness and 117 with CAP available. Compared with manual chart review of a 20% random sample, GPT-4o achieved 100% accuracy for extracting stiffness and CAP, while Claude 3.5 Sonnet achieved 100% for stiffness and 92% for CAP. Extraction required about 6.5 million tokens for both models,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

costing approximately $0.012 per case for GPT-4o (~ $42.54 total) and $0.014 per case for Claude 3.5 Sonnet (~$48.34 total). GPT-4o was approximately 24% faster than Claude 3.5 Sonnet. In LASSO-Cox regression including 58 structured clinical variables (e.g., age, race/ethnicity, MELD, medications) and LLM-extracted measurements, stiffness (HR 1.02, 95% CI 1.00-1.05, p = 0.03) and CAP (HR 0.99, 95% CI 0.99-1.00, p = 0.05) were identified as significant predictors of the composite outcome. **Conclusion:** LLMs can extract FibroScan/VCTE parameters from clinical reports with high accuracy and low cost. When incorporated into regression modeling, extracted stiffness and CAP values are highly associated with progression to high-impact outcomes like mortality and decompensation. Given the scalability of LLM-based approaches and the growing availability of PHI-secure APIs to popular LLMs like GPT-4o and Claude, academic medical centers should facilitate their adoption for research and quality improvement for chronic liver diseases like MASH.

Background: Fibrosis-4 (FIB-4) is a widely used first-line non-invasive test (NIT) for risk-stratification of patients with MASLD, with FIB-4 <1.30 (<2.0 in patients ≥ 65 years) indicating low risk and ≥ 2.67 or ≥ 3.25 suggesting elevated or high risk of advanced fibrosis. The aim was to assess performance of FIB-4 in patients with biopsy-proven MASLD across different age groups. **Methods:** The Global MASLD (G-MASLD) project enrolled MASLD patients with liver biopsy, and laboratory data (FIB-4). Cutoff values for predicting advanced fibrosis (F3-F4) were analyzed by age group. **Results:** 16,867 patients with biopsy and FIB-4 data from 40 countries were included: age 51 ± 13 years, 48% male, 46% type 2 diabetes (T2D), 35% advanced fibrosis. The crude AUC of FIB-4 for predicting advanced fibrosis was 0.80 (95% CI 0.79-0.81), with substantial variability across age-based subgroups: 0.72 (0.68-0.75) in <35 years, 0.78 (0.77-0.79) in 35-64 years, and 0.71 (0.69-0.73) in ≥ 65 years. The low risk cutoff of 1.30 returned pooled sensitivity of 74% (73%-75%) with specificity of 72% (71%-73%); that, however, included sensitivity of 20% (15%-25%) with specificity of 95% (94%-96%) in patients <35 years, 71% (70%- 73%) with 72% (71%-73%), respectively, in 35-64 years, and 92% (91%- 93%) with 26% (24%-29%), respectively, in ≥ 65 years; the respective positive and negative predictive values varied across the age groups from 31% to 62% and from 71% to 91%, respectively. In order to maintain consistent sensitivity of 80% (low risk criterion, to rule out advanced fibrosis), the FIB-4 cutoff of 0.50 would be needed in the <35 years group vs. 1.10 in 35-64 years group and 1.65 in the ≥ 65 years group; even more granular cutoff use may be warranted within those groups (Figure). Similarly, the cutoff of 2.67 returned pooled sensitivity/specificity of 28% (27-29%)/95% (94-96%) which was 4% (2-7%)/99% (98-99%) in the <35 years group, 24% (23-25%)/96% (95-96%) in 35-64 years, and 45% (42-47%)/84% (82-86%) in ≥ 65 years. For the specificity of

95% (high risk criterion, to rule in advanced fibrosis), the age-specific FIB-4 cutoffs would be as follows: 1.33 in <35 years, 2.60 in 35-64 years, and 3.95 in ≥ 65 years. **Conclusion:** The use of FIB-4 cutoff values without adjustment for age results in substantially varying accuracy. Given that FIB-4 is routinely used as the first line NIT, the use of granular age-specific cutoff values, particularly those identifying low-risk patients, may be needed.

2042 | DEVELOPMENT OF A NEURAL NETWORK TO DETECT HEPATIC STEATOSIS IN METABOLIC DYSFUNCTION–ASSOCIATED STEATOTIC LIVER DISEASE

Masashi Hirooka[1] Teruki Miyake[2] Ryo Yano[2] Yoshiko Nakamura[2] Yuki Okazaki[2] Toyoki Shimamoto[2] Takao Watanabe[2] Osamu Yoshida[2] Yoshio Tokumoto[2] Masanori Abe[2] Yoichi Hiasa[2], [1]Ehime University Hospital, [2]Ehime University Graduate School of Medicine

Background: Early identification of metabolic dysfunction-associated steatotic liver disease (MASLD) is critical for risk stratification and timely intervention. Conventional non-invasive indices (Fatty Liver Index (FLI), Hepatic Steatosis Index (HSI), Zhejiang University (ZJU) index, and MASLD index) are limited by linear assumptions and moderate predictive accuracy. We aimed to develop and externally validate a neural network model for non-invasive detection of hepatic steatosis. **Methods:** We used a retrospective cohort of 17,465 Japanese health checkup participants (2010–2020). The cohort was split into a development cohort (n = 8,426) and an internal validation cohort (n = 9,039). A feedforward neural network was trained using clinical and biochemical variables, including body mass index (BMI), abdominal circumference, and existing indices. External validation used the NHANES III cohort (n = 2,759), with hepatic steatosis defined by ultrasonography (GUPHSPFR ≥ 2). Model performance was assessed via area under the receiver operating characteristic curve (AUC), calibration, decision curve analysis (DCA), and subgroup analyses. **Results:** The neural network achieved an AUC of 0.922 (95% CI: 0.913–0.931) in internal validation and 0.924 (95% CI: 0.917–0.931) in external validation, outperforming FLI, HSI, ZJU, and MASLD indices (all $p < 0.001$). At the optimal Youden cutoff (0.357), sensitivity and specificity were 89% and 86%, respectively. Calibration analysis and DCA confirmed strong agreement between predicted and observed risk. Abdominal circumference and BMI were the most influential predictors. **Conclusion:** Our neural network model outperforms conventional indices in detecting moderate-to-severe hepatic steatosis and may facilitate early, scalable MASLD screening in primary care and low-resource settings.

2043 | RISK OF SUBCLINICAL CARDIOVASCULAR DISEASE IN US ADULTS WITH LEAN MASLD: A POPULATION-BASED ASSESSMENT USING CARDIAC BIOMARKERS

Sarpong Boateng[1] PRINCE AMEYAW[1] Yussif Issaka[1] Ikechukwu Eze[2] GUY LOIC NGUEFANG TCHOUKEU[3] Isaac Adjei Opoku[1] Yazan Al-Ajlouni[4] Eunice Omeludike[5] Basile Njei[2], [1]Yale New Haven Health, Bridgeport Hospital, [2]Yale University, [3]Texas Tech University Health Science Center, Permian

Basin, [4]Staten Island University Hospital (Northwell), [5]Piedmont Athens Regional Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly recognized as a systemic cardiometabolic disorder. While obesity is a hallmark feature of MASLD, its occurrence in lean individuals represents a clinically distinct and understudied phenotype. Cardiovascular disease (CVD) remains the leading cause of mortality in MASLD, yet the burden of subclinical CVD among lean individuals with MASLD remains poorly defined. Cardiac biomarkers such as high-sensitivity cardiac troponin T (hs-cTnT) and N-terminal pro–B-type natriuretic peptide (NT-proBNP) allow for early detection of myocardial injury and hemodynamic stress. We aimed to characterize the burden of subclinical CVD among US adults with lean MASLD. **Methods:** We used data from the All of Us Research Program (2016–2022) to identify adults aged ≥ 18 years without known CVD (including prior myocardial infarction, heart failure, atrial fibrillation, or stroke). We also excluded participants with a history of cancer, and those with missing covariates. Lean MASLD was defined as a diagnosis of MASLD and body mass index (BMI) < 25 kg/m². Subclinical CVD was defined as either elevated hs-cTnT (≥ 14 ng/L) or NT-proBNP (≥ 125 pg/mL). We estimated the prevalence of subclinical CVD among individuals with lean MASLD and compared it to those without MASLD. Poisson regression with robust standard errors was used to estimate adjusted relative risks (aRRs), controlling for age, sex, race/ethnicity, BMI, smoking status, medications, hypertension, hyperlipidemia, diabetes, and chronic kidney disease. **Results:** Among 6,871 adults included in the analysis, 493 (7.2%) had lean MASLD. Subclinical CVD was present in 40.2% of individuals with lean MASLD compared to 34.5% of those without MASLD. In fully adjusted models, lean MASLD was independently associated with elevated risk of subclinical CVD (aRR: 1.38, 95% CI: 1.07–1.70, $p = 0.015$). In stratified analyses, subclinical CVD prevalence increased with age—from 28.2% among adults < 50 to 52.8% in those ≥ 80 years. Prevalence was slightly higher among women (40.3%) than men (39.6%). Among racial/ethnic groups, Black adults with MASLD had the lowest prevalence (15.8%) compared to Hispanic (40.3%) and White (42.3%) individuals. **Conclusion:** Lean MASLD is independently associated with a higher burden of subclinical cardiovascular disease, even after accounting for traditional cardiometabolic risk factors. These findings suggest that lean individuals with MASLD should not be overlooked for CVD risk screening and may benefit from early biomarker-based surveillance strategies.

2044 | UNSUPERVISED PARTITIONAL CLUSTERING OF HEMOGLOBIN A_{1C} (HBA_{1C}) LEVEL AND TRAJECTORY STRATIFY THE RISK OF LIVER-RELATED COMPLICATIONS IN PATIENTS WITH TYPE 2 DIABETES (T2D)

Nana Peng[1] Sherlot Juan Song[1] Mary Yue Wang[1] Jimmy Che-To Lai[1] Grace Lai-Hung Wong[1] Vincent Wong[1] Terry Cheuk-Fung Yip[1], [1]The Chinese University of Hong Kong

Background: The relationship between glycemic control indicated by HbA_{1c} levels and trajectories and liver-related complications in patients with T2D remains unclear. We aimed to examine whether HbA_{1c} level and early-stage trajectories impact the risk of liver-related complications, including hepatic decompensation, hepatocellular carcinoma, and liver-related death in patients with T2D, and to what extent optimal glycemic control would benefit patients at high risk of liver outcomes. **Methods:** A territory-wide retrospective cohort of patients with T2D from 2000-2016 was identified in Hong Kong. Patients with type 1 diabetes, chronic viral hepatitis, excessive alcohol use, or liver-related complications before baseline or follow-up < 5 years were excluded. Unsupervised partitional clustering was applied to identify trajectories by testing the number of clusters (k) from 1 to 6. Various distance measures with centroid calculation were employed, including Euclidean distance, dynamic time wrapping (DTW) and move-split-merge (MSM) with arithmetic mean, DTW with DTWbarycenter averaging (DBA), and MSM with MSM barycenter averaging (MBA). Cluster validity indices were summarized to determine the optimal k and the best-performing algorithm. The association between HbA_{1c}

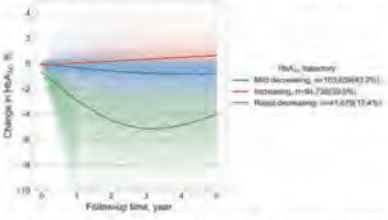
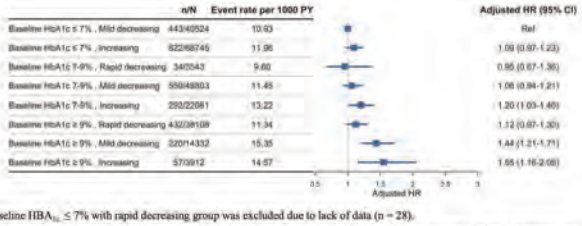
level and trajectories with liver-related complication risk was evaluated using cause-specific hazards models, with non-liver-related death as competing risk. Variation of each trajectory stratified by HbA_{1c} level was quantified by linear mixed models. **Results:** Among 240,076 patients, MSM-MBA identified 3 robust HbA_{1c} trajectories in the first 5 years after T2D diagnosis: mild decreasing (n = 103,659[43.2%]), increasing (n = 94,738[39.5%]) and rapid decreasing (n = 41,679[17.4%]). (Figure A) Patients with baseline $HbA_{1c} \geq 9\%$ had a higher risk (hazard ratio [HR], 1.42 [95% CI, 1.23-1.64]) compared to those with $HbA_{1c} \leq 7\%$. Compared to mild decreasing, patients with rapidly decreasing HbA_{1c} showed a lower risk(HR, 0.80 [95% CI, 0.69-0.92]), while those with increasing HbA_{1c} had a higher risk (HR, 1.10 [95% CI, 1.01-1.20]). Compared to a mild decreasing trajectory with $HbA_{1c} \leq 7\%$, patients with HbA_{1c} levels of 7-9% with an increasing trend, or $\geq 9\%$ with either a mild decreasing or increasing trend, had higher risks of liver-related complications (HR, 1.20 [95% CI, 1.03-1.40], 1.44 [95% CI, 1.21-1.71], and 1.55 [95% CI, 1.16-2.05], respectively), while notably, those with $HbA_{1c} \geq 9\%$ and a rapid decreasing trend did not show increased risk (HR, 1.12 [95% CI, 0.97-1.30]). (Figure B and C) **Conclusion:** Higher baseline HbA_{1c} levels and increasing trajectory are associated with a higher risk of liver-related complications in T2D, while rapid decreasing trajectory is associated with a lower risk. Good glycemic control over time mitigates the risk associated with higher baseline HbA_{1c} levels.

Figure A. HbA_{1c} trajectories across the first 5 years after T2D diagnosis identified by MSM-MBA.



* Individual data belonging to each trajectory was randomly sampled 1,000 times for visualization, and trajectories were fitted using generalized additive models with shrinkage cubic regression splines and 3 knots.

Figure B. Joint association between baseline HbA_{1c} level and HbA_{1c} trajectory and liver-related complications risk in patients with T2D.



* Baseline $HBA_{1c} \leq 7\%$ with rapid decreasing group was excluded due to lack of data (n = 28).

** HRs were adjusted by age, sex, albumin, total bilirubin, platelets, creatinine, ALT and ALT trajectories, cirrhosis, hypertension, dyslipidemia, and the use of statin, insulin, metformin, sulfonylureas, thiazolidinedione, DDP-4 inhibitors, SGLT2 inhibitors and GLP-1 receptor agonists.

Abbreviations: CI = confidence interval, HbA_{1c} = hemoglobin A_{1c}, HR = hazard ratio, MSM-MBA = move-split-merge with MSM barycenter averaging, PY = person years, T2D = type 2 diabetes.

Figure C. Slope and 95% CI of trajectories stratified by baseline HbA_{1c} level group.

	Annual change in HbA_{1c} (95% CI)* (%/year)		
	Mild decreasing	Increasing	Rapid decreasing
Baseline $HbA_{1c} \leq 7\%$	-0.082 (-0.083 to -0.081)	0.152 (0.151 to 0.153)	-0.228 (-0.297 to -0.158)
Baseline HbA_{1c} 7-9 %	-0.180 (-0.181 to -0.179)	0.156 (0.154 to 0.159)	-0.348 (-0.355 to -0.341)
Baseline $HbA_{1c} \geq 9\%$	-0.381 (-0.385 to -0.377)	0.140 (0.129 to 0.150)	-0.700 (-0.704 to -0.696)

2045 | FIBRO-GPT: A LARGE LANGUAGE MODEL FOR ACCURATE PREDICTION OF ADVANCED LIVER FIBROSIS IN MASLD

Basile Njei[1] Nelvis Njei[2] Ysabel Ilagan-Ying[1] Omar Al Ta'ani[3] Sarpong Boateng[4] Yazan Al-Ajlouni[5] Bubu Banini[1], [1]Yale University, [2]Machine Learning and Artificial Intelligence Center, MD, USA, [3]Allegheny Health Network, [4]Yale New Haven Health, Bridgeport Hospital, [5]Department of Medicine, Staten Island University Hospital, NY, USA

Background: Noninvasive liver disease assessment (NILDA) tools, such as Fibrosis-4 index (FIB-4) and NAFLD fibrosis score (NFS), are frequently used to identify patients with metabolic dysfunction-associated steatotic liver disease (MASLD) at risk of advanced fibrosis ($\geq$F3). However, their predictive accuracy is limited. Unlike traditional tools, large language models (LLMs) can dynamically adapt to new data and provide contextual rationales for predictions. Fibro-GPT, a generative pre-trained transformer (GPT)-4-based LLM model, fine-tuned for tabular prediction, was developed to enhance the detection of advanced fibrosis in MASLD. **Methods:** The LLM-based pipeline was developed on a derivation cohort of adults with MASLD (N = 1487) from NHANES 2017–2020. MASLD was defined by hepatic steatosis (CAP $\geq$274 dB/m) assessed on vibration-controlled transient elastography

(VCTE) and at least one cardiometabolic criterion, excluding individuals with significant alcohol use (≥1 drink/day for women, ≥2 drinks/day for men) or viral hepatitis. Fibrosis stage was determined using a two-step method: blood-based NILDA tools (FIB-4, NFS), followed by VCTE. Patient data, including age, platelet count, HbA1c, eGFR, BMI, AST, and ALT, were formatted into standardized text prompts and submitted to GPT-4 via a secure Python Interface. Model performance was assessed by AUROC, sensitivity, specificity, Brier score, F1 score, and calibration plots, using bootstrapped 95% confidence intervals. For external validation, we applied the model to an independent biopsy-confirmed MASLD cohort from Yale (n = 105), where liver histopathology served as the gold standard for fibrosis staging. **Results:** In the derivation cohort, Fibro-GPT achieved an AUROC of 0.91, sensitivity of 84%, and specificity of 86% (Fig. 1). Fibro-GPT demonstrated superior predictive accuracy compared to FIB-4 (AUROC: 0.62; P < 0.001) for detecting advanced fibrosis. In the Yale biopsy cohort, Fibro-GPT maintained robust predictive performance, achieving an AUROC of 0.90 (95% CI 0.88–0.97), and outperformed FIB-4 (AUROC 0.75; p < 0.001). **Conclusion:** Fibro-GPT is a highly accurate LLM-based risk prediction model that improves the detection of advanced liver fibrosis compared to FIB-4 in patients with MASLD. These findings highlight the potential for LLMs to enhance the early detection of advanced liver fibrosis and support clinical decision-making in patients with MASLD. Prospective, multicenter studies are warranted to confirm real-world utility.

2046 | NOVEL MATRICELLULAR SERUM MARKER SCORES FOR IMPROVED PREDICTION OF LIVER FIBROSIS AND FIBROGENESIS IN PATIENTS WITH MASLD UNDERGOING BARIATRIC SURGERY

Rambabu Surabattula[1] Pierre Bel Lassen[2] Sudharani Myneni[1] Judith Aron-Wisnewsky[3] Laurent Genser[3] Jean-Daniel Zucker[4] Karine Clément[5] Detlef Schuppan[1], [1]University Medical Center Mainz, [2]Sorbonne Université, INSERM, Nutrition & Obesities: Systemic Approaches Research Group (NutriOmics)., [3]APHP, Nutrition and surgery departments, Pitié-Salpêtrière hospital), F-75013, Paris, France, [4]UMMISCO, Unité de Modélisation Mathématique et Informatique des Systèmes Complexes, [5]Sorbonne Université, INSERM, Nutrition & Obesities: Systemic Approaches Research Group (NutriOmics),

Background: Severe obesity is a risk factor for MAFLD, and the prevalence in patients eligible for bariatric surgery (BS) can reach 75-100%. We established novel serum markers for liver fibrosis and evaluated them in patients with severe obesity and MAFLD before and after undergoing BS. **Methods:** ELISA tests were established using combinations of recombinant proteins, commercial and self-produced monoclonal and polyclonal antibodies to measure the matricellular fibrosis markers TSP2 (thrombospondin 2), IGFBP7 (insulin like growth factor binding protein 7) and ADAMTS9 (a disintegrin and metalloprotease thrombospondin like-9) in 132 severely obese patients with matched liver biopsies. Sensitivity and specificity were optimized with less than 10% and 15% variation between serum and plasma tests, respectively. 54 patients had moderate to advanced fibrosis (stage F2-4) and 74 had stage F0-1 fibrosis. Follow-up fibrosis markers were analyzed in 51 patients 3 and 12 months after BS. **Results:** Patients with F2-4 vs F0-1 fibrosis displayed significantly higher mean baseline levels for TSP2 (88.6 vs 53.9) and IGFBP7 (208.8 vs 128 ng/ml). TSP2 & IGFBP7 were significantly higher in patients with severe fibrosis F3-4 (means 114.4 & 234.5 ng/ml, resp.) indicating more rapid fibrosis progression compared to fibrosis F0-2 (means 62 & 152.3 ng/ml, resp.). AUROC for fibrosis F2-4 or F3-4 vs F0-1 or F0-2 were 0.74 and 0.84 for TSP2, 0.84 and 0.78 for IGFBP7, and 0.72 and 0.70 for ADAMTS9. Given the good diagnostic performance of TSP2 & IGFBP7, we developed new algorithms (ADAPT-2 & ADAPTI) based on these 2 fibrosis markers along with age, diabetes and platelets. Both ADAPT-2 and ADPTI scores (AUROC: 0.86) out performed FIB4, ADAPT and TSP2 & IGFBP7 alone in detecting significant (≥F2) and advanced fibrosis (≥F3). Serum levels of matricellular markers were also correlated with insulin resistance and type 2 diabetes status. Levels of TSP2 were significantly

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

decreased 3 months after BS – most prominently in patients with baseline F2-4 fibrosis. The underlying biochemistry as well as the results support a prominent role of TSP2 in liver fibrogenesis, and of IGFBP7 (ADAMTS9) in metabolic-fibrogenic inflammation. **Conclusion:** In patients undergoing BS, the markers TSP2 and IGFBP7, and especially the TSP2 and IGFBP7 based algorithms (ADAPT2 and ADAPTI) showed the highest predictive value for F2-4 fibrosis and the antifibrotic effect of BS.

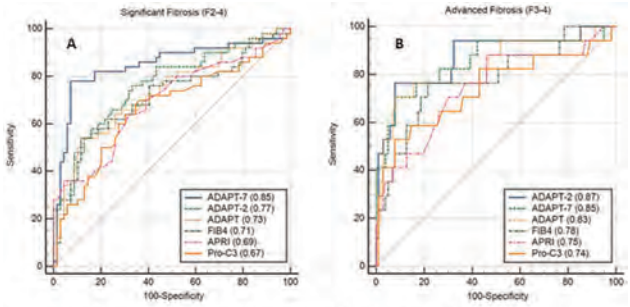

Figure 1. AUROCs to distinguish significant (A) and advanced fibrosis (B).

2047 | FAP INDEX: A NEW STATISTICAL MODEL IN IMPROVING TRIAGE FOR ADVANCED LIVER FIBROSIS IN OBESE OR METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC INDIVIDUALS USING A SPECIFIC MARKER OF ACTIVATED STELLATE CELLS AND MYOFIBROBLASTS

Bobby Boumelhem[1] Ziqi Vincent Wang[1] William Bachovchin[2] Geraldine Ooi[3] Jacob George[4] Mohammed Eslam[4] Leon Adams[5] Hui Zhang[1] Geoffrey McCaughan[1] Avik Majumdar[6] Mark Gorrell[1], [1]The Centenary Institute, The University of Sydney, Sydney, Australia, [2]Tufts University, Boston, United States of America, [3]Monash University, Melbourne, Australia, [4]Westmead Institute of Medical Research, The University of Sydney, Sydney, Australia, [5]The University of Western Australia, Perth, Australia, [6]The Austin Hospital, The University of Melbourne, Melbourne, Australia

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) drives chronic liver injury leading to fibrosis. Fibrosis is the major correlate of adverse health outcomes in MASLD. Non-invasive tests (NITs) for liver fibrosis must accurately discriminate fibrosis severity while minimising indeterminate results. Accurate blood test-based NITs are especially needed for primary screening in general practice, diabetes and obesity clinics. Currently, most NITs include a statistical model based on markers of hepatocyte damage rather than products of activated mesenchymal cells (stellate cells and fibroblasts) that create and regulate fibrosis. Fibroblast activation protein (FAP) digests collagens and TGFbeta precursors and is highly expressed by myofibroblasts and activated stellate cells in cirrhosis. Here, we investigated the utility of circulating FAP (cFAP) to detect fibrosis in MASLD. **Methods:** FAP shed from cell surfaces is an active enzyme that is stable in human serum and plasma. We applied our quantitative, specific, rapid, one-step FAP enzyme assay to sera from a bariatric cohort (training cohort, $n = 160$, 36% diabetic, 20.3% F3-F4) and a bariatric/MASLD cross-validation cohort ($n = 332$, 30% diabetic, 11.4% F3-F4). **Results:** Fibrosis was associated with cFAP in MASLD cohorts ($p < 0.05$). We coined the term FAP Index for a multi-variate model that was developed combining cFAP with age, diabetes status and ALT to evaluate liver fibrosis risk, especially in individuals who had an indeterminate result in an NFS or FIB4 test. The training cohort AUROC was 0.875 with a negative prediction value of 92% and a positive prediction value of 95%, indicating high accuracy. The cross-validation cohort AUROC was 0.84, with 98.5% specificity and 55% sensitivity. By serial application of NFS or FIB4 then FAP Index, the proportion of indeterminate results more than halved, to $< 15\%$. Therefore, applying cFAP measurement as a reflex test following an indeterminate FIB4 or NFS would likely have economies of time and expense, and lower the need for obesity-specialised secondary testing. **Conclusion:** We present a novel, inexpensive fibrosis NIT for assessment and triage of individuals with diabetes, steatosis or obesity. We suggest that an advantage of including FAP Index in clinical fibrosis assessments is that FAP is strongly expressed by liver cell types that regulate the extracellular matrix.

2048 | DEVELOPMENT, VALIDATION, AND PROGNOSTIC EVALUATION OF OBESITYLIVER SCORE FOR SIGNIFIEANT LIVER FIBROSIS IN OVERWEIGHT AND OBESITY POPULATION: A MULTICOHORT STUDY

Bicheng Ye[1] Shanghao Liu[1] Jie Zhang[2] Yilin Zhang[1] Caihong Gu[3] Rong Hu[3] Haiying Feng[4] Xibin Liu[4] Zhenyu Dai[5] Pinglei Pan[5] Yijun Tang[6] Zhongji Meng[6] Puqiang Liu[7] Jianping Zhang[7] Xiao Liang[8] Yongfen Zhu[8] Huizhen Fan[9] Jianwen Sheng[10] Qing He[11] Fengjuan Chen[11] Yong Pan[12] Ruyu Liu[12] Ji JianSong[13] Yanru Xie[13] Manguo Zhao[14] Lingxiao Wang[14] Junhong Yang[14] Yan Yang[14] Yang Hui[15] Zhao Yajuan[15] Yang Bo[16] Jing Wang[16] Shuli Hao[17] Youfang Gao[17] Tongqin Han[18] Yuxia Qi[18] Yongyi Zeng[19] Guo Zhang[20] Wenjuan Wang[20] Qiang Yan[21] Zhaowei Tong[22] Gao-Jun Teng[23] Qi Xiaolong[23], [1]Southeast University, [2]Huai'an Hospital Affiliated to Xuzhou Medical University, [3]The First People's Hospital of Lianyungang, [4]Huanghua People's Hospital, [5]Affiliated Yancheng Hospital, School of Medicine, Southeast University, [6]Taihe Hospital, Hubei University of Medicine, [7]Puxian People's Hospital, [8]Sir Run-Run Shaw Hospital, [9]Yichun People's Hospital, Yichun, [10]Yichun People's Hospital,Yichun,J, [11]Shenzhen third People's Hospital, [12]Xuzhou Infectious Diseases Hospital, [13]The Fifth Affiliated Hospital of Wenzhou Medical University, [14]Baiyin Central Hospital, [15]The Second Affiliated Hospital of Guangzhou Medical University, [16]General Hospital of Ningxia Medical University, [17]Bozhou People's Hospital, [18]Qingdao Public Health Clinical Center, [19]Mengchao Hepatobiliary Hospital of Fujian Medical University, [20]Guangxi Hospita1 Division of The First Affiliated Hospital, [21]Huzhou Central Hospital, [22]Huzhou Key Laboratory of Precision Medicine Research and Translation for Infectious Diseases, [23]Zhongda Hospital, Medical School, Southeast University

Background: Overweight and obesity are closely associated with liver fibrosis and adverse hepatic outcomes. This study aimed to develop a reliable tool for assessing liver fibrosis risk in primary care settings for overweight and obese populations. **Methods:** The ObesityLiver score was developed and validated using five independent cohorts from China, the United States, and England. In the derivation cohort, we used elevated liver stiffness ($\geq$8 kPa) for variable selection and built the model with ten machine learning algorithms. The score was validated across all cohorts to predict elevated liver stiffness, significant liver fibrosis (histological stage $\geq$F2), and liver-related outcomes at 5, 10, and 15 years. Predictive performance was assessed using receiver operating characteristic curves and Kaplan-Meier survival analysis. **Results:** In a derivation cohort of 2,731 participants, we developed ten distinct machine learning models and ultimately selected a gradient boosting machine model based on five pivotal biomarkers including body mass index, gamma-glutamyl transferase, aspartate aminotransferase, glycated hemoglobin percentage, and platelet count. The ObesityLiver score showed good accuracy for predicting elevated liver stiffness in the derivation cohort (AUC 0.81, 95% CI 0.78–0.85) and validation cohorts 1 (n = 3,544; AUC 0.78, 95% CI 0.74–0.81) and 2 (n = 2,371; AUC 0.81, 95% CI 0.78–0.83). Validation cohort 3 (n = 311), which used liver biopsy, also demonstrated strong diagnostic performance with an AUC of 0.77 (95% CI 0.71–0.82) for predicting significant liver fibrosis. The ObesityLiver score outperformed the fibrosis-4 index, non-alcoholic fatty liver disease fibrosis score, aspartate aminotransferase to platelet ratio index, LiverRisk score, and others in predicting significant liver fibrosis and elevated liver stiffness. Furthermore, in the prognosis cohort, the ObesityLiver Score demonstrated robust predictive ability for liver-related outcomes at 5, 10, and 15 years, with AUCs ranging from 0.76 to 0.83. **Conclusion:** The ObesityLiver score reliably identifies clinically significant liver fibrosis and elevated liver stiffness, predicts the risk of liver-related events for overweight and obesity populations in primary care.

2049 | PREDICTIVE VALUE OF NON-INVASIVE TESTS VARIES ACROSS NOVEL DATA-DRIVEN MASLD CLUSTERS

Nicolas Desmons[1] Guillaume Lassailly[1] Violeta Raverdy[1] Macine Bachir Abdelouahab[1] Robert Caiazzo[1] Helene Verkindt[1] Viviane Gnemmi[1] Emmanuelle Leteurtre[1] Philippe Mathurin[1] Guillemette Marot[1] Francois Pattou[1], [1]University of Lille

Background: Non-invasive tests (NITs) are increasingly used to identify patients with at-risk form of MASLD in the general population. The performance of NITs for detecting liver fibrosis and/or MASH may vary with patient characteristics (i.e. age or body mass index). Two novel data-driven endotypes of MASLD at risk for liver fibrosis and MASH have been recently identified (Raverdy et al., Nat Med, 2024 / PMID: 39653777) : the cardiometabolic (CM) cluster and the liver specific (LS) cluster. Despite displaying similar liver histological features, the newly described clusters are characterized by distinct underlying biological profiles and different clinical trajectories. The aim of this study was to compare the predictive value of common NITS to predict fibrotic MASH across novel data driven clusters. **Methods:** Participants in this retrospective study were unselected patients with class II–III obesity who underwent bariatric surgery, and for whom all necessary biological results and liver histology (CRN) were available. Patients were allocated to one MASLD cluster (CM, LS, or Control) using partionning around median hard clustering, based on six simple variables: age, BMI, HbA1c, ALT, LDL-cholesterol, and triglycerides, as initially described. We also calculated in each patient four NITs - fibrosis-4 index (FIB-4), NAFLD fibrosis score (NFS), NAFLD index (FNI), and Liver risk score (LRS) - and analyzed their predictive value to diagnose fibrotic MASH, defined as the coexistence of Steatostis, Ballooning, and Inflammation (≥ 1 each) and Fibrosis (≥ 2). The area under the receiver operating characteristic (AUROC) of the four NITs were calculated in each cluster and compared with DeLong's test. **Results:** A total of 1031 patients were enrolled (median age 42 years, 26% women; BMI 47 kg/m²; HbA1c 5.80%; ALT 27 IU/L; LDL 3.06 mmol/L; triglycerides 1.40 mmol/L). Among them, 132 (13%) were allocated to the CM, 73 (7%) to LS, and 826 (80%) to control cluster, with a prevalence of Fibrotic MASH of 13 (10%), 10 (14%) and 22 (3%) respectively ($p < 0.001$). Figure 1A displays median patient characteristics in each cluster. Figure 1B displays the AUROC (95% CI) to diagnose fibrotic MASH for each NITs across the three clusters. In CM, AUROC values were higher for FNI and LRS and significantly superior than for FIB-4 ($p < 0.001$) and NFS ($p < 0.001$). In LS, AUROC values were higher for NFS and FIB-4 but not significantly different from FNI and LRS. **Conclusion:** The performance of NITs to diagnose fibrotic MASH varied across novel data driven MASLD clusters. FIB-4 and NFS showed acceptable predictive value in patients with LS MASLD, but not in those with CM MASH. In the CM and control clusters, fibrotic MASH was best predicted by FNI and LRS. Our findings highlight the need to consider novel MASLD clusters when evaluating the predictive value of NITs.

A

B

NITs	Cardio-metabolic	Liver specific	Control	All patients
FIB-4	0.55 (0.37-0.74)	0.74 (0.59-0.89)	0.73 (0.62-0.85)	0.73 (0.65-0.8)
NAFLD Fibrosis Score	0.44 (0.27-0.62)	0.79 (0.67-0.91)	0.65 (0.53-0.77)	0.65 (0.58-0.73)
Liver Risk Score	0.75 (0.63-0.87)	0.61 (0.4-0.83)	0.85 (0.78-0.91)	0.82 (0.77-0.88)
Fibrotic Nash index	0.79 (0.66-0.93)	0.69 (0.55-0.83)	0.88 (0.81-0.96)	0.87 (0.82-0.91)

2050 | COMBINING SVCAM-1 OR TSP2 WITH FIB-4 FOR AN IMPROVED DETECTION OF PATIENTS WITH CIRRHOSIS

Sven Francque[1] Bérénice Alard[2] Jérémy Magnanensi[2] Zouher Majd[2] Dean Hum[3] Jerome Boursier[4] Bart Staels[5] Quentin Anstee[6] Vlad Ratziu[7] Arun Sanyal[8], [1]Department of Gastroenterology and Hepatology, Antwerp University Hospital, Antwerp, Belgium, [2]GENFIT SA, [3]GENFIT CORP, [4]Angers University, [5]University Lille 2, [6]Newcastle University, UK, [7]Service D' Hepatogastroenterologie (FR), [8]Virginia Commonwealth University

Background: Prevalence of MASH-related liver cirrhosis (F4) is increasing worldwide. Screening for this largely asymptomatic condition in primary care settings is of major importance as patients (pts) with compensated cirrhosis are at high risk of acute decompensation, development of HCC and liver-related mortality, leading their clinical management to be adapted accordingly. We aimed to compare the diagnostic performances of FIB-4 with single blood-based biomarkers (BM) and evaluate combinations of those BMs with FIB-4 for an improved detection of pts with F4. **Methods:** Among pts screened for potential inclusion in the RESOLVE-IT Phase 3 trial (NCT02704403), those with FIB-4 available and complete values on 40 circulating BMs of interest were selected (discovery cohort, N = 1,640). AUC and associated Delong tests were used to compare the overall performance of the BMs vs FIB-4 for the detection of F4. For BMs with at least similar AUC as FIB-4, cutoffs were derived to achieve similar specificity (spe) as FIB-4 at its threshold indicative of pts referral to specialists (2.67). Corresponding sensitivity (sen), PPV and NPV were computed and compared with FIB-4 ones. Performances of concomitant uses of FIB-4 and single BMs with their associated cutoffs were evaluated to identify conditions that either maximize sen or PPV. An independent single-center (Angers University Hospital, France) cohort of N = 220 pts recruited with suspected MASLD was used to validate the results. **Results:** In the discovery cohort, 5.5% (n = 90) of pts had F4 and FIB-4 achieved an AUC of 0.780 for the detection of those pts. Among the 40 BMs evaluated, 6 achieved similar AUC as FIB-4 and were considered as potential substitutes or for concomitant uses with FIB-4: TSP2 (0.814), sVCAM-1 (0.796), hyaluronic acid (0.784), A2M (0.773), TIMP-1 (0.769) and YKL-40 (0.750). Among these BMs, sVCAM-1 with a cutoff of 1,182 ng/mL was the only marker which detected F4 with a significantly higher sen than FIB-4 (0.42 vs 0.31, p = 0.0253) while keeping similar spe (0.93). Among all concomitant uses of FIB-4 and single BMs, the condition [FIB-4 $\geq$ 2.67 and sVCAM-1 $\geq$ 1,182 ng/mL] achieved the highest PPV, significantly surpassing FIB-4 alone (0.45 vs 0.21, p $<$ 0.0001) with higher spe (0.98 vs 0.93, p $<$ 0.0001) but lower sen (0.26 vs 0.31, p = 0.0253). The condition [FIB-4 $\geq$ 2.67 or TSP2 $\geq$ 98 ng/mL] exhibited the highest sen, significantly surpassing FIB-4 alone (0.59 vs 0.31, p $<$ 0.0001) with similar PPV (0.22 vs 0.21, p = 0.71) but lower spe (0.88 vs 0.93, p $<$ 0.0001). In the validation cohort, 7.8% (n = 17) of pts had F4. Overall, findings were validated in this population. **Conclusion:** sVCAM-1 and TSP2 showed high performances for the detection of pts with cirrhosis. Their concomitant use with FIB-4 significantly surpassed the performances of FIB-4 alone and could thus represent valuable BMs to deploy on large scale for improving the referral pathway in primary care.

2051 | LONGITUDINAL FOLLOW-UP OF A TGF-β PATHWAY-RELATED BIOMARKER PANEL THAT STRATIFIES HCC RISK IN CIRRHOTIC PATIENTS

Lopa Mishra[1] Xiyan Xiang[1] Richard Amdur[2] Brandon Mathew[3] Kirti Shetty[4] Herbert Yu[5] Linda Wong[6] Bibhuti Mishra[1] Sanjaya Satapathy[7] James Crawford[8] Lopa Mishra[1], [1]Feinstein Institutes for Medical Research & Cold Spring Harbor Laboratory, [2]The Institutes for Health Systems Science & Bioelectronic Medicine, [3]Feinstein Institutes for Medical Research, [4]University of Maryland, Baltimore, [5]University of Hawaii Cancer Center, [6]University of Hawaii, [7]Northwell Health and Donald and Barbara Zucker School of Medicine at Hofstra/Northwell, [8]Northwell Health

Background: Current screening for early diagnosis of HCC remains suboptimal particularly in obese individuals with MASLD/MASH. We and others have identified a major role of the TGF-β pathway in fibrosis, MASH and HCC through human genomic analyses (Korkut, Cell Systems, 2018) and mechanistic insight from HCC models (Yang, Cell Reports, 2024). We hypothesized that the TGF-β pathway through its instrumental role in ongoing pathology from fibrosis to cirrhosis to cancer could provide functional markers predicting HCC risk. **Methods:** 7000 serum proteins (Somalogic) assayed in a total of 477 cirrhotic patients (125 with HCC) from four Institutions and revealed a strong TGF-β pathway signature in the retrospective cohort A (n = 216, Xiang, Genes & Cancer, 2024). Clustering analysis in the prospective cirrhotic cohort B (n = 312) was performed. Longitudinal follow up cohort B revealed 18 HCCs in 312 patients over a median of 5-years. ELISA validation was carried out for seven protein markers raised in HCC. A predictive model based on the TGF-β Pathway was developed using multivariable logistic regression analysis in the matched cohort C (109 pairs, n = 328). Model performance was 10-fold cross-validated across the entire cohort (n = 477). **Results:** TGF-β-related protein signature displayed a five-fold increased risk of HCC development (9.68% vs. 1.91%) in the longitudinal cohort B. Compared to cirrhosis, ELISA validated increases in serum MSTN, TGFBR2, and AFP in HCC (odds ratio = 1.4-2.9, $p < 0.05$); MSTN and SPTBN1 were elevated in HCCs with MASLD/ALD ($p < 0.05$); however, no significant alterations were observed for serum HMGB1, IL-6 and COL1A1. In a subsequent matched cohort C, 88 proteins were significantly altered in HCC ($p < 0.05$). The six-protein panel (TGFBR2, MSTN, AFP, COL18A1, GLUL, TP63) displayed a strong performance in this matched cohort C (AUC 0.87, sensitivity 0.88, specificity 0.72), with four clinical factors (Age, Sex, BMI, Bilirubin). This panel performed equally well in specific subgroups including obese and MASLD/ALD (AUC 0.90, 0.92) related patients, and in the longitudinal cohort B of patients with mild to moderate cirrhosis (AUC 0.86). **Conclusion:** TGF-β pathway-related markers can potentially stratify HCC risk in cirrhotic patients in support of our approach towards capturing ongoing pathology in the liver. Next steps will be large-scale validations of this biomarker panel in cirrhotic patients across larger populations in Phase II/III studies.

[1]University Medical Center Homburg and University of the Saarland in Germany, [2]Echosense, [3]Novo Nordisk, [4]University of Florida

Background: There are limited data among individuals on the prevalence of significant fibrosis in patients with MASLD/MASH outside tertiary hepatology centers (e.g. primary care, diabetology units). The aim of this study was to fill that gap in knowledge by determining the Vibration-Controlled Transient Elastography (VCTE FibroScan) prevalence of steatosis. **Methods:** This is a cross-sectional analysis of prospectively enrolled adults with MASLD/MASH (18 to 80 years) from primary care and private diabetology settings in the USA, Germany, Italy and Spain. Liver steatosis and fibrosis were assessed using FibroScan Go™, a connected device designed for upstream centers. All patients had at least 10 valid measurements and IQR/LSM (Liver Stiffness Measurement) ratio < 0.3. Steatosis was defined as CAP (Controlled Attenuation Parameter) $>$ 274 dB/m. The moderate fibrosis, advanced fibrosis and cirrhosis were defined as LSM between 8 and 12 kPa, between 12 and 15 kPa and $>$ 15 kPa, respectively. After a first selection of variables with univariate analyses at the 10% significance level, multivariate analyses were performed to determine the factors associated with CAP > 274 dB/m, with LSM ≥ 8 kPa and with both LSM ≥ 8 kPa and CAP > 274 dB/m (at the 5% significance level). **Results:** The cohort included 2050 participants, 1985 from USA (96.8%), 1072 (52.3%) female, 984 patients with an age between 50 and 70 years (48%) and 755 (36.8%) with a body mass index (BMI) > 30 kg/m²). Main setting was primary care (64.9%). Median (IQR) LSM was 5.1 (2.6) kPa and mean (SD) CAP was 261 (56) dB/m. The prevalence of steatosis (CAP $>$ 274 dB/m) was 38.8%. The prevalence of moderate fibrosis, advanced fibrosis and cirrhosis was 8.6%, 1.9% and 3.1%, respectively. A total of 8.8% of the patients had LSM $\geq$ 8 kPa and CAP $>$ 274 dB/m. By univariate analysis, factors associated with CAP > 274 dB/m were age, gender, BMI and country (US vs Europe). By multivariate analysis, factors associated with CAP > 274 dB/m were age, male gender, and BMI (irrespective of the BMI class). By univariate analysis, factors associated with LSM ≥ 8 kPa were age, gender, BMI, country (US vs Europe) and type 2 diabetes (T2D). By multivariate analysis, factors associated with LSM ≥ 8 kPa were age > 70 years old, male gender, having obesity (BMI) and T2D. By univariate analysis, factors associated with LSM $\geq$ 8 kPa and CAP $>$ 274 dB/m were age, gender, BMI, country and T2D. By multivariate analysis, factors associated with LSM $\geq$ 8 kPa and CAP $>$ 274 dB/m were age $>$ 70 years and male gender. **Conclusion:** The prevalence of moderate to advanced fibrosis and cirrhosis in patients with MASLD/MASH by VCTE is high (13.6%) in patients from centers other than that from tertiary hepatology centers. Therefore, screening with VCTE for clinically significant liver fibrosis in patients with MASLD/MASH offers a unique opportunity for early diagnosis in primary care and diabetes centers in private settings, especially in patients with T2D and obesity.

2053 | NOVEL MULTIPARAMETRIC MRI IMAGING PREDICTS HISTOLOGIC RESPONSE IN RESMETIROM VERSUS PLACEBO IN THE MULTICENTRE, INTERNATIONAL, MAESTRO-NASH PHASE 3 TRIAL

Anneli Andersson[1] Hang Zhang[2] Andrea Dennis[1] Rebecca Taub[2] Dominic Labriola[2] Rohit Loomba[3], [1]Perspectum, [2]Madrigal Pharmaceuticals, [3]University of California, San Diego

Background: Resmetirom was approved by FDA in March 2024 and is indicated for the treatment of adults with noncirrhotic nonalcoholic steatohepatitis (NASH) with moderate to advanced liver fibrosis. The Phase 3 trial MAESTRO-NASH (NCT03900429) evaluated the efficacy of resmetirom in patients with NASH and achieved its primary outcomes. For a subset of patients MRI-derived cT1, a marker of fibro-inflammation, was collected. A reduction in cT1 of 80ms has been identified as the optimal threshold associated histological response. We explored the cT1 responses observed in the MAESTRO-NASH trial. **Methods:** Adults with ≥3 metabolic risk factors, liver stiffness ≥8.5 kPa, hepatic fat ≥8%, biopsy-confirmed NASH with F1B-F3 fibrosis, and NAS ≥4 were eligible to participate in MAESTRO-NASH. cT1 was acquired using LiverMultiScan. Average changes in cT1 with increasing dose, and with histological response was assessed and summary descriptive statistics reported. cT1 responders were considered those who had an ≥80ms reduction in cT1 from baseline. **Results:** 156 patients had cT1 and histology data (mean age: 57 years old, 56% female, mean BMI: 37kg/m^2). cT1 and PDFF were positively correlated (Spearman's rho: 0.68 – 0.83) and cT1 increased with increasing fibrosis stage, PDFF did not. After 16-weeks of Resmetirom treatment, the mean reduction in cT1 was -48ms (SD: 101ms) in the 80mg group (N = 37) and -78ms (SD: 88ms) in the 100mg group (n = 46). There was minimal change in the in the placebo group (-8ms, (SD: 56ms), N = 51). This dose-dependent pattern in cT1 change was maintained at 52 weeks. Additionally, 25% and 36% met the cT1 response criteria in the 80mg and 100mg arms, respectively. cT1 reduction was larger in histological responders than non-responders for NASH Resolution in the 100mg arm (mean change -125ms vs. 46ms; cT1 responders 53% vs. 19%) and for fibrosis Improvement in both 80mg (mean change -84ms vs. 11ms) and 100mg arms (mean change -124ms vs. -74ms; cT1 responders 70% vs. 24%). **Conclusion:** A positive association with fibrosis stage and with MRI-PDFF was observed for cT1 in this subset analysis. cT1 demonstrated a dose dependent reduction with resmetirom treatment, with the greatest reductions in the 100mg group, and a negligible placebo response. A reduction incT1 of >80ms was associated with high likelihood of histological response. These data suggest cT1 may be a suitable test for monitoring response in patients being treated with resmetirom.

2054 | IMPACT OF PNPLA3 P.I148M VARIANT ON QFIBROSIS-BASED LIVER FIBROSIS FEATURES IN MASLD BIOPSIES IN THE MILAN BIOBANK COHORT

Giulia Periti[1] Kutbuddin Akbary[2] Francesco Malvestiti[3] Serena Pelusi[1] Marco Maggioni[1] Luisa Ronzoni[1] Sara Margarita[1] Alessandro Cherubini[4] Jessica Rondena[3] Roberta D'Ambrosio[1] Daniele Dondossola[3] Daniele Prati[1] Dean Tai[5] Luca Valenti[6], [1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico Milano, [2]HistoIndex Pte Ltd, Singapore, [3]University of Milan, [4]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, [5]HistoIndex, [6]Fondazione Ca' Granda OMP Milano

Background: The PNPLA3 p.I148M variant (rs738409) is the main genetic determinant of steatosis and fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD), impacting both hepatocytes and hepatic stellate cells, greatly contributing to global liver disease burden. Its influence on fibrosis biology extends beyond traditional staging systems, yet its impact on collagen morphology has not been fully characterized. We aimed to evaluate the association between PNPLA3 p.I148M and quantitative collagen features using AI-based digital pathology analysis. **Methods:** Fifty liver biopsies from MASLD patients in the Milan Biobank with PNPLA3 genotyping and stain-free Second Harmonic Generation/Two Photon Excitation (SHG/TPE) microscopy imaging were analysed using qFibrosis (qF; HistoIndex Pte Ltd, Singapore). Features linked to qF stage, COMI-F (mortality risk), and CODI-F (decompensation risk) indices were assessed (Kendall et al. Liver Int. 2024). Data were normalized to SHG% area. Associations between PNPLA3 p.I148M genotype and collagen features were assessed using generalized linear models under an additive allelic model, adjusting for SHG% area. Correlation between pathologist-based and qF-derived staging was evaluated using generalized linear models, and correction for multiplicity was performed using the Bonferroni method. **Results:** Mean age was 55.8 ± 11.1 years, BMI 29.8 ± 4.4 kg/m², 90% male; 40% had advanced fibrosis (NASH-CRN stage F3–F4). PNPLA3 genotypes were I/I (28%), I/M (44%), M/M (28%). Pathologist-based NASH-CRN fibrosis staging correlated strongly with qF stage ($R^2 = 0.84$, $p < 0.0001$) and qF value ($\beta = 1.28 \pm 0.11$, $p < 0.0001$). PNPLA3 p.I148M was significantly associated with higher steatosis grade and NAS ($p < 0.05$). In unadjusted models, PNPLA3 variant correlated with greater number of long collagen strings in periportal regions ($\beta = 1.44 \pm 0.59$, $p = 0.018$). After SHG% normalization, PNPLA3 was significantly associated with qF stage ($\beta = 0.66 \pm 0.20$, $p = 0.0014$), COMI-F risk ($\beta = 0.17 \pm 0.07$, $p = 0.016$), and multiple periportal features including distributed thin and long strings (Fig. 1). These associations withstood correction for multiple testing. In cases with advanced fibrosis (F3-F4), PNPLA3 also influenced zone 2 and centrivenular collagen features ($p < 0.05$). **Conclusion:** The PNPLA3 p.I148M variant is associated with distinct collagen architectural patterns, especially in periportal regions, captured by SHG/TPE-based AI analysis. These features correlate with AI-digital analysis based fibrosis stage and clinical risk indices. Findings suggest genotype-specific fibrogenic patterns, which may support future efforts in patient stratification and monitoring of fibrosis improvement in MASLD clinical trials via AI-analysis based precision histology. Further validation in independent cohorts would strengthen these findings.

Table 1. Association of PNPLA3 p.I148M variant with collagen features contributing to qFibrosis stage and value and COMI-F/CODI-F indices

2055 | SERUM MULTIOMICS PREDICTS LIVER HISTOPATHOLOGY AND DISEASE PROGNOSIS IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS (MASH)

Jasna Cotic[1] Paul Newcombe[2] Maria Jimenez Ramos[2] Felix Frauhammer[3] Rebecca Levinson[3] Jonathan Davitte[4] Lauren Brunner[5] Lara Murray[5] Geetika Singh[5] Robert Egger[5] Ylaine Gerardin[5] Tim Kendall[6] Jonathan Fallowfield[6] Michael Allison[7] Marc Goldfinger[1] Mark Harpel[4] Stephen Atkinson[2] Prerak Desai[4], [1]GSK, London, UK, [2]GSK, Stevenage, UK, [3]GSK, Heidelberg, Baden-Württemberg, Germany, [4]GSK, Upper Providence, PA, USA, [5]PathAI, Boston, MA, USA, [6]Institute for Regeneration and Repair, University of Edinburgh, Edinburgh, UK, [7]Cambridge Liver Unit, Cambridge NIHR Biomedical Research Centre, Cambridge University Hospitals NHS

Background: Metabolic dysfunction-Associated Steatohepatitis (MASH) is a complex disease consisting of hepatocyte ballooning and death, inflammation and fibrosis. Non-invasive metrics of disease activity and stage are limited in their ability to predict disease outcomes. Accelerated approval in MASH is dependent upon liver histology, posing significant challenges to drug development – cost, patient risk, sampling and scoring variability. This creates major bottlenecks in the development of novel MASH therapies. Here, we used a machine learning (ML)-based approach to predict liver histology scores from serum-derived multiomics data. **Methods:** Serum was obtained from >100 patients (Cambridge University Hospital, CUH) representing the full spectrum of MASH: steatosis, steatohepatitis and steatohepatitis with cirrhosis. We generated a multiomics dataset including proteomics, metabolomics, and lipidomics data, together with a panel of commercial serum-based biomarkers (Nordic Bioscience; liver disease biomarker panel). Liver fibrosis, hepatocyte ballooning, lobular inflammation, and steatosis Clinical Research Network (CRN) scores were provided by pathologists and by AIM-MASH* (PathAI, Boston, MA). XGBoost models were trained to predict histology scores. Bayesian Variable Selection was applied to construct a disease prognostic score for time to liver decompensation, liver transplantation, or all-cause death based on AI-derived histology features (Liver Explore*; PathAI, Boston, MA) in the SteatoSITE cohort (N~600 patients with up to 20 years follow-up). An XGBoost model was trained to predict this disease prognostic score from the serum multiomics data in the CUH cohort. Models were independently validated using data from UK Biobank, using available surrogate phenotypes. **Results:** Serum-based models achieved high performance for predicting histology scores (cross-validated R^2 as high as 0.75), as well as disease prognosis scores (cross-validated $R^2 = 0.57$). Validation in independent data from UK Biobank confirmed the ability of the models to generalize beyond the development cohort. **Conclusion:** We developed ML models providing reliable out-of-sample prediction of liver disease histopathology and prognosis, demonstrating the power of serum multiomics to capture complex biological signatures of liver disease. This work suggests a way towards less-invasive alternatives to liver biopsy to monitor disease progression and as surrogate endpoints in clinical trials.

* AIM-MASH and Liver Explore are for research use only; not for use in diagnostic procedures.

2056 | LONGITUDINAL ASSESSMENT OF FIBROSIS DISTRIBUTION CHANGES AFTER TREATMENT IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Daniela Allende[1] Laura Wilson[2] Cynthia Behling[3] Patricia Belt[4] Ryan Gill[5] Danielle Carpenter[6] Oscar Cummings[7] Cynthia Guy[8] Matthew Yeh[9] Bryce Hatfield[10] David Kleiner[11], [1]Cleveland Clinic, [2]Johns Hopkins University, [3]University of California, San Diego, [4]Johns Hopkins Bloomberg School of Public Health, [5]University of California, San Francisco, [6]Saint Louis University, [7]Indiana University School of Medicine, [8]Duke University, [9]University of Washington Medical Center, [10]Virginia Commonwealth University, [11]National Cancer Institute, Bethesda

Background: Fibrosis regression in MASLD poses challenges in the setting of recent therapies. This study aims to elucidate the impact of treatment and histologic response on fibrosis location. **Methods:** Biopsies from adult MASLD

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

patients from the NASH CRN PIVENS and FLINT randomized clinical trials with baseline (BL) and end-of-treatment (EOT) biopsies were blindly assessed. Perisinusoidal fibrosis (PSF) grade was recorded as 0-none, 1-mild, or 2-moderate. Relative distribution of fibrosis by location was scored as portal fibrosis (PF) dominant, PSF dominant, equivocal, or undefined if no fibrosis was evident. The analysis included "responders" (>2 point decrease in NAS with no worsening of fibrosis) and non-responders for changes in PSF grade and predominance at BL and EOT. P-values for change were derived from ANCOVA models, relating the change from BL to EOT to response and BL value of the outcome. **Results:** This study included 399 patients (62% female, 84% white, mean age 49 years), with 214 cases from PIVENS (54%) and 185 from FLINT (46%). Patients were randomized to vitamin E ($N=76$), obeticholic acid ($N=93$), pioglitazone ($N=67$), or placebo ($N=162$). At BL, 85% of cases had fibrosis (15% 0, 32% 1a/b, 2% 1c, 25% 2, 25% 3, 1% 4). Among the 341 biopsies with fibrosis, PSF predominance was common (76%), followed by balanced PSF/PF (17%), and PF predominance (7%). PSF grade was none in 17%, mild in 26%, and moderate in 57% of cases. Among responders vs. non-responders, a decrease in PSF was identified when comparing BL versus EOT biopsies (-0.65 vs +0.04, $p<0.0001$). This change in PSF grade was similar across all treatment groups vs placebo (vitamin E: -0.37, obeticholic acid: -0.35, pioglitazone: -0.4 vs placebo: -0.02, $p\leq0.02$). In responders, a shift from PSF to PF predominance in EOT biopsies was seen in 15% of stage 2 and 19% of stage 3 cases vs controls (8% and 7%) ($p\leq0.05$) (Table 1). **Conclusion:** Histologic responders had a reduction in PSF severity and a shift in the fibrosis dominance towards less PSF at EOT, independent of therapy used. Decreased PSF suggests a sequence of fibrosis regression in treatment response which may have implications for prognosis or drug development.

Table 1 – Fibrosis stage, perisinusoidal fibrosis grade, and distribution by histologic response

	Histologic response		
	Responder (N=156)	Non-Responder (N=243)	P
Fibrosis stage, mean (SD)			
Baseline	1.8 (1.0)	1.6 (1.1)	
End-of-treatment	1.1 (1.0)	1.8 (1.2)	
Change (EOT-BL)	-0.71 (0.80)	+0.22 (0.87)	<0.0001
Perisinusoidal fibrosis grade, mean (SD)			
Baseline	1.5 (0.7)	1.3 (0.8)	
End-of-treatment	0.9 (0.8)	1.4 (0.8)	
Change (EOT-BL)	-0.65 (0.77)	+0.04 (0.74)	<0.0001
Change in predominant fibrosis location among fibrosis stage 2 at BL (N=101)			0.04
Central at BL – Central at EOT	14 (36%)	39 (63%)	
Central at BL – Portal at EOT	6 (15%)	5 (8%)	
Central at BL – No predominance at EOT	8 (21%)	11 (18%)	
Central at BL – Undefined at EOT (fibrosis stage 0 at EOT)	11 (28%)	7 (11%)	
Change in predominant fibrosis location among fibrosis stage 3 at BL (N=99)			0.05
Central at BL – Central at EOT	19 (44%)	29 (52%)	
Central at BL – Portal at EOT	8 (19%)	4 (7%)	
Central at BL – No predominance at EOT	13 (30%)	23 (41%)	
Central at BL – Undefined at EOT (fibrosis stage 0 at EOT)	3 (7%)	0 (0%)

2057 | SPATIAL COMPUTATIONAL HISTOLOGY STRATIFIED DENIFANSTAT FIBROSIS RESPONDERS IN THE PHASE 2B FASCINATE-2 MASH STUDY

Vlad Ratziu[1] Wen-Wei Tsai[2] Louis Petitjean[3] Marie O'Farrell[2] Mathieu Petitjean[3] Eduardo Martins[2] Philip Newsome[4] Rohit Loomba[5], [1]Service D' Hepatogastroenterologie (FR), [2]Sagimet Biosciences, [3]PHARMANEST, [4]Kings College School of Medicine, [5]University of California, San Diego

Background: Denifanstat (TVB-2640), an oral fatty acid synthase (FASN) inhibitor, demonstrated significant improvements in fibrosis and MASH resolution in the Ph2b FASCINATE-2 study, and prevented progression to cirrhosis. Fibrosis improvement was shown by both MASH CRN criteria and by AI-based digital pathology. In this exploratory analysis, we used single-fiber analysis to identify fibrotic phenotypes that predict denifanstat response. **Methods:** Liver biopsies were stained with Masson's Trichrome and read by a central pathologist using MASH CRN criteria. Paired biopsy images were available for single fiber analysis from placebo (PBO, $n=45$; F2: $n=22$, F3: $n=23$) and denifanstat ($n=81$ of which 78 analyzed; F2: $n=34$, F3: $n=44$) groups. Responders (F+) had $\geq$1-stage fibrosis reduction by CRN; non-responders (F–) had no change or progression. High resolution quantitative image analysis generated a single-fiber study data lake (sFD). 315 statistical descriptors of fiber populations (fibrosis traits, qFTs) were derived for each biopsy. qFTs differing by $\geq$20% between F+ and F- ($p<0.01$) were normalized and assembled in an equi-weighted response prediction score (RPS). UMAP, a dimensionality reduction technique that preserves both global structure and local relationships, was applied to the sFD to detect phenotypic clusters and spatial patterns associated with histological response. **Results:** 41 and 79 qFTs were identified for fibrosis response in the F3 and F2 baseline groups respectively (Panel A, Volcano plot). These qFTs were assembled to form the RPS(F3) (Panel B) and RPS(F2) respectively. Only 20

qFTs were shared from F2 and F3 phenotypes are distinct. RPS scores significantly discriminated responders from non-responders in both F3 and F2 baseline subgroups: F3+ from F3- : AUROC = 0.77 (95% CI: 0.61–0.91) (Panel C), $p = 0.011$ (F3+: $n = 24$; F3–: $n = 20$) and F2+ from F2-: AUROC = 0.81 (95% CI: 0.63–0.95), $p = 0.007$ (F2+: $n = 11$; F2-: $n = 9$). Patient-level FibroMAP constructed on the sFD identified clearly distinct histological phenotypic clusters for each F stage for baseline and end of study biopsies combined (N = 246) and identified single-fiber clusters enriched in denifanstat responders at baseline, regardless of their F stage. **Conclusion:** Quantitative single-fiber traits and clustering revealed fibrosis phenotypes that predict denifanstat response, supporting that computational pathology could be leveraged for response stratification.

2058 | INNOVATIVE SCORING SYSTEM TO SIMULATE MAGNETIC RESONANCE ELASTOGRAPHY IN PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Isabel Fernandez-Lizaranzu[1] Vanessa Garcia-Fernandez[1] Paloma Carrillo-Fernandez[1] Pedro Montero-Pavon[1] Rocio Gallego-Duran[2] Javier Castell-Monsalve[3] Manuel Romero-Gómez[1], [1]Instituto de Biomedicina de Sevilla (IBiS), [2]Ibis- Biomedicine Institute of Sevilla, [3]Department of Diagnostic Radiology. Virgen del Rocío University Hospital. Seville, Spain

Background: Magnetic resonance elastography (MRE) has emerged as a preeminent non-invasive modality for the assessment of liver fibrosis, exhibiting superior diagnostic precision in both the identification and staging of liver fibrosis (Pavlides et al. EASL2025). However, its accessibility and widespread implementation remain limited. Consequently, this study aims to develop an alternative scoring system that replicates the diagnostic accuracy of MRE, based on widely available biomarkers and clinical parameters. **Methods:** In an estimation cohort comprising N = 85 patients referred from primary care due to MASLD-fibrosis who underwent MRE to stratify fibrosis stage. A logistic regression analysis was conducted to derive the ultimate formula of the score MR-SeLiver that incorporates transient elastography (TE) measurements (kPa), sex, age, and the Hepamet Fibrosis Score (HFS) as independent variables. The accuracy of this score was subsequently validated in a second independent cohort consisting of 178 patients diagnosed with biopsy-proven MASLD who underwent MRE. Advanced fibrosis was defined as F3-F4 on histological examination and a measurement exceeding 3.53 kPa on MRE (Liang et al. J Hep 2023). The area under the receiver operating characteristic curve (AUROC), Youden Index and diagnostic accuracy were calculated to assess the diagnostic capability of the newly developed score. **Results:** 178 patients with biopsy-proven MASLD were finally included in the validation cohort, 67% (121/178) had histologically confirmed advance fibrosis, 47% (32/68) were evaluated by MRE in a non-selected subcohort. Half (89/178) were female, 55.2 years median age, 52% (92/178) type two diabetes. MR-SeLiver demonstrated a diagnostic accuracy for detecting advanced fibrosis by MRE, with an AUROC of 0.845 (95% CI: 0.748, 0.941). When compared to histological

evaluation of advanced fibrosis, it achieved an AUROC of 0.784 (95% CI: 0.708, 0.860). Youden Index pointed 0.6 as the best cut-off for advance fibrosis prediction by MRE with a sensitivity of 75%, specificity of 84.3%, positive predictive value 80.7%, negative predictive value 79.4%, positive likelihood ratio 4.8 and negative likelihood ratio 0.29. **Conclusion:** Despite MRE's exceptional capability to diagnose advanced fibrosis with remarkable sensitivity and specificity, its limited accessibility remains a challenge. Score MR-SeLiver incorporates clinically available variables and standard biomarkers such as sex, age, TE, and HFS, emerges as a highly accessible and alternative score to MRE poised to revolutionize diagnostic of MASLD-fibrosis.

2059 | MULTI-OMICS SIGNATURES OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) IN CHILDREN AND YOUTH

Shiwen Li[1], [1]University of Southern California

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is emerging in pediatric and young adult populations, yet the molecular mechanism remains poorly characterized. Multi-omics integration offers a powerful framework to uncover protein–metabolite networks that can distinguish MASLD patients and may improve early detection. **Methods:** We included two cohorts: the Study of Latino Adolescents at Risk of Type 2 Diabetes (SOLAR) (aged 8–13 years; n = 130) with validation cohort from the Metabolic and Asthma Incidence Research (Meta-AIR) study (aged 17–23 years; n = 122). MASLD was defined as hepatic fat fraction > 5% on MRI plus ≥ 1 cardiometabolic risk factor. Plasma proteins (n = 346) were measured utilizing the proximity extension assay using an Olink Explore Cardiometabolic Panel I. Metabolome (n = 370) was determined using liquid-chromatography/high-resolution mass spectrometry. We then applied the Data Integration Analysis for Biomarker discovery using Latent cOmponents (DIABLO) model to integrate multi-omics data. We then evaluated model performance in the Meta-AIR cohort and extracted the significant multiomics features to conduct pathway analysis in Ingenuity Pathway Analysis. **Results:** The DIABLO model identified 25 proteins, and 5 metabolites linked to MASLD, implicating pathways of detoxification, amino-acid regulation, and energy metabolism. When applied to Meta-AIR, the SOLAR-trained model achieved a balanced error rate of 0.19. Pathway analysis highlighted the upregulation of tryptophan and branched-chain amino acid catabolism (adjusted $p < 0.05$) linking the multi-omics signature to hepatocellular carcinoma and liver-cell proliferation toxicity endpoints. **Conclusion:** This integrative multi-omics approach classified MASLD cases across independent cohorts and identified proteins and metabolites involved in tryptophan and branched-chain amino acid catabolic pathways as mechanistic biomarkers for MASLD detection.

2060 | ISOLATED HBCAB POSITIVITY IS NOT ASSOCIATED WITH HCC RISK IN PATIENTS WITH MASLD

Abdelrahman M Attia[1] Emily Truong[1] Naomy Kim[1] Hasmik Adetyan[1] Rami Hemadeh[1] Manaf Alsudaney[1] Jaeho Park[2] Aarshi Vipani[1] Hirsh Trivedi[1] Yun Wang[1] Walid S Ayoub[1] Alexander Kuo[1] Paul Martin[1] Hyunseok Kim[1] Ju Dong Yang[1], [1]Cedars-Sinai Medical Center, [2]University of Arkansas Medical Sciences

Background: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) is a leading cause of hepatocellular carcinoma (HCC). The role of prior hepatitis B virus (HBV) exposure, indicated by hepatitis B core antibody (HBcAb) positivity in HCC risk among MASLD patients remains unclear. We investigated this association in a racially diverse case and control of MASLD patients. **Methods:** In this single center

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

retrospective case-control study, we analyzed 1,098 MASLD patients (343 HCC cases, 755 controls) without other coexisting liver diseases (e.g., hepatitis C, HBsAg-positive HBV, HIV, alcohol-related liver disease) between 2013 and 2024. HBcAb status, demographics, metabolic comorbidities, and cirrhosis status were extracted via medical records review. Logistic regression was used to investigate the association between HBcAb and HCC risk, adjusting for age, sex, race, BMI, diabetes, hypertension, hyperlipidemia, and cirrhosis. Subgroup analyses focused on Non-Hispanic Asian and Black patients due to higher HBV exposure prevalence. **Results:** HBcAb positivity was higher in HCC cases than controls (11.2% vs 7.4%; $p = 0.062$). Univariate analysis showed HBcAb positivity is associated with HCC (OR 1.59, 95% CI 1.00–2.50, $p = 0.048$), but not in multivariable models (aOR 0.59, 95% CI 0.29–1.19, $p = 0.14$). In Non-Hispanic Asian and Black patients, HBcAb prevalence was high (42.1% and 40.0% in HCC cases and 32.7% and 0% in control), with a univariate association (OR 2.96, 95% CI 1.29–6.93, $p = 0.011$) but association was attenuated after adjustment (aOR 2.24, 95% CI 0.41–14.0, $p = 0.4$). In Hispanic and Non-Hispanic White, HBcAb prevalence was lower (3.9% and 4.0% in HCC cases and 6.7% and 5.0% in control), with no association at univariate (OR 0.86, 95% CI 0.41– 1.68, $p = 0.7$) or multivariable (aOR 0.40, 95% CI 0.15–1.02, $p = 0.06$) analysis. HBcAb positivity was slightly higher in cirrhotic patients (9.4% HCC vs. 9.5% control) than non-cirrhotics (7.7% HCC vs. 6.4% control). No significant association was found between HBcAb positivity and HCC in non-cirrhotics (aOR 0.98, 95% CI 0.03–13.4, $p > 0.9$) or cirrhotics (aOR 0.56, 95% CI 0.27–1.15, $p = 0.11$). **Conclusion:** HBcAb positivity is not independently associated with HCC risk in MASLD after adjusting for demographic and clinical risk factors. While higher HBcAb prevalence were noted in Non-Hispanic Asian and Black patients, there was no independent association with HCC risk.

2061 | VELACUR AS A NON-INVASIVE TEST FOR THE DETECTION OF PEDIATRIC HEPATIC STEATOSIS

Cristian Sanchez Torres[1] Ana Ramirez Tovar[2] Caitlin Schneider[3] Helaina Huneault[2] Kelsey Chatman[1] Geetika Khanna[1] Jack Knight-Scott[4] Adina Alazraki[1] Shasha Bai[2] Jean Welsh[1] Miriam Vos[1], [1]Emory University, Children's Healthcare of Atlanta, [2]Emory University, [3]Sonic Incytes, [4]Children's Healthcare of Atlanta

Background: Noninvasive, point-of-care tests to detect hepatic steatosis (HS) are needed for rapid diagnosis of MASLD in outpatient pediatric clinics, particularly in young children with early onset of the disease. Conventional ultrasound is the most widely used imaging modality due to its safety, tolerability, and ease of use in children. However, its performance is suboptimal, and it typically requires scheduling a separate appointment in radiology. Velacur is a non-invasive, point-of-care, ultrasound-based method for the assessment of attenuation and liver stiffness, demonstrated to be superior to Fibroscan for liver fat detection in adults (referenced to MRI-PDFF). **Methods:** This prospective, cross-sectional study included 113 Hispanic/Latino children prospectively recruited from the community as part of a MASLD prevention trial. Each participant underwent both MRI-PDFF (Proton Density Fat Fraction) and Velacur assessment on the same day. The primary outcome was the presence of liver steatosis ($\geq 5.2\%$) as measured by MRI-PDFF. The performance of Velacur attenuation coefficient estimate (ACE) was evaluated using Area Under Curve (AUC) analyses for hepatic steatosis thresholds of normal ($< 5.2\%$), mild (5.2 - 11%), and moderate ($> 11\%$) defined by MRI-PDFF. **Results:** A total of 113 Hispanic/Latino children, aged 6-9 years, were included in the study (mean age: 7.9 years (SD 1.05), 55% male). 34% of participants were categorized as obese, 18% overweight, and 48% as normal weight. Overall, 35% ($n = 40$) had HS $\geq 5.2\%$ as determined by MRI-PDFF. Velacur ACE had fair diagnostic performance for MASLD in children (AUC 0.76, CI 0.67 – 0.86). Using the optimal ACE cutoff of 250 dB/m, which maximized the combination of sensitivity and specificity, sensitivity was 70%, and specificity was 67%, Positive Predictive Value of 48% and Negative Predictive Value of 84%. For moderate steatosis ($> 11\%$) Velacur ACE

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

diagnostic performance improved to AUC 0.88 (CI 0.78 – 0.98). **Conclusion:** Velacur™ attenuation demonstrated fair to good performance in detecting hepatic steatosis in young children, particularly at higher levels of liver steatosis. While accuracy improves with increasing liver steatosis content, the overall negative predictive value of 84% supports clinical utility. Further validation in a larger more diverse pediatric population is needed.

2062 | NEUTROPHIL-TO-LYMPHOCYTE RATIO PREDICTS RECURRENCE OF MASLD-SUSPECTED HEPATOCELLULAR CARCINOMA AFTER RADIOFREQUENCY ABLATION

Yuoh Namiki[1] Tomoharu Yamada[1] Takuma Kaneko[1] Keisuke Mabuchi[1] Yuki Matsushita[1] Takuma Nakatsuka[1] Masaya Sato[1] Tatsuya Minami[1] Mitsuhiro Fujishiro[1] Ryosuke Tateishi[1], [1]The University of Tokyo

Background: Neutrophil-to-lymphocyte ratio (NLR) reflects systemic inflammation and immune status, which has been reported as a prognostic marker in various cancers. However, its role in predicting recurrence after radiofrequency ablation (RFA) for hepatocellular carcinoma (HCC) remains unclear, particularly among patients suspected of having metabolic dysfunction-associated steatotic liver disease (MASLD). This study aimed to investigate whether NLR level is associated with recurrence risk after RFA in MASLD-suspected HCC. **Methods:** From October 1999 to September 2024, 1,854 patients with newly diagnosed HCC underwent RFA at our institution. After excluding cases of autoimmune hepatitis, primary biliary cholangitis, significant alcohol consumption ($\geq$30 g/day for men, $\geq$20 g/day for women), and viral hepatitis, 144 patients with up to three lesions (each $\leq$3 cm) and at least one cardiometabolic risk factor (obesity, hypertension, diabetes, or dyslipidemia) were identified as MASLD-suspected HCC. Cox proportional hazards regression was used to assess recurrence risk factors, including NLR, with a cut-off of 2.5. **Results:** Among the 144 patients, the median age was 72 years, 42% were male, and 78% were Child-Pugh A. Patients with NLR $\leq$2.5 accounted for 58%. Univariable analysis identified sex ($p = 0.053$), Child-Pugh class B vs. A ($p = 0.010$), albumin ($p = 0.014$), AST ($p = 0.023$), platelet count ($p = 0.001$), NLR ($p = 0.007$), tumor diameter ($p = 0.026$), and tumor number ($p = 0.006$) as factors associated with recurrence ($p < 0.1$). Notably, NLR $>$2.5 was associated with a lower recurrence risk (HR 0.56, 95% CI: 0.37–0.85). In multivariable analysis, platelet count $<$150,000/μL (HR 1.79, $p = 0.012$) and NLR $>$2.5 (HR 0.61, $p = 0.029$) remained independent predictors of recurrence. **Conclusion:** In MASLD-suspected HCC patients undergoing RFA, a lower NLR ($\leq$2.5) was associated with a higher recurrence risk. This finding contrasts with previous reports in other cancers, where higher NLR is typically linked to worse outcomes. The distinct recurrence pattern observed in MASLD-suspected HCC suggests a unique tumor-immune interaction, warranting further investigation and validation in larger cohorts.

2063 | ENHANCING STEATOTIC LIVER DISEASE (SLD) DETECTION VIA OPPORTUNISTIC SCREENING

Vignesh Rajasekaran[1] Asad Aali[1] Andrew Johnston[1] Neera Ahuja[1] Paul Maggio[1] David Svec[1] Robert Boutin[1] Lisa Shieh[1] Allison Kwong[1] Nishita Kothary[1] Roger Sands[1] Jason Hom[1] Akshay Chaudhari[1] Laura Derry[1], [1]Stanford University Medical Center

Background: Steatotic liver disease (SLD), is highly prevalent, and disease progression to fibrosis can lead to major complications such as liver failure, portal hypertension (e.g., ascites, hepatic encephalopathy), hepatocellular carcinoma, and death. Steatosis alone has also been associated with worse outcomes, including reduced survival and increased morbidity. The 2025 AASLD Guidelines recommend the use of biomarker-based (e.g., FIB-4, APRI) and imaging-based tools (e.g., ultrasound, VCTE, MRI) to assess liver disease in high-risk individuals. However, biomarker-based tests lack sensitivity for SLD, and advanced imaging modalities such as MRI are resource-intensive and costly. While non-contrast computed tomography (CT) — and recently contrast-enhanced CT— has good performance for detecting SLD, limited data exists on the role of CT in screening. Given the widespread use of CT imaging, opportunistic CT paired with novel deep learning tools presents an automated, cost-effective, and scalable approach for detection. We aim to determine whether opportunistic CT paired with a novel deep learning algorithm can improve rates of detection of SLD. **Methods:** We used a novel deep learning algorithm, Comp2Comp, to retrospectively assess a cohort of 18,915 contrast-enhanced CT scans performed between 2013–2018 and 2021–2024 at a multisite academic center (Figure 1). SLD was identified using validated radiographic criteria: liver attenuation $\leq$ 90 Hounsfield units (HU) and a liver–spleen attenuation difference $\leq$ –19 HU. We compared detection rates by ICD coding, opportunistic CT image analysis, and the corresponding radiology reports. **Results:** Opportunistic CT image analysis identified SLD in 28% of patients, compared to only 12% in radiology reports and 4% via ICD coding. Among individuals identified by both Comp2Comp with opportunistic CT and radiology reports, only 24% were ICD-coded. Subgroup analysis comparing detection of SLD by opportunistic CT analysis and radiology reports across inpatient and outpatient CT scans revealed that outpatient cases were less likely to be coded (18.1% vs. 38.3%, $p < 0.001$). **Conclusion:** Opportunistic CT with deep learning offers a powerful, scalable, and automated solution for identifying patients with SLD who often remain undiagnosed in standard clinical workflows across the electronic health system. This population-based approach detected over twice as many cases than radiology reports. Although current guidelines allow ICD coders to assign diagnoses directly from outpatient radiology reports, SLD was significantly less likely to be coded in the outpatient setting. These findings highlight the need and opportunities for better integration of imaging data into diagnostic and clinical care pathways— both inpatient and outpatient— to improve early detection, linkage to subspecialty care, and treatment of SLD.

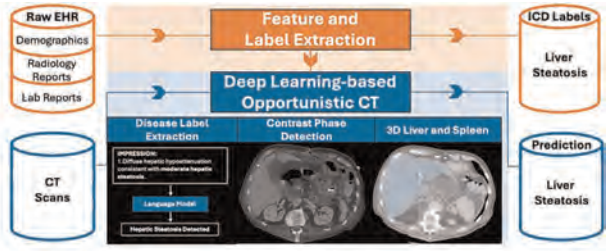

Figure 1. Pipeline for identifying steatotic liver disease using opportunistic CT image analysis, radiology reports, and ICD coding.

2064 | THE METAL SCORE (WESKEL-GP): A PRIMARY CARE FIBROSIS RISK TOOL FOR SILENT METALD – A GUIDELINE-ALIGNED RESPONSE TO THE MASLD CLASSIFICATION GAP

KSHEETIJ KOTHARI[1], [1]Sahyadri Hospital, Pune

Background: Up to 30% of patients with metabolic dysfunction-associated steatotic liver disease (MASLD) report moderate alcohol use (100–200 g/week), forming a "Silent MetALD" subgroup per AASLD/EASL 2023 criteria. These patients face a 2.1-fold higher risk of fibrosis due to metabolic–alcohol synergy, yet lack

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

dedicated risk-stratification tools. Current guidelines exclude them from MetALD classification ($\geq$140 g/week), and FIB-4 $<$1.3 fails to detect ~70% of F2 fibrosis, delaying hepatology referral by 18–24 months. Objective: To develop the METAL Score (WESKEL-GP) for identifying high-risk Silent MetALD using routine clinical parameters in primary care. **Methods:** The Weight-based Etiology Scoring with Key Elements for Liver Disease – Guided for Primary Care (WESKEL-GP) assigns weighted points based on meta-analytic odds: type 2 diabetes (2.0), BMI $>$30 or waist-to-height ratio $>$0.5 (1.5), ALT/AST $<$1 (1.5), GGT $>$1.5×ULN (1.0), family history (1.0), and sex-specific alcohol intake (women: 100–140 g/week = 1.5; men: 140–200 g/week = 2.0). A simulated MASLD cohort (n = 5,000), modeled using Agile 3+/LITMUS fibrosis data, assessed performance for F3+ fibrosis detection (AUROC vs. FIB-4 and NAFLD Fibrosis Score) **Results:** The METAL Score achieved an AUROC of 0.82 (95% CI: 0.79–0.85) for F3+ fibrosis, outperforming FIB-4 (0.78; Δ+0.04, p = 0.03) and NFS (0.75; p = 0.01). At a threshold of $\geq$5.0, it demonstrated 78% sensitivity and 76% specificity, reclassifying 22% of FIB-4 false-negatives. It reduced missed high-risk cases by 19% and avoided unnecessary referrals in one of four low-risk patients **Conclusion:** The METAL Score (WESKEL-GP) is the first clinically actionable tool designed explicitly for Silent MetALD, addressing a critical unmet need in the 2023 AASLD/EASL guidelines. By integrating six routine parameters—validated in a simulated cohort modeled on Agile 3+/LITMUS data—it enables early risk stratification in primary care, reducing delayed referrals by 19% and avoiding 1 in 4 unnecessary specialist consultations. To ensure equitable real-world application, we propose the PROSPECT-METAL trial (*target n = 5,000*), a global consortium initiative to: Refine sex- and ethnicity-specific thresholds, Optimize EHR integration for seamless adoption, Validate long-term outcomes (e.g., cirrhosis, mortality). Clinicians, researchers, and institutions worldwide are invited to join this urgent, guideline-aligned effort, advancing a tool poised to redefine metabolic-alcohol liver disease management.
Disclosures: KSHEETIJ KOTHARI: Nothing to Disclose

2065 | MACHINE LEARNING EXTRACTED FEATURES OF QUANTITATIVE ABDOMINAL IMAGING FINDS VISCERAL FAT AS PRIMARY PREDICTOR OF HEPATIC STEATOSIS

Wesley Dixon[1] Joseph Simeone[2] Jay Luther[2] Wei Zhang[2] Esperance Schaefer[1] Russell Goodman[2],

[1]Brigham and Women's Hospital, [2]Massachusetts General Hospital

Background: Machine learning (ML) algorithms can extract quantitative body composition metrics from abdominal computed tomography (CT) scans, but the relationship between body composition and hepatic steatosis has yet to be defined. These ML metrics may offer a novel approach to phenotyping patients beyond traditional measures like body mass index (BMI). **Methods:** We included adults (age $>$18 years) in the Mass General Brigham Biobank with a ML-processed contrast or non-contrast abdominal CT scan within one year of biospecimen collection. Body composition features, including skeletal muscle, visceral fat, and subcutaneous fat area, were extracted using automated Biobank ML algorithms and reported using z-scores relative to the corresponding demographic group. Hepatic steatosis was quantified using the Liver-to-Spleen Attenuation (L/S) Ratio; categories were defined as: minimal ($>$1.0), mild (0.9-1.0), moderate (0.8-0.9), and severe ($<$0.8). Results were expressed as n (%) or median (interquartile range) and compared using Kruskal-Wallis rank sum tests, Chi-squared tests, or area under the curve (AUC) values derived from univariable logistic regression. Robust scaling was used to allow for feature comparison in heatmaps. **Results:** Among 626 patients [age 69 (57-78) years, 46% female, 91% white], 45% had none or minimal, 20% had mild, 13% had moderate, and 22% had severe hepatic steatosis on abdominal CT (77% contrast-enhanced). Age, race, and gender were similar between steatosis categories (p = 0.40, 0.80, 0.15, respectively). Visceral fat, subcutaneous fat, skeletal muscle, BMI, ALT, and triglycerides, but not LDL, AST, or hemoglobin A1c, differed significantly between hepatic steatosis categories (Figure 1A). Comparing severe versus non-severe hepatic steatosis, visceral fat had the largest AUC (0.65), followed by ALT (0.64), BMI (0.63), subcutaneous fat (0.62), triglycerides (0.61), and skeletal muscle (0.61). When only including the 384 patients with BMI $<$30 kg/m^2 (51% none or minimal, 20% mild, 13% moderate, 17% severe hepatic steatosis), only visceral fat and ALT differed between steatosis categories (Figure 1B). In this non-obese population, comparing severe to non-severe steatosis, visceral fat again had the largest AUC (0.62), followed by ALT (0.61), triglycerides (0.58), and BMI (0.57). **Conclusion:** Visceral fat was the strongest imaging-derived correlate of hepatic steatosis, outperforming BMI and traditional lab markers, especially in non-obese patients. This offers a new approach to phenotyping patients with steatotic liver disease, further enabled by this cohort's banked blood samples.

2066 | MACHINE LEARNING PREDICTION OF AT-RISK MASH USING SEVEN KEY PREDICTORS: DEVELOPMENT AND VALIDATION

Yousif Alyousifi[1] Chinmay Raut[1] Lishi Yin[1] Vincent Chen[2] Yanhua Chen[1] Antonino Oliveri[1] Elizabeth Speliotes[2], [1]University of Michigan, [2]University of Michigan Medical Center

Background: Metabolic dysfunction-associated steatohepatitis (MASH) affects up to 12% of Americans, and it can progress to cirrhosis, increasing the risk of liver-related complications. Early and accurate identification of at-risk MASH is essential for effective clinical management and disease prognosis. Traditional diagnostic methods, like liver biopsy and imaging, are invasive, costly, and sometimes unreliable. Proton density fat fraction (PDFF) and iron-corrected T1 (cT1) are MRI-based measures of liver fat accumulation and inflammation; however, they are expensive and not readily available. Here, we aim to leverage machine learning techniques using clinical, biochemical, and genetic data to develop and validate an efficient predictive model for at-risk MASH. **Methods:** The UK Biobank cohort includes individuals with cT1 measures (n = 33,966, mean age = 64.3 years, male = 47.6%). MASH was defined as cT1 > 800 and PDFF ≥ 5. The dataset was split into training (N = 27,467) and testing (N = 6,867) sets. BorutaShap algorithm selected 7 key predictors out of 338 initially considered, encompassing baseline characteristics, physical measures, metabolites, serum biomarkers, and genetics. These 7 selected predictors were then utilized to train six machine learning algorithms - CatBoost, XGBoost, Random Forest, Logistic Regression, K-Nearest Neighbors, and Multilayer Perceptron and evaluated on testing set using the area under the receiver operating characteristic curve (AUC) for identifying at-risk MASH. Hyperparameters of our models were tuned using Optuna algorithm with 10-fold cross-validation. External validation was conducted using the Michigan Genomics Initiative (MGI) cohort (n = 20,195; mean age = 62.3 years; 46.2% male), MASH was defined based on ICD-10 code K75.81 or via pathology staining, using only five predictors, as two of the original seven were not available in MGI. **Results:** Among the evaluated machine learning models, CatBoost achieved the best performance, with the highest test AUC of 0.87 (95% CI: 0.87 - 0.89) and 0.86 (95% CI: 0.85 - 0.88) in UKBB using 7 and 5 predictors, respectively, and a validated AUC of 0.78 (95% CI: 0.75 - 0.81) in MGI (Figure). **Conclusion:** Our model demonstrated high accuracy for identifying at-risk MASH. Implementing this model in the electronic medical record may allow for early intervention to reduce progression to advanced liver disease. We are working to generalize the model, perform time-to-event analysis, and compare its performance with existing scores.

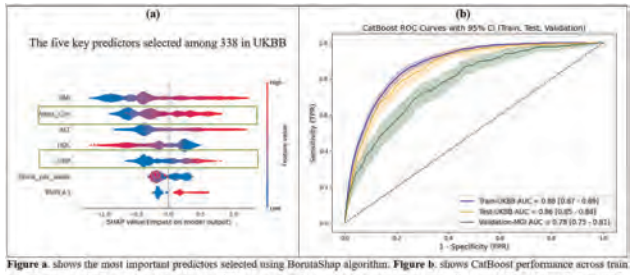

Figure a. shows the most important predictors selected using BorutaShap algorithm. **Figure b**. shows CatBoost performance across train and test sets in UKBB and the validated set in MGI cohort using five available predictors in both UKBB and MGI. **Abbreviations**: BMI, body mass index; HDL, high-density lipoprotein cholesterol; ALT, alanine aminotransferase; CRP, C-reactive protein; Waist_Circ, waist circumference; Drink_per_week, alcohol consumption per week; PNPLA3 rs738408_dosage, genetic variant. **Note**: Waist_Circ and CRP were not available in the MGI dataset.

2067 | MASLD EXACERBATES CARDIOVASCULAR MORTALITY RISK IN ADVANCED STAGES OF CARDIOVASCULAR-KIDNEY-METABOLIC SYNDROME: A POPULATION-BASED COHORT STUDY

Tong Bu[1] Tianyuan Yang[1] Qi Wang[1], [1]Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, China

Background: Background and Aims: The "cardiovascular-kidney-metabolic (CKM) syndrome" is a newly proposed staging framework aimed at enhancing the prevention, risk stratification, and multidisciplinary management of metabolic diseases. Metabolic dysfunction–associated steatotic liver disease (MASLD), recognized as a condition associated with adverse cardiovascular outcomes, may exert differential impacts on cardiovascular risk across various CKM stages. While previous studies have demonstrated varying cardiovascular risks across CKM stages, the distribution of CKM stages within the MASLD population is heterogeneous. This study aims to evaluate whether MASLD increases the risk of cardiovascular mortality across different CKM stages. **Methods:** This population-based prospective cohort study analyzed data from individuals aged 20 to 79 years who participated in the National Health and Nutrition Examination Survey (NHANES) from 2005 to 2018 and NHANES III, with mortality follow-up data available through 2019. The Fine-Gray competing risk model was employed to evaluate the risk of adverse cardiovascular outcomes and to assess the association between MASLD and cardiovascular mortality across different CKM stages. The model was adjusted for potential confounders including age, sex, educational attainment, and poverty level, with further adjustments for comorbid conditions such as hypertension, diabetes mellitus, and dyslipidemia. **Results:** In the adjusted Model 1, MASLD was significantly associated with an increased risk of cardiovascular mortality among individuals with CKM stages 0–3 (HR = 1.25, 95% CI: 1.13–1.52, P = 0.003). Subgroup analysis by CKM stage revealed that this association remained significant in individuals with CKM stage 2 and stage 3 (HR = 1.42, 95% CI: 1.18–1.84, P = 0.001; HR = 1.35, 95% CI: 1.11–1.79, P = 0.006). However, in a further adjusted model(adjusted Model 2) accounting for additional confounding factors, the association between MASLD and cardiovascular mortality among CKM stage 0–3 individuals was no longer statistically significant (HR = 1.18, 95% CI: 0.91–1.35, P = 0.1). Nonetheless, the association remained significant in individuals with CKM stage 2 and stage 3 (HR = 1.32, 95% CI: 1.15–1.75, P = 0.003; HR = 1.29, 95% CI: 1.08–1.70, P = 0.02, respectively). **Conclusion: Conclusion:** MASLD significantly increased the risk of cardiovascular mortality among individuals with CKM syndrome, particularly in those at CKM stages 2 and 3. In clinical practice, special attention should be given to the management of MASLD in patients at CKM stages 2 and 3, with enhanced screening efforts aimed at reducing the risk of adverse cardiovascular outcomes.

Table. Hazard Ratios (HR) for Cardiovascular Mortality Risk in Different Stages of CKM Syndrome with MASLD as an Exposure.

	Adjustment Model 1			Adjustment Model 2		
Group	HR	(95%CI)	P value	HR	(95%CI)	P value
0-3 CKM group	1.25	(1.13-1.52)	0.003	1.18	(0.91–1.35)	0.1
CKM stage 1	1.40	(0.41-4.79)	0.59	1.26	(0.52–2.5)	0.68
CKM stage 2	1.42	(1.18-1.84)	0.001	1.32	(1.15-1.75)	0.003
CKM stage 3	1.35	(1.11-1.79)	0.006	1.29	(1.08-1.70)	0.02
CKM stage 4	1.56	(0.63-3.85)	0.33	1.45	(0.75–2.58)	0.25

The table presents the hazard ratios (HR) and 95% confidence intervals (CI) for cardiovascular mortality risk in individuals at different stages of cardiovascular-kidney-metabolic (CKM) syndrome, with metabolic dysfunction-associated steatotic liver disease (MASLD) as an exposure factor. Model 1 was adjusted for age, sex, education level, and poverty status. Model 2 further adjusted for additional confounding factors, including hypertension, diabetes, and hyperlipidemia.

2068 | DEEP LEARNING-BASED MODEL FOR ASSESSING HEPATIC STEATOSIS IN LIVING LIVER DONOR

Jonggi Choi[1] Hyunseok Lim[2] Chaeyeon Lim[3] Jina Park[3] Won-Mook Choi[3] Danbi Lee[3] Ju Hyun Shim[3] Kang Mo Kim[3] YOUNG-SUK LIM[3] Han Chu Lee[3] Namkug Kim[3], [1]University of Ulsan, Asan Medical Center, [2]University of Ulsan College of Medicine, ASAN medical Center, Seoul, South Korea, [3]Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea

Background: Liver biopsy is the gold standard for diagnosing hepatic steatosis, but its invasiveness limits widespread use, particularly among potential living liver donors. With the growing prevalence of fatty liver disease, there is an urgent need for accurate, noninvasive diagnostic tools. This study aimed to develop a deep learning–based model that predicts hepatic steatosis by integrating clinical, laboratory, and CT imaging data. **Methods:** This retrospective study analyzed 6,259 individuals who underwent both liver biopsy and CT imaging during living donor evaluation at Asan Medical Center from January 2005 to April 2024. Of these, 4,370 had biopsy and CT within 30 days and were included in the modeling. Liver and spleen segmentation was applied to CT images to mask relevant regions of interest. Clinical and laboratory features used included sex, age, alcohol use, hypertension, AST, ALT, protein, albumin, cholesterol, and glucose. Data preprocessing involved outlier removal and minor label perturbations to address rounding bias in histological grading. Due to class imbalance, class-balanced sampling and augmentation techniques were employed. For model architecture, Inception v3 was used for CT imaging, FT-Transformer for tabular data, and the outputs were fused for prediction. **Results:** Median age was 29.5 years, 65.7% were male, and median BMI was 23.3 kg/m². Mild-to-

moderate and heavy alcohol use were reported in 47.8% and 4.1% of participants, respectively. The training dataset included 3,791 samples, and the test set included 236 samples. Internal and external validation sets comprised 72 and 36 samples, respectively. In internal validation, the model achieved a concordance correlation coefficient (CCC) of 0.8802, RMSE of 0.0860, R^2 of 0.6740, and MAE of 0.0600. In external validation, CCC was 0.6467, RMSE was 0.0669, R^2 was 0.0380, and MAE was 0.0669. **Conclusion:** This deep learning–based model demonstrated strong performance in predicting hepatic steatosis using CT and clinical data, showing good correlation with histologic findings. The model offers a promising non-invasive alternative to liver biopsy, especially in evaluating living liver donor candidates amidst the rising global burden of fatty liver disease.

2069 | A REAL-TIME NATURAL LANGUAGE PROCESSING PIPELINE TO EXTRACT ELASTOGRAPHY RESULTS: FROM ELECTRONIC HEALTH RECORD

Lale Ertuglu[1] Christina Grimes[2] Dario Giuse[2] Cathy Jenkins[3] Qingxia Chen[3] Qingxia Chen[3] Ashley Spann[2], [1]Department of Medicine, Vanderbilt University Medical Center, [2]Vanderbilt University Medical Center, [3]Department of Biostatistics, Vanderbilt University Medical Center

Background: Shear wave (SWE) and magnetic resonance elastography (MRE) are crucial non-invasive diagnostic modalities for quantifying liver stiffness and assessing hepatic fibrosis. MRE provides quantification of liver fat as Proton Density Fat Fraction (PDFF). Traditionally, the extraction of these values from electronic health records (EHRs) for clinical studies has been manual, time-intensive, and prone to human error. This study aims to evaluate the accuracy of a novel real-time natural language processing (NLP) pipeline designed to automate the extraction of discrete data elements from liver elastography data from EHRs. **Methods:** An NLP pipeline was designed and embedded directly in the EHR system to facilitate extraction of real-time liver elastography data from all patients within the Vanderbilt University Medical Center Health System undergoing either SWE/MRE studies. The NLP pipeline was embedded in the EHR and prospectively validated from 02/11/2025 through 04/21/2025. We evaluated the NLP pipeline's performance for extraction of quantifiable liver stiffness (kPa) and liver steatosis (PDFF) data compared to manual review of the original SWE/MRE reports obtained during the study period. Evaluation metrics of the extraction methods were reported with their corresponding 95% Wilson confidence intervals. **Results:** A total of 415 studies (186 MRI, 229 SWE) were completed during the observation period. For fibrosis assessment, a small percentage of studies were either nondiagnostic (5/415; 1.2%) or did not have discrete fibrosis values documented in the report (10/415; 2.4%), representing the true negatives in our study. For both SWE and MRE, the NLP pipeline resulted in 100% sensitive, specific, and positive/negative predictive in extracting the resultant discrete fibrosis values, regardless of modality used to diagnose. For quantified steatosis assessments, the NLP pipeline successfully captured 182/186 (97.8%) PDFF values from the completed MRE studies. NLP sensitivity and positive predictive values for PDFF were 98% (95%, 99%) and 100% (98%, 100%), respectively. Discrepancies were primarily attributed to studies with both non-diagnostic kPa values but available PDFF data, and studies that reported the presence of a single PDFF value instead of a range. **Conclusion:** Our NLP pipeline demonstrates excellent test characteristics in extracting liver elastography data from EHRs, with substantial time savings over manual methods. This tool has the potential to streamline data extraction processes in clinical and research settings, facilitate guided decision support for clinicians, and enhance efficiency in longitudinal data registries.

Table. Test characteristics with 95% Wilson confidence intervals for manual vs NLP extraction of liver stiffness (kPa) and liver fat content (PDFF)

	Estimate	95% CI
Liver stiffness		
Overall (kPa)		
Sensitivity	1.00	(0.99, 1.00)
Specificity	1.00	(0.80, 1.00)
Positive Predictive Value	1.00	(0.99, 1.00)
Negative Predictive Value	1.00	(0.80, 1.00)
Shear wave elastography (kPa)		
Sensitivity	1.00	(0.98, 1.00)
Specificity	1.00	(0.74, 1.00)
Positive Predictive Value	1.00	(0.98, 1.00)
Negative Predictive Value	1.00	(0.74, 1.00)
MR elastography (kPa)		
Sensitivity	1.00	(0.98, 1.00)
Specificity	1.00	(0.51, 1.00)
Positive Predictive Value	1.00	(0.98, 1.00)
Negative Predictive Value	1.00	(0.51, 1.00)
Liver fat content		
MR elastography (PDFF)		
Sensitivity	0.98	(0.95, 0.99)
Specificity	-	-
Positive Predictive Value	1.00	(0.98, 1.00)
Negative Predictive Value	0.00	(0.00, 0.49)

2070 | TRANSIENT ELASTOGRAPHY ENHANCED MACHINE LEARNING MODELS OPTIMIZE SENSITIVITY AND NEGATIVE PREDICTIVE VALUE FOR DETECTING SIGNIFICANT FIBROSIS IN MASLD

Zheng'ao Xu[1] Yongfen Zhu[1] Fengjuan Chen[2] Ruiqi Wang[3] Yilong Fu[3] Jiale Niu[3] Qiongyue Fan[4] Dan Xu[5] Guohong Ge[5] Dongmei Quan[6] Wei wu[6] Li Zhu[7] Xunxun Wu[7] Fushuang Ha[8] Qing Ye[9] Junping Shi[10] Qingxian Cai[11] Minghua Zhen[4] Zhongjie Hu[12] Xiao Liang[1],
[1]Zhejiang Key Laboratory of Multi-omics Precision Diagnosis and Treatment of Liver Diseases, [2]Department of Gastroenterology, The First Affiliated Hospital of jinan University, [3]School of Life Science, Zhejiang Chinese Medical University, [4]Department of Hepatology, the First Affiliated Hospital of Wenzhou Medical University, [5]Department of Hepatology, Zhenjiang Third People's Hospital, [6]Hepatobiliary surgery, The Sixth People's Hospital of Shenyang, [7]Department of Infectious Diseases, The Affiliated Infectious Diseases Hospital of Soochow University, [8]hafushuang@126.com, [9]The Third Central Hospital of Tianjin, [10]Zhejiang Key Laboratory of Medical Epigenetics, Hangzhou, [11]Department of Liver Diseases, The Third People's Hospital of Shenzhen, [12]Liver Disease Center, Beijing You'An Hospital, Capital Medical University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) has emerged as a prevalent chronic liver condition associated with lifestyle changes and obesity. Current severity assessment relies on invasive liver biopsy, with significant fibrosis (stage $F \geq 2$) representing a critical threshold for markedly increased liver-related mortality. This study aimed to develop a diagnostic model integrating demographic, laboratory, and transient elastography (TE) data to improve noninvasive fibrosis staging in MASLD patients. **Methods:** A total of 791 patients with histologically confirmed MASLD were retrospectively enrolled from nine medical centers between July 2018 and July 2024. The cohort was divided into training/internal validation (712 patients from five centers) and external validation (79 patients from four centers) sets. Clinical variables included age, sex, BMI, diabetes status, hypertension history, laboratory parameters (ALT, AST, ALP, GGT, albumin, ferritin, uric acid, triglycerides, total cholesterol, LDL, HDL) and liver stiffness measurement (LSM) from fibroscan. Six machine learning algorithms—random forest (RF), elastic net regression (ENET), XGBoost, support vector machine (SVM), LightGBM, and k-nearest neighbors (KNN)—were employed to develop a base model. An enhanced model incorporating TE was subsequently constructed. Bootstrap resampling (1,000 iterations) was used to calculate confidence intervals, with DeLong's test comparing AUC differences between models. High-performing models underwent external validation. **Results:** Of 791 patients, 305 (38.6%) had $F \geq 2$ fibrosis. Enhanced models demonstrated superior diagnostic performance compared to base models, and LSM emerged as the top-contributing feature across all enhanced models. RF, ENET, and SVM enhanced models showed statistically significant AUC improvements and these models improved mainly in sensitivity and negative predictive value. Several models with an AUC above 0.75 in the internal validation also maintained high levels of sensitivity and negative predictive value in the external validation. Detailed performance metrics are presented in Table 1. **Conclusion:** Transient elastography significantly enhances noninvasive detection of significant fibrosis in MASLD. Enhanced machine learning models incorporating LSM demonstrate high sensitivity and NPV, suggesting clinical utility for excluding low-risk individuals in high-prevalence populations. This approach may reduce unnecessary biopsies while ensuring accurate risk stratification.

2071 | MOUSE HEPATIC STELLATE CELL ACTIVATION HETEROGENEITY IN THREE COMMONLY USED MASH DIETS

Simeng Wang[1], [1]*UT Southwestern Medical Center*

Background: MASH-induced fibrosis is a result of insulin resistance, and it requires triglyceride accumulation in hepatocytes and stellate cell activation. Here, we used single-cell sequencing (scRNA-seq) to define the time-dependent molecular events that lead to stellate cell activation and liver fibrosis induced by three distinct MASH diets. **Methods:** Mice (n = 30) were fed chow, High Sucrose/Fat (45% fat, 17% sucrose, 0.02 % cholesterol), Western (40% fat, 29% sucrose, 0.14% cholesterol), or AMLN (40% fat, 20% fructose, 9% sucrose, 2% cholesterol) diets for 26, 34, or 45 weeks. Livers were then harvested for histology, bulk RNA sequencing, and scRNA-seq. Analysis of scRNA-seq utilized Seurat, RNA velocity, and Cellrank. **Results:** A total of 96 high-yield cell clusters were identified that were composed of hepatocytes, nonparenchymal liver cells and their corresponding subpopulations. 6,391 single-cell transcriptomes of stellate cells were further analyzed. After 45 weeks, the AMLN diet caused the highest stellate cell activation (67%) and liver fibrosis, with a 22-fold increase in collagen production. The Western diet led to intermediate effects (26% activation, 15-fold collagen increase), while the high sucrose/fat diet had minimal impact (7% activation, 5-fold collagen increase). The expressions of genes related to actin cytoskeleton, myofibroblast differentiation, and fatty acid catabolism were significantly upregulated in stellate cells, especially in stellate cells from mice fed the AMLN diet. Among the fully activated stellate cells, a total of 24,897 differentially expressed genes are identified, 25 of which potentially serve as new hepatic stellate cell activation markers. Fras1 gene associated with extracellular matrix formation and interactions was exclusively induced in activated stellate cells from mice fed the Western diet, while Utp18 gene played a crucial role in cell growth and proliferation was uniquely induced in activated stellate cells from mice fed the high sucrose/fat diet. **Conclusion:** This study is the first to comprehensively quantify how hepatic stellate cell (HSC) activation varies over time in response to three commonly used MASH diets, using single-cell transcriptome analysis. The AMLN diet triggered the most robust HSC activation and proliferation. However, both Western and high sucrose/fat diets also significantly activated HSCs, each through distinct mechanisms.

2072 | UNDERSTANDING THE FUNCTIONAL AND PHYSIOLOGIC HETEROGENEITY OF ADVANCED MASH AS DEFINED BY THE ORAL CHOLATE CHALLENGE TEST MAY ENHANCE CLINICAL TRIAL DESIGN

Mazen Noureddin[1] Naim Alkhouri[2] Eric Lawitz[3] Stephen Harrison[4] Michael McRae[5] Joanne Imperial[6] Gregory Everson[7], [1]Houston Methodist Hospital, [2]Summit Clinical Research, [3]Texas Liver Institute, University of Texas Health San Antonio, [4]University of Oxford, [5]Custom DX Solutions LLC, [6]HepQuant, LLC, [7]HepQuant

Background: Liver function in patients with advanced MASH may vary from normal to severe impairment and portal-systemic shunting which may impact treatment responses in drug trials. The oral cholate challenge test (HepQuant DuO) characterized baseline liver function and shunting in three recent MASH drug trials. **Methods:** Subjects were enrolled in 3 clinical trials linking the Test results to treatment response. Trial 1 was a Phase 2 trial conducted in patients with CP A MASH cirrhosis. Trial 2 was a Phase 3 open-label trial in patients with well-compensated CP A MASH cirrhosis. Trial 3 was a Phase 2 open-label trial in patients with MASH $\geq$F3 fibrosis. Test parameters were quantified from 20- and 60-min concentrations of orally administered d4-cholate. Serum was analyzed for cholate concentrations by LC-MS/MS. Baseline Test parameters, including the disease severity index (DSI) and portal systemic shunting (SHUNT%), were calculated. **Results:** A total of 134 subjects with MASH underwent the Test. Subjects were on average 61 $\pm$ 9 years of age, BMI 37 $\pm$ 8 kg/m^2, 99% overweight, 86% obese, 43% male, and 58% Hispanic ethnicity. A wide range of functional impairment and shunting was observed in these cohorts of patients with MASH. Mean ($\pm$ SD) values for the Test were 18.7 $\pm$ 5.5 for DSI and 29.4% $\pm$ 10.5% for SHUNT%. The diagram below, based on DSI (function) and SHUNT%, indicated 6 (4.4%) with normal function, 19 (14.2%) with only portal-systemic shunting, 67 (50%) with mild functional impairment, 18 (13.4%) with significant functional impairment, and 24 (18%) with significant functional impairment and shunting. Using the RISK ACE model (Kittelson 2025), the individual estimated 1-year risk for clinical outcome ranged from 0.4% (DSI 7.7) to 61.4% (DSI 40.0). **Conclusion:** The oral cholate challenge test (HepQuant DuO) uncovered significant heterogeneity in functional and physiologic impairment at baseline in patients enrolled in MASH drug trials. Quantitative functional assessment to risk stratify study populations to reach clinical liver events could improve efficiency and lower the cost of clinical trials by enhancing statistical power, thereby reducing sample size and study duration.

2073 | FIB-4 SERVES AS A REFERRAL INDEX FOR CORONARY ARTERY CALCIFICATION IN PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Chung-Feng Huang[1] Ming-Lung Yu[2], [1]Kaohsiung Medical University Hospital, Kaohsiung, Taiwan, [2]Kaohsiung Medical University/ Kaohsiung Medical University Hospital

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) and liver fibrosis is linked to cardiovascular disease (CVD), but their association with coronary artery calcification (CAC) remains unclear. This study aimed to investigate the relationship between MASLD and CAC, and the diagnostic accuracy of non-invasive fibrosis marker in predicting CAC. **Methods:** The study included 6,058 subjects undergoing coronary computed tomography (CT) from 2015 to 2024. Steatotic liver disease (SLD) was identified via ultrasonography or a hepatic steatosis index (HSI) > 36. MASLD was defined as SLD with at least one of the five cardiometabolic risk factors (CMRFs). Liver fibrosis severity was assessed using the FIB-4 index to assess its association with CAC and predictive performance at different CAC thresholds. **Results:** 39.8% of participants (n = 2,411) were classified as having MASLD whereas the remaining 60.2% (n = 3646) were with non-MASLD. MASLD patients had a higher prevalence of CAC than non-MASLD individuals (51.1% vs. 42.5%, $p < 0.001$). Factors associated with the presence of CAC included age (odds ratio [OR]/95% confidence intervals [CI]: 1.117/1.106-1.128, $P < 0.001$), male gender (OR/CI: 4.448/3.660-5.406, $P < 0.001$), MASLD (OR/CI: 1.570/ .342–1.837, $P < 0.001$), and FIB-4 (OR/CI: 1.217/ 1.034–1.433, $P = 0.018$). Among MASLD subjects, prevalence of CAC increased with FIB-4 value and cardiometabolic burdens. FIB-4 values increased progressively in patients with higher CACS ranging from 0.91 in patients without CAC, 1.16 in patients with mild CAC, 1.39 in patients with moderate CAC to 1.52 in patients with severe CAC. (P trend = 0.0091). A FIB-4 cut-off of ≥ 2.67 provided the highest positive predictive value (PPV: 89.7%) for the presence of CAC, while a cut-off of 1.26 offered the best negative predictive value (NPV: 95.1%) for severe CAC

(≥400). **Conclusion:** MASLD patients with liver fibrosis were at a greater risk of CAD. The FIB-4 index, with optimized cut-offs, served as a valuable tool for cardiovascular risk stratification in MASLD, helping identify individuals with high-risk CAD.

2074 | RELIABLE MONITORING OF PATIENTS WITH MASLD USING IMAGING: SYSTEMATIC LITERATURE REVIEW AND META-ANALYSIS ON MEASUREMENT REPEATABILITY

Michael Ndaa[1] Anneli Andersson[1] Cayden Beyer[1] Walid Ayoub[2] Andrea Dennis[1], [1]Perspectum, [2]Cedars-Sinai Medical Center

Background: As treatments for patients with metabolic dysfunction-associated steatotic liver disease (MASLD) emerge, monitoring of changes in liver health is becoming increasingly important. Reliable detection of treatment response requires quantitative metrics that are sensitive to change and highly reproducible. To assess the robustness of non-invasive imaging technologies in MASLD, we systematically reviewed the literature for same-day and different-day repeatability of various modalities. **Methods:** We searched PubMed Central and MEDLINE from 2015 to April 2025 for studies that examined the repeatability of non-invasive image-based technologies in adults with MASLD, specifically MRI iron-corrected T1 (cT1), MRI liver fat content (LFC; also known as proton density fat fraction, MRI-PDFF), magnetic resonance elastography (MRE), vibration controlled transient elastography liver stiffness measure (VCTE LSM), controlled attenuation parameter (CAP) and shear wave elastography shear wave speed (SWE-SWS). Two authors independently screened records and extracted data. The within subject standard deviations (wSD), mean and coefficient of variation (CV) were used to calculate the repeatability coefficient (RC) when not directly reported. The absolute (RC) and relative (%RC) for same-day (RC_{SD}) and different-day (RC_{DD}) repeat tests were summarized with a random-effects meta-analysis. **Results:** The searches resulted in 13 studies (cT1 n=2; LFC n=6; MRE n=4; VCTE n=3; CAP n=3; SWE n=2), with 328 individuals. The $\%RC_{SD}$ was 4% for cT1 and 21% for SWE-SWS, the random-effect average was 9% for LFC, 12% for MRE, 40% for VCTE LSM, and 21% for CAP. The random-effect average $\%RC_{DD}$ was 7% for cT1, 12% for LFC, 22% for MRE, 73% for VCTE LSM, 26% for CAP, and 32% for SWE-SWS, with a median time between repeat scans of 2.3 weeks. The RC_{SD} and average RC_{DD} for cT1 were 32ms and 65ms. To place these measurement variabilities in the context of monitoring in MASLD, the RC_{DD} can be compared to the established thresholds for clinically significant change for treatment responders: absolute change of 80ms for cT1 and relative reductions of 30% for LFC, 15% for MRE and 30% for VCTE, while not well established for CAP and SWE. **Conclusion:** This systematic review and meta-analysis showed that different day measurement repeatability is sufficiently robust for cT1 and LFC, not for MRE or VCTE, to detect individual clinically significant changes in liver health at treatment follow-up in MASLD.

2075 | SOMASIGNAL DEFINED MASH DISEASE COMPONENTS ARE PROGNOSTIC OF SECONDARY CARDIOVASCULAR DISEASE – A POST-HOC ANALYSIS OF THE SELECT TRIAL

Arun Sanyal[1] Steen Ladelund[2] Michelle Long[2] Sune Boris Nygård[2] Adel Belloum[2] Jörn Schattenberg[3], [1]Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, Richmond, VA, USA, [2]Novo Nordisk A/S, Søborg, Denmark, [3]Metabolic Liver Research Program, University Medical Center Mainz, Mainz, Germany

Background: The SELECT trial confirmed the preventive effect of semaglutide vs placebo on secondary cardiovascular (CV) events in patients without diabetes but with a body mass index (BMI) ≥ 27 kg/m^2 and CV disease (CVD). The metabolic dysfunction associated steatohepatitis (MASH) SomaSignal® (SS) test uses protein profiling to predict histologic MASH disease components; however, the prevalence, and treatment effect of semaglutide on SS-MASH disease components within the SELECT trial population is unknown. Additionally, it is unknown if SS-MASH disease components are prognostic of 3-point major adverse CV events (3P-MACE) or CV- and all-cause mortality. **Methods:** This post-hoc, secondary analysis of SELECT participants with available SS-MASH data at baseline, weeks 20 and 104 used descriptive statistics and odds ratios (ORs) to determine the prevalence of SS-MASH disease components and the treatment effect of semaglutide 2.4 mg once weekly vs placebo on SS-MASH disease components at week 20 and 104, respectively. Cox proportional hazards regression adjusted for sex, age, BMI, pre-diabetes status and CV inclusion criteria were applied to analyse the association of baseline predicted disease components with time to event CV endpoints. **Results:** Of 17,604 participants, 11,568 (66%) (mean age 62 years, mean BMI 34 kg/m^2) had available SS-MASH data. SS-predicted steatosis was the most prevalent MASH disease component (39%), whilst lobular inflammation (grade ≥ 2) (6%), hepatocyte ballooning (6%), or fibrosis stage ≥ 2 (clinically significant fibrosis) (7%) were lower. Treatment with semaglutide statistically significantly reduced the odds of SS-MASH disease components at weeks 20 and 104. ORs (95% confidence interval [CI]) at week 104 were 0.22 (0.18-0.28) for steatosis, 0.28 (0.19-0.43) for lobular inflammation, 0.18 (0.11-0.28) for ballooning, and 0.43 (0.29-0.65) for fibrosis. In the placebo group, SS-predicted fibrosis was associated with subsequent CV-death (hazard ratio [HR], [95% CI] 2.29 [1.50-3.50]), all-cause death (2.06 [1.48-2.85]) and incident 3P-MACE (1.42 [1.04-1.94]) after adjustment for age, sex, BMI, CVD, and pre-diabetes status. SS-predicted hepatocyte ballooning was associated with subsequent CV-death (2.03 [1.25-3.29]) and all-cause death (2.10 [1.46-3.02]). There was a treatment effect of semaglutide vs placebo on 3P-MACE, CV- and all-cause death, and this was similar in the groups with or without baseline SS-predicted significant fibrosis. **Conclusion:** MASH SomaSignal® investigated the prevalence and semaglutide treatment effects on MASH disease components in a large CV outcome trial in a population with expected high prevalence of metabolic dysfunction associated steatotic liver disease, without biopsy data. We also established predicted MASH disease components as important secondary CV prognostic factors.

2076 | NEW MASHFIB-12 MACHINE LEARNING MODEL: AFFORDABLE, SIMPLE, AND EFFECTIVE ALTERNATIVE TO CURRENT AGA/AASLD TWO-STEP GUIDELINES TO SCREEN MASLD

Devon Chang[1] Madeleine Chang[1] Mazen Noureddin[2], [1]Harvard University, [2]Houston Methodist Hospital

Background: According to current AGA/AASLD guidelines, patients with metabolic dysfunction-associated steatotic liver disease (MASLD) at risk for advanced liver fibrosis should be screened using FIB-4 followed by transient elastography, FibroScan® (FIB-Fibro). In this study, we evaluated a new machine learning model, MASHFIB-12, and compared it to FIB-Fibro in risk-stratifying patients with MASLD. **Methods:** The new MASHFIB-12, a random forests model, was used to predict the risk of significant/advanced fibrosis in 763 prospectively followed patients with MASLD from multiple US centers with labs, FibroScan and liver biopsy performed within six months of one another. MASHFIB-12 uses 12 routine clinical/demographic features to make predictions. We split the cohort so that 80% was used for training MASHFIB-12 and 20% was used for testing MASHFIB-12 against FIB-4 alone, FibroScan alone, and sequential FIB-Fibro. Additionally, we tested sequential MASHFIB-12 followed by FibroScan (MASHFIB-12-Fibro) against FIB-Fibro. **Results:** In Table 1, results that are statistically significantly different from MASHFIB-12 ($p < 0.05$) are marked with an asterisk (*), while results that are significantly different from MASHFIB-12-Fibro ($p < 0.05$) are marked with a double asterisk (**). For low cutoffs ($\geq$F2), MASHFIB-12 had higher accuracy, AUC, sensitivity, positive predictive value (PPV), and negative predictive value (NPV) versus FIB-4, and higher accuracy, AUC, specificity, and PPV versus FibroScan (all $p < 0.05$). For high cutoffs ($\geq$F3), it had higher accuracy, AUC, sensitivity, and NPV versus FIB-4, and higher AUC and sensitivity than FibroScan (all $p < 0.05$). There was no difference between MASHFIB-12 and FIB-Fibro in percentage of indeterminate-risk patients ($p > 0.05$). MASHFIB-12 displayed higher correctly classified (CC) measurement than FIB-Fibro, and MASHFIB-12-Fibro demonstrated higher CC and lower percentage of indeterminate-risk patients versus FIB-Fibro (all $p < 0.05$). **Conclusion:** MASHFIB-12 performs better than or similar to FIB-4 alone, FibroScan alone, and FIB-Fibro in several metrics while utilizing variables that can be quickly, easily, and inexpensively obtained, unlike FIB-Fibro, which requires FibroScan, a complex and costly imaging technology that is not frequently available in primary care settings. However, if FibroScan is available, MASHFIB-12-Fibro, which outperforms FIB-Fibro in all metrics, could be used instead for increased performance.

2077 | MAXIMIZING THE DIAGNOSTIC YIELD OF NON-INVASIVE TESTS: SIMULTANEOUS OPTIMIZATION OF KEY PERFORMANCE METRICS FOR FIBROTIC LIVER DISEASE WITH A FIB-4 AND MASEF (OWLIVER) STRATEGY

Ibon Martinez-Arranz[1] REBECA MAYO[1] Mirella Zulueta[2] Mazen Noureddin[3] Emily Truong[4] Jesus Banales[5] Marco Arrese[6] Kenneth Cusi[7] Paula Iruzubieta[8] Radan Bruha[9] Manuel Romero-Gómez[10] rocio aller[11] Javier Ampuero[12] JOSE LUIS CALLEJA PANERO[13] luis Ibañez-Samaniego[14] Patricia Aspichueta[15] antonio Martín-Duce[16] Tatyana Kushner[17] Arun Sanyal[18], [1]Rubió Metabolomics, [2]CIMA Sciences, [3]Houston Methodist Hospital, [4]Karsh Division of Gastroenterology and Hepatology, Cedars-Sinai Medical Center, Los Angeles, CA, [5]Biodonostia Research Institute, Donostia University Hospital, University of the Basque Country (UPV-, [6]Department of Gastroenterology, School of Medicine, Pontificia Universidad Católica de Chile, Santia, [7]University of Florida, [8]Marqués de Valdecilla University Hospital, Cantabria University, IDIVAL, Santander, Spain, [9]Charles University in Prague, 1st Faculty of Medicine, [10]Valme University Hospital, CIBERehd, Seville, Spain, [11]Clinic University Hospital, University of Valladolid, Valladolid, Spain, [12]Virgen del Rocío University Hospital, Sevilla, Spain, [13]Puerta del Hierro University Hospital, Madrid, Spain, [14]Gregorio Marañón University Hospital, Madrid, Spain, [15]National Institute for the Study of Liver and Gastrointestinal Diseases (CIBERehd, Instituto de Salu, [16]Príncipe de Asturias University Hospital, Alcalá University, Madrid, Spain, [17]Division of Liver Diseases, Icahn School of Medicine at Mount Sinai, New York City, New York, USA, [18]Virginia Commonwealth University

Background: Non-invasive tests (NITs) for metabolic dysfunction-associated steatotic liver disease (MASLD) diagnosis and staging face hurdles due to performance limits, especially the sensitivity-specificity trade-off. Robust NITs are needed. The low-cost, simple FIB-4 index is a recommended first-line tool for fibrosis risk. The Metabolomics-Advanced Steatohepatitis Fibrosis Score (MASEF) (part of the OWLiver test) accurately predicts MASH/at-risk MASH. This study evaluated a novel FIB-4 + MASEF strategy to maximize accuracy, sensitivity, specificity, PPV, and NPV, aiming to overcome current limitations. **Methods:** This multicenter study analyzed a cohort of 1122 patients at elevated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

risk for MASLD due to various metabolic comorbidities. FIB-4 and MASEF were determined and compared against the histopathological reference standard. To identify optimal diagnostic thresholds for FIB-4, a grid-based evaluation of all possible FIB-4 cutoff pairs was performed. For each pair, the MASEF score (part of the OWLiver test) was applied exclusively to the indeterminate zone (patients with FIB-4 values between the two cutoffs). This approach allowed for the systematic assessment of the combined strategy's performance across a multidimensional space. A rigorous statistical analysis, including ROC curve modeling and joint maximization of accuracy, sensitivity, specificity, PPV, and NPV, was conducted focusing on identifying a method capable of the simultaneous optimization of all five metrics. **Results:** Analysis of the 1122-patient cohort led to the identification of optimized FIB-4 thresholds (1.08 and 2.61) that enabled a balanced trade-off across all five key diagnostic metrics for detecting at-risk MASH. Using this strategy, the combined FIB-4 and MASEF (cutoff 0.33) approach achieved an accuracy of 78%, sensitivity of 71%, specificity of 82%, PPV of 64%, and NPV of 88%. **Conclusion:** This study demonstrates that the simultaneous maximization of all five key diagnostic metrics is an achievable benchmark for non-invasive testing with the combination of FIB-4 index and MASEF score (OWLiver test). This approach can enhance clinical confidence, streamline diagnostic pathways, and ultimately improve the management of patients with MASLD by providing a more complete and reliable assessment of disease severity.

2078 | DIAGNOSTIC PERFORMANCE OF DIFFERENT NON-INVASIVE FIBROSIS SCORES IN THE GENERAL POPULATION WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Hui Shi[1] Xiaolin Wang[2] Rong Hu[1] Caihong Gu[1] Yilin Zhang[2] Shanghao Liu[2] Xiaolong Qi[2], [1]The First Affiliated Hospital of Kangda College of Nanjing Medical University, [2]Zhongda Hospital, Medical School, Southeast University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a prevalent condition associated with significant liver-related morbidity and mortality, primarily due to progressive liver fibrosis. Non-invasive fibrosis scores are widely used to assess fibrosis risk in MASLD patients. This study evaluates the diagnostic performance of various non-invasive fibrosis scores in identifying advanced fibrosis among MASLD patients in the general population. **Methods:** This study enrolled participants from Lianyungang, China, who underwent standardized health examinations in 2024. Comprehensive physical examination data, venous blood samples for serological biomarkers, and transient elastography for controlled attenuation parameter (CAP) values and liver stiffness measurements (LSM) were collected. Participants with CAP ≥ 248 dB/m and at least one cardiometabolic risk factor were included, excluding other causes of hepatic steatosis. Participants were stratified into two age groups: 18 - 60 years and ≥ 60 years. Eight non-invasive fibrosis scores, including SAFE, FIB-4, MAF-5, LiverRisk, NFS, APRI, AST/ALT Ratio, and Forns index, were calculated. Their diagnostic performance for clinically significant fibrosis (F2, LSM ≥ 8 kPa) and advanced fibrosis (F3, LSM ≥ 10 kPa) was assessed using ROC curve analysis, with AUC as the primary metric. **Results:** The study cohort included 985 MASLD patients (mean age: 49.09 years; 507 males, 478 females). F2 was identified in 61 patients (6.19%), and F3 in 26 patients (2.64%). All eight scores showed robust diagnostic performance for both fibrosis stages ($p < 0.01$). For F2, SAFE had the highest AUC (0.8273, 95% CI 0.76 - 0.89), followed by MAF-5 (AUC = 0.8081). For F3, SAFE (AUC = 0.8815), MAF-5 (AUC = 0.8784), APRI (AUC = 0.8431), and NFS (AUC = 0.8479) performed best. Age-stratified analyses confirmed the consistent reliability of SAFE, MAF-5, LiverRisk, and NFS. MAF-5 was the most stable predictor for F3, with AUC values of 0.9104 in the 18 - 60 age group and 0.8249 in those over 60 years. SAFE maintained strong performance across both age groups (AUC = 0.8909 for 18 - 60 years; AUC = 0.8202 for over 60 years). **Conclusion:** This study demonstrates that SAFE is the superior non-invasive score for detecting significant and advanced fibrosis in MASLD, with consistent diagnostic accuracy across all age groups (AUCs ranging from 0.89 to 0.80).

2079 | EVALUATING THE NONINVASIVE DIAGNOSTIC PATHWAYS FOR IDENTIFYING MASH PATIENTS ELIGIBLE FOR RESMETIROM THERAPY

Larissa Lushniak[1] Alice Parish[1] Amreen Dinani[1], [1]Duke University

Background: Resmetirom was conditionally approved to treat individuals with metabolic dysfunction-

associated steatohepatitis (MASH) and significant fibrosis ($\geq$ F2 fibrosis) in March 2024. The ongoing Phase 3 trial, which led to its approval, relied on biopsy-proven diagnosis, yet the real-world eligibility criteria can be determined with noninvasive tests (NITs). The aim of this study is to understand the pathways employed to assess eligibility for Resmetirom in a tertiary care center. **Methods:** A retrospective cohort of patients with MASH and significant fibrosis deemed eligible for Resmetirom was included (March 2024 to May 2025). Descriptive analysis was used to summarize patient characteristics, lab values, NITs, and, when available, liver biopsy data. Utilization of type and/or combination of NIT was assessed to confirm eligibility. **Results:** A total of 91 patients were considered eligible for Resmetirom prescription, 43 (47.3%) female, 74 (81.3%) white, with mean age of 57 years (SD 13.6), and mean BMI 33.5 (SD 6.2). Statins were the most common concurrent medication (61.5%), followed by GLP1 agonists (39.6%) and metformin (35.2%). Transient Elastography (TE) was the most employed NIT (87%) with mean liver stiffness measurement (LSM) of 10.6 kPa (SD 3.3), followed by Enhanced Liver Fibrosis (ELF) at 45% with mean score of 9.7 (SD 0.8), and MRI elastography (MRE) at 23% with mean LSM of 3.4kPa (SD 0.9). One NIT was performed in 51%, 2 NITs in 37%, and 3 NITs in 11%. One patient had a liver biopsy and no NITs. To determine stage of fibrosis via one NIT (N = 46), TE was utilized solely in 85%, ELF in 13%, and MRE in 6.5%. Among those evaluated by 2 NITs (N = 34), 71% had TE and ELF, 18% TE and MRE, and 12% ELF and MRE. Patient demographics, comorbidities, and laboratory data stratified by number of NITs are described in Table 1. The main reason for performing MRE was due to discordance between previous NITs (12/21, 57%). Liver biopsy was performed in 46 patients: 9% due to discordance in NITs. Of the 46 patients with biopsies, significant fibrosis was determined by histology in 93%, and a majority (72%) had NIT staging that correlated with histologic staging. **Conclusion:** This cohort of patients with MASH and significant fibrosis demonstrates how NITs can be employed to accurately identify individuals eligible for Resmetirom prescriptions. Despite heterogeneity in diagnostic approach, NITs demonstrate a high concordance with histologic staging, supporting their use in place of biopsy. These results provide reassurance and guidance on how to utilize NITs to diagnose MASH with significant fibrosis and guide the use of NITs in disease monitoring and response to treatment.

	Total (N=91)	1 NIT (N=46)	2 NITs (N=34)	3 NITs (N=10)

limited by the absence of in vitro human models that capture hepatic-immune interactions. We developed a macrophage-incorporated liver organoid (MILO) model from human induced pluripotent stem cells (iPSCs) to investigate fibrosis induced by HIV and metabolic stress. **Methods:** Human liver organoids (HLOs) were generated via a 25-day protocol to form 3D spheroids with hepatocyte- and hepatic stellate cell–like populations. In parallel, iPSCs were differentiated into $CD14^+$ macrophages using a feeder- and serum-free 32-day protocol. Pre-macrophages (day 25) were added to HLOs at a 1:4 ratio to generate MILOs. Organoids were treated with HIV or free fatty acids (FFAs) to model HIV and MASLD. qPCR, immunofluorescence, and flow cytometry were used to evaluate responses. Iodixanol gradients enabled cell-type–specific analysis. **Results:** Organoids exhibited hepatic function, including albumin production and FFA-induced lipid accumulation. Macrophages integrated into organoids and enhanced immune representation. HIV and/or FFA exposure led to nuclear translocation of Yes-associated protein (YAP; a key regulator of liver fibrosis) along with upregulation of fibrogenic genes (TIMP1, αSMA, COL1A1). HIV induced both M1 (CD80, CCR7, IL1B) and M2 (CD163, CD206, ARG1) markers, with M2 predominating. siRNA knockdown of PI3K, AKT, ERK, and JNK pathways downregulated YAP and reduced hepatic stellate cell activation. **Conclusion:** This iPSC-derived MILO model recapitulates HIV- and MASLD-associated fibrogenesis and enables cell-type–specific analysis. It represents a robust platform for dissecting mechanisms and testing antifibrotic therapies for HIV-related liver disease.

2081 | SOLUBLE CD46 AS A MARKER OF HEPATIC STEATOSIS IN LIVER SURGERY

Paul Kupke[1] Florian Bitterer[1] Laura Kupke[1] Gunther Glehr[1] Katja Evert[1] Ingo Einspieler[1] Matthias Hornung[1] Christian Stroszczynski[1] Hans Schlitt[1] Juergen Wenzel[1] Edward Geissler[1] James Hutchinson[1] Jens Werner[1], [1]University Hospital Regensburg

Background: We recently discovered interleukin-4-secreting ($IL\text{-}4^+$) iNKT cells to be overrepresented in steatotic liver. This could be attributed to stress-induction of matrix metalloproteases (MMP) in hepatocytes, which led to indiscriminate cleavage of immune receptors. Loss of cell-surface CD46 then resulted in unrepressed differentiation of $IL\text{-}4^+$ iNKT cells. Here, we asked whether sCD46 levels could predict steatosis in patients planned for liver surgery and thereby improve the detection of high-risk steatosis identifying patients that would benefit from alternative treatment options. **Methods:** sCD46 was measured in stored plasma from 156 prospective living liver donors and serum from 91 tumor patients. Steatosis was assessed by ultrasonography, computed tomography and liver histology. Clinical data were collected from hospital records. Waist circumference was measured from abdominal CT images. Significance tests and receiver operating characteristic (ROC) curve analyses were performed in R (4.3.3). ROC curves were compared with the DeLong test. Results were validated by training/validation sets and cross-validation. **Results:** Prospective living liver transplant donors and patients with liver tumors with moderate or severe steatosis had higher sCD46 levels than those without. After stratified random assignment of cases, we found that sCD46 performed well in classifying steatotic donors. In the validation set, the correct classification rate (CCR) was 78.8 %. We further demonstrated sCD46 was superior to Fatty Liver Index (FLI) in classifying steatotic donors. In liver tumor patients, histologically verified high-grade steatosis could be predicted with a CCR of 97.8%. The perfomance of sCD46 could be further improved by combination with pre-surgery computed tomography (AUC 0.956). **Conclusion:** sCD46 is a reliable diagnostic marker of hepatic steatosis, which can be conveniently and non-invasively measured in serum and plasma samples. Our work raises the possibility of using sCD46 as a biochemical screening tool for evaluating patients before liver surgery regarding high-risk steatosis.

Background: The Fibrosis-4 (FIB-4) index is widely used to exclude advanced fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD), using a threshold of <1.3. However, its diagnostic accuracy varies, and misclassification may delay treatment. This study evaluated the negative predictive value of FIB-4 <1.3 using liver stiffness measurement (LSM) and liver biopsies as comparators, and identified factors associated with false negatives. **Methods:** MASLD patients referred for Fibroscan (2012–2016) were retrospectively identified. Clinical, biochemical, and anthropometric data were extracted from electronic health records. FIB-4 was compared with LSM ($\geq$8kPa), staging in liver biopsy, and clinical outcomes. Statistical analysis was performed using SPSS and R. **Results:** Among 832 patients (64% male; median age 51 years; median BMI 29.7 kg/m², 41% non-White), FIB-4 misclassified 31.4% (262/832) relative to LSM. Of 324 patients with FIB-4 ≥ 1.3, 55.6% had normal LSM; of 508 with FIB-4 <1.3, 16.1% had elevated LSM. Biopsy was performed in 299 patients; of 176 with FIB-4 <1.3, 33.5% had advanced fibrosis (stage ≥ 3, NASH CRN). False negatives were more likely in those with diabetes (T2DM) (26.8% vs 11.7%, $p<0.001$), hypertension (26.2% vs 12.3%, $p<0.001$), and BMI ≥ 27.5 kg/m² (21.6% vs 8.6%, $p=0.004$). On multivariate analysis, BMI (OR 1.11, 95% CI 1.04–1.18; $p<0.001$) and hypertension (OR 2.27, 95% CI 1.06–4.86; $p=0.036$) independently predicted false negatives. A combined predictive model including FIB-4, BMI, hypertension, and diabetes (P(advanced fibrosis) = 1/(1+e-(-5.5280+0.7499 (FIB-4)+0.0941(BMI)+0.3146(HTN)+0.8563(Diabetes) - coefficients were calculated using logistic regression models in R), outperformed FIB-4 alone (NRI 0.0433, $p=0.03$; IDI 0.2320, $p<0.001$). During follow-up, 14% of false negatives developed liver complications, 16% had cardiovascular events, and 2% died. Cox regression showed no significant differences in liver (HR 0.80–0.66, $p>0.3$), cardiovascular (HR 1.18–1.35, $p>0.4$), or mortality outcomes (HR 2.04–3.66, $p>0.2$) for false negative results, though trends suggest possible clinical implications. **Conclusion:** FIB-4 <1.3 misses advanced fibrosis in 1 in 6 patients by LSM and 1 in 3 by biopsy. Elevated BMI and hypertension increase the risk of false negatives. These findings support incorporating metabolic risk factors into MASLD fibrosis stratification to improve diagnostic accuracy and avoid delayed care.

2083 | RISK STRATIFICATION USING NON-INVASIVE TESTS AND MAGNETIC RESONANCE ELASTOGRAPHY REVEALS SIMILAR PATTERNS IN METALD AND MASLD

Akash Roy[1] Shardhya Chakroborty[1] Surabhi Jajodia[2] Usha Goenka[2] Anand Kulkarni[3] Nipun Verma[4] Awanish Tewari[1] Nikhil Sonthalia[1] Uday Ghoshal[1] Rajender Reddy[5] Mahesh Goenka[1], [1]Apollo Hospitals, [2]Radiology, Apollo Hospitals, [3]AIG Hospitals, [4]PGIMER, Chandigar, [5]University of Pennsylvania

Background: Non-invasive tests (NITs) for fibrosis risk stratification are central to optimized care in metabolic dysfunction-associated steatotic liver disease (MASLD). However, data on their performance in individuals with metabolic dysfunction and alcohol-associated liver disease (MetALD) are scarce. We aimed to assess the performance of measures of NITs against magnetic resonance elastography (MRE) in this population. **Methods:** Adults ($\geq$ 18 years) meeting MASLD criteria based upon cardiometabolic risk factors (CMRFs) and evidence of hepatic steatosis were prospectively enrolled. Self-reported alcohol history, anthropometry indices (AI), and biochemical indices were recorded. Contemporaneous MRE served as the outcome measure with cut-offs for significant fibrosis (SF, $\geq$F2) and advanced fibrosis (AF, $\geq$F3) as 3.14kPa and 3.53kPa, respectively and compared with Fibrosis-4 (Fib-4), AST platelet ratio index (APRI), and NAFLD fibrosis score (NFS) in MASLD and Met-ALD. **Results:** Among 1010 individuals [44(35-54years),35.2%females] 842(83.3%) had MASLD and 168(16.6%) had MetALD. Anthropometric indices (AI) [BMI, 27.2(24.8-30.4) vs27.6(25.2-30.4), hip circumference [105(100-111) vs 105(100-110.5)], waist circumference [98.7 (91-104) vs 98(92.5-105)] and CMRF [diabetes,36.6% vs.30.9%, $p=0.15$], hypertension (38.2%vs.58 34.5% $p=0.36$), dyslipidaemia (31.5% vs 33.9%, $p=0.55$) were similar. The burden of fibrosis (SF, 21.6% vs 27.9%, $p=0.07$; AF,15.4% vs 18.4%, $p=0.33$) among MASLD and Met-ALD was also similar. Performance of APRI in the entire cohort was suboptimal [AUC 0.63(0.60-0.66 for AF)]. In MetALD, FIB-4 had an Sn, Sp, PPV, and NPV of 67.7%,73.7%,36.8% and 91%, respectively, for AF. Corresponding metrics for NFS were 77.4%,72.3%,38.7% and 93.4%. AUC for FIB-4 for MASLD and Met-ALD in predicting AF were similar [0.77(0.74-0.79), 0.78(0.71-0.84),$p=0.82$]. The AUC of NFS for MASLD and Met-ALD [0.80 (0.70.83) and 0.80 (0.73-0.86), $p=0.98$] were also similar. NFS performed better than FIB-4 in MASLD but showed equivalent performance in Met-ALD (AUC 0.80 vs 0.78, $p=0.48$) **Conclusion:** In a prospective cohort, MASLD and Met-ALD showed similar AI, CMRF, and fibrosis burden. Compared with MRE, FIB-4 and NFS show acceptable performance in MetALD, replicating MASLD performance, and may be used for Met-ALD risk stratification.

2084 | EVALUATING ELASTOGRAPHY IN LEAN NASH PATIENTS: A SUPERIOR DIAGNOSTIC TOOL OVER ULTRASOUND?

Simardeep Singh[1] Boniface Mensah[1] Manish Arora[2], [1]MedStar Health Georgetown University (Baltimore) Program, [2]Decatur Morgan Hospital

Background: Fatty liver disease, particularly non-alcoholic steatohepatitis (NASH), often remains underdiagnosed. While liver biopsy is the diagnostic gold standard, its invasive nature limits widespread application. Ultrasound, commonly used for hepatic evaluation, may overlook fibrosis, especially in lean NASH patients. Elastography, with its enhanced sensitivity, may address this gap. This study assesses the utility of elastography in detecting fibrosis in patients with negative ultrasound findings but significant metabolic risk factors, particularly diabetes and hyperlipidemia. **Methods:** This retrospective cohort study, conducted between 2023 and 2024, included 450 adults without pre-existing liver disease who underwent screening via ultrasound and elastography. Patients with incomplete records or liver-impacting malignancies were excluded. The study focused on individuals with negative ultrasound findings for fatty liver but positive elastography results, meeting the inclusion criteria. Data were sourced from institutional electronic health records, with liver stiffness (kPa) measured by elastography serving as the primary variable. Secondary variables included demographics, BMI, diabetes, and hyperlipidemia. Statistical analyses involved descriptive statistics, chi-square tests, and logistic regression to identify predictors of fibrosis.

Results: In a cohort with a mean age of 63 years and an equal gender distribution, metabolic comorbidities were prevalent, with • 44% having diabetes, • 50% hyperlipidemia, and • 50% being classified as overweight or obese. Among 450 patients with negative ultrasound, 11% were diagnosed with fibrosis through elastography, with F2 fibrosis staging in 86%, F3 in 12%, and F4 in 2%. Notably, 18% of fibrosis cases were found in lean individuals (BMI < 25), highlighting the presence of lean NASH. Diabetes and HLD emerged as significant predictors of fibrosis ($p < 0.01$ and $p < 0.05$, resp.), with the highest risk observed in individuals with both conditions, accounting for 32% of fibrosis cases. **Conclusion:** Elastography significantly enhances fibrosis detection in patients with negative ultrasound findings, particularly in lean NASH cases. Metabolic risk factors such as diabetes and hyperlipidemia were more predictive of fibrosis than obesity. This underscores elastography's potential as a superior non-invasive tool for liver disease screening in at-risk populations. Future studies should incorporate larger cohorts and prospective designs to validate these findings.

2085 | ENHANCED LIVER FIBROSIS (ELF) TEST CORRELATES BETTER WITH MRE THAN VCTE IN A REAL-WORLD COHORT OF PATIENTS WITH SUSPECTED MASH

Cecilia Katzenstein[1] Anna Mageras[1] Mark Miller[1] Xiaotao Zhang[1] Meena Bansal[2], [1]Icahn School of Medicine at Mount Sinai, [2]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: The Enhanced Liver Fibrosis (ELF) test, FDA-approved for prognostication, shows promise for identifying patients with at-risk metabolic dysfunction-associated steatohepatitis (MASH), but its real-world use remains underexplored. Magnetic Resonance Elastography (MRE) is limited by cost and availability, vibration-controlled transient elastography (VCTE) is less reliable in patients with obesity and is operator-dependent, while FIB-4 has a substantial indeterminate range. We evaluated ELF's ability to predict fibrosis severity assessed by MRE (kPa) compared with other non-invasive tests. **Methods:** This prospective study included patients evaluated for MASH at an urban, academic center who underwent FIB-4, VCTE, ELF, and MRE as part of routine care. Due to right-skewness and nonlinearity, ELF and MRE values were log-transformed to improve model fit. Model assumptions were confirmed via regression diagnostics. Spearman's correlation assessed ELF–MRE association. Univariable linear regression on log-transformed values was used, with β interpreted as percent change in stiffness per 1% change in ELF. This approach was applied consistently in subgroup analyses by diabetes status, sex, age, and indeterminate FIB-4 value. Variance explained was quantified by R^2. **Results:** The cohort ($n = 57$) had a mean age of 57.5 years (SE 2.0); 57% were female, and 60% Hispanic. MRE stiffness averaged 3.8 kPa (SE 0.20), and ELF 9.5 (SE 0.17). ELF was strongly correlated with MRE ($\rho = 0.68$, $p < 0.001$). In a log-log regression, a 1% increase in ELF was associated with a 2.01% increase in liver stiffness, explaining 50% of the variance. VCTE and FIB-4 explained 48% and 23% of variance, respectively. Subgroup analyses confirmed ELF's strong predictive power: in those with diabetes, ELF explained 51% variance; in males, 54%. Predictive strength was highest in younger patients and declined with age. ELF outperformed FIB-4 in all groups and VCTE in women and patients under 40 years old. In those with indeterminate FIB-4, ELF showed a stronger association with MRE than VCTE (table 1). **Conclusion:** In this real-world cohort, ELF outperformed VCTE and FIB-4 in predicting liver stiffness. ELF performed most consistently across all subgroups and added predictive value when FIB-4 was inconclusive. As an FDA-approved, blood-based test, ELF offers a scalable alternative when MRE is unavailable. These results support the potential use of ELF to identify patients eligible for MASH therapies and highlight the need for broader coverage and adoption in clinical practice, particularly in settings where patients may not have access to evaluation via MRE.

Table 1. Predictive Performance of ELF, VCTE, and FIB-4 for MRE-Assessed Liver Stiffness Using Linear Regression with Log-Transformed Variables

	N	ELF R^2	ELF β		VCTE R^2	VCTE β		FIB-4 R^2	FIB-4 β

2086 | SECOND HARMONIC GENERATED IMAGING WITH QFIBROSIS PROVIDES QUANTITATIVE INFORMATION ON FIBROSIS SEVERITY AND PREDICTS THE FUTURE COURSE OF FIBROSIS IN METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

David Kleiner[1] Ekaterina Smirnova[2] Dean Tai[3] Cynthia Behling[4] Oscar Cummings[5] Ryan Gill[6] Patricia Belt[7] Daniela Allende[8] Danielle Carpenter[9] Cynthia Guy[10] Matthew Yeh[11] Shailaja Reddy[2] Faridoddin Mirshahi[2] Arun Sanyal[12], [1]National Cancer Institute, Bethesda, [2]Virginia Commonwealth University, Richmond, VA, [3]HistoIndex, [4]Department of Pediatrics, University of

California San Diego, San Diego, CA, [5]Indiana University School of Medicine, Indianapolis, IN, [6]University of California San Francisco, San Francisco, CA, [7]Johns Hopkins University, Baltimore, MD, [8]Cleveland Clinic, Cleveland, OH, [9]Saint Louis University, St. Louis, MO, [10]Duke University, [11]University of Washington, Seattle, WA, [12]Virginia Commonwealth University

Background: Fibrosis progression or regression can occur in MASLD even without specific therapy. Conventional fibrosis stages do not predict the future course of fibrosis. Second harmonic generation/two-photon excitation (SHG/TPE) with qFibrosis analysis quantitatively captures collagen fibers which also correlates with fibrosis severity. Its ability to predict the future course of fibrosis is not known. This study aims to: (1) independently validate the qFibrosis scoring, and (2) evaluate the prognostic performance of qFibrosis parameters (qFPs) in MASLD. **Methods:** A retrospective ancillary study of the NIDDK NASH CRN cohort included subjects with ≥ 2 biopsies > 1 year apart, with no intervening treatment. The biopsies were read by the NASH CRN pathology committee using the NASH CRN system masked to qFibrosis stage. SHG/TPE imaging was performed on unstained tissue sections and quantitative fibrosis (qFibrosis) stage computed by investigators masked to NASH CRN pathology committee scores. Data analysis was performed by an independent statistician using a pre-specified analytical plan. Baseline biopsies were related to qFibrosis stage and continuous value. Baseline fibrosis parameters were related to progression, no change or regression in CRN stage using lasso regression. The changes were further quantified in portal, peri-portal, mid-zonal, pericentral and central vein regions. Model performance was assessed by area under receiver operating characteristic (AUROC) curves. **Results:** Baseline composite qFibrosis scores correlated strongly with CRN fibrosis staging ($r = 0.75$, $p < 0.001$). Zonal analysis revealed moderate to strong correlations between fibrosis severity and qFPs in periportal and portal regions (r ~0.68–0.75). Progressors exhibited an inverse correlation with periportal features and a direct correlation with midzonal collagen density, suggesting loss of collagen in periportal region and mid-zonal accumulation of collagen as indicators of worsening disease. In contrast, regressors demonstrated higher baseline periportal and portal collagen complexity, consistent with a preserved architecture conducive to fibrosis reversal. Predictive models achieved AUROCs of 0.773 (progression) and 0.802 (regression). **Conclusion:** qFibrosis stages and scores correlate well with NASH CRN fibrosis staging. SHG analysis of fibrosis may have prognostic utility in MASLD and be used to enrich study populations for patients most at risk for fibrosis progression. Additional modeling approaches are needed to further strengthen the predictive framework. A larger validation study involving over 1,000 biopsies is underway.

2087 | EFFECT OF VITAMIN E ON LIVER STIFFNESS IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

seungteak Lee[1] Juneyoung Lim[1] Eun Sun Jang[2] Min Kyung Park[3] Jin-Wook Kim[1], [1]Seoul National University Bundang Hospital, [2]Seoul National University College of Medicine, [3]Seoul National University Hospital

Background: Current guidelines on the therapeutic efficacy of vitamin E on metabolic dysfunction-associated steatotic liver disease (MASLD) are based on limited evidence and it is not clear if vitamin E affects liver fibrosis in MASLD patients. Vibration-controlled transient elastography (VCTE) is a well-established non-invasive method for assessing liver fibrosis in MASLD. In this study, we evaluated the effect of vitamin E on the liver stiffness measured by VCTE in patients with MASLD. **Methods:** In this retrospective cohort study, we identified MASLD patients who underwent serial measurements of liver stiffness by VCTE. Patients with viral hepatitis were excluded. Administration of other hepatotonics, i.e., ursodeoxycholic acid, silymarin, biphenyl dimethyl dicarboxylate, were controlled as covariates by multivariate logistic regression analysis. **Results:** A total of 5,055 patients with MASLD received at least 2 measurements of liver stiffness by VCTE during the period between July 2020 and March 2025. After excluding 1,206 patients with chronic hepatitis B and 105 patients with chronic hepatitis C, 3,746 patients were finally selected for analysis. The median duration of follow-up was 724 days (interquartile range = 549). The median change in liver stiffness measurement (LSM) was -0.2 kPa, -3.6% from baseline (interquartile range = 2.2kPa, 40%). The median duration of vitamin E therapy was 455 days (interquartile range = 720). Multivariate logistic regression analysis showed that use of vitamin E for more than 3 months was associated with significant improvement in LSM: the odds ratio for improvement of LSM more than 50% from baseline was 2.40 (95% confidence interval, 1.68 – 3.43). **Conclusion:** Use of vitamin E was associated with significant improvement of LSM in MASLD patients.

2088 | NON-INVASIVE MACHINE LEARNING MODEL IMPROVES MID-STAGE FIBROSIS DETECTION IN MASLD

Laith Alomari[1] Zaid Al-Fakhouri[2] Tinsae Tsegaye Anebo[1] Emmanuel Otabor[1] Justin Riley Lam[1] Daniel Simadibrata[3] Jana Alomari[4] Karecia Byfield[1] Jordan Carty[1] Delano Carty[1] Thai Hau Koo[5] Oluwanifemi Balogun[1] Ghideon Ezaz[1], [1]Jefferson Einstein Philadelphia Hospital, [2]The MetroHealth System, CWRU, [3]MetroHealth Medical Center, Case Western Reserve University, [4]Faculty of Medicine, Jordan University of Science and Technology, [5]University of Sciences Malaysia Specialist Hospital

Background: Non-invasive tests like FIB-4 reliably distinguish both ends of the liver fibrosis spectrum but have limited performance at intermediate stages. We developed and validated a machine-learning classifier using routine demographics and laboratory values for two tasks: discriminating $\leq$ F2 versus $\geq$ F3 (advanced fibrosis) and separating mild fibrosis (F1 or F2) from F3 in biopsy-proven MASLD patients. Performance of the model was compared against FIB-4. **Methods:** Data from 452 consecutive MASLD patients obtained from NAFLD Adult database with contemporaneous liver biopsy and 16 baseline laboratory/demographic variables obtained within 6 months of liver biopsy were retrospectively analyzed. A LightGBM gradient-boosting classifier with class-balanced focal loss ($\alpha = 0.25$, $\gamma = 1.5$) was trained on 75 % of the cohort and evaluated on a held-out 25 % test set. Performance was evaluated by area under the receiver operating characteristic curve (AUROC), sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV); FIB-4

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

was calculated on the same dataset for benchmarking. **Results:** In distinguishing ≤ F2 versus ≥ F3 (test n = 113), the classifier achieved an AUROC of 0.851 (95% CI: 0.826, 0.891), significantly outperforming FIB-4's AUROC of 0.788 ($p < 0.001$). It reached 95% sensitivity and NPV of 85% for ruling out advanced fibrosis and 73% specificity and 73.3% PPV for detecting ≥ F3 fibrosis. When separating milder fibrosis stages (F1 or F2) from F3 (excluding F0 and F4; test n = 72), it attained an AUROC of 0.801 (95% CI: 0.797, 0.825), with a specificity of 92% distinguishing F3 from F1 or F2. **Conclusion:** A focal-loss LightGBM model built on routine labs and demographics outperforms FIB-4 for ruling in advanced fibrosis and delivers actionable discrimination of mid-stage fibrosis. This non-invasive, scalable approach could enhance triage for imaging or biopsy and merits prospective validation.

2089 | IRON MARKERS IN MASLD AND METALD: A COMPARATIVE ANALYSIS FROM NHANES 2017-2020

Sheena Bhushan[1] Kris Kowdley[1], [1]Liver Institute Northwest

Background: Elevated serum ferritin (SF) levels have been associated with hepatic injury and fibrosis in metabolic dysfunction-associated steatotic liver disease (MASLD). Experimental evidence suggests that alcohol consumption may contribute to iron dysregulation, thereby exacerbating hepatic inflammation and fibrogenesis. However, to date, no population-based comparative studies have evaluated the role of iron-related biomarkers in MASLD and metabolic dysfunction-associated alcohol-related liver disease (metALD). The objective of this study is to compare serum ferritin (SF) and transferrin saturation (TSAT) levels and examine their associations with liver stiffness measurement (LSM) in individuals with MASLD and metALD. **Methods:** Data from the 2017–2020 cycles of the National Health and Nutrition Examination Survey (NHANES) were analyzed. The study population included 843 individuals who met the diagnostic criteria for MASLD, defined as a controlled attenuation parameter (CAP) ≥288 dB/m, and 67 individuals who met criteria for metALD. SF levels greater than 400 in men and gretaer than 300 in women were considered elevated. A TSAT greater than 45% was considered elevated. Statistical analyses included Mann–Whitney U tests for group comparisons and Spearman correlation coefficients to assess associations between variables. Multivariable logistic regression models were employed to adjust for potential confounders, including age, sex, BMI, diabetes mellitus, and dyslipidemia. **Results:** Individuals with meALD has significantly higher SF and TSAT levels compared to MASLD (ferrtin p = 0,0057; TSAT p = 0.0148), while liver stiffness did not differ significantly (p = 0.3808). LSM showed weak correlations with ferritin in MASLD (p = 0.08) and TSAT (p = -0.077), whereas LSM in metALD was more strongly correlated with both ferritin (p = 0.239) and TSAT (p = 0.204). **Conclusion:** Iron biomarkers were more strongly associated with LSM in metALD, thereby suggesting that SF and TSAT may have the potential to be utilized as makers for risk stratification. Our study is limited by a small sample size in the metALD group which may limit power to detect subtle associations.

Disclosures: Sheena Bhushan: Nothing to Disclose, Kris Kowdley: Nothing to Disclose

2090 | THE OBESITY-RELATED MUTATION GENES ON HEPATOCARCINOGENESIS IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Jee-Fu Huang[1] Ming-Lun Yeh[2] Wan Long Chuang[1] Ming-Lung Yu[1] Shu-Chi Wang[1], [1]Kaohsiung Medical University, [2]National Sun Yat-Sen University

Background: In addition to liver injury, metabolic dysfunction-associated steatotic liver disease (MASLD) carries a potential risk for hepatocellular carcinoma (HCC) development. The study aimed to investigate the characteristics of obesity-related driver gene mutations in hepatocarcinogenesis. **Methods:** We investigated the impact of body mass index (BMI) on HCC survival by using the Cancer Genome Atlas Liver (TCGA-LIHC) dataset. To explore the effects of obesity-related gene mutations on HCC, we analyzed the driver mutation genes between 34 patients with obese BMI ≥ 27 kg/m^2 and 23 patients with BMI < 27 kg/m^2. We also validated the peripheral blood mononuclear cells (PBMC) and exosome samples for the variant rate by digital PCR in 96 MASLD patients. **Results:** Using Cbio-portal, we identified 414 driver mutation genes in patients with obesity and 127 driver mutation genes in their non-obese counterparts. Obesity HCC patients had significantly worse survival outcomes. Functional analysis showed that obese-related genes significantly enriched the regulated lipid and insulin pathways in HCC. The insulin secretion pathway in obese patients with HCC-specific survival identified ABCC8 and PRKCB as significant genes ($p < 0.001$). The significant differences in gene mutation

and gene expression profiles were observed in obese patients compared to non-obese patients. The ABCC8 variants detected by digital PCR test in PBMC samples had a variant rate of 14.5%, which was significantly higher than that of non-obese MASLD patients. **Conclusion:** The study showed that an obesity-related gene mutation, ABCC8, predicted for HCC development in MASLD.

2091 | LIPIDOMIC ANALYSIS AND MACHINE LEARNING MODELS FOR PREDICTING SIGNIFICANT LIVER FIBROSIS IN PATIENTS WITH SEVERE OBESITY UNDERGOING BARIATRIC SURGERY

Chien-Hung Lu[1] Yin-Ru Hsieh[2] Shih-Yi Huang[2] Weu Wang[3] Ching-Wen Chang[4] Binar Panunggal[5] I-Wei Chang[6] Chi-Long Chen[6] Chun-Chao Chang[7] Wei-Yu Kao[1], [1]Division of Gastroenterology and Hepatology, Taipei Medical University Hospital, Taipei, Taiwan, [2]School of Nutrition and Health Sciences, Taipei Medical University, Taipei, Taiwan, [3]Division of Digestive Surgery, Taipei Medical University Hospital, Taipei, Taiwan, [4]Graduate Institute of Metabolism and Obesity Sciences, Taipei Medical University, Taipei, Taiwan, [5]Department of Nutrition Science, Faculty of Medicine, Diponegoro University, Semarang, Indonesia, [6]Department of Pathology, Taipei Medical University Hospital, Taipei, Taiwan, [7]TMU Research Center for Digestive Medicine, Taipei Medical University, Taipei, Taiwan

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) affects over 30% of the global population and is strongly associated with obesity. Significant liver fibrosis, an advanced stage of MAFLD, poses a major risk factor for hepatocellular carcinoma. Despite its increasing prevalence, the accuracy and cost-effectiveness of current non-invasive tools for liver fibrosis assessment remain limited, with liver biopsy still considered the gold standard. Lipidomic analysis offers a promising approach for identifying potential biomarkers across diverse lipid profiles. This study aimed to apply statistical methods and machine learning models to lipidomic data to identify potential biomarkers and predict significant liver fibrosis. **Methods:** This prospective study included 50 patients with severe obesity who underwent wedge liver biopsy and metabolic bariatric surgery at Taipei Medical University Hospital between September 2016 and December 2020. Significant liver fibrosis was defined as a fibrosis score of ≥ 2. Pre-surgery liver samples and both pre- and post-surgery serum samples were collected and prepared for mass spectrometric analysis. Statistical methods, including fold change analysis and one-way ANOVA with post-hoc tests were performed to identify lipid differences between groups. Additionally, machine learning algorithms, including Random Forest, logistic regression, support vector machine, AdaBoost, and XGBoost, were employed to predict significant liver fibrosis, with 70% of the entire dataset used for training and 30% for testing. **Results:** Patients with normal liver histology (n = 10), MASH without or with mild fibrosis (n = 19), and MASH with significant fibrosis (n = 21) were included. Lipidomic analysis identified the relative abundance of diradylglycerolipid 34:1 and triradylglycerolipid 52:3 as promising biomarkers for assessing liver fibrosis. Machine learning algorithms consistently demonstrated robust prediction of significant liver fibrosis (AUROC: 0.967–0.989) across different models and further identified phosphatidylinositol 36:2 as a key feature of importance. **Conclusion:** Lipidomic analysis using statistical methods and machine learning models is a promising and robust approach for predicting significant liver fibrosis. These findings provide insights into underlying mechanisms, therapeutic targets, and predictive biomarkers, and may be incorporated into current clinical tools for predicting significant liver fibrosis in patients with severe obesity and MAFLD.

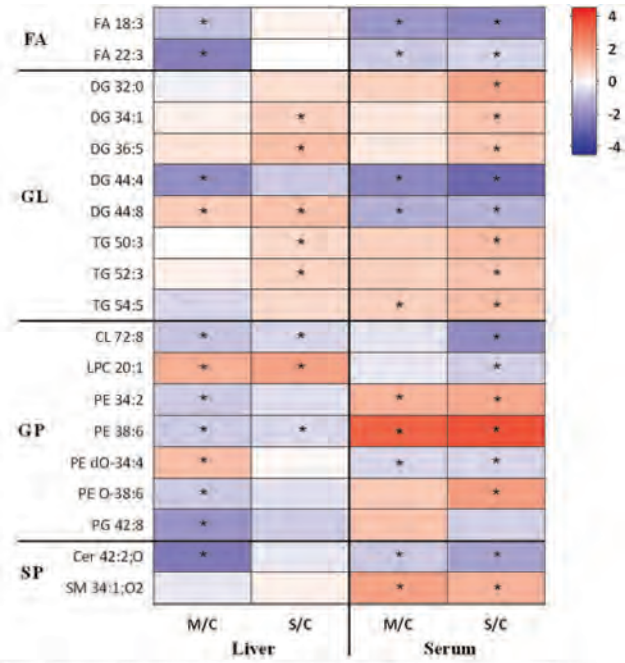

Figure. Statistical analysis of lipid species overlapping between liver and serum samples. Statistical analysis between groups was performed with fold change analysis and ANOVA with post-hoc tests. C, normal liver histology; M, MASH with no or mild fibrosis; S, MASH with significant fibrosis.

2092 | CLINICAL OBESITY IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) IS ASSOCIATED WITH ADVANCED FIBROSIS AND SEVERE STEATOSIS: VALIDATING CLINICAL OBESITY DEFINITION IN A MASLD COHORT

Karen Cheuk Ying Ho[1] Rex Wan-Hin Hui[1] Trevor Kwan-Hung Wu[1] Chi Ho Lee[1] David Tak-Wai Lui[1] Wai-Kay Seto[2] Man-Fung Yuen[2] Lung Yi Mak[2], [1]Department of Medicine, Queen Mary Hospital, The University of Hong Kong, [2]State Key Laboratory of Liver Research, The University of Hong Kong

Background: The Lancet Diabetes & Endocrinology Commission has proposed a new definition of clinical obesity due to inadequacy of current body mass index (BMI)-based measurements[1]. This study aims to apply clinical obesity criteria in a cohort of Asian patients with metabolic dysfunction associated steatotic liver disease (MASLD) to evaluate its associations with liver-specific parameters. **Methods:** We enrolled 642 patients with MASLD and valid vibration-controlled transient elastography (VCTE). A subgroup of 254 patients underwent additional bioelectrical impedance analysis (BIA). The diagnosis of clinical obesity required fulfillment of both anthropometric (waist circumference $\geq$90 cm in Asian male or $\geq$80 cm in Asian female, in addition to BMI $\geq$25 kg/m2) and clinical criteria (at least one signs or symptoms of ongoing dysfunction of organ system due to obesity, excluding liver disease). Univariate and multivariate analysis were applied to calculate p-value, odds ratio (OR) and 95% confidence intervals (95%CI). Severe steatosis and advanced fibrosis/cirrhosis (F3/F4) were defined by VCTE parameters, at-risk metabolic dysfunction-associated steaotohepatitis (MASH) was defined by FAST score[2] and major adverse cardiovascular events (MACE) were defined by acute myocardial infarction, cardiac revascularization procedure and stroke. **Results:** Among 642 MASLD patients (mean age 55.76+/-12.47 years; 49.20% male, mean BMI 28.24+/-4.66 kg/m^2, 76.0 % severe steatosis, 12.46% F3/F4), 46.11% of patients fulfilled the diagnosis of clinical obesity. Compared to BMI-based criteria, clinical obesity criteria identified more patients with F3/F4 (8.11% vs 20.61%, $p<0.001$), severe steatosis (67.57% vs 83.79%, $p<0.001$), at-risk MASH (0% vs 3.38%, $p=0.056$) and MACE (2.70% vs 11.15%, $p=0.006$). Clinical obesity was an independent predictor of F3/F4 (OR 4.07, 95%CI 2.20-7.56) and severe steatosis (OR 2.44, 95%CI 1.64-3.64). Other independent predictors of F3/F4 included aspartate transaminase level (OR 1.04, 95%CI 1.02-1.05), platelet count (OR 0.98, 95%CI 0.98-0.99), and diabetes mellitus (OR 2.70, 95%CI 1.53-4.74). Male gender (OR 3.35, 95%CI 1.77-6.35), age (OR 1.10, 95%CI 1.06-1.13) and hypertriglyceridemia (OR 3.65, 95%CI 1.58-8.40) were independent predictors of MACE. BIA revealed a lower appendicular skeletal muscle mass percentage (27.04% vs 41.09%, $P<0.001$) and a greater visceral fat index (15.0 vs 9.0, $p<0.001$) in patients fulfilling clinical obesity criteria versus BMI-based criteria.
Conclusion: Clinical obesity criteria effectively identify MASLD patients with advanced fibrosis, severe steatosis, at-risk MASH and MACE.

2093 | THE UTILITY OF ROUTINELY COLLECTED NON-INVASIVE TESTS TO ASSESS MORTALITY RISK IN A LARGE REAL-WORLD COHORT OF PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS FROM THE UNITED STATES

Jörn Schattenberg[1] Zuleika Aponte-Torres[2] Ronald Herrera[3] Mireia Raluy[4] Mark Yates[4] Ramy Younes[3] Claudio Sartini[3], [1]Saarland University Medical Center Homburg, [2]Boehringer Ingelheim Pharmaceuticals, Inc., [3]Boehringer Ingelheim International GmbH, [4]Evidera, Data Analytics

Background: Fibrosis Score 4 (FIB-4) is a well-established liver fibrosis risk assessment tool. Higher scores indicate more severe disease and are associated with increased mortality. Nevertheless, it is uncertain whether other biomarkers that are routinely collected, such as aspartate transaminase (AST), alanine transaminase (ALT), the AST/ALT ratio, platelet count, estimated glomerular filtration rate (eGFR), and glycated hemoglobin (HbA1c), can serve as prognostic indicators. This study aimed to establish predictors of prognosis as it is crucial for identifying high risk patients and facilitating healthcare providers to appropriately

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

focus on early interventions. **Methods:** This was a retrospective cohort study using Optum Market Clarity data (2016-2021). MASH was identified by ICD10-CM code K75.81, with AST, ALT, and platelets tests within 3 months of diagnosis, excluding prior liver diseases. At MASH diagnosis, patients were classified by presence of cirrhosis based on ICD-10 codes and FIB-4 score was calculated. Fine-Gray models were used to assess the association between non-invasive tests (NITs) and all-cause mortality, and were adjusted for age, sex, region, and ethnicity. **Results:** A total of 18,710 MASH patients were included in the study. In the overall MASH population, a FIB-4 score greater than 2.67, compared to a score of 2.67 or lower, was a strong predictor of mortality, associated with a seven-fold increase in risk (adjusted hazard ratio [aHR] = 7.06; 95% confidence interval [CI] = 6.37–7.83). Elevated AST levels (>40 U/L vs. ≤ 40 U/L; aHR = 1.38, 95% CI = 1.24–1.53) and lower platelet counts ($<150 \times 10^3/\mu L$ vs. $\geq 150 \times 10^3/\mu L$; aHR = 2.83, 95% CI = 2.54–3.14) were linked to increased mortality. Additionally, reduced kidney function (eGFR <60 mL/min/1.73 m² vs. ≥ 60 mL/min/1.73 m²) was associated with a more than two-fold heightened risk of mortality. **Conclusion:** It is important to measure FIB-4, its components (AST or platelets) and eGFR in routine practice, as they showed potential as prognostic biomarkers for overall mortality. The eGFR association with mortality indicated that assessing kidney disease severity in MASH is also important. However, more research is needed to understand whether these biomarkers confirm their prognostic value in different populations and different countries. The findings from this study can inform future MASH clinical guidelines regarding risk stratification and clinical assessment.

2094 | CENTRAL OBESITY INDICES PROVIDE BETTER PROGNOSTIC VALUE WHILE ENSURING ROBUST MASLD DIAGNOSIS

Tianyuan Yang[1] Tong Bu[1] Qi Wang[1], [1]Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, China

Background: Obesity is a significant risk factor for nonalcoholic fatty liver disease (NAFLD). While BMI remains part of the diagnostic criteria for metabolic dysfunction-associated steatotic liver disease (MASLD), its limitations in predicting prognosis and risk stratification have been noted. Central obesity indices may offer superior predictive value, prompting evaluation as potential replacements for BMI. **Methods:** We analyzed 12,156 adults from NHANES III, including 2,387 MASLD cases. Density plots assessed the variability of central obesity indices across BMI levels. Residuals from regression of central obesity indices on BMI were used as predictors in proportional hazards models, and Bayesian survival analysis compared model performance. Consistency between original and central obesity-based MASLD diagnostic criteria was also evaluated. **Results:** BMI was strongly correlated with WC ($r = 0.86$) and WHtR ($r = 0.89$), but weakly with CI, and showed

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

negligible correlation with WHR. Despite these differing degrees of correlation, central obesity indices displayed considerable variability within specific BMI ranges, necessitating broad intervals to capture 95% of all observed values. Among 1,180 deaths, residual WC (HR: 1.41, $P = 0.001$), WHR (HR: 1.15, $P = 0.001$), WHtR (HR: 1.45, $P < 0.001$), and CI (HR: 1.22, $P < 0.001$) remained significant predictors even after adjusting for BMI (HR: 1.20, $P = 0.01$). Bayesian analysis confirmed that models incorporating central obesity indices outperformed those using BMI (Bayes factor for WHR = 2,392.5; for CI = 6,703.4). High consistency between original and central obesity-based criteria was observed (Cohen's Kappa $\geq$ 0.9). **Conclusion:** Central obesity indices demonstrate superior prognostic value over BMI in MASLD and support their use as diagnostic replacements, given high consistency with original criteria.

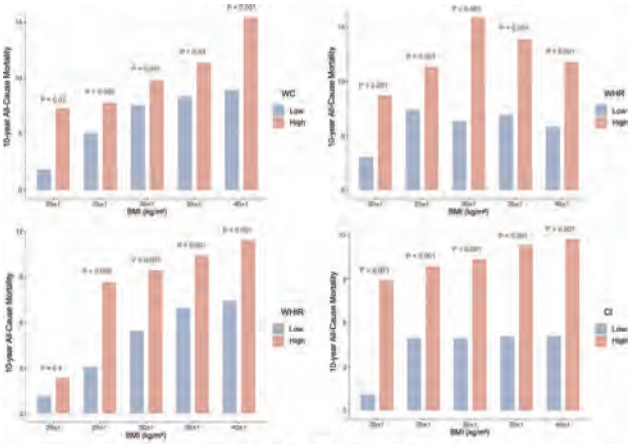

Figure 2. Ten-year risk of all-cause mortality for high vs. low levels of WC, WHR, WHtR, and CI Across Different BMI levels. This figure illustrates the 10-year Kaplan–Meier estimates of all-cause mortality for individuals with high (right bar, ≥1 SD above the mean) and low (left bar, ≤1 SD below the mean) levels of waist circumference (WC), waist-to-hip ratio (WHR), waist-to-height ratio (WHtR), and conicity index (CI) at varying BMI ranges (20, 25, 30, 35, and 40 kg/m² ±1).

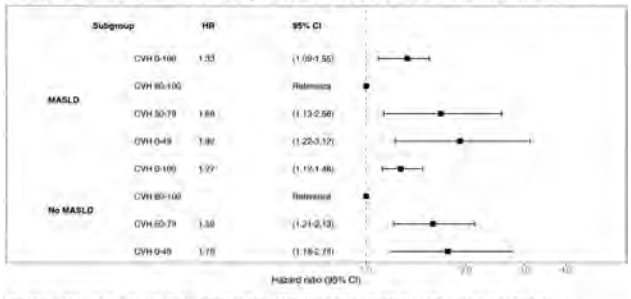
2095 | LIFE'S ESSENTIAL 8 SCORE AS A PREDICTOR OF CARDIOVASCULAR MORTALITY IN MASLD PATIENTS: A NHANES-BASED COHORT STUDY

Tianyuan Yang[1] Tong Bu[2] Qi Wang[1], [1]Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, China, [2]Center of Liver Diseases, Beijing Ditan Hospital, Capital Medical University, Beijing, Chin

Background: The Life's Essential 8 (LE8) cardiovascular health score is a tool used to assess individual health behaviors and has been widely applied in the risk evaluation of various diseases. In patients with metabolic dysfunction–associated steatotic liver disease (MASLD), adverse cardiovascular outcomes are common complications. Although the LE8 score has been shown to be significantly associated with all-cause mortality among individuals with MASLD, its relationship with cardiovascular mortality risk in this population remains unclear and warrants further investigation. **Methods:** This study is a population-based prospective cohort study that analyzed data from individuals aged 20 to 79 years participating in the National Health and Nutrition Examination Survey (NHANES) and NHANES III from 2005 to 2018, with mortality follow-up data available through 2019. The Fine-Gray competing risk model was employed to evaluate the risk of adverse cardiovascular outcomes and to examine the association between LE8 cardiovascular health score and cardiovascular mortality among patients with MASLD. **Results:** A total of 21,726 participants were included in this study, of whom 6,582 (30.3%) were diagnosed with MASLD. The median follow-up duration was 15.6 years. The overall LE8 cardiovascular health score was significantly associated with cardiovascular mortality risk among MASLD patients (HR = 1.33, 95% CI: 1.09–1.55). Compared with individuals with ideal LE8 scores, those with intermediate and poor scores had a higher risk of adverse cardiovascular outcomes (intermediate: HR = 1.68, 95% CI: 1.13–2.56; poor: HR = 1.92, 95% CI: 1.22–3.12). Similar associations were observed among MASLD patients with liver fibrosis. **Conclusion:** The LE8 cardiovascular health score serves as a significant predictor of cardiovascular mortality risk among patients with MASLD. Incorporating the LE8 score into clinical risk assessment may enhance the identification of individuals at elevated risk for adverse cardiovascular outcomes. These findings highlight the importance of targeted interventions and effective management of health behaviors in MASLD patients to improve cardiovascular prognosis.

Table. Hazard Ratios for Cardiovascular Mortality Risk in MASLD Patients Based on LE8 Health Behavior Score



The table presents the hazard ratios (HR) and 95% confidence intervals (CI) for cardiovascular mortality risk in individuals with MASLD, based on LE8 health behavior scores. The analysis was adjusted for potential confounding factors, including age, sex, education level, hypertension, diabetes, and hyperlipidemia.

2096 | DIVERGENT IMMUNE-INFLAMMATORY SIGNATURES IN STEATOTIC LIVER DISEASE PHENOTYPES WITH A UNIFIED LAB-BASED FIBROSIS PREDICTION TOOL

Akshay Verma[1], [1]Dr. S.N. Medical College, Jodhpur, Rajasthan, India

Background: Liver fibrosis is a major prognostic factor in chronic steatotic liver diseases, including Metabolic dysfunction-associated steatotic liver disease (MASLD), MetALD (metabolic and alcohol-associated liver disease), and Alcohol-related liver disease (ALD). As systemic inflammation is increasingly recognized as a central driver of fibrosis and adverse liver-related outcomes, understanding the differences in inflammatory signatures between these steatotic liver disease phenotypes is critical. This study aims to (1) compare systemic inflammation and fibrosis across phenotypes, (2) evaluate correlations between immune-inflammatory markers and fibrosis severity, and (3) develop a lab-based composite score to predict advanced fibrosis. **Methods:** A total of 180 patients were categorized into MASLD (n = 69), MetALD (n = 43), and ALD (n = 68) based on metabolic and alcohol criteria. Liver stiffness (FibroScan), FIB-4, APRI, MELD, CTP scores, and systemic immune inflammatory markers like Neutrophil Lymphocyte Ratio (NLR) and Lymphocyte Monocyte ratio (LMR), Systemic Immune-Inflammation Index (SII), Platelet–Lymphocyte Ratio (PLR) were assessed. Correlation and multivariate logistic regression analyses were performed to build a predictive score for advanced fibrosis ($\geq$F3). **Results:** ALD patients had the highest neutrophilic burden (mean NLR 6.56 $\pm$ 1.61), followed by MetALD (5.16 $\pm$ 1.36) and MASLD (4.30 $\pm$ 1.60) ($p < 0.001$). MASLD exhibited a lymphocyte-predominant profile (mean LMR 4.86 $\pm$ 1.17), as compared to MetALD (3.46 $\pm$ 0.74)and ALD (3.31 $\pm$ 0.98) ($p < 0.001$). Fibrosis burden followed a similar gradient: highest in ALD, intermediate in MetALD, lowest in MASLD. NLR (spearman coefficient, $\rho = 0.44$) and LMR ($\rho = -0.33$) significantly correlated with fibrosis severity. The derived composite score using inflammatory markers predicted advanced fibrosis with high accuracy (AUC = 0.90) with a excellent positive predictive value of 95.4%. The high positive predictive value (PPV) observed in our model indicates a strong capacity to accurately identify patients with advanced fibrosis ($\geq$F3) among those classified as positive by the algorithm. **Conclusion:** Despite overlapping clinical features, MASLD, MetALD, and ALD exhibit distinct inflammatory profiles. Systemic immune-inflammatory markers, especially NLR, are closely associated with fibrosis severity. The developed composite score, derived entirely from routine labs, offers a scalable, cost-effective tool for detecting advanced fibrosis across phenotypes in real-world settings.

2097 | C7 AS A PREDICTOR OF FIBROSIS AND LIVER-RELATED EVENTS IN MASLD

Shohei Kondo[1] Takefumi Kimura[1] Naoki Tanaka[2], [1]Department of Gastroenterology, Shinshu University Hospital, [2]International Relations Office, Shinshu University School of Medicine

Background: In metabolic dysfunction-associated steatotic liver disease (MASLD), advanced fibrosis and liver-related events (LRE) are major prognostic factors. However, current non-invasive biomarkers lack sufficient accuracy in predicting fibrosis and LRE risk. This study aimed to identify novel biomarkers for fibrosis severity and LRE prediction. **Methods:** Transcriptomic, proteomic, and spatial transcriptomic analyses were integrated to identify candidate biomarkers. Two independent MASLD cohorts were examined: a biopsy-proven cohort and a VCTE-based validation cohort. Kaplan–Meier analysis and Cox proportional hazards models were used to assess LRE risk. Single-nucleus RNA sequencing (snRNA-seq), in situ hybridization (ISH), and cell experiments were conducted to validate molecular relevance. **Results:** Complement component 7 (C7) emerged as a top candidate from hepatic transcriptomics and plasma proteomics. Spatial transcriptomics and ISH localized hepatic C7 expression mainly to hepatic stellate cells (HSCs) in fibrotic areas. Serum C7 levels correlated with liver stiffness and fibrosis stage, and levels $\geq$140 μg/mL were associated with significantly higher LRE risk ($p < 0.0001$), validated in a VCTE cohort. Multivariate analysis confirmed serum C7 as an independent predictor of LRE (HR 4.54, 95% CI 1.49–13.82, $p = 0.008$). Notably, C7 outperformed FIB-4,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

autotaxin, APRI, and AAR in ROC analysis (AUROC: 0.90 vs. 0.85, 0.84, 0.77, 0.67, respectively). C7 knockdown in LX-2 cells suppressed extracellular matrix genes such as LAMA2, LAMB1, and COL6A3. **Conclusion:** C7 is a robust biomarker for assessing fibrosis severity and predicting LRE in MASLD, outperforming conventional markers and offering potential for clinical application.

2098 | ASSOCIATION OF CIRCULATING Z-POLYMER WITH HEPATIC FIBROSIS IN ADULTS AT-RISK FOR MASLD AND THE ALPHA-1 ANTITRYPSIN PI*MZ VARIANT

Monika Sigg[1] Catherine Chang[1] Kevin Larimore[1] Jack Brownrigg[1] Rohit Loomba[2], [1]BioMarin, [2]University of California, San Diego

Background: Mutations in the *SERPINA1* gene, which encodes alpha-1 antitrypsin (AAT), lead to the accumulation of polymers in hepatocytes, triggering cellular injury that leads to liver fibrosis. The E342K mutation (Pi*Z) produces a mutant AAT protein (Z-AAT) that is especially prone to polymerization. In individuals with MASH, the Pi*MZ genotype increases risk of liver disease progression. Gaining insights into the relationship between circulating AAT polymer levels and liver disease severity in individuals with MASLD and the Pi*MZ genotype could inform prognosis, enrich trial populations and allow monitoring of treatment response for this understudied patient population. **Methods:** To identify Pi*MZ individuals with or at-risk of MASLD, we screened 792 people with preexisting MASLD, cirrhosis, or diabetes and their relatives for the Pi*MZ proteotype using an AAT isoelectric focusing assay. We identified 15 individuals with the Pi*MZ proteotype. We measured both total and polymeric AAT plasma levels by Enzyme-Linked ImmunoSorbent Assay (ELISA) in these individuals as well as 10 age-, sex-, and BMI-matched Pi*MM individuals. We then carried out a correlation analysis between plasma polymer concentration and non-invasive measures of fibrosis, steatosis, and for a subset of 8 individuals with available data, histological fibrosis and MASLD assessment (METAVIR and NAS, respectively). **Results:** As expected, plasma AAT polymers were not detected in most Pi*MM individuals, while all Pi*MZ individuals had measurable levels. Plasma AAT polymer correlated positively with multiple non-invasive measures of liver fibrosis: magnetic resonance elastography ($r = 0.75$, $p = 0.005$), vibration controlled transient elastography ($r = 0.54$, $p = 0.072$) and Fibrosis-4 ($r = 0.67$, $p = 0.006$). METAVIR fibrosis scores also showed a positive correlation with AAT polymer levels ($r = 0.52$, $p = 0.191$). Plasma AAT polymer did not correlate significantly with non-invasive measures of steatosis or NAS. Total AAT levels were lower in Pi*MZ individuals than Pi*MM and did not correlate significantly with fibrosis measures. **Conclusion:** The correlation between plasma AAT polymers and liver fibrosis in Pi*MZ individuals with or at-risk of MASLD suggests that polymeric AAT may be a key driver of hepatic fibrogenesis in this patient population. More studies with larger sample sizes and clinical outcome data are needed to better understand the relationship between MASLD and the Pi*MZ genotype.

Background: Liver biopsy, a current necessity for diagnosing metabolic dysfunction-associated steatohepatitis (MASH) and evaluating drug efficacy, is invasive and poses risks to patients. Thus, the development of non-invasive methods for assessing MASH lesions is a crucial research direction. **Methods:** MASH was induced in a group of diet-induced obese (DIO) male cynomolgus monkeys fed with a high-fat diet (40% fat, 0.5% cholesterol) to BMI > 35 kg/m² and fat mass > 25%. Hepatic MASH lesions in liver biopsy specimens were evaluated using a histopathological scoring system from the NIH MASH clinical network. A 3.0T SIEMENS MAGNETOM Prisma was employed for MRI imaging. Subcutaneous and visceral fat volumes were measured with a protocol that included structural localization and a Six-echo VIBE-Dixon gradient echo sequence. Liver proton density fat fraction (PDFF) images were obtained via the mge-6 echoes protocol and analyzed by VivoQuant 3.0 software. Liver extracellular volume (ECV) was determined by acquiring native and post-contrast (Magnevist) T1 mapping images with MOLLI/WIP780 sequences and calculated using T1 mapping parameters from selected liver regions of interest. Virtual MR elastography (vMRE) was performed using a fat-suppressed spin-echo echo-planar sequence and analyzed with ITK-SNAP software and custom MATLAB software. **Results:** 10 lean healthy and 34 obese monkeys were evaluated on their subcutaneous volumes (476.8 ± 52.8 vs. 1585.3 ± 623.6 cm^3) and visceral fat volumes (719.3 ± 181.4 vs. 1522.7 ± 482.4 cm^3). The obese monkeys treated with weight loss compound showed significant visceral fat reduction by over 30%. PDFF was elevated significantly elevated in DIO monkeys in contrast to lean healthy monkeys ($9.5 \pm 4.8\%$ vs. $4.3 \pm 0.5\%$) and a FGF-21 analogy reduced the elevated PDFF in DIO monkeys by 45%. The elevated PDFF is positively correlated with liver triglycerides analyzed by biochemical approach, and also positively correlated with the steatosis scoring by pathological approach. The calculated hepatic ECV was greatly increased in MASH/fibrosis monkeys compared to healthy animals and positively correlated with the fibrosis scores of liver biopsy specimen by pathology (F0 of $24.8 \pm 3.6\%$, F1 of $26.5 \pm 2.4\%$, F2 of $28.9 \pm 2.0\%$ and F3 of $35.2 \pm 5.2\%$). The vMRE reflects liver stiffness (kPa) which may implicate fibrosis in the liver of MASH monkeys. Significant elevation of kPa was observed in MASH monkeys ($n = 33$, 6.8 ± 3.3 kPa) in comparison to lean healthy monkeys ($n = 10$, 3.1 ± 0.5 kPa). MASH monkeys treated with a siRNA compound responded ~29% reduction in kPa at 12 week post the dosing. **Conclusion:** Noninvasive MRI procedures for have been validated in NHP models of obesity and MASH/fibrosis. The utilization of these translatable technologies in preclinical studies with NHP models should accelerate drug development targeting the obesity and MASH diseases.

2101 | VALIDATING THE PERFORMANCE OF INSULIN RESISTANCE INDICES AND VISCERAL ADIPOSITY INDICES IN PREDICTING METABOLIC DYSFUNCTION-ASSOCIATED FATTY LIVER DISEASE IN PATIENTS WITH POLYCYSTIC OVARY SYNDROME AND CONSTRUCTING A NEW PREDICTIVE MODEL

Zixiang Huang[1] Fang Fang[2] Nan Wu[1], [1]Peking University People's Hospital, Peking University Hepatology Institute, Beijing 100044, China, [2]Department of Obstetrics and Gynecology, Peking University People's Hospital, Beijing 100044, China

Background: Metabolic dysfunction-associated fatty liver disease (MAFLD) and polycystic ovary syndrome (PCOS) have shared risk factors, but the risk of MAFLD is ignored in PCOS patients. The performance of clinical indices in predicting PCOS concurrent with MAFLD has not been fully validated. An accurate and efficient predictive model is needed for MAFLD screening in PCOS patients. **Methods:** A total of 357 PCOS patients who underwent abdominal ultrasonography were retrospectively enrolled from 2015 to 2024 at the Reproductive Medical Center of Peking University People's Hospital. The performance of eight insulin resistance indices (IRIs) (HOMA-IR, QUICKI, Bennet ISI, G/I ratio, TyG, TyG-BMI, METS-IR, and CHG) and eight visceral adiposity indices (VAIs)(Obesity level, ALT/TG ratio, TG/HDL ratio, HSI, LFS, FSI, ZJU, and MAFLD-S) in predicting concurrent MAFLD were validated. The least absolute shrinkage and selection operator (LASSO) regression was performed to select variables for model construction, which were included in a multivariate logistic regression model. The area under the receiver operating characteristic curve (AUC), Delong test, calibration curve and decision curve analysis (DCA) were applied to validate and compare the predictive efficacy of different indices and models. **Results:** In this cohort, 129 (36.1%) PCOS patients were concurrent with MAFLD. Among the sixteen clinical indices validated, VAIs demonstrated better performance in predicting MAFLD than IRIs in general. FSI (AUC 0.8293, sensitivity 0.860), ZJU (AUC 0.8244, sensitivity 0.880), TyG-BMI (AUC 0.8163, sensitivity 0.899), LFS (AUC 0.8079, sensitivity 0.791) and MAFLD-S (AUC 0.8054, sensitivity 0.814) were the five clinical indices with the highest AUC, but only showed moderate discrimination and sensitivity. Six clinical

characteristics, including body mass index (BMI), insulin, aspartate transaminase (AST), creatinine, triglyceride and diabetes, were used to construct a new predictive model (AUC 0.8606, sensitivity 0.899). This predictive model showed a better discrimination than the AUC-top-five clinical indices (Delong $p < 0.05$) but had a similar calibration with these indices. In DCA, this new model also had a higher clinical usefulness and benefit in predicting PCOS concurrent with MAFLD than existing clinical indices. **Conclusion:** This new model has a better performance in predicting PCOS concurrent with MAFLD than existing IRIs and VAIs and can be helpful in MAFLD screening in PCOS patients.

2102 | DIGITAL PATHOLOGY IDENTIFIES INTRA-STAGE RESPONDERS IN THE ALPINE4 CIRRHOSIS STUDY

Lei Ling[1] Louis Petitjean[2] Mathieu Petitjean[2] Mary Rinella[3], [1]NGM Biopharmaceuticals, Inc, [2]PHARMANEST INC, [3]The University of Chicago

Background: The ALPINE 4 Phase 2b study evaluated aldafermin, an FGF19 analog, in 160 patients with MASH and compensated cirrhosis over 48 weeks. The primary endpoint (ELF reduction) was achieved at 3 mg. Fibrosis improvement ($\geq$1-NASH-CRN stage) was reported in 23% (3 mg), 21% (1 mg), and 15% (placebo), p = NS. We retrospectively reanalyzed the biopsies using a continuous digital pathology biomarker for fibrosis severity. **Methods:** Paired biopsies from placebo (n = 45), 1 mg (n = 32), and 3 mg (n = 41) groups were scanned at 40X and analyzed uploaded for analysis to FibroNest, a robust, high-resolution phenotypic digital pathology method generating a continuous fibrosis severity score (Ph-FCS) based on ~100 features quantiifying collagen deposition, fiber morphometry, and fibrosis architectural distortion (doi.org/10.1111/liv.15768). A $\geq$20% relative Ph-FCS change reflects a full NASH-CRN stage shift, and $\geq$0.3 absolute change indicates intra-stage improvement (doi:10.1097/HEP.0000000000000980). Additional metrics included Parenchymal Tissue Area %, Scar Tissue Area %, and faint and fine fiber count/mm² in the nodular parenchymal tissue. **Results:** Responder analysis using a 20% relative Ph-FCS reduction showed no significant differences (Pbo: 24.4%, 1 mg: 25.0%, 3 mg: 26.8%). When applying a 0.3 absolute Ph-FCS threshold, "no change" responder rates dropped (Pbo: 17.8%, 1 mg: 18.8%, 3 mg: 9.8%). Placebo-corrected response rates using $\geq$1-NASH-CRN stage reduction, 20% relative, or 0.3 absolute Ph-FCS reduction also showed no statistical significance: 1 mg (6%, 0.6%, 12.7%) and 3 mg (8%, 2.4%, 7%). Mean Ph-FCS changes from baseline also did not reach significance. For 20% relative change: Pbo: -0.033 ($\pm$0.283), 1 mg: -0.110 ($\pm$0.206), 3 mg: -0.080 ($\pm$0.366); p = NS. For 0.3 absolute change: Pbo: -0.131 ($\pm$1.306), 1 mg: -0.515 ($\pm$1.096), 3 mg: -0.313 ($\pm$1.725); p = NS. No significant changes were detected in tissue- or nodule-based markers. **Conclusion:** Continuous digital pathology biomarkers did not confirm a significant antifibrotic effect of aldafermin in patients with compensated cirrhosis. Across multiple analysis thresholds—including both relative and absolute Ph-FCS changes—and additional parenchymal-tissue based biomarkers, no dose group demonstrated a statistically meaningful improvement compared to placebo. These results underscore the value of continuous digital quantification in complementing traditional histological endpoints for the assessment of therapeutic impact.

2103 | ANALYSIS OF FACTORS ASSOCIATED WITH LIVER FIBROSIS IN TYPE 2 DIABETES PATIENTS AND THE PREDICTIVE VALUE OF CHI3L1 FOR LIVER FIBROSIS

Lixia Sun[1] Shuangshuang Du[1] Aili Fan[2] Jiawen Feng[2] Fei Wang[1] Jia Lian[1] Qing Ye[1], [1]Department of Hepatology of The Third Central Hospital of Tianjin, China, [2]The Third Central Clinical College of Naikai University, China

Background: The prevalence of Metabolic dysfunction–associated steatotic liver disease (MASLD) is significantly increased in patients with Type 2 diabetes mellitus (T2DM), elevating the risk of cirrhosis and hepatocellular carcinoma. Therefore, early diagnostic assessment of liver fibrosis in T2DM patients is critically important. Our study investigated the factors associated with liver fibrosis in T2DM patients with comorbid MASLD and evaluated the predictive value of chitinase-3-like protein 1 (CHI3L1) for liver fibrosis in these patients. **Methods:** This is a retrospective study that enrolled T2DM patients who received care at Tianjin Third Central Hospital between January 2023 and August 2024. Liver fibrosis was assessed in both the total T2DM population and in T2DM patients with comorbid MASLD using liver stiffness measurement (LSM) and non-invasive assessment indicators including APRI, FIB-4, and CHI3L1. The LSM value $\geq$ 8kPa was established as the threshold for significant liver fibrosis (SLF). Correlation analysis was applied to evaluate the relationships between LSM, CHI3L1, and other indicators. Logistic regression analyses were conducted to identify risk factors associated with liver fibrosis, and receiver operating characteristic (ROC) curve analysis was used to assess the predictive value of CHI3L1. **Results:** This study included 236 patients with T2DM, of whom 176 had comorbid MASLD (74.6%) and 89 had significant liver fibrosis (37.7%). Among T2DM-MASLD patients, 74 had significant liver fibrosis, with a prevalence rate of 42%.In the T2DM-MASLD population, patients with significant liver fibrosis demonstrated significantly higher levels of BMI, TSH, AST, GGT, LDH, CHI3L1, APRI, LSM, and CAP compared to the non-significant fibrosis subgroup, with all differences being statistically significant ($P < 0.05$). Conversely, the significant fibrosis subgroup exhibited significantly lower levels of PLT, LDL-C, and PWR compared to the non-significant fibrosis subgroup ($P < 0.05$).CHI3L1 showed positive correlation with LSM ($r = 0.48$, $P < 0.001$). Multivariate logistic regression analysis identified CHI3L1, APRI, and CAP as potential independent risk factors for significant liver fibrosis in T2DM-MASLD patients. The area under the ROC curve (AUC) for CHI3L1 in predicting significant liver fibrosis was 0.717 (95% CI: 0.638-0.796, $P < 0.05$), with an optimal cutoff value of 96.6 ng/mL. **Conclusion:** The prevalence of MASLD among T2DM patients was 74.6%, while the prevalence of significant liver fibrosis was 37.7%. T2DM patients with significant liver fibrosis exhibited higher levels of BMI, CHI3L1, AST, LDH, TSH, APRI, LSM, and CAP compared to those without significant liver fibrosis. Serum CHI3L1 demonstrated a significant correlation with liver fibrosis, suggesting that serum CHI3L1 may serve as a predictive indicator for liver fibrosis in T2DM patients.

2104 | EVALUATING THE IMPACT OF ELECTRONIC HEALTH RECORD (EHR) EMBEDDED METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) CARE PATHWAYS TO IMPROVE DETECTION OF ADVANCED FIBROSIS IN ADULTS WITH TYPE 2 DIABETES

Robert Schwartz[1] Sonal Kumar[2] Anna Mageras[3] Sujit Janardhan[4] Brendan McQuillen[4] Jihae Jeon[3] Jacob Debroff[3] Rama Hussein[3] Holly Jain[5] Mohanish Savanth[5] Kristi Cohn[5] Meena Bansal[6], [1]Weill Cornell Medical College, [2]Weill Cornell Medicine, [3]Icahn School of Medicine at Mount Sinai, [4]Rush University Medical Center, [5]MASHNET, [6]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) impacts ~38% of adults, including ~65% of patients with type 2 diabetes (T2D). Left undetected, it can progress to metabolic steatohepatitis (MASH), cirrhosis, hepatocellular carcinoma (HCC), or death. Guidelines recommend MASLD screening in high-risk populations, but clinical adoption is limited. Mount Sinai Health System (MSHS), Weill Cornell Medicine (WCM), and Rush University Medical Center (Rush) implemented EHR-embedded MASLD care pathways. **Methods:** MSHS, WCM and Rush developed unique approaches to embedding MASLD care pathways within their EHRs leveraging Passive (clinician activated) or Active (automatically activated) interventions and evaluated performance for ≥ 5 months using a common data framework. Passive approaches used by MSHS and WCM included implementation of an age-adjusted Fibrosis-4 (FIB-4) SmartPhrase, in which clinicians could type the phrase and subsequently receive a score, interpretation, and recommended next steps. Two active approaches were used by MSHS and Rush. MSHS leveraged a backend FIB-4 calculation, in which a FIB-4 was calculated for eligible patients, and high/indeterminate patients flagged for outreach. Rush built a series of silent best practice alerts (BPAs) using EPIC care paths, starting with an auto-calculated FIB-4 for patients with T2D. Both active and passive interventions were implemented in tandem with provider education in attending or teaching clinics. Statistical analyses were conducted at the site level and reported as population-level summary statistics. Primary endpoints were rate of FIB-4 calculation for eligible patients and rate of referral. Those eligible for screening included adults who were ≥ 18 years old, diagnosed with T2D, and had an encounter with a pilot provider. New screening eligibility was defined as individuals who had not been screened in the past 12-months. **Results:** 24,125 patients with T2D were seen over the pilot, and 13,631 (56.50%) were eligible for screening. 4,672 patients were newly screened, of which 774 (16.57%) were high-risk (> 2.67) and 1,945 (41.63%) were indeterminate risk (1.3-2.67 for < 65, 2.0-2.67 for 65+). Figure 1 represents the baseline and follow up screening rates of eligible patients at each institution by intervention type. **Conclusion:** Passive and active EHR-embedded interventions have utility in improving identification of patients at risk for advanced fibrosis, and trainees demonstrated greater receptivity to adopt new pathways.

2105 | OPTIMIZING THE USE OF NON-INVASIVE TESTS FOR PATIENT SELECTION FOR MASLD PHARMACOTHERAPY

Vlad Ratziu[1] Antoine Pilon[2] Vittoria Zambon[3] Francisca Dora Copil[3] An Ngo Kim Tu[4] Raluca Pais[5] Leila Kara[3] Dominique Thabut Damais[6] Michel Vaubourdolle[7], *[1]Service D' Hepatogastroenterologie (FR), [2]Hopital St Antoine, [3]ICAN Institute for Cardiometabolism and Nutrition, [4]Hospital Pitié-Salpêtriere, Paris, France, [5]Pitié-Salpêtrière Hospital, [6]Hospital Pitié-Salpêtrière, Paris, [7]Hospital Saint Antoine*

Background: Selection of patients (pts) for MASLD pharmacotherapy relies on the diagnosis of stage 2&3 fibrosis based on non-invasive tests (NIT). However, concordance of NIT results and their optimal use (single or combined, algorithm, confounding factors) is unknown. **Methods:** Pts with chronic liver disease (CLD) including MASLD (steatosis on ultrasound or CAP > 280 dB/m and no other CLD) were assessed with NITs for liver fibrosis: liver stiffness (LSM) by vibration controlled transient elastography (VCTE), LSM by Shear wave elastography (SWE), ELF and FibroSure® (FS, LabCorp). Thresholds proposed to reflect stages 2 or 3 fibrosis for initiation of pharmacotherapy were used (PMID: 39038768). **Results:** 587 CLD pts (488 MASLD) were included: men 53% mean age 57.8 yrs (≥60yrs: 49.5%), BMI 29.6 kg/m² (sd 6.2), type 2 diabetes 34%. Eligibility based on a single or a pair of NITs. The proportion of pts eligible for pharmacotherapy when NITs were used alone was highly variable: 38% for ELF (9.2-10.5); 17.5% for FS (0.49-0.72); 10.5% for LSM and 7.2% for SWE (both 10-15 kPa). With 2 NITs the proportion of concordant results fell to 6% for ELF+LSM, 3.7% for ELF+SWE, 2.8% for FS+SWE and 2.4% for FS +LSM. Exclusion of mild fibrosis. Among pts not eligible for treatment based on ELF < 9.2 (N = 259), 93% were confirmed by LSM and 96% by SWE (< 10 kPa). Conversely, among 410 pts not eligible by LSM (< 10 kPa) only 59% were confirmed by ELF (< 9.2). Confirming eligibility based on advanced fibrosis. Among patients eligible for treatment based on ELF (9.8-10.49, N = 73), 75%-84% would have been underscored by LSM or SWE (< 10 kPa). For FS (0.49-0.72) the proportion was 79% for both LSM and SWE (< 10 kPa). Conversely, among pts eligible by LSM or SWE (10-15 kPa) only 25.5% or 17%, respectively, were underscored by ELF(< 9.2). Confounding factors. LSM was correlated with BMI ($r = 0.30$, $p < 0.001$). ELF was strongly correlated with age in both sexes, in MASLD and the whole cohort ($r = 0.49$, $p < 0.001$, Figure). In pts without fibrosis (LSM < 6kPa) median ELF increased with age: 8 if < 40 yrs; 8.29 if 40-49; 8.66 if 50-59; 9.07 if 60-69; 9.53 if > 70. Starting age 40 an age correction should be applied: ELFcorr = ELF-[0.3x(decade-4)]. **Conclusion:** NITs with current thresholds are highly discordant when used for selecting pts for pharmacotherapy. Exclusion of candidates can be based on ELF < 9.2 but not on LSM. Confirmation should rely primarily on LSM with concordant ELF. ELF should be age-corrected.

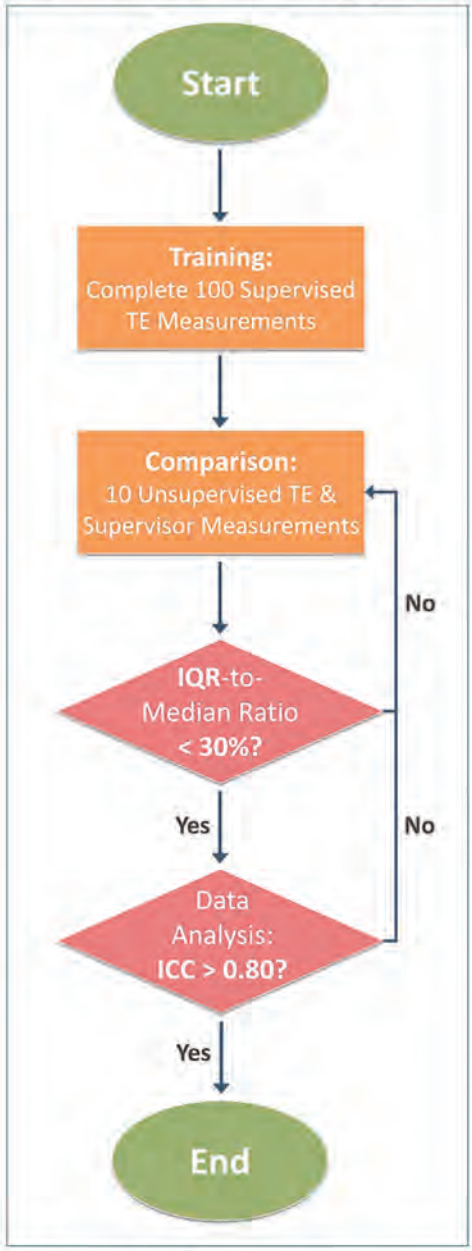
2106 | ACHIEVING OPERATOR COMPETENCY IN TRANSIENT ELASTOGRAPHY (TE): A STRUCTURED PROTOCOL FOR TRAINING NON-EXPERTS TO ASSESS METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) — A MULTICENTER EXPERIENCE

Faisal Abaalkhail[1] Shadan AlMuhaidib[1] Faisal Sanai[2] Duna Barakeh[1] Haifa Alotaibi[3] Saleh Alessy[1] Ali Hazazi[4] Sahar Alnasrallah[3] Alaa AlGhamdi[3] Abdulmohsen Alshammari[1] Mohammed Alghamdi[5] Mariam Seria[5] Waleed Alomaim[1] Bandar Aljudaibi[1] Waleed Alhazzani[3] Saleh Alqahtani[1], [1]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [2]King Abdulaziz Medical City, KAIMRC, Jeddah, Saudi Arabia, [3]Ministry of Defense Health Services, Riyadh, Saudi Arabia, [4]Alfaisal University, Riyadh, Saudi Arabia, [5]King Fahad Military Medical Complex, Dhahran, Saudi Arabia

Background: Non-invasive assessment of liver fibrosis and steatosis is critical in MASLD screening, with TE emerging as the preferred modality. Despite its procedural simplicity, reliability and diagnostic accuracy vary with operator proficiency. We aimed to develop and validate a standardized TE training protocol for implementation across multiple healthcare settings. **Methods:** A multicenter, prospective study was conducted between March 2024 and May 2025 across 6 centers in three main regions of Saudi Arabia. A team of hepatologists and gastroenterologists developed a standardized TE training protocol using FibroScan®. Nine healthcare workers, assigned as research coordinators and lacking prior TE experience, received structured hands-on training from 9 certified supervisors. Each trainee performed 100 supervised and 10 unsupervised TE scans with real-time feedback (Figure 1). Supervisors, blinded to the trainees' unsupervised results, performed parallel TE assessments on the same patients. We recorded the controlled attenuation parameter (CAP), liver stiffness measurements (LSM), and the interquartile range (IQR) for both trainee and supervisor measurements. LSMs were considered reliable if the IQR-to-median ratio was $<30\%$. We assessed inter-operator reliability using intraclass correlation coefficients (ICCs), with values >0.80 indicating strong concordance. **Results:** Trainees (55.6% female) had a median age of 28 years (range: 23–38) and four years of clinical experience (range: 0–13). Their backgrounds included nursing (44.4%), radiology (22.2%), genomics (22.2%), and pharmacy (11.1%). Supervisors (88.9% female) came from diverse disciplines: pharmacists (33.3%), hepatologists/gastroenterologists (22.2%), ultrasound technologists (11.1%), biochemists (11.1%), and genomics (11.1%). The median training period was 20 days (range: 14–22), with a median of 6 hours daily (4–8). Each trainee was supervised by a median of 2 supervisors (range: 1–3). Seven trainees (77.8%) achieved competency on first attempt; the median ICC for CAP was 0.95 (IQR: 0.92–0.98), and for fibrosis scores was 0.96 (0.82–0.99). Median IQR-to-median ratios were 13.5% for trainees and 14.0% for supervisors. **Conclusion:** A short-term, structured training protocol, involving 100 supervised TE assessments over ~20 days, can effectively train novice operators to achieve expert-level proficiency. This approach enhances diagnostic reliability and supports implementation across diverse healthcare settings.

Figure 1
Flowchart for training protocol



Abbreviation: ICC, intraclass correlation coefficient; IQR, interquartile range; TE, transient elastography.

2107 | DEVELOPMENT OF A NOVEL MODEL USING MACHINE LEARNING ALGORITHMS TO PREDICT PRESENCE OF METABOLIC ASSOCIATED STEATOTIC LIVER DISEASE IMPROVING ON FIB-4 AND ELF. A POPULATION SCREENING TOOL

Charlene Cheong[1] Thomas Ashdown[2] Jorg Taubel[2] Ulrike Lorch[2] Dilshat Djumanov[3] James Rickard[4], [1]Richmond Research Institute, [2]Richmond Pharmacology Ltd, [3]King's College London, [4]Richmond Research Institiute

Background: Metabolic associated steatotic liver disease (MASLD) affects approximately one in four of the global adult population, and ranges in severity from benign fatty liver infiltration, to hepatitis, cirrhosis, hepatocellular carcinoma, and death. Routinely used clinical tools FIB-4 and ELF used to identify patients that require further diagnostic assessment. FIB-4 has limitations with extremes of age at best achieving 0.73 predictive power, with an aging population the score is falsely elevated, the ELF having a predictive power of 0.8. We set about to improve on FIB-4 and ELF for predictive power to offer a more accurate referral tool for further assessment of MASLD to reduce unnecessary diagnostics requested, using readily available clinical assessments. **Methods:** An observational cross-sectional study of 1970 volunteers was completed, Age range 18-90 years, collecting bioimpedance vector analysis (visceral fat%, total body fat% and skeletal muscle %), anthropometric measurement and laboratory bloods. A FibroScan is performed as a pragmatic gold standard 'outcome' for MASLD using $>$248dB/m or $>$7.6kPa as a positive. The data was divided into a training set of (75%) used to build the model, (25%) used to validate its predictive accuracy. Lasso Logistic Regression, Elastic Net Logistic Regression, Random Forest and XGBoost were then compared for model with highest performance. SHAP analysis was used to identify feature importance and remodelling with reduced features to simplify clinical data needed for the model. **Results:** All models achieved an AUROC $>$0.88, Elastic Net Logistic Regression produced the highest performing model using all features achieving AUROC 0.892, Accuracy 0.807, F1 score 0.796 and NPV 0.844. A reduced feature model developed with 5 features (Waist, Height, Weight, ALT & Age) using LASSO Logistic Regression achieving AUROC 0.888, Accuracy 0.809, F1 Score 0.801 and NPV 0.854. **Conclusion:** The model developed produces a highly accurate tool using waist circumference, height, weight, ALT and Age – all readily available in clinical settings. The data collected spans a wide demographic of participants to provide a representative population and current dataset as a foundation of this model. Implementation of this tool in the clinical setting has potential to reduce unnecessary Hepatology referral, Transient Elastography by 10% reducing patient burden and releasing diagnostic capacity to reduce clinic waiting lists on strained health systems.

2108 | NORMAL LIVER ENZYMES IN PATIENTS WITH DIABETES MELLITUS AND ADVANCED FIBROSIS BY FIB-4

Emily Leven[1] Anna Mageras[1] Rabab Ali[1] Meena Bansal[2], [1]Icahn School of Medicine at Mount Sinai, [2]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: Diabetes mellitus (DM) is a risk factor for both metabolic-associated steatotic liver disease (MASLD) and morbidity and mortality in patients with MASLD. MASLD, even with advanced fibrosis, may exist without abnormal liver tests, potentially delaying diagnosis. The primary aim of this study was to describe patients with DM and Fibrosis-4 scores (FIB-4) suggesting advanced fibrosis in the absence of abnormal transaminases and to evaluate referral patterns for specialty liver care. **Methods:** Retrospective review of electronic medical records at a single center was performed. Adults aged 18-90 with DM seen in primary care from 2022-2024 were included. FIB-4 scores were calculated using ambulatory encounter labs within 2 years. Patients with viral hepatitis (B or C) and those seen in oncology or hepatology clinics were excluded to evaluate only undiagnosed patients with probable MASLD. Upper limit of normal (ULN) values for alanine transaminase (ALT) and aspartate transaminase were 44 IU/L and 40 IU/L, respectively, per our laboratory's standard. Patients were considered to have advanced

fibrosis if maximum FIB-4 was > 2.67. Referrals to gastroenterology, hepatology, and vibration-controlled transient elastography (VCTE) for any reason were considered. **Results:** 3389 patients (1584 female) had FIB-4 > 2.67. 433 (18%) were between 35-65 years old; 2956 (87%) were older than 65 and 0 were between 18-34. Among patients aged 35-65 with FIB-4 > 2.67 (Table), all available levels of ALT and AST were below the ULN in 177 (40% of patients aged 35-65, 5% of all patients). 9 (5%) and 8 (5%) of these patients were referred for VCTE or hepatology, respectively. 31 females (42% of females with ALT and AST within normal limits per lab cut-off) had maximum levels of ALT and AST that were below the lab ULN but greater than the sex-adjusted cut-off of 20 IU/L. 1 (3%) and 3 (10%) of these patients were referred for VCTE or hepatology, respectively. **Conclusion:** Only a minority of patients with DM and possible advanced MASLD were referred to hepatology or VCTE regardless of whether transaminases were abnormal. Although 5% of patients with advanced fibrosis by FIB-4 did not have elevated transaminases, 43% of females with "normal" transaminases by lab cut-offs actually had elevated liver enzymes by sex-adjusted norms. These patients are at particularly high-risk for missed diagnosis of advanced liver disease, with the lowest demonstrated likelihood of specialty referral.

	All patients age 35-65 with ALT>44 or AST >40	All patients age 35-65 with ALT≤44 IU/L and AST ≤40 IU/L	Females age 35-65 with ALT 20-44 IU/L and AST 20-40 IU/L
Females (n, %)	83 (32.43%)	74 (41.81%)	31 (–)

2109 | DISTINCT TRANSCRIPTOMIC SIGNATURES IN PLATELET-DERIVED EXTRACELLULAR VESICLES (PEVS) ASSOCIATED WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Vanessa Garcia-Fernandez[1] Sheila Gato-Zambrano[1] Antonio Gil-Gómez[1] Angela Rojas[1] María José Castro[2] Carl Hernderson[2] Javier De la Peña Noya[3] Patricia Bernal[4] Rocio Gallego-Duran[1] Douglas Maya-Miles[1] RAQUEL MILLÁN DOMÍNGUEZ[1] José Borrero de Acuña[4] Carmen Lara Romero[1] Javier Ampuero Herrojo[1] rocio aller[5] Manuel Romero-Gómez[1] Rocío Muñoz Hernández[1], [1]Seliver Group. Instituto De Biomedicina De Sevilla (IBiS), Hospital Universitario Virgen Del Rocí, [2]Servicio de Citometría. Instituto De Biomedicina De Sevilla (IBiS), Hospital Universitario Virgen, [3]Department of Microbiology. University of Seville, Seville, Spain, [4]Department of Microbiology. University of Seville, Seville, Spain., [5]Hospital Clínico Universitario de Valladolid.

Background: Platelet-derived extracellular vesicles (PEVs) are membrane-bound vesicles released by platelets during activation or apoptosis. They carry genetic and protein material from their cells of origin, acting as vectors for intercellular communication and contributing to the initiation, pathogenesis, and progression of various liver diseases. Both platelets and platelet-derived EVs interact with liver cells, playing a role in hepatic injury. Objectives: (i) To determine the use of platelet-derived EVs as biomarkers for the severity of MASLD, (ii) to determine the differential miRNA profile contained in platelet-derived EVs in patients with different severity degrees. **Methods:** A total of 97 biopsy-proven MASLD patients were recruited and classified into steatosis (n = 23) or steatohepatitis (n = 70) based on the SAF score. EVs quantification was performed by flow cytometry (LRS Fortessa) using Annexin V-PE and CD41-FITC antibodies. Isolation of EVs was carried out on the Facs Aria Fusion cell sorter (Becton Dickinson) in plasma from 16 patients with steatohepatitis and 8 patients with steatosis. The size and yield of particles isolated was determined by nanoparticle tracking analysis and CD41 + EVs were also characterized by transmission electron microscopy (TEM). Total RNA enriched in miRNAs was extracted using the miRNeasy Mini Kit (Qiagen), and the differential expression profile of microRNAs was determined by microarray (GeneChip miRNA 4.0 Assay

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Affymetrix, ThermoFisher CA, USA). **Results:** CD41+ EVs levels were significantly elevated in patients with steatohepatitis compared to those with steatosis (1511 ± 268 vs. 2882 ± 542.5; $p = 0.04$). The results of the differential analysis showed that 8 microRNAs were upregulated in platelet-derived EVs from patients with steatohepatitis (fold change > 2, p-value < 0.05): miR-3141, miR-6791-5p, miR-6803-5p, miR-6786-5p, miR-6763-5p, miR-3656, miR-4763-3p y miR-4467; and one downregulated: miR-4679-1. After comparing transcriptomic profile in patients with advanced fibrosis (F3-F4), we found an overexpression of miR-139-3p. Specifically, overexpression of miR-6803-5p, miR-3656 and miR-139-3p has been previously associated with hepatocellular carcinoma, proliferation and metastasis. Furthermore, miR-4763-3p and miR-4467 are associated with liver inflammation **Conclusion:** Platelet-derived EVs are elevated in patients with steatohepatitis, suggesting their potential as biomarkers for disease severity. Furthermore, preliminary data indicate a distinct miRNA profile within PEVs, which may help explain their role in the progression of MASLD to more advanced stages.

2110 | EXPERIENCE USING PORTABLE ULTRASOUND FOR METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE DETECTION IN RURAL COLOMBIAN MUNICIPALITIES

Jimmy Daza[1] Sara Tamayo[2] Eduardo Mazuera[2] Juan Fernando Mesa Valencia[3] Yeinis Paola Espinoza Herrera[4] Vanessa Cuadrado Cardenas[4] Victor De La Espriella[4] Maria Cristina Navas[4] Andreas Teufel[1] Milena Alcázar Paternina[2], [1]Div. of Hepatology, Dep. of Medicine II, Medical Faculty Mannheim of Heidelberg University, Germany, [2]Department of Radiology, Universidad de Antioquia, Medellin, Colombia., [3]LivingLab Telesalud, Universidad de Antioquia, Medellín, Colombia., [4]Gastrohepatología Research Group, Universidad de Antioquia, Medellín, Colombia

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the leading cause of chronic liver disease, with a global prevalence of over 25%. Early detection is crucial but challenging in rural areas due to limited healthcare access and MASLD's asymptomatic nature in its initial stages. Although liver biopsy remains the gold standard, its invasive nature limits its use for population-wide screening. Non-invasive methods, such as portable ultrasound, emerge as viable alternatives, particularly in rural areas with limited healthcare access. This study evaluates portable ultrasound efficacy for MASLD detection and characterize disease prevalence in underserved Colombian rural populations. **Methods:** We conducted a cross-sectional study in adults (> 18 years) with cardiovascular risk factors from three rural Colombian municipalities (Gómez Plata, Leticia, and Frontino). Exclusion criteria included cirrhosis, hepatocellular carcinoma, or active viral hepatitis. Hepatic steatosis was assessed using Clarius® portable ultrasound with standardized grading protocols. Statistical analysis included descriptive statistics, comparative tests (Shapiro-Wilk, Student's t-test, Mann-Whitney U, χ^2) and logistic regression in Stata v14. **Results:** Among 271 participants (67% female, mean age 60.5 ± 12.3 years), hepatic steatosis prevalence was 63% (grade I: 34%, grade II: 23%, grade III: 7%). Obesity demonstrated the strongest association with MASLD (OR: 2.10, 95% CI: 1.23-3.58, $p = 0.007$), followed by diabetes mellitus (OR: 1.71, 95% CI: 1.02-2.86, $p = 0.041$). No significant associations were found with sex, age, or hypertension. Portable ultrasound enabled real-time imaging with cloud-based storage and telemedicine integration, facilitating remote expert consultation. **Conclusion:** Portable ultrasound represents an effective, accessible diagnostic tool for MASLD screening in rural populations. This technology enables early detection, timely interventions, and reduces geographic healthcare disparities, supporting decentralized care models in resource-limited settings.

2111 | EARLY DIAGNOSIS OF SARCOPENIA IN PATIENTS WITH MASLD USING OXIDATIVE STRESS MARKERS

Hiroko Setoyama Toshinori Toyoda[1] Takahiro Mizuta[2] Daiki Maeda[1] Kentaro Tanaka[1] Hiroki Inada[1] Satoshi Narahara[1] Etsuko Iio[1] Yoko Yoshimaru[1] Takehisa Watanabe[1] Katsuya Nagaoka[1] Yasuhito Tanaka[1], [1]Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University, [2]Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University,

Background: Sarcopenia is a common comorbidity in patients with metabolic dysfunction-associated steatotic liver disease (MASLD) and is a recognized risk factor for the progression of metabolic dysfunction-associated steatohepatitis (MASH) and liver fibrosis. Oxidative stress is considered one of the key mechanisms underlying sarcopenia. We previously reported that human mercaptalbumin (HMA), the reduced form of albumin, serves as a sensitive marker of oxidative stress in patients with chronic liver disease. The aim of this study was to investigate the associations between oxidative stress markers—particularly HMA and advanced oxidation protein products (AOPPs)—and muscle strength and body composition in patients with MASLD/MASH. **Methods:** A total of 67 patients with MASLD/MASH who visited or were admitted to our department between June 2021 and May 2024 were included. Clinical assessments included grip strength, skeletal muscle mass, body fat percentage, and liver stiffness. Muscle mass and fat percentage were measured using bioelectrical impedance analysis (BIA). Additionally, computed tomography (CT) at the L3 vertebral level was used to evaluate skeletal muscle, subcutaneous fat, and visceral fat via a 3D imaging analysis system. Serum HMA was measured using electrospray ionization time-of-flight mass spectrometry (ESI-TOFMS), while AOPPs were measured using a commercial colorimetric assay kit. **Results:** Among the 67 patients analyzed, 11 were diagnosed with liver cirrhosis. The mean grip strength was 25.2 ± 6.9 kg, BIA-measured muscle mass was 10.3 ± 2.2 kg/m², body fat percentage was 24.2 ± 7.9%, and CT-measured muscle area at the L3 level was 48.2 ± 10.1 cm²/m². The mean HMA level was 2.83 ± 0.6 g/dL, and the mean AOPP concentration was 185.4 ± 61.7 μM. Notably, grip strength demonstrated a remarkably strong positive correlation with HMA ($r = 0.903$), while CT-assessed muscle mass at L3 showed a strong inverse correlation with AOPPs ($r = –0.718$) and a moderate positive correlation with HMA ($r = 0.536$). Despite the limited sample size, these findings provide compelling evidence that oxidative stress markers—particularly HMA and AOPPs—are closely linked to muscle strength and mass in patients with MASLD/MASH, underscoring their potential as clinically relevant biomarkers of early sarcopenic changes. **Conclusion:** Our findings suggest that HMA is associated with muscle strength, whereas AOPPs are more closely correlated with muscle mass in patients with MASLD/MASH. Given that AOPPs can induce reactive oxygen species, inflammatory cytokines such as TNF-α, and myokines, they may represent a novel therapeutic target for sarcopenia. Moreover, both HMA and AOPPs may serve as valuable biomarkers for the early detection of pre-sarcopenia in patients with MASLD/MASH.

2112 | PROGNOSTIC VALUE OF THE TLM3 BIOMARKER PANEL FOR EARLY FIBROSIS DEVELOPMENT IN MASLD WITHIN THE GENERAL POPULATION

Lars Verschuren[1], [1]TNO

Background: Fibrotic MASLD is associated with increased morbidity and mortality, often remaining asymptomatic until advanced stages of disease. Predicting fibrosis onset and progression would improve risk stratification and treatment allocation. This study aims to investigate whether a previously identified fibrosis biomarker panel for active fibrogenesis (TLM3) can serve as a prognostic marker panel for fibrosis development in a population at cardiometabolic risk of fibrotic MASLD. **Methods:** The temporal dynamics of a molecular fibrosis gene expression signature associated to histologically-proven fibrosis development was investigated in a diet-induced MASLD mouse model (LDLr-/-.Leiden). The corresponding proteins were measured in baseline serum from individuals at risk of MASLD from the general population HELIUS-cohort and correlated to established fibrosis proxies (ELF, VCTE and FIB4) at 7 years follow-up. **Results:** The molecular fibrosis gene expression signature was upregulated in a murine MASLD model before the onset of histopathological features of fibrosis. In humans, serum levels of IGFBP7, Ssc5D, Sema4D, VCAN, THBS1 and TNC at baseline correlated with fibrosis proxies at follow-up. IGFBP7 at baseline was able to predict new onset fibrosis, defined as ELF ³9.8 at

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

follow-up in participants with ELF <9.8 at baseline, with an area under the curve (AUC) of 0.79 (95% CI: 0.64-0.94). **Conclusion:** Together, these findings indicate the potential predictive capacity of the TLM3 biomarker panel in early stages of MASLD-fibrosis, both in a murine model as well as in individuals from the general population at risk of MASLD.
Disclosures: Lars Verschuren: Nothing to Disclose

2113 | PREVALENCE AND ASSOCIATED FACTORS OF STEATOSIS, STEATOHEPATITIS AND FIBROSIS DIAGNOSED WITH NON-INVASIVE METHODS: DURING ANNUAL CHECK-UPS IN AN INDUSTRIAL WORKER POPULATION

Pietro Guerra[1] Javier Lopez Perez[2] Silvia Cagnin[1] Patrizia Pontisso[3] Maria Martinez Chantar[4] Andrea Martini[5], [1]University of Padova, [2]Bridgestone Hispania Manufacturing S.L, Bilbao, Spain, [3]Univeristy of Padova, [4]Liver Disease Lab, CIC bioGUNE, Basque Research and Technology Alliance, BRTA, Derio, Spain, [5]Department of Medicine, Azienda Ospedale-Università di Padova (AOPD), Padova, Italy

Background: Steatotic liver disease (SLD), which may progress to fibrosis and cirrhosis, is increasing due to the rising incidence of metabolic dysfunction-associated SLD (MASLD). Although general screening is not recommended, incidental findings should prompt evaluation. SLD with elevated liver enzymes (Setatohepatitis - SH) and fibrosis carries prognostic relevance. Non-invasive scores like FIB-4 and APRI can identify fibrosis risk. Using routine health data, we assessed the prevalence and associated factors of SLD, SH, and fibrosis among workers at the Bridgestone factory in Bilbao. **Methods:** 886 workers were enrolled during the 2024 annual checkups. Data included ultrasound, anthropometry, blood tests, and a qualitative alcohol questionnaire. Complete data were available for 362 individuals. Participants were grouped into: Healthy (no steatosis), SLD (steatosis, normal enzymes), and SH (steatosis, elevated enzymes). Group differences were analysed using ANOVA or Kruskal-Wallis and chi-square tests. Logistic and linear regressions identified predictors of SLD, SH, and fibrosis (FIB-4/APRI). **Results:** The Healthy Group accounted for 68% of the patients, while the remaining patients were divided into the other two groups (SLD 20%; SH 12%). Analysis of variance showed a statistical significant increase in age, BMI, creatinine, haemoglobin, triglycerides and serum glucose between healthy individuals, SLD and SH. A progressive increase also in individuals with arterial hypertension, with increased alcohol consumption and male sex was noted. At post-hoc analysis the only differences between SLD and SH patients were higher BMI, higher triglycerides and lower HDL. The prevalence of SLD diagnosed with ultrasound was 31.9%, [95% CI: 27.6%-36.6%]. Also, the prevalence of fibrosis diagnosed with FIB4 or APRI score was: 0.55% [0.15% - 1.9%], defined by a FIB4 score $>$ 2.67; and 0.2% [0.04% - 1.5%] defined by a APRI score $>$ 1.5. Factors associated with SLD at multivariable logistic regression were: BMI (aOR 1.18 [1.06, 1.33]), hypertension (aOR 2.69 [1.22, 6.03]), alcohol consumption (aOR 2.40 [1.16, 5.12]) and ALT (aOR 1.03 [1.00, 1.06]). Factors associated with SH at multivariable logistic regression were: BMI (aOR 1.33 [1.19, 1.50]) and triglycerides (aOR 1.00 [1.00, 1.01]). Predictors of FIB4 were sex (coefficient: 1.30 [1.15, 1.47]), serum magnesium (coefficient: 0.67 [0.52, 0.84]) and HDL (coefficient: 1.01 [1.01, 1.01]). The only predictor of APRI score was serum magnesium (coefficient: 0.85 [0.76, 0.95]). **Conclusion:** The prevalence of SLD and liver fibrosis in this working population was consistent with existing literature. Opportunistic screening with ultrasound and liver enzymes identified a subset of patients at increased risk (SH), emphasizing the value of incorporating liver assessments into routine occupational health evaluations.

2114 | CHANGES IN THE FIBROSIS-4 (FIB-4) SCORE ACCURATELY REFLECTS THE DISEASE TRAJECTORY OF METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE

Vinay Jahagirdar[1] Breda Munoz-Hernandez[2] Andrea Mospan[2] Philip Newsome[3] Brent Neuschwander-Tetri[4] Kenneth Cusi[5] A. Sidney Barritt IV[6] Michael Fried[2] Arun Sanyal[1], [1]Virginia Commonwealth University, [2]Target RWE, [3]Foundation for Liver Research and King's College Hospital; University of Birmingham, [4]Saint Louis University, [5]University of Florida-Gainesville, [6]University of North Carolina

Background: A FIB-4 score of 1.3-2.6 reflects an intermediate risk stratum of MASLD where secondary tests with VCTE or repeat testing is recommended. VCTE is not however universally available and the utility of repeat FIB-4 testing to assess changes in clinical status in MASLD is not known. This is particularly relevant since MASLD can both progress and regress without specific intervention. We hypothesized that

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

changes in FIB-4 will coordinately track the risk of clinical outcomes in MASLD. The aim of this study was to define the performance of changes in FIB-4 as a disease-monitoring test in MASLD. **Methods:** A retrospective analysis of a US cohort with MASLD followed prospectively in a non-interventional longitudinal registry (TARGET-NASH) was performed. MASLD was diagnosed by metabolic risk factors, histology or NITs, and AUDIT score < 7 (Am J Gastroenterol, 2024; 119 (8):1624-1627). Adults with FIB-4 between 1.3-2.6 who had 2 FIB-4 measurements > 6 mths apart within 3 years from baseline and a total of 5 years of follow up were included. Changes in FIB-4 from baseline up to yr. 3 was related to outcomes between yrs. 3-5. Key outcomes included death and major adverse liver outcomes (MALO) i.e. ascites, overt encephalopathy and variceal hemorrhage. Regression analysis was performed to determine if FIB-4 effects were independent of age, type 2 diabetes and other confounders. Bootstrap validation of the model was performed. **Results:** A total of 974 individuals were analyzed. Baseline data included: mean age 61 (9.7 SD) yrs, FIB-4 1.8 (0.34 S.D.) including T2DM (28%) and HTN (63%). 221 MALO events were noted by yr 3 and a total of 94 clinical events were noted between yr 3 and 5. From baseline to yr 3, FIB-4 declined by >10% in 434 patients and increased by >10% in 304 patients. MALO incidence decreased with decreasing FIB-4 and increased with rising FIB-4 (O.R. 1.4 (1.08-1.9)(Figure 1). Age and BMI did not impact outcomes while T2DM increased outcome risk (OR 2.36(1.5-3.8)). A total of 7 and 11 individuals died by yr. 3 and between yrs. 3-5 respectively; changes in FIB-4 were also associated with mortality risk. Bootstrap validation confirmed the robustness of the model. **Conclusion:** Changes in FIB-4 predict future risk of adverse health outcomes independent of age and changes in BMI. Thus, in this intermediate risk FIB-4 category especially with T2DM, repeat testing and change in FIB-4 can be used to assess prognosis and disease trajectory.

★ 2116 | PREVALENCE AND HEALTH CHECKUP-BASED DETECTION OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE IN JAPANESE YOUNG ADULTS

Satoko Tajirika[1] Takao Miwa[2] Tatsunori Hanai[2] Masahito Shimizu[2] Mayumi Yamamoto[1], [1]Gifu University, Gifu, Japan, [2]Graduate School of Medicine, Gifu University, Gifu, Japan.

Background: The new nomenclature of steatotic liver disease (SLD) has been announced for a clear definition based on cardiometabolic criteria and alcohol consumption. This study aimed to reveal the prevalence of SLD based on the new nomenclature in Japanese young adults. Additionally, health checkup-based markers to identify metabolic dysfunction-associated steatotic liver disease (MASLD) in this population were explored. **Methods:** We recruited Japanese young adults (aged 18–29 years) attending a health checkup. Abdominal ultrasonography and health checkup data were used to diagnose and classify SLD based on the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

new nomenclature. Regarding health checkup-based markers to identify MASLD, the diagnostic ability of serum alanine aminotransferase (ALT), fatty liver index (FLI), and hepatic steatosis index (HSI) were evaluated using receiver operating characteristic curve analysis. **Results:** Of the 1632 participants, 1004 (62%) were male, and SLD was observed in 271 (17%). In the SLD subclass, 143 (9%), 1 (<1%), 0 (0%), and 127 (8%) were diagnosed with MASLD, metabolic and alcohol-related/associated liver disease, alcohol-associated/related liver disease, and cryptogenic SLD, respectively, which was more frequent males than females (Figure 1). Regarding markers of MASLD, ALT, FLI, and HSI had a favorable ability to identify MASLD with an area under the curve of 0.76, 0.85, and 0.84, respectively, in the total cohort, 0.81, 0.87, and 0.86, respectively, in males, and 0.63, 0.83, and 0.79, respectively, in females. The cutoff value of ALT to rule-in (specificity 0.90) MASLD was 31 IU/L. **Conclusion:** The prevalence of SLD and MASLD in Japanese young adults was 17% and 9%, respectively. Regarding health checkup-based markers for MASLD, FLI, HSI and ALT had favorable ability to identify MASLD. In addition, ALT >30 IU/L was identified as a reasonable cutoff value to identify MASLD in Japanese young adults.

2117 | THE EFFICACY OF MEASURING NATURAL KILLER ACTIVATING RECEPTOR LIGANDS AND BILE ACIDS TO PREDICT THE PATHOGENESIS OF MASLD

Jun Arai[1] Akinori Okumura[1] Shun Futagami[1] Masato Yano[1] Tomoya Kitada[1] Satoshi Kimoto[1] Kazumasa Sakamoto[1] Rena Kitano[1] Tadahisa Inoue[1] Sayaka Nishimura[1] Kiyoaki Ito[1], [1]Department of Gastroenterology, Aichi Medical University, Nagakute, Aichi, Japan.

Background: The proportion of non-B/non-C hepatocellular carcinoma cases is increasing, and the principal cause is metabolic dysfunction-associated steatotic liver disease (MASLD). The degree of intrahepatic natural killer (NK) cell infiltration has been reported to correlate with MASLD progression. However, reports on MASLD are limited. Previous studies have also revealed that the disruption intrahepatic bile acid homeostasis could be one of the major mechanisms of progression to MASH. We aimed to investigate the involvement of NK cell-activating receptor ligands and bile acid in MASLD pathogenesis. **Methods:** This study cohort comprised 69 patients with biopsy-proven MASLD treated between 2012 and 2018 at our institute. The concentrations of major histocompatibility complex class I polypeptide-related sequences A and B (MICA and MICB, respectively) B7H6, total bile acids (TBA), and Chenodeoxycholic acid (CDCA) in patient sera were measured. Data were statistically compared between those with metabolic-associated steatotic liver (MASL, n = 25) and those with metabolic dysfunction-associated steatohepatitis (MASH, n = 44). The clinical characteristics related to higher concentrations of each NK cell-activating receptor ligand were also investigated. **Results:** The MASH group had a higher level of the ligands than the MASL group. Furthermore, the MASH group had a significantly higher level of the Mac-2-binding protein glycosylation isomer (M2BPGi) and Fib-4 index than the MASL group ($p < 0.001$). MICA and MICB were positively correlated, and all three ligands were strongly correlated with alpha-fetoprotein and protein induced by vitamin K absence 2. Although MICB levels positively correlated with aspartate transaminase and alanine transaminase levels ($p < 0.005$), patients with higher MICA and B7H6 levels had higher M2BPGi levels. Interestingly, concentrations of B7H6 were significantly correlated with portal inflammation ($p < 0.001$), rather than lobular inflammation. On the other hand, there were no significant differences in TBA and CDCA between MASL and MASH groups. CDCA shows significant positive correlations with age, M2BPGi, and Fib-4 index ($p < 0.001$). Furthermore, CDCA/TBA ratio was positively associated with MICB level ($\rho = 0.41$, $p < 0.001$). **Conclusion:** The three NK-activating receptor ligands were higher in the sera of the MASH group than those of the MASL group and strongly correlated with tumor markers, indicating the potential for hepatocarcinogenesis. Higher concentrations of serum B7H6 were correlated with advanced fibrosis and the degree of portal inflammation, which is a potential biomarker for predicting the pathogenesis of MASH. The CDCA/TBA ratio could predict the activation of the NK cells. **Disclosures:** Jun Arai: Nothing to Disclose, Akinori Okumura: Nothing to Disclose, Shun Futagami: Nothing to Disclose, Masato Yano: Nothing to Disclose, Tomoya Kitada: Nothing to Disclose, Satoshi Kimoto: Nothing to

2118 | PREDICTING HEPATIC STEATOSIS: A STUDY OF DECEASED LIVER DONORS

Jaimie Chang[1] Darren Nin[1] Stephanie Trautmann[1] Maria Charina Benavidez[1] Jarren Takaki[1] Kabeer Masih[1] John Klein[1] Edie Chan[1], [1]Rush University Medical Center

Background: Hepatic steatosis in donor grafts is associated with poorer liver transplantation outcomes. While liver biopsy remains the gold standard for diagnosis, it is not always readily available. This study aims to evaluate how donor risk factors and imaging features correlate with hepatic steatosis. **Methods:** This study used data from the Organ Procurement and Transplantation Network (OPTN). Adult liver donors in the United Stated between 2020-2024 with liver biopsy results and CT scans were identified from the OPTN database. Hounsfield units (HU's) of the liver, spleen, anterior abdominal wall thickness and dimensions of the waist and peritoneal cavity at the level of the umbilicus were measured on CT scans. **Results:** A total of 2972 donors with liver recovered met inclusion and exclusion criteria. 2673 had $<30\%$ steatosis and 299 had $\geq 30\%$ steatosis. The absolute intraclass correlation coefficient was high, ranging from 0.73-0.91 for HU measurements and between 0.84-0.99 for abdominal measurements. Younger age, Hispanic ethnicity, higher body mass index (BMI), Weight-Adjusted Waist Index (WWI), abdominal wall thickness, and peritoneal cavity area, lower liver to spleen (L/S) ratio, elevated total bilirubin, and a history of heavy alcohol use were identified as risk factors on the univariate analysis. On the adjusted analyses the only significant predictors of steatosis were Hispanic ethnicity [OR: 1.74, 95% CI:1.13-2.66] and L/S ratio [OR: 0.02, 95%CI: 0.01-0.04]. **Conclusion:** Donor related risk factors including BMI, bilirubin, and drinking, history, as well as CT measurements including waist dimensions, abdominal wall thickness, are all correlated to hepatic steatosis, but Hispanic ethnicity and L/S ratio were the most significant predictors on adjusted analysis. This may inform donor selection when biopsy is not available.

2119 | META-ANALYSIS OF THE PERFORMANCE OF THE ENHANCED LIVER FIBROSIS (ELF) TEST TO IDENTIFY SIGNIFICANT FIBROSIS, ADVANCED FIBROSIS AND CIRRHOSIS IN PATIENTS WITH MASLD

Matthew Gee[1] Donald Chalfin[1] Edward De Vol[1] Mario Gutierrez Casale[1] Artem Boltyenkov[1] H. Roma Levy[1] Arun Sanyal[2], [1]Siemens Healthineers, [2]Virginia Commonwealth University

Background: Non-invasive tests, such as the ELF Test, are increasingly employed to evaluate the presence of liver fibrosis and the likelihood of disease progression in patients with MASLD. This meta-analysis aimed to determine the optimal ELF cutoffs for detecting histologically-staged significant fibrosis ($\geq$F2), advanced fibrosis ($\geq$F3), and cirrhosis (F4) in patients with MASLD; and to validate the accuracy of established cutoffs (9.00, 9.80, and 11.30). This study incorporates several reports not included in prior meta-analyses. Additionally, this is the first meta-analysis to evaluate the performance of the ELF Test in MASLD patients with cirrhosis. **Methods:** We searched MEDLINE (PubMed), EMBASE, the Cochrane Library, and CINAHL databases for studies reporting ELF Test performance published between 2004-01-01 and 2023-10-10, followed by an additional PubMed search in May 2024 for liver fibrosis and ELF. One author extracted data with confirmation by two reviewers. Study quality was assessed using the QUADAS-2 tool. Multiple thresholds published in the various reports were integrated into a hierarchical summary receiver operating characteristic (HSROC) model. For each fibrosis category ($\geq$F2, $\geq$F3, F4), a bivariate random-effects model was used to estimate sensitivity and specificity across thresholds, generating summary areas (AUCs) under the ROC curve. **Results:** Of 8004 articles identified by keyword search, 981 abstracts were screened, of which 107 articles were selected for whole article review. Upon review, 33 separate cohorts from 30 studies were extracted for inclusion in the meta-analysis. The AUC was 0.827 (95% CI: 0.787, 0.860) for $\geq$F2 fibrosis, 0.829 (95% CI: 0.791, 0.861) for $\geq$F3 fibrosis, and 0.773 (95% CI: 0.707, 0.826) for cirrhosis. For detection of $\geq$F2, the pre-established ELF threshold of 9.00 yielded 86% sensitivity and 63% specificity. The 9.80 cutoff was confirmed to be a balanced threshold for $\geq$F3 (sensitivity = 71%, specificity = 81%), while the recognized cutoff of 11.30 was useful to rule in F4 (sensitivity = 22%, specificity = 96%). A higher sensitivity cutoff of 10.50 was determined to be an effective alternate threshold for identification of cirrhosis (sensitivity = 51%, specificity = 86%). **Conclusion:**

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Incorporating the highest number of MASLD cohorts of any meta-analysis to date, our study confirms that the ELF Test accurately identifies significant fibrosis, advanced fibrosis, and cirrhosis in patients with confirmed or suspected MASLD. An ELF cutoff <9.00 may be useful to rule out significant fibrosis, while ≥ 9.80 represents a balanced cutoff to identify advanced fibrosis. For cirrhosis, ELF ≥ 11.30 is a high-specificity rule-in cutoff, whereas ≥ 10.50 offers higher sensitivity for F4 detection. These findings support recent MASH treatment initiation guidelines based on non-invasive determination of fibrosis stage.

2120 | EVALUATION FOR HEPATIC FIBROSIS RISK BY FIB4 SCORE, LIVER STIFFNESS (FIBROSCAN, SHEARWAVE), LIVERRISK SCORE AND EASL/AASLD-2 STEP APPROACH IN 1169 PATIENTS FOLLOWED FOR MASLD, NEW SUBMISSION

Denis Ouzan[1] Guillaume Maeva[2] Penaranda Guillaume[3] guivarch mathieu[4] guillouche Pauline[5] Chagneau Corinne[6] delasalle Patrick[7] Boussoukaya Samy[8] Toulemonde Pierre[9] Lim Annie[10] Maeva Salimon[10] Hanslik Bertrand[11] Jacques Liautard[12] Dukan Patrick[13] Ingiliz Patrick[14] Ouizeman Dann Joseph[15] Bonny Corinne[16] Ancel David[17] Marion Audibert Anne Marie[18] Debono Emmanuel[19] Fontanges Thierry[20] Vallin Melanie[20] Guillaud Olivier[21],
[1]HEPATOLOGIE Institute Arnault Tzanck, [2]Clinique Pasteur Toulouse, [3]AlphaBio Marseille, [4]CHU Puepan Toulouse, [5]Clinique Jules Vernes Nantes, [6]Nantes (6) Polyclinique Bordeaux Rive Droite, Lormont, [7]Clinique du Palais, Grasse, [8]Clinique du Palais Grasse, [9]Cabinet Médical Toulouse, [10]Clinique Santé Atlantique, Saint Herblain, [11]Cabinet Medical Montpellier, [12]Clinique Beau Soleil, Montpelier, [13]Maison de Santé du Valon de Malpassé, Marseille, [14]MSP Chemin vert Paris, [15]Clinique Saint George Nice, [16]Cabinet Médical, Beaumont, [17]Clinique Turin, Paris, [18]Clinique du Val d'Ouest, Ecully, [19]Hôpital Privé la Casamance, Aubagne, [20]Cabinet Médical, Bourgoin-Jallieu, [21]Clinique de la Sauvegarde, Lyon

Background: The STEATOLIB cohort was established to prospectively monitor patients with steatosis in hepatology private practice over a decade. This study focuses on liver fibrosis evaluation by FIB4 score, liver stiffness (Fibroscan, ShearWave), and LiverRisk score.
Methods: From February 2021 to June 2023, 18 centers enrolled 1,169 adult patients with morphological and/or histological steatosis and abnormal liver tests (ASAT, ALAT, GGT, and/or PAL) into the STEATOLIB cohort. **Results:** Among the 1,169 patients included, 56% were men, with a mean age of 56 years (SD: 13). Comorbidities included diabetes (37%), hypertension (45%), and dyslipidemia (36%). Weekly alcohol consumption was: no consumption (56%), 1–10 units (33%), and >10 units per week (11%). The mean BMI was 31 ± 5.8 kg/m². Fibrosis was assessed using the FIB-4 score in 936 patients: 69% had a low fibrosis risk (FIB-4 <1.3/<2, age-dependent), 23% had an intermediate (FIB-4: 1.3–2.67), and 8% had a high risk (FIB-4 >2.67). Liver stiffness measurement (LSM) was available in 836 patients: FibroScan (n = 407) showed a mean stiffness of 8.3 kPa (SD 6.1), with 66% <8 kPa, 19% between 8–12 kPa, and 15% >12 kPa, Shear Wave Elastography (n = 429) yielded similar results (mean: 8.0 kPa (SD 5.2)). The LiverRisk Score (LRS) was calculated in 654 patients: 41% had minimal risk (LRS <6), 51% had low risk (LRS <10), 7% had medium risk (LRS 10–15), and 1% had high risk (LRS >15). Advanced fibrosis (LSM ≥8 kPa) was significantly associated with diabetes, FIB-4 >1.3/> 2, and LRS >6. Liver biopsy, performed in 90 patients (8%), revealed fibrosis F2–F4 in 55 patients, significantly correlated with age, diabetes, and LSM. Using the EASL-recommended 2-step approach: low fibrosis risk by FIB-4 was confirmed by LSM (<8 kPa) in 79% and by LRS (<10) in 96% of cases. Intermediate FIB-4 risk was confirmed by LSM (≥8 kPa) in 55% of cases and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

by median or high-risk LRS ($\geq$10) in 16%. High FIB-4 risk was confirmed by LSM ($\geq$8 kPa) in 77% of cases and by medium or high-risk LRS ($\geq$10) in 30%. Using the AASLD- 2-step approach using FIB-4 then LSM measurement, low fibrosis risk was observed in 81 % and confirmed by LRS ($<$10) in 96% of cases, intermediate risk in 29% of cases confirmed by LRS ($\geq$10) in 24 % and high risk of fibrosis in 12% of cases confirmed and by LRS ($\geq$10) in 26 % of cases. LRS $<$6 was observed in: 52%, 20%, and 4% of patients with low, intermediate, and high FIB-4 risks, respectively ($p<0.001$), in 47% of patients with LSM $<$10 kPa vs. 4% with LSM $\geq$10 kPa ($p<0.001$). **Conclusion:** Hepatic fibrosis was confirmed in one-third of patients consulting for MASLD in hepatology private practice. The EASL and AASLD 2-step approaches are effective in identifying liver fibrosis. In resource-limited settings, second-line fibrosis testing can be restricted to patients with intermediate FIB-4 scores. While FIB-4 and LRS show strong concordance in low-risk zones, their agreement is more limited in the intermediate or high-risk zones of the FIB-4.

2121 | DIAGNOSTIC PERFORMANCE OF FIB-4, LIVERRISK SCORE, SAFE AND MAF-5 AS INDEX SCREENING TOOL FOR LIVER FIBROSIS AMONG COMMUNITY-DWELLING INDIVIDUALS WITH HIGH METABOLIC RISK

Laurens van Kleef[1] Jesse Pustjens[1] Maja Thiele[2] Maurice Michel[3] Adriaan Holleboom[4] Manuel Castro Cabezas[5] Maarten Tushuizen[6] Harry Janssen[1] Jörn Schattenberg[7] Sven Francque[8] Zobair Younossi[9] Aleksander Krag[10] Willem Pieter Brouwer[1],

[1]Department of Gastroenterology and Hepatology, Erasmus MC, University Medical Center, [2]Odense University Hospital, [3]Department of Internal Medicine II, University Medical Center Saarland, [4]Amsterdam UMC, [5]Sint Franciscus Gasthuis, [6]Leids Universitair Medisch Centrum, [7]Department of Internal Medicine II, Saarland University Medical Center, [8]Department of Gastroenterology and Hepatology, Antwerp University Hospital, [9]The Global NASH Council, Washington DC, [10]University of Southern Denmark

Background: Screening for advanced liver disease is indicated in $>$60% of the US population, of whom up to 30% may require liver stiffness measurement (LSM) due to an elevated FIB-4. We investigated the diagnostic performance of FIB-4, LiverRisk score and MAF-5 in individuals at high risk for liver fibrosis. **Methods:** Using NHANES 2017-2020 data, we analysed high-risk individuals defined as having (1) diabetes with obesity and/or elevated ALT (2) or obesity – either class III, class II with elevated ALT or class I with elevated ALT and $\geq$ 3 cardiometabolic risk factors. Individuals with excessive alcohol consumption were excluded. Analyses included assessment of the proportion having FIB-4 $\geq$1.3 (or $\geq$2.0 in individuals aged $\geq$65), LiverRisk score $\geq$ 6, SAFE $\geq$0 and MAF-5 $\geq$1 together with the diagnostic characteristics. Analyses were repeated among individuals with diabetes (regardless obesity or ALT). **Results:** We included 1,408 individuals (mean age 51, 51% male) of whom 52.7% had diabetes, 95.3% obesity and 44.7% ALT $\geq$ 30. The median LSM was 6.1 kPa [4.9-8.0] and 25.8% had LSM $\geq$8 kPa. Among this high-risk population, 14.2% had an increased FIB-4, 39.3% had a LiverRisk score $\geq$6, 70.7% a SAFE $\geq$0 and 73.3% had a MAF-5 $\geq$ 1, indicating high risk of fibrosis. This translated into a sensitivity (for LSM $\geq$8 kPa) of 20.7% for FIB-4, 50.4% for LiverRisk score, 79.6% for SAFE and 90.4% for MAF-5 (specificity: 88.0, 64.5, 32.4 and 32.6, respectively). FIB-4 had a PPV of 37.5% and NPV of 76.1%, the LiverRisk score had a PPV of 32.8% and NPV of 79.1%, the SAFE had a PPV of 29.1% and NPV of 82.0% and MAF-5 had a PPV of 31.5% and NPV of 90.8%. Comparable differences in test performance were observed with higher LSM thresholds or when 1,045 individuals with diabetes (irrespective of ALT and class obesity) were assessed. **Conclusion:** Among individuals at high risk, the FIB-4 had the lowest sensitivity for detecting increased LSM and seems not suitable as a primary screening test. In contrast, MAF-5 identified the largest proportion of individuals, yet achieved a similar positive predictive value (PPV) as the FIB-4 and a markedly higher negative predictive value (NPV). To avoid inefficient screening pathways, alternative tests other than FIB-4, with better diagnostic performance, should be considered.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Table 1: Diagnostic accuracy of NITs as index test in high-risk populations

	Sensitivity	Specificity	PPV	NPV
FIB-4	20.7	88	37.5	76.1
LiverRisk score	50.4	64.5	32.8	79.1
SAFE	79.6	32.4	29.1	82
MAF-5	90.4	32.6	31.5	90.8

Increased FIB-4 was defined as ≥ 1.3 (or ≥ 2.0 among individuals aged ≥ 65 years), increased LiverRisk score as ≥ 6, increased SAFE as ≥ 0 and increased MAF-5 as ≥ 1.

2122 | RISK STRATIFICATION IN STEATOTIC LIVER DISEASES: CHANGING THE REFERENCE TO DEVELOP NEW NON-INVASIVE TESTS WELL ADAPTED TO THE CONTEXT OF USE

Jérôme Boursier Adele Delamarre[1] Charlotte Costentin[2] Christophe Bureau[3] Jeanne Fichez[4] Isabelle Fouchard[4] Adrien Iannes[4] frederic oberti[4] Marine Roux[5], [1]Bordeaux University Hospital, [2]Grenoble University Hospital, [3]Toulouse University Hospital, [4]Angers University Hospital, [5]Angers University

Background: The Liver Risk Score (LRS) is a simple blood fibrosis test that was recently developed using vibration-controlled transient elastography (VCTE) as the reference rather than liver biopsy. We aimed to evaluate this concept of changing the reference for non-invasive tests of liver fibrosis. **Methods:** Cohort #1 included 1,510 patients with steatotic liver disease (MASLD or alcohol) who underwent liver biopsy, VCTE, and blood sampling in four tertiary care centers. This cohort was divided into a derivation (one center, n = 739) and a validation set (three other centers, n = 771). Cohort #2 included 2,526 consecutive patients with steatotic liver disease who underwent VCTE and blood sampling in the Hepatology department of a tertiary care center, with further follow-up for liver-related events (LRE: cirrhosis complication or hepatocellular carcinoma). **Results:** In cohort #1 (biopsy cohort), the calibration plot showed that LRS underestimated VCTE result. As a consequence, 76% of F3 patients and 49% of F4 patients were classified as minimal/low risk by LRS (LRS < 10, PMID 37572680). We hypothesized this poor diagnostic accuracy was due to the use of VCTE as reference when deriving LRS. We therefore developed two tests based on simple biology in the derivation set: one using VCTE as reference and the other using biopsy (target: F3/4). Both tests showed similar accuracy for F3/4 in the validation set, with respective AUROC at 0.76 ± 0.03 and 0.78 ± 0.03 (p = 0.098). We then hypothesized that underestimation by LRS was due to its development in a set with low prevalence of fibrosis (mean VCTE result: 5.9 kPa [SD: 5.8], PMID 37572680). We therefore recalibrated LRS in the derivation set (prevalence F3/4: 38%), which improved sensitivity: only 29% of F3 patients and 16% of F4 patients were classified as minimal/low risk in the validation set. All these results suggested that non-invasive tests could be developed using VCTE as reference, provided the derivation set has a sufficient prevalence of at-risk patients and covers the full range of VCTE results to ensure the best calibration. This led to develop a new test using VCTE as reference in cohort #2, an inception cohort corresponding to the context of use of liver specialists. The new test included 8 variables (AST, ALT, gamma-GT, ALP, albumin, platelets, glycaemia, HDL-cholesterol). Calibration between the new test and VCTE result was very good. AUC(t) for predicting LRE at 3 years was 0.86 ± 0.02 with the new test, versus 0.76 ± 0.03 with LRS (p < 0.001) and 0.86 ± 0.03 with VCTE (p = 0.700). AUC(t) for 5-year prediction was 0.86 ± 0.02 with the new test, versus 0.77 ± 0.03 with LRS (p < 0.001) and 0.85 ± 0.03 with VCTE (p = 0.500). **Conclusion:** VCTE can be used as reference for developing new non-invasive tests, without decreasing diagnostic and prognostic accuracy compared to tests developed using liver biopsy. This approach enables tests to be derived in the correct context of use, reducing bias in the development process.

2123 | EVALUATION OF NUTRITIONAL ABNORMALITIES AND FRAILTY INDICES IN PATIENTS WITH ALD, MASLD AND METALD

Anastasia Xynogala[1] Arpit Amin[1] Caprice Pierre[1] Tumininu Ayorinde[2] Yash Shah[1] Guergana Panayotova[1] Lianhua Jin[1] Nedine Abdelhamid[1] Grace Lee-Riddle[1] Flavio Paterno[3] Zaid Tafesh[1] Mumtaz Niazi[1] Vivek Lingiah[3] Paul Gaglio[1] James Guarrera[1] Keri Lunsford[1], [1]Rutgers New Jersey Medical School, [2]Rutgers New Jersey Medical Scool, [3]Rutgers University - New Jersey Medical School

Background: There is little information in the literature about differences in nutritional abnormalities and frailty indices in patients with alcohol-associated liver disease (ALD), metabolic dysfunction-associated liver disease (MASLD) and the overlap of these two conditions (MetALD). **Methods:** This is a single-center, prospective study evaluating nutritional abnormalities and different frailty indices in adult patients (n = 179) with ALD, MASLD and MetALD presenting for liver transplant evaluation from 12/2023 to 05/2025. We analyzed the micronutrient and vitamin levels in our study population. Additionaly, we performed a variety of frailty indices including Katz index (KI), Short Physical Performance Battery (SPPB), Fried Frailty Index (FFI) and Liver Frailty Index (LFI) in these patients. Categorical variables were analyzed with chi-square test and continuous variables were analyzed with one-way analysis of variance test. **Results:** The median age of patients with ALD (49 years) was significantly lower

compared to those with MASLD (65 years) and MetALD (61 years) ($p = 0.001$). The median MELD 3.0 score at initial evaluation was significantly higher in ALD patients (27) compared to both MetALD (17) and MASLD (17) patients ($p < 0.001$). Greater proportion of ALD patients (66%) were evaluated in the inpatient setting compared to MetALD (40%) and MASLD (43%) patients ($p = 0.003$). Copper levels were significantly lower in patients with ALD and MetALD compared to patients with MASLD ($p = 0.036$). Zinc levels were significantly lower in the ALD group compared to the MetALD group ($p = 0.012$). Vitamin C levels were significantly lower in both ALD and MASLD patients compared to MetALD patients ($p = 0.026$). Vitamin D deficiency was noted in all three groups with ALD patients having significantly lower vitamin D levels compared to MASLD and MetALD patients ($p = 0.011$). Vitamin B1 levels were significantly lower in the MASLD group compared to ALD group ($p = 0.001$). Vitamin B12 levels were significantly lower in the MetALD group compared to ALD group ($p = 0.01$). Frailty assessment using the FFI showed MASLD patients to be significantly frail compared to ALD and MetALD patients ($p = 0.002$). No significant difference in frailty was observed across the three groups when assessed using the KI, SPPB, or LFI. **Conclusion:** We demonstrate that there are distinct patterns of micronutrient and vitamin deficiencies in patients with ALD, MASLD and MetALD underscoring the importance of targeted nutritional screening and nutritional supplementation.

	Alcohol (n=113)	MASLD (n=52)	MetALD (n=14)	p-value

2124 | NO LONGER MISSING HALF: CONCURRENT FIB-4&GE;1.3 AND ELF &GE;9.4 ENHANCES FIBROTIC MASH DETECTION - EVIDENCE FROM A PROSPECTIVE STUDY

Alina Allen[1] Olivia Bobek[2] Rachel Canning[3] Maysa Eslami[3] Joanne Benson[3] Fang-Shu Ou[3], [1]Mayo Clinic Rochester, [2]Mayo Clinic, Rochester MN, [3]Mayo Clinic, Rochester, MN

Background: Societal guidelines recommend Enhanced Liver Fibrosis (ELF) score as second-line test for metabolic dysfunction-associated steatohepatitis (MASH) with fibrosis in patients with FIB-4 ≥ 1.3, using a rule-out cutoff of < 7.7. However, this cutoff may be too low, and the performance of this algorithm is uncertain. We aimed to: 1) identify optimal ELF cutoffs for fibrotic MASH using biopsy and elastography as reference, and 2) assess guideline-recommended algorithm performance using ELF 7.7 vs. an optimized cutoff. **Methods:** In this prospective study, patients with/at risk for MASLD at liver or obesity clinics underwent FIB-4, ELF testing, liver stiffness measurement (LSM) by magnetic resonance elastography (MRE), and liver biopsy within one month. Histology was evaluated by two blinded pathologists. Fibrotic MASH was defined as fibrosis stage ≥ 2 by histology or LSM ≥ 3.1 kPa by MRE. We evaluated several diagnostic pathways using different ELF cutoffs applied sequentially (after FIB-4 ≥ 1.3) or concurrently (further evaluation needed if either test exceeds the cutoff). Pathway performance was assessed using area under the receiver operating curve (AUROC), sensitivity and specificity. **Results:** Among 237 participants, 186 had complete data. Median age was 51 (range 19–74), 69% were women, median BMI 40 (range 22–70) kg/m², and 36% had type

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

2 diabetes. Fibrotic MASH was present in 71 (38%), with median ELF 10.1 (IQR: 9.5–10.7). ELF alone yielded AUROC 0.77 (95% CI: 0.70–0.84); the optimal Youden cutoff was 9.4 (80% sensitivity, 65% specificity). Lower ELF cutoffs of 8.7 and 7.7 had sensitivity of ≥ 90% and 100%, respectively, with low specificity of 34% and 4%, respectively. FIB-4 ≥ 1.3 had 57% sensitivity and 92% specificity, missing 43% of fibrotic MASH, limiting sequential testing utility of a second-line test. A concurrent approach, applying both FIB-4 and ELF as first-line tests with follow-up if either is elevated, improved performance. Among candidate ELF rule-out thresholds (7.7, 8.7, 9.0, 9.4, 9.8), 9.4 offered the best balance (87% sensitivity, 64% specificity) (Figure). **Conclusion:** A first-line test should have high sensitivity (ideally > 80%) to minimize the false negative results, and FIB-4 lacks adequate sensitivity, missing nearly half of fibrotic MASH cases. A concurrent first-line strategy using FIB-4 ≥ 1.3 and ELF ≥ 9.4 improves fibrotic MASH detection and balances false positives and negatives. This approach may significantly enhance the performance of noninvasive tests pathway.

2125 | THE NEW ASSAY TYPE IV COLLAGEN 7S (CLEIA) IS A USEFUL TEST TO IDENTIFY PROGRESSIVE FIBROSIS IN CHRONIC LIVER DISEASE: A STUDY BASED ON MAGNETIC RESONANCE ELASTOGRAPHY

Miwa Kawanaka[1] Masahiko Sue[1] Takuya Adachi[1] Hideki Onishi[1] YASUTO TAKEUCHI[1] Akinobu Takaki[1] Motoyuki Otsuka[2], [1]Faculty of Medicine, Dentistry and Phaemaceutical Sciences,Okayama University, [2]Okayama University

Background: Liver fibrosis is a critical prognostic factor for chronic liver disease that influences morbidity and mortality. While imaging-based methods such as magnetic resonance elastography (MRE) offer precise fibrosis staging, they are not widely available.Noninvasive serum biomarkers, such as the fibrosis-4 (FIB-4) index, M2BPGi, and hyaluronic acid, are widely used but have limitations, particularly in low inflammatory states or elderly patients. Type IV collagen 7S (T4C7S), a basement membrane component, reflects fibrotic extracellular matrix remodeling. With the advent of a new chemiluminescent enzyme immunoassay (CLEIA) method, this marker now allows for more sensitive quantification. We aimed to evaluate the diagnostic performance of CLEIA-based T4C7S against MRE as the reference standard and to explore a novel two-step stratification model using T4C7S to refine risk categorization within the intermediate FIB-4index. **Methods:** A total of 307 patients with chronic liver disease (235 with MASLD) were prospectively enrolled and underwent same-day MRE and biomarker measurement. Liver stiffness was categorized as F0–F4 based on kPa thresholds. Serum levels of T4C7S, FIB-4 index, M2BPGi, and hyaluronic acid were analyzed across fibrosis stages. The primary outcome was AUROC for detecting ≥ F2 fibrosis, with sensitivity, specificity, PPV, and NPV calculated using the Youden Index. Subgroup analyses were performed based on ALT levels (≤ 30 vs > 30 U/L) and age (≤ 60 vs > 60 years). A two-step diagnostic algorithm combining FIB-4 (cutoff 1.3–2.66) with T4C7S (cutoff ≥ 3.8 ng/mL) was tested to improve triage efficiency. **Results:** T4C7S showed the highest correlation with MRE ($\rho = 0.591$, $p < 0.001$), outperforming FIB-4 ($\rho = 0.532$), M2BPGi ($\rho = 0.503$), and hyaluronic acid ($\rho = 0.509$). For diagnosing ≥ F2 fibrosis, T4C7S achieved an AUROC of 0.795, versus 0.759 for FIB-4 and 0.745 for M2BPGi. Its diagnostic performance remained consistent across ALT and age subgroups, indicating greater robustness under low-inflammation and aging-related confounding. In the FIB-4 intermediate range (1.3–2.66), applying the T4C7S cutoff of ≥ 3.8 ng/mL improved specificity (from 55% to 78%) and PPV (from 54% to 67%), while only minimally reducing NPV (from 82% to 78%). This approach also reduced the number of unnecessary specialist referrals by 20%, highlighting its cost-effective potential. Among intermediate FIB-4 cases, 71% of ≥ F2 fibrosis cases were correctly reclassified using T4C7S. **Conclusion:** CLEIA-based type IV collagen 7S is a superior noninvasive biomarker for liver fibrosis, with strong correlation to MRE-derived stiffness. Its diagnostic robustness across ALT and age subgroups makes it especially valuable in populations where traditional markers underperform. Incorporating T4C7S into a two-step FIB-4-based model enhances diagnostic precision and reduces unnecessary referrals.

2126 | DECREASE IN LIVER STIFFNESS IS NOT ASSOCIATED WITH REDUCED CARDIOVASCULAR EVENTS IN PATIENTS WITH DIABETES MELLITUS: A PROSPECTIVE STUDY

Yoonseok Lee[1] Oh Sang Kwon[2] SEUNG KAK SHIN[2] Yun Soo Kim[2] Ju Hyun Kim[2] Kiyoung Lee[2] Young Sil Eom[2] Byung-Joon Kim[2], [1]Gachon University Gil Medical Center, [2]Department of Internal Medicine, Gachon University Gil Medical Center

Background: Patients with diabetes mellitus (DM) are at an increased risk of developing cardiovascular disease (CVD). Hepatic fibrosis is common among patients with DM and is associated with liver-related events. However, its impact on CVD risk remains unclear. This study aimed to prospectively assess the association between hepatic fibrosis and CVD risk in patients with DM. **Methods:** A total of 323 patients with DM were prospectively enrolled from January 2022, excluding those with viral hepatitis, overt cirrhosis, or cancer. The following parameters and data were assessed: body weight (BW), body mass index (BMI), waist circumference (WC), laboratory data, presence of hypertension (HTN), dyslipidemia, alcohol consumption, smoking status, liver steatosis measured by the controlled attenuation parameter (CAP) using FibroScan®, and CVD events. Hepatic fibrosis was quantified by liver stiffness measurement (LSM) using FibroScan®, assessed at baseline and after two years. CVD was defined as ischemic heart disease or ischemic/hemorrhagic stroke. **Results:** A total of 277 patients completed the 2-year follow-up and underwent repeat LSM. The mean age was 57 ± 12 years, and 56.3% were male. The baseline mean LSM was 6.9 ± 3.7 kPa. A history of CVD was present in 86 (31%) patients, while 6 (3.2%) developed new CVD events during follow-up. LSM decreased in 157 patients (d-LSM group) and increased in 120 patients (i-LSM group). The mean LSM change was -1.7 ± 2 kPa in the d-LSM group and +1.5 ± 1.3 kPa in the i-LSM group. The d-LSM group had significantly higher baseline ALT (39 ± 30 vs. 32 ± 21 IU/L, $p = 0.018$), CAP (281 ± 51 vs. 264 ± 49 dB/m, $p = 0.005$), and LSM (7.9 ± 4.2 vs. 5.7 ± 2.3 kPa, $p < 0.001$) than the i-LSM group. Alcohol consumption was more prevalent in the i-LSM group (30.8% vs. 17.8%., $p = 0.011$). There were no significant differences between the two groups in mean age, male proportion, BW, BMI, WC, HTN, dyslipidemia, laboratory results excluding ALT, or smoking status. When stratified by LSM change, the incidence of new CVD was 2% (1/49) in patients with a decrease LSM of ≤-2 kPa, 2% (4/198) in those with changes between -2 and +2 kPa, and 3.3% (1/30) in those with an increase of ≥+2 kPa ($p = 0.897$). **Conclusion:** Hepatic fibrosis, as measured by LSM, can change dynamically in patients with DM. A decrease in LSM was not associated with a reduced risk of CVD. Therefore, LSM monitoring may have limited value in assessing CVD risk in this population.

2127 | ASSOCIATION BETWEEN NON-HIGH-DENSITY LIPOPROTEIN CHOLESTEROL TO HIGH-DENSITY LIPOPROTEIN CHOLESTEROL RATIO AND RISK OF DEVELOPING MASLD AND ITS SUBGROUPS

ge yidi[1] Wen Xie[1], [1]Beijing Ditan Hospital, Capital Medical University,

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD), is a relatively common chronic liver disease. This study aimed to explore the relationship between the non-high-density lipoprotein cholesterol to high-density lipoprotein cholesterol ratio (NHHR) and the risk of developing MASLD, and to explore the differences between the pure MASLD and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

metbolic and alcohol related/associated liver disease (MetALD) subgroups. We also compared other predictors, such as albumin-to-alkaline phosphatase ratio (AAPR), albumin-to-glutamyl transpeptidase ratio (AGTR), atherogenic index of plasma (AIP) and uric acid to high-density lipoprotein cholesterol ratio (UHR). **Methods:** We included 1,648 participants from the National Health and Nutrition Examination Survey in 2019- 2020. Logistic regression evaluated the relationship between NHHR and the risk of MASLD. The dose-response association between NHHR and MASLD was determined using restricted cubic splines, and the predictive power of NHHR in comparison to traditional lipid markers for MASLD was evaluated using receiver operating characteristic (ROC) curves. **Results:** We found that the NHHR was positively associated with the risk of MASLD [OR:14.11, 95%CI:5.37, 37.07]. We further discover the NHHR was positively associated with the risk of pure MASLD and MetALD, the results respectively are [OR:5.41, 95%CI: 2.91, 10.04], [OR: 5.05, 95%CI: 1.06, 24.07]. The RCS results showed that there was a linear relationship between NHHR and MASLD (P **Conclusion:** According to our research, NHHR may be a helpful biomarker for identifying individuals at risk of MASLD. Clinical risk assessment and early intervention methodologies could get advantages from it. Additional longterm studies are required to corroborate these findings and explore the mechanisms between NHHR and MASLD.

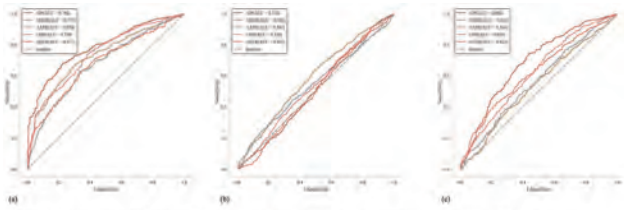

Figure 1 The ROC curve for internal validation between different predictors with the risk of MASLD. (a) The participants were diagnosis of MASLD. (b) The participants were diagnosis of pure MASLD. (c) The participants were diagnosis of MetALD. AAPR, albumin-to-alkaline phosphatase ratio; AGTR, albumin-to-glutamyl transpeptidase ratio; AIP, atherogenic index of plasma; NHHR, non-high-density lipoprotein cholesterol to high-density lipoprotein cholesterol ratio; UHR, uric acid to high-density lipoprotein cholesterol ratio.

2128 | DEFINING CUT-OFFS OF ANTHROPOMETRIC AND METABOLIC MARKERS IN MEXICO FOR EARLY DETECTION AND PREVENTION OF CHRONIC METABOLIC DISEASES

Leonardo Leal-Mercado[1] Sonia Roman[1] Arturo Panduro[1], [1]UNIVERSIDAD DE GUADALAJARA

Background: The main mortality causes in Mexico include diabetes, cardiovascular, liver, and kidney diseases, which are often underdiagnosed and detected at advanced stages. Current clinical cutoffs derived from European and North American populations underestimate risk in Mexicans, who exhibit distinct anthropometric and metabolic traits. This study aimed to identify the onset of metabolic risk factors (MRFs) and define anthropometric and metabolic cutoffs for Mexico. **Methods:** We conducted a cross-sectional analysis on 1,012 youngsters and adults from Mexico. We identified overweight, obesity, and metabolic risk factors (MRF) using standard clinical measures: Body mass index (BMI) ($\geq$25 kg/m²), triglycerides ($\geq$150 mg/dL), total cholesterol ($\geq$200 mg/dL), HOMA-IR ($\geq$2.5), glucose ($\geq$100 mg/dL), and liver enzymes (ALT and AST $\geq$40 U/L). We assessed the frequency of overweight and obesity and the presence of at least 1 MRF across BMI and age groups. Receiver operating characteristic (ROC) curve analysis helped us find the age and BMI when metabolic risk factors (MRF) start to appear and looked at how well different body measurements (waist circumference, waist-to-hip ratio, and waist-to-height ratio) and blood markers (triglycerides, cholesterol, glucose, HOMA-IR, ALT, and AST) perform. Finally, using the ROC curve results, we compared how well the standard thresholds work against the new thresholds to see if they improve our ability to identify people at risk. **Results:** We found a high prevalence (71.17%) of individuals with $\geq$1 MRF, and 53.31% of normal-weight subjects (BMI $<$25 kg/m²) had $\geq$1 MRF. MRFs and anthropometric markers were significantly higher in overweight/obese individuals ($<$0.05). Among youngsters (15–19 years), 32% were overweight/obese, and 40% had $\geq$1 MRFs. ROC analysis showed early MRF onset at 22.5 years, with insulin resistance as the first abnormality. MRFs emerged at a BMI of 23.4 kg/m², with hypercholesterolemia appearing earliest. Based on Youden index results, we propose lower cut-offs: BMI $\geq$23.4 kg/m², triglycerides $\geq$109.5 mg/dL, cholesterol $\geq$174.5 mg/dL, glucose $\geq$87 mg/dL, HOMA-IR $\geq$2.4, ALT $\geq$21.5 U/L, and AST $\geq$22 U/L. These changes helped find metabolic risk factors 28.8% more often, especially for liver enzymes (high AST increased by 32.4%, high ALT by 28.6%), glucose by 24.7%, and total cholesterol by 23.4%. **Conclusion:** These results underscore that current clinical guidelines underestimate metabolic risk within the Mexican population. Adopting these newly identified anthropometric and metabolic cutoffs can facilitate early detection, reducing the prevalence and progression of chronic metabolic diseases.

Türkiye, [2]Ruhr University, [3]Department of Gastroenterology, School of Medicine, Recep Tayyip Erdogan University, Rize, Türkiye, [4]Recep Tayyip Erdoğan University

Background: An algorithm incorporating non-invasive methods was proposed to guide the prescription of resmetirom, a newly introduced therapeutic option for metabolic dysfunction-associated steatotic liver disease (MASLD). The widespread use of these non-invasive diagnostic tools may lead to overprescription, potentially imposing an added financial burden on the healthcare system. In this study, we aim to analyze the Turkish NAFLD Biobank, which includes biopsy-confirmed MASLD cases, compare the performance of different diagnostic algorithms, and assess the clinical implications of resmetirom prescribing based on these proposed strategies. **Methods:** After excluding patients with missing FibroScan data, a total of 242 patients from the Turkish NAFLD Biobank database were included in the study. Non-invasive diagnostic criteria were applied using a three-step algorithm. In the first step, patients with a FIB-4 score <1.3 and a NAFLD Fibrosis Score (NFS) <-1.455 were excluded from further evaluation. In the second step, AST levels >17 U/L for female patients and >20 U/L for male patients, along with a controlled attenuation parameter (CAP) value ≥ 280 dB/m, were required. In the third step, patients were considered eligible for treatment if their liver stiffness measurement (LSM) was between 10 and 19.9 kPa or if their FAST score was ≥ 0.67. The patients with signs of cirrhosis or platelet count $\geq 140{,}000/\mu L$ were excluded. Finally, the concordance of this algorithm with histological diagnosis was analyzed. **Results:** A total of 139 patients (57.4%) had a FIB-4 score <1.3, and 103 patients (42.9%) with NFS $<$ -1.455 did not proceed to the next step of the algorithm. Among these, 56 patients (40.3%) and 37 patients (35.9%), respectively, actually met the MASH + F2–F3 fibrosis criteria. When the LSM-based algorithm was applied following the FIB-4 screening, 42 patients (17.4%) met the eligibility criteria. When the FAST algorithm was applied instead, 33 patients (13.6%) qualified. The LSM algorithm correctly identified 28 patients (23.3%) as eligible for treatment, while 14 patients (11.5%) would have been incorrectly prescribed the drug. In the FAST algorithm, these figures were 21 patients (17.5%) correctly identified and 12 patients (9.8%) incorrectly identified. Similar results were observed with the NFS-based algorithm. Both algorithms demonstrated poor concordance with the histological gold standard (Kappa values: 0.119 and 0.077 for FIB-4; 0.080 and 0.080 for NFS). Although the overall concordance slightly improved when FIB-4 or NFS pre-screening was omitted, agreement with histology remained weak (Kappa values: 0.130 for the LSM algorithm and 0.122 for the FAST algorithm). **Conclusion:** These findings suggest that non-invasive diagnostic algorithms may not be sufficiently reliable and prescribing resmetirom based on liver biopsy may represent a more cost-effective approach from a healthcare perspective.

2130 | TO VERIFY THE DIAGNOSTIC EFFICACY OF FAST SCORE FOR HIGH-RISK MASH IN PATIENTS WITH METABOLIC-RELATED FATTY LIVER DISEASE BASED ON LIVER BIOPSY

shicheng Ren[1] WU Xu[2] LI Xue[2] Dou Jing[3] Zhang Rong[3] LIU Ruonan[2] SUBINUR ·Kurban[2] Guo Feng[3] Wang Xiaozhong[3], [1]Affiliated Hospital of Traditional Chinese Medicine, Xinjian, [2]The Fourth Clinical Medical College of Xinjiang Medical University, [3]Traditional Chinese Medical Hospital Affiliated to Xinjiang Medical University

Background: The prevalence of MAFLD is increasing year by year in the world. MASH and liver fibrosis are the intermediate links of disease progression and are closely related to the long-term survival rate of patients. Noninvasive diagnostic methods have great potential in the diagnosis of MASH patients. The FAST score was used to assess the severity of MAFLD. This study will verify the diagnostic efficacy of FAST score for high-risk MASH in MAFLD patients based on liver biopsy, and analyze the clinical characteristics of high-risk MASH, in order to provide a basis for the early diagnosis of high-risk MASH. **Methods:** Patients who underwent liver biopsy and were diagnosed with NAFLD or MAFLD in the Department of Hepatology, the Fourth Clinical Medical College of Xinjiang Medical University from October 2018 to September 2024 were selected. The area under the receiver operating characteristic curve (AUROC) was used to analyze the diagnostic efficacy of FAST score for high-risk MASH in MAFLD patients. **Results:** Compared with the non-high-risk MASH group, the age and the proportion of drinking history in the high-risk MASH group were higher ($P < 0.05$), the levels of PLT, Alb, CHE, TG, TC and LDL-C were lower ($P < 0.05$), and the levels of PT, PT-INR and LSM were higher ($P < 0.05$). The AUROC value of FAST score in the diagnosis of high-risk MASH was 0.708 (95 % CI : 0.610-0.806). The AUROC values of FAST score in the diagnosis of high-risk MASH in patients with mild steatosis and non-obese patients were 0.762 (95 % CI : 0.655-0.868) and 0.731 (95 % CI : 0.609-0.854), respectively. **Conclusion:** FAST score has good diagnostic efficacy for high-risk MASH, and has higher

2131 | AI-ASSISTED DIGITAL PATHOLOGY UNVEILS PATIENT HETEROGENEITY IN THE ANTIFIBROTIC RESPONSE FOLLOWING BARIATRIC SURGERY

Desiree Abdurrachim[1] Clare Yong[2] Sahana Abdul Rahim[1] Raluca Pais[3] Judith Aron-Wisnewsky[3] Frederic Charlotte[3] Serene Lek[4] Dean Tai[4] Elaine Chng[4] Gideon Ho[4] Richard Baumgartner[5] Chih-Liang Chin[6] Leila Kara[3] Saswata Talukdar[6] Asad Abu Bakar Ali[1] Vlad Ratziu[3], [1]Quantitative Biosciences, MSD, Singapore, [2]Chief Technology Office, MSD, Singapore, [3]Sorbonne Université, ICAN institute, Hôpital Pitié-Salpêtrière, Paris, France, [4]HistoIndex Pte. Ltd., Singapore, [5]Biostatistics and Research Decision Sciences, Merck & Co., Inc., Rahway, NJ, USA, [6]Cardiometabolic Diseases, Merck & Co., Inc., South San Francisco, CA, USA

Background: We compared AI-assisted digital pathology (DP) with conventional pathology to assess features and dynamics of fibrosis regression in patients undergoing bariatric surgery for morbid obesity. **Methods:** Unstained paired liver biopsies (pre and >1-year post-bariatric surgery) from 41 patients were staged by NASH-CRN: 17 early (F0-F2), 24 advanced (F3-F4). SHG/TPEF images (Histoindex®) extracted 184 zone-specific fibrosis features and the corresponding qFibrosis stage (qFst) and qFibrosis continuous score (qFcs). K-means clustering evaluated changes in fibrosis features post-bariatric surgery. Fibrosis response (R, defined as >1 stage F or qFst reduction or >2SD qFcs reduction), no change (NC) or progression was noted. **Results:** Fibrosis response was more frequently seen by DP (qFst: 71%, qFcs: 80.5%) than by NASH-CRN (44%) and with a higher sensitivity: 10 NC by NASH-CRN reclassified as R by DP. DP showed a time-dependent fibrosis reduction, 24% R at 3-6 years post-bariatric surgery vs 41.5% at >6 years, not visible by NASH-CRN (22% and 22%, respectively). A clear trend towards less fibrosis reduction in F3-F4 than F0-F2 patients was shown by qFst (58% vs 88%) and qFcs (71% vs 94%), but not by NASH-CRN (41% vs 46%). There was significant heterogeneity in the pattern of intralobular fibrosis changes following bariatric surgery: a strong reduction in portal and periportal fibrosis features and a reduction in chicken-wire fibrosis coexisted with no change or a slight increase in central and pericentral fibrosis parameters. Unsupervised clustering revealed four clusters (C) based on changes in zone-specific fibrosis features (Figure). Baseline characteristics (including fibrosis severity) were similar between clusters, as were changes post-bariatric surgery in BMI or metabolic parameters. However, the proportion of response was different: clusters C1 (N = 7) and C2 (N = 5) had 1 R each, while C3 (N = 18) had 10 R and C4 (N = 11) had 6 R. There was significant individual heterogeneity in the antifibrotic response post-bariatric surgery across clusters with more pronounced changes in C3-C4 than in C1-C2 and a higher rate of fibrosis regression (-0.21 qFst/yr and -0.16 qFcs/yr vs -0.03 to 0.02 qFst/yr and -0.04 to 0.08 qFcs/yr, respectively). **Conclusion:** AI-assisted DP characterizes the extent of antifibrotic effect with higher resolution and sensitivity than traditional pathology. It also unveils significant heterogeneity in the antifibrotic response at the tissue and the individual level. These findings should help better understand the potency of antifibrotic interventions and individual response.

2132 | COMPARING NON-INVASIVE FIBROSIS SCORES TO TRANSIENT ELASTOGRAPHY MEASUREMENTS ACROSS THE SPECTRUM OF STEATOTIC LIVER DISEASE: A US NHANES 2017–2020 STUDY

Alex Chang[1] Joao Filipe Monteiro[1] Neha Wadhavkar[1] Adam Burton[1] Kittichai Promrat[1], [1]Brown University School of Medicine

Background: Non-invasive fibrosis scores (NIFS) and transient elastography (TE) are important tools for screening patients for steatotic liver disease. While validated in patients with metabolic-associated steatotic liver disease, neither tool has been well-studied in patients with metabolic risk factors and concurrent alcohol consumption. The current study compares how well NIFS agree with TE measurements across the spectrum of steatotic liver disease in a national dataset. **Methods:** The NHANES 2017–2020 dataset, comprising 9,693 adult participants, was utilized for the current study. Clinically significant fibrosis (CSF) is defined as a liver-stiffness measurement (LSM) $\geq$ 8 kPa, and advanced fibrosis (AF) as LSM $\geq$ 12 kPa. Non-invasive fibrosis scores assessed in the study includes the APRI, BARD, FIB-4, and NAFLD fibrosis score (NFS). A total of 7,100 participants without a complete TE examination, with past history of viral or autoimmune hepatitis, or without evidence of steatosis on TE (CAP $<$ 285) were excluded. The final analytic sample consisted of 2,593 patients with steatotic liver disease (SLD)–MASLD, MetALD, or ALD. The determination of MASLD, MetALD, or ALD was based on weekly alcohol consumption cutoffs in accordance to the AASLD guidelines. The concordance of each NIF to TE was evaluated using receiver operating characteristic (ROC) curves, including calculations of the area under curve. All analyses were conducted using SAS version 9.4. **Results:** Using the 2017-2020 NHANES cohort, 2,431 participants met MASLD criteria, 104 met MetALD criteria and 58 met ALD criteria. CSF was detected in 19.1% of MASLD, 17.3% of MetALD and 19.0 % of ALD, while AF affected 6.7%, 5.8% and 6.9%, respectively. MASLD subjects were older (52.0 $\pm$ 16.6 years) with higher BMI (BMI 34.5 $\pm$ 7.5 kg/m^2) than those with MetALD (32.9 $\pm$ 7.7 kg/m^2) or ALD (32.0 $\pm$ 6.1 kg/m^2). Diabetes (53%) and hypertension (43%) were common in MASLD, whereas ALD participants were predominantly younger males (89%) with lower metabolic burden. NIFs were not significantly different at predicting clinically significant fibrosis (range of AUC from 0.549 - 0.742) on TE across the entire spectrum of SLD and were, in fact, better at predicting advanced fibrosis (range of AUC 0.836 - 0.945) on TE in patients with ALD compared to MetALD or MASLD (Figure 1). NFS was significantly better at predicting CSF and AF on TE than the BARD score for MASLD and MetALD patients, but not in ALD patients. **Conclusion:** While NIFS and TE have only been validated for patients with MASLD, the current study shows that concordance of NIFS and TE does not change significantly across the spectrum of SLD, incldiuing MetALD and ALD. NFS has closer concordance to TE measurements than the BARD score in SLD patients with cardiometabolic risk factors. Future studies should look to compare NIFS and TE measurements to liver biopsy results to validate NIFS and TE in the MetALD and ALD populations.

2133 | LIMITATIONS OF FIB-4 SCREENING FOR MASLD IN PATIENTS WITH OBESITY

Sanjna Shelukar[1] Ananya Venkatesh[1] Breanne McDermott[1] Julietta Gervase[1] Maria Winte[1] Rebecca Loh[1] Dina Halegoua-De Marzio[1], [1]Thomas Jefferson University Hospital

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver disease. Comorbidities such as obesity, hypertension, hyperlipidemia, and diabetes place patients at higher risk for developing MASLD. Early diagnosis is critical to prevent progression to advanced fibrosis. While the Fibrosis-4 (FIB-4) index is commonly used to assess fibrosis risk, there is currently no validated screening tool for MASLD, potentially contributing to underdiagnosis. We aimed to assess the prevalence of incidentally identified MASLD in patients with obesity who underwent abdominal imaging for non-screening purposes and would not have received further evaluation for MASLD otherwise. **Methods:** We conducted a retrospective chart review of patients with obesity at an urban resident-run primary care clinic. FIB-4 scores were calculated using available laboratory data, and patients were stratified into risk categories: low (< 1.30), indeterminate (1.30-2.67), and high (> 2.67). Abdominal imaging, when available for non-screening purposes (abdominal pain, kidney stones, trauma, etc.), was reviewed for findings consistent with MASLD. Relevant terminology included hepatic steatosis, hepatomegaly, fatty infiltration, increased echogenicity, and nodularity. **Results:** 172 patients with obesity were identified. All patients had BMI > 36 (range 36.4-70.3) and several had other risk factors for MASLD including hypertension (69%), hyperlipidemia (67%), and diabetes (46%). There were 108 females (63%), median age was 53 years (range 36-65), and racial composition was 45% Caucasian, 40% African American, and 9% Hispanic individuals. Of the 172 patients, 59 underwent abdominal imaging for non-screening purposes. Of these 59 patients, 24 (41%) had incidental MASLD. Notably within the low-risk FIB-4 subgroup (N = 144), 52 patients had imaging done for non-screening purposes. Of these 52 patients, 23 (44%) had incidental MASLD and one patient had nodularity suggesting advanced fibrosis (Figure 1). **Conclusion:** Nearly half of patients with obesity had incidental MASLD on abdominal imaging performed for non-screening purposes, including nearly half of those classified as low-risk by FIB-4. Current AASLD guidelines recommend periodic laboratory testing in low-risk patients, rather than further workup with elastography or specialized serum testing, which can delay diagnosis in patients with obesity. These findings highlight a critical limitation of the FIB-4 as a screening tool and suggest that obesity and other metabolic risk factors be more directly integrated into MASLD screening strategies.

2134 | ATHEROSCLEROTIC CARDIOVASCULAR DISEASE RISK USING THE TWO-STEP ALGORITHMS FROM THE KASL/EASL AND AGA GUIDELINES IN INDIVIDUALS WITH MASLD

Jungpyo Hong[1] Jaehong Jeong[1] Jae Seung Lee[1] Mi Na Kim[1] Beom Kyung Kim[1] Do Young Kim[1] Sang Hoon Ahn[1] Hye Won Lee[1] Seung Up Kim[1], [1]Yonsei University College of Medicine

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is linked to cardiovascular disease (CVD) risk factors, and liver fibrosis severity importantly correlates with atherosclerotic cardiovascular disease (ASCVD) risk. Recent KASL/EASL and AGA guidelines introduced two-step algorithms using non-invasive tests (NITs) to help identify high-risk MASLD patients. This retrospective cohort study aimed to assess whether these algorithms can effectively evaluate ASCVD risk in individuals with MASLD. **Methods:** A total of 12,738 subjects undergoing health check-ups (2012-2020), including FIB-4 and vibration-controlled transient elastography (VCTE), were screened. Following 6,219 exclusions, 6,519 study subjects (mean age 50.3 years; 41.7% female) were ultimately selected[홍1]. ASCVD risk was then determined using the 2025 ACC/AHA Pooled Cohort Equations (PCE); High-risk ASCVD was specifically defined as a 10-year risk $\geq$20%. ANOVA and Chi-square tests were used for statistical analysis ($P < 0.05$). **Results:** High-risk ASCVD was identified in 375 subjects (5.8%) and was significantly associated with older age, a higher comorbidity prevalence, and elevated FIB-4 levels (all $P < 0.001$). Applying the KASL/EASL guidelines, mean ASCVD scores increased from 5.1% in low-risk individuals to 18.8% in high-risk individuals. The proportion of subjects with high ASCVD risk correspondingly rose from 4.7% (low-risk) to 38.6% (high-risk) (P trend < 0.001). Similarly, the AGA guidelines also showed an increase in mean ASCVD scores from 1.5% (very low-risk) to 8.2% (intermediate/high-risk). The proportion with high ASCVD risk also increased from 0.3% (very low-risk) to 9.1% (intermediate/high-risk) (P trend < 0.001). **Conclusion:** These findings indicate that the KASL/EASL and AGA proposed two-step algorithms can effectively assess ASCVD risk in MASLD subjects.

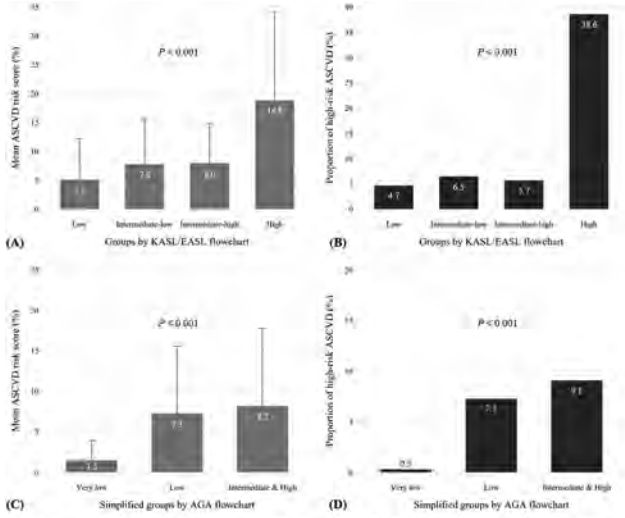

Figure 1. Comparison of ASCVD risk by groups stratified using KASL/EASL and AGA flowcharts. (A) Mean ASCVD risk scores in KASL/EASL flowchart-stratified groups. (B) Proportion of high-risk ASCVD (≥ 20%) in KASL/EASL flowchart-stratified groups. (C) Mean ASCVD risk scores in AGA flowchart-stratified groups. (D) Proportion of high-risk ASCVD (≥ 20%) in AGA flowchart-stratified groups. 2135 | ELEVATED M2BPGI AS A NON-INVASIVE MARKER FOR BRAIN WHITE MATTER CHANGES IN OLDER ADULTS WITH MASLD: A CROSS-SECTIONAL STUDY

Katsuya Nagaoka[1] Maiko Nagaoka[2] Naoto Kajitani[3] Yoko Yoshimaru[1] Takehisa Watanabe[1] Hiroko Setoyama[1] Hirofumi Soejima[2] Noboru Fujise[4] Minoru Takebayashi[3] Yasuhito Tanaka[1], [1]Faculty of Life Sciences, Kumamoto University, [2]Kumamoto University, [3]Center for Metabolic Regulation of Healthy Aging, Faculty of Life Sciences, Kumamoto University, [4]Kumamoto University Hospital

Background: Mac-2 binding protein glycan isomer (M2BPGi), a non-invasive serum biomarker for liver fibrosis identified in 2013 (Kuno et al., Sci Rep 2013), is increasingly linked to systemic conditions including cardiovascular risk and silent atherosclerosis. We investigated the association between M2BPGi and cerebral white matter hypo-intensity (WMH), an

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

indicator of ischemic changes using brain MRI in community-dwelling older adults, examining the modifying effects of MASLD status. **Methods:** This cross-sectional study included participants from a prospective population-based cohort in Arao City, Japan. Out of 1,448 residents aged 65 years or older who underwent a health survey between 2016 and 2017, we analyzed 607 participants after excluding those with histories of stroke, myocardial infarction, heart failure, cancer, head trauma, or current smoking to minimize confounders. Key measurements included serum M2BPGi, HbA1c, and diagnosis of steatotic liver disease (SLD), defined by a Fatty Liver Index $\geq$ 30, with MASLD confirmed according to recent criteria. Cerebral white matter hypointensities were quantified from T1-weighted brain MRI scans using FreeSurfer 5.3 software. Statistical analyses included chi-squared tests and linear regression, adjusted for age, sex, hypertension, and hyperlipidemia. **Results:** Among the 607 participants, 253 subjects (41.7%) met the criteria for MASLD. When the MASLD group was divided into two groups based on M2BPGi values of 0.9 or higher (n = 157, 48.5%) and less than 0.9 (n = 96, 36.4%), a chi-squared analysis demonstrated that MASLD participants were significantly more likely to have elevated M2BPGi levels (M2BPGi $\geq$ 0.9: 157 [48.5%] vs. M2BPGi $<$ 0.9: 96 [36.4%]; p = 0.03). Furthermore, within the MASLD group, higher M2BPGi levels (specifically M2BPGi $\geq$ 0.9) were significantly associated with an increase in WMH volumes (β = 1927.64, p = 0.017), even after adjusting for age, sex, hypertension, and hyperlipidemia. **Conclusion:** These findings suggest M2BPGi ($\geq$0.9) may be a useful non-invasive marker for early detection of silent brain ischemic disease in individuals with MASLD.

2136 | PERFORMANCE OF ATTENUATION IMAGING (ATI) COMPARED TO CONTROLLED ATTENUATION PARAMETER (CAP) FOR NON-INVASIVE ASSESSMENT OF HEPATIC STEATOSIS IN A COHORT OF MIXED CHRONIC LIVER DISEASES

Thales Saad[1] Joao Marcello de Araujo-Neto[2] Flavia Fernandes[3] Cristiane Villela-Nogueira[2] Priscila Pollo-Flores[4] Priscila Barreiro[5] Vania Cristina Nunes[5],

[1]Centro da Imagem Diagnósticos, [2]Federal University of Rio de Janeiro, [3]Hospital Federal de Bonsucesso, [4]Fluminense Federal University, [5]Clínica Diagnósticos Avançados

Background: While the Controlled Attenuation Parameter (CAP, FibroScan®) is widely validated, new ultrasound-based technologies such as Attenuation Imaging (ATI, Canon) have emerged as potential alternatives. This study aimed to assess the diagnostic performance of ATI in comparison with CAP for the detection and grading of hepatic steatosis. **Methods:** This prospective, cross-sectional study was conducted in a private diagnostic clinic specialized in liver diseases. Adult patients underwent CAP and ATI evaluations, performed on the same day by blinded operators. CAP values were classified according to Karlas et al. (2014): S0 ($<$234 dB/m), S1 (234–269), S2 (270–301), S3 ($>$301). ATI performance was assessed using ROC curve analysis with CAP as the reference standard for detecting any steatosis (S $\geq$ 1), moderate (S $\geq$ 2), and severe steatosis (S $\geq$ 3). Optimal ATI cutoff values were determined by maximizing Youden's index. **Results:** A total of 375 adult patients were included, with a mean age of 53.6 years ($\pm$13.3); 55.7% were female; median BMI was 30.1 kg/m² ($\pm$9.5). MASLD was the most frequent etiology (67.2%), followed by chronic hepatitis C (15.7%), hepatitis B (6.9%), and other causes (10.2%). The mean CAP was 272.9 $\pm$ 67.1 dB/m, and ATI was 0.69 $\pm$ 0.14 dB/cm/MHz. The prevalence of steatosis using CAP as reference was 68.8%. ATI values demonstrated a strong correlation with CAP (ρ = 0.750, p $<$ 0.001). – For S $\geq$ 1, ATI cutoff of 0.63 dB/cm/MHz showed AUROC 0.88, sensitivity 82.6%, specificity 81.2%. – For S $\geq$ 2, ATI cutoff of 0.69 dB/cm/MHz showed AUROC 0.91, sensitivity 82.4%, specificity 88.1%. – For S $\geq$ 3, ATI cutoff of 0.70 dB/cm/MHz showed AUROC 0.89, sensitivity 86.4%, specificity 78.6%. In the MASLD subgroup (n = 252), diagnostic performance remained high: – For S $\geq$ 1, AUROC was 0.84 with cutoff 0.68, sensitivity 73.9%, specificity 85.3%. – For S $\geq$ 2, AUROC was 0.89 with cutoff 0.69, sensitivity 83.1%, specificity 82.5%. – For S $\geq$ 3, AUROC was 0.83 with cutoff 0.74, sensitivity 77.9%, specificity 76.8%. **Conclusion:** In this double-blinded cross-sectional study with a large cohort of patients, ATI demonstrated strong correlation and excellent diagnostic performance for detecting hepatic steatosis, particularly among patients with MASLD. These findings support ATI as a reliable non-invasive tool in hepatology practice and highlight its applicability in routine liver assessment, especially in settings where CAP is unavailable or limited. The method's strong performance in the MASLD subgroup reinforces its relevance amid the growing burden of metabolic liver disease.

2137 | LIVER SHEAR WAVE DISPERSION SLOPE MEASUREMENT IS HIGHER IN PATIENTS WITH SIGNIFICANT AND ADVANCED FIBROSIS DUE TO MASLD

Joao Marcello de Araujo-Neto[1] Thales Saad[2] Priscila Pollo Flores[3] Priscila Calvet Nelson-Smith Barreiro[4] Vania Cristina de Santana Roch Nunes[4] Flávia Ferreira Fernandes[4] Claudia Oliveira[5], [1]Federal University of Rio de Janeiro, [2]Centro da Imagem Diagnósticos, [3]Fluminense Federal University, [4]Clínica Diagnósticos Avançados, [5]University of Sao Paulo School of Medicine

Background: Shear-wave dispersion slope (SWDS), a parameter derived from two-dimensional shear-wave elastography, has been proposed as a non-invasive biomarker for hepatic inflammation and fibrosis. Previous studies have examined its diagnostic utility across various liver diseases, including Metabolic dysfunction-associated steatotic liver disease (MASLD). However, data from large-scale cohorts remain limited. **Methods:** A prospective, cross-sectional, multicentric study was conducted between October 2023 to May 2025 at a tertiary university hospital and a private hepatology clinic. Consecutive adult patients with suspected MASLD were assessed using transient elastography (TE), controlled attenuation parameter (CAP), conventional B-mode ultrasound, and SWDS (Canon Aplio i800). Steatosis severity was graded based on CAP as S0: < 234db/m, S1: 234 - 267 dB/m, S2: 268 - 304 dB/m, S3: > 304 dB/m. The characteristics of steatosis on B mode ultrasound were categorized according to the US-FLI score. **Results:** A total of 864 patients were included (mean age 55.6 ± 13.9 years; 52.3% female). Steatosis distribution according to CAP was: S0 – 3.9%, S1 – 14.9%, S2 – 15.4%, and S3 – 25.2%. The median liver stiffness (TE) was 5.2 kPa (range: 2–39 kPa) and 14.8% of patients exhibited liver stiffness >7 kPa, 6.5% >10 kPa, and 2.9% >15 kPa. The median SWDS was 11.2 m/s/kHz (range: 4.8–23.8). Patients with liver stiffness >7 kPa demonstrated significantly higher SWDS values compared to those with lower stiffness (13.3 *vs*. 11.3 m/s/kHz; $p < 0.001$). This association remained consistent across higher TE thresholds >10kPa (14.5 *vs* 11.3; p< 0,001) and > 15 kPa (15.5 *vs* 11.4; p< 0,001). No clinically meaningful correlation was observed between SWDS and steatosis severity assessed by CAP (11.8 vs. 11.4 vs 11.5 vs 11,5 m/s/kHz for S0, S1, S2, S3 respectively, p = 0,148). Similarly, no significant association was identified between SWDS and steatosis quantified by the US-FLI score (threshold: ≥4 points) (11.6 vs. 11.5 m/s/kHz; $p = 0.59$). **Conclusion:** In this large prospective cohort of patients with MASLD, SWDS was not associated with the degree of hepatic steatosis as assessed by either CAP or B-mode ultrasound. In contrast, SWDS demonstrated a robust and consistent association with liver fibrosis across various TE-defined thresholds. Given that hepatic inflammation is a key upstream event in fibrogenesis, these findings support further investigation into the utility of SWDS as a marker of liver inflammation in MASLD using alternative study designs.

2138 | BEYOND METABOLIC SYNDROME: ELEVATED FERRITIN PREDICTS HIGHER LIVER STIFFNESS IN ADULTS

Sheena Bhushan[1] Kris Kowdley[1], [1]Liver Institute Northwest

Background: Elevated Serum Ferritin (SF) is frequently observed in individuals with metabolic liver disease. However, the independent relationship between SF and liver stiffness measurement (LSM)- beyond the effects of metabolic syndrome and demographic factors- is unclear. The aim of this study is to evaluate whether an elevated SF level is independently

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

associated with increased liver stiffness measurement (LSM), after adjusting for relevant demographic and metabolic covariates. **Methods:** Data were analyzed from 2,473 participants in the 2017-2020 cycles of the National Health and Nutrition Examination Survey (NHANES) who underwent transient elastography (VCTE). Elevated SF was defined as levels >450 ng/mL in men and >300 ng/mL in women. Covariates included diabetes status, age, a proxy for menopausal status (women 50), and number of metabolic syndrome features. A robust linear regression model was used to estimate the independent association between elevated SF and LSM after adjusting for the aforementioned covariates. **Results:** An elevated SF level was independently associated with increased LSM ($\beta = 0.53$, 95% CI:0.28-0.78, $p < 0.001$). Other significant predictors included diabetes mellitus. ($\beta = 0.68$, $p < 0.001$), metabolic syndrome burden ($\beta = 0.24$ per feature, $p < 0.001$), and menopausal status ($\beta = -0.46$, $p < 0.001$). Interestingly, age was associated with a slightly LSM ($\beta = -0.009$ per year, $p < 0.001$). **Conclusion:** Elevated SF is independently associated with increased liver stiffness, even after controlling for key metabolic and demographic confounders. These findings support the role of SF as a clinically useful biomarker in non-invasive assessment and risk stratification of hepatic fibrosis, particularly in populations with metabolic risk.

2139 | QUANTIFYING VISCERAL FAT ON MAGNETIC RESONANCE ELASTOGRAPHY (MRE)- A COMPARATIVE STUDY BETWEEN EARLY AND ADVANCED STAGES OF METABOLIC DYSFUNCTION-RELATED STEATOTIC LIVER DISEASE WITH HEALTHY CONTROLS

Ameet Mandot[1] Sachi Banker[2] Kevin Shah[1] Nafe Chinde[1] Ajay Bang[1] Samriddhi Poyekar[1] Chetan Kalal[1] Sitaram Sabane[1], [1]Gleneagles Hospital, Mumbai, [2]Gleneagles hospitals, Mumbai

Background: Obesity, especially visceral adiposity, is a significant risk factor for Metabolic Dysfunction-Related Steatotic Liver Disease (MASLD) and contributes to the progression of liver disease. MR Elastography (MRE) is the best non-invasive modality to diagnose various stages of MASLD, and can also be used to quantify visceral fat. Our aims were to correlate the amount of visceral fat on MRE in patients at various stages of MASLD with the severity of the disease and to compare the amount of visceral fat in normal subjects and those with MASLD. **Methods:** This retrospective observational study in a tertiary care hospital in Mumbai, India included 133 subjects: 48 patients with MASLD-related early and intermediate stages of fibrosis (F0-F3) -group 1, 43 patients with MASLD-related compensated cirrhosis -group 2 and 42 healthy liver donors as controls -group 3. Demographic, clinical and laboratory data were collected. The fat fraction and the Liver Stiffness Measurement (LSM) on MRE were noted. Visceral abdominal tissue (VAT) cross-sectional area was quantified at L3 vertebral level on MRE using semi-automated software. Statistical analyses included Welch's one-way ANOVA test, Tukey's post-hoc tests, and Pearson correlation. **Results:** Patients with group 1 and group 2 were notably older than healthy controls (group 3), had a higher BMI (group 1: 28.81kg/m^2, group 2: 27.44kg/m^2, group 3: 22.8kg/m^2) and a larger proportion of males. Diabetes, hypertension, and dyslipidemia were more prevalent in the MASLD groups. Mean LSM was 2.29 kPa in group 3, 2.9 kPa in group 1, and 7.44 kPa in group 2 patients. Fat fraction was found to be highest in the group 1 (11.77%). Mean VAT levels were significantly elevated in MASLD groups (group 1: 165.02m^3, group 2:155.28m^3) compared to healthy controls (group 3: 31.23m^3), although no significant difference existed between the two MASLD subgroups. VAT levels positively correlated with LSM, fat fraction, and HbA1C, and inversely with HDL levels. **Conclusion:** Our study provides compelling evidence of increased visceral fat in MASLD, irrespective of fibrosis stage. Our study did not find any significant difference in the amount of visceral fat in the various stages of MASLD. The consistently high VAT levels across all MASLD stages highlight visceral adiposity as a critical therapeutic target, underscoring the importance of lifestyle interventions to prevent, modulate, and mitigate cardiometabolic risks associated with MASLD.

2140 | AI-POWERED PATHOLOGY REVEALS SURGERY-INDUCED CHANGES IN THE CELLULAR COMPOSITION OF THE LIVER IN PATIENTS WITH MASLD

Alina Iuliana Onoiu[1] Lara Murray[2] Ylaine Gerardin[2] Geetika Singh[2] Robert Egger[2] David Parada[3] Jorge Joven[4], [1]Unitat de Recerca Biomèdica, Universitat Rovira i Virgili, Reus, Spain, [2]PathAI Inc., Boston, MA, US, [3]Departament d'Anatomía Patològica, Hospital Universitari Sant Joan de Reus, Reus, Spain, [4]Unitat de recerca biomèdica, Hospital Universitari Sant Joan de Reus, Reus, Spain

Background: Severe obesity increases the risk of metabolic dysfunction-associated steatotic liver disease (MASLD), fibrosis, and related complications. Lifestyle changes, medications (e.g., Semaglutide), and bariatric surgery may lead to substantial weight loss. However, an opportunity remains to better understand the effects of these interventions on liver histology. In this study, we assessed changes in liver histology that occur with laparoscopic sleeve gastrectomy (LSG) in patients with severe obesity using Liver Explore[1], an AI-powered tool for the characterization of liver microarchitecture. **Methods:** Patients with severe obesity were enrolled in a cross-sectional observational study for LSG intervention (NCT0554224). Liver wedge biopsies were obtained prior to LSG, and a second biopsy was obtained from a subset of patients with MASLD (N = 44) after an average of 5 years. Biopsies were stained with hematoxylin and eosin, digitized (Ventana DP200, 40X), and analyzed using Liver Explore. Liver Explore-derived cell features from pre- and post-LSG were compared using non-parametric statistical analysis, specifically the Wilcoxon signed-rank test. Immunohistochemistry (IHC) was performed on serial biopsy sections using a Ventana BenchMark ULTRA autostainer (Roche, Indianapolis, IN, USA) and anti-CD15 monoclonal antibody (Roche, Indianapolis, IN, USA), and CD15 positivity was quantified using QuPath. **Results:** In the subset of patients assessed here, BMI was reduced from 52.4 to 40.6 kg/m^2 after LSG. Significant changes in liver composition were observed following LSG intervention (Fig. 1). The proportion of normal hepatocytes increased, while the proportions of steatotic and ballooned hepatocytes decreased. In addition, the proportion of immune cells increased, driven by an increase in neutrophils. This neutrophil increase was further validated by CD15+ IHC on neighboring sections. **Conclusion:** AI-based digital pathology allows objective, reproducible, and quantitative examination of histology and here provides precise evaluation of the effects of LSG on liver histology. These findings reveal that LSG may improve MASLD features, such as steatosis and ballooning, but may exacerbate inflammation, driven by a rise in neutrophil density. These findings underscore LSG's role in managing MASLD while highlighting the need to monitor inflammatory changes.

2141 | POLYMORPHISM RS7903146 OF TCF7L2 GENE IS ASSOCIATED WITH TYPE 2 DIABETES AND CARDIOVASCULAR RISK BIOMARKER IN PATIENTS WITH METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Brian Lam[1] James Estep[2] Mustafa Kanat[3] Mehmet Agirbasli[4] Maria Stepanova[5] Zobair Younossi[6], [1]INOVA Fairfax Hospital, [2]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, [3]Diabetes Research Center (DIMER), Istanbul Medeniyet University, Istanbul, Turkey, [4]Department of Cardiology, Medeniyet University School of Medicine, Istanbul, Turkey, [5]Center for Outcomes Research in Liver Disease, [6]The Global NASH Council

Background: Components of metabolic syndrome (MS) have been linked to genetic risk factors. Our aim was to assess the impact of 2 polymorphisms in the *TCF7L2* gene on the clinical profile of patients with MASLD. **Methods:** Clinico-laboratory data were collected from consented MASLD patients. Genomic DNA was extracted from the whole blood and used for determination of minor allele frequency for genomic loci rs7903146 and rs12255372 in the *TCF7L2* gene. Individual alleles were evaluated for association with components of MS, liver disease severity [FIB-4 score, Enhanced Liver Fibrosis (ELF) score], coronary artery

disease (by history or coronary angiography), metabolic biomarkers (fasting c-peptide and insulin), and cardiac biomarkers [high-sensitivity CRP (hsCRP), N-terminal pro-brain natriuretic peptide (NT-proBNP), high-sensitivity cardiac troponin I (hs-cTnI)]. Associations of clinical and laboratory variables with minor alleles of *TCF7L2* gene were carried out using univariate and multivariate analysis. **Results:** We included 254 MASLD patients with at least one polymorphism available: mean ± SD age 61 ± 9 years, 84% male, BMI 30.9 ± 5.3, 33% type 2 diabetes (T2D), 61% with insulin ≥ 20 μIU/mL (insulin resistance), 72% with c-peptide < 1.0 ng/mL (impaired beta cell function). Of these patients, the distributions of alleles for 2 studied polymorphisms were as follows: rs7903146 – 43% CC, 54% CT, 3% TT; rs12255372 – 13% GG, 76% GT, 11% TT. Patients with CT/TT at rs7903146 had higher prevalence of T2D (40% vs. 24%, p = 0.018) and higher levels of hs-cTnI (median (IQR) = 6.5 (4.3-14.4) pg/ml vs. 4.6 (3.3-8.8) pg/ml, p = 0.030) in comparison to CC. Although there were no differences in clinical or laboratory parameters of MASLD by rs12255372 allele (all p > 0.05), hs-cTnI level trended to be higher in GT/TT vs. GG groups (median (IQR) = 6.3 (4.3-11.5) pg/ml vs. 4.0 (3.3-11.9) pg/ml, p = 0.086). In multivariate analysis, having C- > T minor allele in the rs7903146 locus was independently associated with an increased risk of T2D in MASLD: OR (95% CI) = 2.3 (1.2-4.6), p = 0.018. Other independent predictors of T2D included older age (OR = 1.059 (1.015-1.104) per year, p = 0.007) and higher BMI (OR = 1.138 (1.062-1.220) per kg/m2, p = 0.0003). **Conclusion:** In patients with MASLD, polymorphism rs7903146 in the *TCF7L2* gene is not only independently associated with T2D but also with higher troponin levels suggesting a potentially increased risk of cardiovascular disease in those patients.

2142 | EVALUATION OF MULTISENSORIAL ELECTRONIC TECHNOLOGIES AS NONINVASIVE TOOLS FOR THE DETECTION OF FIBROTIC-MASH IN MASLD PATIENTS

Francesca Terracciani[1] Alessandro Zompanti[2] Simone Grasso[2] Antonio De Vincentis[3] Aldo Marrone[4] Paolo Gallo[1] Andrea Falcomatà[1] Valentina Flagiello[1] Maria Rocco[5] Riccardo Fuso[1] Alfredo Caturano[6] Ferdinando Carlo Sasso[6] Antonio Picardi[1] Marco Santonico[2] Giorgio Pennazza[2] Raffaele Antonelli Incalzi[7] Umberto Vespasiani-Gentilucci[1], [1]Research Unit of Hepatology, Università Campus Bio-medico di Roma, Italy, [2]Research Unit of Electronics for Sensor Systems, Università Campus Bio-Medico di Roma, Rome, Italy, [3]Unit of Internal Medicine, Università Campus Bio-medico di Roma, Italy, [4]Università della Campania, [5]4University of Campania Luigi Vanvitelli, Naples, Italy, [6]University of Campania Luigi Vanvitelli, Naples, Italy, [7]Research Unit of Internal Medicine, Università Campus Bio-medico di Roma, Italy

Background: Fibrotic-MASH, the progressive inflammatory phenotype of MASLD defined by significant necroinflammatory activity (NAS ≥ 4) and fibrosis (≥ stage 2), is the most clinically relevant and treatment-eligible form of the disease. Accordingly, noninvasive detection methods are a key focus of current research. In recent years, multisensory technologies such as the electronic nose (e-nose) and electronic tongue (e-tongue) have emerged as promising diagnostic and prognostic tools across various conditions, including liver diseases. This study aims to evaluate their performance as novel noninvasive tools for identifying fibrotic-MASH. **Methods:** Consecutive MASLD patients were prospectively enrolled at the Hepatology Unit of "Fondazione Policlinico Universitario Campus Bio-Medico" of Rome. MASLD was diagnosed by the presence of cardiometabolic criteria and either histological or ultrasonographic steatosis. Fibrotic-MASH was defined by Fibroscan-AST (FAST) score ≥ 0.67 or, histologically, by NAS ≥ 4 and fibrosis ≥ 2. All patients underwent breath collection for analysis via BIONOTE e-nose, and urine and saliva sampling for BIONOTE e-tongue analysis. Diagnostic performance for fibrotic-MASH was assessed using Partial Least Squares Discriminant Analysis (PLS-DA) and described by confusion matrices. **Results:** A total of 121 MASLD patients were enrolled (median age 57.4 years, 60% male, mean BMI 31.9 kg/m²), of which 75 in the non-invasive cohort and 46 in the histological cohort. Overall, FAST score was available in 107 cases. Fibrotic-MASH was identified in 15/107 patients by FAST and in 24/46 by histology. Suitable breath, urine, and saliva samples were obtained from 102, 118, and 116 patients, respectively. The accuracies of e-nose (breath) and e-tongue (saliva and urine) in predicting fibrotic-MASH according to FAST score were 77%, 80%, and 82%, respectively. In the histological cohort, e-tongue saliva showed the highest accuracy (79%), followed by e-nose (74%) and e-tongue urine (65%) in predicting fibrotic-MASH, while combining all three sample types resulted in a predictive performance of 79%. Overall, e-technologies outperformed FAST (68% accuracy) in predicting histologically confirmed fibrotic-MASH. **Conclusion:** E-technologies exhibit good

accuracy in identifying fibrotic-MASH, outperforming FAST, one of the widely used noninvasive score. These findings highlight the potential of these tools for clinical risk stratification in MASLD/MASH, though confirmation in larger, prospective cohorts remains necessary.

2143 | MULTIPLE QUANTITATIVE ULTRASOUND PARAMETERS FOR THE EVALUATION OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS: A PROSPECTIVE STUDY

Yi Dong[1] Yunlin Huang[1] Ying Wang[1] Juan Cheng[1] Li Wei[1] Rui Cheng[1], [1]Department of Ultrasound, Xinhua Hospital Affiliated to Shanghai Jiao Tong University School of Medi

Background: Metabolic dysfunction–associated steatohepatitis (MASH), a subtype of metabolic dysfunction-associated steatotic liver disease (MASLD), is characterized by inflammation and hepatocyte injury, leading to liver fibrosis and ultimately, cirrhosis. Early detection and treatment of individuals with hepatic steatosis may potentially prevent cirrhosis-related outcomes. This study aims to develop optimized models integrating multiple ultrasound parameters to evaluate at-risk MASH in liver biopsy-proven MASLD patients. **Methods:** In this prospective study, patients scheduled for liver biopsy due to clinical suspicion of MASH were enrolled. All abdominal ultrasound examinations were performed using the Resona A20 ultrasound system (Mindray, China) with a SC7-1U probe (1.0 – 7.0 MHz). After producing an M-Ref map, the multiple ultrasound parameters were measured, including the attenuation coefficient obtained with UltraSound ATtenuation Imaging Technology (USAT) (in dB/cm/MHz), shear wave speed (SWS) (in m/s), and viscosity (in Pa·s). The at-risk MASH was defined as MASH with F2-F3 fibrosis. Receiver operating characteristic curves (AUCs) were performed to assess the diagnostic performance of multiple ultrasound parameters. **Results:** From November 2023 to January 2025, 52 patients (median age of 46 years) were included. The risk score model from multiple ultrasound parameters was developed using USAT, viscosity values, and SWV, which were associated with the degree of hepatic steatosis, lobular inflammatory activity, and fibrosis (all $P < 0.05$). For the USAT, the risk score was assigned using the cutoff values of USAT for detecting hepatic steatosis as follows: score 1, USAT value between 0.55 and 0.58 dB/cm/MHz (S1); score 2, USAT value between 0.58 and 0.75 dB/cm/MHz (S2); and score 3, USAT value greater than 0.75 dB/cm/MHz (S3). The risk score of viscosity was assigned using the cutoff values of viscosity as follows: score 1, viscosity value between 2.00 and 2.05 Pa·s (A2); score 2, viscosity value between 2.05 and 2.11 Pa·s (A3); and score 3, viscosity value greater than 2.11 Pa·s (A4). The risk score of SWV was assigned using the cutoff values of SWV as follows: score 1, SWV value between 1.77 and 2.01 m/s (F2), and score 2, SWV value greater than 2.01 m/s (F3). The final at-risk score was defined as the unweighted sum of each score from USAT, viscosity, and SWV values, ranging from 0 to 8. The diagnostic performance of the risk score model for detecting at-risk MASH was higher than that of ultrasound parameters alone (AUC = 0.70 vs. AUC = 0.53 – 0.66). **Conclusion:** The risk score model integrating multiple ultrasound parameters (attenuation coefficient, viscosity, and SWV) improved noninvasive diagnostic performance for detecting at-risk MASH in patients with MASLD.

2144 | IMPACT OF PNPLA3 RS738409 VARIANT ON IL-6-MEDIATED INFLAMMATION IN AFRICAN AMERICANS WITH MASLD

Morinne Osborne[1] Tanmoy Mondal[2] Coleman Smith[3] Christopher Loffredo[4] Ruth Quartey[2] Charles Howell[5] Brent Korba[4] Zaki Sherif[2] Gail Nunlee-Bland[2] Leanna Rucker[4] Gemeyel Moses[2] Somiranjan Ghosh[2], [1]Howard University College of Medicine, [2]Howard University, [3]Georgetown University Hospital, [4]Georgetown University, [5]Howard University Hospital

Background: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) is a global health problem and is one of the primary causes of liver disease. An earlier study conducted at Howard University revealed

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

that African Americans (AA) are moderately protected from MASLD due to a Single Nucleotide polymorphism (SNP) at position rs738409 on *PNPLA3* converting an amino acid from isoleucine to methionine. This conversion causes Interleukin 6 (*IL-6*) to be upregulated and overexpressed, causing an acute and chronic inflammatory response in the liver and in turn can cause hepatic steatosis. Due to allele frequencies in PNPLA3, other ethnic groups have a higher chance of developing fatty liver disease compared to AA. Within the gene, there are three possible alleles that the general population could have that affects inflammation activity (C/C, C/G, G/G). In this pilot study, we compared each of the three alleles to determine the upstream and downstream effects that the SNP has on IL-6. **Methods:** AA MASLD patients ($n = 11$; mean age 45 ± 8.15 y) were selected from the previous study cohort, along with non-MASLD AA controls ($n = 10$; mean age 27 ± 11.42 y) from the Washington DC area. Their sociodemographic, lifestyle exposures, and medical background information were recorded. To categorize the PNPLA3 polymorphism (rs738409), we performed SNP genotype analysis. RNA Sequence analysis and IPA (Qiagen) analysis were used to map the metabolic pathway of IL-6 and to understand the gene networks. **Results:** The SNP analysis revealed the following frequency of the three alleles: 62% for the wildtype allele (C/C), 29% for the heterozygous allele (C/G), and 10% for the homozygous allele (G/G). The differential gene expression analysis disclosed an activation of IL-6 when we compared the wild type with the mutated allele type. Additionally, we identified 10 key genes that are significantly ($p < 0.05$) up and downregulated ($> \pm 4$ fold), viz., RSS53, CORO7-PAM16, MAPK12, CNIH3, CATIP, WDR74, TPTE, UTP14C, H3C14, and CRYBB2. Hepatic Fibrosis Signaling Pathway and Hepatic Satellite cell activation are observed as key canonical pathways (CP) when compared with wildtype variants over the mutated type. Additionally, we observed activation of IL-1B, EXOSC3, PRTN3 and inactivation of MYOCD, MAP3K5, E2F1 through causal network analysis. **Conclusion:** This pilot study opens an opportunity to gain insight into MASLD disease dynamics at different polymorphisms levels of PNPLA3 in AA. This study may further help in developing molecular classifiers to identify the disease risks and the progression of MASLD in the future that necessitates further large-scale multiethnic population validation as well as using large sample size as well as comparisons of blood and liver biopsies is necessary to strengthen our findings.

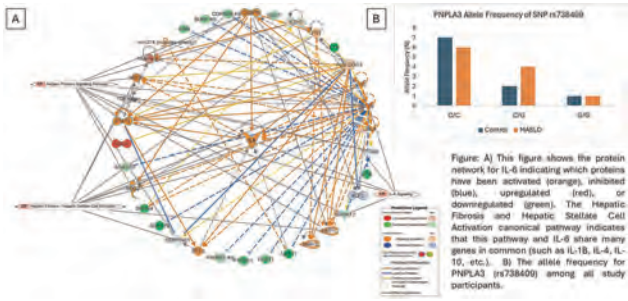

Figure: A) This figure shows the protein network for IL-6 indicating which proteins have been activated (orange), inhibited (blue), upregulated (red), or downregulated (green). The Hepatic Fibrosis and Hepatic Stellate Cell Activation canonical pathway indicates that this pathway and IL-6 share many genes in common (such as IL-1B, IL-4, IL-10, etc.). B) The allele frequency for PNPLA3 (rs738409) among all study participants.

2145 | EVALUATION OF ACCURACY OF AST TO PLATELET RATIO INDEX (APRI) IN VARIOUS AGE GROUPS WITH BIOPSY-PROVEN MASLD OR MASH: A COMPREHENSIVE RETROSPECTIVE STUDY

Frank Lin[1] Ayah Obeid[1] Parampreet Kaur[1] Kimberly Chaput[1] Hammad Liaquat[1], [1]St. Luke's University Health Network

Background: Metabolic dysfunction-associated steatotic liver disase (MASLD) can involve advanced fibrosis and has implications with cardiovascular and liver disease related mortality. The definitive diagnosis of MASLD and metabolic dysfunction-associated steatohepatitis (MASH) is liver biopsy. We aim to evaluate and compare the accuracy of the AST to platelet ratio index (APRI) in predicting hepatic fibrosis among various adult age groups with biopsy proven MASLD or MASH. **Methods:** We conducted a retrospective chart review to identify patients who were 18 years of age and over who underwent a liver biopsy between 2020 and 2023. Data was collected on patient demographics, comorbidities, and liver biopsy findings. Stage of fibrosis was determined using the Metavir Scoring System (F0-F4). Exclusion criteria for the study focused on identification of other causes of steatosis, steatohepatitis, and chronic liver disease. Patients were split into two age groups: young (18-44 years) and older (45 years or more). All statistical analyses were conducted using Stata V.18 to compute means and frequencies of patient data to determine accuracy of

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

APRI. **Results:** A total of 254 patients were included with a mean age of 53.1 years, 62.2% females, and 80.3% Caucasians. The majority of patients had metabolic syndrome (50.8%), obesity (75.2%), hypertension (62.6%), and dyslipidemia (64.9%). APRI was interpretable in all 254 patients with a scoring threshold of 0.5. Of the 254 patients, 50.8% were predicted to have advanced fibrosis. Overall, APRI had higher sensitivity (72.7%) and lower specificity (50.2%) in predicting advanced fibrosis with the best outcomes seen in the older age group for sensitivity and negative predictive value (NPV) (Table 1). Area under the receiver operating characteristic (AUROC) curve analysis showed unsatisfactory accuracy of APRI in the overall sample, young, and older age groups with AUROC of 51.2%, 43.5%, and 53.7%, respectively. **Conclusion:** Our results suggest that APRI has good sensitivity for predicting fibrosis and even stronger predictability for non-advanced fibrosis (F0-F2) based on the NPV among all patients. APRI as a diagnostic tool and biomarker appears to have greater clinical utility for increasing the pre-test probability for non-advanced fibrosis. The results in the young age group can be further improved with a larger sample size. A comparison of results with other non-invasive liver fibrosis biomarkers is needed.

Table 1: AST to Platelet Ratio (APRI) Index scores in patients with biopsy proven MASLD or MASH.

Characteristics	All MASLD or MASH patients (n=254) n (%)	Age 18-44 years (n=62) n (%)	Age 45 years and above (n=192) n (%)
F0-F2 *(APRI ≤ 0.5)*	125 (49.2)	29 (46.8)	96 (50)
F0-F2 on APRI *and* liver biopsy	122 (48)	26 (41.9)	96 (50)
F0-F2 on APRI *but* F3-F4 on liver biopsy	3 (1.2)	3 (4.8)	0 (0)
F3-F4 *(APRI > 0.5)*	129 (50.8)	33 (53.2)	96 (50)
F3-F4 on APRI *and* liver biopsy	8 (3.1)	1 (1.6)	7 (3.6)
F3-F4 on APRI *but* F0-F2 on liver biopsy	121 (47.6)	32 (51.6)	89 (46.3)
Sensitivity / NPV, (%)	72.7 / 97.6	25 / 89.7	100 / 100
Specificity / PPV, (%)	50.2 / 6.2	44.8 / 3	51.9 / 7.3
AUROC (%)	51.2	43.5	53.7

PPV- positive predictive value; NPV- negative predictive value, AUROC - area under the receiver operating characteristic curve; CI - confidence interval.

2146 | DEVELOPMENT OF A NONINVASIVE MODEL FOR SIGNIFICANT FIBROSIS IN MAFLD USING LASSO REGRESSION

Wen Deng[1] Yao Xie[2] Minghui Li[2], [1]Capital medical university, [2]Beijing Ditan Hospital, Capital Medical University

Background: The progression of liver fibrosis in patients with Metabolic dysfunction-Associated Fatty Liver Disease (MAFLD) is often insidious, and there remains a clinical unmet need for noninvasive diagnostic models capable of effectively identifying significant fibrosis in MAFLD (SigFib-MAFLD). This study aimed to develop an assessment model for the early identification of significant liver fibrosis in MAFLD patients. **Methods:** Patients with biopsy-confirmed MAFLD were enrolled from Beijing Ditan Hospital, Capital Medical University between 2008 and 2018. Predictors associated with significant fibrosis were selected using LASSO regression. A multivariable logistic regression model was then constructed based on the selected variables and internally validated using the bootstrap method. The predictive performance of the model was evaluated by receiver operating characteristic (ROC) curve analysis, with calculation of the area under the curve (AUC), and compared with existing indices (FIB-4, APRI, and LSM). Decision curve analysis (DCA) was performed to assess the clinical net benefit of the model. **Results:** A total of 466 patients with biopsy-confirmed MAFLD were ultimately included in this study. The final model incorporated four independent predictors: BMI (aOR = 1.92, 95% CI:1.51-2.44; Z = 5.42, P < 0.001), ALT (aOR = 1.50, 95% CI:1.10-2.04; Z = 2.59, P = 0.010), CHE (aOR = 1.68, 95% CI:1.34-2.12; Z = 4.41, P < 0.001), and CAP (aOR = 2.26, 95%CI:1.77-2.89; Z = 6.51, P < 0.001), all demonstrating significant positive associations with risk of significant fibrosis in MAFLD. The model achieved an AUC of 0.798 (95%CI:0.757-0.840), with diagnostic accuracy significantly superior to existing indices including FIB-4, LSM and APRI (all P < 0.05). Internal validation confirmed good model calibration, while decision curve analysis (DCA) demonstrated favorable clinical utility. **Conclusion:** The composite model comprising BMI, ALT, CHE, and CAP showed excellent diagnostic accuracy for detecting significant fibrosis in MAFLD (AUC 0.798, 95% CI 0.757-0.840).

2147 | COMBINATION OF ELF SCORE AND CYTOKERATIN-18 FRAGMENT FOR EFFICIENT DETECTION OF AT-RISK MASH

Takemi Akahane[1] Masafumi Oyama[1] NORIHISA NISHIMURA[1] Shinya Sato[1] Kosuke Kaji[1] Tadashi Namisaki[1] Hitoshi Yoshiji[1], [1]Nara Medical University

Background: The prognosis of MASLD/MASH is primarily determined by the degree of liver fibrosis progression. High-risk MASH (at-risk MASH), defined as NAFLD activity score (NAS) ≥ 4 with liver fibrosis stage $F \geq 2$, requires early intervention. Cytokeratin-18 fragment (CK18F) is released into the blood as a result of apoptosis in damaged hepatocytes. CK18F has been shown to be significantly elevated in MASH and is considered useful for MASH detection. Enhanced liver fibrosis (ELF) score is also valuable for diagnosing the degree of liver fibrosis progression. We investigated whether CK18F and ELF are useful for identifying at-risk MASH patients. **Methods:** We measured ELF and CK18F using stored serum samples from 108 MASLD patients who underwent liver biopsy at our hospital. We examined the associations between these biomarkers and biochemical tests as well as pathological findings, and developed a predictive model for detecting at-risk MASH using CK18F and ELF. **Results:** CK18F showed positive correlations with AST, ALT, and HOMA-IR. CK18F levels increased significantly with higher degrees of ballooning and were significantly higher in patients with $NAS \geq 4$ compared to $NAS \leq 3$. The cutoff value of CK18F for predicting ballooning or $NAS \geq 4$ was 329 U/L, with AUROCs of 0.714 and 0.775, respectively. Regarding liver fibrosis, CK18F was significantly higher in the $F \geq 2$ group compared to $F \leq 1$, with a cutoff value of 351 U/L for predicting $F \geq 2$ (AUROC: 0.723). In the at-risk MASH group, CK18F was significantly higher compared to the non-at-risk MASH group, with a cutoff value of 351 U/L for predicting at-risk MASH (AUROC: 0.714). ELF also increased significantly with higher inflammation and ballooning scores in NAS, and was significantly higher in the $F \geq 2$ group compared to $F \leq 1$. ELF was significantly higher in the at-risk MASH group compared to the non-at-risk MASH group, with a cutoff value of 9.91 (AUROC: 0.764). Decision tree analysis for predicting at-risk MASH revealed ELF in the first layer and CK18F in the second layer. **Conclusion:** Both CK18F and ELF reflect ballooning and liver fibrosis, and their combined use may enhance the predictive ability for at-risk MASH. The combination of ELF and CK18F enables efficient identification of at-risk MASH patients, potentially improving patient selection for early intervention and reducing unnecessary liver biopsies.

2148 | EVALUATING THE CORRELATION BETWEEN NAFLD ACTIVITY SCORE (NAS) WITH NON-INVASIVE FIBROSIS-4 (FIB-4) AND AST TO PLATELET RATIO INDEX (APRI) IN VARIOUS AGE GROUPS WITH BIOPSY-PROVEN MASLD OR MASH: A TERTIARY HEALTH CARE NETWORK RETROSPECTIVE STUDY

Ayah Obeid[1] Frank Lin[1] Parampreet Kaur[1] Kimberly Chaput[1] Hammad Liaquat[1], [1]St. Luke's University Health Network

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD) can lead to advanced fibrosis, increasing cardiovascular and liver-related mortality. Liver biopsy is the gold standard for diagnosing NAFLD and Metabolic Dysfunction-Associated Steatohepatitis (MASH), but non-invasive tests like the Fibrosis-4 (Fib-4) index and AST to Platelet Ratio Index (APRI) are increasingly used to assess fibrosis risk. This study evaluates the correlation between the NAFLD Activity Score (NAS) and these non-invasive markers in patients with biopsy-proven MASLD or MASH. **Methods:** We conducted a retrospective analysis of 252 patients with biopsy-proven MASLD or MASH (2020- 2023). Fibrosis risk from the liver biopsy was categorized into mild to moderate (score: 1-2) and advanced fibrosis (score: 3-4). NAS was divided into 0–2 (indeterminate), 3–4 (low to moderate risk), and 5–8 (high risk to advanced fibrosis). Fib-4 was divided into low likelihood of advanced fibrosis, high likelihood, and indeterminate (needs more testing). APRI scores were categorized as low (< 0.5), high (> 1.5), and indeterminate (0.5–1.5). Fib-4 and NAS were combined to create a composite variable, as were Fib-4 and APRI, to compare against the liver biopsy for detecting advanced fibrosis. Statistical tests included unpaired t-tests, Mann-Whitney U tests, Chi-square, and Fisher's exact tests. Diagnostic performance was assessed using sensitivity, specificity, predictive values, and the area under the curve (AUC). **Results:** The cohort had a mean age of 52.94 years (SD: 13.80), with 61.9% female participants. Advanced fibrosis was identified in 6.01% of patients. Among non-invasive markers, Fib-4 demonstrated the highest diagnostic accuracy, with a sensitivity of 66.67%, specificity of 67.86%, and an AUC of 67.26% (Table 1). APRI had lower accuracy, with a sensitivity of 40%, specificity of 77.5%, and an AUC of 58.75%. The NAS score exhibited limited diagnostic utility, with a

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

sensitivity of 40%, specificity of 59.29%, and an AUC of 49.64%. Combining Fib-4 with APRI provided marginal improvement, achieving an AUC of 62.17% (Table 2). High NAS scores (5–8) were associated with increased likelihood of advanced fibrosis, with 22.45% and 10.20% of patients in this group classified as high risk by Fib-4 and APRI, respectively (Table 3). However, statistical significance was limited, with p-values of 0.350 for Fib-4 and 0.058 for APRI, reflecting the variability in correlation between NAS and these non-invasive markers. **Conclusion:** Fib-4 is the most reliable non-invasive marker for detecting advanced fibrosis as compared to NAS, APRI, Fib-4 & NAS combined, and Fib-4 & APRI combined. However, NAS alone provides limited diagnostic value, and combining Fib-4 with APRI offers only marginal improvement. These findings suggest that while Fib-4 is a valuable tool, further studies are needed to evaluate non-invasive markers and reduce the reliance on liver biopsy.

Table 1: Diagnostic accuracy of the Fib-4 test against the liver biopsy results for fibrosis.

Fib-4 Score	Liver Biopsy: Advanced fibrosis (3-4)	Liver Biopsy: Mild to moderate (1-2)	Total
High risk	4 (66.67%)	38 (32.14%)	40
Low risk	2 (33.33%)	78 (76.86%)	78
Total	6	112	118

Parameter	Score (95% C.I.)
Sensitivity	66.67% (52.19, 75.17)
Specificity	67.86% (59.43, 76.28)
Positive predictive value	10% (3.59, 15.61)
Negative predictive value	97.44% (94.68, 100)
Area under the curve	67.26% (46.15, 88.37)

Table 2: Diagnostic accuracy of the Fib-4 and APRI test combined against the liver biopsy results for fibrosis.

Fib-4 & APRI combined Score	Liver Biopsy: Advanced fibrosis (3-4)	Liver Biopsy: Mild to moderate (1-2)	Total
High risk (1-2)	4 (57.41%)	41 (32.80%)	45
Low risk (3-4)	3 (42.86%)	84 (67.20%)	87
Total	7	125	132

Parameter	Score (95% C.I.)
Sensitivity	57.14% (18.70, 85.09)
Specificity	67.20% (58.19, 75.21)
Positive predictive value	8.89% (4.03, 13.74)
Negative predictive value	96.55% (93.44, 99.66)
Area under the curve	62.17% (41.96, 82.38)

Table 3: Assessing the correlation between the NAFLD Activity Score (NAS) and non-invasive fibrosis markers (FIB-4, APRI) in patients diagnosed with MASLD or MASH.

Factor	NAS 0-2	NAS 3-4	NAS 5-8	p-value
N	4	51	49	
Fib-4 score				0.350
Indeterminate	0 (0.00%)	19 (38.00%)	23 (46.94%)	
Low likelihood	0 (0.00%)	20 (40.00%)	15 (30.61%)	
High likelihood	1 (100.00%)	11 (22.00%)	11 (22.45%)	
APRI score				0.058
Indeterminate	0 (0.00%)	27 (52.94%)	26 (51.22%)	
Low likelihood	0 (0.00%)	10 (27.25%)	14 (28.57%)	
High likelihood	1 (100.00%)	5 (9.80%)	5 (10.20%)

2149 | ASSOCIATION OF SENSITIVITY TO THYROID HORMONES AND METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE IN EUTHYROID ADULTS

Hyun Woo Oh[1] Yoosoo Chang[1] Kyoung A Ko[1] Won Sohn[1] Seungho Ryu[1] Yong Kyun Cho[1] Byung Ik Kim[1], [1]Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine

Background: Thyroid hormones are key regulators of hepatic lipid metabolism, and recent evidence highlights the potential role of thyroid hormone sensitivity, particularly the free triiodothyronine to free thyroxine (FT3/FT4) ratio, in the pathogenesis of metabolic dysfunction-associated steatotic liver disease (MASLD) among euthyroid individuals. However, most prior studies have been cross-sectional, limiting insight into temporal or causal associations. To overcome this limitation, we designed a longitudinal study to determine whether baseline FT3/FT4 ratio can predict the onset or progression of MASLD in a euthyroid population. **Methods:** We performed a prospective longitudinal cohort study of 209,729 South Korean euthyroid adults, free of MASLD at baseline, who participated in repeated health screening examination annually or biennially from January 1, 2011 to December 31, 2021. Steatotic liver disease was diagnosed by ultrasonography. FT4, FT3, and thyroid stimulating hormone levels were measured by ECLIA. The adjusted hazard ratio (aHR) with 95% confidence interval (CI) was estimated using a Cox proportional hazards model. **Results:** Mean age of 209,729 participants was 35.7 years. During a mean follow-up of 5.98 years, 51,205 participants (32.3%) developed MASLD. High FT3/FT4 levels were associated with elevated risk of MASLD with a corresponding multivariable aHR 1.32 (95% CI: 1.29-1.35) for men and 1.21 (95% CI: 1.16-1.27) for women. Subjects with higher FT3/FT4 quintiles were associated with progressively increased risks of MASLD in a dose-response manner in both men and women groups ($P < .001$). **Conclusion:** In a large cohort of euthyroid men and women, increased FT3/FT4 were significantly associated with development of MASLD. FT3/FT4 could be used as new indicators for predicting development of MASLD.

Table 1. Development of MASLD by **Free T3 - Free T4 ratio levels** among participants without MASLD at baseline (n = 209,729)

2150 | IMPROVING METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE SCREENING IN A RESIDENT CLINIC: A QUALITY IMPROVEMENT INITIATIVE

Reeti Gulati[1] Karen Young[1] Larissa Lushniak[1] Ryan Duffy[2] Cynthia Moylan[3], [1]Duke University Medical Center, [2]Duke University School of Medicine, [3]Duke University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver disease worldwide and present in 32% of U.S. adults. A majority of U.S. Veterans have at least one cardiovascular risk factor increasing risk for MASLD. Fibrosis index (FIB-4) is a non-invasive test recommended for estimating liver fibrosis in patients with suspected MASLD. Despite its utility, only 14.8% of eligible patients at a single resident-run primary care clinic had a FIB-4 completed in the previous year. **Methods:** We implemented a quality improvement initiative to increase FIB-4 testing in Veterans aged 35-70 seen in a resident-run primary care clinic affiliated with the Durham Veterans Affairs Medical Center who had at least 1 cardiometabolic risk factor, including body mass index (BMI) $\geq$ 25 kg/m^2, diabetes mellitus type 2 (DM2), pre-diabetes (pre-DM), hypertension (HTN), or hyperlipidemia (HLD). Our intervention consisted of designing and sharing an infographic in clinical work areas with instructions on FIB-4 screening. Data was collected on FIB-4 screening and follow-up testing for 3 months (March-May 2025). We compared FIB-4 screening rates in the baseline and post-intervention periods using a Chi-squared test. **Results:** At baseline, 14.8% of eligible veterans had a FIB-4 completed in the past year. Following the intervention, we saw a 34% relative increase in FIB-4 testing among eligible patients to 230/1,154 (19.9%, $p < .001$). Characteristics of eligible and screened patients are shown in Table 1. The most common MASLD risk-factors among screened patients were HTN (57.1%) and HLD (33.2%). Among those with a FIB-4 score > 1.3 ($n = 78$), 16.7% had a vibration controlled transient elastrography scan (VCTE) ordered to measure their liver stiffness. Of these, 92.3% had VCTE completed, and 7.7% had VCTE discontinued. **Conclusion:** Our study shows that a simple, targeted infographic intervention effectively increased FIB-4 screening rates among Veterans at risk for MASLD in a resident-run primary care clinic. HTN and HLD were the most common risk factors among the screened population. Limitations include lack of data on abdominal imaging and hepatic steatosis assessments. Next steps include a larger cohort, longer follow-up, and improvements in appropriate follow-up testing among patients with elevated FIB-4 scores.

Demographics	Patients eligible for screening (N=1154)	Patients screened with FIB-4 (N=230)
Age (years)		
Mean (SD)	56.4 (10.2)	57.7 (10.6)

2151 | EXPLORING THE MULTIDIMENSIONAL STRUCTURE OF NONINVASIVE LIVER FIBROSIS ASSESSMENTS IN MASLD

stephanie Chang[1] Edward De Vol[2] Molly Ma[1] Yu Chen[1] Cecilia Miller[1] Miki Kwan[1] Alex Ma[1] Om Patel[1] Oluwademilade Dada[1] Vibhas Desphande[2] Daniel Ennis[3] Donald Chalfin[2] Ramsey Cheung[4], [1]VA Palo Alto Healthcare System, [2]Siemens Healthineers, [3]Stanford University, [4]Stanford University Medical Center

Background: Liver fibrosis is typically assessed using a combination of serologic, imaging, and demographic features. We analyzed 69 type II diabetic individuals from a larger cohort of 101 patients. Our goal was to understand how commonly used fibrosis-related features co-vary and supports the use of multivariate methods to explore the structure of imperfect proxy measures. **Methods:** We performed principal components analysis on seven standardized variables to assess fibrosis: Fibrosis-4 Index (FIB-4), Enhanced

Liver Fibrosis (ELF), vibration-controlled transient elastography (VCTE), ultrasound auto-point shear wave elastography (auto-pSWE) (US), magnetic resonance imaging elastography (MRE), body mass index (BMI), and age. Only subjects with both diagnostic VCTE and MRE were included in the analysis. **Results:** Three principal components (PCs) appeared significant based on scree plot inspection, accounting for 48% (PC1), 21% (PC2), and 13% (PC3) of total variance. PC1 represented a general fibrosis severity axis, with strong loadings from MRE (0.91), VCTE (0.92), US (0.75), [SC1] FIB-4 (0.72), ELF (0.53), and BMI (0.49). This suggests these features collectively describe an underlying dimension of liver disease burden. PC2 was dominated by age (0.85), with moderate contributions from ELF (0.49) and FIB-4 (0.49), and a negative association with BMI (-0.46). This component may reflect an age-associated pattern of fibrosis expression or marker responsiveness. PC3 had high loading from BMI (0.69) and a strong negative loading from US (-0.56), possibly representing a BMI-US interaction, where adiposity may affect imaging performance. **Conclusion:** Our findings suggest that a set of underlying dimensions can capture key variations across noninvasive fibrosis-related measures to potentially streamline fibrosis assessment and support more efficient risk stratification. The first component supports combined use of VCTE, US, MRE, ELF, and FIB-4 to assess fibrosis burden, while the second highlights age-related differences in fibrosis profiles, potentially useful for refining stratification in older patients. The third supports an inverse relationship between BMI and US, highlighting how body composition may influence fibrosis interpretation. Overall, these findings reinforce the multi-factorial nature of liver fibrosis.

2152 | DESIGN OF A NON-INTERVENTIONAL STUDY TO ESTIMATE THE PREVALENCE OF UNDIAGNOSED MASH USING US REAL-WORLD DATA THROUGH MACHINE LEARNINGNEW SUBMISSION

Zuleika Aponte Torres[1] Jörn Schattenberg[2] Lu Zhang[1] Katrine Lindvig[3] Zobair Younossi[4] Mireia Raluy[5] Mark Yates[5] Claudio Sartini[6], [1]Boehringer Ingelheim Pharmaceuticals, Inc., [2]Saarland University Medical Center, [3]Odense University Hospital, [4]The Global NASH Council, [5]Evidera, [6]Boehringer Ingelheim International GmbH

Background: The US prevalence of metabolic dysfunction-associated steatohepatitis (MASH; previously non-alcoholic steatohepatitis [NASH]) is estimated at 5%. Administrative databases rely on International Classification of Diseases (ICD) codes for NASH, so only patients who were assigned NASH-related ICD codes can be identified in these datasets. However, they inadequately describe the condition, particularly the stage of fibrosis, so MASH is often underdiagnosed and underreported in routine clinical care. This is compounded by the invasive and costly nature of liver biopsy for large-scale screening. Advances in non-invasive tests (NITs), and machine learning (ML) approaches, may offer new tools for MASH screening, using combinations of blood-based biomarkers. We aim to estimate how the prevalence of MASH in the US could vary using criteria that incorporate the use of ICD codes and NITs using different methods, including ML. **Methods:** This is an observational, non-interventional, retrospective study using electronic health record and claims data from the Optum Market Clarity US database between January 1, 2021, and December 31, 2023. Eligible individuals are aged ≥18 years as of January 1, 2021. Patients with liver disease etiologies other than

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

MASH, and with missing age data, are excluded. Case definitions for different criteria used to define diagnosed and undiagnosed MASH, using ICD codes, Fibrosis-4 (FIB-4), and LiverPRO parameters are described in Table 1. LiverPRO is a novel, validated, algorithm-based medical device that estimates liver fibrosis risk using routinely collected NITs and patient age. **Results:** The primary outcome is the period prevalence of MASH, as indicated by the different case definitions, within the study population. Secondary and exploratory outcomes are patient demographics and clinical characteristics, number of cases of undiagnosed MASH for each case definition compared with specific ICD codes, distribution of patients diagnosed with MASH across fibrosis stages identified by LiverPRO or FIB-4 scores, and quantification of undiagnosed individuals with laboratory values indicative of MASLD. **Conclusion:** We predict that diagnosed prevalence will be low compared with undiagnosed prevalence. By leveraging advanced screening methods that combine traditional diagnosis codes with laboratory-based biomarkers, we aim to enhance the understanding of the clinical and demographic landscape of MASH, improve case detection, and inform future public health and clinical strategies.

Table 1. Operational case definitions of MASH and undiagnosed MASH

Case definition	Operational criteria	
	Inclusion criteria	Exclusion criteria
#1: ICD-10 based MASH (Diagnosed MASH)	At least one ICD-10 (K75.81) code for MASH	At least one ICD-10 code for liver disease other than MASLD/MASH, or selected alcohol-related diseases
#2: ICD-10 for MASLD and FIB-4 ≥1.3 (Undiagnosed MASH)	At least one ICD-10 code (K76.0) for MASLD and a FIB-4 score ≥ 1.3	Same exclusion criteria as listed for 1
#3: ICD-10 for MASLD and LiverPRO-identified F2, F3, F4 (Undiagnosed MASH)	At least one ICD-10 (K76.0) code for MASLD and LiverPRO predicting fibrosis stages F2, F3, or F4	Same exclusion criteria as listed for 1
#4: ICD-10 based MASLD (Diagnosed MASLD)	At least one ICD-10 code (K76.0) for MASLD	Same exclusion criteria as listed for 1
#5: FIB-4 ≥1.3 without ICD-10 codes for MASLD or MASH (Undiagnosed MASH)	Patients with a FIB-4 score ≥ 1.3	At least one ICD-10 code for MASLD (K76.0) or MASH (K75.81) or as listed for 1
#6: LiverPRO F2, F3, F4 without ICD-10 codes for MASLD or MASH (Undiagnosed MASH)	Patients meeting LiverPRO criteria for fibrosis stages F2, F3, or F4	At least one ICD-10 code for MASLD (K76.0) or MASH (K75.81) or as listed for 1

ICD-10, International Classification of Diseases, 10th Revision; MASH, metabolic dysfunction-associated steatohepatitis; MASLD, metabolic dysfunction-associated steatosis liver disease.

2153 | UTILIZATION OF ENHANCED LIVER FIBROSIS (ELF) TEST IN THE EVALUATION OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Amreen Dinani[1] Karen Young[2] Chukwuemeka Oko[2], [1]Duke University School of Medicine, [2]Duke University

Background: Identifying individuals who are at risk for significant liver fibrosis is key step in risk stratification for metabolic dysfunction-associated steatotic liver disease (MASLD). The Enhanced Liver Fibrosis (ELF) test is a non-invasive test (NIT) recommended by society guidelines as a secondary tool for liver fibrosis assessment. The purpose of this study was to examine the application of ELF across two hepatology clinics with differing diagnostic testing availability. **Methods:** This was a retrospective study including 287 adult patients referred for MASLD evaluation from September

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

2023 and May 2024 at two clinics (Clinic 1: access to transient elastography [TE] and Clinic 2: no access to TE). 50 participants were excluded due to pre-existing diagnosis of cirrhosis or unmet MASLD criteria. Data included demographics, clinical characteristics, and modalities of fibrosis staging (ELF, TE, magnetic resonance elastography [MRE], liver biopsy). Differences in ELF utilization by clinic location were assessed with a chi-square analysis. Secondary analyses compared FIB-4 and ALT levels between ELF-tested and non-tested groups and correlated FIB-4 with ELF scores. **Results:** Our final cohort of 237 participants (140 in Clinic 1 and 97 in Clinic 2), with 43.5% male, mean age 53.1 years (SD 14.16), and mean BMI 34.1 kg/m² (SD 7.9). ELF testing was performed in 27.8% (66/237), with a mean score of 9.61 (SD 1.10). Of those tested, 59.1% (n = 39) had indeterminate risk for significant fibrosis (ELF 9.80–11.29), and 37.9% (n = 25) had high risk (ELF > 11.29). In Clinic 2, the primary reasons for ELF testing included indeterminate FIB-4 (30%, n = 9), age (20%, n = 6), and clinic location (20%, n = 6); in Clinic 1, indeterminate FIB-4 was the leading reason (36.1%, n = 13). Clinic location was not significantly associated with ELF test utilization ($\chi^2 = 3.06$, $p = 0.92$). In Clinic 2, 37.74% (n = 20) of patients with FIB-4 > 1.3 underwent ELF testing, compared to 23.26% (n = 10) with FIB-4 < 1.3. ELF scores showed a moderate correlation with FIB-4 ($R = 0.42$, $p < 0.05$). Among patients with high-risk ELF scores (> 11.29) who underwent further evaluation, TE (n = 18), MRE (n = 11), or liver biopsy (n = 8) confirmed advanced fibrosis in a subset (e.g., 33.3% of TE and MRE in Clinic 2 showed elevated stiffness; biopsies showed stages 0–4), supporting ELF's role in identifying at-risk patients, though small sample sizes limit definitive conclusions. **Conclusion:** ELF testing was utilized in over a quarter of MASLD patients and correlated moderately with FIB-4. Its application varied by clinic, with greater reliance in Clinic 2 due to the absence of TE. These findings suggest that ELF can enhance risk stratification in MASLD, particularly in resource-limited settings, warranting further prospective studies to validate its integration into clinical algorithms.

Table 1. Reason for ELF test by clinic location

	Clinic 1 (access to TE)	Clinic 2 (no access to TE)
Clinic location	4 (11.11%)	6 (20%)
Age	8 (22.22%)	6 (20%)
Indeterminate FIB4	13 (36.11%)	9 (30%)
Unsuccessful TE	0 (0%)	1 (3.33%)
Patient not NPO for TE	2 (5.56%)	1 (3.33%)
Patient or provider preference	3 (8.33%)	4 (13.33%)
Low FIB4	6 (16.67%)	3 (10%)

2154 | THE NFS SCORE DEMONSTRATES SUPERIOR DIAGNOSTIC PERFORMANCE IN PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)-RELATED CIRRHOSIS

SUN Wei[1] YU Hong[2] Dou Jing[3] WU Xu[4] LI Jingtao[1] Wang Xiaozhong[3] Guo Feng[3], [1]Affiliated Hospital of Shaanxi University of Traditional Chinese Medicine, [2]Xinjiang Karamay Central Hospital, [3]Traditional Chinese Medical Hospital Affiliated to Xinjiang Medical University, [4]The Fourth Clinical Medical College of Xinjiang Medical University

Background: Early diagnosis of metabolic dysfunction-associated steatotic liver disease (MASLD)-related cirrhosis is critical for improving patient outcomes. However, liver biopsy, the traditional gold standard, is limited by its invasiveness. This study evaluated the diagnostic performance of non-invasive methodologies, including FIB-4, APRI, FAST, NFS, ABIDE, and SIRI. The results demonstrated that the NFS score exhibited superior diagnostic efficacy, thereby establishing itself as a highly efficient and safe screening tool for MASLD-related cirrhosis. **Methods:** Hospitalized patients diagnosed with non-alcoholic fatty liver disease (NAFLD) at the Fourth Affiliated Hospital of Xinjiang Medical University (January 2018–December 2024) were enrolled. Demographic, clinical, and serological data were collected. Non-invasive indices (FIB-4, APRI, FAST, NFS, ABIDE, SIRI) were calculated. Patients were stratified into cirrhosis and non-cirrhosis groups based on liver biopsy (gold standard). Multivariate logistic regression identified predictors of MASLD-related cirrhosis. Cut-off values were determined, and diagnostic performance was assessed using the area under the receiver operating characteristic curve (AUROC). **Results:** 1. Among 144 MASLD patients (50.23 ± 13.14 years), 49 (34%) had cirrhosis. 2. Multivariate analysis identified FAST [OR = 2.63, 95% CI: 1.16–5.94, P = 0.020] and NFS scores [OR = 2.02, 95% CI: 1.27–3.22, P = 0.003] as independent predictors of MASLD-related cirrhosis. 3. The AUROCs for NFS and FAST scores were 0.86 (95% CI: 0.80–0.92) and 0.68 (95% CI: 0.58–0.79), respectively, with optimal cut-off values of -0.91 and -0.75. Both scores demonstrated superior diagnostic performance compared to FIB-4 and APRI. **Conclusion:** The NFS and FAST scores serve as effective non-invasive tools for diagnosing MASLD-related cirrhosis, with the NFS score exhibiting significantly higher diagnostic accuracy.

2155 | COMMON SINGLE NUCLEOTIDE POLYMORPHISM DISTRIBUTION AND ASSOCIATIONS WITH A SURROGATE OF LIVER DISEASE SEVERITY IN MASLD PATIENTS FROM THE UNITED STATES (U.S.) AND TAIWAN

Maria Stepanova[1] Mei-Hsuan Lee[2] James Estep[3] Yan-Ling You[2] Xia-Rong Liu[2] Leyla de Avila[1] Brian Lam[1] Zobair Younossi[1], [1]The Global NASH Council (GNC), Washington DC, United States, [2]Institute of Clinical Medicine, National Yang Ming Chiao Tung University, Taipei, Taiwan, [3]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, United States

Background: Genetic risk factors have been linked to liver disease severity in patients with MASLD. The association of the genetic factors with non-invasive tests (NITs) in various global populations is less well established. We aimed to assess the distribution of common Single Nucleotide Polymorphism and their association with FIB-4 as a surrogate of disease severity in MASLD. **Methods:** Two groups of MASLD patients from the U.S. (hepatology clinic) and Taiwan (Taiwan Biobank, community settings recruitment) were analyzed. Both groups had genomics data for loci rs738409 (*PNPLA3*), rs641738 (*MBOAT7*), and rs58542926 (*TM6SF2*). Individual alleles were evaluated for association with FIB-4 ≥ 1.30 (elevated) or ≥ 2.67 (high). **Results:** In comparison to the U.S. MASLD patients (n = 1,969), MASLD patients from Taiwan (N = 4477) were older (age 53 ± 10 years vs. 52 ± 13 years) and had a higher proportion of females (69% vs. 44%), while the U.S. patients had higher BMI (37 ± 10 vs. 26 ± 4 kg/m²), more type 2 diabetes (36% vs. 7%) and higher liver enzymes (AST, ALT), fasting glucose, and triglycerides (all $p < .01$). Genotypic analysis revealed differences in allele distributions of rs738409 (*PNPLA3*), rs58542926 (*TM6SF2*), and rs641738 (*MBOAT7*) between 2 groups (all $p < 0.01$). In Taiwanese and U.S. patients, the frequency of the *PNPLA3* GG (high-risk) genotype was 17% and 13%, while CC *PNPLA3* genotype (low-risk) was present in 35% vs. 47% ($p < 0.0001$). The *MBOAT7* TT and CC genotypes were observed in 6% (Taiwanese) vs. 14% (U.S.) and 58% (Taiwanese) vs. 30% (U.S.), respectively ($p < 0.0001$). Taiwanese patients had a lower frequency of the *TM6SF2* CT/TT genotypes (15%) compared to 18% in the U.S. ($p < 0.01$). The FIB-4 scores were lower in Taiwanese patients with MASLD than the U.S. patients (1.19 ± 0.52 vs. 1.54 ± 1.61, $p < 0.0001$). Logistic regression adjusted for age and sex showed that *PNPLA3* CC/CG alleles were significantly associated with elevated FIB-4 in both groups ($p < 0.05$) (Table). The *TM6SF2* CT/TT allele was associated with high FIB-4 in Taiwanese but not in the U.S. patients, while the minor alleles at rs641738 (*MBOAT7*) showed no association with high FIB-4 in either cohort (Table). **Conclusion:** The polymorphism rs738409 (C- > T) in the *PNPLA3* gene is associated with high FIB-4 score as a surrogate of disease severity in both the U.S. and Taiwanese patients with MASLD.

Table

Allele	Taiwanese patients with MASLD		U.S. patients with MASLD	
	OR (95% CI)	p	OR (95% CI)	p
Outcome: FIB-4 ≥1.30

Universitário Clementino Fraga Filho- Universidade Federal do Rio de Janeiro

Background: Persons living with obesity are at high risk for metabolic dysfunction- associated steatotic liver disease (MASLD) and its complications. Few studies analyze the accuracy of non-invasive tests for detecting significant/advanced liver fibrosis in individuals with obesity grade equal or higher than grade II. This study evaluated FIB-4 data and VCTE accuracy in patients with grade II-III obesity. **Methods:** Individuals living with grade II-III obesity on the waiting list for bariatric and metabolic surgery (BMS) in three tertiary centers were included. Clinical and laboratory data were collected two months before surgery, and VCTE was performed by Fibroscan® 430 mini + with continuous CAP with XL probe (Echosens, Fr) one week before BMS. All patients performed a liver biopsy (LB) during BMS. Regarding FIB-4, the sensitivity (S), specificity (Sp), negative (NPV) and positive predictive values (PPV) were calculated for a cut-off of 1.3. AUROC curves were plotted to evaluate the accuracy of VCTE to identify significant and advanced fibrosis in this population. **Results:** A total of 474 individuals were included (79% women, 41.5 ± 10.2 yrs, BMI 44.1 ± 6.1 kg/m2, 82.7% obesity grade III). Exclusion due to unreliability of liver stiffness by Fibroscan® was only 1.1%. At LB, 94% were F0-F1, 2.5% F2, 2.1 % F3 and 1.9% F4. FIB-4 lower than 1.3 was identified in 93.1%; among those, only five patients (26.3%) had F ≥ 3. Regarding FIB-4 with a 1.3 cut-off, S of 73%, Sp of 93%, PPV = 31% and an NPV of 98% was found. The AUROC of VCTE for F ≥ 2 and F ≥ 3 were 0.83 (0.74-0.92; $p < 0.001$) and 0.93 (0.80 – 1.00; $p = 0.001$), respectively. **Conclusion:** FIB-4 is a valuable tool for excluding advanced fibrosis in individuals with obesity grade II or III. The accuracy of VCTE by 430 mini + with continuous CAP with XL probe showed good performance in stratifying liver fibrosis in both F2 and F3 individuals on the BMS waiting list, and it may be an useful non-invasive tool in this population.

2157 | HIGH CONCORDANCE OF MASLD AND NAFLD NOMENCLATURES IN PREGNANCY

Sindhu Chadalawada[1] Cecilia Katzenstein[2] Nina Rodriguez[2] Tatyana Kushner[3] Monika Sarkar[4], [1]University of California San Francisco, [2]Icahn School of Medicine at Mount Sinai, New York, NY, USA, [3]Division of Gastroenterology & Hepatology, Weill Cornell Medicine, New York, NY, USA, [4]University of California, San Francisco

Background: Nonalcoholic fatty liver disease (NAFLD) diagnosis by traditional criteria has high concordance with the updated definitions for metabolic dysfunction-associated steatotic liver disease (MASLD). However, concordance of these entities has not been validated in pregnancy. **Methods:** This retrospective cohort study aimed to validate MASLD nomenclature in pregnancies with previously established NAFLD within obstetric practices at two large academic health systems. Chart review of all cases was used to confirm NAFLD and MASLD criteria among pregnant patients in their second trimester onwards seen at our centers between January 2013 to September 2024. Demographic and clinical data including imaging, transient elastography, and/or liver biopsy evidence of steatosis within 1.5 years of pregnancy, as well as pre-conception and gestational metabolic risk factors were noted. Descriptive statistics for continuous variables were reported for mean, median interquartile range (IQR), and standard deviation (SD). **Results:** Among 302 women with one or more pregnancies having a NAFLD diagnosis by imaging and/or biopsy confirmed steatosis, 100% were identified to have ≥ 1 metabolic risk factors (body mass index [BMI] > 25 kg/m2, HbA1c ≥ 5.7%, hypertension [HTN] or anti-HTN treatment, triglycerides > 150 mg/dL, HDL < 50 mg/dL or lipid lowering therapy), therefore meeting MASLD criteria in the absence of alternative causes of steatosis. Most patients reported Hispanic ethnicity (60.9%), with a mean age of 31 years (median 32 [IQR 27-36] SD 6.8), BMI of 36.3 kg/m2 (median 35 [IQR 32-40] SD 6.6), and HbA1c of 5.8% (median 5.5 [IQR 5.2-5.9] SD 1.5). All patients met MASLD criteria by BMI cutoff > 25 kg/m2 (> 23 kg/m2 for Asian race) (Table 1). Of these patients, five met NAFLD criterion when considering gestational diabetes (GDM) in place of pregestational diabetes. Pregnancy-specific metabolic conditions were evenly distributed within the cohort and included gestational hypertension (19.2%), preeclampsia (18.9%), and GDM (22.2%). **Conclusion:**

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Concordance of NAFLD and MASLD definitions was high in pregnancy at 98.3%. When polycystic ovarian syndrome (PCOS) and gestational risk factors were considered, there was a 100% concordance rate.

Table 1. Metabolic Risk Factors in Pregnancy

	UCSF N=74	Sinai N=228	Total N=302 (%)
Pre-conception Risk Factors			
BMI > 25 kg/m^2 (23 for Asian race)	74	228	302 (100%)
HgA1c ≥ 5.7% or T2DM	40	43	83 (27.2%)
HTN or Anti-HTN Rx	24	33	57 (18.9%)
TG > 150 or Lipid Rx	35*	6*	41 (13.6%)
HDL < 50 (F) or Lipid Rx	35*	6*	41 (13.6%)
Gestational Risk Factors			
Gestational HTN	13	45	58 (19.2%)
Preeclampsia	25	32	57 (18.9%)
Gestational Diabetes	33	34	67 (22.2%)
PCOS	23	22	45 (14.9%)

*May be underreported as lipid panels are not routinely ordered in pregnancy

2158 | ASSOCIATED PARAMETERS THAT MAY AFFECT PDFF TRIAL OUTCOMES

Elisabeth Verwest[1] Ian McCauley[1] Nicholas Kruzdlo[1] Dominika Budai[1] Cameron Rolph[1] Raymond Bell[1] Kyla Thiel[1] Yovanni Rosario[1] Isabelle Crotsley[1] Guy Neff[1], *[1]Covenant Metabolic Specialists, LLC*

Background: Metabolic associated steatohepatitis (MASH) has become the most prevalent form of chronic liver disease in the United States, with an adult incidence of 20% expected by 2030. Accurate non-invasive testing for chronic liver disease is vastly needed. In clinical research, MRI-PDFF (proton density fat fraction) is the most widely accepted non-invasive method to identify and quantify hepatic steatosis causing fibrosis and inflammation. The purpose of this study is to evaluate MRI-PDFF data to analyze and establish a link between various morbidity-associated diseases, as well as explore the extent to which these risk factors may serve as predictors of PDFF results. **Methods:** Data from 93 subjects of a MASH clinical trial was collected for retrospective analysis. Qualifying criteria for presumed MASH was a liver fat fraction of 8% or higher. FibroScan scores for controlled attenuation parameter (CAP) were compared with MRI-PDFF results to establish correlation using statistical analysis. Comorbid risk factors of BMI and Type II Diabetes Mellitus (T2DM) were collected and analyzed in association with CAP scores and PDFF values above and below 8% fat content. **Results:** The relationships between the patients' various comorbidities (i.e., T2DM, HbA1c, and BMI) were analyzed with CAP and MRI-PDFF scores. As predicted, MRI-PDFF and CAP score were positively correlated. In total, approximately 70% of those with CAP scores of at least 300 also had MRI-PDFF of 8% or higher, and 100% of CAP scores over 350 showed at least 8% liver fat in MRI. Only 10.8% of patients with CAPs below 300 resulted in MRI-PDFFs qualifying for MASH. Analysis of comorbidities revealed mixed results. While only 34.7% of patients with MRI-PDFF of 8% or above were type II diabetic, approximately 83.9% of all diabetic patients who completed MRI-PDFF met the criteria for MASH. Neither BMI nor HbA1c appeared to have any significant correlation with CAP or MRI-PDFF results. **Conclusion:** In support of the broader body of MASH research, the data analysis indicates that a variety of factors likely contribute to overall risk of MASH development and shows a correlation between T2DM and hepatic steatosis. The findings suggest direct parameters such as comorbidity incidence will help guide use of MRI-PDFF and other diagnostic tools. The potential to determine a level of predictiveness for comorbid risk factors of MASH may have applications in optimizing the screening process for clinical trials by increasing the probability of identifying subjects with elevated PDFF fat % values.

Total:	CAP≥300, ≥8%	CAP≥300, <8%	CAP<300, ≥8%	CAP<300, <8%
93	65	9	10	9

CAP ≥300, >8%	CAP ≥325, ≥8%	CAP >350, ≥8%
69.90%	89%	100%

◆ 2159 | HOW THE CAUSE OF LIVER FAILURE SHAPES THE POST-TRANSPLANT JOURNEY: PATIENT-REPORTED OUTCOMES ACROSS ETIOLOGIC CATEGORIES

Lorrinda Gray-Davis[1] Richard Jaenisch[1] David Jaenisch[1] Karen Hoyt[1] Mustafa Behan[2] Jutta Kurz[2] Valeriia Aksakovska[2] Michael Tunkelrott[3] Rachma Purnama[3] Emmanuel Gorospe[4] Tarek Hassanein[5], [1]None, [2]Amsety, [3]Amsety LLC, [4]Burrell College of Osteopathic Medicine, [5]Southern California Liver Centers

Background: While one-year survival post-liver transplant (LTx) exceeds 93%, 38.1% of grafts fail by year ten. This pilot study suggests the underlying cause of liver failure, regardless of underlying etiology, significantly influences long-term experiences, needs, and complications over uniform survivorship model for post-transplant follow-up care. **Methods:** We conducted an exploratory survey (March–April 2025) of 200 LTx patients from a world-wide network, yielding 76 responses. The HIPAA-compliant Amsety database has over 650,000 U.S. individuals, including 13,000 self-identified LTx cases. Participants were stratified by transplant indication. Survey covered complications, follow-up frequency, medication changes, testing patterns, psychosocial stressors, and educational priorities. **Results:** Respondents with NASH/MASH reported the highest overall complication burden, including elevated liver enzymes and kidney problems, as well as the greatest unmet need for nutrition guidance, exercise support, and education about rejection signs. Alcohol-related recipients showed high rates of skin cancer and frequent medication adjustments and were more likely to cite adherence and mental health as ongoing challenges. By contrast, viral hepatitis recipients experienced fewer complications and greater medication stability, while autoimmune and drug-induced injury groups showed higher testing frequency and dynamic immunosuppression changes. Educational and support needs were strongly etiology-dependent. Nutrition was the most requested topic across all groups, but those with NASH/MASH or alcohol-related causes also emphasized peer support and mental health resources. As expected, the first post-transplant year emerged as the most vulnerable time, with the highest rates of complications and information needs. **Conclusion:** Transplant indication meaningfully shapes the post-transplant course. A uniform survivorship model may miss critical differences in complications, care engagement, and psychosocial needs. Etiology-specific approaches integrating nutrition, mental health, and long-term monitoring are likely warranted. This pilot study emphasizes the need for more research exploring etiology-specific survivorship care planning in liver transplantation.

[1]Department of Global and Community Health, George Mason University, Fairfax, VA, USA, [2]Beatty Liver and Obesity Research Program, Inova Health System, Falls Church, VA, USA

Background: Fatigue has been well-documented to negatively impact cognitive performance, including working memory. MASLD is associated with systemic inflammation and metabolic dysregulation both of which can affect brain health by influencing brain metabolism, thereby leading to cognitive performance deficits such as impaired working memory. However, the interactive effects of MASLD and fatigue on cognitive performance have not been well studied. The current project examined the working memory performance of individuals with MASLD and fatigue. **Methods:** Subjects enrolled in this cross-sectional study from a liver clinic. Subjects completed informed consent. Participants attended a one-time research visit where clinical, demographic, and cognitive performance data were collected. Working memory was tested using the WAIS-IV arithmetic and digit span tests. The scores from these tests were combined into a composite score that yields an overall working memory index (WMI). FACIT-Fatigue self-report tool was also completed. Presence of fatigue was defined as a score of 40 or less on the FACIT-Fatigue. MASLD was defined as presence of hepatic steatosis by ultrasonography or CAP $\geq$ 280 by transient elastography (TE) and at least 1 of 5 cardiometabolic risk factors (BMI $\geq$ 25, BP $\geq$ 130/85, type 2 diabetes, triglycerides $\geq$ 150 mg/dl; HDL cholesterol $\leq$ 40mg/dl). **Results:** There were 101 participants in the study, 65 MASLD [29 with MASLD and fatigue and MASLD without fatigue (n = 36)] and 36 controls without MASLD [Controls with fatigue (n = 14) and Controls without fatigue (n = 22)]. Those with MASLD and fatigue had statistically significantly higher BMI's than the others. The WMI was statistically significantly lower in those with MASLD and fatigue (99.7 ± 13.8) compared to the others (106.3 ± 14.8; $p = 0.04$). When we compared those with MASLD (n = 65) to those without (n = 36) and when comparing those with fatigue (n = 43) to those without fatigue (n = 58), the WMI was not statistically significantly different (p's > 0.10). **Conclusion:** Cognitive performance deficit (lower working memory performance) in MASLD seems to exist with fatigue. These findings suggest that fatigue negatively impacts cognitive performance in individuals with MASLD, and is likely an important factor to consider when managing MASLD-related health outcomes. Further research is warranted to explore the underlying mechanisms driving this association in MASLD.

2161 | LIVERPAL: A FORMATIVE EVALUATION OF A LONGITUDINAL SPECIALTY-ALIGNED PALLIATIVE CARE INTERVENTION FOR HOSPITALIZED PATIENTS WITH ADVANCED LIVER DISEASE (ADVLD)

Nancy Mason[1] Erin Plews-Ogan[2] Alyssa Fenech[3] Samantha Berliss[4] Michaela Rowland[1] Kirsten Engel[1] Karen O'Brien[1] Michelle Diop[1] Sara Kenimer[1] Teresa Indriolo[5] Lucinda Li[6] Enya Zhu[7] Malia Armstrong[1] Grace Bizup[1] Anushka Dalvi[1] Brett Nava-Coulter[8] Anna Revette[8] Vicki Jackson[1] Raymond Chung[1] Areej El-Jawahri[1] Nneka Ufere[1], [1]Massachusetts General Hospital, [2]University of Virginia, [3]University of Delaware, [4]Legacy Health, [5]Stanford University, [6]UCLA, [7]Duke University, [8]Dana Farber Cancer Institute

Background: Hospitalized patients with AdvLD experience substantial symptom burden, frequent readmissions, and high mortality, yet palliative care is underutilized for this population. Much of the evidence base for inpatient palliative care interventions has come from oncology. However, instead of a "one-size-fits-all" approach, there have been increasing calls for population-specific (i.e., specialty-aligned) palliative care interventions that are targeted to the unique palliative care needs of patients with non-cancer serious illnesses. In response, we developed *LiverPal,* a longitudinal specialty-aligned inpatient palliative care intervention delivered by palliative care clinicians. We conducted a formative evaluation of a single-arm open pilot trial of *LiverPal* to refine the intervention in preparation for a larger efficacy RCT. **Methods:** Between 6/2022-9/2022, we conducted individual interviews with adult patients with AdvLD recently hospitalized at a large academic transplant center, their caregivers and their inpatient clinicians (internal medicine, hepatology, transplant surgery, critical care, palliative care) enrolled in the *LiverPal* pilot trial. We explored their perspectives regarding: 1) unique features of AdvLD care; 2) challenges to inpatient palliative hepatology care; and 3) benefits and areas of ongoing need regarding delivery of *LiverPal* to patients and caregivers (Figure). We conducted a team-based qualitative thematic analysis using a multistage iterative approach, including

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

both prefigured and emergent dimensions. **Results:** Nineteen individuals (3 patients, 3 caregivers, 13 clinicians) participated in interviews. Participants identified the following unique features of AdvLD care: rollercoaster illness trajectory, lack of culture of ownership of AdvLD patients, the possibility of transplantation as cure, and stigma. These features resulted in challenges to inpatient palliative care delivery, including difficult symptom management, fragmented care, prognostic distress, and goal discordant care. Respondents highlighted the value of having one team that provided longitudinal care across multiple hospitalizations, which engendered trust from all participants and facilitated serious illness conversations and management of pain and mood symptoms by the LiverPal team. Areas of refinement included developing: 1) evidence-based symptom management manual in collaboration with a palliative care pharmacist, 2) serious illness communication scripts to support transplant and dialysis decision-making, and 3) AdvLD-specific care pathways for both end-of-life and transplant survivorship care. **Conclusion:** A longitudinal model of inpatient palliative care promoted trust and facilitated serious illness conversations and symptom management for hospitalized patients with AdvLD. Our refined *LiverPal* intervention is now being evaluated in an ongoing efficacy RCT.

2162 | ACLF – THE ADVANCED PRACTICE PROVIDER EXPERIENCE FROM A LIVER ICU

Leah Psellas[1] Cheryl Milani[1] Alaina Miller[1] Wesam Aleyadeh[2] Kelly Bowen[3] Aanchal Kapoor[1] Christina Lindenmeyer[4], [1]Cleveland Clinic Foundation, [2]Toronto Centre for Liver Disease/Cleveland Clinic Akron General Hospital, [3]Cleveland Clinic Lerner College of Medicine, [4]Cleveland Clinic

Background: The Medical Intensive Liver Unit (MILU) at Cleveland Clinic was established in August 2018 to care for critically ill patients with acute and chronic liver disease, many of whom develop acute-on-chronic liver failure (ACLF). Advanced Practice Providers (APPs) are often frontline caregivers in the multidisciplinary teams caring for these patients, making the recognition of ACLF and initiation of early liver transplant (LT) referrals core responsibilities. Increased awareness and early identification of ACLF by APPs may inform prognosis and early referrals to LT centers. This analysis from a quaternary LT referral center's Hepatology APP team characterizes common ACLF presentations and outcomes to guide timely, informed intervention. **Methods:** Patients admitted to the MILU between 08/2018-08/2023 were prospectively enrolled in a patient registry. Out of 1570 admissions, 614 were for ACLF (EASL-CLIF criteria, 494 unique patients). We analyzed associated mortality and outcome profiles, according to the admitting diagnosis, to better understand early presentation patterns of ACLF. **Results:** Hepatology and Intensive Care Unit (ICU) APPs collaborate and lead the multi-disciplinary morning MILU huddle. Pending transfers are triaged, patients with ACLF are identified, and LT candidacy assessments are immediately reviewed with the interprofessional LT team. The most common admission diagnoses for ACLF patients identified in huddle by the APPs were shock/hypotension (n = 200), gastrointestinal bleeding (GIB, n = 118), altered mental status (AMS, n = 105), acute kidney injury (AKI, n = 99), and acute respiratory failure (ARF, n = 72). Shock/hypotension was associated with the highest in-hospital mortality rate (48%), followed by ARF (40%), AMS (35%), GIB (34%), and AKI (25%). 92% (564/614) of all admissions with ACLF were complicated by AKI, regardless of the admitting diagnosis. Ninety patients (18.2%) with ACLF underwent successful LT; 65 directly from MILU and 25 following ICU discharge. **Conclusion:** These findings underscore the critical role of frontline APPs in the prompt recognition of ACLF, the identification of patients at highest risk of mortality, the initiation of

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

timely referrals to transplant, and the early anticipation of dialysis. Targeted education to increase awareness and empower frontline APPs in referring centers and ICUs may improve outcomes and facilitate access to LT in this high-risk population.

2163 | NAVIGATING THE HEPATITIS C CARE CASCADE WITH ADVANCED PRACTICE PROVIDER AND ELECTRONIC HEALTH RECORD IN AN URBAN EMERGENCY DEPARTMENT AND OUTPATIENT CLINICS

Vicki Shah[1] Colleen Folkers[2] Nancy Reau[2] Bevelry Sha[2], [1]Rush University and Gilead Sciences, [2]Rush University Medical Center

Background: Centers for Disease Control and Prevention (CDC) and U.S. Preventive Services Task Force (USPSTF) recommended universal HCV screening at least once in a lifetime for all adults 18-79 years of age to correspond with World Health Organization (WHO) goal of eliminating hepatitis C virus (HCV) as a public health concern. There is a significant loss of individuals at each step of the HCV treatment cascade from screening to linkage to care. Our aim was to increase HCV screening, diagnosis, and linkage to care in an academic tertiary care system. **Methods:** Beginning October 2016, we utilized the electronic health record (EHR) and hepatology Advanced Practice Providers (APPs) to enhance HCV testing and linkage-to-care in patients seen in the emergency departments and ambulatory clinics. Strategies included auto-order HCV Ab test linked to complete blood count, use of a "best practice advisory" alert, and dedicated hepatology APPs to monitor HCV Ab results. **Results:** From October 2016 to March 2021, 385,683 patients met our testing criteria, and 36,922 (9.57%) HCV Ab tests were performed. 1261 of the 36,922 HCV Ab tests (3.42%) were reactive and 520 (1.41%) of patients tested were found to have detectable HCV viral load. For the 520 patients with HCV infection, 244 (46.9%) were linked for HCV treatment. **Conclusion:** With EHR modifications, HCV viral load reflex testing, and dedicated APPs, we demonstrated higher identification of HCV infected patients and removed several barriers in the HCV care cascade. Successful linkage-to-care varied greatly by where the patient was initially screened.

2164 | BARRIERS AND FACILITATORS TO ENGAGING IN ALCOHOL TREATMENT AMONG PERSONS WITH ALCOHOL-ASSOCIATED LIVER DISEASE: A MIXED-METHODS: SYSTEMATIC REVIEW

Sue Hyon Kim[1] Sasha Deutsch-Link[2] Alison Buttenheim[1] Laura Starbird[1] Michael Stawnychy[1] Marina Serper[3], [1]University of Pennsylvania, [2]UNC Chapel Hill, [3]University of Pennsylvania Health System

Background: Alcohol use disorder (AUD) treatment rates among patients with alcohol-associated liver disease (ALD) are low; 16% report active treatment engagement and less than 5% receive medications for alcohol use disorder (MAUD). Factors influencing stages of need recognition, initiation, and maintenance of AUD treatment are not clearly defined for ALD patients, resulting in limited actionable knowledge. **Methods:** We conducted a mixed methods systematic review synthesizing diverse study designs and data types on facilitators and barriers to AUD treatment engagement among individuals with ALD. Searches were performed in PubMed, CINAHL, Embase, and PsycINFO. We followed the convergent integrated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

approach recommended by the Joanna Briggs Institute and performed directed content analysis based on the Capability, Opportunity, Motivation-Behavior (COM-B) model. **Results:** Twenty-three studies revealed COM-B elements uniquely influencing distinct stages of the AUD treatment care continuum (Table 1). We observed discordance between patients' and providers' treatment need recognition; patients had limited insight into their AUD treatment needs when they were asymptomatic, while providers mainly focused on AUD treatment during asymptomatic ALD. Patient confidence in self-management further reduced their desire for professional help. Their liver transplant (LT) status also influenced motivations for concealing alcohol use and limited their acceptance of AUD treatment; LT candidates feared reprimand or disqualification, and recipients felt shame. Provider training on MAUD was ineffective at increasing prescription rates due to persistent unfamiliarity with pharmacotherapy and practice norms that do not incorporate its routine use. Unclear delineation of responsibilities emerged across the care continuum, as patients relied on providers to recommend AUD treatment, providers cited patient unwillingness as a primary reason for non-referral, and role ambiguity between hepatology and addiction specialists disrupted continuity of care. **Conclusion:** We suggest the following strategies to enhance AUD treatment engagement among patients with ALD: (1) Deepen patient and provider insights into the importance of treating AUD in asymptomatic and symptomatic ALD (2) Normalize AUD treatment for LT candidates and recipients (3) Increase provider comfort with MAUD to promote prescription initiation (4) Offer collaborative multidisciplinary care models integrating addiction medicine with hepatology to maintain treatment engagement.

2165 | REDUCED HEALTH-RELATED QUALITY OF LIFE PREDICTS UNFAVORABLE OUTCOMES IN PATIENTS WITH ADVANCED HEPATOCELLULAR CARCINOMA TREATED WITH ATEZOLIZUMAB AND BEVACIZUMAB. NEW SUBMISSION

Masako Shomura[1] Haruka Okabe[1] Maya Sakakibara[1] Emi Sato[2] Koichi Shiraishi[3] Yoshitaka Arase[3] Kota Tsuruya[3] Shunji Hirose[3] Yusuke Mishima[3] Tatehiro Kagawa[4], [1]Faculty of Nursing, Tokai University School of Medicine, [2]Department of Nursing, University of Tokyo Health Science, [3]Division of Gastroenterology, Department of Internal Medicine, Tokai University School of Medicin, [4]Tokai University

Background: Patient-Oriented Outcomes (PRO), particularly Health-related Quality of Life (HRQoL), are vital for patients with hepatocellular carcinoma (HCC). These outcomes are increasingly important for evaluating new treatments like the combination of atezolizumab and bevacizumab (Atezo+Bev). HRQoL can be affected by cancer symptoms and treatment-related adverse events (AEs). This study aimed to identify factors related to treatment efficacy, duration, and overall survival (OS) in HCC patients receiving Atezo+Bev, focusing on their characteristics, including AEs and HRQoL assessed at three months. **Methods:** We followed up consecutive HCC patients treated with Atezo+Bev from November 2020 to March 2025, with tracking until May 2025, or the patient's death. Treatment efficacy was assessed using modified RECIST criteria at 6 to 9 weeks. HRQoL was monitored monthly with the EORTC-QLQ C30. We analyzed relationships between baseline characteristics, AEs, HRQoL, treatment efficacy, OS, and treatment duration using multivariate logistic regression and Cox's proportional hazards models. A nursing intervention program included education on self-monitoring, AE management, and telephonic consultations. **Results:** A total of 91 patients were enrolled in the study, mostly men (81%), with 56% aged 70 or older. Most had a Child-Pugh score of 5 (48%) and were classified as Barcelona Clinic Liver Cancer Stage C (36%). The disease control rate was 78.4%, and the objective response rate was 29.5%, with a median treatment duration of 8.6 months and an overall survival of 19.6 months. Common adverse events included fatigue (90%), hypoalbuminemia (80%), and thrombocytopenia (59%). HRQoL scores for general health, physical function (PF), role function (RF), and cognitive function (CF), along with symptoms like fatigue, nausea, and financial difficulties, significantly worsened in the first four months. CF score greater than 80 at 3 months (Odds Ratio [OR] 3.39, 95% Confidence Interval [CI]: 1.03–11.21, $p = 0.04$) was associated with a higher ORR. In contrast, TNM stage IV (OR 0.32, 95% CI: 0.12–0.87, $p = 0.02$) was associated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

with lower ORR. PF score of 80 or above (Hazard Ratio [HR] 0.48, 95% CI: 0.27–0.86, p = 0.01) and RF score of 80 or above (HR 0.53, 95%CI: 0.30-0.95) were associated with a more extended treatment duration, while DCP value greater than 1000 (HR 1.75, 95% CI: 1.75–2.85) was connected to shorter treatment duration. Predictors of longer OS included PF score of 80 or above (HR 0.50, 95% CI: 0.26-0.97) and RF score of 80 or above (HR 0.46, 95% CI: 0.25–0.86). Conversely, shorter OS was associated with grade 2 or more worsened hypoalbuminemia (HR 3.57, 95%CI: 1.48–8.59). **Conclusion:** HRQoL scores significantly declined by the fourth month of Atezo+Bev therapy in HCC patients. Decreased CF, PF, and RF scores indicated poorer prognosis. Managing AEs effectively with a multidisciplinary team can enhance HRQoL and improve outcomes during cancer treatment.

Background: MENA region is undergoing rapid demographic and metabolic shifts that may contribute to the growing burden of MASLD and its complications. We assessed trends in MASLD prevalence and associated disease burden, including cirrhosis and liver cancer (LC), from 2010 to 2021 across MENA countries. **Methods:** This ecological study analyzed data from the Global Burden of Disease (GBD) study, United Nations Population Division, and the NCD Risk Factor Collaboration from 2010 to 2021 across 21 MENA countries. Annual percent change (APC) was estimated using Joinpoint regression. Prevalence of compensated (CC) and decompensated cirrhosis (DCC) due to MASLD was modeled using country-level regression models. All prevalence and mortality estimates are age-standardized rates based on the entire population, including both children and adults. **Results:** Between 2010 and 2021, MENA region experienced significant demographic growth, with the population increasing from 518 million to 623 million with progressive aging trends. Modest improvements were observed in the Socio-demographic Index, reflecting gains in education, income, and fertility-related indicators. Concurrently, the region underwent significant metabolic shifts, with adult diabetes prevalence rising from 7.4% to 12.1% and obesity increasing from 25.4% to 31.3%. During this period, MASLD prevalence increased from 26.3% (117.97 million) in 2010 to 27.7% (164.31 million) in 2021 (APC = 0.47%; 95% CI, 0.35-0.59), with a steeper increase among adults aged ≥ 20 years (from 37.1% to 41.0%; APC = 0.90%; 95% CI, 0.79-1.01). MASLD-related cirrhosis increased from 0.22% (1.13 million) to 0.28% (1.73 million) (APC = 2.18%; 95% CI, 2.05-2.31) [CC (0.20% to 0.25%; APC = 2.24%) and DCC (0.020% to 0.025%; APC = 2.23%)]. Algeria, Iraq, Morocco, and Turkey had the highest increases (APCs > 2.8% for both CC and DCC). MASH-related cirrhosis mortality (APC = 0.60%), and DALYs (APC = 0.47%) increased. MASH-LC also increased in prevalence (APC = 2.90%), incidence (APC = 2.90%), mortality from 0.50 to 0.69

per 100,000 (APC = 2.87%), and DALYs (APC = 2.51%). Iran exhibited the most rapid increases (APC > 6%) for all LC outcomes, while Egypt accounted for over half of the region's LC DALYs in 2021. **Conclusion:** The prevalence of MASLD and associated complications, including cirrhosis and LC, increased substantially across MENA region from 2010 to 2021, with considerable variation across countries.

Figure. Trends in Age-Standardized (A) MASLD Prevalence (B) MASLD-related Cirrhosis Prevalence (C) MASLD-related Cirrhosis Mortality in the MENA Region, 2010–2021

◆ 2167 | SEXUAL HEALTH AFTER LIVER TRANSPLANTATION: AN UNRECOGNIZED PROBLEM AFFECTING QUALITY OF LIFE

Chanattha Thimphitthaya[1] Alvaro Noriega Ramirez[1] Dyanna Gregory[1] Arjmand Mufti[1] Shannan Tujios[1] Lisa VanWagner[1] Amit Singal[1] Nneka Ufere[2] Sarah Lieber[1], [1]University of Texas Southwestern Medical Center, [2]Massachusetts General Hospital

Background: Sexual health (SH) is an overlooked aspect of patient experiences and is greatly impacted by chronic health conditions. It remains unclear what factors are associated with better or worse sexual outcomes after liver transplantation (LT) and associated health-related quality of life (HRQoL). **Methods:** We performed a cross-sectional study of all adult LT recipients (LTRs) at least 1-year post-LT being followed at a large U.S. transplant center. An electronic survey assessed: 1) sexual activity after LT, 2) sexual interest and satisfaction,3) HRQoL using validated questionnaires from Patient-Reported Outcomes Measurement Information System (PROMIS). Sociodemographic and clinical data were also captured. Scores were reported as T-scores, with scores <40 representing low sexual interest or satisfaction. Factors associated with lower sexual satisfaction for LTRs were assessed using bivariate and multivariate analysis adjusting for age, gender, comorbidity, income, and LT indication. **Results:** A total of 239 LTRs completed surveys (response rate 43.9%); 59.8% were male with median (IQR) age of 58 (47,67 years) and median (IQR) time of 5.0 (2.9, 7.5) years post-LT. LT indications were alcohol-related (34.3%), metabolic dysfunction-associated steatotic liver disease (19.7%) and viral hepatitis (14.7%). A majority (77.6%) of patients were sexually active since LT; median time to sexual activity was 4-6 months. The most common reason for sexual inactivity was lack of interest (40.8%). Mean (SD) sexual interest scores were 45.9 (11.9) while mean sexual satisfaction scores were 49.5 (8.3). Of all patients, 75 (32.2%) reported low sexual interest. Among sexually active LTRs, 15 (11.4%) had low sexual satisfaction scores. Sexual interest and satisfaction scores positively correlated with physical and mental HRQoL scores ($p < 0.01$), especially for male patients. Age > 65 years, female gender, lower-income, and alcohol use disorder were associated with lower sexual satisfaction score (although non-significant) (Table1). Interestingly, LTRs with higher Charlson comorbidity index (i.e., higher comorbidity) were less likely to report low sexual satisfaction (adjusted odds ratio 0.10, 95% CI 0.02-0.58). **Conclusion:** Most LTRs return to sexual activity within 4-6 months post-LT. Sexual interest and satisfaction scores positively correlated with physical and mental HRQoL. These findings highlight the need for more proactive, patient-centered approaches to sexual health assessment and support in long-term transplant survivorship care.

Table 1. Odd ratios of factors associated with low sexual satisfaction scores after LT

Variable	Unadjusted OR (95% CI) (N = 132)	Adjusted OR (95% CI) (N = 125)

◆ 2168 | SOCIOECONOMIC DISPARITIES IN INCIDENCE, TREATMENT AND SURVIVAL AFTER HEPATOCELLULAR CARCINOMA IN ALCOHOL-ASSOCIATED CIRRHOSIS: NATIONWIDE DATA FROM DENMARK

Gro Askgaard[1] Morten Daniel Jensen[2] Joe West[3] Colin Crooks[3] Peter Jepsen[2], [1]Zealand University Hospital, [2]Aarhus University Hospital, [3]University of Nottingham

Background: Reducing socioeconomic disparities in health is a key strategic objective. This study investigated the socioeconomic pattern of hepatocellular carcinoma (HCC) incidence, treatment and mortality after HCC in patients with alcohol-associated (ALD) cirrhosis in a country with universal healthcare. **Methods:** We followed newly diagnosed patients with ALD cirrhosis identified in the nationwide Danish healthcare registries 2000-2018. Socioeconomic position was measured by educational length in four levels. First, we estimated the hazard ratio (HR) of HCC with increasing educational length in patients with ALD cirrhosis. Second, we followed the subset who developed HCC to examine the association between educational length and A) curative-intent HCC treatment (liver transplantation, liver resection or ablation), B) consultation with a specialized palliative care team, and C) mortality. All HRs were adjusted for age, sex, calendar-year, comorbidity and decompensation status. **Results:** During follow-up in 32,532 patients with ALD cirrhosis, HCC was diagnosed in 1430, and death occurred in 22,962 patients. There was a trend towards a higher HCC incidence in ALD cirrhosis patients with lower socioeconomic position compared to higher with a HR of 1.04 (0.99-1.09) per one-level decrease in socioeconomic position. Patients of lower socioeconomic position tended to be younger at HCC diagnosis and have more comorbidity, and they were less likely to receive curative intent-treatment and also less likely to have consultations with specialized palliative team (Table 1). For example, curative-intent HCC treatment was given to 25% versus 34% of patients of low versus high socioeconomic position. In addition, lower socioeconomic position was associated with increased mortality risk with a HR for mortality of 1.06 (1.00-1.11) per one-level decrease in socioeconomic position. **Conclusion:** Despite universal healthcare, we found socioeconomic disparities in the HCC incidence, treatment and mortality after HCC in patients with ALD cirrhosis. These findings highlight the need for individualized support for ALD patients.

Table 1. Treatment and survival after diagnosis of hepatocellular carcinoma in patients with alcohol-associated cirrhosis, according to socioeconomic position in Denmark 2000-2016.

Socioeconomic position	N	Men	Median age (IQR)	Curative-intent treatment*	Referral to specialised palliative care	Rate of death per 1000 person-years	Hazard ratio of all-cause death*
Low	583	79%	65 (60-71)	144 (25%)	137 (23%)	825 (755-898)	1.26 (1.03-1.70)
Medium-low	636	86%	66 (60-72)	176 (28%)	153 (24%)	787 (725-854)	1.16 (0.96-1.70)
Medium-high	158	82%	66 (60-71)	52 (33%)	41 (26%)	671 (569-792)	1.07 (0.77-1.50)
High	53	92%	58 (55-74)	18 (34%)	17 (32%)	704 (527-940)	(Reference)
Total	1430	83%	66 (60-72)	392 (27%)	348 (24%)	783 (741-827)	1.06 (1.00-1.11)

◆ 2169 | NOURISHING THE MIND: FOOD INSECURITY IS A KEY DETERMINANT OF HEPATIC ENCEPHALOPATHY RISK IN CIRRHOSIS

Somaya Albhaisi[1] Jennifer Dodge[1] Diana Segura[1] Norah Terrault[1] Ani Kardashian[1], [1]University of Southern California

Background: Hepatic encephalopathy (HE), a debilitating complication of cirrhosis, impairs quality of life and worsens prognosis. While malnutrition is a known risk factor for HE, the role of social determinants of health—particularly food insecurity (FI)—in HE is unknown. We investigated the association of FI and diet quality (DQ) with HE in a diverse cohort of outpatients with cirrhosis. **Methods:** We performed a cross-sectional analysis of 177 adults with decompensated cirrhosis evaluated for liver transplant (July 2023-present) from a single-center prospective cohort. FI was assessed by the validated USDA Household Food Security Survey. Participants were categorized as food secure if they had high or marginal food security and food insecure if they had low or very low food security. Individual DQ components were assessed by the NCI Dietary Screener Questionnaire. Participants were categorized as having HE, the primary

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

outcome, if they carried a chart diagnosis based on review of hepatology clinic notes and took 45 seconds to complete the Numbers Connect Test A. Logistic regression models examined the association of HE with (1) FI and (2) DQ, testing relevant covariates, (age, sex, ethnicity, cirrhosis etiology, BMI, income, MELD 3.0, and ascites severity), with the final models including only covariates with $p < 0.05$ per backward elimination. Results were reported as adjusted odds ratios (aOR) with 95% CI. **Results:** Of 177 participants (median age 56 years, 53% male, 74% Hispanic, median MELD 16), 24% experienced FI. HE was present in 35% of all participants and was more prevalent in the food insecure, compared to the food secure, group (52% vs 30%, $p = 0.007$). In multivariable analysis, odds of HE increased with FI (aOR for HE: 2.73, 95% CI: 1.27–5.87; $p = 0.01$) after adjusting for etiology [alcohol-associated liver disease (ALD), metabolic dysfunction-associated steatohepatitis (MASH)] and moderate-severe ascites (Figure 1). Individual dietary components (fruits, vegetables, added sugars, whole grains, dairy, fiber) were not associated with HE in unadjusted or adjusted models. **Conclusion:** FI is highly prevalent and linked to significantly increased odds of HE in decompensated cirrhosis. Given the lack of association with DQ, our findings suggest the FI-HE pathway may extend beyond conventional DQ and involve other mechanisms. Future studies should examine social factors that may present in the context of FI. Integrating social risk assessments into routine hepatology care may help identify high-risk individuals and improve HE outcomes, positioning FI as a modifiable factor directly impacting liver health equity.

Figure 1. Multivariable regression analysis demonstrating factors associated with greater odds of hepatic encephalopathy.

◆ 2170 | RISK FACTORS FOR LIVER INVOLVEMENT OF HYPERTENSIVE DISORDERS OF PREGNANCY

Sorvena Yoyo[1] Amy Shui[1] Cynthia Felton[1] Gabrielle Jutras[1] Roxanna Irani[1] Monika Sarkar[2], [1]University of California San Francisco, [2]University of California, San Francisco

Background: Hypertensive disorders of pregnancy (HDP) defined as gestational hypertension, pre-eclampsia, and Hemolysis, Elevated Liver Enzymes, Low Platelet (HELLP) syndrome may progress to liver involvement, adversely affecting maternal and fetal outcomes, and timing of delivery. However, risk factors for hepatic involvement of HDP are unknown, which is relevant to pregnancy counseling, risk stratification, and management. **Methods:** We evaluated risk factors for hepatic involvement of HDP (defined as pre-eclampsia plus ALT $\geq$ 50) or HELLP syndrome among all pregnancies at UCSF Health between 2014-2023 in patients aged 13-55, excluding those with chronic liver disease. Chart validation confirmed all HDP cases with liver involvement. Multivariable analysis included biologically relevant covariates, using generalized estimating equations models with exchangeable correlation structure to account for multiple pregnancies per patient. Risk factors for HDP with liver involvement were evaluated in the larger cohort of all pregnancies, with secondary analysis in the subgroup of pregnancies with HDP. **Results:** Among 50,517 pregnancies at our center, 6529 (13%) had an HDP, of which 430 (6.6%) manifested with liver involvement. In the HDP cohort without liver involvement, the racial/ethnic distribution was 31% White, 16% Asian, 6.9% Black or African American, and 15% Latina, vs 27% White, 12% Asian, 4.7% Black, and 25% Latina for those with HDP with liver involvement. Mean age was 34 vs 33 years in the HDP and HDP with liver involvement groups, and 19% vs 21% developed gestational diabetes (GDM), respectively. HDP subtypes included 1.2% with HELLP syndrome and $<1\%$ with eclampsia. On multivariable analysis of all pregnancies (Figure 1a), risk factors for liver involvement included BMI 25-29.9 (Adjusted OR 1.45, 95% CI 1.08-1.95), BMI $\geq$ 30 (AOR 2.54, 95% CI 1.88-3.44), GDM (AOR 1.32, 95% CI 1.03-1.68), and multiparity (AOR 4.81, 95% CI 3.58-6.47). Estimates overall persisted in the subgroup with HDP (Figure 1b), with Latina patients additionally having a higher risk for HDP with liver involvement (AOR 1.62, 95% CI 1.21-2.17). **Conclusion:** Liver involvement occurred in nearly 7% of pregnancies complicated by HDP. Risk factors for hepatic involvement included overweight/obesity, multiparity, GDM, and self-identified Latina ethnicity. These novel findings can inform risk-based counseling and management in the growing number of women at risk for hypertensive disorders of pregnancy.

◆ 2171 | DEMOGRAPHIC DISPARITIES IN RECRUITMENT FOR LIVER TRANSPLANT CLINICAL TRIALS IN THE UNITED STATES

Razan Aburumman[1] Saqr Alsakarneh[2] Saif Aburumman[3] Sarine Tahmazian[4] Tala Al Saleh[5] Mohammad Abuassi[6] Syed-Mohammed Jafri[7], [1]Department of Internal Medicine, Henry Ford Hospital, Detroit, MI, [2]Gastroenterology and Hepatology, The Mayo Clinic, Rochester, MN, [3]Department of medicine, The University of Jordan, [4]Henry Ford Hospital, Detroit, MI, [5]Department of Medicine, Henry Ford Hospital, Detroit, MI, [6]UCF/HCA Florida North Florida Hospital, [7]Henry Ford Health System

Background: Liver transplantation enhances survival rates and quality of life for patients with end-stage liver disease. However, concerns persist about the inclusivity of patient recruitment for clinical trials, leading to challenges in generalizing trial results to the broader population. Our goal is to compare the demographics of patients enrolled in clinical trials with those who receive liver transplants in the United States. **Methods:** We searched ClinicalTrials.gov for studies related to liver transplantation conducted between January 1, 2000, and December 31, 2024. National data on liver transplantation activity in the United States were obtained from the Organ Procurement and Transplantation Network (OPTN) website. We only included trials focused on the liver only as the transplanted organ, did not involved countries other the US, and that specified in their inclusion criteria that participants must be liver transplant reciepients or listed to recieve a live transplant. Statistical comparisons between the two groups were performed using IBM SPSS Statistics, version 26. **Results:** Based on OPTN data between 2000 and 2024, a total of 181,657 liver transplants were performed in the United States. We identified 141 liver transplantation studies conducted in the U.S. in the same time frame. Out of these, 86 studies met the inclusion criteria, involving 5,461 participants (Figure 1). 6 studies (7.0%) included participants under the age of 18, though two were limited to pediatric age ranges ("up to 12 only" and "3m–12y"). 78 studies (90.7%) included participants over the age of 65. The mean age of participants in studies that reported age (88.3%) was 54.5 years. From the 86 included trials, 62 (72.1%) were completed. Regarding transplant status, 45 trials (52.3%) included patients who had already received a transplant, while 38 (44.2%) included listed patients; only trials (3.5%) included both. Most studies were interventional (94.2%), with only 5 observational trials (5.8%). In terms of trial settings, 49 (57.0%) were single-center (Table 1). In the clinical trials, 1,748 participants (32.01%) were female, compared to 66,079 (36.4%) female liver recipients ($P < 0.001$). Race data were available from 48 studies, showing that 2,716 participants (82.4%) were White, compared to 126,651 (69.7%) White liver recipients ($P < 0.001$). Thirty-three trials reported ethnicity, with 359 (13.1%) participants identified as Hispanic, compared to 27,947 (15.4%) Hispanic liver recipients ($P = 0.001$) (Table 2) **Conclusion:** Liver transplant outcomes have been shown to vary based on demographics such as gender, race, and ethnicity. Our study found that women and racial minorities are underrepresented in liver transplantation trials compared to actual transplant recipients. This lack of diversity limits the generalizability of findings and underscores the need for more inclusive recruitment practices.

Table 1: Summary of Liver Transplant Clinical Trials (n = 86)

Category	Subcategory	Number of Trials	Percentage (%)
Trial Status	Completed	62	72.1%
	Terminated	24	27.9%
Transplant Inclusion	Received Only	45	52.3%
	Listed Only	38	44.2%
	Both Listed/Received	3	3.5%
Study Type	Interventional	81	94.2%
	Observational	5	5.8%
Center Type	Single-Center	49	57.0%
	Multi-Center	37	43.0%

◆ 2172 | SIGNIFICANT DISPARITIES IN INPATIENT PALLIATIVE CARE CONSULTATION AND MORTALITY AMONG HOSPITALIZED ADULTS WITH DECOMPENSATED CIRRHOSIS

Shyam Patel[1] Sohil Patel[2] Robert Wong[3], [1]California Pacific Medical Center, [2]University of California, San Francisco School of Medicine, [3]Division of Gastroenterology and Hepatology, Department of Medicine, Stanford University

Background: Patients with decompensated cirrhosis have decreased quality of life, higher healthcare resource utilization, and high mortality. Although palliative care (PalCare) services have the potential to enhance health-related quality of life, they are often underutilized in vulnerable populations. We assessed socio-demographic and racial/ethnic disparities in PalCare utilization and all-cause mortality among U.S. adults hospitalized with decompensated cirrhosis. **Methods:** Adult hospitalizations for decompensated cirrhosis were identified using relevant ICD-10 codes from the 2021 to 2022 National Inpatient Sample (NIS). PalCare utilization was compared between groups, and adjusted multivariable logistic regression models evaluated for independent predictors of receiving PalCare. Comparisons of all-cause inpatient mortality were similarly evaluated with adjusted multivariable logistic regression models. **Results:** Among 117,476 hospitalizations for decompensated cirrhosis (median age 58 years, 61% male, 65.2% non-Hispanic white (NHW), 16.9% Hispanic, 8.9% African American (AA), 4.1% Asian/Pacific Islander (API), 2.6% American Indian/Alaska Native (AI/AN), 67.3% publicly insured, and 31.1% < $25,000 annual household income), 12.0% received PalCare consultation. Compared with NHW patients, significantly lower odds of receiving PalCare was observed among AA (aOR, 0.92; 95% CI, 0.86-0.99, $P < 0.05$) and Hispanics (aOR, 0.75; 95% CI, 0.71-0.79, $P < 0.05$). Overall inpatient mortality among decompensated cirrhosis hospitalizations was 9.2%, which was significantly higher in non-white ethnic minorities (10.8% in AA, 10.7% in API, 10.5% in AI/AN) compared to NHW (8.9%). On multivariable regression, compared to NHW patients, significantly greater odds of inpatient mortality was observed among AA (aOR, 1.13; 95% CI, 1.05-1.21, $P < 0.05$), API (aOR, 1.21; 95% CI, 1.09-1.34, $P < 0.05$), and AI/AN patients (aOR, 1.18; 95% CI, 1.04-1.33, $P < 0.05$). Patients with lower annual household income also had significantly higher odds of mortality compared to those from higher income households (Table 1). **Conclusion:** Significant disparities in inpatient PalCare utilization and mortality persists among hospitalized adults with decompensated cirrhosis, particularly among racial/ethnic minorities and lower income groups. Further efforts should focus on enhancing access to appropriate PalCare services among vulnerable populations.

Table 1. Multivariable Logistic Regression Models for Receipt of Palliative Care Consultation and Inpatient Mortality

Dental College, [5]Quinnipiac University Frank H. Netter MD School of Medicine / St. Vincent's Medical Center, [6]CMH Kharian Medical College, [7]Jersey Shore University Medical Center, [8]Methodist Dallas Medical Center, [9]Beth Israel Deaconess Medical Center/ Harvard Medical School, [10]Bacha Khan Medical College, [11]Asian Institute of Medical Sciences, [12]UAB Montgomery program/Heersink school of Medicine

Background: Alcoholic liver disease (ALD) is a major contributor to chronic liver injury and a well-established risk factor for hepatocellular carcinoma (HCC). With rising alcohol consumption and earlier onset of liver dysfunction, ALD-driven HCC poses a growing public health concern in the United States. However, national-level mortality trends in ALD-associated HCC, particularly among older adults, remain underexplored. This study aims to analyze 25-year mortality trends of ALD-related HCC in U.S. adults aged 45 and older, with emphasis on demographic and regional disparities. **Methods:** Mortality data from the CDC WONDER database (1999–2023) were analyzed using Joinpoint regression to assess ALD and HCC-related deaths among U.S. adults aged 45 and older. Age-adjusted mortality rates (AAMRs) per million were calculated, along with the average annual percent change (AAPC) and corresponding 95% confidence intervals (CI). **Results:** Over the 25-year study period, ALD-associated HCC accounted for 16,729 deaths. From 1999 to 2023, the AAMR increased from 0.08 to 0.41 per 100,000, reflecting a 412.5% rise (AAPC: 6.86; 95% CI: 5.62 to 8.25; $p < 0.000001$). Females experienced a more pronounced increase compared to males (females: AAPC: 8.05; 95% CI: 5.24 to 11.26 vs. males: AAPC: 6.89; 95% CI: 5.66 to 7.98; both $p < 0.000001$). Among racial and ethnic groups, Hispanics or Latinos had the highest AAMR (0.56), indicating an 82.5% increase, followed by non-Hispanic (NH) Whites (AAMR: 0.21), reflecting a 457.14% increase. The steepest rise was seen among NH Whites (AAPC: 8.07; 95% CI: 6.83 to 10.11; $p < 0.000001$), followed by Hispanics or Latinos (AAPC: 3.66; 95% CI: 2.58 to 5.77; $p < 0.000001$). Regionally, the West bore the highest mortality burden (AAMR: 0.41), followed by the South (AAMR: 0.22) and the Midwest (AAMR: 0.21). The Midwest showed the fastest increase in mortality (AAPC: 8.77; 95% CI: 7.34 to 11.05; $p < 0.000001$), followed closely by the South (AAPC: 8.63; 95% CI: 7.67 to 9.89; $p < 0.000001$). States in the 90th percentile for mortality included Oregon, Vermont, and New Mexico, while those in the 10th percentile included New Jersey, West Virginia, and Arkansas. Urban and rural areas showed comparable AAMRs (0.23 vs. 0.22, respectively). Adults aged 65 and older consistently exhibited higher mortality rates than those aged 45–64 (AAMR: 0.52 vs. 0.43), with a steeper increase in the older age group (AAPC: 7.58 vs. 5.41; $p < 0.000001$ for both). **Conclusion:** ALD-related HCC mortality has surged by 412.5% over 25 years in the U.S., with the highest burden in adults aged 65+, females, non-Hispanic Whites, and Hispanics. The Midwest and South saw the fastest increases, while the West had the highest rates. These findings highlight the urgent need for targeted prevention in high-risk groups.

◆ 2174 | NATIONAL TRENDS IN DIABETES-ASSOCIATED HEPATOCELLULAR CARCINOMA MORTALITY BY SEX, AGE, AND RACE, 1999–2023

Sarpong Boateng[1] Bubu Banini[2] Ece Tolgay[2], [1]Yale New Haven Health, [2]Yale University

Background: Diabetes Mellitus (DM) is a well-established risk factor for hepatocellular carcinoma (HCC), and its rising prevalence may be contributing to increased liver cancer mortality. However, national trends in DM-related HCC mortality and disparities across demographic groups remain poorly characterized. Understanding the burden of diabetes-related HCC deaths by sex, race, age, and ethnicity can inform prevention strategies and guide surveillance efforts. We aimed to characterize national trends in diabetes-related HCC mortality in the United States (US) from 1999 to 2023. **Methods:** We analyzed U.S. mortality data from the CDC Wide-ranging Online Data for Epidemiologic Research (WONDER) from 1999 to 2023. Decedents aged ≥15 years with both HCC (ICD-10 code C22.0) and DM (E10–E14) listed as causes of death were identified. Mortality rates (MRs) per 100,000 population were calculated and stratified by year, sex, race/

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

ethnicity, and 10-year age groups. Mortality rate ratios (MRRs) used 1999 as the reference year, and the ratio of MRRs (RMRRs) compared trends by sex. Joinpoint regression identified temporal inflection points and estimated annual percent changes (APCs) with 95% confidence intervals (CI). **Results:** Between 1999 and 2023, 27,729 diabetes-related HCC deaths were reported among U.S. adults. Crude mortality rates increased from 0.2 to 0.5 per 100,000. Males exhibited higher rates than females, with a widening gap over time. In 1999, mortality rates were 0.3 per 100,000 in males and 0.1 in females. By 2023, rates rose to 0.8 in males and 0.3 in females. Male MRR increased from 1.00 (95% CI: 0.77–1.15) to 2.99 (2.68–3.06), and female MRR from 1.00 (0.90–0.90) to 2.45 (1.79–2.69). Joinpoint regression showed significant increases in mortality for both sexes over the entire period: males had an APC of 4.66% (95% CI: 4.11–5.14%) and females 4.58% (3.01–6.03%). White and American Indian/Alaska Native (AI/AN) individuals experienced the highest increases in crude mortality. Among Whites, mortality rose from 0.2 to 0.5 per 100,000 (APC: 6.67%, 95% CI: 6.09–7.25%). AI/AN rates rose from 0.3 to 0.8 (APC: 5.20%, 3.83–6.60%). Increases were also observed among Black (APC: 3.66%, 2.68–4.65%) and Asian/Pacific Islander populations (APC: 2.05%, 1.07–3.04%). Age-stratified analyses showed mortality acceleration among older adults. For those aged ≥85 years, APC was 5.60% (95% CI: 4.43–6.62%). Among individuals aged 75–84, APCs were 2.65% (1.41–3.25%) from 1999–2018 and 11.08% (5.01–25.55%) from 2018–2023. **Conclusion:** Diabetes-related HCC mortality in the US has more than doubled over the past 25 years, with growing disparities by sex, race, and age. Males and older adults carry a disproportionate burden, and rates are rising fastest among AI/AN and White populations. Tailored prevention strategies, early intervention, and equitable access to DM and liver disease care are critical to addressing the shifting epidemiology of HCC.

2175 | HEPATOCELLULAR CARCINOMA (HCC) IN CIRRHOTICS VS NON-CIRRHOTIC PATIENTS: DEMOGRAPHICS, SURVIVAL GAPS, RACIAL DISPARITIES: A SEER REGISTRY DATA ANALYSIS (2011-2021)

Eunice Aregbesola[1] Chiamaka Nwachukwu[2] Jonas McCaffrey[1] Ali Ahmad[1] Jamal Ibdah[1], [1]University of Missouri, Columbia, [2]Tulane University

Background: Hepatocellular carcinoma (HCC) accounts for over 90% of liver tumors. Although well-known to be associated with liver cirrhosis, HCC can be identified in patients without liver cirrhosis. In our study, we compared demographic and stage at diagnosis, as well as outcomes, in individuals with and without cirrhosis using a large database cohort. **Methods:** We analyzed 17,481 HCC cases from SEER 17 Registries (2011-2021) in individuals aged 20 and older with documented histological data. Cases were categorized based on biopsy-proven cirrhosis status and we classified cirrhosis based on METAVIR and ISHAK scores of F4 and 5-6, respectively. We used descriptive statistics, multivariate logistic regression, and Kaplan-Meier survival analysis to evaluate group differences. **Results:** Cirrhosis was present in 81.2% of the cases, reinforcing its central role in the development of HCC, while 18.8% of the cases were not cirrhotic. Cirrhotic cases were generally older (peak 60-69 years), Most patients were non-Hispanic White (48.13%), Hispanic (23.25%), and Black (11.01%), with a male predominance. Gender did not significantly affect cirrhosis status ($p = 0.6626$), but being over 40 was linked to cirrhosis ($p < 0.05$). Non-Hispanic patients had lower odds of cirrhosis when compared with Hispanic patients. This was statistically significant among non-Hispanic Black (OR = 0.44, CI = 0.44- 0.53), non-Hispanic white (OR = 0.66 CI = 0.57-0.76) and Asian/Pacific Islanders (OR = 0.38 CI = 0.31-0.45). American Indian/Alaska natives had slightly lower odds, which was not statistically significant (OR = 0.90, CI = 0.54-1.57). Non-cirrhotic patients were more often diagnosed at a later stage (odds ratio = 0.8803, $p = 0.045$). Non-cirrhotic patients had better survival rates despite later diagnoses ($p < 0.001$). **Conclusion:** HCC is more common among older and non-Hispanic white patients. Cirrhosis is strongly linked to HCC, with Hispanic patients having a higher likelihood of being affected compared to non-Hispanic patients. The non-cirrhotic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

group was diagnosed at more distant stages compared to the cirrhotic group, which was diagnosed at earlier (regional and localized) stages. This difference is likely due to increased surveillance. However, despite being diagnosed earlier, the cirrhotic group had poorer survival outcomes. These findings highlight the need for targeted prevention, improved early detection strategies, and interventions to address disparities in liver cancer outcomes.

2176 | REDUCED PULMONARY FUNCTION IS A LIVER FIBROSIS RISK FACTOR AMONG WORLD TRADE CENTER RESPONDERS BUT NOT AMONG THE GENERAL POPULATION

Ning Ma[1] Rowena Yip[1] Meena Bansal[2] michael crane[1] Sara Lewis[1] David Yankelevitz[1] Claudia Henschke[1] Andrea Branch[2], [1]Icahn School of Medicine at Mount Sinai, [2]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: Exposure to the World Trade Center (WTC) dust cloud caused extensive pulmonary damage and may have injured additional vital organs. We investigated reduced forced expiratory volume in 1-second (FEV_1) as a risk factor for advanced liver fibrosis (LF), comparing WTC General Responders (WTC-GRs) to the U.S. population, while adjusting for toxic metal exposure and other established LF risk factors. **Methods:** We analyzed data of 20,905 WTC-GRs and 11,602 National Health and Nutrition Examination Survey (NHANES) participants (Fig.1A). Advanced-LF was indicated by FIB-4 $\geq$2.67 plus alanine aminotransferase (ALT) elevation ($\geq$40 IU/L men, $\geq$31 IU/L women); FEV_1 was determined by spirometry. Cadmium data was from WTC-GR self-reports of pre-9/11 exposure and NHANES blood measurements. Univariable/multivariable logistic regression models were used to estimate odds ratios (ORs). Regression models included no less than 10 cases of advanced-LF per predictor and alternative models were built with different sets of predictors to accommodate the limited number of cases. Propensity score matching by age and sex was used in sensitivity analyses (n = 7,568 per group). **Results:** Among WTC-GRs, FEV_1 and cadmium exposure were associated with advanced-LF, with ORs of 0.74 (95%CI: 0.58-0.95) and 1.73 (95%CI: 1.42-2.09), respectively. Among NHANES participants, FEV_1 was not significantly associated with advanced-LF (OR = 0.68, 95% CI: 0.36-1.27), while cadmium had an OR of 1.42 (95%CI: 1.01-2.0). In a sensitivity analysis of participants matched on age and sex (Fig.1A), FEV_1 was associated with advanced-LF among WTC-GRs (OR = 0.68, 95%CI: 0.48-0.97) after adjusting for the sets of covariates indicated in Figure 1B, but FEV_1 was not associated with advanced-LF among NHANES participants (Fig.1C); cadmium exposure was positively, but not significantly, associated with advanced-LF among WTC-GRs (OR = 1.84, 95% CI: 0.91-3.73), while the blood levels of cadmium were significantly associated with advanced-LF among NHANES participants (OR = 1.41, 95% CI: 1.00-1.99). **Conclusion:** People with lung damage caused by extremely high toxic exposures to the upper respiratory track may have increased risk of advanced liver fibrosis and may benefit from liver disease screening. Cadmium exposure should be considered when assessing liver disease risk in all populations.

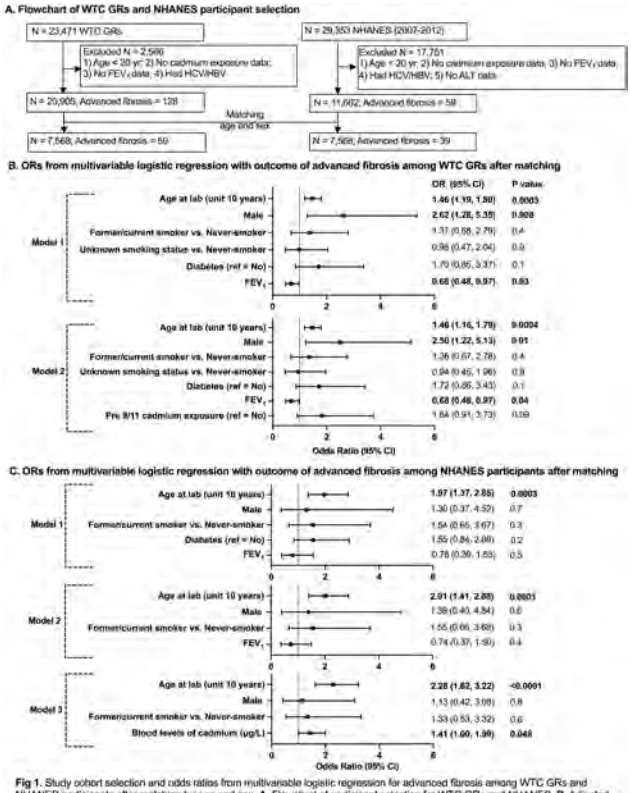

Fig 1. Study cohort selection and odds ratios from multivariable logistic regression for advanced fibrosis among WTC GRs and NHANES participants after matching by age and sex. **A.** Flowchart of participant selection for WTC GRs and NHANES. **B.** Adjusted odds ratios (ORs) for advanced fibrosis among WTC GRs after matching. **C.** Adjusted odds ratios (ORs) for advanced fibrosis among NHANES participants after matching.Abbreviations: OR, odds ratio; WTC GRs, World Trade Center General Responders; NHANES, National Health and Nutrition Examination Survey.

2177 | DIFFERENTIATING BETWEEN PREGNANCY- AND NON-PREGNANCY RELATED CAUSES OF LIVER ENZYME ELEVATIONS IN THE SECOND AND THIRD TRIMESTER: A MULTICENTER RETROSPECTIVE COHORT STUDY

Jeffrey Lowell[1] Nitzan Roth[2], [1]Northwell, Department of Medicine, New Hyde Park, NY, USA, [2]Northwell, Division of Hepatology, Department of Medicine, New Hyde Park, NY, USA and Zucker School

Background: Elevated liver enzymes in late pregnancy present a clinical dilemma given the need to rapidly differentiate between serious pregnancy-specific diagnoses and non-pregnancy-related liver disease to improve maternal-fetal outcomes through optimal delivery timing. Established diagnostic criteria for pregnancy-specific conditions may not effectively capture atypical presentations, leading to delayed recognition. We aimed to differentiate pregnancy- from non-pregnancy-related enzyme elevations in the second and third trimesters using patient and laboratory characteristics. **Methods:** We conducted a 5-year retrospective cohort study across two tertiary centers of 526 patients with elevated liver enzymes (AST and/or ALT ≥ 40 U/L) during the second or third trimester. Patients had peak antepartum liver enzyme levels ≤ 24 hours from delivery, and ≥ 2 antepartum measurements and ≥ 2 postpartum measurements peripartum. Liver injury was as classified pregnancy-related if both AST and ALT decreased postpartum prior to discharge or non-pregnancy-related otherwise. Demographic, clinical, and laboratory variables including diagnostic criteria for acute fatty liver of pregnancy, intrahepatic cholestasis of pregnancy, preeclampsia, and HELLP syndrome were analyzed. **Results:** Comparing pregnancy-related to non-pregnancy-related cases (Table 1), peak liver enzyme levels were significantly higher (ALT 99 [54-192] vs. 47 [34-72]; AST 84 [53-151] vs. 51 [41-64] U/L; both $p < 0.001$) and rapidly normalized postpartum ($p < 0.001$), while AST:ALT ratio was lower (0.87 [0.69-1.18] vs. 0.96 [0.72-1.47], $p = 0.007$). Pregnancy-related injury associated with higher LDH (301 vs. 260.5 U/L, $p = 0.003$) and WBC (12.9 [10.4-15.6] vs. 11.9 [9.6-14.9] K/μL, $p = 0.043$), with more frequent fulfillment of preeclampsia features (≥ 2, $p < 0.001$; ≥ 3, $p = 0.004$) and HELLP syndrome criteria (≥ 1, $p < 0.001$; ≥ 2, $p = 0.02$). A simplified diagnostic approach using either platelet count ≤ 150 K/μL or LDH > 300 U/L had 75% positive predictive value for identifying pregnancy-related cases ($p = 0.002$). Peak ALT emerged as the strongest independent predictor in multivariate analysis ($p = 0.016$; cutoff 79.5 U/L, AUROC 0.73; Fig 1). **Conclusion:** Among patients with liver enzyme elevations peaking ≤ 24 hours before delivery, two-thirds had pregnancy-related injury characterized by higher absolute liver enzyme values but rapid postpartum normalization. Peak ALT value, AST:ALT ratio, LDH, WBC, and platelet count aid in discriminating between pregnancy- and non-pregnancy-related liver injury. While established diagnostic criteria for pregnancy-related liver diseases provide important clinical frameworks, simplified diagnostic approaches meeting fewer formal criteria may facilitate earlier recognition of atypical pregnancy-related liver disease presentations.

2178 | IMPROVING LINKAGE TO CARE FOR HBV/HCV-EXPOSED MOTHER–INFANT DYADS IN NORTH CAROLINA: UNIVERSITY OF NORTH CAROLINA RELINK PROGRAM

Cory Spencer[1] Lauryn Ursery[2] Carl Seashore[3] Andrea Knittel[3] Elisabeth Johnson[3] Richard Moore[3] Asher Schranz[3] Peyton Thompson[3], [1]School of Medicine, University of North Carolina, Chapel Hill, USA, [2]Gillings School of Global Public Health, University of North Carolina, Chapel Hill, USA, [3]University of North Carolina, Chapel Hill, USA

Background: Hepatitis B virus (HBV) and Hepatitis C virus (HCV) are leading causes of liver-related mortality, resulting in 1.3 million global deaths each year. Elimination efforts focus on preventing vertical transmission but follow-up for postpartum individuals and infants is insufficient. The University of North Carolina (UNC) Relink program seeks to identify pregnant or postpartum people and infants affected by HBV and HCV to (i) identify diagnosed but untreated patients, (ii) describe their demographic characteristics, and (iii) provide linkage to care and testing. **Methods:** We systematically searched UNC Health (15 hospitals, 15.6% of statewide births) records for HBV+ or HCV+ pregnant or postpartum individuals May 2023-June 2024. HBV positivity was defined by a positive HBV surface antigen test and HCV positivity by detectable HCV RNA viral load. Medical records were reviewed to collect demographic, socioeconomic, and health information and identify whether mother-infant dyads were connected to care. Unlinked patients, defined as diagnosed but not receiving hepatitis care, were contacted by phone or MyChart to link them to follow-up care. Medical record and linkage data were collected in REDCap, and summary statistics were computed in R. **Results:** We identified 83 HCV+ and 17 HBV+ pregnant or postpartum individuals across NC (23% in eastern, 54% in central and 23% in western NC). Among HCV+ and HBV+ birthing persons, 92% (n = 76) and 71% (n = 12), respectively, were unlinked to care. Most unlinked HCV+ birthing persons were White (88.2%, n = 67), 100% spoke English, and half (52.6%, n = 40) had a diagnosed opioid use disorder (OUD), whereas unlinked HBV+ birthing persons were more racially diverse (Asian: 50%, n = 6; Other race: 25%, n = 3), 50% (n = 6) were non-English speaking, and none had an OUD diagnosis. We successfully contacted 37% (n = 28) of HCV+ and 83% (n = 10) of HBV+ unlinked birthing persons. To date, 18% (n = 5) and 20% (n = 2) of contacted HCV+ and HBV+ birthing persons have been linked to care, respectively (Figure 1). We also identified 79 HCV-exposed and 15 HBV-exposed infants, of whom 76% (n = 60) and 87% (n = 13), respectively, had not yet undergone testing. We successfully contacted families of 40% (n = 24) of HCV-exposed and 62% (n = 8) of HBV-exposed infants, of whom 25% (n = 6) and 50% (n = 4) have been linked to testing, respectively. **Conclusion:** Major care gaps remain for postpartum people and infants affected by HCV and HBV, and linkage efforts must be enhanced to achieve hepatitis elimination. UNC's Relink project has highlighted these gaps and the need for interventions to link untreated patients to care.

2179 | HEPATOCELLULAR CARCINOMA CARE DELIVERY: WHO IS AT RISK FOR DELAYS?

Elizabeth Ayomide Fashakin[1] Varun Rohatgi[1] Robert Brown[1] Resmi Charalel[1], [1]Weill Cornell Medicine

Background: HCC is curable if found and treated at an early stage. Prior studies have demonstrated an ideal timeline of less than 28 days between presentation to diagnosis and less than 62 days between diagnosis and treatment. Still, many patients experience delays in screening and diagnosis of HCC and further delays in treatment once officially diagnosed. Here, we identify where gaps in care are most likely to occur within our tertiary care center and who is most at risk. **Methods:** Retrospective, single-center cohort study of patients presenting with a new diagnosis of HCC (new LI-RADS 4 or 5 lesion or positive biopsy) between Jan 2018-Dec 2020 and Jan 2023-Dec 2023. Patients diagnosed in 2021 and 2022 were excluded due to changes in cancer care workflow during the COVID-19 pandemic. EHR was reviewed for clinical data and general demographic

information including age at diagnosis, race, native language, medical comorbidities, cirrhosis etiology, and socioeconomic status (via patient zip code and insurance status). Milestone timepoints for each patient's care were evaluated including dates of initial presentation, HCC diagnosis, treatment initiation, and referral to/evaluation by multidisciplinary specialists. Delays in presentation to diagnosis and diagnosis to treatment were defined as >28 and >62 days respectively. Categorical data were evaluated using Chi-square and continuous data via Kruskal Wallis testing. Bonferroni correction was applied for pairwise comparisons. **Results:** Among 2,504 records screened, 194 presented with new lesions suspicious for a new HCC with 187 formally diagnosed with HCC and 135 receiving treatment. Mean age was 67 years and the study population was racially and ethnically diverse (40% White, 11% Black, 27% Asian, 18% Other/Combined, 3% Not Reported) with 15% identifying as Hispanic/Latino. 41/187 (22%) experienced delays in diagnosis and 36/187 (27%) experienced delays in treatment. Nine of 194 patients (4.64%) passed away prior to receiving treatment. The most commonly referred specialties were hepatology (137/187, 73.3%) with a median diagnosis-to-evaluation time of 9 days (IQR: 0.5, 41), interventional radiology (122/187, 65.2%) with median time of 23 days (10, 46.25), and surgery (111/187, 59.4%) with median time of 14 days (0, 34). Time to diagnosis was shorter for those with private insurance (15.6 days) compared to Medicaid (27.8 days, $p = 0.003$) or Medicare (21.8 days, $p = 0.0023$). Otherwise, there was no significant association found between diagnostic delays and racial group, native language, or liver disease etiology (all p-values > 0.05 or exceeded corrected alpha). **Conclusion:** While most HCC patients receive timely care, even in our tertiary medical center with well-equipped multidisciplinary teams, about one-quarter of patients continue to experience diagnostic and treatment delays, with longer times to diagnosis for those insured by Medicaid and Medicare.

2180 | METABOLIC AND ALCOHOL-ASSOCIATED LIVER DISEASE IN HISPANICS: DISPARITIES IN OUTCOMES USING REAL-WORLD DATA

Mohamed Eldesouki[1] Ashlynn Black[2] Karimar Amador-Martinez[2] Ahmed Salem[3] Ahmed Ibrahim[4] Mohammed Youssef[5] Abdallah Hussein[6] Mona Ahmed[7] Nikki Duong[2], [1]New York Medical College at Saint Michael Medical Center, [2]Stanford University School of Medicine, [3]Maimonides Medical Center, [4]Medical University of South Carolina, [5]Hunt regional medical center, [6]Virtua our Lady Of Lourdes Hospital, [7]Mansoura University School of Medicine

Background: Metabolic and Alcohol-related Liver Disease (Met-ALD) is a newly defined subset of steatotic liver disease that combines ≥ 1 cardiometabolic risk factor with at-risk alcohol use. Liver-related outcomes in Hispanics with Met-ALD have been understudied. We used a large U.S. real-world data set to compare liver outcomes between Hispanic and non-Hispanic adults with Met-ALD. **Methods:** TriNetX U.S. Collaborative Network was queried for adults (≥ 18 y), diagnosed with Met-ALD. Patients were then stratified by ethnicity into Hispanic and non-Hispanic groups. Propensity-score matching (PSM) (1:1) balanced age, sex, body-mass index, diabetes, hypertension, dyslipidemia, and smoking. Matched patients were followed for up to three years from the Met-ALD index date. Study outcomes were cirrhosis, portal hypertension (HTN), variceal bleeding, acute liver failure (ALF), hepatocellular carcinoma (HCC), ascites, and hepatorenal syndrome (HRS). Adjusted odds ratios (aORs) with 95 % confidence intervals (CI) were calculated. **Results:** A total of 15,741 Hispanic and 120,507 non-Hispanic patients with Met-ALD were identified. After PSM, a total of 15,727 patients were identified in each group with balanced baseline covariates. BMI was 39.9 ± 22 in Hispanic group, and 38.4 ± 17.8 in non-Hispanics. (Table 1). After PSM, Hispanics had a higher rate of cirrhosis (14.37 vs. 12.15; OR = 1.21, 95% CI: 1.14–1.30, $p < 0.001$), portal HTN (9.15 vs. 7.36; OR = 1.27, 95% CI: 1.17–1.37, $p < 0.01$), ALF (7.55 vs. 6.87; OR = 1.11, 95% CI: 1.02–1.21, $p = 0.02$), variceal bleeding (1.20 vs. 0.86; OR = 1.41, 95% CI: 1.13–1.75, $p = 0.003$), and HCC (1.88 vs. 0.94; OR = 2.02, 95% CI: 1.66–2.46, $p < 0.01$) when compared to non-Hispanics. Ascites and HRS showed no significant difference (7.75 vs. 8.05; OR = 0.96, 95% CI: 0.89–1.04, $p = 0.30$), and (1.57 vs. 1.44; OR = 1.09, 95% CI: 0.91–1.31, $p = 0.35$), respectively. (Table 2). **Conclusion:** In this national cohort, Hispanic adults with Met-ALD experienced significantly greater liver-related morbidity including cirrhosis, portal

hypertension, variceal bleeding, acute liver failure, and HCC risk versus non-Hispanics. These findings underscore the urgent need for culturally tailored alcohol-reduction programs, equitable access to hepatology care, and enhanced HCC surveillance to mitigate the disproportionate burden of Met-ALD in Hispanic patients.

Table 1 Baseline characteristics for the study cohorts before and after propensity score matching

Variable (%)	Hispanics 15,741	Non-Hispanics 120,597	P-value	Hispanics 15,727	Non-Hispanics 15,727	P-value
Age	46.3 ± 13.1	52 ± 13.2	< 0.01	46.3 ± 13.1	46.3 ± 13.1	0.96
Female	3,888 (24.72)	39,995 (33.3)	< 0.01	3,888 (24.72)	3,886 (24.71)	0.97
CKD	711 (4.5%)	6,686 (5.5)	< 0.01	711 (4.52)	694 (4.41)	0.64
HTN	5,067 (32.21)	53,001 (44.13)	< 0.01	5,067 (32.22)	5,056 (32.15)	0.8

2181 | ADDRESSING FOOD INSECURITY AMONG PATIENTS WITH AND AT-RISK FOR MASLD: A QUALITATIVE STUDY TO OPTIMIZE A FOOD PHARMACY PROGRAM

Rebecca Kim[1] April Ballantyne[2] Hanna Hedges[2] Heather Williamson[2] Ellen Maxfield[2] John Inadomi[1] Molly Conroy[1] Andrew Gawron[1] Jennifer Price[3], [1]University of Utah Health, [2]University of Utah, [3]University of California, San Francisco

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD), the liver disease concomitant with obesity, diabetes, hypertension, and metabolic syndrome, disproportionately impacts individuals with lower income. Food insecurity (FI), the lack of consistent access to healthy foods, has been associated with advanced fibrosis and all-cause mortality among patients with MASLD. Our Food Pharmacy Program (FPP) is a mobile trailer equipped with hospital-grade foodservice equipment, designed to serve patients experiencing FI and nutrition-related chronic disease. Patients receive six month food prescriptions redeemable for healthy foods or gift cards, along with personalized health coaching that includes nutrition education, meal planning, and strategies for preparing affordable, healthy meals. We aimed to understand the experiences of former participants with and at-risk for MASLD, to optimize the FPP in preparation for a MASLD focused FPP. **Methods:** Seventeen participants were recruited through outreach methods, screened for eligibility with REDCap surveys, and provided verbal consent prior to focus groups. Groups followed a semi- structured interview guide and were recorded. Participants were given $75. Thematic analysis was performed using a codebook developed from audit trails. **Results:** Overall, 94% were women, mean age 55 yrs, 18% Black, 18% Hispanic, 53% White; all had FI. 59% had diabetes, 41% had hypertension, 59% had obesity, 12% had heart disease, 12% with MASLD. Themes emerged including: 1) health and nutrition education, 2) program benefits, 3) engagement and motivation, 4) suggestions for improvement. Participants reported that the FPP enhanced their knowledge of healthy eating, leading to healthier eating habits, improved cooking skills using fresh ingredients, and a more comprehensive understanding of nutrition. Many participants noted the high quality and variety of food provided by the FPP. They also valued the coaching sessions and found virtual appointments to be convenient and facilitated greater accountability. Reported barriers to engagement in the FPP included restricted operating hours, lack of transportation, inadequate internet access, limited length of prescription, and prior negative experiences with dieticians. Participants recommended increasing FPP awareness to providers, expanding accessibility through additional locations, and extending FPP hours and food availability. **Conclusion:** Former FPP participants with or at-risk for MASLD found the program to be beneficial to improve nutrition knowledge, eating habits, and food access. Their feedback describes opportunities to enhance the program as it is adapted for the MASLD population.

2182 | SOCIAL DEPRIVATION IS ASSOCIATED WITH AN INCREASED RISK OF DECOMPENSATION AND DECREASED ACCESS TO SPECIALTY CARE

Joy Obayemi[1] Mitchell Paukner[2] Bima Hasjim[3] Dominic Vitello[2] Aditya Jain[4] Federico Crippa[4] Kiarri Kershaw[5] Therese Banea[2] Lisa VanWagner[6] Lihui Zhao[2] Charles Manski[4] Daniela Ladner[2] Daniela Ladner[2], [1]University of Michigan / Northwestern University, [2]Feinberg School of Medicine, Northwestern University, [3]University of California, Irvine, [4]Department of Economics, Northwestern University, [5]Northwestern University, [6]Department of Medicine, University of Texas Southwestern Medical Center

Background: The transition from compensated to decompensated cirrhosis is associated with significant morbidity and mortality. Little is known about how structural and socioeconomic environments may correlate with the timing of this transition and access to specialty care. **Methods:** A longitudinal, retrospective, cohort study of patients with compensated cirrhosis using administrative claims data from 2011-2021 was conducted. Diagnoses, decompensation events, and access to gastroenterology (GI) specialists were defined by validated ICD/CPT/provider specialty codes. Structural and socioeconomic deprivation was categorized using the standardized Area Deprivation Index (ADI) [ADI1 = least deprived (0-20), ADI2 = less deprived (21-40), ADI3 = moderately deprived (41-60), ADI4 = more deprived (61-80), ADI5 = most deprived (81-100)]. Time-to-event analysis of first decompensation event was performed using a Cox model adjusted for clinicodemographic covariates and restricted mean survival time (RMST). Descriptive statistics were used to calculate median time to decompensation and access to specialty care. **Results:** Among 200,823 patients identified with cirrhosis, 51.8% (n = 104,095) were male and most patients had MASLD (n = 72,805; 36.25%), MetALD (n = 36,533; 18.19%) or ≥ 2 etiologies (n = 42,894; 21.36%). 28.6% (n = 57,489) experienced a decompensation in the 10-year follow-up period. Patients in areas of higher deprivation (ADI2 HR 1.06; ADI3 HR 1.12; ADI4 HR 1.16; ADI5 HR 1.13; all $p < 0.001$) were at higher risk of decompensation than those in the least deprived areas (ADI1) [Figure 1]. The median time to decompensation for patients in ADI5 was 9.89y (95% CI 9.49-10.30) compared to 6.73y (95%CI 6.45-6.96) in ADI 1 ($p < 0.001$). Patients in ADI 5 were expected to survive 6.69y (95% CI 6.65-6.74) in 10 years of follow-up without a decompensation event compared to an expected 5.98y for patients in ADI 1 (95% CI 5.92-6.03) (pairwise RMST $p < 0.001$). As deprivation increased, the proportion of patients who saw a GI specialist in the 6 months prior to cirrhosis diagnosis (ADI1 22.38% vs ADI5 11.14%) and in the 12 months following cirrhosis diagnosis (ADI1 29.53% vs ADI5 15.02%) decreased. **Conclusion:** Structural and socioeconomic deprivation is associated with faster decompensation and decreased access to GI specialists for patients with cirrhosis. This presents an opportunity for targeted patient interventions in deprived neighborhoods to slow disease progression.

2183 | LOW DISEASE AWARENESS AMONG METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) AND MASLD CIRRHOSIS IN THE UNITED STATES

Zobair Younossi[1] James Paik[2] Leyla de Avila[3] Brian Lam[4] Andrei Racila[1] Annette Paik[1] Arianna Nader[1] Asrar Alaklabi[5] Fatema Nader[1] Andrei Racila[1] Linda Henry[1] Saleh Alqahtani[5], [1]The Global NASH Council, [2]Beatty Liver and Obesity Research Program, [3]Beatty Liver and Obesity Research Program, Inova, [4]INOVA Fairfax Hospital, [5]Liver, Digestive, and Lifestyle Health Research Section, and Organ Transplant Center of Excellenc

Background: Despite the growing burden of MASLD, patients' awareness has been low. We assessed liver disease awareness among U.S. adults with MASLD. **Methods:** We analyzed data from U.S. adults participating in NHANES (2007–2023). MASLD was defined using either a validated U.S. Fatty Liver Index or controlled attenuation parameter (CAP $\geq$280 dB/m) in accordance with recent consensus. Chronic hepatitis B (HBV), chronic hepatitis C and cirrhosis were defined as HBsAg (+), HCV RNA (+) and liver stiffness measurement $\geq$20 kPa. Liver disease awareness was determined by self-reported current liver diseases including fatty liver, hepatitis, or cirrhosis. **Results:** The study included 24,676 participants (2007 to 2023). Over this period, liver disease awareness among MASLD increased from 4.39% to 5.76% (trend $p = 0.016$), while awareness among those with HBV or HCV remained stable ($p > 0.05$). In the most recent NHANES cycle (2017-2023, N = 12,976), 33.6% had MASLD, 1.2% MASLD-related cirrhosis, 0.9% HCV, and 0.3% HBV. In this period, awareness of fatty liver among MASLD was 4.8%, awareness of cirrhosis among MASLD-cirrhosis was 6.5% while awareness of hepatitis among HCV and HBV was 21.8% and 26.1%.Awareness of liver disease varied according to age [highest 45–64 yrs (5.9%)], race/ethnicity [lowest in Non-Hispanic Black individuals (1.0%) but highest among Other Hispanics (8.0%)] (all $p < 0.02$). According to the healthcare setting, attendees of Veterans Affairs (VA) medical center had the highest awareness (15.8%) compared to community health centers (6.4%), emergency departments (6.1%), and urgent care centers (4.9%) ($p < .017$). Awareness also differed by insurance: highest awareness among those with military health coverage (9.6%) and lowest among the uninsured (2.4%). Sociodemographic and metabolic conditions-adjusted model showed male sex and non-Hispanic Black race were significantly associated with lower awareness, while receiving care at a VA medical center was associated with higher awareness of liver disease. (Table). **Conclusion:** Despite some improvements, awareness among MASLD patients remains very low. This low awareness is especially concerning among MASLD with cirrhosis.

Table. Awareness of Liver Disease Among U.S. Adults with MASLD by Demographic and Healthcare Access Characteristics, NHANES 2017–2023

	Awareness % (95% CI)	p-value
Age Group		0.0364
18 - 29	2.07 (0.08 - 4.05)	
30 - 44	4.26 (1.88 - 6.64)	
45 - 64	5.86 (4.65 - 7.07)	
≥ 65	4.81 (3.28 - 6.34)	
Race		<.0001
Non-Hispanic White	4.69 (3.49 - 5.88)	
Non-Hispanic Black	0.95 (0.31 - 1.59)	
Mexican American	6.41 (3.41 - 9.41)	
Other Hispanic	7.97 (4.74 - 11.20)	
Asian	4.23 (2.47 - 5.99)	
Education		0.0109
Less than high school	5.06 (2.57 - 7.55)	
High School	5.59 (4.17 - 7.01)	
College	3.28 (2.26 - 4.29)	
Primary Source of Routine Healthcare		<.0001
Community Health Center / Clinic	6.37 (4.88 - 7.86)	
Emergency	6.11 (1.41 - 10.80)	
Urgent Care Facility	4.94 (-0.27 - 10.14)	
Veterans Affairs Medical Center	15.75 (5.58 - 25.92)	
Health Insurance		0.0174
Private Insurance	4.10 (2.85 - 5.36)	
Medicare	6.78 (4.25 - 9.32)	
Medicaid/CHIP & Other Govt	7.64 (3.97 - 11.30)	
Military Health Care	9.60 (-6.05 - 25.24)	
Uninsured	2.40 (0.66 - 4.14)	

Adjusted Odds Ratios of Factors Associated With Liver Disease Awareness Among U.S. Adults With MASLD, NHANES 2017–2023

	OR (95% CI)	P
Male	**0.43 (0.21 - 0.89)**	**0.0265**
Non-Hispanic Black	**0.13 (0.04 - 0.50)**	**0.0052**
Veterans Affairs Medical Center	**4.97 (1.61 - 15.32)**	**0.0084**

2184 | OVERLOOKED AND UNDERDOSED: HEPATITIS B TREATMENT INEQUITIES IN US MIGRANTS

Raissa Nana Sede Mbakop Forlemu[1] Anuj Sharma[1] Manasa Ginjupalli[1] Arnold Nongmoh Forlemu[1] Madhavi Reddy[1], [1]The Brooklyn Hospital Center

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Chronic hepatitis B (HBV) disproportionately affects migrants in the United States, particularly those from high-prevalence regions such as East and Southeast Asia, sub-Saharan Africa, and the Pacific Islands. Although effective treatments are available, many migrants face barriers to diagnosis and care, including language difficulties, lack of insurance, limited health literacy, and fear related to immigration status. These challenges contribute to delayed treatment and higher rates of liver complications such as cirrhosis and hepatocellular carcinoma. Despite national screening guidelines, significant disparities persist in HBV care among migrant populations. We evaluated adverse events and rates of underdosing of hepatitis B antiviral treatment in migrant Hepatitis B patients with the goal of informing policies and interventions that promote more equitable access to care. **Methods:** We included hepatitis B patient population seen in United States health care facilities from 2018-2022 using the Nationwide inpatient sample database. We further subdivided the migrants per geographic location in the US. Propensity score matching was used to balance confounding factors between migrants to natives. Time to hepatitis B treatment adverse events and dosing were estimated using Kaplan-Meier. Adjusted hazard odds ratios for hepatitis B treatment adverse events and dosing were estimated using Cox-proportional hazards regression models, while accounting for competing events. Adjusted hazard ratios (HR) and confidence intervals (CI) at 95% were reported. **Results:** The number of patients with hepatitis B was 352,860, 3.8% of them were immigrants. The mean age of study population was 55.6 years. Majority of immigrant hepatitis B patients were male at 76.4%. On regression analysis, Migrant patients with hepatitis B were more likely to have treatment related disparities including adverse events with a hazard ratio of 2.20 (CI 1.35-3.61, $p = 0.002$) compared to natives. Also, migrants were more likely to have their hepatitis B treatment underdosed with a hazard ratio of 3.65 (CI 2.15-6.19, $p = 0.001$), compared to natives. Time to event curves also showed a significant trend to underdosing and adverse events among immigrants compared to natives (Figure 1). No meaningful differences were observed between natives and migrant hepatitis B populations within geographic US regions. **Conclusion:** Migrants were more likely to have side effects to hepatitis B treatment and to be under dosed. It is known that many migrants have irregular access to care including insurance issues, making dose monitoring difficult. In addition, misunderstanding treatment instructions by migrants can lead to incorrect dosing, nonadherence, or combining with harmful substances. Addressing this requires policy reform, provider education, and tailored care models that account for the unique challenges faced by migrant populations.

2185 | MEDICAL MISTRUST AMONG PATIENTS WITH EARLY-STAGE ALCOHOL-ASSOCIATED LIVER DISEASE: INSIGHTS FROM THE PROSPECTIVE DALLAS DIONYSUS COHORT

Elias Rady[1] Hamza Dahshi[2] Ahmad Anouti[1] Bill Zhang[1] Courtney Roberts[3] Thomas Kerr[1] Nicole Rich[1] Amit Singal[1] Amit Singal[1] Mack Mitchell[1] Thomas Cotter[1], [1]University of Texas Southwestern Medical Center, [2]Case Western Reserve University School of Medicine, Medical Scientist Training Program, [3]University of Texas Southwestern Medical School

Background: Medical mistrust is a known barrier to care, particularly for stigmatized conditions like alcohol-associated liver disease (ALD), which frequently coexists with alcohol use disorder (AUD). Despite its potential impact on care delays and late-stage disease presentation, few studies have explored mistrust in patients with ALD. We aimed to characterize the prevalence of medical mistrust among patients with early-stage ALD to inform strategies for improving patient engagement with care. **Methods:** We conducted a survey among adults with early-stage ALD enrolled at UT Southwestern Medical Center and Parkland Health between September 2024 to present. Participants completed the validated 12-item Group-Based Medical

Mistrust Scale (GBMMS), which evaluates perceived discrimination, lack of support and suspicion toward healthcare providers. Each item was rated on a 5-point Likert scale, with scores >3 indicating high mistrust (range 1-5). Surveys were administered in person by trained research staff. We calculated mean GBMMS scores and used Wilcoxon Rank Sum test or Kruskal-Wallis for categorical variables and linear regression for continuous variables to examine the association between mistrust and clinical, demographic, and psychosocial factors. **Results:** Among 88 patients approached, 70 (80%) participated in the survey (median age 54.6 years, 86% men, 20% Hispanic). Mean GBMMS scores ranged from 1.22 to 2.09 (mean 1.59; SD 0.79), with 10.1% of participants reporting high mistrust. Item 2 (doubts about doctors' intentions toward their ethnic group) exhibited the highest frequency of high mistrust at 22.7%, while the frequency for all other items remained below 14%. Higher mean GBMMS summary scores were significantly associated with younger age ($p < 0.01$), single marital status ($p = 0.027$), and immigrant status ($p = 0.031$). Hispanic patients were more likely than non-Hispanic counterparts to perceive information withholding by doctors (46% vs 2%; $p = 0.01$), have doubts about doctors' intentions toward their ethnic group (38% vs 19%; $p = 0.02$), and fear that information confided to healthcare providers may be used against them (23% vs 4%; $p = 0.04$). **Conclusion:** We found medical mistrust is common among patient with early-stage ALD, particularly among Hispanic, single, and immigrant individuals, and may be a barrier to ALD care. These findings highlight the opportunity for interventions to promote trust, increase care engagement, and improve ALD outcomes.

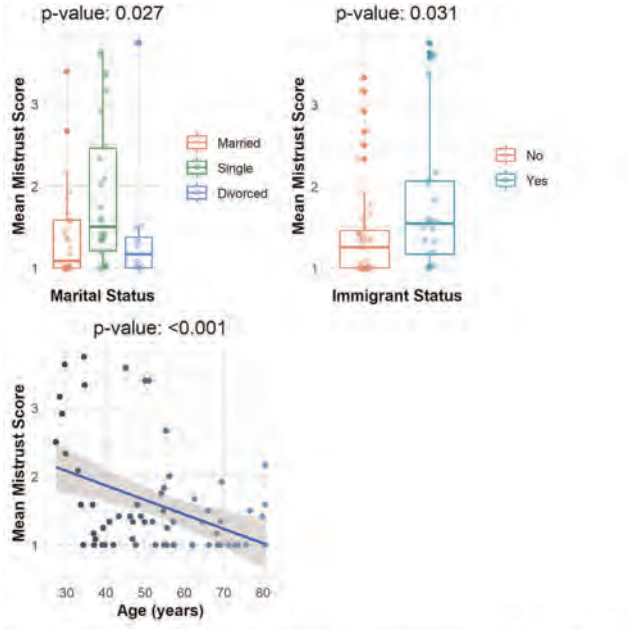

Figure 1 – Mean Group-Based Medical Mistrust Scale (GBMMS) scores by marital status, immigrant status, and age.

2186 | ANALYZING THE READABILITY OF LLM-GENERATED PATIENT INFORMATION FOR LIVER DISEASES

Husayn Ramji[1] Aishwarya Gatiganti[1] Shaquille Lewis[1] Anveet Janwadkar[1] Jacob Lampenfeld[1] Stephanie Mrowczynski[1] Larry Zhou[1] Matthew Houle[1] Pooja Arumugam[1] Luis Morales[1] Sharan Poonja[1] Peng-

Sheng Ting[2], [1]Tulane University School of Medicine, [2]Tulane University School of Medicine Department of Gastroenterology and Hepatology

Background: Numerous generative artificial intelligence (AI) tools are available today. Many large language models (LLMs), such as ChatGPT, are already being utilized to generate educational materials for patients on both an inpatient and outpatient basis. Although LLMs have made strides in providing evidence-based information, the degree to which they are consistently meeting the Agency for Healthcare Research and Quality's (AHRQ) recommendation of presenting information to patients at a sixth grade reading level or below remains to be seen. LLMs are powerful tools, but they must consistently be able to meet the needs of our patients to be reliable tools. This project is one of the first to analyze the readability of AI-generated educational materials in hepatology. **Methods:** ChatGPT 4o, Gemini 2.5, Claude 3.7, and OpenEvidence were each asked three distinct prompts: Prompt 1 ("Explain [condition]"), Prompt 2 ("I am a patient who was just diagnosed with [condition]. What is that?"), and Prompt 3 ("Explain [condition] to a patient"). The conditions that the LLMs were asked to explain were Cirrhosis, Hepatocellular Carcinoma (HCC), hepatitis, NAFLD, and MASLD. Each LLM was asked the same prompt three times for every condition, leading to a total of 180 outputs across the prompts and LLMs. The grade reading level of each output was assessed with the Sydney Health Literacy Lab (SHeLL) Health Literacy Editor tool, which provides the validated SMOG index measure of reading level, alongside other metrics. After testing for normality, appropriate analysis and significance testing took place for within-model comparisons across prompts, and for between-model comparisons with the same prompt, with $p < 0.05$ being deemed statistically significant. **Results:** All four LLMs demonstrated statistically significant improvements in reading level from Prompt 1 to Prompt 3 ($p < 0.001$), but none of the LLMs reached the goal of providing information at or below a sixth grade reading level. Of the LLMs, ChatGPT provided information that was the objectively easiest to read, going from an average reading level of 12.29 on Prompt 1 to an average of 10.23 ($p < 0.001$) on Prompt 3. The others ranged from 14.66 to 21.90 on Prompt 1, and 11.18 to 13.41 on Prompt 3. Gemini consistently provided the longest outputs, while OpenEvidence provided the most complex. **Conclusion:** Current leading LLMs require further refinement before they can be consistently utilized to address the health literacy gap and assist in educating patients about liver diseases. Until LLMs can consistently provide information at the reading level of the patient, utilization of LLMs on inpatient and outpatient settings must be approached with caution and oversight. Future directions will involve testing more specific prompts, formally evaluating the accuracy of outputs, and potentially testing liver-disease specific LLMs in their ability to educate patients effectively.

Table 1: Average SMOG Index by LLM, with within-model Prompt Comparisons

	ChatGPT	Gemini	Claude	OpenEvidence
Prompt 1 (P1) ± SD	12.29 ± 1.66	14.66 ± 0.75	14.97 ± 2.22	21.90 ± 3.30
Prompt 2 (P2) ± SD	10.97 ± 0.84	12.99 ± 0.47	13.87± 1.38	21.72 ± 3.19
Prompt 3 (P3) ± SD	10.23 ± 0.75	12.09 ± 0.47	11.18 ± 0.62	13.41 ± 1.13
Normal	No	Yes	No	No
Significance	p<0.001	p<0.001	p<0.001	p<0.001
P1 v P2	<0.05	<0.001	0.4076	0.8476
P1 v P3	<0.001	<0.001	<0.001	<0.001

2187 | ALCOHOL, INEQUALITY, AND LIVER CIRRHOSIS: CAN DRINKING PATTERNS AND CARDIOMETABOLIC RISK FACTORS EXPLAIN THE SOCIOECONOMIC GAP?

Jonas Rønn[1] Gro Askgaard[1] Lone Madsen[1] Jessica Mellinger[2] Peter Jepsen[3] Matilde Winter-Jensen[4] Marie Eliasen[4] Merete Osler[4], [1]Zealand University Hospital, Køge, Denmark, [2]Department of Gastroenterology, Henry Ford Health System, Detroit, Michigan, USA, [3]Department of Hepatology and Gastroenterology, Aarhus University Hospital, Aarhus, Denmark, [4]Center for Clinical Research and Prevention, Bispebjerg and Frederiksberg Hospital, Denmark

Background: There is socioeconomic inequality in the incidence of cirrhosis. We investigated 1) the contribution of alcohol drinking pattern and cardiometabolic factors to socioeconomic inequality in cirrhosis incidence, and 2) whether the association of these risk factors with cirrhosis risk depended on socioeconomic status. **Methods:** We included participants from the population-based Danish National Health Surveys 2010-2017 and followed them until December 31st, 2022, for an incident hospital diagnosis of cirrhosis, linking data from questionnaires and health registries. Socioeconomic position was measured by educational length. The socioeconomic inequality of cirrhosis incidence was estimated as the hazard ratio (HR) of cirrhosis in those with short ($<= 9$ years) vs. long (> 17 years) educational length. 1) The contribution of alcohol drinking pattern (drinks per week, drinking days per week, drinking outside of meals) and cardiometabolic factors (body mass index (BMI), diabetes, hypertension, dyslipidemia, smoking) to socioeconomic inequality of cirrhosis was measured by

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

the socioeconomic inequality in HR for cirrhosis with versus without adjustments for these risk factors. 2) We used interaction tests to examine whether the association of alcohol and cardiometabolic risk factors on the incidence of cirrhosis depended on socioeconomic position. All analyses were weighted for sampling procedure and differential participation in the health surveys according to sociodemographic and health variables. **Results:** The study included 301,559 participants with a median age of 49 years (IQR 40.3-59.1), 50% were female, 19% had a short education length, and 12% had a long education length. With decreasing educational length, there was a gradual increase in the prevalence of drinking above 28 drinks/week, smoking, BMI >30, and the other cardiometabolic risk factors. During 2,711,309 person-years of follow-up, 1015 participants were diagnosed with cirrhosis. The HR for cirrhosis in short vs. long education length was attenuated from 3.85 (95% CI: 2.60; 5.71) in the age- and sex adjusted analysis to 3.60 (95% CI, 2.44; 5.32) when further adjusted for alcohol drinking pattern, and to 2.72 (95% CI, 1.84; 4.03) when fully adjusted for alcohol drinking pattern and cardiometabolic factors. The strength of the association between alcohol drinks per week and any cardiometabolic risk factor on cirrhosis risk did not depend on education length (p-values for interactions were all $>$ 0.4). Figure 1 shows the similar associations of drinks per week with cirrhosis incidence across socioeconomic position. **Conclusion:** When alcohol drinking pattern and cardiometabolic factors were considered, there was still a nearly three-fold higher incidence of cirrhosis in short vs. long educated. The relative harmful effect of alcohol was irrespective of educational level, and a similar pattern was observed for the influence of cardiometabolic factors.

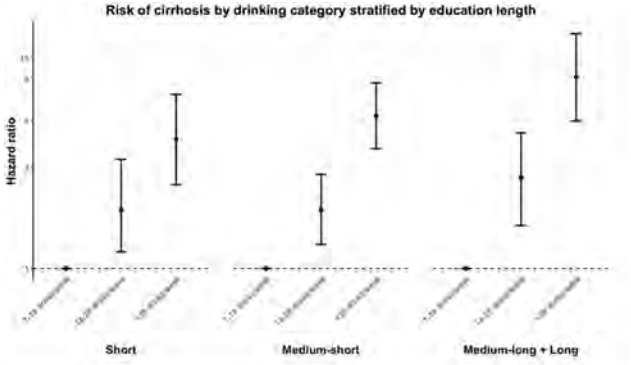

Figure 1. Incidence of cirrhosis according to alcohol consumption by education length. Hazard ratios for incident cirrhosis for participants in the Danish National Health Surveys 2010-2017 (n = 301,559) with follow-up until 31st December 2022. Hazard ratios are adjusted for age, sex, BMI, drinking days, drinking outside meals, smoking status, diabetes, hypertension, and dyslipidemia. Medium-long and Long educational groups have been pooled.

2188 | HEPATOLOGY AND THE HOME: A NOVEL HOME-BASED ETHNOGRAPHIC APPROACH TO INFORMAL CAREGIVING FOR END-STAGE LIVER DISEASE IN A U.S. URBAN SAFETY NET SETTING

Ramón Casillas-Salazar[1] Simon Beaven[1] Shaun Chandna[1] Soma Wali[1] Arleen Brown[2] Philippe Bourgois[2] Utpal Sandesara[2], [1]Olive View-UCLA Medical Center, [2]University of California - Los Angeles

Background: End-stage liver disease (ESLD), a major cause of morbidity and mortality, exhibits significant socioeconomic disparities. While caregiving can be a critical determinant of health, we lack comprehensive analyses of ESLD caregivers' experiences, particularly in settings of poverty, linguistic/ethnic minority status, and limited healthcare access. Our aim is to ethnographically assess experiences of multiethnic informal caregivers for ESLD patients in close collaboration with a U.S. urban safety-net health system. **Methods:** This study leverages the strengths of inductive anthropological data collection and grounded theory analysis. We combine domestic observation, longitudinal home-based ethnographic interviews, clinical observation, and health system personnel interviews to explore how caregivers experience disease-specific learning, monitoring, management, communication, advance care planning, and caregiving assets and challenges. We are guided by a 6-member community action board that brings together researchers, hepatologists, community health workers, caregivers, and patients. **Results:** Based on preliminary in-depth engagement with 7 families (of an anticipated 24 total), we present 3 findings with bearing on practice and policy: (1) Caregiver and patient understandings of the liver's regenerative capacity can foster an optimism that belies the biological precarity of advanced fibrosis/cirrhosis, thereby hindering timely intervention to prevent progression. (2) Breakdowns in communication with providers who diagnose ESLD frequently position caregivers and families to potentially misunderstand the severity, nature, and volatility of the disease. (3) An ESLD diagnosis can reconfigure family dynamics, shifting power in ways that create new agency; this may allow caregivers to reclaim autonomy, reintegrate households, and better support patients. **Conclusion:** We lack comprehensive analyses of ESLD caregivers' experiences, particularly in the U.S. safety net. Deeper understandings of ESLD caregiving can guide direct interventions, clinical care adaptations, and upstream measures to improve health system-caregiver

partnership. This project's community-engaged, anthropological approach shows how home-based research can inform better hepatologic care. Our findings suggest potentially untapped opportunities for partnering with caregivers to enhance ESLD prevention, improve disease knowledge, and leverage novel family dynamics to augment clinical interventions.

2189 | ESCALATING LIVER CANCER BURDEN IN WOMEN ACROSS THE UNITED STATES: A 22-YEAR ANALYSIS OF GEOGRAPHIC, RACIAL, AND AGE-BASED DISPARITIES

Raghava Rao Alluri[1] Parvinder Kaur[2] Yashkumar Kamani[3] Sandeep Kotnani[4] Jainil Parikh[5] Mahir Modi[6] Madhu babu Adusumilli[7] Hardik Desai[8], [1]Prime South GME Consortium/Harlingen Medical Center Program, [2]The Crimean State Medical University named after S.I. Georgievsky, Simferopol, Ukraine, [3]"BronxCare Health System ", [4]Rutgers Monmouth Medical Center, [5]GMERS MEDICAL COLLEGE, GOTRI, VADODARA, [6]GCS Medical College Hospital and Research Centre, [7]HCA Ocala Florida hospital -UCF, [8]Independent Clinical and Public Health Researcher

Background: While breast, lung, and colorectal cancers remain the leading malignancies in U.S. women, liver cancer has shown one of the most rapid increases in incidence and mortality. Its rising burden, coupled with poor prognosis and modifiable risk factors, warrants focused epidemiologic evaluation across diverse subgroups. **Methods:** We utilized data from the CDC WONDER database spanning 1999–2021 to evaluate LC incidence and mortality in U.S. women. Annual counts and age-adjusted rates per 100,000 population were extracted. Annual Percent Change (APC) was computed using Joinpoint regression for both absolute and age-standardized rates, stratified by census region, state, race, Hispanic origin, and age group. **Results:** From 1999 to 2021, LC deaths among women increased from 3,287 to 5,538 (APC: +2.84%), with the age-adjusted mortality rate rising from 2.09 to 2.40 per 100,000 (APC: +0.95%); incidence counts rose from 3,432 to 7,539 (APC: +4.11%), and the age-adjusted incidence rate increased from 2.24 to 3.34 per 100,000 (APC: +2.14%). The most pronounced regional increases in LC mortality were observed in the South and West, with death counts rising annually by 3.55% and 3.50%, respectively. At the state level, Montana exhibited the most significant increase in incidence, rising from 22 cases in 1999 to 75 in 2021 (APC: 9.11%), followed by Tennessee (6.79%) and South Carolina (6.38%). Marked racial disparities were observed, with American Indian or Alaska Native women experiencing the highest escalation in both incidence (8.68%) and mortality (6.05%), while incidence among Black and White women rose by 5.02% and 3.96%, respectively. Hispanic women showed a steeper increase, with incidence rising from 413 to 880 cases (6.49%) and deaths from 291 to 528 (5.41%). Age-specific analyses revealed that women aged 60–64 years demonstrated the most accelerated rise in disease burden, with incidence increasing by 7.59% and mortality by 6.13% annually, followed by the 65–69 and 55–59 age groups. **Conclusion:** LC burden among U.S. women has escalated markedly over the past two decades, with disproportionate increases in the South and West, among American Indian or Alaska Native and Hispanic populations, and in women aged 60–69 years. These findings underscore the need for urgent, tailored public health strategies to mitigate rising LC disparities through improved screening, risk reduction, and equitable access to care.

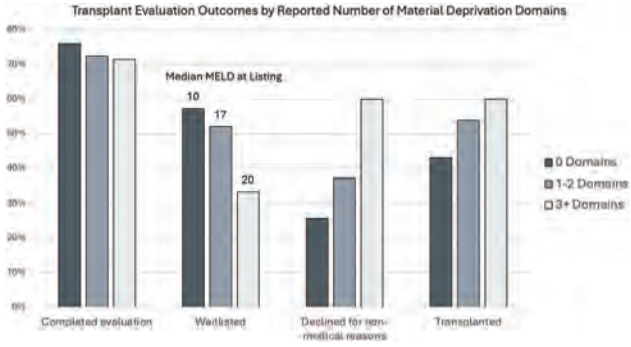
2190 | SOCIAL RISK SCREENING AMONG LIVER TRANSPLANT CANDIDATES: IMPACT OF MATERIAL DEPRIVATION ON TRANSPLANT OUTCOMES

Mark Wang[1] Christopher Wong[1] Kali Zhou[1], [1]Keck School of Medicine, University of Southern California

Background: Social barriers play a major role in successful navigation of the liver transplant (LT) process. Few studies have conducted prospective social risk screening among adult LT candidates. We examined frequency of material deprivation (lack of access to basic necessities) derived from a social risk screener and impact on transplant outcome. **Methods:** Adult LT candidates who completed an adapted AHC Health-Related Social Needs Screening Tool at initial LT evaluation clinic visit at a high-volume transplant center between 11/1/2021-12/31/2022 were included. Material deprivation was assessed across five domains: housing, food, finances, transportation, and social support insecurities. Sociodemographic, clinical, and LT outcome data (through 4/2025) were abstracted from medical records and compared by deprivation status. Associations of material deprivation (individual domains and categorized into 0, 1-2, or 3+ domains) with LT waitlisting were examined using univariate logistic regression. **Results:** 219 patients were screened with median follow-up of 14.4 (3.6-28.7) months. Median cohort age was 59 (52-65), 56% male, 64% Hispanic, and 42% alcohol etiology. Prevalence of material deprivation was as follows: 27% reported food insecurity, 15% transportation insecurity, 15% financial insecurity, 14% housing insecurity, and 5% social support insecurity. 59%, 32%, and 10% reported material deprivation in 0, 1-2, and 3+ domains, respectively. Candidates reporting material deprivation were more likely to be foreign-born, Medicaid-insured, unemployed, and lower income, with higher median MELD at evaluation (15 vs 12), more hepatic encephalopathy, and less hepatocellular carcinoma (all $p < 0.05$). Higher material deprivation categories had lower proportion waitlisted, but higher proportion transplanted, potentially driven by medical urgency evidenced by higher MELD at listing (Figure). Of the five domains, only housing insecurity was significantly associated with lower odds of listing (OR = 0.30, 95% CI 0.12-0.76, $p = 0.01$), while there was a trend towards lower odds of listing with 3+ domains (vs 0) (OR = 0.38, 0.13-1.11, $p = 0.08$). **Conclusion:** Over 40% of LT candidates report having material deprivation in at least one social risk domain. Housing insecurity and having more than three affected domains may impact likelihood of waitlisting. Studies are needed on the impact of material support interventions on increasing LT equity for populations experiencing social vulnerability.



Disclosures: Mark Wang: Nothing to Disclose, Christopher Wong: Nothing to Disclose, Kali Zhou: Gilead Sciences Inc: Grant/Research Support, Merck: Grant/Research Support

2191 | THE ROLE OF SOCIAL DETERMINANTS OF HEALTH ON HEPATITIS B DURING PREGNANCY IN MASSACHUSETTS AND WITHIN THE UNITED STATES

Ami Patel[1] Katherine Cooper[2] Alessandro Colletta[1] Deepika Devuni[2], [1]Univeristy of Massachusetts, [2]University of Massachusetts

Background: Hepatitis B Virus (HBV) is the leading cause of chronic hepatitis worldwide. HBV during pregnancy poses significant risk, in the absence of appropriate immunoprophylaxis the risk of vertical transmission is up to 90%. Given the high risk of transmission both the United States Preventive Services Task Force and the American Congress of Obstetricians and Gynecologists have recommended screening for HBV during pregnancy. **Methods:** In this study we evaluated the impact of social determinants of health (SDOH) on HBV during pregnancy leveraging state and national databases. Data was obtained from the Perinatal Hepatitis B Prevention Program (PHPP) housed by the Massachusetts Department of Public Health (MADPH). The PHPP is a case management program for women with HBV during pregnancy to ensure access to care. Baseline characteristics were reported among the cohort and compared to expected values in Massachusetts (MA). Next, United States (U.S) census data was used to overlay the percent living below poverty and percent born outside the US in each county from which patients were referred. A query of the TriNetX database was then used to validate these findings in database containing health record data from 70 health care organizations in the U.S using specific ICD-10 codes for SDOH (Z55-X65). Z-score was used to compare race of women with HBV to the MA population. **Results:** A total of 215 women (median age 36 years) were enrolled in PHPP in 2022. Most women were of Asian (30%, z = 0.39) or African (25%, z = 0.32) decent, which was disproportionately

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

higher than expected compared to MA population (79% white, z = 1.25, 10% African, z = .0.13, 8% Asian, z = 0.10). A greater than expected proportion were also born outside the U.S. (53%, z = 0.72vs. 18%, z = 0.23). Most participants were from Suffolk County (23%) which had the highest proportion of women living below poverty per 2022 census data. Vertical transmission was 0% in neonates born to mothers who were positive for HBV and in PHPP. In a nationally representative cohort, 1,522 pregnant women with HBV were compared to 232,829 pregnant women without HBV. Women with HBV were older (32.1 ± 5.4 vs. 30.9 ± 5.9, $p < 0.01$), more likely to be Hispanic/Latino (33% vs. 18%, $p < 0.01$) and Asian (11% vs 5%, $p < 0.01$). Women with HBV during pregnancy were significantly more likely to have problems related to housing/economic insecurity (OR 2.75, 95% CI 2.10-3.39, $p < 0.01$) and social support (OR 2.53, 95% CI 1.78-3.51, $p < 0.01$). **Conclusion:** Women with HBV during pregnancy have complex SDH concerns. Immigration status, primary language, poor English literacy, and housing/economic instability contribute to HBV diagnosis during pregnancy. Further interventions are needed to target high-risk communities and increase access to care for both prevention and treatment. Lastly, programs such as PHPP allow for close monitoring of patients with HBV during pregnancy and are effective at reducing vertical transmission to neonates.

2192 | SEX-SPECIFIC DIFFERENCES IN CARDIOMETABOLIC RISK FACTORS AND RISK OF SIGNIFICANT LIVER FIBROSIS IN THE U.S. GENERAL POPULATION: AN ANALYSIS OF NHANES 2017-2020

Somaya Albhaisi[1] Steve Kim[2] Norah Terrault[1] Jennifer Dodge[1], [1]University of Southern California, [2]Keck/USC Department of Population and Public Health Sciences

Background: Cardiometabolic risk factors (CMRFs) are key drivers of metabolic dysfunction–associated steatotic liver disease, yet sex-specific links to advanced fibrosis remain unclear. Clarifying this can improve risk stratification, screening, and sex-informed management. This study examines the sex-stratified differential effect of CMRFs on significant fibrosis in U.S. adults. **Methods:** We conducted a population-based, cross-sectional analysis of U.S. adults ≥ 20 years without viral hepatitis using 2017–2020 NHANES data, which included transient elastography measurements. Primary outcome: significant fibrosis (defined as liver stiffness ≥ 8.0 kPa). CMRFs were defined per ATP III: waist circumference (WC) > 102cm [M]/ > 88cm[F]; fasting glucose ≥ 100 mg/dL or treatment; BP ≥ 130/85 mmHg or treatment; triglycerides ≥ 150 mg/dL or treatment; HDL < 40 mg/dL(M)/ < 50 mg/dL(F) or treatment. Obesity (BMI ≥ 30 kg/m² or ≥ 27.5 for Asians) was also assessed. Multivariable logistic regression evaluated associations between CMRFs and significant fibrosis, stratified by biologic sex, adjusting for age, race/ethnicity, smoking, and alcohol, with sex-by-CMRF interactions tested. Subgroup analyses were performed: (a) adults with severe steatosis (CAP ≥ 280 dB/m); (b) excluding heavy alcohol use (> 50 g/day women, > 60 g/day men). **Results:** Among 5,981 adults, women (N = 2992) compared to men (N = 2989) had a higher prevalence of high WC (69.0% vs 48.6%) and low HDL (42.6% vs 39.7%) and a lower prevalence of HTN (41.0% vs 44.9%), glucose intolerance (31.1% vs 41.7%) and hypertriglyceridemia (36.6% vs 48.8%). Obesity prevalence (41.9% vs 42.3%) was similar by sex. The prevalence of significant fibrosis was 6.9% (95%CI 5.4-8.8) in women and 10.7% (95%CI 8.8-12.9) in men. The association of significant fibrosis was significantly greater in women versus men for high WC (aOR 13.45 [95%CI 5.70–31.78] vs 4.44 [95%CI 3.00–6.57]; $p = 0.01$), glucose intolerance (2.94 [1.64–5.28] vs 1.51 [1.08–2.13]; $p = 0.04$), and presence of ≥ 2 CMRFs (10.22 [4.76–21.95] vs 2.87 [1.91–4.31]; $p = 0.002$) (Figure 1). In the subgroup with steatosis (N = 2,452), odds of significant fibrosis were disproportionately greater in women vs men for presence of ≥ 2 CMRFs (4.88 [1.62–14.74] vs 1.83 [0.98–3.42]; $p = 0.06$). Results were similar when individuals with heavy alcohol use were excluded with statistically significant differences for high WC (13.22 [5.55-31.50] vs 4.58 [3.01-6.95]; $p = 0.02$) and presence of ≥ 2 CMRFs (10.07 [4.70-21.60] vs 2.88 [1.88-4.40]; $p = 0.003$). **Conclusion:** In U.S. adults, women with ≥ 2 CMRFs had a nearly 5-fold higher likelihood of having significant fibrosis than men, revealing key sex-specific vulnerabilities. These findings suggest that women—despite historically being considered lower risk—may harbor a hidden burden of significant liver disease when multiple CMRFs are present and that

sex-specific screening strategies warrant consideration.

2193 | THE IMPACT OF INDIVIDUALIZED SOCIOECONOMIC MEASURES ON LIVER TRANSPLANT WAITLIST OUTCOMES IN A MULTICENTERED STUDY

Saurav Panda[1] Bradley Johnson[1] Chung-Il Wi[2] Elizabeth Krusemark[1] Ummah Salma Nisar[3] Kymberly Watt[1], [1]Mayo Clinic Rochester, MN, [2]Mayo Clinic, Rochester, MN, [3]East Tennessee State University, Johnson City, TN

Background: Data suggests socio-economic factors impact outcomes on the liver transplant (LT) waitlist but lack granularity on an individual basis. We aimed to investigate the application of a novel socioeconomic index termed the HOUSES index for its impact on waitlist outcomes in a multicentered setting compared to Area deprivation index (ADI). **Methods:** This multicentered retrospective study included 1448 patients listed for LT between 2010-2020 specifically with diagnoses of MASH, cholestatic disorders and ALD. Baseline laboratory values, clinical characteristics and demographics were recorded at the time of listing and removal from the waitlist. The HOUSES index provides socioeconomic data derived for each patient, based on the individual addresses provided at the time of listing (analyzed by highest socio-economically disadvantaged quartile(Q1) to the least (Q4)) while the ADI state ranking is based on the census block group. Cox proportional hazards models were fit using HOUSES quartiles and ADI ranking to assess waitlist mortality at 5 years. **Results:** Mean age of the cohort was 56.4 (SD 10.2), 61% male and 87% non-Hispanic ethnicity. Patients with MASH or ALD were more prevalent in the lower HOUSES quartiles (Q1&2) than patients with cholestatic disease (39% and 41% vs 19%, $p = 0.03$). Of the 1448 patients waitlisted, 184 were removed due to death ($N = 97$) or being 'too sick' ($N = 87$) for LT, while 1264 received a LT. In the adjusted multivariate model, Quartile 2 (Q2) [HR:2.50; 1.14 – 5.50, $p < 0.022$], age [HR:1.05; 1.01 –1.09, $p = 0.008$], MELDNa at listing [HR: 1.11; 1.05 – 1.17, $p < 0.001$] and driving distance from transplant center between 180-360 miles [HR: 2.48; 1.04 – 5.91, $p = 0.041$] turned up as significant predictors for death/too sick waitlist removal. Candidates in Q2 had an 18% lower likelihood of receiving LT [aHR: 0.82; 0.70-0.95, $p < 0.011$] while those in Q3 it was 15% lower [aHR: 0.85; 0.74-0.99, $p < 0.03$], when compared to Q4. In contrast, the ADI model was unable to show any significant results for its ranking system when predicting waitlist mortality. Cohen's weighted test between the two indices showed a κ of 0.244 (0.212, 0.277),$p <$ 0.001, highlighting only meagre agreement. **Conclusion:** This study demonstrates the use of individualized socioeconomic measures (i.e., HOUSES index) are superior to area dependent indicators and may help identify increased risk of waitlist mortality. The ability to identify individual risk will allow for individualized intervention addressing these needs.

2194 | SOCIAL NEEDS SCREENING AND COMMUNITY RESOURCE REFERRALS INTEGRATED INTO ROUTINE HEPATOLOGY CARE

Rebecca Kim[1] April Ballantyne[1] Jia-Wen Guo[1] Bob Wong[1] John Inadomi[2] Molly Conroy[2] Jennifer Price[3] Andrea Wallace[1], [1]University of Utah, [2]University of Utah Health, [3]University of California, San Francisco

Background: Health-related social needs (HRSN) contribute to worse outcomes in chronic liver disease (CLD), yet routine HRSN screening remains uncommon in hepatology. To address this gap, we implemented HRSN screening in liver clinics at our academic medical center to integrate screening into clinical workflows and to connect patients with needs to available community resources. **Methods:** From 12/2024-03/2025, a validated 10-item HRSN screener was integrated into routine hepatology care through electronic health record-based workflows and staff training. Screening was completed via MyChart or in person during pre-visit check-in. Beginning 04/01/2025, patients reporting social needs and interested in assistance were referred to external support. Descriptive analyses included mean and frequency. Comparative analyses were performed using Chi-Square and Fisher's exact tests. **Results:** Among 1,064 liver clinic patients screened, 53% were female, 76% White, 9% Hispanic/Latino, 5% Asian, 3% Native American/Alaska Native (NA/AN), 2% Black, 1% Native Hawaiian/Pacific Islander (NH/PI). Most (96%) spoke English. Reported needs included limited finances for household items (11%), food insecurity (FI) (10%), utility insecurity (10%), and housing costs (9%). No significant differences in HRSN were found by gender, language (English vs. non-English), rural vs. urban residence, or clinic visit type (transplant vs. general hepatology). However, differences emerged by race/ethnicity: transportation needs were more common among NH/PI (33%) and NA/AN (7%) ($p = 0.022$). Utility insecurity differed significantly: Black (22%), NH/PI (17%), NA/AN (14%), Hispanic/Latino (13%) ($p = 0.048$). Similarly, housing cost challenges were reported by 33% NH/PI, 17% Black, 14% NA/AN, and 10% Hispanic/Latino patients ($p = 0.036$). There was a trend toward significance in FI by race/ethnicity ($p = 0.063$). Small sample sizes of subgroups may have impacted results. Of the 10 people referred to resources, 70% were male, 80% White, 10% NA/AN, 10% undisclosed race. High rates of reported HRSN were observed: limited finances for household items (60%), utility insecurity (60%), housing cost burden (80%), and unemployment (40%). An additional 110 patients selected "prefer not to answer" for one or more question, and were excluded from analysis. Over half (54%) of these patients selected "yes" for at least one social need. Therefore, this exclusion likley led to an underestimation of HRSN, as those declining to answer all questions disproportionately reported other HRSN. **Conclusion:** HRSN screening was successfully integrated into liver clinic workflows, revealing unmet social needs, particularly among racial/ethnic minority groups. However, these findings also demonstrate the need to further assess the acceptability of and stigma related to HRSN screeners among CLD patients.

2195 | DEMOGRAPHIC AND REGIONAL DISPARITIES IN GLP-1 RECEPTOR AGONIST CLINICAL TRIALS FOR WEIGHT LOSS WITH A SPECIFIC FOCUS ON MASLD/MASH: A COMPARATIVE META-ANALYSIS OF US AND INTERNATIONAL RCTS

Kimberly Ho[1] Taranika Sarkar Das[2] Joao Filipe Goncalves Monteiro[3] Sonali Paul[4] Paige McLean Diaz[5], [1]Brown University, [2]NYU Langone Health, [3]Brown Medicine, [4]University of Chicago Medical Center, [5]Brown Medicine/Brown University Health

Background: GLP-1 receptor agonists (GLP-1 RAs) treat obesity, a key driver of metabolic-dysfunction

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

associated steatotic liver disease (MASLD) and steatohepatitis (MASH). The burden of these liver diseases is poorly defined in GLP-1 RA trials. We conducted a meta-analysis of RCTs to assess MASLD/MASH burden, lipid disorders, and global representation in GLP-1 trials. **Methods:** We reviewed 149 English-language RCTs that looked at GLP-1 RAs for weight loss from 2015 to 2024. Random-effects meta-analyses assessed demographic and clinical differences in US vs international trials using relative risk (RR). **Results:** Of the 149 studies screened, 24 met inclusion criteria and were included in the meta-analysis (N = 16,600), comprising 15 US-based studies (N = 12,906) and 9 international studies (N = 3,694). The pooled prevalence of MASLD/MASH was 18% (95% CI: 8%–27%, N = 6,479; I^2 = 99.47%). Prevalence was significantly lower in US RCTs at 8% (95% CI: 4%–13%) compared to 26% (95% CI: 11%–41%) in international RCTs. MASLD/MASH was 66% less likely among US participants (RR = 0.34 [0.20–0.49]). There was limited international data, including only 4 of 11 studies (573/962 subjects, 60%) that were conducted outside the US in Asia, Europe, and South America. No studies reported liver function test results or FibroScan data. Lipid disorders were reported in 45% of participants overall (95% CI: 34%–55%, N = 7,327, I^2 = 98.94%) with a slightly lower prevalence in US studies (41%, 95% CI: 25%–58%) than in international RCTs (48%, 95% CI: 35%–61%). Compared to international studies, US participants were 27% less likely to have lipid disorders (RR = 0.72 [0.63–0.82]). Across all studies, participants experienced a mean weight loss of 10.8% ± 5.8% from baseline. Weight reduction was slightly greater in US participants (11.3% ± 5.9%) compared to those in international studies (10.0% ± 5.7%). **Conclusion:** US GLP-1 RA RCTs reported MASLD and lipid data less often than international trials. Despite high US MASLD prevalence, only 8% included MASLD data, limiting the generalizability of GLP-1 RA efficacy in metabolic liver disease. Broader inclusion and greater focus on MASLD/MASH are needed to better guide GLP-1 RA use in obesity-related liver disease.

Figure 1. Demographic and MASLD/MASH data reported in US and international GLP-1 RA clinical trials.

2196 | LONGITUDINAL ADHERENCE TO HEPATOCELLULAR CARCINOMA SURVEILLANCE FOLLOWING ULTRASOUND LI-RADS IMPLEMENTATION IN A SAFETY NET HEALTHCARE SYSTEM

Stephanie Kim[1] Kang Wang[1] Hailey Choi[1] Amy Shui[1] Mandana Khalili[2], [1]University of California San Francisco, [2]University of California, San Francisco

Background: Hepatocellular carcinoma (HCC) surveillance is suboptimal, especially in high-risk populations. The Ultrasound Liver Imaging Reporting and Data System (US LI-RADS) was recently introduced to standardize US reporting and follow-up for HCC surveillance. This study aims to assess longitudinal trends in adherence to HCC surveillance and its associated factors following US LI-RADS implementation in a safety net healthcare system. **Methods:** Radiology and medical records were retrospectively queried for demographic, clinical, and imaging data in patients who underwent US LI-RADS-based HCC surveillance between 6/1/2020 - 5/31/2021, follow-up was through 12/31/2024. Full adherence to radiologist recommendation was defined as US imaging follow-up in 5-7 months for US-1, 3-6 months for US-2, and CT/MRI in 2 months for US-3. Multivariable repeated measures logistic regression assessed factors associated with full (vs partial/none) adherence after adjusting for age, sex, race, time from 1st imaging, and including variables with $p < 0.1$ on univariable analysis. **Results:** Among 1004 patients (mean age 60 years; 56% men; 61% Asian) and a median follow-up of 50 months, full adherence to surveillance was 38% at 1st visit (33% non-adherent) and 64% by 4th visit. Liver disease etiologies were hepatitis B (65%), hepatitis C (18%), steatotic liver disease (metabolic 18%, alcohol related 12%); 36% had cirrhosis. 43% were current or past smokers, 23% reported current or past alcohol use, and 7.5% experienced homelessness. Multivariable analysis showed that older age, male sex, prior hepatology clinic visit, and longer time since 1st imaging were significantly associated with full adherence, whereas current or past smoking and current alcohol use were significantly associated with lower odds of adherence (Table 1). These associations did not significantly change when time variable was replaced by post-pandemic (vs pandemic) time in the model. **Conclusion:** Adherence to US LI-RADS HCC surveillance increased from 38% at 1st visit to 64% by 4th visit. On follow-up, higher adherence was associated with prior hepatology clinic visit and certain demographics while health risk behaviors such as alcohol and smoking use were

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

associated with lower adherence. These findings highlight the effectiveness of US LIRADS uptake but also emphasize the need for lifestyle interventions, expanded access to specialty care, and integrated care models to improve surveillance for at-risk populations.

Table 1. Multivariable Analysis of Factors Associated with Full vs Partial/Non-Adherence

	Odds Ratio (95% CI)	P-value

2197 | CHRONIC LIVER DISEASE AND ASSOCIATED SOCIAL, BEHAVIORAL, AND METABOLIC RISK FACTORS IN TRANSGENDER AND GENDER-DIVERSE ADULTS: A 15-YEAR RETROSPECTIVE SAFETY-NET HOSPITAL COHORT STUDY

thanh nguyen[1] Christina Chou[2] George Cholankeril[3] Howard (Tzu-Hao) Lee[3], [1]Department of Internal Medicine, Highland Hospital, Oakland, CA, United States, [2]Division of Gastroenterology and Hepatology, Highland Hospital, Oakland, CA, United States., [3]Section of Gastroenterology and Hepatology, Department of Medicine, Baylor College of Medicine

Background: Introduction: Transgender and gender-diverse (TGD) individuals experience unique psychosocial stressors that affect social determinants of health and health behaviors, increasing their risk for chronic liver disease (CLD). However, data on CLD prevalence and associated risk factors in TGD populations remain limited. This study aims to compare CLD prevalence and risk factors between TGD and cisgender adults through a large retrospective cohort analysis. **Methods:** We conducted a retrospective cohort study from May 2010 to May 2025 at a safety-net hospital in the United States, identifying 528 TGD patients among 1,696,544 individuals using ICD-10 codes and medication records. The CLD cohort included alcohol-related liver disease, metabolic dysfunction-associated steatohepatitis, hepatic fibrosis, and cirrhosis, confirmed through ICD-10 codes, chart review, and imaging. We also collected data on housing instability, substance and alcohol use, metabolic risk factors (hypertension, dyslipidemia, diabetes, obesity), infectious comorbidities (HIV, hepatitis B and C), and mental health disorders. **Results:** Total cohort: TGD individuals had significantly higher prevalence ($p < 0.001$) of all measured risk factors and comorbidities compared to cisgender patients (Table 1). Notably, TGD patients exhibited higher rates of alcohol use disorder (18.4% vs. 1.2%), HIV infection (10.0% vs. 0.1%), housing instability (16.9% vs. 1.1%), and mental health disorders (65.2% vs. 3.7%). CLD sub cohort: TGD patients had a significantly higher prevalence of CLD compared to cisgender individuals (4.4% vs. 0.8%, $p < 0.001$). Compared to the general cohort, several disparities between TGD and cisgender patients were further amplified in the CLD subgroup, with TGD individuals experiencing greater burdens of alcohol use disorder (47.8% vs. 26.9%, $p = 0.04$), HIV infection (34.8% vs. 1.9%, $p < 0.001$), housing instability (39.1% vs. 13.0%, $p < 0.001$), and mental health disorders (73.9% vs. 34.2%, $p < 0.001$). **Conclusion:** TGD adults exhibited disproportionately high rates of chronic liver disease compared to cisgender peers. Key disparities among TGD patients with CLD included alcohol use disorder, HIV infection, housing instability, and mental health disorders. These risk factors and comorbidities were not only more prevalent in the overall cohort but were further amplified within TGD patients with CLD. These findings emphasize the need for tailored, culturally sensitive interventions addressing CLD and its unique disparities in TGD patients, delivered through a multidisciplinary approach to ensure equitable hepatology care.

2198 | BEYOND PRIMARY CARE: SPECIALIST DENSITY AS A DRIVER OF LIVER DISEASE MORTALITY IN NON-ALD POPULATIONS

Olivia Blocker[1] Xiaophan Ying[2] Robert Brown[3] Russell Rosenblatt[3], [1]Weill Cornell Medical Center, [2]Weill Cornell, [3]Weill Cornell Medicine

Background: Non-alcohol-associated liver disease (non-ALD), often due to metabolic dysfunction, is now the leading cause of liver- related mortality in the United States. Yet, this mortality is not equal as geographic disparities, particularly in rural and poorer populations, have limited access to care. While primary care providers (PCPs) manage chronic diseases, the role of Gastroenterologist (GI) availability in reducing liver-related mortality - especially in non-ALD remains underexplored. While previous research has shown that higher GI density is associated with reduced mortality in ALD, non-ALD likely has a different clinical trajectory. Therefore, this study examines the impact of GI density on non-ALD liver disease mortality.We hypothesized that GI density would be inversely associated with non-ALD liver mortality even after accounting for PCP density and county level health disparities. **Methods:** We conducted a retrospective analysis using CDC WONDER data (2018-2022) to calculate crude mortality rates for non-ALD liver disease and Hepatocellular Carcinoma (HCC), based on ICD-10 codes. Counties lacking sufficient mortality data were excluded. GI and family medicine (FM) physician densities were derived from HRSA. Given our focus was on rural communities, FM providers were used to represent PCPs. A Community Health Score (CHS, 0-40) was constructed from ten health indicators (County Health Rankings). Rurality was defined using USDA Rural-Urban Continuum Codes. Our Primary outcome was crude rate of death from non-ALD and HCC. Multivariable linear regression assessed the impact of GI density on mortality, controlling for FM density and an interaction term between CHS and rurality due to a significant interaction effect. **Results:** Median crude non-ALD mortality was 11/100,000 (100K)(IQR 7.8-14.9). The median GI density was 2/100K; FM median was 21/100K. Higher GI density was associated with decreased non-ALD mortality (coefficient = -0.52, 95% CI -1.02 to -0.02, P = 0.04), even when controlling for FM and CHS- rural interaction. FM density was also significantly associated with lower non-ALD mortality. For HCC mortality, GI density trended toward significance (coefficient = -0.13, 95% CI -0.26 to 0.00, P = 0.055). **Conclusion:** Our findings suggest that greater specialist density - particularly that of GIs - is associated with lower mortality from non-ALD liver disease. While no significant association was observed for HCC, this may reflect the complex, multidisciplinary care required for cancer management, including oncology, surgery, and hepatology. In contrast, the management for non-ALD may rely more directly on GI for early detection and intervention, in addition to the known impact of PCPs. These findings emphasize the need for targeted investment in specialist availiablity- particularly in rural or high-risk counties-to address liver disease disparities.

Outcome	Predictor	Adjusted Coefficient*	(95% CI)	P-value
Non-ALD Mortality	GI crude density	-0.52	(-1.02 to -0.02)	0.04
	FM crude density	-0.14	(-0.26 to -0.02)	0.02
HCC Mortality	GI crude density	-0.13	(-0.26 to 0.00)	0.06
	FM crude density	0.04	(-0.001 to 0.081)	0.06

2199 | RACIAL/ETHNIC DISPARITIES IN ACCESS TO LIVER TRANSPLANTATION - A SYSTEMATIC REVIEW AND META-ANALYSIS

Rajalakshmi Govalan Thomas Hunold[1] Elliot Tapper[2], [1]University of Michigan, [2]University of Michigan Medical Center

Background: Cirrhosis is the 10th leading cause of death in the United States, and liver transplantation (LT) remains the only definitive treatment. We must strive to provide equitable access to LT and to that end we must determine if there are disparities – and address them. We therefore conducted a systematic review and meta-analysis to evaluate racial disparities in LT access and disease severity at the time of listing between Black and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Non-Hispanic White patients in the U.S. **Methods:** We searched MEDLINE (2000–2024), identifying 1,753 studies. After independent screening and full-text review, 26 studies met inclusion criteria. Meta-analyses were conducted to assess pooled mean differences (MD) in MELD scores at listing and odds ratios (OR) for LT access between Black and Non-Hispanic White patients. Leave-one-out and duplicate cohort sensitivity analyses were performed. Publication bias was assessed using funnel plots and Egger's regression. Study quality was evaluated using the Newcastle-Ottawa Scale. **Results:** Among the 26 included studies, 11 reported MELD scores at listing, 10 reported odds of transplantation, 5 examined referral rates, and 3 assessed waitlisting odds by race. Two key findings emerged: 1. Black patients were listed with significantly more advanced liver disease, with a pooled mean MELD score difference of 2.07 (95% CI: 1.67–2.46). 2. Black patients had 20% lower odds of receiving a liver transplant compared to Non-Hispanic Whites (OR 0.80, 95% CI: 0.70–0.92). Substantial heterogeneity was observed, reflecting differences in healthcare practices, study design, and population demographics. Risk of bias across studies was rated mild to moderate. Sensitivity analyses confirmed the robustness of findings. No publication bias was detected. **Conclusion:** Our review and analysis highlights that Black patients not only have more severe liver disease at the time of listing but are also at lower odds of access to liver transplantation compared to Non-hispanic whites. Persistent racial disparities in liver transplant access and disease severity likely stem from a combination of social determinants of health, limited access to specialty care, implicit bias, and variability in referral practices. Tackling these inequities will require comprehensive strategies, including earlier screening, standardized referral pathways, and culturally tailored education. Future studies should examine region-specific and systemic contributors to inform targeted policy reforms.

2200 | CLINICIAN KNOWLEDGE AND PRACTICE OF TRANSGENDER AND GENDER DIVERSE HEALTHCARE IN LIVER TRANSPLANT

Sonali Paul[1] Ana Rossi[2] Elisa Gordon[3] Jody Jones[4] Wendy Balliet[5] Lisa Coscia[6] Goni Katz-Greenberg[7] Vineeta Kumar[8] Howard (Tzu-Hao) Lee[9] Rohan Ravirala[10] Alexandra Shingina[11] Laura Targownik[12] Monika Sarkar[10], [1]University of Chicago Medical Center, [2]Piedmont Healthcare, [3]Vanderbuilt University Medical Center, [4]University Hospitals Cleveland Medical Center-Transplant Institute, [5]Medical University of South Carolina, [6]Transplant Pregnancy Registry International, [7]Duke University School of Medicine, [8]University of Alabama at Birmingham, [9]Baylor College of Medicine, [10]University of California, San Francisco, [11]University of Michigan, [12]Sinai Health, Ontario Canada

Background: Nearly 1.6 million transgender and gender diverse (TGGD) individuals in the U.S. face significant health disparities driven by stigma, provider knowledge gaps, and systemic barriers. This survey assessed transplant professionals' knowledge, perceptions, and institutional support related to TGGD care. **Methods:** An online 33-question survey was administered through the American Society of Transplantation Communities of Practice member hubs. The survey assessed clinician knowledge, experience, communication practices, confidence, perceived barriers, and institutional infrastructure for TGGD care. Univariate analyses evaluated differences across transplant specialties. **Results:** Of 242 survey respondents, 125 completed the full survey. Most identified as female (68%) and White (80%); 44.8% were physicians. Transplant specialties included: kidney (67.2%), liver (48%), pancreas (41.6%), heart (20.8%), lung (14.4%), intestinal (9.6%), and vascularized composite allograft (2.4%). Most had previously cared for a TGGD patient (90.4%) and evaluated one for transplant (69.6%). Among liver transplant providers (n = 60, 48%), few reported feeling "very knowledgeable" about general (5%) and transplant-specific (3.3%) TGGD healthcare (Figure 1a). During initial evaluations, 27.8% asked about pronouns, and 22.2% asked about both gender identity and mental health (Figure 1b). Fewer inquired about sex assigned at birth (3.7%), gender affirmation steps (13.0%), or sexual orientation (5.5%). When evaluating TGGD patients for transplant, nearly half of liver transplant providers considered the impact of hormone therapy on transplant outcomes, immunosuppression interactions, and thrombosis risk (Figure 1c). About one-third accounted for prior (33.3%) or planned (28.3%) gender-affirming surgeries in their evaluations. Only 28.3% reported receiving required training on TGGD care, while half reported adequate institutional support in delivering gender-affirming liver transplant care. **Conclusion:** Liver transplant professionals report limited knowledge,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

confidence, and institutional support in providing care to TGGD patients. Our findings underscore a critical need for targeted education, resources, and institutional policy development to advance equitable, gender-affirming transplant care.

2201 | WOMEN OF REPRODUCTIVE AGE WITH UNTREATED HCV: POSITIVE AND NEGATIVE PATIENT-REPORTED EXPERIENCES FROM A QUALITATIVE SURVEY

Mai Sedki[1] Jennifer Price[2] Matthew Caliz[2] Katrina Alcantara[2] Jeff McKinney[2] Tasha Toliver[2] Michael Helle[2] Rena Fox[3], [1]Stanford University, University of California San Francisco, [2]University of California San Francisco, [3]University of California, San Francisco

Background: Many patients with hepatitis C virus (HCV) do not complete the HCV care cascade. Understanding these patients' experience with the healthcare system is important to successfully relink them to care. Women of childbearing age are a particularly important population as only 17% of postpartum women initiated DAAs. We conducted a qualitative survey of women of reproductive age with untreated HCV to understand their prior HCV care. **Methods:** At a large urban tertiary health system, we identified all female patients aged 18-50 years seen between 2020-2024 with 1) current HCV viremia or 2) incomplete HCV diagnosis, defined by a reactive HCV Ab without RNA testing. A navigator called each patient, offered a clinician appointment, and conducted a phone survey. Patients were asked to answer on a Likert scale regarding their prior experience of HCV 1) overall care, 2) testing, 3) explanation of results, 4) education, 5) recommendation for treatment, 6) time with clinician, and 7) courtesy from clinic staff. Two open-ended questions were asked about how the healthcare system could be improved for patients and specifically women. No study incentives were offered to patients. **Results:** We identified 73 women who met criteria for outreach. Of those, 33 were successfully reached by phone within three attempts; 88% (29/33) completed the survey. The mean age of survey respondents was 38.9 years (SD 7.4), the majority were White (65%) and had Medi-cal insurance (14/29). Most were currently viremic (20/29) and the remainder were HCV Ab+ without any RNA testing. Only three had a primary care provider or had seen hepatology, and one had ever been prescribed a DAA, yet over a quarter (27%) were obese, two patients had cirrhosis, and one was decompensated. Of the 29 respondents, 41% reported they had received no prior healthcare for HCV, 45% had not been given or were dissatisfied with receiving their HCV results, 45% had no patient education or were dissatisfied, 48% had never been offered HCV treatment. Still, most responses were

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

either positive or neutral. Patients' ideas about how healthcare for HCV could improve are shown in Table 1. **Conclusion:** In our cohort of young women with untreated HCV, patients reported a mix of positive and negative prior experiences. Although there was an 88% survey response rate, the study findings may be limited by small sample size. The women provided informative open-ended responses, and told us that attentive listening, more convenient care, and increased numbers of providers are ways that HCV care delivery could be improved for all and especially for women.

Table 1. Qualitative survey of women of childbearing age with untreated HCV: Free-response themes and quotes about how hepatitis C care can be improved

Response Theme	Question How can HCV care be improved for all patients?	Question Are there ways that hepatitis C care can be improved for women?
Improve how clinicians listen to patients	Having medical professionals give pts more information instead of treating every pt like they are the same person. We know that pts get Hep C for different reasons.	Listen to women when talking about HCV.
	It is important to make sure, that healthcare workers are caring and sensitive as possible because hepatitis C is a sensitive subject and painful because Hep C can cause physical and mental pain (depression) which can prevent people from getting treated.	Specifically for women, having available female specialists could make the care process more comfortable.
	Show awareness of how hep C is exposed	Someone being more present, actively asking questions and advocating testing.
		Talk and listen to women who have HCV.
Make HCV care more streamlined, convenient, and accessible	Help make patients' experience streamlined, like when the Rx was sent to the home directly. Make things more convenient.	Helping people who have problems with transportation
	If tests were positive, looping people in with providers.	Help people while they are doing treatment, such as if a patient has to care for children.
	Helping people with transportation for Hep C treatment	Investing more in healthcare for women
	Mobile testing sites.	
Make HCV care more affordable and investing more in HCV	Lower the financial barriers to testing. Provide free testing for people.	Universal healthcare.
	There needs to be more providers that will work with Medicaid, because there are limited providers. More availability.	Putting more money towards women's health
	Everyone should have universal healthcare/ access to healthcare.	
	More specialists that will handle HCV treatment.	
Continue current processes and this kind of outreach to patients	This hospital is doing a pretty good job in reaching out to previous patients.	Nothing to change, the process is straightforward.
	The fact that this institution is personally reaching out to patient's and taking initiative to call them is helpful on the patient's wellbeing.	Nothing else needed
	Care for Hep C is pretty decent	Nothing else needed

2202 | MISSED OPPORTUNITIES FOR LIVER HEALTH IN WOMEN WITH SUBSTANCE USE DISORDER

Iva Kosuta[1] Lea Kozina[2] Paula Cizmic[3] Leo Kosuta[4] Anna Mrzljak[5] Zrnka Kovacic Petrovic[6], [1]Division of Intensive Care, Department of Internal Medicine, [2]University Psychiatric Hospital Vrapče, [3]School of Medicine, University of Zagreb, [4]School of Medicine, Univeristy of Zagreb, [5]University Hospital Center Zagreb, [6]University Psychiatric Hospital Vrapce

Background: Women with substance use disorder are at increased risk for liver disease yet liver health is rarely assessed systematically in psychiatric settings. This study aimed to determine the proportion of women treated for substance use disorder with advanced liver disease, based on non-invasive fibrosis scores, and to evaluate whether they had been appropriately referred for hepatology evaluation. **Methods:** We retrospectively analysed liver fibrosis risk using FIB-4 and APRI scores in hospitalized women with substance use disorder who had no previously known liver disease, applying standard cutoffs. Demographic, psychiatric, and biochemical data were reviewed to assess hepatology referral rates among at-risk patients. Additional analyses explored the association between fibrosis severity and socioeconomic indicators. **Results:** One hundred ninety-nine patients with a median age 50.1 years (IQR 39.8-59.5) were included. Alcohol use was documented in 91.5% of patients. Psychiatric comorbidities were frequent including personality, anxiety, and post-traumatic stress disorders. Based on FIB-4 score, 21.6% were at intermediate risk and 7.0% at high risk of fibrosis, but only 12.3% were referred to hepatology services. According to APRI score, 10.1% patients were classified as having significant fibrosis or probable cirrhosis, of whom only 15% were referred to hepatology services. FIB-4 scores differed significantly across education levels ($p = 0.004$), with both low and high educational attainment associated with higher fibrosis severity, suggesting a bimodal distribution. However, marital status was not associated with liver disease severity. **Conclusion:** Despite the availability of simple non-invasive tools to estimate liver fibrosis, many at-risk women were not referred to liver services. Lack of familiarity with the availability of such scores among psychiatric providers contribute to under-recognition and lack of referral. Improved training, a model of integrated care - collaboration between psychiatric and hepatology services and referral-pathways are needed

2203 | BARRIERS TO OBTAINING BREAST CANCER SCREENING DURING LIVER TRANSPLANT EVALUATION: A CONTRIBUTOR TO SEX DISPARITIES IN LIVER TRANSPLANTATION LISTING

Madison Force[1] Caroline Conlon[2] Emily Chiacchiaro[2] Dina Halegoua-De Marzio[2] Danielle Tholey[2], [1]Thomas Jefferson University Hopsital, [2]Thomas Jefferson University Hospital

Background: Sex disparities persist in liver transplantation (LT), with women experiencing longer wait times and lower rates of transplant compared to men. This is due to differences in body habitus, access to care and until MELD3, lower GFR in women. We propose that completing inpatient breast cancer screening during liver transplant evaluation (LTE) is an additional barrier disadvantaging women. We examine the perceived impact of inpatient breast cancer screening on timely LTE in women at U.S. LT centers. **Methods:** Surveys were distributed via REDCap to the medical director (when available) or a single hepatologist at all 115 active adult LT centers listed in the Organ Procurement and Transplantation Network (OPTN) as of 5/1/2025. The survey included questions regarding breast cancer screening protocols for patients too ill to be discharged from the inpatient setting and perceived impact on listing timelines. Responses were collected anonymously. **Results:** In all, 31 centers completed the survey with a response rate of 27%. Survey responses were geographically diverse representing centers across 9 of the 11 OPTN regions and 20 US states. All responders reported that breast cancer screening was part of the inpatient LTE, but only 81% of centers had access to inpatient breast cancer screening. The most common screening tools used were mammography (77%), breast ultrasound (45%) and MRI (16%). 61% reported experiencing delays in completing breast cancer screening for inpatient LTE. On a 5-point difficulty scale, 63% of respondents rated the challenge of completing inpatient screening as moderate to high (scores of 3–5). The primary barriers cited are displayed in Figure 1. 24% of centers waive breast cancer screening in selected high MELD patients. Several centers attempted to overcome delays, via direct coordination with radiology and breast centers, developing pathways for same-day inpatient access, and using bedside breast exams or breast ultrasound when patients are too ill for a mammogram. **Conclusion:** A majority of participants reported logistical and clinical barriers to completing breast cancer screening for women undergoing inpatient LTE. Limited access to inpatient mammography, low prioritization by radiology, and the critical illness of candidates impede timely completion of required screening. These delays disproportionately affect women and represent a modifiable contributor to sex-based disparities in liver transplantation. Strategies to improve access to inpatient breast cancer screening are needed to promote equitable transplant listing.

Figure 1. Main barriers to completing inpatient breast cancer screening reported by survey responders.

2204 | SEX FOR THE PURPOSES OF MELD 3.0 CALCULATION: WHEN THIS DIFFERS FROM ASSIGNED SEX AT BIRTH AND IMPLICATIONS FOR POLICY

Nikki Duong[1] Daniel Huynh[2] Newsha Nikzad[3] W. Ray Kim[4] Neil Shah[5] Scott Biggins[6] Allison Kwong[7], [1]Stanford University, [2]University of Washington, [3]The University of Chicago Medical Center, [4]Mayo Clinic Arizona, [5]University of North Carolina at Chapel Hill,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

[6]University of Pittsburgh, [7]Stanford University Medical Center

Background: Adults with chronic liver disease are prioritized on the US liver transplant waiting list by their MELD 3.0 score, which was updated in July 2023 from MELD-Na to incorporate sex and albumin as additional variables. With MELD 3.0, women receive an additional 1.33 points to their MELD score, to better represent their waiting list mortality and correct a longstanding sex disparity in waiting list and transplant outcomes. With this policy update, the data field labeled "Gender" was relabeled as "Birth sex," and an additional field for adult liver transplant candidates was created "Sex for the Purposes of Adult MELD calculation." We evaluate the effect of this policy update in candidates who report their sex as different than their birth sex for MELD 3.0 calculation. **Methods:** We analyzed OPTN data for adult liver transplant candidates registered between July 2023 (when these data fields were created) and March 2025. The response to this data collection is left to the discretion of the transplant program in consultation with the candidate and their clinical team. OPTN guidance suggests that programs may consider the candidate's sex for the purposes of adult MELD calculation to be different from their birth sex, for example, if the candidate is taking gender-affirming hormone therapy. **Results:** Among 26,324 patients registered on the liver transplant list during the study period, 80 patients reported differing sex at birth and sex for the purposes of the MELD 3.0 calculation. 43 patients identified as female who reported male sex at birth (0.4% of women), and 37 patients identified as male and reported female sex at birth (0.3% of men). MELD 3.0 did not significantly differ between cisgender and transgender patients at listing ($p = 0.90$). Additionally, there were no significant differences between the groups in terms of age at the time of transplant evaluation, race, days to transplant, or waitlist mortality. There were no instances of patients being listed at multiple centers. **Conclusion:** The introduction of MELD 3.0 reflects continued efforts to mitigate sex-based disparities in liver transplant allocation. The OPTN database has the capacity to further illuminate implications of MELD 3.0 on health outcomes for transgender patients referred for transplantation. The addition of the field "Sex for the Purposes of Adult MELD calculation" is a critical step towards accurately stratifying mortality risk and promoting equitable allocation. This is an important study demonstrating that this variable appears to be used appropriately by transplant centers, or at the very least, not manipulated to gain waitlist advantage. However, ongoing vigilance is essential as more data become available.

2205 | EXPLORING INTERPERSONAL BIAS IN TRANSPLANTATION: A CROSS-SECTIONAL STUDY OF ATTITUDES, CULTURAL INTELLIGENCE, AND IMPLICIT BIAS AMONG ABDOMINAL TRANSPLANT CENTER EMPLOYEES

Joy Obayemi[1] Kenny Chen[2] Harika Reddy[2] Maggie Jones-Carr[3] Shaina Alexandria[2] Kiarri Kershaw[2] Dinee Simpson[2] Daniela Ladner[2], [1]University of Michigan / Northwestern University, [2]Feinberg School of Medicine, Northwestern University, [3]University of Alabama at Birmingham

Background: Black/African American patients are less likely to be waitlisted for abdominal organ transplantation and have poorer outcomes once transplanted. While the etiology of these disparities is multifactorial, little is known about the interpersonal biases held by transplant center employees, which may contribute to these findings. **Methods:** A cross-sectional study was performed using employee responses to a cultural assessment conducted at a large, metropolitan transplant center from July-September 2024. The assessment was created with iterative feedback from content experts in a multi-institutional consortium and included a race-based implicit association test (IAT), which assesses the speed of rapid association as an indirect measure of bias. The assessment was distributed to all patient-facing transplant center employees. Descriptive statistics were performed on respondent demographics and arithmetic mean response latency calculated with IAT data. **Results:** Of 178 employees of the transplant

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

centers, 158 (88.8%) individuals completed the cultural assessment. Most respondents were female (n = 117;68.3%). 90 (57.0%) respondents were 18-40yo, 57 (36.1%) were 41-60yo, and 11 (7.0%) were ≥ 61yo. Most identified as White (n = 97, 61.4%), Asian (n = 25, 15.8%) or Black/African American (n = 20, 12.7%). 92 (58.3%) employees were non-Physician clinicians (i.e. nurse, APP, social worker, psychologist), 43 (27.2%) were office personnel, and 23 (14.6%) were physicians. The mean d score for the cohort was 0.26 (SD = 0.44) compared to a d score of 0, which would indicate no bias. This denotes a significant preference towards associating White people with positive words and Black people with negative words among the total cohort ($p < 0.001$, 95% CI 0.15,0.33) with a medium effect size (Cohen's d = 0.59) [Figure 1]. No significant differences in degree of bias were found when stratified by gender, age category, or position at the transplant center. Respondents who had been working in the transplant center for longer (> 10 years, d = 0.41) displayed more bias towards White individuals than those who were relatively new employees (0-5 years, d = 0.21)($p = 0.047$). **Conclusion:** These results suggest that anti-Black implicit bias exists among employees at a large metropolitan transplant center. This highlights the need for continued education and evidence-based efforts to mitigate bias, which has the potential to impact transplant access, outcomes, and experiences for minority patients.

2206 | UNEQUAL BURDEN: DISPARITIES IN CIRRHOSIS AND LIVER CANCER MORTALITY IN THE U.S.,1999–2022

Yousaf Zafar[1] Areesha Hafeez[2] Shanzay Akhtar[2] Syed Sarmad Javaid[3], [1]Cleveland Clinic Florida, [2]Karachi Medical and Dental College, [3]University of Mississippi Medical Center

Background: Cirrhosis is advanced liver scarring caused by chronic liver diseases, leading to impaired liver function. Hepatocellular carcinoma (HCC), on the other hand, is the most common type of primary liver cancer world-wide identifying as an aggressive cancer most common in people with advanced liver disease, like cirrhosis. This study analysed CDC WONDER data to examine trends in mortality in patients with cirrhosis and HCC in the United States (U.S). **Methods:** Using the CDC WONDER database, we queried mortality records from 1999 to 2022 among HCC-related deaths (ICD-10: C22.0) and cirrhosis-related deaths (ICD-10: K70.3, K74.5, K74.6) in adults aged 25+. Joinpoint regression analysis was utilized to assess trends in annual percentage change (APC) for contributing causes of death. Age-adjusted mortality rates (AAMR) were computed and compared cumulatively across subpopulation demographics. **Results:** From 1999 to 2022, Cirrhosis and hepatocellular carcinoma caused 63,484 deaths among U.S adults aged 25 years and older. Overall AAMR rose from 0.68 in 1999 to 1.58 in 2022. After the initial increase from 1999-2006 (APC: 2.13; 95% CI: 0.07 to 3.28), the mortality surged in the 2006-2017 period (APC: 5.57; 95% CI: 5.14 to 6.50), with a more gradual increase from 2017 to 2022 (APC: 1.78; 95% CI: 0.43 to 2.75) (Figure 1A). AAMR had an increasing trend in both sexes, men had consistently higher AAMR than women from 1999 (AAMR; men: 1.19 vs women: 0.25) to 2022 (AAMR; men: 2.60 vs women: 0.66) (Figure 1B). Among racial groups, Hispanics and Latino had the highest AAMRs, followed by Non-Hispanic (NH) Black or African American, and lastly NH White (2022; Hispanic or Latino: 2.98, NH Black: 1.48, NH White: 1.36) (Figure 2A). AAMR also showed significant regional variation, with the West region reporting the highest AAMR in 2022, and the Northeast region reporting the lowest (AAMR 2022; West: 2.10, South: 1.67, Midwest: 1.27, Northeast: 1.06) (Figure 2B). Across the states, Oregon reported the highest AAMR in 2022 (3.21), and West Virginia the lowest (0.73). **Conclusion:** This study highlights discrepancies in HCC mortality related to liver cirrhosis

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

among U.S. adults. The steady rise in AAMRs from 1999 to 2022 underscores the need for specific public health interventions to address these growing inequalities. Our findings stress the importance of targeted, locally tailored programs and policies to reduce the dual mortality burden of HCC and cirrhosis.

2207 | TRENDS IN MAT AND GLP-1 UTILIZATION AFTER LIVER TRANSPLANTATION BASED ON SOCIODEMOGRAPHIC VARIABLES: A NATIONAL COHORT ANALYSIS

Ami Patel[1] Taylor Seacor[2] Katherine Cooper[2] Anita Krishnarao[2], [1]Univeristy of Massachusetts, [2]University of Massachusetts

Background: Alcohol Associated Liver Disease (ALD) and Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) are the most common etiologies of liver disease in the US. Medical assisted therapy (MAT) for alcohol use disorder and Glucagon-like peptide -1 agonists (GLP-1) for metabolic syndrome have been shown to improve outcomes pre-LT, although less is known about their impact and utilization after LT. Sociodemographic disparities have been identified regarding access to hepatology care and LT referral. This study aimed to evaluate if disparities in medication utilization persist even after gaining access to multidisciplinary care post-LT. **Methods:** This analysis was completed using a TriNetX query of the United States Collaborative Network- a network of 70 healthcare organizations. Patients who underwent transplantation between 2017-2025 and had either MASLD or ALD were identified using ICD-10 codes and those with prescriptions for MAT (Naltrexone, Acamprosate, and Disulfiram) and GLP-1 (Exenatide, Semaglutide, Liraglutide, Dulaglutide, and Tirzepatide) were included. Baseline characteristics such as age, sex, race, and ethnicity were analyzed in the MAT and GLP-1 group and then compared to no MAT and no GLP-1. Data was analyzed using TriNetX and statistical significance was evaluated at $p < 0.05$. **Results:** A total of 12,468 patients with ALD underwent LT, of which 744 (6%) were prescribed MAT post-LT. Patients on MAT were predominantly male (63%), non-Hispanic (67%), and white (78%). When compared to those without MAT, MAT recipients were younger (mean 49 vs. 54, $p < 0.01$) and more likely to be female (36% vs 27%, $p < 0.01$) with no differences in race or ethnicity: White (78% vs 75%, $p = 0.06$) or non-Hispanic (67% vs 67%, $p = 0.87$). Additionally, 15,514 patients with MASLD underwent LT, of which 1,925 (12%) were prescribed GLP-1 therapy post-LT. The GLP-1 cohort ($n = 1,925$) was again predominantly male (55%), non-Hispanic (66%), white (76%), and had a mean age of 59 years. When compared to the cohort without GLP-1, GLP-1 recipients were older (mean 59 vs. 56, $p < 0.01$) and more likely to be female (43% vs. 41%, $p = 0.02$). There were again no differences in race or ethnicity: White (76% vs 75%, $p = 0.26$) or non-Hispanic (66% vs 68%, $p = 0.19$). Notably, a majority of MAT (45%) and GLP-1 (47%) recipients resided in the southern US as compared to other regions. **Conclusion:** MAT and GLP-1 therapies are underutilized post-LT, despite their potential benefit. While there were fewer females overall in the post-LT cohort, there was a greater percentage of females in both the MAT and GLP-1 groups. In contrast to our hypotheses, there were no racial or ethnic differences related to MAT or GLP-1 utilization post-LT, though geography may play a role in prescribing practices. While MAT and GLP-1 utilization is low in the post-LT setting overall, the socioeconomic disparities related to healthcare access prior to LT do not seem to persist after our analysis.

2208 | INCIDENCE OF ETIOLOGY OF HEPATOCELLULAR CARCINOMA BY SOCIAL DETERMINANTS OF HEALTH, A TREND FROM 2016-2021

Andrej Sodoma[1] James Pellegrini[2] Samuel Greenberg[3] Mark Baginski[4] Mary Thomas[4], [1]Northwell, [2]NUMC, [3]Stony Brook, [4]SSUH

Background: Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer in adults and the third leading cause of cancer-related deaths worldwide. Cirrhosis remains the predominant cause of HCC. The etiologies of cirrhosis over the years have changed with an increase in metabolic dysfunction-associated fatty liver disease (MAFLD) without much improvement in management while the primary prevention of virus-related cirrhosis and a decrease in rates of viral-related HCC. **Methods:** In this study, we used the National Inpatient Sample (NIS) from 2016-2021 to trend changes in the etiologies of HCC. The International Classification of Disease (ICD) 10 codes were used to identify patients with cirrhosis, HCC, and the leading causes of cirrhosis: Hepatitis B (Hep B), Hepatitis C (Hep C), Alcohol use disorder (AUD), and MAFLD. The groups were split by the cause of cirrhosis, creating four groups. Records were weighted per the NIS algorithm to produce accurate population estimates. The patients were analyzed for baseline characteristics: age, Charlson Comorbidity Index (CCI), sex, race, insurance, hospital size, region, income, hypertension (HTN), coronary artery disease (CAD), diabetes type two (DM2), current smoker, and opioid use. The percentage and number of patients for each cause of cirrhosis were organized, and the Cochran-Armitage test for trend significance was used. **Results:** A weighted total of 108,795 HCC patients from 2017-2021, with 7615 Hep B, 39765 Hep C, 16625 AUD, and 8745 MAFLD patients were analyzed. Patients were 65.1 years old on average ($p < 0.05$), average CCI of 7.65. Hep B and Hep C from 2016 to 2021 steadily decreased (Hep B: 8.04% 2016, 7.81% 2017, 6.44% 2018, 6.5% 2019, 6.94% 2020, 6.23% 2021 ($p < 0.0011$); Hep C: 45.19% 2016, 39.63% 2017, 39.6% 2018, 34.43% 2019, 31.24% 2020, 28.08% 2021 ($p < 0.0001$)). AUD Hep C remained relatively lateral from 2016 to 2021 (16.8% 2016, 14.46% 2017, 17.19% 2018, 14.54% 2019, 14.19% 2020, 14.38% 2021 ($p < 0.0024$)). MAFLD doubled from 2016 to 2021 (5.87% 2016, 6.66% 2017, 7.42% 2018, 9.78% 2019, 8.48% 2020, 10.19% 2021). **Conclusion:** The incidence of HCC is directly correlated with variations in the etiology of cirrhosis, as evidenced by the rise in MAFLD and the decline in the proportion of patients with HCC attributable to hepatitis B and C. The research methodology offers a clear and dependable framework for comprehending the trends associated with the etiology of HCC.

2209 | A REVIEW OF THE IMPACT OF BIAS IN ARTIFICIAL INTELLIGENCE IN ENSURING HEALTH EQUITY IN HEPATOLOGY

Sara Romero-Otero[1] Joaquín Dopazo[2] Manuel Romero-Gómez[2] Isabel Fernandez[1] Vanessa Garcia-Fernandez[1], [1]Instituto de Biomedicina de Sevilla (IBiS), [2]University Hospital Virgen del Rocío

Background: Artificial Intelligence (AI) has shown great promise as a tool for hepatology, both in routine clinical practice and in more specific forms of healthcare delivery. However, these technological advances have been noted to introduce new forms of statistic and social bias that may further broaden the systematic gap between socioeconomic minorities and their access to healthcare. As such, this review seeks to note the health inequities that have arisen or may arise from statistical and linguistic bias in AI used in routine clinical practice for hepatology, focusing specifically on how it has been shown to exacerbate gender disparities in liver transplant waitlists and worsen polyp detection in various ethnic minority groups. **Methods:** Scientific articles were collected through PubMed using the search criteria “Artificial Intelligence” + “bias” + “Hepatology” and limiting their publication date from 2020 to 2025. The platform offered 41 matches to the search criteria, 6 of which were classified as meta-analyses, 22 as reviews, and 16 as systematic reviews. All 41 articles were published in English, with only 2 of them featuring a female specialist as corresponding author. Other socioeconomic factors, such as the authors’ race or sexual identity, were later taken into consideration by contacting each corresponding author to request such information. **Results:** Our findings show that, while the impact of language and system bias on health equity has been somewhat reported in the field of hepatology,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

only 6 of the 41 articles offer a thorough analysis of the impact of bias on minorities' access to high-quality and accurate diagnosis, while also shedding light on the biases presents in AI chatbots used directly by patients to complement their treatment, as is the case with inappropriate and/or insensitive responses received when seeking advice for weight loss. Conversely, 11 of the 41 articles offer a brief discussion offer brief discussions of bias-related issues in hepatology, particularly in specific treatments and/or diagnostic procedures; 18 of them note bias mitigation as part of their methodology without discussing its socioeconomic impact; finally, 3 of them fail to address bias or do so from another medical specialty. **Conclusion:** These findings show that addressing bias in AI tools for hepatology remains an unmet need. It is of utmost importance to address these existing and/or potential biases in order to minimize racial and gender disparities within healthcare, both throughout the data collection process and through auditing processes once the devices have been deployed into routine clinical practice. The creation of an ethical framework applying specifically to the use AI in hepatology will also further help in mitigating any existing socioeconomic biases, while also enhancing the quality of care offered to all liver patients.

Table 1. Forms of language and system bias with impact on health equity observed in AI tools for hepatology and gastroenterology

Procedure/condition	Bias detected
Hepatocellular carcinoma and liver transplantation	HCC is 2 to 4 times more common in men, and as such the inclusion of this variable has been found to deprioritize women and perpetuate sex disparities: women are 20% less likely to receive a liver transplant and 8.6% more likely to die on the transplant waitlist
Alcohol Associated Liver Disease	Insufficiencies have been noted in the application of AI tools dependent on psychosocial variables, thus discriminating against socially vulnerable groups as candidates for liver transplantation
Weight loss	Inappropriate and/or insensitive responses to patient queries regarding forms of weight loss, thus affecting their treatment through stigmatization

2210 | EPIDEMIOLOGICAL TRENDS AND DISPARITIES IN DIGESTIVE CANCERS AMONG HEPATITIS PATIENTS IN THE UNITED STATES: A CDC WONDER DATABASE ANALYSIS (1999-2022)

Simran Joshi[1] Muhammad Ali[2] Husnain Ahmad[3] Matthew Manoj[4] Jeevin Sandhu[5] Marquise Soto[6] Sushrut Ingawale[7] Corinne Caissie[1] Abhiraj Patel[1] Rishi Chowdhary[8] Shijia Li[1] Muhammad Abdullah Humayun[9] Simardeep Singh[10] Noor ul Ain Saleem[11] Faizan Ahmed[12] Cheng-Hung Tai[1] Atiqul Mohammad[1] Sandeep Nayak[1], [1]Yale New Haven Health/Yale University School of Medicine, [2]Jinnah Postgraduate Medical Center, [3]Shalamar Medical and Dental College, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, [5]Methodist Dallas Medical Center, [6]Massachusetts General Hospital, Harvard Medical School, [7]Quinnipiac University - Frank H Netter MD School of Medicine, [8]MetroHealth Medical Center, [9]Mayo Clinic, [10]Medstar Health Georgetown University, [11]FMH College of medicine and dentistry, [12]Jersey Shore University Medical Center

Background: The prevalence of hepatitis-specific digestive cancer in the United States is underexplored, however, chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections are well-established etiological agents for certain digestive cancers, particularly hepatocellular carcinoma (HCC) and gastric cancer. Long-term infection with either virus increases the risk of various GI malignancies, including colorectal, gastric, esophageal, and pancreatic cancers, likely due to mechanisms involving chronic inflammation, liver damage, and potential integration of viral DNA into host cells, leading to oncogenesis. Despite recent advances in antiviral therapies and public health interventions, disparities in digestive cancer mortality among hepatitis-infected individuals remain underexplored on a national scale. **Methods:** We conducted a retrospective study using CDC WONDER Multiple Cause of Death data from 1999 to 2022. Deaths were included if both DCs (ICD-10: C15–C26) and viral hepatitis (ICD-10: B15–B19) were listed. Age-adjusted mortality rates (AAMRs) per 100,000 were calculated using the 2000 U.S. standard population. Joinpoint regression was employed to estimate annual percent changes (APCs). Subgroup analyses stratified trends by sex, age, race/ethnicity, U.S. census region, and urban-rural classification. **Results:** A total of 80,310 deaths were attributed to concurrent DCs and viral hepatitis from 1999–2022. The overall AAMR increased from 0.56 in 1999 to a peak of 1.80 in 2012 (APC: +7.8%), followed by a steady decline to 1.25 in 2022 (APC: -6.2%). Men consistently exhibited higher mortality than women. HCC was the most common cause of death (68%), followed by lower GI and pancreatic cancers. Non-Hispanic (NH) Asians and NH Blacks had the highest AAMRs, with NH Asians demonstrating the most significant post-2012 decline. Regionally, the West had the highest mortality, and urban areas consistently exceeded rural counterparts. The most impacted age group was 55–74 years. Notably, states in the 90th percentile had AAMRs nearly three times higher

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

than those in the 10th percentile. **Conclusion:** While mortality from hepatitis-associated digestive cancers has declined over the past decade—likely due to improved screening, HBV vaccination, and direct-acting antivirals—significant disparities persist by sex, race, geography, and urbanization. HCC remains the predominant contributor to mortality. Targeted public health strategies are critical to address these inequalities and improve outcomes among hepatitis-infected populations.

2211 | INFLUENCE OF SOCIAL VULNERABILITY ON COMPLICATIONS OF ALCOHOL-ASSOCIATED LIVER DISEASE

Pojsakorn Danpanichkul[1] Kanyaphak Charnpatanakorn[2] Donghee Kim[3] Thanathip Suenghataiphorn[4] Narathorn Kulthamrongsri[5] Karn Wijarnpreecha[6] Mazen Noureddin[7] Suthat Liangpunsakul[8], [1]Texas Tech University Health Sciences Center, [2]Faculty of Medicine, King Mongkut's Institute of Technology, Bangkok, Thailand, [3]Stanford University, [4]Griffin Hospital, [5]University of Hawaii, [6]University of Arizona, [7]Houston Methodist Hospital, [8]Indiana University

Background: Alcohol-associated liver disease (ALD) poses a significant and growing public health concern, with patient outcomes increasingly influenced by social determinants of health (SDoH). While factors such as poverty and social isolation are known to worsen outcomes in many medical conditions, their direct impact on ALD-related complications remains unclear. This study aimed to assess how social deprivation influences clinical outcomes in individuals with ALD. **Methods:** Using the TriNetX research network, which compiles real-time electronic health data from a broad range of U.S. healthcare institutions, we identified adults with a diagnosis of ALD. Social deprivation was defined by the presence of ICD-10-CM codes for extreme poverty (Z59.5), low income (Z59.6), or living alone (Z60.2). Patients were matched 1:1 using propensity scores to control for demographic characteristics, comorbidities, medications, and alcohol use disorder treatments. Cox proportional hazards models were applied to calculate hazard ratios (HRs) and 95% confidence intervals (CIs) for clinical outcomes. **Results:** The matched cohort consisted of 998 ALD patients, split evenly between socially deprived and non-deprived groups (499 each). Social deprivation was not significantly linked to all-cause mortality (20.1% vs. 19.5%; HR 0.93, 95% CI 0.70–1.22). However, socially deprived individuals had significantly higher risks of major adverse cardiovascular events (MACE) (20.6% vs. 11.4%; HR 1.76, 95% CI 1.22–2.56), arrhythmia (24.6% vs. 15.7%; HR 1.58, 95% CI 1.13–2.22), heart failure (13.5% vs. 6.2%; HR 2.15, 95% CI 1.34–3.43), alcohol-associated hepatitis (AH) (24.7% vs. 16.2%; HR 1.44, 95% CI 1.09–1.90), and sepsis (21.8% vs. 10.2%; HR 2.03, 95% CI 1.41–2.93). No meaningful differences were found in the rates of major adverse liver outcomes (MALO) or acute pancreatitis. **Conclusion:** Among patients with ALD, social deprivation

is independently linked to increased risks of cardiovascular events, sepsis, and alcohol-associated hepatitis. These results highlight the importance of addressing social vulnerabilities to improve health outcomes in this high-risk group.

2212 | A LOWER SOCIAL DEPRIVATION INDEX IS ASSOCIATED WITH INCREASED MORTALITY AND MAJOR ADVERSE CARDIOVASCULAR EVENTS IN PATIENTS WITH ALCOHOL-ASSOCIATED LIVER DISEASE

Leith Ghani[1] Claire Faulkner[2] Majd Aboona[1] Pradhan Hariharan[1] Pooja Rangan[3] David Garcia[4] Vincent Chen[5] Donghee Kim[6] Juan Pablo Arab[7] Mazen Noureddin[8] Luis Díaz[9] Mike Fallon[10] Karn Wijarnpreecha[11], [1]University of Arizona College of Medicine - Phoenix, [2]Boston Medical Center, [3]Division of Clinical Data Analytics and Decision Support, University of Arizona College of Medicine, [4]University of Arizona Mel and Enid Zuckerman College of Public Health - Tucson, [5]University of Michigan Medical Center, [6]Stanford University Medical Center, [7]Virginia Commonwealth University, [8]Houston Methodist Hospital, [9]MASLD Research Center,Division of Gastroenterology and Hepatology,University of California San Diego, [10]University of Arizona, [11]University of Arizona College of Medicine-Phoenix

Background: Significant health disparities persist in alcohol-associated liver disease (ALD), largely driven

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

by social determinants of health (SDOH). However, the influence of neighborhood-level SDOH on ALD outcomes remains underexplored. In this study, we aimed to evaluate how neighborhood-level SDOH impacts disease burden, comorbid conditions, and mortality in individuals with ALD. **Methods:** We conducted a retrospective cohort study of patients with ALD from 2012 to October 2024 in the Banner Health System, representing hospitals across Arizona, California, Nevada, Wyoming, and Colorado. We used ICD codes with a random chart review of over 250 cases to validate ICD codes for ALD and extrahepatic outcomes. Neighborhood-level SDOH were quantified using the Social Deprivation Index (SDI), a validated composite metric derived from American Community Survey data. Patients were stratified into quartiles based on SDI score, with Quartile 4 representing the most socioeconomically disadvantaged neighborhoods. Primary outcomes included the incidence of mortality, cirrhosis, liver-related events, type 2 diabetes mellitus, any cancer, and major adverse cardiovascular events (MACE). A multivariable competing risk analysis was performed adjusting for confounders. **Results:** Among 11,394 patients with ALD and available SDI data, 6,747 had $\geq$ 365 days of follow-up with average age 51 years and 65.6% are female. 68.8% were Non-Hispanic White, 19.7% Hispanic, 5.9% Native American/Alaskan Native (NA), 3.2% Black, and 0.4% Asian/Pacific Islanders. Patients residing in the most disadvantaged neighborhoods (Quartile 4) were significantly younger, more likely to be female, had higher average body max index, and more frequently reported a non-English primary language compared to those in the least disadvantaged areas (Quartile 1). Patients in the most deprived areas (Quartile 4) were more likely to be Hispanic, Black, or Native American/Alaska Native. Individuals in Quartile 4 were more likely to be uninsured or on Medicaid, whereas those in Quartile 1 predominantly had private insurance. Individuals in quartile 4 had an increased mortality (adjusted hazard ratio (aHR), 1.51; 95% Confidence Interval (CI) (1.11-2.04) and increased MACE (aHR 1.24; 95% CI, 1.02-1.51) compared to individuals in quartile 1. **Conclusion:** In this large and demographically diverse ALD cohort, residing in socioeconomically disadvantaged neighborhoods was associated with increased risk of mortality and MACE. These findings underscore the critical need for not only individualized clinical interventions but also broader intervention strategies that identify and target upstream social and environmental factors. Addressing neighborhood-level SDOH through community engagement, policy reform, and cross-sector collaborative partnerships may be essential to reducing health disparities in ALD.

Table 1. Competing risk analysis for death and incidence of disease by SDI quartile.

SDOH Quartile		Q1 SDI	Q2 SDI	Q3 SDI	Q4 SDI

2213 | IMPACT OF SOCIAL DETERMINANTS OF HEALTH ON CLINICAL OUTCOMES IN ALCOHOL-ASSOCIATED HEPATITIS: A NATIONAL INPATIENT ANALYSIS 2020–2021

Nakul Ganju[1] Shubham Gupta[2] Shaunak Ganju[3] Juan Santiago-Gonzalez[1] Mesay Asfaw[1] Farshad Aduli[1], [1]Howard University Hospital, [2]Virtua Health, [3]Sidney Kimmel Medical College

Background: Alcohol-associated hepatitis (AH) is a severe liver disease with high morbidity and mortality, especially in hospitalized patients. AH-related hospitalizations are rising in the U.S., disproportionately among younger adults and women—a trend worsened by COVID-19. Though clinical outcomes are well studied, the role of social determinants of health (SDOH)—income, insurance, and geography—remains underexplored. **Methods:** We conducted a retrospective cohort study using 2020–2021 National Inpatient Sample (NIS) data to identify adults ($\geq$18) hospitalized with primary AH. Independent variables included income quartile, primary payer, and hospital location; outcomes were in-hospital mortality, length of stay (LOS), and total charges, adjusted via multivariable regression. **Results:** Among 31,273 AH hospitalizations, mortality was 4.9%, median LOS 4 days, charges $40,686. Lowest-income quartile had higher mortality (5.1% vs. 4.2%) and lower charges ($68,828 vs. $79,510) than highest; adjusted mortality odds were elevated (OR 1.22, 95% CI 0.99–1.51). Medicare patients had highest mortality (7.0%) and LOS (7.1 days); self-pay patients had lowest mortality (4.0%), LOS (5.5 days), charges ($60,843). Mortality was higher in rural hospitals (5.1%) vs. large metro centers (4.4%) and lowest in small metros. Black patients had shorter LOS, lower charges, and lower mortality ($\beta = -0.308$, $p = 0.0028$); Native Americans had higher mortality ($\beta = 0.496$, $p = 0.0007$). Asian/Pacific Islander, Hispanic, and other groups had higher charges without significant LOS or mortality differences. Disparities persisted after adjustment. Women had longer LOS despite similar mortality. SDOH differences suggest a need for stratified AH care. Resource use variation signals inefficiencies in care models. Subgroup trends may reflect delayed specialty access. Findings highlight equity gaps despite standardized settings. Unmeasured factors like alcohol severity or support may contribute. Regional variation in hospital capacity or care protocols may also influence disparities. Including clinical and behavioral data in future studies may improve precision. **Conclusion:** SDOH—including income, insurance, and race—independently influence AH outcomes and utilization. Persistent disparities, despite adjustment, imply systemic inequities in access, care quality, and resource allocation. This nationally representative analysis offers post-COVID insight into AH outcomes. The study quantifies cumulative SDOH effects, supporting their inclusion in risk models and care planning. Embedding SDOH in quality metrics may guide equity-focused reforms. Interventions addressing underinsurance, rural care gaps, and structural racism are essential to reduce disparities. Addressing these inequities is critical to improve AH survival and reduce alcohol-related liver disease burden.

2214 | DETERMINANTS OF CONTINUITY OF CARE BEYOND DIRECT-ACTING ANTIVIRAL INITIATION IN PATIENTS WITH HEPATITIS C

WonKyung Cho[1] Timea Csak[2] Ngan Nguyen[3], [1]Long Island Jewish Forest Hills Hospital, Northwell Health, [2]Sandra Atlas Bass Center for Liver Diseases & Transplantation, Northwell Health, [3]Center for Liver Diseases and Transplantation, Northwell Health Department of Medicine

Background: Hepatitis C virus (HCV), a major cause of chronic liver disease, affects an estimated 58 million people globally and remains a critical public health concern in the U.S. HCV disproportionately impacts underserved populations, including non-Hispanic Black individuals, those with a history of intravenous drug use (IVDU), and individuals of low socioeconomic status. While prior studies have assessed disparities in direct-acting antiviral (DAA) initiation, few have investigated the post-treatment continuum, including sustained virologic response (SVR-12) confirmation and ongoing hepatology follow-up. Here, we identify patient-level determinants of care continuity during and following DAA therapy. **Methods:** A retrospective cohort study was conducted among HCV patients who initiated DAA therapy between January 1, 2022 and December 15, 2024 within Northwell Health. Demographic and clinical variables included age, sex, race/ethnicity, language, insurance type, comorbidities, and route of infection. Primary outcome was continuity of care, defined by confirmed SVR-12 labs and post-treatment hepatology follow-up. Secondary analysis assessed AASLD-concordant HCC surveillance among cirrhotic patients. Logistic regression models adjusted for age, sex, and race were used to estimate odds ratios (OR) and 95% confidence intervals (CI). **Results:** Among 206 patients (mean age 60; 42.8% female), 47.1% were White and 23.5% Black. While continuity of care rates did not differ by race, patients with substance use disorder (SUD) enrolled in treatment programs had higher odds of missing SVR-12 labs (OR 4.2; $p = 0.008$), though this was attenuated after adjustment (aOR 2.9; $p = 0.073$). Mental health diagnoses remained significantly associated with lower SVR-12 lab completion (aOR 2.2; $p = 0.040$). Commercial insurance was protective (aOR 0.3 vs. Medicare; $p = 0.033$), and lower copay amounts were associated with continuity of care (aOR 0.9; $p = 0.044$). In cirrhotic patients ($n = 74$), younger age (OR 0.9; $p = 0.020$) and non-English language (OR 0.14; $p = 0.059$) were associated with increased adherence to HCC surveillance guidelines. **Conclusion:** Disparities in HCV care continuity persist even after DAA initiation. Psychiatric illness, substance use, insurance type, and out-of-pocket costs contribute to gaps continued follow up beyond DAA initiation. Surprisingly, non-English speakers demonstrated improved follow-up in cirrhotics, suggesting potential benefits of targeted language-concordant care. Culturally tailored, low-barrier interventions addressing mental health, substance use, and financial access are critical to achieving equity in HCV outcome.

2215 | UNMASKING HEALTH DISPARITIES IN APPALACHIA: THE IMPACT OF THE COVID-19 PANDEMIC ON LIVER RELATED MORTALITY

Jordan Woodard[1] Katharine Cook[1] Kory Heier[2] Kristen McQuerry[2] Nimish Thakral[3], [1]University of Kentucky College of Medicine, [2]University of Kentucky, [3]University of Kentucky Medical Center

Background: According to the Centers for Disease Control and Prevention (CDC), chronic liver disease (CLD) was the 10th leading cause of death in the United States as of 2022. Previous studies have highlighted geographic hotspots for CLD mortality, with central Appalachia experiencing an increasing CLD prevalence prior to the COVID-19 pandemic. However, a study conducted in collaboration with the Appalachian Regional Commission (ARC) found no significant difference in CLD mortality between Appalachian counties (AC) and non-Appalachian counties (nAC) across the 13 states served by the ARC from 1999 to 2015. The

prevalence of the CLD has continues to rise through the COVID-19 pandemic with data from the ARC for 2019 showing increase in the rates of cirrhosis in both AC and nAC. Despite these trends, the disparities in CLD mortality between AC and nAC post-pandemic have not been adequately examined. This study aims to address this gap by investigating the evolving disparities in CLD mortality in wake of the COVID-19 pandemic. **Methods:** This cross-sectional study used mortality data from the CDC from 1/1/2018 – 9/15/2018 for the 13 states containing Appalachian counties. ICD-10 codes for alcohol-associated liver disease, cirrhosis, liver cancers, primary biliary cholangitis and primary sclerosing cholangitis were included. Counties with less than 10 deaths were excluded. Deaths per 10,000 were calculated as incidence ratios (IR) using 2020 U.S. Census data at the county level. Death rates were compared between AC and nAC, overall and at the state level. Statistical analyses were conducted using R-studio version 4.4.2 (R Foundation for Statistical Computing,Vienna, Austria). **Results:** 1,098 counties across 13 states were included. In all states, the AC had higher combined liver related deaths per 10,000 than nAC. The highest IRs by state were observed in West Virginia (WV) at 37.55 (36.65-38.46) followed by Kentucky at 32.33 (31.80-32.85). The AC in Kentucky had the highest crude IR at 42.22 (41.04-43.42). The lowest crude IR was New York at 16.80 (16.62-16.98). Virginia had the largest gap with ACIR being 23.69 points higher than nAC IR. Using geographical mapping, a mortality hotspot was identified in the Kentucky, West Virginia, and Virginia (figure 1). Using negative binomial regression, AC had an incidence rateratio of 1.30 ($p < 0.001$) compared to nAC. **Conclusion:** Previously, the ARC showed no difference between AC and nAC prior to 2019. As the incidence of CLD rises, we now identified that liver related mortality is 1.3 times higher in AC. Central Appalachia has the highest IR of liver deaths, likely related to the disproportionate increase in CLD previously documented in this region.

2216 | PREVALENCE OF ADVANCED HEPATIC FIBROSIS AND STEATOSIS IN AN UNDERSERVED HISPANIC POPULATION

Christopher Danford[1] Gabriela Portugal-Bouza[2] Silvia Rosas[2] Ivan Zendejas[1], [1]Intermountain Medical Center, [2]Alliance Community Services

Background: Increased risk of metabolic dysfunction-associated steatotic liver disease (MASLD) and cirrhosis in the Hispanic community is well-established.[1] However most studies have occurred in a healthcare setting and among those with health insurance and may not be representative of the Hispanic community as a whole which has among the lowest rates of health insurance coverage.[2] In order to assess the prevalence of MASLD and hepatic fibrosis in an underserved Hispanic community, we performed transient elastography measurements in patients presenting for free health services through the Ventanilla de Salud. **Methods:** The Ventanilla de Salud is a free service sponsored by the Mexican Consulate that provides free health services and screenings regardless of national origin, insurance, or immigration status. We performed transient elastography measurement in 209 consecutive patients who presented to the Ventanilla de Salud. MASLD was defined as a CAP score $\geq$ 285 dB/m, advanced fibrosis as a liver stiffness $\geq$ 8.5 kPa, and cirrhosis as liver stiffness $\geq$ 13 kPa. We also collected patient reported comorbidities, comprehensive metabolic panel, anthropomorphic measurements, and a brief survey about healthcare access. **Results:** Among 209 patients, 87 (42.2%) had evidence of MASLD and 31 (15%) had advanced fibrosis, and 9 (4.4%) had cirrhosis by transient elastography. The cohort had a mean age of 50 years, 21.9% had a known history of type 2 diabetes, 44.7% had a BMI $\geq$ 30 kg/m^2, 55.6% were uninsured, and 34.9% had a total household income $<$ \$35,000/year. Those with advanced fibrosis had a significantly higher BMI, AST, and ALT. Of note, none were aware of any prior diagnosis of liver disease. The primary reported reason for not having a routine source of healthcare was “seldom or never get sick” (44.2%) followed by lack of health insurance (15.4%). Nearly half (45.2%) of those with advanced fibrosis on transient elastography reported they do not seek medical care because they “seldom or never get sick” (Table 1). **Conclusion:** In an unselected cohort of Hispanic subjects with limited access to healthcare, the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

prevalence of MASLD was 42.2% and advanced fibrosis was 15%. While the majority of patients were uninsured (55.6%) and a significant proportion low income (34.9%), most patient reported they did not have a routine source of healthcare since they "seldom or never got sick". None were previously aware of any chronic liver disease. These findings point to improved screening, patient education, and community awareness as potential interventions to improve early diagnosis and management of MASLD in the Hispanic community.

Table 2. Demographics by advanced fibrosis (kPa ≥ 8.5)

	No advanced fibrosis (n = 175)	Advanced fibrosis (n = 31)	p value

2217 | PERSISTENT LIVER INJURY AND RECURRENCE AFTER HELLP SYNDROME: INCIDENCE AND OUTCOMES IN A RETROSPECTIVE COHORT (2009–2024)

Nina Rodriguez[1] Cecilia Katzenstein[1] Keith Sigel[1] Rhoda Sperling[1] Tatyana Kushner[2], [1]Icahn School of Medicine at Mount Sinai, [2]Weill Cornell Medicine

Background: Hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome is a severe obstetric complication with significant morbidity. While acute management is well described, data on hepatic recovery and outcomes in subsequent pregnancies is limited. We aim to characterize the acute complications and longitudinal hepatic and obstetric outcomes in patients with HELLP. **Methods:** We conducted a retrospective cohort study of singleton HELLP pregnancies at a large academic center (2009-2024). Data was extracted from the electronic medical record. We defined persistent ALT elevation as > 25 U/L within 6 months postpartum (PP). Variables were compared using Fisher's exact tests and t-tests. Time-to-event analysis was performed using a Cox proportional hazards model. **Results:** A total of 91 patients were identified (mean age 33 yrs; BMI 28 kg/m²); 51% were White, 19% Hispanic, 16% Black, 8% Asian. Six-month PP data was available for 53%; 76% had any post-delivery follow-up. Preexisting hypertensive disorders were present in 18%, prothrombotic conditions in 14%. Median gestational age at diagnosis was 36 weeks; 31% met Mississippi Class I criteria and 15% required ICU care. Acute hepatic complications were rare (two liver failures, one capsule rupture). Acute non-hepatic complications occurred in 16%: AKI (8%), pulmonary edema (4%), eclampsia (3%), DIC (2%), PRES (2%). Fetal outcomes include intrauterine demise (7%) and NICU admission (48%). ALT normalized in 52% by 6 months PP (median 34 days); 89% normalized at any point post-delivery (median 354 days). No preexisting factors were significantly associated with normalization (Table 1). Six-month PP follow-up was more common in patients with IVF pregnancies, ICU admission, higher peak ALT, and acute complications (all $p < 0.05$). Time to ALT normalization was shorter in those with acute non-hepatic complications (HR 2.5 95% CI 1.1-5.8). No new chronic liver diseases were documented in follow-up, though three patients had incidental hepatic steatosis on imaging. Among 27 patients with a subsequent pregnancy, HELLP recurred in 23% (median interval: 25 months). **Conclusion:** Liver injury persisted in many patients after HELLP, yet follow-up was inconsistent and more common in those with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

severe presentations. This raises concern that delayed hepatic recovery may go unrecognized in those perceived as lower risk. This underscores the need for structured surveillance after HELLP to ensure timely recognition of lingering hepatic injury. Given the risk of recurrence in future pregnancies, anticipatory counseling and interdisciplinary follow-up should also be integral to PP care.

Table 1. Demographic, Clinical, and Obstetric Characteristics by ALT Normalization Status Within 6 Months Postpartum

Variable	Normal ALT within 6 months PP (n=25)	Elevated ALT within 6 months PP (n=23)	p

2218 | HBV VACCINATION STATUS AMONG INDIVIDUALS IN THE NYC JAIL SYSTEM BORN BEFORE AND AFTER US UNIVERSAL CHILDHOOD VACCINATION RECOMMENDATIONS

Chibuzo Enemchukwu[1] Batya Koenigsberg[1] Raphael Simonson[1] Malia Mackey[1] Natalia Gonzalez Varela[1], [1]NYC Health+Hospitals

Background: Hepatitis B virus (HBV) vaccination is critical for the prevention of HBV infection and potential sequelae. Vaccination is recommended for adults 18-59 years, and for all adults with risk, such as incarceration. Additionally, universal vaccination of all infants has been recommended in the US since 1991. HBV vaccination status is not well studied in the jail setting. This study aims to examine HBV vaccination status among persons in the NYC jail system born before and after universal infant vaccination recommendations. Results will provide critical insights into potential HBV prevention strategies for short-stay carceral settings. **Methods:** This retrospective study included all individuals in the NYC jail system between October 2019 and December 2023 who had HBV serologic testing in our system. We divided the sample into two cohorts: (1) those born before November 22, 1991 (pre-recommendation (pre-rec)), and (2) those born after (post-recommendation (post-rec)). We used multivariate regression to examine differences in HBV susceptibility, vaccination status, and past infection (HBV core-antibody positivity) by birth cohort. Regressions were adjusted for histories of serious mental illness, select substance use disorders, HIV, hepatitis C, housing status, jail length of stay, gender, and number of previous incarcerations in the prior year. **Results:** Our study comprised 2282 persons, of whom 2014 (88.3%) were men, and 268 (11.7%) women. 1912 persons (83.8%) were in the pre-rec cohort, and 370 persons (16.2%) in the post-rec cohort. The post-rec cohort had higher odds of susceptibility to HBV (adjusted odds ratio [aOR] = 1.42, 95% CI: 1.12-1.82), higher odds of HBV vaccination (aOR = 1.71, 95% CI: 1.35-2.15), and lower odds of past HBV infection (aOR = 0.181, 95% CI: 0.117-0.278) when compared to the pre-rec cohort. **Conclusion:** Individuals born after universal HBV infant vaccination recommendations were more likely to be vaccinated for HBV, yet were also more likely to be susceptible to HBV and therefore vaccine-eligible. We found that these individuals were also less likely to have had past HBV infection, compared to those born before universal infant HBV vaccine recommendations. These findings suggest that birth cohort stratification may not be an effective strategy for targeted HBV screening and prevention protocols in short-stay carceral settings.

Dentici[1] Al'ona Furmanchuck[1] Nikhilesh Mazumder[2] Lisa VanWagner[3] Lihui Zhao[1] Andres Duarte-Rojo[4] Sanjay Mehrotra[1] Daniela Ladner[1], [1]Northwestern University, Chicago, IL, [2]University of Michigan Hospitals and Health Centers, [3]University of Texas Southwestern Medical Center, [4]Northwestern Medicine

Background: Liver transplant is a curative treatment for patients with cirrhosis. We examined mortality, waitlisting and liver transplant rates by race/ethnicity.
Methods: CAPriCORN, a large EHR data repository across 7 health care systems in a large US metropolitan area, was used to identify adult patients with cirrhosis from 2016-2021. Demographics and clinical factors were collected including age, sex, race/ethnicity, etiology, Area Deprivation Index (ADI) [Q1: high resourced, Q5: low resourced) and decompensation. Outcomes included all-cause mortality, waitlisting and transplant. HCC was excluded from mortality but included in waitlisting and transplant analyses. Multivariable Cox proportional hazard models were used to assess mortality and multivariable logistic regression to assess waitlisting and transplant probability. Significance = $P < 0.05$. **Results:** 18,718 patients with cirrhosis were included. Mean age was 59.8, 43.1% were women, 45% were white, 19% black, 21% Hispanic. Most common etiologies were MASLD (28.6%), MetALD (23.1%), ALD (12.8%). ADI (Q1: 5.7%, Q2: 30.8%, Q3: 36.4%, Q4: 23.6%, Q5: 2.4%). 29.7% were decompensated at inclusion. Mortality per 100 PY was 13.26 (white: 16.13, black: 9.08, Hispanic: 8.86 per 100PY). Waitlisting occurred in 9.63% of white, 3.83% of black, and 7.48% of Hispanic patients. Transplant occurred in 7.26% of white, 2.8% of black patients and 7.06% of hispanic patients. Adjusted mortality was highest in white patients; black (HR 0.52, 95% CI 0.46–0.60) and Hispanic (HR 0.59, 95% CI 0.52–0.67) patients had significantly lower mortality ($P < 0.001$). Black patients had lower odds of waitlisting compared to white patients (OR 0.34, 95% CI 0.27–0.42, $P < 0.001$), but similar odds of transplant once listed (OR 0.86, 95% CI 0.51–1.51, $P = 0.6$). (Figure) **Conclusion:** In a real-world cohort of patients with cirrhosis living in a metropolitan area, white patients have the highest all-cause mortality, while black patients were significantly less likely to be waitlisted. However, transplant probability was similar for white and black patients once waitlisted, suggesting differences in transplant access.

2220 | RACIAL DIFFERENCES IN FIBROSIS PROGRESSION AFTER LIVER TRANSPLANTATION

Michael Attanasi[1] Mathew Gregoski[2] Don Rockey[2], [1]Northwell Health, [2]Medical University of South Carolina

Background: Liver transplant remains an important tool in the treatment of end stage liver disease. However, the progression of post-transplant fibrosis has not been studied thoroughly in different racial groups. We hypothesized that the progression of post-transplant fibrosis varies in different racial groups, and examined this progression histologically. **Methods:** We examined all adults who had a liver biopsy with a transplant at our institution from January 1, 2013 through July 1, 2021. Histology, fibrosis stage, rejection activity index (RAI) and complete clinical data were abstracted via the medical record. We included only patients who had undergone liver transplantation, and excluded patients having a biopsy specifically to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

evaluate liver lesions. The median time to developing fibrosis levels (F0-F4) was calculated. Race was self-identified by patients. **Results:** Of 515 transplant patients having a liver biopsy, we identified 206 White and 69 Black patients who had fibrosis staged (a total of 688 biopsies among these patients). White patients were significantly older than Black patients at the time of transplant (53 (+/- 0.7) vs 46 (+/- 1.7) years, respectively ($p < 0.01$)). White patients were significantly more likely to be male, and Black patients were significantly more likely to be female. White patients were significantly more likely to have ALD and MASLD than Black patients (44/206 (21%) vs 2/69 (3%);32/206 (16%) vs 2/69 (3%), respectively; each $p < 0.01$), whereas Black patients were significantly more likely to have AIH, PBC, and PSC than White patients (20/69 (29%) vs 19/206 (9%); 7/69 (10%) vs 6/206 (3%); 9/69 (13%) vs 6/206 (3%), respectively; each $p < 0.01$). The median time to develop F4 fibrosis was 6 years in White patients and 9 years in Black patients (Figure 1). Sensitivity analysis of liver disease etiology by race demonstrated that this trend of more rapid fibrosis progression was preserved in White patients, with the exception of HCV, where Black patients had a slightly higher rate of fibrosis progression. **Conclusion:** In conclusion, White patients appear to have more rapid fibrosis progression than Black patients after liver transplantation. It should be recognized that the causes of liver disease leading to transplant are different in Black and White patients, and may represent a confounding factor for fibrosis progression; however, sensitivity analysis of this generally demonstrated the same trend.

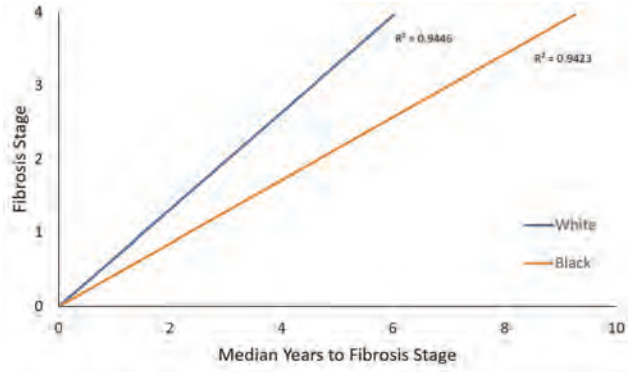

Figure 1. Median years to fibrosis stage. All liver biopsies taken in Black and White patients were analyzed and the median time to develop each stage of fibrosis was calculated and plotted. Biopsies in White patients: n = 480; Biopsies in Black patients: n = 208

2221 | GLOBAL BURDEN AND TRENDS OF LIVER CANCER IN INDIVIDUALS < 20 YEARS IN 204 COUNTRIES AND ITS TERRITORIES: A 30-YEAR GLOBAL EPIDEMIOLOGICAL PERSPECTIVE

Sandeep Kotnani[1] Raghava Rao Alluri[2] Ker Patel[3] Parvinder Kaur[4] Madhu babu Adusumilli[5] Mili Ashar[6] JUHI PATEL[7] Yashkumar Kamani[8] Hardik Zinzala[9] VISHRANT AMIN[10] Hardik Desai[11], [1]Rutgers Monmouth Medical Center, [2]Prime South GME Consortium/Harlingen Medical Center Program, [3]Surat Municipal Institute of Medical Education and Research, Surat,India, [4]The Crimean State Medical University named after S.I.Georgievsky, Simferopol, Ukraine, [5]HCA Ocala Florida hospital -UCF, [6]Rural Medical College, Lonhi, Maarashtra (Pravara Institute of Medical Sciences), [7]GMERS Medical College Valsad, [8]"BronxCare Health System ", [9]Jonelta foundation school of medicine, [10]HMH JFK University Medical Center, [11]Independent Clinical and Public Health Researcher

Background: Although liver cancer is typically associated with adult populations, its occurrence in individuals under 20 years of age poses a significant yet underexplored public health concern. Emerging evidence highlights distinct etiologies, such as viral hepatitis, alcohol use, non-alcoholic steatohepatitis (NASH), and hepatoblastoma, which contribute to this burden. Understanding long-term trends in prevalence, incidence, and mortality is crucial for informing early interventions and global pediatric cancer strategies. **Methods:** We utilized data from the Global Burden of Disease (GBD) 2021 framework to assess liver cancer trends among individuals aged < 20 years across 204 countries and territories between 1990 and 2021. We examined temporal changes in prevalence, incidence, and deaths due to various liver cancer etiologies and calculated the Annual Percentage Change (APC) to quantify trends. Subgroup analyses were conducted by region, age, sex, and cause-specific attribution. **Results:** The greatest rise in global prevalence was attributed to liver cancer due to NASH, with an APC of +1.96% (from 176 in 1990 to 283 in 2021), followed by alcohol use (+0.94%; from 16 to 21), hepatitis C (+0.55%; from 41 to 48), and other causes (+0.20%; from 508 to 541). In contrast, hepatoblastoma showed a marked decline (APC: –1.28%; from 56,183 to 33,829), along with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

hepatitis B (–0.81%; from 1,565 to 1,169). Regionally, Sub-Saharan Africa reported the highest APC in liver cancer incidence (+0.26%) and deaths (+0.35%), whereas other regions experienced a decline. Among age groups, the highest incidence rate in 2021 was noted in infants aged 6–11 months (1.23 per 100,000; 95% UI: 0.93–1.59). Notably, the 15–19-year age group experienced the highest total percentage change (TPC) in incidence due to hepatitis C (24%), alcohol use (23%), and NASH (55%). Gender-specific analysis revealed a greater TPC in deaths among females compared to males for NASH (55% vs 39%), alcohol-related liver cancer (25% vs 12%), and hepatitis C (18% vs 4%). **Conclusion:** Liver cancer in the pediatric and adolescent population shows a heterogeneous pattern across causes and regions. The rising burden of NASH and alcohol-related liver cancer, particularly among older adolescents and females, underscores the need for early life preventive strategies and global pediatric oncology surveillance. Focused interventions targeting metabolic and infectious etiologies could curb this emerging burden in youth populations.

2222 | DISPARITIES IN MORTALITY TRENDS OF ALCOHOLIC LIVER FAILURE WITH MENTAL AND BEHAVIORAL DISORDERS IN THE U.S., 1999–2020: INSIGHTS FROM THE CDC WONDER DATABASE

Sandeep Kotnani[1] Yashkumar Kamani[2] Raghava Rao Alluri[3] Mahendra Kumar[4] Fagun Viramgama[5] Nimrat Dhillon[6] Nivid Patel[7] Mahir Modi[8] VISHRANT AMIN[9] Dhrumil Sakariya[10] Hardik Desai[11], [1]Rutgers Monmouth Medical Cente, [2]BronxCare Health System, [3]Prime South GME Consortium/Harlingen Medical Center Program, [4]Sardar Patel Medical College, Bikaner, India, [5]Surat Municipal Institute of Medical Education and Research (SMIMER),Surat, India, [6]Sri guru Ram das institute of medical sciences and research, vallah, Amritsar, Punjab, [7]American university of Barbados, [8]GCS Medical College Hospital and Research Centre, [9]HMH JFK University Medical Center, [10]Davao Medical School Foundation Poblacion District,Davao City, Philippines, [11]Independent Clinical and Public Health Researcher

Background: Alcoholic liver failure (ALF) is a medical emergency with high fatality, increasingly linked to the rising burden of mental and behavioral disorders (MBDs) in the U.S. Disorders such as alcohol use disorder, depression, and schizophrenia not only drive chronic alcohol misuse but also delay management of liver injury. Despite this critical overlap, the contribution of MBDs to ALF remains poorly quantified. **Methods:** We utilized nationally representative mortality data to assess the burden of ALF with coexisting MBDs in the U.S. from 1999 to 2020. Both absolute and age-standardized mortality rates were used to calculate the annual percent change (APC). Analyses were stratified by age, sex, year, race, location to identify demographic and geographic disparities. **Results:** From 1999 to 2020, the total number of deaths increased from 3,461 to 6,370, with a sharp rise observed between 2007-2020 at an APC of 8.83%. Across U.S. Census Regions, the Midwest showed the highest annual percent change (APC) in deaths at +1.91%, followed by the South (+0.54%), while the West experienced a decline (–1.79%). By 2013 urbanization levels, the highest APC was noted in small metro areas (+1.72%) and micropolitan nonmetro regions (+1.68%), with the lowest in large fringe metro areas (+0.34%). State-level analysis revealed the most pronounced increases in Indiana (+6.16%), Minnesota (+5.38%), and Iowa (+4.32%). Racial disparities were evident, with American Indian or Alaska Native populations experiencing the highest APC (+1.36%), while Black or African American populations showed a decline (–2.25%). By Hispanic origin, deaths increased among non-Hispanic individuals (+0.11%) but declined significantly among Hispanic or Latino populations (–1.71%). Age-wise, the sharpest rise was observed in the 55–64 age group (+2.64%), followed by 25–34 years (+2.15%), whereas a decline was noted in those aged 75–84 (–1.72%). Lastly, gender-based trends indicated an increase among females (+0.45%) and a slight decline among males (–0.33%). **Conclusion:** The rising mortality from ALF in individuals with MBDs—especially among American Indian populations,

2223 | ALCOHOL INTAKE ADJUSTMENT AND PREVIOUS HISTORY OF ALCOHOL USE UNCOVER HIDDEN RISK OF PREMATURE MORTALITY AMONG PATIENTS WITH STEATOTIC LIVER DISEASE

James Paik[1] Dana Ivancovsky Wajcman[2] Shira Zelber-Sagi[3] Andrei Racila[2] Saleh Alqahtani[4] Zobair Younossi[2], [1]Beatty Liver and Obesity Research Program, [2]The Global NASH Council, [3]Tel-Aviv Sourasky Medical Center, [4]Liver, Digestive, and Lifestyle Health Research Section, and Organ Transplant Center of Excellenc

Background: SLD encompasses a spectrum from metabolic dysfunction–associated SLD (MASLD), metabolic dysfunction–associated alcohol-related liver disease (MetALD) and alcohol-related liver disease (ALD). Self-reports often underestimate current and previous alcohol intake. This study aimed to compare the risk of premature mortality across the SLD spectrum using U.S. per capita–adjusted alcohol intake estimates. **Methods:** The National Health and Nutrition Examination Survey (1988-1994) with mortality follow-up to 2019 was used. Alcohol intake was adjusted to align with 1990 U.S. per capita alcohol consumption estimates based on national sales data. Participants were categorized as: abstainers (<12 drinks lifetime), former drinkers (≥ 12 drinks lifetime but none in past 12 months), low ($<20/30$ g/day for W/M), moderate (20–49.9/30–59.9 g/day), or heavy ($\geq 50/60$ g/day). SLD was diagnosed by ultrasound and sub-grouped according to the recent consensus to MASLD, MetALD and ALD. Premature mortality (death $\leq 80/75$ years for W/M) and age-standardized mortality rates (per 1,000 person-years) were calculated using the 2000 U.S. standard population. **Results:** Among 12,927 adults (mean age 42.8 years; 48.1% men), 19.0% had SLD ($n=2,807$, (79.9% MASLD, 8.4% MetALD, and 11.7% ALD). Within the MASLD group, 45.1% were former drinkers. Compared to MASLD-abstainers who never drunk, MASLD-former drinkers had higher fibrosis scores (FIB-4 >2.67: 2.01% vs. 0.44%, $p=0.038$), but lower than MetALD and ALD groups (FIB-4 >2.67: 4.21% and 6.56%, respectively). Premature mortality rates were also highest among individuals with ALD (13.5 per 1,000 person-years), followed by MetALD (11.5), MASLD (8.3), and non-SLD groups (Table). In Cox models adjusted for sociodemographic and lifestyle factors, the risk of premature death was greatest for ALD, followed by MetALD, and MASLD-former drinkers as compared to non-SLD abstainers, while no significant increase in risk of death was observed for MASLD-abstainers (Table). **Conclusion:** This U.S. study, using per capita–adjusted alcohol intake, highlight that both current and past alcohol use significantly increase premature mortality risk across SLD subtypes. ALD, MetALD, and MASLD with a history of alcohol use were all associated with increased premature mortality risk.

Table. Hazard Ratios for Premature Mortality by SLD and Alcohol Use Categories

	Premature Mortality (per 1,000)	Sociodemographic- and lifestyle-adjusted model	
		HR (95% CI)	P-value
Non-SLD (Abstainer)	5.93	Reference	
MASLD (Abstainer)	6.69	1.26 (0.82 - 1.92)	0.282
MASLD (Former drinkers)	9.87	**1.55 (1.11 - 2.16)**	**0.011**
MetALD	11.54	**1.77 (1.01 - 3.09)**	**0.046**
ALD	13.46	**1.80 (1.13 - 2.87)**	**0.014**

Abbreviations: HR, Hazard ratio.
Hazard ratios estimated using Cox proportional hazards models adjusted for age, sex, race/ethnicity, educational attainment, household income, Healthy Eating Index (<56.9), and no physical activity.

2224 | HEPATORENAL MORTALITY TREND AND HEALTHCARE DISPARITIES IN THE UNITED STATES (1999–2020)

Tooba Laeeq[1] Ayesha Saleem[2] Syed Ali Hussain[2] Muhammad Asjad Saleem[3] Khadija Mohib[4], [1]University of Nevada Las Vegas, [2]Dow University of Health Sciences, [3]The Indus Hospital, [4]University of Nevada, Las Vegas

Background: Hepatorenal syndrome (HRS) is a severe liver disease complication marked by progressive renal failure. Despite clinical gains, mortality remains high. This study examines long-term HRS mortality trends in U.S. adults aged 55+, highlighting gender, ethnic, geographic, and urbanization differences from 1999-2020. **Methods:** Data from the Centers for Disease Control and Prevention Wide-ranging Online Data for Epidemiologic Research (CDC WONDER) Multiple Cause of Death database were used to identify hepatorenal syndrome deaths (ICD-10 code K76.7) in U.S. adults aged 55 years and older from 1999 to 2020. Age-adjusted mortality rates (AAMRs) per 100,000 population were calculated using the 2000 U.S. Standard Population. Analyses were stratified by sex, race/ethnicity, urbanization (metropolitan vs. non-metropolitan), and U.S. Census region. Temporal trends were assessed using the Joinpoint Regression Program (v5.3.0) to estimate annual percent change (APC) and average annual percent change (AAPC), with 95% confidence intervals. Statistical significance was set at $p < 0.05$. **Results:** Between 1999 and 2020, a total of 63,389 hepatorenal-related deaths were recorded in the U.S. The AAMR declined from 4.63 in 1999 to 4.07 in 2020. In 1999, the highest AAMR was observed among NH American Indian/Alaska Natives (9.44), males (6.52), residents in the West (5.30), and non-metropolitan areas (4.98); the lowest were seen among NH White individuals (4.27), females (3.15), Midwest residents (4.12), and metropolitan areas (4.56). In 2020, the highest AAMR persisted among NH American Indian/Alaska Natives (11.32), males (5.44), West (5.01), and non-metropolitan areas (5.38); the lowest were among NH Asian/Pacific Islanders (2.12), females (2.95), Northeast (3.28), and metropolitan areas (3.84). Females showed a smaller decline (AAPC: −0.59%; 95% CI: −0.97, −0.27), while males had a greater decline (AAPC: −1.26%; CI: −1.57, −0.93). The Northeast experienced the most significant decline (AAPC: −1.93%; CI: −2.24, −1.62), while the Midwest showed the most significant increase post-2018 (APC: +9.24%; CI: 1.30, 13.87). The smallest decline was in the West -0.67(-1.30,-0.17).NH Asian/Pacific Islanders had the steepest decline (AAPC: −3.54%; CI: −4.73, −2.63), while NH American Indian/Alaska Natives showed the least change (AAPC: −0.20%; CI: −1.26, 1.15), which was not significant. White showed a statistically significant least decline with an AAPC -0.37% (-0.69,-0.12). Metropolitan areas had a notable decrease (AAPC: −1.18%; CI: −1.46, −0.86), compared to non-metropolitan areas (AAPC: -0.19%; CI -0.78,0.49). **Conclusion:** Despite the overall decline in hepatorenal mortality, sharp increases after 2018 in the Midwest with persistent gaps, especially in NH American Indian/Alaska Natives and rural areas, highlight ongoing inequities. Addressing this need requires culturally and regionally tailored public health efforts.

2225 | CHALLENGES FACING PATIENTS WITH CIRRHOSIS

Deanna Oliver[1] Anna Marie Hefner[1] Julian Diaz-Moreno[1] Ahmed Atalla[1] Usman Gul[1] Mustafa Behan[2] Jutta Kurz[2] Valeriia Aksakovska[2] Michael Tunkelrott[3] Emmanuel Gorospe[4] Fatma Barakat[5] Tarek Hassanein[1], [1]Southern California Liver Centers, [2]Amsety, [3]Amsety LLC, [4]Burrell College of Osteopathic Medicine, [5]SCTI Research Foundation

Background: Up to 8% of patients with cirrhosis develop liver cancer (LC). Over 10 years, the risk for LC can reach 30%, particularly in high-risk populations. Given new treatments for LC, early identification is essential for timely intervention. The aim of this analysis is to identify data-driven challenges for patients with cirrhosis. **Methods:** The Amsety database comprises of 650,000 participants (pts) in the United States with a history of liver disease. Out of those, about 36,000 have cirrhosis. In March 2025, 200 pts were asked to answer additional questions about their cirrhosis diagnosis and management. **Results:** Average age of respondents was 53 years. 62% were overweight, obese, morbidly obese. 27% were diagnosed with cirrhosis within the previous year, 46% between 1 and 5 years, 12% between 5 and 10 years, and 10% more than 10 years earlier. Etiology: 29% NAFLD/MASLD, 23% alcohol, 8% chronic viral hepatitis. Prior to cirrhosis diagnosis: 27% struggled with unusual fatigue and 23% experienced abdominal discomfort. 19% had swelling (legs, ankles, or abdomen), 12% itchy skin/jaundice. After diagnosis: 31% adopted a healthier diet, 21% reduced or eliminated alcohol consumption, 20% limited over-the-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

counter medications use, increased physical activity, started supplements, or focused on mental health. Monitoring: 35% followed by a liver specialist and 55% by primary care physicians. 19% visit their doctor once a month, 43% every 3 months, 29% every 6 months, 4% once a year or less. 62% reported monitoring their disease progression by blood tests vs. imaging in only 12%. Pt concerns: 46% disease progression, 25% development of LC, 17% future need for liver transplant. 48% cited healthcare providers as primary source of information, 27% used online resources, 10% relied on social media/online communities, 10% support groups/family and friends. **Conclusion:** Per patient reporting, 1) screening for LC is still not enforced and underutilized, 2) pts seek more education, support/monitoring, 3) pts lack consistent care and face barriers to early disease detection and intervention, 4) lifestyle changes are often initiated but not uniformly adopted. As the acceptance of digital tools is high, a liver-specific Gen AI solution could provide accessible, personalized information and guidance. Such tools may empower patients to better manage their condition, improve engagement, and potentially delay or prevent progression.

2226 | CLINICAL OUTCOMES OF NATIVE AMERICANS WITH ALCOHOL-ASSOCIATED LIVER DISEASE: A RETROSPECTIVE COHORT STUDY

Pojsakorn Danpanichkul[1] Supapitch Sirimangklanurak[2] Romelia Barba Bernal[3] Ana Marenco-Flores[4] Thanathip Suenghataiphorn[5] Omar Al Ta'ani[6] Khawaja Hassam[7], [1]Texas Tech University Health Sciences Center, [2]Chiang Mai University, [3]Texas Tech University, [4]BIDMC, [5]Griffin Hospital, [6]Allegheny Hospital, [7]Lahey Hospital

Background: Alcohol-associated liver disease (ALD) is a significant contributor to liver mortality. Despite this, limited evidence exists regarding clinical outcomes among American Indian and Alaska Native (AI/AN) populations affected by ALD. Recent data show that AI/AN communities experienced a sixfold higher death rate than Whites. This study aims to evaluate disparities in clinical outcomes between AI/AN and non-AI/AN patients with ALD over 10 years. **Methods:** We conducted a retrospective cohort study utilizing the TriNetX network to examine patients diagnosed with ALD. The study compared outcomes between AI/AN and non-AI/AN patients with ALD. To reduce potential confounding, we applied 1:1 propensity score matching based on demographics, comorbidities, and medication use. The primary outcome assessed was all-cause mortality, while secondary outcomes included liver-related and cardiovascular complications. Hazard ratios (HRs) with 95% confidence intervals (CIs) were calculated using Cox proportional hazards models over a five-year follow-up. **Results:** A total of 3,652 patients with ALD were included after propensity score matching. After propensity score matching, AI/AN individuals with ALD had a significantly higher risk of death from any cause compared to non-AI/AN patients (HR: 1.32; 95% CI: 1.14–1.52). They were also more likely to experience major adverse liver outcomes (HR: 1.35; 95% CI: 1.14–1.61). The rate of hepatocellular carcinoma did not differ significantly between groups (HR: 0.73; 95% CI: 0.24–2.23). Cardiovascular outcomes—including major adverse cardiac events (HR: 1.01; 95% CI: 0.81–1.26), ischemic heart disease (HR: 1.25; 95% CI: 0.74–2.10), arrhythmias (HR: 0.96; 95% CI: 0.79–1.16), stroke (HR: 1.20; 95% CI: 0.86–1.67), thrombotic events (HR: 1.51; 95% CI: 0.86–2.66), and heart failure (HR: 0.96; 95% CI: 0.73–1.28)—were not significantly different between the two cohorts. **Conclusion:** AIAN individuals with ALD face a markedly

elevated risk of mortality and severe liver complications when compared to other racial and ethnic groups. These disparities necessitate targeted public health efforts and customized clinical strategies to enhance liver-related health outcomes in AI/AN communities.

2227 | DIGITAL HEALTH LITERACY IS IMPAIRED IN LIVER CIRRHOSIS PATIENTS WITH A LOWER EDUCATION LEVEL: A CROSS-SECTIONAL MULTI-CENTER STUDY

Britt van Ruijven[1] Yunike Budiono[1] Luuk Mom[2] Matthijs Kramer[1] Marieke Pierik[1] Roos van der Vaart[3] Joost Drenth[4] Govert Veldhuijzen[2] Tom Gevers[1], [1]Maastricht University Medical Center, [2]Gelre Ziekenhuizen, [3]De Haagse Hogeschool, [4]Amsterdam University Medical Center

Background: Although healthcare increasingly adopts digital technologies, the impact of digital health literacy in patients with liver cirrhosis remains limited. We performed a comprehensive analysis of the digital health skills of liver cirrhosis patients using the Digital Health Literacy Instrument (DHLI) 2.0. **Methods:** A cross-sectional, multicenter questionnaire study was conducted involving liver cirrhosis patients identified by ICD-10 codes, treated at a secondary and tertiary medical center in the Netherlands. Eligible patients were diagnosed with liver cirrhosis and had a liver cirrhosis-related consultation in the past year. The DHLI 2.0 questionnaire was distributed through email. All non-responders and patients without a known e-mail address were invited by regular mail and received a reminder in case of no response. DHLI scores are reported on a 1-4 scale, with 4 indicating optimal digital health literacy. The questionnaire separately investigated digital device access, and education level categorized into low (no education, primary school, or lowest high school level), middle (higher levels of high school, or secondary vocational education), or high (bachelor's degree or higher). Patient demographics and disease characteristics, including MELD score, Child-Pugh score, and decompensation state according to Baveno VII at time of at last consultation, were collected from electronic patient records. Statistical analyses included Independent T-Tests, Kruskal-Wallis Tests, Mann-Whitney Tests, Spearman's Rank Correlations, and Generalized Linear Models. **Results:** Of 331 invited patients, 87 participated in this study (26.3%). Response rates for digital and physical DHLI 2.0 were 19.3% and 19.7%, respectively (27/140 vs. 60/304). Patients were predominantly male (71.3%), with a median age of 69.8 (IQR 64.1-75.6), treated in the tertiary center (65.5%), and with a lower education level (31.0%). Liver cirrhosis was caused by alcohol (34.5%) or MASLD (27.6%), most patients were compensated at time of participation (92.0%; 77% with Child-Pugh A). The majority of patients reported access to internet (79.3%), a smartphone (72%), and a computer or laptop (60%). The mean DHLI score was 3.1, and patients with low education demonstrated lower DHLI scores compared to middle or high education levels in the univariate analysis ($p = 0.026$) and Generalized Linear Model ($p = 0.034$). No statistically significant differences in DHLI scores were observed amongst liver cirrhosis etiologies ($p = 0.855$), (de)compensation ($p = 0.171$), Child-Pugh score ($p = 0.782$), MELD score ($p = 0.847$), or age ($p = 0.956$). **Conclusion:** This cross-sectional, multicenter study demonstrated lower digital healthcare literacy in liver cirrhosis patients with lower education levels, but showed no association with etiology or disease stage. The next step is to investigate how lower digital health literacy impacts the digital care of patients with liver cirrhosis.

Michigan Medical Center, [4]Stanford University Medical Center, [5]Virginia Commonwealth University, [6]Houston Methodist Hospital, [7]University of California San Diego, [8]University of Arizona, [9]University of Arizona College of Medicine-Phoenix

Background: Alcohol-associated liver disease (ALD) is the leading cause of cirrhosis in Western countries. Alcohol can also contribute to the development of multiple extrahepatic manifestations. However, there is limited literature regarding the extrahepatic outcomes of ALD among diverse patient populations especially among the Native American population. We conducted a study to assess racial disparities in the incidence of cirrhosis and extrahepatic manifestations in ALD from a racially diverse cohort in the US. **Methods:** We conducted a study on ALD patients seen at the Banner Health System, representing hospitals across Arizona, California, Nevada, Wyoming and Colorado from 2012 to October 2024 using ICD codes with randomly selected chart review over 250 cases to validate ICD codes for ALD and extrahepatic outcomes. We excluded patients with other causes of liver disease and decompensated cirrhosis at baseline. Primary outcomes included incidence of mortality, major adverse liver outcomes (MALO), cardiovascular disease, type 2 diabetes mellitus (T2D), cirrhosis, major adverse cardiovascular events (MACE), any cancer, and alcohol-related cancer [gastrointestinal tract, liver, breast, prostate, and oropharyngeal cancer]. A multivariate analysis was performed and adjusted for variables such as age, sex, body mass index, and smoking status. **Results:** We included 9,542 patients with ALD. The median age in the cohort was 49.9 years, 66.3% were male, 67.0% were Non-Hispanic White (NHW), 18.4% Hispanic, 11.0% Native American (NA), and 3.2% Black. Compared to NHW patients, NAs had increased mortality (adjusted hazard ratio (aHR) 1.93; 95% Confidence Interval (CI): 1.53-2.44), higher incidence of MALO (aHR 1.34; 95% CI 1.17-1.53), and T2D (aHR 1.40; 95% CI 1.12-1.74). Hispanic patients had a higher incidence of MALO (aHR 1.50; 95% CI: 1.03-1.28) and higher incidence of alcohol-related cancer (aHR 1.30; 95% CI 1.03-1.64). Cardiovascular disease, any cancer, cirrhosis, MACE were nonsignificant among racial groups. **Conclusion:** In this multicenter cohort of patients with ALD, the NA population has a significantly disproportionately higher mortality than NHWs likely secondary to the higher incidence of MALO. Similarly, Hispanic patients had a high incidence in MALO, likely contributing to higher alcohol-related cancer. Attention to racial disparities is critical in ALD, highlighting the importance of earlier intervention to prevent MALO in underserved populations.

2229 | HIGH ADHERENCE TO A PLANETARY HEALTH DIET IS ASSOCIATED WITH LOWER RISK OF HEPATOCELLULAR CARCINOMA

Roselyn Tanghal[1] Zhenjiang Li[1] Adelynn Paik[1] Jesse Goodrich[1] David Conti[1] Douglas Walker[2] Lynne Wilkens[3] Veronica Setiawan[1] Lida Chatzi[1], [1]University of Southern California, [2]Emory University, [3]University of Hawai'i

Background: Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related deaths globally, with increasing incidence in the U.S. Current prevention strategies are limited, underscoring the urgent need for modifiable risk factors. Diet is a key determinant of liver cancer risk, and dietary patterns that prioritize plant-based foods and limit red and processed meat intake may offer protection. The Planetary Health Diet (PHD), a new dietary framework proposed by the EAT-Lancet Commission to promote both human and environmental health, provides a diet-model characterized by increased consumption of plant-based foods and decreasing processed meat consumption. However, its role in HCC prevention remains unclear. This study examines the association between PHD adherence and HCC risk in a diverse population in the U.S. and explores potential biological mechanisms using metabolomics data. **Methods:** We evaluated the association between PHD and HCC risk in the Multiethnic Cohort, a large prospective cohort in the U.S. PHD adherence was quantified using the Planetary Health Diet Index (PHDI), derived from validated food frequency questionnaires. HCC cases were identified through cancer registry linkage. Cox proportional hazards models were used to estimate hazard ratios (HRs) and 95% confidence intervals (CIs) for HCC across quintiles of PHDI scores. Pre-diagnostic plasma samples from 477 participants were analyzed using untargeted metabolomics via liquid chromatography coupled with high-resolution mass spectrometry (LC-HRMS). A meet-in-the-middle approach was applied to identify metabolites mediating the association. **Results:** Among 186,735 participants followed for an average of 20 years, we identified 1,003 incident HCC cases. High adherence to the PHD was significantly associated with reduced HCC risk (Q5 vs. Q1 HR: 0.75, 95% CI: 0.61, 0.93, P trend = 0.002). The association was consistent across racial and ethnic groups, with the strongest inverse association observed among Japanese Americans (Q5 versus Q1 HR: 0.62, 95% CI: 0.43,0.89; P trend = 0.002). Metabolomics analysis identified Hippurate, a gut-derived metabolite linked to plant-based diets, as a significant mediator, mediating approximately 15% of the total effect of PHDI on HCC risk ($p = 0.018$). **Conclusion:** Greater adherence to a nutritionally balanced and environmentally sustainable diet is inversely associated with HCC risk. These findings highlight the potential clinical utility of dietary modification as a primary prevention strategy for liver cancer and support public health efforts to promote sustainable dietary patterns.

2230 | FOOD INSECURITY EXPERIENCES IN LIVER DISEASE: A PILOT OF FOOD INSECURITY SCREENING IN PATIENTS WITH CIRRHOSIS

Ollie Desrochers[1] Therese Bittermann[2] David Goldberg[3] Grace Jung[1] Sahana Kannan[1] Harlene Kaur[1] Victoria Younes[1] Elena Byhoff[1], [1]UMass Chan Medical School, [2]Perelman School of Medicine, [3]University of Miami

Background: Food insecurity is the condition of not having consistent access to sufficient food for an active healthy life. Patients with cirrhosis may be more vulnerable to the health effects of food insecurity and may face additional barriers related to complex dietary recommendations. **Methods:** This

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

was a cross-sectional study of adult outpatients with cirrhosis who were screened for food insecurity using the validated 2-item Hunger Vital Sign tool and two additional questions on perceived difficulties in making cirrhosis-specific dietary choices. Patients competed the survey in the waiting room on the day of their appointment. All survey responses were then linked to electronic medical record data for demographic, comorbidity, and healthcare utilization data. Descriptive statistics were calculated for patients who were food insecure vs food secure.Of 150 survey respondents, 25% (n = 38) screened positive for food insecurity using the Hunger Vital Sign. In total, 69% (n = 104) reported difficulty making the best food choices for their cirrhosis, 89% (n = 34) among food insecure and 54% (n = 60) among food secure. Not knowing which foods were appropriate for their cirrhosis was the most common difficulty reported by patients, followed by difficulty affording the best foods for their cirrhosis. Compared to food secure individuals, those with food insecurity were younger (mean age 58.1 vs. 63.5 years, $p = 0.02$), had lower BMI (mean 27.9 vs. 30.9, $p = 0.03$), and were more likely to be Hispanic (15.8% vs. 4.5%, $p = 0.05$) and Medicaid-insured (28.9% vs. 10.7%, $p = 0.01$). Both groups had similar cirrhosis etiologies, co-morbidities, decompensation events and number of ED visits and inpatient hospital days within 12 months prior to their screening date. **Results:** Of 150 survey respondents, 25% (n = 38) screened positive for food insecurity using the Hunger Vital Sign. In total, 69% (n = 104) reported difficulty making the best food choices for their cirrhosis, 89% (n = 34) among food insecure and 54% (n = 60) among food secure. Not knowing which foods were appropriate for their cirrhosis was the most common difficulty reported by patients, followed by difficulty affording the best foods for their cirrhosis. Compared to food secure individuals, those with food insecurity were younger (mean age 58.1 vs. 63.5 years, $p = 0.02$), had lower BMI (mean 27.9 vs. 30.9, $p = 0.03$), and were more likely to be Hispanic (15.8% vs. 4.5%, $p = 0.05$) and Medicaid-insured (28.9% vs. 10.7%, $p = 0.01$). Both groups had similar cirrhosis etiologies, co-morbidities, decompensation events and number of ED visits and inpatient hospital days within 12 months prior to their screening date. **Conclusion:** One in four patients with cirrhosis experience food insecurity with a higher burden experienced by Hispanic and publicly-insured individuals. Notably, over 69% of patients report difficulties with making cirrhosis-specific food choices, most of whom did not screen positive for food insecurity.

2231 | A CAPACITY BUILDING INITIATIVE TO EXPAND HEPATITIS B AND C SCREENING AND TREATMENT IN VULNERABLE COMMUNITIES

Brianna Norton[1] Mark Sulkowski[2] Su Wang[3] Melissa Rodriguez[4] Jenniffer Meza Jimenez[4] Jeffrey Carter[4] Laura Simone[4] Leah Molloy[4], [1]Albert Einstein College of Medicine, Bronx, NY, [2]Johns Hopkins Medicine, [3]Cooperman Barnabas Medical Center, [4]PRIME Education

Background: Community clinics can play a frontline role in hepatitis elimination, but implementation barriers persist. This project aimed to identify gaps and improve HBV/HCV screening and linkage to care. **Methods:** Baseline surveys were completed by 76 healthcare professionals (HCPs) in 5 community clinics assessing current practices and barriers in HBV/HCV screening and treatment. Responses informed the development of live clinic-based audit-feedback sessions at the clinics from 11/2024 – 2/2025, each additionally attended by leaders from local community-based organizations to share community perspectives. Pre- and post-program surveys were administered, team-based action plans developed, and follow-up surveys completed 2-3 months later. **Results:** On baseline surveys, clinics reported inconsistent performance of one-time universal HBV/HCV screening: 65% of respondents reported that their practices offer this service, 17% did not and 18% were unsure. Most reported managing only 10% or fewer patients with HBV or HCV independently without specialist referral (58% and 52%, respectively). The top reported challenges in routine screening and treatment initiation were low patient awareness (66%) and selecting appropriate treatment (43%), respectively. Patients with ongoing substance use disorders were most frequently identified as the population for which HCPs were most hesitant to implement hepatitis treatment without specialist involvement (47%). Among the 160 HCPs who attended the live sessions, knowledge of HCV treatment for people who inject drugs was low and improved after education (Figure 1). Action plans prioritized by the HCPs following the sessions included: public outreach to improve screening (64%), expanding education and support for people diagnosed with HBV/HCV (64%), and establishing clinical criteria to differentiate patients with hepatitis who may be managed in a primary care setting from those who require specialist referral (40%). Follow-up surveys were completed by 15 HCPs. Respondents reported caring for a combined 46 patients with HCV

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and 32 patients with HBV since participating in the initiative, 57% (26/46) and 59% (19/32) of whom were managed independently in clinic without specialist referral, respectively. **Conclusion:** Tailored discussion with live audit-feedback and action planning informed by community perspectives in community clinics led to measurable improvements in HBV/HCV knowledge and practice. These outcomes may inform other practice-changing implementation needs.

Figure 1. HCP responses to: "Which of the following is true about HCV treatment among people who inject drugs?"

2232 | ASSOCIATION BETWEEN COUNTRY OF BIRTH AND LIVER FIBROSIS SEVERITY IN OBESE U.S. ADULTS: AN NHANES 2017–2023 STUDY

Mahinaz Mohsen[1] Ziad Mohsen[2] Rohan Karkra[1] David Kim[1] John Esli Medina Morales[1] Michael Bebawy[1] Menna-Allah Elaskandrany[3] Paul Gaglio[1], [1]Rutgers New Jersey Medical School, [2]Rutgers University, [3]Lenox Hill Hospital

Background: Obesity is a key contributor to metabolic dysfunction-associated steatotic liver disease (MASLD), with liver fibrosis severity serving as a critical marker of disease progression. Identifying factors associated with liver fibrosis severity is essential for risk stratification and targeted care in patients with MASLD. While prior studies have noted racial and ethnic disparities in hepatic fibrosis, the impact of nativity (U.S.-born vs. foreign-born) remains underexamined. This study investigates whether foreign-born status is associated with increased liver fibrosis severity among obese U.S. adults. **Methods:** This is a retrospective database analysis using combined data from the National Health and Nutrition Examination Survey (NHANES) from 2017 to 2023. Adults aged ≥ 18 with obesity (BMI ≥ 30) and no history of viral hepatitis were included. Participants with missing data or unreliable liver stiffness measurements, as defined by NHANES, were excluded. Liver fibrosis severity was measured by median liver stiffness. Univariate analyses were performed using IBM SPSS Statistics 25. Weighted multivariable analysis was performed using R (4.4.1). Significance was set at $p < 0.05$. **Results:** Out of 27,493 participants, 1,729 met inclusion criteria (84% U.S.-born, 16% foreign-born). The average age was 51 ($\pm$ 16), with 46% male and 48% white participants. Average BMI was 36.2 ($\pm$ 5.7). Univariate analysis showed that median liver stiffness was lower in foreign-born individuals, but the difference was not statistically significant ($p = 0.742$). Foreign-born individuals had significantly higher levels of hyperlipidemia ($p = 0.028$), less access to healthcare ($p < 0.05$), and a lower poverty income ratio ($p < 0.05$). Multivariable analysis (Table 1) showed that country of birth was not significantly associated with liver stiffness severity ($p = 0.598$). However, older age ($p = 0.002$), male gender ($p < 0.001$), higher BMI ($p < 0.001$), and lower income ($p = 0.0365$) were linked to increased fibrosis severity. Black ethnicity was associated with lower fibrosis severity ($p = 0.004$). **Conclusion:** In this nationally representative sample of obese U.S. adults, country of birth was not independently associated with liver fibrosis severity. However, older age, male gender, higher BMI, and lower income were significantly associated with increased fibrosis, while Black ethnicity was protective. This highlights metabolic and social determinants of health over nativity as possible risk factors in the development of liver fibrosis in immigrant patients.

Table 1. Weighted Multivariable Linear Regression Analyses of Comorbidities and Risk Factors for Liver Fibrosis in Obese Patients

		β Coefficient (95% CI)	p-value
Country of Birth, U.S.		0.16 (-0.47 to 0.74)	0.598
Age		0.040 (0.02 to 0.07)	**0.002**
Male		1.28 (0.74 to 1.95)	**<0.001**
Ethnicity*	Asian	1.38 (-0.08 to 3.20)	0.075
	Black	-0.90 (-1.52 to -0.39)	**0.004**
	Mexican American	0.050 (-0.86 to 0.83)	0.925
	Other Hispanic	-0.10 (-0.85 to 0.55)	0.799
	Other	-0.45 (-1.40 to 0.48)	0.361
BMI		0.22 (0.16 to 0.29)	**<0.001**
Diabetes		0.89 (0.11 to 1.6)	0.076
Hypertension		0.032 (-0.55 to 0.53)	0.878
Hyperlipidemia		-0.13 (-0.78 to 0.59)	0.658

2233 | BREAST CANCER SCREENING AS A BARRIER TO EXPEDITED LIVER TRANSPLANT LISTING IN INPATIENTS: A RETROSPECTIVE CHART REVIEW

Madison Force Caroline Conlon[1] Emily Chiacchiaro[1] Khoa Nguyen[1] Danielle Tholey[1] Dina Halegoua-De Marzio[1], [1]Thomas Jefferson University Hospital

Background: Women receive liver transplantation (LT) less often than men. In 2023, MELD3.0, which includes sex, was introduced to help address sex disparities. We propose that difficulty accessing inpatient breast cancer screening during liver transplant evaluation (LTE) contributes to delayed listing for women. **Methods:** From 8/22/23-2/5/2025, we retrospectively reviewed consecutive, adults referred for inpatient LTE at a large, high MELD, LT center. Variables included: demographics, MELD 3.0 scores at referral and activation, and key transplant timeline dates (referral, activation, transplant, death, or lost to follow-up). For females aged $\geq$40, we reviewed prior breast cancer screening, inpatient imaging orders, modality, and completion time. Time to activation and LT were analyzed with Kaplan-Meier curves and compared by sex using log-rank tests. Patients who were not activated, transplanted, or died by the end of the study period (or were lost to follow-up) were considered censored; their time-to-event was calculated up to their last available evaluation date. Activation rates were assessed using chi-square tests. **Results:** Among 139 patients, 129 had valid dates for activation or eval date closure; 70 were female. Mean age was 56.5 years (SD = 9.39), and 74.4% were White. MELD 3.0 scores at referral and activation were similar between males and females. Activation rate was lower for females (34.3% vs. 39%), but not statistically significant ($\chi^2(1) = 0.31$, p = 0.58). Median time to activation or censoring was longer for females (9 vs. 7 days), but hazard distributions were not different ($\chi^2(1) = 0.90$, p = 0.40). Among activated patients, median time to transplant was 4 days for men and 7.5 days for women ($\chi^2(1) = 0.01$, p = 0.90). Of 70 female patients, 24 (34.3%) had prior screening; 20 (28.6%) had inpatient screening ordered. Median time from order to imaging was 2 days; from order to activation was 5.5 days. Transplant rate was 23.7% for males (n = 14) and 20% for females (n = 14). Deaths occurred in 32.2% of males (n = 19) and 31.4% of females (n = 22). **Conclusion:** Breast cancer screening requirements did not lead to statistically significant delays in LT activation for female inpatients, but modest delays were observed. All imaging was done via breast ultrasound, a less sensitive modality than mammography. These findings highlight a gap in screening access for high MELD female patients and the need for transplant-specific protocols that consider inpatient imaging limitations and listing urgency. Ongoing analysis with a larger cohort and subdistribution hazard models for competing risks are planned to determine whether these observed delays reach statistical significance. Results may be positively biased by our center's access to bedside breast imaging and buy-in from radiology.

Table 1. MELD 3.0 scores at referral to and activation on transplant list in men and women.

	Females		Males		
	M	SD	M	SD	t-test
MELD3 at Referral	30.18	7.09	29.29	8.46	t(152) = 0.71, p = 0.48
MELD3 at Activation	31.61	6.97	32.19	8.56	t(58) = 0.29, p = 0.78

2234 | LIVER TRANSPLANT ACCESS FOR UNDOCUMENTED IMMIGRANTS IS CONSTRAINED BY POLICY AWARENESS, INSTITUTIONAL PROTOCOLS, AND SOCIAL VULNERABILITY: A MIXED-METHODS: STUDY

Carolyn Singleton[1] Amanda Thayer[1] Lauren Nephew[2], [1]Indiana University School of Medicine, [2]Indiana University

Background: Undocumented immigrants with end-stage liver disease face significant structural barriers to liver transplantation (LT). While some U.S. states have adopted policies supporting access to LT for this population, national-level data on provider attitudes, practices, and policy awareness remain limited. **Methods:** We conducted a cross-sectional, mixed-methods survey of transplant hepatologists and surgeons in 16 states (emails sent to 808). The survey assessed provider attitudes, center protocols, and perceived barriers. To explore the role of policy and precedent, we classified states into a 2×2 matrix based on whether they (1) had ever performed LT in an undocumented

immigrant and (2) offered expanded Medicaid coverage (Figure 1A). Quantitative data were summarized descriptively; two open-text responses underwent rapid qualitative analysis. **Results:** Among 55 respondents from 12 states, 75.4% practiced in states with a history of LT in undocumented patients. Most were transplant hepatologists (58.6%). While 77.8% agreed they had an ethical obligation to evaluate undocumented patients, only 52.0% reported their center had ever listed undocumented patients. Although insurance was frequently cited as a barrier, 46.3% of respondents were unsure if their state offered expanded coverage. Only 14.8% reported clear center-level guidelines, more common in states with expanded Medicaid (62.5% vs 37.5%, $p = 0.046$). Most respondents (77.8%) reported no change in their willingness to evaluate or list undocumented immigrants following recent Executive Orders, but 20.4% were less willing or uncertain. The 2x2 policy matrix revealed four states (Colorado, Oregon, Washington, and District of Columbia) with expanded coverage but no reported LT history—highlighting gaps between permissive policy environments and clinical practice (Figure 1A). Qualitative themes (75 responses from 54 participants) included lack of insurance (31 references), financial concerns (17), risk of deportation (15), limited social support (13), and poor post-LT follow-up (10). Ten respondents identified immigration policy shifts, including Executive Orders, as direct barriers to care. **Conclusion:** Transplant providers broadly support equitable access to LT for undocumented immigrants but face persistent institutional and policy-related barriers. Greater policy transparency, provider education, and standardized protocols may help align ethical intent with practice, particularly in states where permissive policies remain underutilized.

2235 | LIVER ABSCESSES IN A MEDICALLY UNDERSERVED, PREDOMINANTLY BLACK POPULATION: A RETROSPECTIVE STUDY FROM 2013 TO 2024 AT A U.S. SAFETY-NET HOSPITAL

Nakul Ganju[1] Jinal Makhija[1] Ahmed Ebeid[1] Sameer Garlapati[1] Pinky Bai[1] Hetu Patel[1] Ali Chand[1] Abay Gobezie[1] Lakshmi Chirumamilla[1] Fatemeh Homayounieh[1] Sneha Adidam[1] Farshad Aduli[1] Jhansi Gajjala[1], [1]Howard University Hospital

Background: Pyogenic liver abscesses (PLAs) are uncommon but serious infections. Their impact on younger, underserved patients with comorbidities and structural barriers remains undercharacterized, as most U.S. data focus on older, insured, non-minority populations. This study examines clinical, microbiologic, and socioeconomic features of PLA patients at a Washington, DC safety-net hospital **Methods:** We retrospectively reviewed radiologically confirmed PLA cases from 2013–2024, analyzing demographic, clinical, microbiologic, and socioeconomic variables, including Area Deprivation Index (ADI) and insurance status. Hospital length of stay (LOS) was analyzed and further stratified by cofactors. Descriptive statistics were used, and group comparisons were performed using t-tests and chi-square or Fisher's exact test, where appropriate. **Results:** Among 37 patients, 70.3% were Black, with a mean age of 55.2 years (range 19–88), younger than national PLA cohorts (mean ~63 years). Most were uninsured (48.6%), and 75.7% lived in the two highest ADI quartiles. Median LOS was 19.0 days, exceeding national medians of 9–12; mortality rate was 5.4%. LOS and mortality differences across subgroups were not statistically significant. Uninsured and Medicaid patients had longer LOS (21.0–22.0 days) and 11.1% mortality. Highest ADI quartile had the longest LOS (25.0 days) and 11.1% mortality. Drainage, performed in 86.5%, was linked to longer LOS (20.0 vs. 14.0 days) and lower mortality (3.1% vs. 20.0%), neither significant. Cultures were positive in 83.3%, most commonly E. coli, with frequent polymicrobial infections. Colonoscopy in 13 patients identified one colorectal adenocarcinoma. **Conclusion:** This cohort challenges prevailing PLA paradigms, revealing a younger, predominantly African American population with limited insurance and high comorbidity—features rarely reflected in national data. Elevated polymicrobial and post-procedural rates suggest delayed diagnoses and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

systemic barriers to care. Socioeconomic disadvantage, captured by ADI and insurance status, strongly correlated with prolonged hospitalization, indicating deprivation worsens clinical outcomes. This is among the few U.S. studies to longitudinally characterize PLA in a predominantly Black, uninsured population. Our findings highlight the urgent need to incorporate social determinants into PLA management and hepatology research frameworks. Our findings fill a critical knowledge gap by characterizing PLA in a U.S. safety-net population—a setting largely absent from prior studies. These data support targeted interventions to improve early recognition, diagnostic efficiency, procedural access, and equitable outcomes in underserved communities. Closing these persistent gaps requires collaboration across hepatology, public health, and health policy sectors to reduce disparities and improve care delivery.

2236 | IDENTIFYING PROVIDER PRESCRIBING PRACTICES FOR GLP1RAS AND SGLT-2IS IN PATIENTS WITH TYPE 2 DIABETES TO ADDRESS PHARMACOINEQUITY IN LIVER DISEASE

Parnnate Wongsirisakul[1] Vincent Chen[1] Ponni Perumalswami[1], [1]University of Michigan Medical Center

Background: Evidence-based treatment of metabolic dysfunction-associated steatotic liver disease in patients with type 2 diabetes (T2DM) focuses on glycemic control and lifestyle modification to achieve weight loss, which slows the progression of liver disease and reduces the risk of liver-related complications. In the past 20 years, two newer classes of more effective T2DM medications became available in the United States—glucagon-like peptide receptor agonists (GLP-1RAs) and sodium/glucose cotransporter 2 inhibitors (SGLT-2is). However, studies observed racial and ethnic disparities in prescription rates despite controlling for high cost-sharing. **Methods:** We identified a cohort of 189 outpatient adult primary care providers who cared for at least 50 annual T2DM patients in a tertiary academic health system in 2021. GLP-1RA and SGLT-2i prescribing rates were crudely calculated with a median rate of 0.494 (IQR 0.594-0.393). Nine providers from the high prescribing quartile (prescribing rate 59.5-78.6%) and eight from the low (prescribing rate 4.8-39.3%) participated in 1:1 interviews guided by the Consolidated Framework for Implementation Research, which considers individual and system level factors. **Results:** On average, high prescribing providers had more patient-facing hours and exposure to GLP-1RAs and SGLT-2is in residency. In general, all providers cited task-sharing, patient-provider relationship longevity, and medication effectiveness as facilitators of GLP-1RA and SGLT-2i prescription. Barriers included patient mistrust of new therapies, insufficient access to care, and prescription inertia. However, medication costs and insurance prior authorization processes were the most mentioned deterrents, which varied along socioeconomic lines. High prescribers mitigated cost barriers by directing patients to in-system financial programs and leveraging prior authorization teams as opposed to low prescribers, who lacked prior authorization personnel and struggled to navigate cost issues sustainably. These factors allowed providers with strong administrative support systems to start metformin and GLP1-RAs co-first line but fostered hesitancy in prescription initiation for resource-deprived providers. Using the Expert Recommendations for Implementing Change, we mapped provider-proposed solutions to address concerns such as patient expectations, insurance gaps, and staff shortages in pursuit of pharmacoequity. **Conclusion:** This interview series revealed the GLP1-RA and SGTL-2i prescribing determinants and treatment approaches of primary care providers. Implementation strategies may help address determinants and improve prescribing newer, highly effective treatments in patients with T2DM.

High Versus Low GLP-1RA and SGLT-2i Prescribing Provider Determinants

Determinant	High Providers	Low Providers	Quotes
Cost mitigation	Willing to navigate in-system resources	Cost issues seem insurmountable; unsustainable options	"It's a lot of work, but we have several patients, though, who we were able to get them [GLP-1RAs] through the patient assistance program." – High provider 8 "When I think about it [GLP-1RAs or SGLT-2is], or a patient asks about it, I kind of get like a visceral reaction like, 'Oh, God. I'm going to have to go through this circus of what does your insurance cover?'" – Low provider 17
Insurance processes	Effective in-clinic prior authorization teams	Poor prior authorization due to centralization and overwork	"We have a prior auth team now that helps, you know, get the medicines approved or denied without the burden on the clinics as much as it used to be." – High provider 4 "We used to do prior for these medications on site at our clinic. And then they centralized it. And the centralized version just does not work that well...They don't spend the time like looking through the patient's chart. They just route everything back to you a zillion times." – Low provider 2
Support	Strong reliance on embedded pharmacist	Opts for specialist referrals or search engines	"I get most of my information from the pharmacist. She sends me updated information on comparisons between the different medications, what the hemoglobin a1c reductions are" – High provider 13 "I've never done this, but if I had a question, in theory, I would do probably an E-consult just to run it by them (a specialist). If I have questions about the medications, I'll usually use UpToDate or ChatGPT" – Low provider 15
Treatment approach	Metformin and GLP1-RAs co-first line	Emphasis on lifestyle modification first	"I actually prefer a GLP-1RA to Metformin, depending on what else they have. If somebody comes in and they have obesity, even if their a1c is 6.5, and they are open to being on an injection medication, I will pretty much always do a GLP-1RA first." – High provider 14 "The first thing is always exploring lifestyle, which is probably better than any medication we're going to prescribe." – Low provider 9
Major concerns	Side effects and patient preference	Polypharmacy and lack of long-term research for newer meds	"First, I talk to the patient about what they might prefer and make sure they understand the side effects. I have some patients, for example, with the SGLT-2is that don't want to even try them if they already have issues with urinary symptoms or recurrent yeast infections." – High provider 5 "These medications add to the pill burden, and so we have to justify why we have to utilize this. If they have multiple reasons to be on this medication, that way, we're checking off multiple boxes with one pill." – Low provider 3

2237 | MELD AND THE RISK OF MORTALITY IN BLACK AND WHITE PATIENTS WITH ADVANCED FIBROSIS

Michael Attanasi[1] Mathew Gregoski[2] Don Rockey[2], [1]Northwell Health, [2]Medical University of South Carolina

Background: MELD has been well established as the gold standard metric for predicting mortality in patients with cirrhosis. Here, we hypothesized that race is an important factor in predicting mortality in patients with cirrhosis. **Methods:** All adults who had a liver biopsy showing F3 or F4 fibrosis at our institution from January 1, 2013 through July 1, 2021 were identified. Histology, fibrosis stage, and complete clinical data were abstracted via the medical record. Patients were propensity matched based on age, gender, Charlson Comorbidity Index, and the CDC/ATSDR Social Vulnerability Index Themes 1,2, and 4. Logistic regression analysis was performed comparing race, MELD 3.0, and their interaction on ninety-day mortality. **Results:** Of 3,572 patients having a liver biopsy, 92 Black and 372 White patients had F3/F4 fibrosis. Final propensity matching resulted in 143 White patients and 89 Black patients. Hypertension and chronic kidney disease were more prevalent in Black patients than in White patients (respectively: 63/89 (71%) vs 71/143 (50%); 12/89 (13%) vs 4/143 (3%); $p < 0.01$). HCV and AIH were more prevalent in Black patients than White patients (respectively: 23/89 (26%) vs 17/143 (12%); 18/89 (20%) vs 10/143 (7%); $p < 0.001$), and ALD and MASLD were more prominent in White patients than Black patients (respectively: 59/143 (41%) vs 20/89 (23%); 27/143 (19%) vs 3/89 (3%); $p < 0.001$). White patients were more likely to have hepatic encephalopathy (58/143 (41%) vs 22/89 (25%), $p < 0.05$) than Black patients. No significant differences between these groups existed for MELD scores. Liver-related mortality at ninety days and five years was not significantly different between White and Black patients (Figure 1). Logistic regression analysis did not reveal an association of race with liver-related mortality. ROC curves examined the relationship between race and MELD 3.0 demonstrated an AUC of 0.915 for White patients and 0.910 for Black patients. **Conclusion:** Black and White patients with similar comorbidities and social vulnerabilities had comparable liver-related mortality at similar MELD 3.0 scores in spite of increased evidence of portal hypertension and morbidity in White patients. The data suggest that the MELD 3.0 score is equally predictive of mortality in Black and White patients.

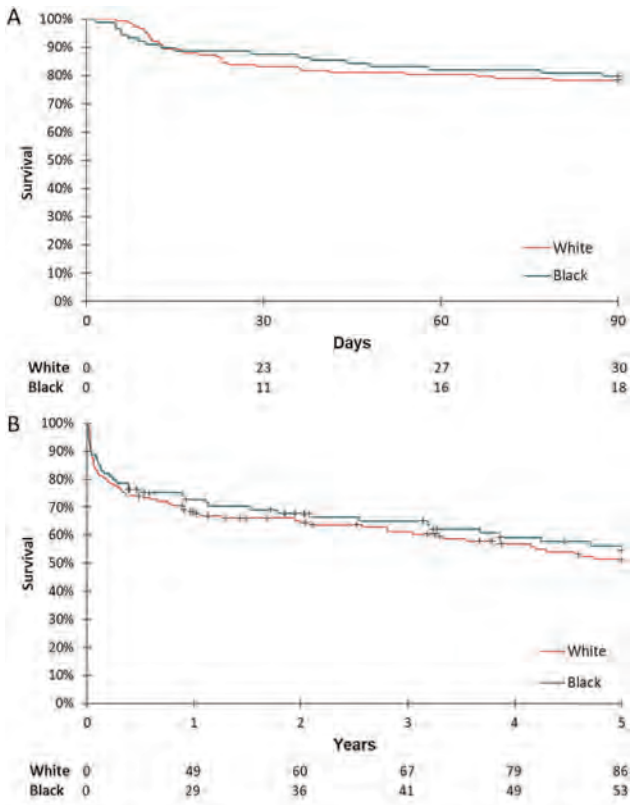

Figure 1. Kaplan Meier liver-related mortality at 90 days and 5 years for overall cohort

2238 | DISPARITIES AMONG SOCIAL DETERMINANTS OF HEALTH AMONG LIVER TRANSPLANT RECIPIENTS IN A DIVERSE NATIONAL COHORT: FINDINGS FROM THE ALL OF US DATABASE

Ashley Spann[1] Dameia Brewster[1] Qingxia Chen[1] Andrew Guide[1] Haoyang Yi[2] Monica Tincopa[3], [1]Vanderbilt University Medical Center, [2]Vanderbilt University, [3]University of California, San Diego

Background: Social determinants of health (SDOH) contribute significantly to disparities in receipt of liver transplantation within the United States. However, for patients who do undergo liver transplantation, the status of SDOH after transplantation are unclear. In this study, we sought to explore potential sex-based, racial, and ethnic differences in various SDOH domains among liver transplant recipients (LTR). **Methods:** The All of Us (AOU) database is a NIH-funded national dataset of electronic health records composed of diverse adult participants with an emphasis on recruiting individuals historically underrepresented in medical research. The database was queried for patients with prior liver transplantation as determined by ICD-9, ICD-10, or CPT coding. Liver transplant recipients with complete SDOH survey data were included in the analysis. The SDOH survey data includes 3 domains: social & community context, economic stability, neighborhood environment metrics, and health & healthcare. Each domain was summarized using predefined methodology. Resultant SDOH summary scores are outlined in Table 1 with pairwise comparisons of SDOH subdomain scores between subgroups of race, sex, and ethnicity. Statistical significance was determined by Benjamini-Hochberg thresholds to adjust for multiple comparison from two-sample t-test for continuous scores, with a significance level of alpha (False discovery rate) = 0.05 corresponding to a p value of 0.013 or less. **Results:** A total of 1019 LTR were identified, with 387 (38% of LTR) having available SDOH survey data. For the social & community context domain, Hispanic LTR reported significantly lower social support compared to non-Hispanic LTR. Daily spiritual experiences were of greater importance to female, non-white, and Hispanic LTR; with both women and non-white individuals reporting significantly higher attendance to religious services. Regarding the neighborhood and environment domain, greater neighborhood walkability was appreciated among non-white and Hispanic LTR. Additionally, significantly higher neighborhood crime was reported by male, white, and non-Hispanic LTR. Lastly, in the health and healthcare domain, Hispanic individuals more often delayed medical care than non-Hispanic individuals. **Conclusion:** Racial, ethnic, and sex-based disparities exist across various SDOH domains among LTR and awareness of these can facilitate the development of mitigating or promoting strategies to enhance post-transplant survivorship. Some determinants may be protective of post-transplant outcomes (e.g. spirituality and religiosity for females, non-white, and Hispanic LTR). In contrast, others may have negative impacts after transplant (e.g. poor social support & delaying medical care among Hispanic LTR). The influence of these differences should be further explored to understand their role in overall post-transplant graft survival and quality of life.

Table 1: Social Determinants of Health Scores Stratified by Subgroup Analyses for Sex, Race and Ethnicity

Social & Community Context Domain (mean, SD)	Sex at Birth			Race			Ethnicity		
	Male	Female	P (SMD)	White	Non-White	P (SMD)	Non-Hispanic	Hispanic	P (SMD)

2239 | HEALTH LITERACY AS A DETERMINANT OF FRAILTY IN PATIENTS WITH LIVER CIRRHOSIS

ISMAEL YEPES[1] NICOLE CHAMORRO[2] GUILLERMO DONADO[2], [1]UNIVERSIDA DE CARTAGENA. ASOCIACION COLOMBIANA DE HEPATOLOGIA., [2]UNIVERSIDAD DE CARTAGENA

Background: Health literacy (HL) is a critical social determinant of health, particularly in chronic conditions like cirrhosis, where successful disease management depends on patients' understanding and engagement. HL refers to the ability to access, comprehend, and apply health information to make informed decisions. Frailty, which reflects decreased physiological reserve and increased vulnerability to stressors, is strongly associated with poor clinical outcomes in cirrhotic patients. While the Liver Frailty Index (LFI) is widely used to assess physical frailty, the influence of HL on this condition remains understudied. Understanding this relationship could reveal modifiable targets for improving care and reducing disparities. **Methods:** We conducted a cross-sectional study in adults with confirmed liver cirrhosis attending outpatient hepatology clinics in Cartagena, Colombia, from September to December 2024. HL was measured using the Short Assessment of Health Literacy for Spanish Adults (SAHL-S), and frailty using the LFI, based on handgrip strength, chair stands, and balance testing. Trained clinicians administered all functional tests under standardized conditions using calibrated equipment. Clinical and demographic variables were collected through medical records and structured interviews, including age, sex, BMI, Child-Pugh score, and history of decompensation or variceal bleeding. Patients with encephalopathy or severe mobility limitations were excluded. Frailty was defined as LFI $\geq$ 4.5. Descriptive statistics were used, and univariable and multivariable logistic regression analyses identified independent predictors of frailty. **Results:** A total of 89 patients were included; 57.3% were women, with a mean age of 64.8 years. Most were Child-Pugh A (85.4%). Prior decompensation and variceal bleeding were reported in 24.7% and 13.5%, respectively. LFI classified 15.7% as robust, 65.2% as prefrail, and 19.1% as frail. In univariable analysis, age, decompensation, variceal bleeding, and HL level were associated with frailty. In multivariable analysis, low HL (OR 2.8; 95% CI 1.3–6.0) and variceal bleeding (OR 3.2; 95% CI 1.4–7.1) remained independent predictors. **Conclusion:** Low HL is an independent predictor of frailty in patients with cirrhosis, along with clinical history of variceal bleeding. These findings underscore the relevance of HL as a modifiable risk factor and support its integration into routine hepatology practice. Targeted education may help reduce frailty and improve quality of life in this vulnerable population.

Variable	Value (n)
Female sex	57.3% (51)
Arterial hypertension	49.4% (44)
Child Classification	
Child B	14.6% (13)
History of ascites	12.4% (11)

2240 | LONGITUDINAL CHANGES IN HEPATOCELLULAR CARCINOMA SURVEILLANCE PATTERNS AMONG SAFETY-NET HEALTH SYSTEM PATIENTS WITH CIRRHOSIS

Robert Wong[1] Patricia Jones[2] Bolin Niu[3] Paulo Pinheiro[4] Mae Thamer[5] Onkar Kshirsagar[6] Yi Zhang[6] Ronnie Fass[3] Daniela Prieto Bello[4] Lisa Quirk[7] George Therapondos[8] Amit Singal[7] Mandana Khalili[9], [1]VA Palo Alto Healthcare System, [2]University of North Carolina at Chapel Hill, [3]MetroHealth Medical Center, [4]University of Miami, [5]Medical Technology and Practice Patterns Institute, [6]Medical Technology and Pratice Patterns Institute, [7]University of Texas Southwestern, [8]Oschner Health System, [9]University of California, San Francisco

Background: Hepatocellular carcinoma (HCC) surveillance is suboptimal in patients with cirrhosis, particularly those with low socioeconomic status, which was further impacted by disruptions in care during the pandemic. Whether HCC surveillance has improved in recent years remains unclear. We aim to evaluate changes in HCC surveillance patterns among cirrhosis patients from pre-pandemic to four years following pandemic onset. **Methods:** We evaluated the proportion of cirrhosis patients who received HCC surveillance within 6 months of study entry among those who had $\geq$6 months of follow-up across three periods: 3/1/2018-2/29/2020 vs. 3/1/2020-2/28/2022 vs. 3/1/2022-2/29/2024. Patients with baseline HCC were excluded. Appropriate HCC surveillance was determined by CPT codes for imaging type and associated ICD-9/10-CM codes for indication. Proportions receiving HCC surveillance across the three periods were compared using

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

paired t-tests and stratified by gender, race/ethnicity, and insurance. **Results:** Among 4,229 patients with cirrhosis (60.3% men, mean age 56.8y, 72.3% non-White race/ethnicity, 28.3% Medicare, 25.8% Medicaid, 25.7% uninsured/indigent care), HCC surveillance declined from 19.5% to 15.4% following pandemic onset, but has improved to 21.8% in the "post" COVID-19 period (Figure). Similar patterns were observed by gender. Surveillance in all race/ethnic groups except Asians declined following pandemic and have since increased. However, surveillance among Hispanics and Black/African Americans remains below pre-pandemic levels. In the most recent years, HCC surveillance occurred in 30.6% of Asians vs. 23.1% in non-Hispanic whites ($p < 0.01$), the group with the next highest proportion. Medicare and Medicaid patients experienced lower HCC surveillance following pandemic onset, but have since increased to pre-pandemic levels. Surveillance in commercially insured patients declined and remained low. Surveillance among uninsured/indigent care patients continued to decline even 4 years following pandemic. **Conclusion:** Among a multi-center safety-net cohort of cirrhosis patients, declines in HCC surveillance following pandemic have since improved, with the exception of Black/African Americans, Hispanics, and commercially insured patients. HCC surveillance among uninsured/indigent care patients continued to decline even four years following pandemic onset, highlighting the need for novel targeted interventions to improve HCC surveillance among this high-risk group.

2241 | SOCIO-DEMOGRAPHIC FACTORS ASSOCIATED WITH LINKAGE TO SPECIALTY CARE AMONG PATIENTS WITH CIRRHOSIS-RELATED DIAGNOSES AT TWO LARGE HOSPITAL SYSTEMS

Reid Grinspoon[1] Allison McCoy[2] Jianhua Li[3] Sara Horst[2] Julia Wattacheril[3], [1]NewYork-Presbyterian Hospital, [2]Vanderbilt University Medical Center, [3]Columbia University Irving Medical Center

Background: Specialty care from a gastroenterologist or hepatologist is associated with better outcomes in patients with liver disease. Sociodemographic factors are also associated with outcomes in liver disease, but the relationship between these factors and access to specialty care is not fully characterized, particularly within large hospital networks. **Methods:** Using electronic health record data from Vanderbilt University Medical Center (VUMC) and Columbia University Irving Medical (CUIMC), we identified patients whose records contained at least one of fifteen ICD 9/10 codes associated with cirrhosis with a clinical encounter at VUMC or CUIMC between 2/1/2020 and 8/31/2023. We determined if each patient had at least one outpatient visit with a gastroenterologist or hepatologist ('specialty care') in their hospital network in this period. We analyzed elements including gender, language, ethnicity, race, and primary insurance and compared patients with and without specialty care at each site. **Results:** There were 37899 patients that met criteria at VUMC and 24319 at CUIMC. 40% of patients at VUMC who met criteria had specialty care, versus 20.3% at CUIMC. At VUMC there was a higher proportion of female patients among those with specialty care (50.4% vs 45.9%, $p < 0.001$), but no significant difference at CUIMC. At VUMC, English as primary language was

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

more common among specialty patients (98.3% vs 96.3%, p < 0.001), which was not seen at CUIMC (69.3% vs 76.9%, p < 0.001). At VUMC, Spanish as primary language was rarer among specialty patients (0.7% vs 2.4%, p < 0.001) in contrast with CUIMC where Spanish language was common and associated with specialty care (23.2% vs 12.8%, p < 0.001). At VUMC Medicare/Medicaid as primary insurance was less common in the specialty care group (51.6% vs 55.6%, p < 0.001), in contrast to CUIMC (66.3% vs 64.5%, p = 0.02). At VUMC, White race was more common (81.6% vs 77.2%, p < 0.001) and Hispanic ethnicity less common (3.3% vs 5.5%, p < 0.001) in the specialty group, while at CUIMC White race was less common (39.5 vs 45.9%, p < 0.001) and Hispanic ethnicity more common (36.4% vs 23.3%, p < 0.001) in the specialty group. **Conclusion:** The associations between select sociodemographic factors and linkage to specialty care varied significantly between sites. This reflects differences in patient populations, network practices, or other factors. Further study to better characterize these differences and contributing factors may lead to improved linkage to specialty care at large referral centers.

2242 | REACHING THE REMAINING ONE-THIRD: A REVIEW OF BARRIERS TO HEPATITIS C ELIMINATION WITHIN A LARGE ACADEMIC MEDICAL CENTER

Hannah Laird[1] Margaret Hayden[2] Shaina Hasan[2] Tsola Efejuku[2] Neeral Shah[2] Kathleen McManus[3] Sanjay Kishore[2], [1]University of Virginia Medical Center, [2]University of Virginia, [3]Division of Infectious Diseases and International Health, University of Virginia Medical Center

Background: Hepatitis C elimination is a national priority. However, national data suggest fewer than 1 in 3 patients initiate treatment within a year of diagnosis. Reasons for a failure of linkage to care is poorly understood. We aimed to characterize gaps in the care cascade for those with a confirmed HCV RNA + but without treatment. **Methods:** The HCV cascade of care from January 2023 - February 2025 was analyzed using structured EHR queries at a single academic medical center. Chart reviews were performed on all patients with a detectable HCV viral load but without evidence of treatment. Descriptive statistics were used to compare patients who were treated and those that were not (Wilcoxon rank-sum test for continuous and Pearson's chi-square test for categorical variables). Finally, a primary barrier to treatment was characterized using thematic analysis. Treatment barriers were classified as a health systems gap (lack of referral, referral outside of system without follow-up), medical complexity (cancer diagnosis, transplant evaluation, advanced illness), or social determinants of health (incarceration, transportation, homelessness, inability to contact for follow-up). **Results:** Of 391 viremic patients, 245 (63%) had a record of treatment, there were no significant differences with the population by age, race, PCP, or fibrosis status; patients not prescribed antivirals were more likely to have documented mental health (74 vs. 51%; p < 0.001) and substance use diagnoses (41% vs. 26%; p < 0.001), and less likely to have commercial insurance (12% vs. 24%, p = 0.002). Of 146 patients without treatment, 68% had a referral, 58% had been contacted for future care, and 39% had an in-person appointment. Chart review revealed 53% had a social determinant, 18% had a medical barrier, and 22% for a health systems gap. **Conclusion:** Even within an academic medical center with above-average treatment rates, over one-third of patients with HCV RNA + remain untreated. Most had identifiable barriers ranging from incarceration and homelessness to terminal illness and missed referrals. Though much progress has been made, HCV elimination among may require proactive, decentralized interventions - including population health surveillance, inpatient/ED-initiated treatment, mobile outreach, telehealth, and enhanced data interoperability.

Background: Esophageal varices (EV) on esophagogastroduodenoscopy (EGD) indicate the presence of or characterize clinically significant portal hypertension (CSPH). Non-invasive tests (NITs) are used for assessing the risk for CSPH with EV in several liver diseases, but HDV specific cut-offs are yet to be defined. We sought NITs-based criteria to predict EV in CHD patients. **Methods:** Untreated patients with HDV cirrhosis and available liver stiffness measurement (LSM) and EGD from the multicenter SAVE-D and D-SHIELD studies were included. To "rule in" CSPH the Baveno VII and AASLD criteria were applied (LSM $\geq$25 kPa; LSM $>$20 kPa + platelets [PLT] $<$150x10^9/L). To "rule out" LSM $\leq$15 kPa plus PLT 150x10^9/L. Spleen stiffness measurement (SSM) was added to combined criteria: "rule in" if $\geq$2 of LSM $>$20 kPa + PLT $<$150 x10^9/L + SSM $>$50 kPa; "rule out" if $\geq$2 of LSM $\leq$ 15 kPa + PLT 150x10^9 + SSM $<$21 kPa. **Results:** 347/660 patients with HDV-related compensated cirrhosis from the SAVE-D and D-SHIELD studies were included. 154 (44%) showed EV. 53/85 (62%) fulfilling Baveno VII "rule in" criteria had EV (62%), but 101 (66%) with EV had LSM $<$25 kPa, corresponding to a Specificity (Sp) of 83% and a Positive Predictive Value (PPV) of 62%. 70/108 (65%) patients fulfilling the AASLD "rule in" criteria had EV. 84 (55%) patients with EV did not fulfill these "rule in" criteria, resulting in Sp of 80% and PPV 65%. The "rule out" criteria featured a Sensitivity (Sn) of 21% and a Negative Predictive Value (NPV) of 50%, with 41/46 (89%) patients with the "rule out" criteria not showing EV. 5 (11%) patients had missed varices. 216 (62%) and 185 (53%) patients fell in the "grey zone", with a prevalence of varices of 44% and 41%, respectively. Among 74 patients who performed SSM, the addition of SSM $>$50 kPa to the "rule in" criteria improved Sn (73% *vs.* 46%) but reduced Sp (73% *vs.* 80%) while PPV did not change (69% *vs.* 65%). As for "rule out" criteria, the addition of SSM $<$20 kPa improved both Sn (34% *vs.* 21%) and NPV (53% *vs.* 50%). **Conclusion:** The Baveno VII and AASLD criteria, show suboptimal performances in identifying HDV cirrhotics with clinically significant portal hypertension (CSPH) with gastroesophageal varices (EV), compared to other liver disease etiologies. Relying solely on NIT-based criteria to avoid endoscopic screening in these patients may misclassify individuals who have developed EV and are at increased risk of decompensating events.

◆ 2244 | ONE-POT ASSAY BASED ON CRISPR/CAS13A TECHNOLOGY FOR HEV RNA POINT-OF-CARE TESTING

Feng Ren[1] Zihao Fan[1] Ling Xu[1], [1]Beijing Institute of Hepatology/Beijing Youan Hospital, Capital Medical University, Beijing, China

Background: Hepatitis E virus (HEV) poses a serious threat to both public health and animal food safety, thereby highlighting the demands for rapid, sensitive, and easy-to-use detection. This study aimed to develop a One-Pot assay using CRISPR/Cas13a for detecting HEV RNA, suitable for point-of-care testing (POCT) in resource-limited settings. **Methods:** We established, optimized, and evaluated the methods for HEV RNA detection using CRISPR/Cas13a combined with reverse transcription polymerase chain reaction (RT-

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

PCR) and reverse transcription recombinase-aided amplification (RT-RAA). Additionally, a large cohort of 154 HEV-infected patients and 74 HEV-infected animal specimens were utilized for application validation. **Results:** The RT-PCR/RT-RAA+CRISPR/Cas13a assays for HEV RNA detection (genotypes: HEV-1, HEV-3, and HEV-4) were established, optimized, and validated, achieving a limit of detection (LoD) of 1copy/μL and 100% specificity. In the HEV-infected application validation (ddPCR assay as the gold standard), the positivity rates of patients detected by RT-qPCR, RT-PCR-CRISPR and RT-RAA-CRISPR assays were 70.8%, 98.6%, and 79.2%, respectively, and among animals were 75.8%, 95.2%, and 87.1%, respectively, which were superior to those of RT-qPCR. Furthermore, sample rapid lysis, reagent lyophilization, and the One-Pot device were integrated to construct a One-Pot assay with an LoD of 102copies/μL. The 5-minute rapid lysis of processed specimens (serum and feces) significantly reduces the assay time to 35min, making it easy to perform, minimizing contamination, and meeting the requirements for screening. **Conclusion:** We developed a One-Pot assay for HEV RNA detection using CRISPR/Cas13a, which effectively achieves a "sample in, result out" POCT system, maximizes the potential for POCT implementation, and shows promise as a valuable tool for detecting and monitoring HEV infection.

◆ 2245 | PERSISTENT LOW VIREMIC RELAPSE VS HIGH VIREMIC RELAPSE AFTER THE END OF TREATMENT WITH BULEVIRTIDE WITH OR WITHOUT PEGYLATED INTERFERON IN PATIENTS WITH CHRONIC HEPATITIS DELTA VIRUS

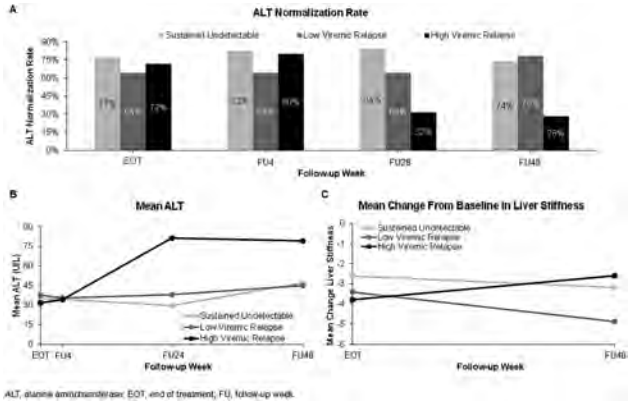
Fabien Zoulim[1] Tarik Asselah[2] Soo Aleman[3] Maurizia Brunetto[4] Vladimir Chulanov[5] Adrian Streinu-Cercel[6] George Gherlan[7] Pavel Bogomolov[8] Tatiana Stepanova[9] Viacheslav Morozov[10] Olga Sagalova[11] Amos Lichtman[12] Dmitry Manuilov[12] Yuejiao Jiang[12] Heiner Wedemeyer[13] Pietro Lampertico[14], [1]Lyon Hepatology Institute, Lyon, France, [2]Hôpital Beaujon APHP, Université de Paris-Cité, INSERM UMR1149, Clichy, France, [3]Karolinska University Hospital/ Karolinska Institutet, Stockholm, Sweden, [4]University Hospital of Pisa; University of Pisa, Pisa, Italy, [5]Sechenov University, Moscow, Russian Federation, [6]NIID Prof Dr Matei Bals; University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania, [7]Dr Victor Babes Foundation; Univ of Medicine & Pharmacy "Carol Davila" Bucharest, Bucharest, Romania, [8]M.F. Vladimirsky Moscow Regional Research and Clinical Institute, Moscow, Russian Federation, [9]LLC Clinic of Modern Medicine, Moscow, Russian Federation, [10]LLC Medical Company Hepatolog, Samara, Russian Federation, [11]South Ural State Medical University, Chelyabinsk, Russian Federation, [12]Gilead Sciences, Inc., [13]Hannover Medical School, Hannover, Germany, [14]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico and University of Milan, Milan, Italy

Background: Bulevirtide (BLV) 2 mg is approved for treatment of chronic hepatitis delta virus (HDV) infection. Previous analyses showed that achieving undetectable HDV RNA at end of treatment (EOT) is required to maintain undetectable viremia post-treatment; patients (pts) with low-level viremia at EOT are likely to have increased HDV RNA off treatment. This pooled analysis of BLV 2 or 10 mg monotherapy or combined with pegylated interferon alpha (PegIFNα) investigated the posttreatment outcomes in pts who achieved undetectable HDV RNA by EOT and had low viremic relapse with HDV RNA below the lower limit of quantitation (<LLOQ; target detected [TD]). **Methods:** Pts from the MYR204 (NCT03852433) and MYR301 (NCT03852719) studies were included; pts received BLV 2 mg + PegIFNα for 48 weeks (W) followed by 48W of BLV 2 mg monotherapy (n = 50); BLV 10 mg + PegIFNα for 48W followed by 48W of BLV 10 mg monotherapy (n = 50); BLV 10 mg for 96W (n = 100), BLV 2 mg for 144W (n = 49), or BLV 10 mg for 144W (n = 50) and were followed up (FU) for 48W (FU48) after EOT. HDV RNA was determined using RoboGene 2.0 (LLOQ = 50 IU/mL; limit of detection = 6 IU/mL). High viremic relapse was defined as HDV RNA levels ≥LLOQ. **Results:** At EOT, 131 of 299 (44%) pts achieved undetectable HDV RNA and had FU data available. Of these, 57 (44%) had undetectable HDV RNA at all posttreatment FU visits, 60 (46%) had high viremic relapse, and 14 (11%) had low-level viremia that remained <LLOQ. Pts with low viremic relapse maintained their rates of alanine aminotransferase (ALT) normalization in the posttreatment period: 9/14 (64%) at EOT and 11/14

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(79%) at FU48; results were similar in pts with no relapse (44/57 [77%] and 42/57 [74%] at EOT and FU48, respectively). In contrast, rates of ALT normalization in pts with high viremic relapse decreased during FU: 43/60 (72%) at EOT; 17/60 (28%) at FU48. Similar results were seen with mean ALT during FU. Mean liver stiffness increased only in pts with high viremic relapse. **Conclusion:** Most pts treated with BLV alone or in combination with PegIFNα who achieved undetectable HDV RNA at EOT either sustained undetectable HDV RNA post-treatment or had high viremic relapse, which was associated with loss of biochemical response. However, a small subset of pts had only low-level virological relapse (< 50 units) and maintained biochemical response; there was no progression to high viremic relapse after 1 year. The clinical significance of low-level viremia in the posttreatment period remains to be elucidated.



ALT, alanine aminotransferase; EOT, end of treatment; FU, follow-up week.

◆ 2246 | IMPACT OF HDV GENOMIC SEQUENCE VARIATION ON VIRAL INFECTIVITY, INNATE IMMUNE RESPONSES, AND ANTIVIRAL TREATMENT EFFICACY IN PRIMARY HUMAN HEPATOCYTES

Daniel Pinski[1] Ju Won Kim[1] Masashi Okawa[1] Yein Woo[1] Garnik Arustamyan[1] Meng Li[1] Takeshi Saito[1], [1]Keck School of Medicine, University of Southern California

Background: Hepatitis delta virus (HDV) is a subviral agent dependent on hepatitis B virus (HBV) that potently accelerates liver disease progression and, thus, poses a significant global health burden. HDV exhibits substantial genetic heterogeneity, forming eight distinct genotypes with unique geographic distributions. The genetic divergence among HDV genotypes is postulated to influence clinical manifestations, such as the severity of hepatic necroinflammation, fibrosis progression, and hepatocellular carcinoma incidence. However, clinical outcomes may also be affected by genomic variability of co-infecting HBV strains, host genetics, and region-specific comorbidities. Thus, this study aims to decipher the poorly understood genotype- and strain-specific factors underlying HDV-associated clinical heterogeneity using our state-of-the-art in vitro primary human hepatocyte (PHHs) culture system. **Methods:** We selected 16 distinct HDV strains across all eight genotypes, with each genotype represented by clinically aggressive strains and genetically distinct counterparts. For each strain, a 1.2-fold full-length HDV genomic RNA sequence flanked by ribozyme sites was cloned into a pcDNA3.1(+) expression vector. Each HDV-encoding plasmid was co-transfected with an HBsAg-expressing plasmid into Huh7.5 cells to produce HDV infectious particles. These particles were used to mono-infect or HBV-HDV coinfect PHHs maintained under optimized culture conditions that preserve the genuine characteristics of human hepatocytes. Following infection, intracellular and extracellular HDV RNA, HBV DNA, and virus-host interactions were genetically quantified. **Results:** Each HDV strain demonstrated substantial variability in viral replication efficiency and activation of innate antiviral responses, as quantified by the induction of interferon-stimulated genes (ISGs). Notably, these differences were not only genotype-specific but also strain-specific. Intergenotype comparison revealed that HDV-3c and HDV-1a exhibited the highest replication efficiencies, which correlated with strong activation of the innate antiviral response. Within each HDV genotype, subgenotype strains presented significant variability in ISG induction, replication efficiency, and sensitivity to IFN-based antiviral treatment. **Conclusion:** This study presents the first comprehensive cross-sectional comparison of multiple strains within each of the eight HDV genotypes and subgenotypes utilizing the most physiologically relevant model available. Our observations highlight

genotype- and strain-specific differences in viral fitness, activation of hepatic innate antiviral responses, and responsiveness to antiviral therapy. These factors underscore the strain-specific nature of HDV, potentially influencing natural history of the disease and therapeutic outcomes. **Disclosures:** Daniel Pinski: Nothing to Disclose, Ju Won Kim: Nothing to Disclose, Masashi Okawa: Nothing to Disclose, Yein Woo: Nothing to Disclose, Garnik Arustamyan: Nothing to Disclose, Meng Li: Nothing to Disclose, Takeshi Saito: PhoenixBio: Grant/Research Support, Sekisui USA: Grant/Research Support, EA Pharma: Consultant, Quotient Therapeutics: Consultant, CytoPathfinder, Inc.: Consultant

◆ 2247 | RATES OF HDV RNA UNDETECTABILITY DURING LONG-TERM BULEVERTIDE MONOTHERPAY IN PATIENTS WITH CHD ARE ASSAY-DEPENDENT

Maria Paola Anolli[1] Sara Uceda Renteria[1] Elisabetta Degasperi[1] Floriana Facchetti[1] Dana Sambarino[1] Marta Borghi[1] Riccardo Perbellini[1] Roberta Soffredini[1] Sara Monico[1] Annapaola Callegaro[1] Pietro Lampertico[1], [1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy

Background: A recent pooled analysis from the MYR2 204 and MYR301 studies suggested that, in patients with compensated CHD, the achievement of undetectable HDV RNA at EOT predicts maintaining undetectable viremia in the posttreatment period. [PL1] In this study, we compared two sensible methods for HDV-RNA quantification in long-term Bulevirtide (BLV)-treated CHD patients. **Methods:** Frozen plasma samples from BLV–treated CHD patients were tested in parallel on the same day by 2 different sensitive commercially available assays: Robogene HDV-RNA Quantification Kit 2.0 [Roboscreen GmbH; Lower Limit of Detection (LOD) 6 IU/mL)], and AltoStar HDV RT-PCR RUO Kit 1.5 (Altona Diagnostics GmbH, estimated LOD 1.12 IU/mL). **Results:** 173 plasma samples collected from 69 BLV-treated compensated CHD patients were studied by 2 different assays (overall 346 tests): median age was 54 (43-62), 71% were men, 90% had cirrhosis, 100% were HDV genotype 1 (available in 68 patients), 91% were HBeAg negative. Median ALT levels were 33 (27-40) IU/mL. Overall, HDV RNA levels were 2.79 (1.87-4.11) Log IU/mL with Robogene 2.0, and 2.78 (1.99-4.18) IU/mL with AltoStar ($p < 0.001$). Rates of HDV RNA undetectability, defined as target not detected (TND), during BLV therapy differed between the two assays after a median duration of BLV monotherapy of 60 weeks (IQR 36-120), 28 (16%) samples tested TND with Robogene 2.0 and 15 (9%) with AltoStar ($p = 0.049$). Of the 28 samples TND by Robogene 2.0, 16 (57%) tested positive with AltoStar, median HDV RNA being 0.54 (IQR 0.30-1.01) log IU/mL. Conversely, only 2 (13,3%) samples of the 15 testing TND with AltoStar resulted positive with Robogene 2.0, HDV RNA being 2.27 and 1.0 Log IU/mL, respectively. **Conclusion:** The proportion of patients achieving HDV RNA TND during long-term BLV monotherapy significantly differed according to the quantification assay used. These findings call attention to the urgency for further studies in this clinical setting to adequately identify patients who could safely withdraw BLV monotherapy.

◆ 2248 | PLASMA METABOLOMICS AND 16S RRNA SEQUENCING IDENTIFIES DISTINCT SIGNATURES OF WORSE OUTCOMES IN HEPATITIS A-INDUCED ACUTE LIVER FAILURE COMPARED TO DRUG INDUCED LIVER FAILURE

Anoushka Saxena[1] Rakhi Maiwall[2] Babu Lal Meena[3] jaswinder singh Maras[1] Varun Suroliya[4] Guresh Kumar[5] Shiv Kumar Sarin[3] Nirupma Trehanpati[1], [1]Department of Molecular and Cellular Medicine, Institute of Liver and Biliary Sciences, India, [2]Department of Hepatology, Institute of Liver and Biliary Sciences, New Delhi, India, [3]Department of Hepatology, Institute of Liver and Biliary Sciences, New Delhi, India., [4]Genome Sequencing Lab, Institute of Liver and Biliary Sciences, New Delhi, India., [5]Facility of Biostatistics, Institute of Liver and Biliary Sciences, New Delhi, India.

Background: Acute liver failure due to Hepatitis A (ALF-A), is an important cause of ALF in Asia. Outcomes in ALF depend on gut microbiota, immunity, systemic inflammation and altered metabolic milieu. We aimed to identify distinct signatures in ALF-A versus drug induced ALF to identify etiology specific signatures, specially predicting 90-day survival. **Methods:** One-hundred seventeen subjects (aged 26 ± 9 yrs) were compared: 1)acute viral hepatitis (IgM HAV positive,AVH-A, $n = 27$, ALT/AST > 10xULN), 2)acute liver failure (ALF-A, $n = 33$, ALT/AST > 10xULN with INR > 1.5 and hepatic encephalopathy), 3)drug-induced acute liver failure (ALF-D, $n = 37$, ALF features with definite evidence of DILI, and 4)healthy controls

(HC, n = 20). 16SrNA sequencing was performed in stool at baseline; plasma metabolomics and multiplex cytokines were assessed till one week. Clinical and biochemical parameters and indices were compared in survivors (S) and non-survivors (NS) in ALF-A vs ALF-D upto 90 days. **Results:** ALF-A patients had worse outcomes;21% meeting KCH criteria,SOFA score 7.97 ± 2.89, 60.6% with SIRS and 39% required mechanical ventilation compared to ALF-D (11% met KCH criteria, SOFA score 5.87 ± 2.32, 18.4% SIRS and 21% required mechanical ventilation). Within 90 days, 33% were NS in ALF-A (11/33) compared to 19% in ALF-D (7/37)(Fig.A). ALF-A_NS exhibited marked enrichment of inflammatory and mucin-degrading pathobionts (LDA > 3); *Enterocloster*, *Flavonifractor*, *Thomasclavelia ramosa*, *Enterobacter*, *Klebsiella quasivariicola*, *Enterococcus testudinis* compared to ALF-D_NS (Fig.B). This altered pathobiont positively correlated with KCH, SOFA, SIRS, MELD scores ($r > 0.5$, $p < 0.05$) (Fig.C). These pathobionts also positively correlated with pro-inflammatory cytokines, such as IL-1β, TNFα, IFN-γ, IL-8, IL-18, IL-21 in ALF-A_NS(Fig.D). On the other hand, significant increase in butyrate, tryptophan, histidine/histamine degradation in ALF-A_S patients was seen compared to ALF-A_NS, which inversely correlated with KCH, SOFA scores,SIRS ($r < -0.5$, $p < 0.05$)(Fig.E). ALF-D_NS were uniquely characterized by enrichment of fatty acid, glycerophospholipid metabolism, histidine degradation, distinguishing them from ALF-A_NS. **Conclusion:** In ALF-A non-survivors, enrichment of inflammatory pathobionts positively correlated, while depleted butyrate/tryptophan negatively correlated with clinically established mortality predictors- KCH, SOFA, SIRS, MELD scores, serving as unique mechanistic biomarkers that predict poor 90-day survival beyond clinical risk scores.

◆ 2249 | HEPATITIS D IN PRISON POPULATIONS: HIGH PREVALENCE, COINFECTION WITH HCV/HIV, AND LIMITED TREATMENT ACCESS IN SPAIN

Adriana Palom[1] Indiana Abdo[2] Ariadna Rando-Segura[3] Josefina Ayats[4] Andrés Marco[2] Maria Buti[1], [1]Liver Unit, Hospital Universitari Vall d'Hebron, CIBERehd, Barcelona, Spain, [2]Group of infectious diseases in Prisons of Catalonia (GRUMIP), Barcelona, Spain, [3]Microbiology Unit, Hospital Universitari Vall d'Hebron, Barcelona, Spain, [4]Microbiology Area, Clinical Laboratories Directorate, Catalan Institute of Health, Barcelona, Spain

Background: Prisons provide a valuable setting for screening and monitoring of blood-borne diseases, which are typically more common among inmates. In 2023, the prevalence of HBsAg in Spanish prisons was 1.7%, being 0.7% among Spanish inmates and 2.6% among immigrant inmates. Unlike hepatitis B and C, testing for hepatitis D still remains infrequent in prison settings. The aim of the current study was to characterize individuals who tested positive for anti-HDV antibodies and to assess their co-infection rates with HCV and HIV across 9 Spanish prisons. **Methods:** A multicenter prospective study was conducted, including all HBsAg+ samples analyzed at 9 Spanish prisons. A double reflex testing for anti-HDV and HDV RNA was performed, as well as HCV and HIV screening. Demographic, epidemiological, clinical and laboratory data for all anti-HDV positive patients were recorded on a digital platform. **Results:** From Jan 1, 2024 to 31 Mar, 2025 a total of 71 anti-HDV+ subjects were identified from the participant prisons. The median age was 42 (36-43), 93% were male, 83% were immigrants (mostly from Romania [17%] and Morocco [15%]). Seven (10%) subjects presented detectable HDV-RNA. Twenty-four (34%) had elevated ALT levels and 6/33 (18%) were cirrhotic. A total of 13 (18%) had HCV coinfection, 1 of them with active HCV infection, and 9 (13%) were anti-HIV+, 3 of them with active HIV infection. Two had a liver decompensation event (ascitis in both cases), and 1 developed an hepatocellular carcinoma. No subject underwent liver transplant or died of a liver-related cause. No viremic patients received Bulevirtide treatment during these 15 months. The majority of subjects (70%) reported no risk factors, while the most common identified risk was injection drug use (7%), followed by sexual risk behavior (4%) and blood transfusions pre-1975 (3%). **Conclusion:** This study highlights a notable presence of anti-HDV positivity among

HBsAg+ inmates in Spanish prisons, predominantly affecting middle-aged immigrant men, with a 31% rate of HCV/HIV co-infection. These findings show the need for targeted, integrated blood-borne diseases screening programs and improved access to antiviral therapies in prison settings. This study has been financed by Gilead Sciences (IN-ES-980-7058).

◆ 2250 | TWO DECADES OF HEPATITIS D IN THE UNITED STATES: ESCALATING INCIDENCE, SEX- AND RACE-SPECIFIC PATTERNS, AND NEARLY-DOUBLED RISKS OF CIRRHOSIS AND DECOMPENSATION AMONG ADULTS WITH CHRONIC HEPATITIS B

Himsikhar Khataniar[1] Renuka Verma[2] Leandro Sierra Carrero[3] Kaitlyn Gernhard[1] Daniel Huynh[4] Hany Habib[1] Nabeeha Mohy-ud-din[1] Nikki Duong[5], [1]Allegheny General Hospital, [2]UNLV, [3]Cleveland Clinic, [4]University of Washington, [5]Stanford University

Background: Globally, an estimated 12 million people are affected by hepatitis D virus (HDV), a co-infection known to accelerate the progression of chronic hepatitis B (CHB). Although the WHO recommends testing for all individuals with CHB, the AASLD recommends a risk-based screening approach. However, national real world data examining temporal and demographic trends in this population remain limited. **Methods:** Adults ≥18 years with laboratory-confirmed or ICD-coded CHB were identified across 67 health-care organizations (January 1st 2005–December 31st 2024). HDV infection was ascertained by antibody, antigen, or RNA positivity. Prevalence and incidence rates were calculated within successive five-year epochs (2005-10, 2010-15, 2015-20, 2020-25). Two separate multivariable Cox proportional-hazard models compared (A) time to first diagnosis of fibrosis/cirrhosis (ICD-10: K74) and (B) composite decompensating events (ascites, variceal bleeding, or hepatic encephalopathy) between CHB + HDV and CHB-alone cohorts. Covariates included sex, race, and Hispanic ethnicity. **Results:** Among 21,247 adults with CHB, the incident proportion of HDV infection increased 80-fold—from 0.17 % in 2005–2010 to 13.5 % in 2020–2025. Similar trends in HDV prevalence were noted, with an increase from 0.17% to 19.0%. In the most recent interval from 2020-2025, the incidence was higher in males than in females (14.2% vs 12.7%). Incidence rates also varied among the racial groups: American Indian/Alaska Native 30%, Black 17%, White 15%, and Asian 11%, though the AI/AN estimate was limited by small cell counts. Multivariable Cox analysis of 114,304 patients (4,506 with CHB + HDV and 109,798 with CHB alone) showed that HDV co-infection independently predicted both fibrosis/cirrhosis (adjusted hazard ratio [aHR] 1.96, 95 % CI 1.86–2.07; P < 0.001) and hepatic decompensation (aHR 1.79, 95 % CI 1.66–1.94; P < 0.001). Across both models, male sex (aHR = 1.7) and White race (aHR = 1.4–1.5) were linked to higher risks, whereas Black and Asian race conferred lower risks, and Hispanic ethnicity conferred moderately increased risks. **Conclusion:** This is the first study using real-world data to demonstrate that HDV increases the risk of developing cirrhosis and hepatic decompensation by nearly two-fold in patients with CHB. With rising rates of HDV over the last two decades, we must continue to prioritize our understanding of patients who are co-infected. This should begin with mandating universal HDV screening of all HBsAg-positive individuals and targeted outreach to high-risk demographic groups highlighted in our study. These findings address key knowledge gaps surrounding hepatitis D—a silent yet lethal virus—and underscore the urgent need for future research into emerging therapies and the social determinants of health that contribute to disparities in HDV-related outcomes.

Figure 1. Incidence proportion (%) of newly detected HDV per 100 adults with chronic HBV across four five-year intervals (TriNetX 2005–2025).

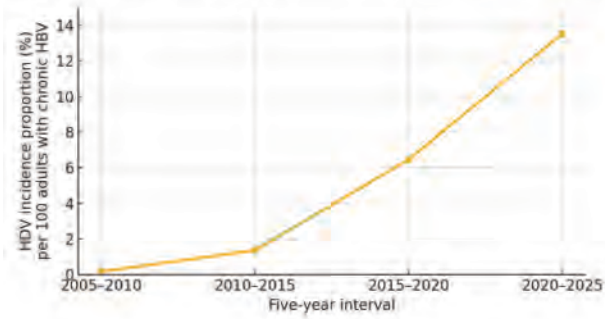

Table 1. Adjusted hazard ratios for HDV co-infection and demographic covariates

Predictor	Outcome: Fibrosis/Cirrhosis aHR (95 % CI)	Outcome: Decompensation aHR (95 % CI)
HDV co-infection	1.96 (1.86–2.07)	1.79 (1.66–1.94)
Male vs Female	1.77 (1.72–1.82)	1.73 (1.66–1.81)
White vs Other*	1.41 (1.35–1.47)	1.49 (1.40–1.58)
Black vs Other*	0.86 (0.82–0.91)	0.85 (0.79–0.91)
Asian vs Other*	0.87 (0.83–0.91)	0.68 (0.64–0.73)
Hispanic vs Non-Hispanic	1.20 (1.14–1.27)	1.27 (1.18–1.38)

*Reference category for race in TriNetX is "All Other Categories".

Dijon, Service d'Hépato-gastroentérologie et oncologie digestive, Inserm EPICAD LNC-UMR1231, [49]Service d'hépatogastroentérologie, Centre Hospitalier Intercommunal, Créteil, [50]School of Medicine and Surgery University of Milano Bicocca

Background: Bulevirtide (BLV) monotherapy achieved >70% virological response in patients with chronic hepatitis D (CHD), however, rates of HDV RNA undetectability are lower and data about maintenance of HDV RNA undetectability during long-term treatment are still limited. **Methods:** CHD patients achieving undetectable HDV RNA at week 48 upon BLV 2 mg/day monotherapy in the retrospective European multicenter SAVE-D study were enrolled. HDV-RNA undetectability was defined as HDV RNA below the lower limit of quantification (1 log increase of HDV-RNA compared to previous levels. Virological (HDV-RNA undetectable or ≥2-log decline *vs.* baseline), biochemical (ALT <40 U/L), combined response (biochemical + virological), and liver-related events were also assessed. **Results:** Among 261 CHD patients with cirrhosis treated with BLV monotherapy for at least 48 weeks in the SAVE-D study, 70 (27%) patients achieved HDV RNA undetectability at week 48. At the same timepoint, overall rates of virological, biochemical and combined response resulted 66%, 66% and 46%, respectively. Among the 70 HDV RNA undetectable patients, paired HDV RNA data between W48 and W96 were available for n = 41, and W96-W144 data for n = 23, respectively. In W48-W96 analysis, 32/41 (78%) maintained persistent HDV RNA undetectable, 4 (10%) patients showed a transient VBK at week 72 and then returned undetectable at week 96, while 5 (12%) patients showed a stable VBK (~1 Log_{10}IU/mL in 2; ≥2 Log_{10}IU/mL in 3). Among VBK patients, biochemical response was maintained in all but one case. In the paired W96-W144 analysis, 15/23 (65%) of patients maintained HDV RNA undetectability throughout week 144, 3 (13%) showed transient VBK then returning undetectable at week 144, and 5 (22%) showed a stable VBK (~1 Log_{10}IU/mL in 3; ≥2 Log_{10}IU/mL in 2). VBK occurred mostly after W96; at the time of VBK, 3/5 patients maintained the biochemical response. De-novo liver-related events were observed in 3 patients with maintained HDV RNA undetectability (HCC n = 2; ascites n = 1) and 1 VBK (HCC); 1 VBK patient showed ascites recurrence. **Conclusion:** During long-term BLV monotherapy in CHD patients with cirrhosis, HDV RNA undetectability at week 48 was maintained overtime in most of the patients. Only few patients experienced a stable VBK and most maintained biochemical response.

◆ 2252 | CLINICO-PATHOLOGICAL SPECTRUM AND OUTCOMES OF HEPATITIS-A OUTBREAK IN SOUTHERN INDIA: A MULTICENTRIC CROSS-SECTIONAL STUDY AND AN UPDATED ANALYSIS

Arun Valsan[1] Gowri Priya Nair[1] Nipun Verma[2] Charles Panackel[3] KT Shenoy[4] Hasim Ahamed[5] Benoy Sebastian[6] R Nandakumar[7] Nimitha Mohan[3] Gerog Gutjahr[8] Sudhindran Surendran[1] Zubair Mohamed[1] Arathi Venu[1] Dr George Eapen Puthusseril[1] Sharon Paul Methala[1] Smitha Krishnamoorthy[1] Ajay Duseja[9] Zachariah Paul[1] Priya Nair[1] Anupama P[1] V Devanand[1], [1]Amrita Institute of Medical Sciences, Kochi, [2]Postgraduate Institute of Medical education and Research, CHandigarh, [3]Aster Medcity, Kochi, [4]Sree Gokulam Medical College & Research Foundation, Trivandrum, India, [5]Lissie Hospital, [6]Medical Trust Hospital, Kochi, [7]EMS Memorial Co-operative Hospital & Research Centre Ltd, Perinthalmanna, India, [8]Amrita CREATE, Amritapuri, India, [9]Postgraduate Institute of Medical Education & Research

Background: Hepatitis A virus (HAV) infection is classically considered a self-limiting disease, however, a recent resurgence of HAV in Kerala State, India, raised public health concerns. Physicians reported atypical clinical phenotypes marked by persistent fever, early renal and pulmonary involvement, and occurence of hemophagocytic lymphohistiocytosis (HLH). **Methods:** We conducted a multi-centre, cross-sectional study across six tertiary care hospital in serologically confirmed acute HAV infection who were prospectively enrolled and grouped into :usual HAV (u-HAV) and atypical HAV (a-HAV). Detailed demographic, epidemiological, and clinicopathological data were collected. **Results:** A total of 324 patients (a-HAV = 179, u-HAV = 145), with the mean age of 32 ± 12.8 years, 68.2% males constitued the cohort. Clinically, a-HAV cases had significantly higher incidence of persistent fever (93% vs 12%), hepatomegaly (64% vs 44%), splenomegaly (30% vs 17%), ascites (30% vs 9%). Atypical complications like prolonged cholestasis (16%), clinical HLH (13%), acute kidney injury (AKI) (13%), metabolic acidosis (6.7%), autoantibody positivity (18% vs 0.7%; $p < 0.001$). Lab parameters reflected severe disease in a-HAV, with higher mean bilirubin (12.9 vs 6.9 mg/dL), AST (3306 vs 1880 IU/L), ALT (3350 vs 2492 IU/L), triglycerides (218.7 vs 171.4 mg/dL), ferritin (19385 vs 3154 IU/L), LDH (1955 vs 502 IU/L), INR (2.5 vs 1.5), and ammonia (99.3 vs 56.8 μmol/L). There was increased steroid use (30% vs 4.1%), plasma exchange (PLEX) (21%), continuous renal replacement therapy (CRRT) (5%), development of ACLF (7.3%), mechanical ventilation (10%), readmissions (9%) in a-HAV group. Multivariable analysis identified ALF presentation, any grade HE, RRT, ACLF, AKI, presence of autoantibodies, HLH, and mechanical ventilation independent predictors of mortality. Overall mortality in the cohort was 13%. Genotypic analysis of 56 samples identified genotype IIIA, consistent with the endemic variant. **Conclusion:** This study provides strong evidence for achanging clinico-pathological profile and possibly altered virulence of hepatitis A virus. Unlike previous outbreaks, a significant proportion of patients in our cohort had severe immune dysregulation, and multi-organ involvement. These findings underscore the need for clinical vigilance, early identification of atypical presentations, and the need for tailored management strategies to improve patient outcomes.

Background: Bulevirtide (BLV) 2 mg/day monotherapy demonstrated safety and effectiveness in patients with chronic hepatitis Delta (CHD), however data in large real-world cohorts of patients is lacking. **Methods:** Consecutive CHD patients starting BLV monotherapy from the multicenter SAVE-D and D-SHIELD studies were included. Virological (HDV-RNA undetectable or $\geq$2-log decline *vs.* baseline), biochemical (ALT $<$40 U/L), combined response (biochemical + virological), and liver-related events were assessed. HDV RNA was tested locally. Viral breakthrough (VBK) was defined as at least 1 Log_{10}IU/mL HDV-RNA increase from nadir. **Results:** 689 CHD patients treated with BLV 2 mg/day were enrolled. At BLV start, age was 52 (IQR 42-60) years, 58% men, ALT 75 (34-50) U/L, liver stiffness measurement 14.4 (10.4-22.3) kPa, platelets 116 (77-166) x 10^3/mm^3, 84% with cirrhosis, 33% with varices, 52% IFN-experienced, 8% HIV-positive, 93% on NUC, 6% with history of ascites and 7% of HCC. Baseline HBsAg and HDV-RNA levels were 3.7 (3.2-4.1) and 5.3 (4.1-6.3) Log_{10}IU/mL, respectively. Following 48 weeks of BLV monotherapy, 67% of patients achieved a virological, 66% biochemical, and 48% combined response, 30% HDV-RNA undetectability. At week 72, the corresponding rates were 66%, 64%, 49%, and 35%, respectively. 18% of patients had $<$1 Log HDV-RNA decline *vs.* baseline (non-virological response, NR), and 16% 1-2 Log decline (partial virological response, PR). 45% of patients with a suboptimal response (NR or PR, n = 95) achieved a biochemical response, 16% without biochemical response had at least a 50% ALT decrease compared to baseline. Among 261 patients with paired W24-48-72 data, 14 patients (5%) who had achieved a week 24 virological response had a VBK at week 48: prolonged BLV treatment rescued virological response in 4, 2 patients achieved a PR, 8 remained NR (normal ALT in 50%). In the overall population, no significant effect of BLV on HBsAg levels was observed. At multivariate analysis, lower baseline HDV RNA levels were associated with HDV RNA undetectability at week 48. De-novo liver-related events occurred in 20 cirrhotic patients: 14 HCC and 6 decompensations. **Conclusion:** BLV monotherapy 2 mg/day confirmed effectiveness and safety in two large multicenter cohorts of real-world CHD patients, independently of baseline cirrhosis. Lower baseline HDV RNA levels predicted HDV RNA undetectability at week 48. VBK and liver-related events occurred in few patients only.

Background: Bulevirtide (BLV) is an entry inhibitor for chronic hepatitis delta virus (HDV) infection. This study presents integrated virology analyses from the MYR204 and MYR301 clinical trials, evaluating the virological response to BLV and assessing whether treatment was associated with emergent substitutions in the HBV PreS1 region, HDAg, or phenotypic shifts in clinical isolates from patients receiving BLV monotherapy. **Methods:** A total of 199 patients received BLV monotherapy (BLV 2 mg, N = 49; BLV 10 mg, N = 150). A control group included n = 51 patients who remained untreated during a delayed-treatment phase. Virologic response (VR): HDV RNA drop ≥ 2 $\log_{10}$ IU/mL from baseline (BL) or undetectable. The Resistance Analysis Population (RAP) included BLV-treated patients meeting virologic nonresponder (NR; < 1 $\log_{10}$ IU/mL decline at specified points through Week 144) or virologic breakthrough (VB; two consecutive HDV RNA $\geq$ LLOQ post-LLOQ, or confirmed ≥ 1 $\log_{10}$

IU/mL rise from nadir at two visits) criteria. Resistance testing included sequencing analyses of HBV PreS1 BLV region, HDAg, NTCP, as well as in vitro BLV EC50 evaluation. **Results:** Among the HDV clinical isolates in this cohort, HBV genotype D (GTD) was the most prevalent (176 of 199, 88%), followed by genotype A (GTA, 14 of 199, 7%). At Week 96, 87% of patients receiving BLV 10 mg with HBV GTD (N = 129) achieved VR. Among patients with GTA (N = 12), 50% achieved VR and 58% attained ALT normalization. These endpoints were rarely achieved aamong patients in the control group. A total of 48 patients on BLV monotherapy qualified as RAP. No treatment-emergent amino acid substitutions were identified in the HBV BLV homologous region or conserved HDAg sites. NTCP polymorphisms were rare and also showed no association with BLV treatment outcome. Phenotypic analysis showed that BLV EC50 values were similar between VR and RAP isolates at BLand during BLV monotherapy through Week 144 (Fig. A-D). BLV EC50 values remained within assay variation across all subgroups, regardless of HBV/HDV polymorphisms (Fig A-D). **Conclusion:** BLV monotherapy demonstrated efficacy in patients with chronic HDV, including those with HBV GTD and GTA. Integrated virology and resistance analysis through Week 96 did not identify genotypic or phenotypic resistance to BLV, supporting its continued use as a monotherapy for the treatment of HDV infection.

2255 | COMPARATIVE PERFORMANCE OF COMMERCIAL HDV ASSAYS

Gian Rodriguez Franco[1] Ashli Rode[2] Lezlie Kelzenberg[2] Marc Ghany[3], [1]National Institutes of Health, [2]DiaSorin, [3]NIH/NIDDK

Background: Chronic hepatitis D (CHD) is associated with faster progression to cirrhosis, hepatic decompensation, and an increased risk of liver cancer compared to other chronic hepatotropic viral infections. The approval of safe and effective therapy in Europe, highlights the need to identify cases of CHD. However, there is no approved screening assay for CHD in the U. S and how available anti-HDV assays compare in performance is unknown. Our aim was to evaluate the performance of a fully automated anti-HDV assay, LIAISON® XL MUREX Anti-HDV (LXL) compared to three commercially available, non-FDA approved, manual laboratory developed anti-HDV assays. **Methods:** Serum samples from HBsAg positive patients at a tertiary liver clinic were tested concurrently for anti-HDV using three Laboratory Developed Tests (LDTs) as well as the LXL (Research Use Only). Specimens were categorized as positive if two of the three LDTs results were reactive, independent of the LXL Anti-HDV assay result. An equivocal result was considered positive for this analysis. Performance characteristics (sensitivity, specificity, and concordant and discordant rates) were compared among the four assays. **Results:** Among 900 samples obtained from HBsAg positive individuals 10 had quantity not sufficient (QNS) for testing. The mean subject age was 57 years and 61% were men, 29.2% White 23.5% Black 41.9% Asian, and 5.4% of unknown or other race. The prevalence of anti-HDV ranged from 16.7%-19.7%. Using 2/3 consensus among tests sensitivity ranged from 94%-100% and specificity from

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

98.4%-99.4%. Alternative consensus methods were evaluated by including the LXL results in the consensus. Using a consensus of 3/4 tests, 133 were considered positive with the LXL yielding 3 false positives, LDT 1 12 false positives, LDT 2 10 false positives and LDT 3 4 false positives. 553 samples were classified as negative. LXL and LDT 2 yielded no false negative results, LDT 1 reported 8 false negatives and LDT 3 had 1 false negative result; 211 specimens were QNS for testing by all methods. Consensus could not be determined in 3 samples because results were discordant. Consensus (4/4) could be determined for 648 specimens with 524 specimens resulting negative by all four methods and 124 specimens resulting positive; 31 specimens could not be categorized as at least one test reported discordant results. **Conclusion:** A high rate of discordance, affecting sensitivity, was observed among commercially available, non-approved anti-HDV tests potentially impeding efforts to introduce universal HDV screening in the U.S. An accepted standard for anti-HDV testing is urgently needed to enable screening efforts for CHD to identify persons who may benefit from emerging therapies.

Antonio Hospital, Azienda Ospedale-Università Padova, Padua, Italy

Background: Bulevirtide (BLV) has shown efficacy in reducing viral load and improving liver tests in patients with chronic hepatitis delta (CHD), the most severe form of viral hepatitis. However, real-world data on patient-reported outcomes (PROs), including health-related quality of life (HRQoL), adherence, and safety, remain limited. Here we analysed the long-term impact of the EXPLAIN program – a pharmacist-led intervention combining medication counselling with proactive surveillance and individualized support – on adherence, HRQoL, and adverse effects (AEs) in CHD patients receiving BLV. **Methods:** Thirty-one CHD patients initiating BLV therapy at Padua University Hospital, Italy, were prospectively enrolled and followed for 60 weeks. Virological (HDV-RNA undetectable or $\geq$2log decline from baseline), biochemical (ALT **Results:** BLV led to a significant reduction of HDV RNA by week 24, with continued decline through weeks 48 and 60. Liver enzymes improved at week 24 and remained stable thereafter. Combined response rates increased significantly from 14.8% at week 24, to 36.4% and 43.7% at week 48 and 60, respectively ($p < 0.01$). Optimal adherence (PDC $\geq$90%) was achieved by 87.1% patients at week 24 and consistently maintained throughout follow-up. HRQoL improve significantly, with mean VAS scores increasing from 72.4 ($\pm$17.88) at baseline to 83 ($\pm$15.07) at week 24 ($p = 0.01$), 83.11 ($\pm$ 12.14) at week 48 and 84.6 ($\pm$ 10.74) at week 60 (+12.2, $p = 0.03$). EQ-5D-5L showed significant improvement in usual activities and anxiety/depression domains, while the other domains remained either stable or slightly improved. AEs were infrequent, mild, and rarely led to treatment discontinuation. **Conclusion:** In this real-world cohort, the EXPLAIN program was associated with excellent adherence, favourable virological, biochemical, and combined response, and significant HRQoL improvements during 60-weeks of BLV therapy. These findings support the integration of structured pharmacist-led education programs into routine care to enhance long-term outcomes in CHD management.

2257 | HEPATITIS D VIRUS INFECTION PREVALENCE IN PERSONS WITH HUMAN IMMUNODEFICIENCY VIRUS AND HEPATITIS B VIRUS COINFECTION: A THREE-COUNTRY, CROSS-SECTIONAL STUDY IN EUROPE

Anders Boyd[1] Thomas Lutz[2] Kathrin van Bremen[3] Miłosz Parczewski[4] Iwona Cielniak[5] Luz Martin Carbonero[6] Juan Berenguer[7] Juergen Rockstroh[8] Pablo Ryan[9], [1]Stichting hiv monitoring, [2]Infektiologikum, [3]Bonn University Hospital, [4]Pomeranian Medical University, [5]Collegium Medicum Cardinal Stefan Wyszynski University, [6]Hospital Universitario La Paz, [7]Instituto de Investigación Sanitaria Gregorio Marañón, [8]3Bonn University Hospital, [9]Instituto de Salud Carlos III

Background: People with human immunodeficiency virus (PWH) who have hepatitis B virus (HBV) are at increased risk of also having hepatitis D virus (HDV) given the shared transmission pathways. Accordingly, the guidelines of the European AIDS Society (EACS) recommend HDV screening in all PWH and concomitant HBV. However, the current prevalence of HDV among people with HIV/HBV is not well established. **Methods:** Across 47 HIV treatment centers (Germany, $N = 20$; Spain, $N = 21$; Poland, $N = 6$), all people with a confirmed HIV diagnosis and hepatitis B surface antigen positive serology for more than 6 months, aged ≥ 18 years, and actively in care on December 31, 2023 were recruited. We assessed HDV testing rates in the total cohort. In addition, we calculated the prevalence of individuals who ever had an anti-HDV positive serology (i.e., past/current infection) and the prevalence of individuals whose last HDV RNA result was positive (i.e., active infection). **Results:** Overall, 1,253 PWH and HBV coinfection were included (Germany, $n = 419$; Spain, $n = 774$; Poland, $n = 60$). The majority were male ($n = 1057$, 85.5%) and median age was 56 years (IQR = 48-61). Almost all individuals were on antiretroviral therapy ($n = 1231$, 98.3%), of whom 1082 (87.8%) had undetectable HIV viral load, 1162 (94.3%) were receiving antiviral dual active therapy, and 1111 (90.2%) had undetectable HBV-DNA. Anti-HDV antibody results were available in 981 (78.3%) individuals. Of them, 176/981 (17.9%) had past/current HDV infection. 110/176 individuals with HDV-positive serology had an HDV-RNA determination, of whom 53/110 (48.2%) were positive and thus had active infection. The resulting overall prevalence of active infection was 5.4% (95%CI = 4.1-7.1; $n = 53/981$). All individuals with active HDV infection were in Spain ($n = 39$) or Germany ($n = 14$), and the majority likely acquired HDV from injection drug use ($n = 34$) or sexual contact between males ($n = 10$). **Conclusion:** In this contemporary cohort of PWH with HBV from European centers, HDV serology was performed in roughly 75%, and HDV-RNA testing in two-thirds of those seropositive. Considering the overall 5% prevalence of active HDV, these findings highlight that HBV/HDV coinfection is not uncommon and reveal significant gaps in screening within this vulnerable population.

2258 | ECLIPSE: A PIVOTAL PROGRAM EVALUATING ONCE-MONTHLY COMBINATION THERAPY WITH TOBEVIBART AND ELEBSIRAN FOR CHRONIC HDV INFECTION - RATIONALE, STUDY DESIGN, AND OBJECTIVES

Nancy Reau[1] Pietro Lampertico[2] Tarik Asselah[3] Michael Chattergoon[4] Tamara Palagashvili[4] Richie Phan[4] Cara Pilowa[4] Todd Correll[4], [1]Rush University Medical Center, [2]University of Milan, [3]Hôpital Beaujon, [4]Vir Biotechnology, Inc.

Background: Chronic hepatitis delta virus (HDV) infection is the most severe form of viral hepatitis, with no approved therapies in the US and limited options globally. Tobevibart (VIR-3434), a broadly neutralizing anti-HBsAg monoclonal antibody that blocks HBV + HDV entry into hepatocytes and clears circulating viral particles, and elebsiran (VIR-2218), an HBV-targeted small interfering RNA that degrades HBV transcripts to reduce HBsAg production, are investigational agents with complementary mechanisms against HDV. In the Phase 2 SOLSTICE study, monthly subcutaneous administration of tobevibart+elebsiran led to HDV RNA $<$ LLOQ (63 IU/mL) in 100% of participants and 41% achieved HDV RNA $<$ LLOQ, target not detected (TND) (HDV RNA TND) by Week 24. This investigational combination has the potential to address a global unmet need for people with chronic HDV infection. **Methods:** ECLIPSE, a global registrational program launched in March 2025, evaluates monthly combination therapy with tobevibart+elebsiran in chronic HDV infection and consists of 3 global trials addressing 3 distinct HDV populations (see table). ECLIPSE 1, placebo-controlled, enrolls participants with elevated ALT who either have no approved therapy options or decline existing therapy. ECLIPSE 2 compares tobevibart+elebsiran vs bulevirtide (BLV) monotherapy in participants who have not achieved HDV RNA TND

on BLV. ECLIPSE 3, head-to-head, evaluates tobevibart+elebsiran vs. BLV monotherapy in BLV-naive participants. Eligible participants are adults (18 to 70 years) with all stages of liver fibrosis and compensated cirrhosis. ECLIPSE will be conducted across North America, Europe, and Asia-Pacific. The long-term efficacy and safety of tobevibart+elebsiran therapy will be evaluated over 5 years. Additionally, impact on ALT, HBV serologies including HBsAg levels, liver fibrosis changes over time and occurrence of liver-related events will be assessed. **Results:** ECLIPSE 1, planned in 13 countries, was activated in early 2025. As of May 2025, ECLIPSE was initiated in the US, Canada, and several European countries. ECLIPSE 2 and 3 are projected to be initiated mid-2025 in 7 and 12 countries, respectively. Updated country/site activation, screening, and enrollment data will be presented. **Conclusion:** Tobevibart+elebsiran combination therapy has the potential to address a significant unmet need in chronic HDV infection, including in participants who do not have an approved treatment and those who did not achieve HDV RNA TND on BLV monotherapy.

ECLIPSE PIVOTAL DEVELOPMENT PROGRAM OVERVIEW

STUDY	DESIGN	SAMPLE SIZE	PRIMARY ENDPOINTS
ECLIPSE 1 Phase 3 NCT06903338 EU CT: 2024-515919-22-00	Immediate vs. delayed treatment with tobevibart+elebsiran	N=120 Randomized 2:1	• HDV RNA TND + ALT normalization at Week 48* • Incidence of Treatment Emergent Adverse Events (TEAEs) and Serious Adverse Events (SAEs) through Week 12
ECLIPSE 2 Phase 3	Tobevibart+elebsiran vs. continued bulevirtide in participants who failed to achieve HDV RNA TND with ≥ 6 months of bulevirtide	N=150 Randomized 2:1	Primary Part 1 (on treatment): • HDV RNA TND at Week 24 • Incidence of TEAEs and SAEs through Weeks 24, 48 and 96 Primary Part 2 (off treatment): • HDV RNA TND 24 weeks after end of treatment • Incidence of AEs and SAEs and lab abnormalities from Week 96 through Week 240
ECLIPSE 3 Phase 2b	Head-to-head tobevibart+elebsiran vs bulevirtide in bulevirtide naive participants	N=100 Randomized 2:1	Primary Part 1 (on treatment): • HDV RNA TND at Week 48 • Incidence of TEAEs and SAEs through Week 48 Primary Part 2 (off treatment): • HDV RNA TND 24 weeks after end of treatment

*HDV RNA TND will be a key secondary endpoint

2259 | A CONSERVED G-QUADRUPLEX IN HEPATITIS E VIRUS NEGATIVE-STRANDED RNA PROMOTES VIRAL REPLICATION VIA RNA STABILIZATION

Yuebao Li[1] Tianxu Liu[1] Fengmin Lu[1] Lin Wang[1],
[1]Peking University

Background: Hepatitis E virus (HEV) is one of the most common causes of acute hepatitis worldwide, it results in 20 million infections at least annually with approximately 3.3 million cases of acute illness. G-quadruplex (G4) is a kind of non-canonical structure formed in DNA or RNA which is composed of four guanine stretches into stacked quartets. Because the genetic material of viruses is also nucleic acids, which have the structural basis for the formation of G4s. Currently, G4s have been found in the genomes of many species of viruses, and they play an important role in the regulation of viral life cycle. The presence of G4s within the HEV genomic RNA remains unknown and their potential involvement in regulating viral replication warrants investigation. **Methods:** First, comparative genomic alignment of eight HEV genotypes was performed to identify conserved contiguous guanine(G)-rich sequences. Then, the genome of HEV Kernow-C1/p6, was predicted for Potential G-quadruplex Sequences (PQSs) by using QGRS Mapper online tool, and the multiple sequence alignment analysis of PQSs using 497 complete genomic sequences of HEV retrieved from the NCBI database. To validate the existence of G4s in HEV, three G4 ligands (PDS, CX-5461, TMPyP4) were used to diverse HEV infection models (HepG2/C3A, Caco-2, Primary Gerbil Hepatocytes) for antiviral efficacy assessment. G4 formation of candidate PQSs was validated in vitro through Circular Dichroism (CD) spectroscopy and native polyacrylamide gel electrophoresis, followed by functional characterization of critical PQSs using the HEV replicon system. **Results:** Comparative alignment of eight genotypes of HEV genomic RNA sequence revealed eight conserved contiguous guanine-rich motifs. In silicon analysis and scoring using the HEV Kernow-C1/p6 strain validated evolutionary conservation of eight PQSs. Meanwhile, three G4 ligands (PDS, CX-5461, TMPyP4) demonstrated antiviral efficacy against multiple HEV strains in diverse cellular models including HepG2/C3A, Caco-2, and Primary Gerbil Hepatocytes (PGHs). CD and Native PAGE analyses demonstrated that four of eight

candidate PQSs could form G4 structure in vitro, with two localized to the positive-stranded RNA and two to the negative-stranded RNA of HEV. An optimized Gaussia Luciferase reporter system based on HEV Kernow-C1/p6 was developed, and combined with a full-length HEV replicon system, demonstrated the critical role of the negative-strand-localized NPQS-2 in viral replication. Finally, synonymous mutations disrupting G4 formation of NPQS-2 significantly accelerated viral RNA degradation. **Conclusion:** Collectively, these results demonstrate four conserved PQSs in HEV RNA capable of folding into stable parallel G4 structures in vitro. Notably, the NPQS-2 located on the HEV negative-stranded RNA is crucial for HEV, facilitating viral replication through RNA stabilization.

Background: Hepatitis delta virus (HDV) infection, in patients coinfected with hepatitis B virus (HBV) accelerates liver disease progression and is linked to higher rates of cirrhosis and hepatocellular carcinoma. The DDR Spain study aims to standardize HDV screening by implementing a reflex anti-HDV and HDV-RNA testing strategy nationwide, and characterize HDV-infected individuals in Spain. **Methods:** DDR Spain is a multicenter, national, ambispective observational study, comprising a retrospective evaluation of DDR implementation during 2022–2023 and a prospective phase starting in 2024. The prospective phase, launched in Q3 2024, includes clinical, demographic, and virological data collection in anti-HDV-positive patients across participating centers. **Results:** From 2022 to 2024, 65,763 HBsAg-positive individuals were included from 80 centers across 16 out of Spain's 17 Autonomous Communities. Reflex anti-HDV testing increased from 55.1% (2022) to 64.8% (2023), and to 85.9% (2024) ($p < 0.05$), with anti-HDV prevalences of 5.6%, 4.9%, and 4.8%, respectively. Regional differences persisted throughout. HDV-RNA testing coverage improved from 72.6% in 2022 to 91% in 2024 ($p < 0.05$). Active HDV infection decreased from 40.2% (2022) to 31.1% (2024). By May 2025, the prospective cohort had enrolled 288 anti-HDV-positive patients. Median age was 55 years (IQR 43–61), 57.4% were male, and 52.3% were of Spanish origin. Genotyping revealed 90% were genotype 1. Co-infections were found in 17.9% (HIV) and 21.9% (HCV). Advanced fibrosis was common: 29.7% had FIB-4 >2.67, 17.3% had APRI >1.5, and in 123 patients with available transient elastography, the mean liver stiffness was 7.4 kPa. According to METAVIR staging, 15% had F3 and 30% had F4 fibrosis, highlighting the severity of liver disease. Prior hepatic decompensation was recorded in 23% of evaluable cases. **Conclusion:** DDR Spain is the largest HDV diagnostic initiative in Spain to date. It demonstrates substantial improvements in HDV reflex testing, while revealing persistent regional disparities. The prospective phase offers a detailed snapshot of the current HDV population. These findings support the need for unified screening policies, continued clinical education, and greater awareness to improve detection and management of HDV nationwide.

2261 | LONAFARNIB AS FINITE TREATMENT FOR CHRONIC HEPATITIS D: LONG-TERM FOLLOW-UP DATA

Cihan Yurdaydin[1] Müge Gülnar[1] Olga Metin[2] Ozgur Aktas[3] Esra Yurdcu[4] Selin Ozer[5] Onur Keskin[6] Mesut Gumussoy[6] Emin Bodakci[6] Xheni Deda[6] Sevda Aghayeva[6] Genco Gencdal[7] Müjdat Zeybel[7] Ramazan Idilman[6] Mithat Bozdayi[4] Ingrid Choong[8] Jeffrey Glenn[9], [1]Koç University Hospital, Istanbul, Türkiye, [2]Prof. Dr. Cemil Tascioglu Sehir Hastanesi, Istanbul, Turkey, [3]Faculty of Medicine, Koç University School of Medicine, [4]Hepatology Institute, Ankara University, Ankara, Turkey, [5]Koç University Medical School, Istanbul, Türkiye, [6]Department of Gastroenterology, Ankara University Medical School, Ankara, Turkey, [7]Department of Gastroenterology and Hepatology Koç University, İstanbul, Türkiye, [8]Eiger BioPharmaceuticals, Inc., Palo Alto, California, USA, [9]Palo Alto Veterans Administration, Palo Alto, California, USA

Background: Hepatitis delta virus (HDV) infection leads to the most severe form of viral hepatitis. New treatment options are urgently needed. The farnesyl transferase inhibitor lonafarnib (LNF) may be an option for finite treatment as it possesses a dual mode of action: it interferes with virion assembly (Glenn et al Science 1992) and also has immunomodulatory properties (Lempp et al, Nat Commun 2019). The aim of this study was to assess if finite treatment with a LNF-based regimen is able to prevent hard endpoints such as complications of liver disease and death from liver disease on long-term follow-up (LTFU). **Methods:** All patients subject to this study had received LNF-based treatment in two phase 2 (LOWR 1 and 2) and one phase 2 (LIFT) studies in Ankara (TR) and NIH (USA), respectively, and one phase 3 (DLIVR) study in Istanbul (TR). LOWR 1 and 2 studies contained 21 and 55 patients, respectively, the LIFT study 26 and the phase 3 Istanbul study contained 27 patients with a LNF-based treatment. Start date used for LTFU (median 79.5 months (0-134, n = 97) and survival analysis was EOT date of LNF-based treatment. End of follow-up (EOFU) was set to either the last date of data collection (March 2025), or the date of liver-related event, the start date of a new potential treatment against HDV or loss to follow-up. Short-term viral response (STVR) was defined as undetectable HDV RNA or a ³ 2 log decline of HDV RNA compared to baseline and biochemical response (BR) as ALT normalization at off treatment month 6. BR and VR were the co-primary endpoints. Cumulative probabilities of any event occurrence were estimated by the Kaplan-Meier method and compared with the log-rank test. Uni- and multivariate logistic regression models with forward Wald deletion were used to estimate the effect of various on and off-treatment variables on clinical outcome. **Results:** STVR was achieved in 12 patients. On LTFU none of these patients developed a clinical event in up to 10 years of follow up. Out of 85 patients without VR+BR, 17(20%) developed an event (Figure, $p < 0.05$ by the log rank test). **Conclusion:** Patients achieving a 2 log drop in HDV RNA from baseline and normal ALT at 6 months after stopping any finite lonafarnib-based treatment regimen have no major clinical events (liver decompensation, liver cancer, or death) in up to 10 years of follow up.

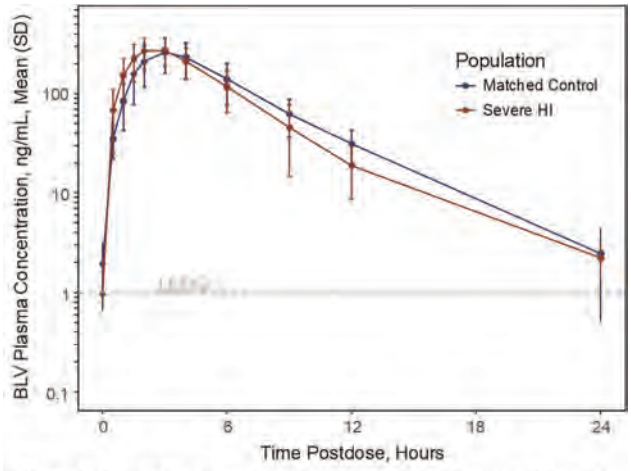
2262 | PHARMACOKINETICS, PHARMACODYNAMICS, AND SAFETY OF BULEVIRTIDE 10 MG ONCE DAILY FOR 6 DAYS IN PARTICIPANTS WITH SEVERE HEPATIC IMPAIRMENT AND IN MATCHED CONTROL PARTICIPANTS WITH NORMAL HEPATIC FUNCTION

Parag Kumar[1] Wildaliz Nieves[1] David Pan[1] Jack Chang[1] Steve Tseng[1] Yuejiao Jiang[1] Yehong Wang[1] Ann Qin[1] Teckla Akinyi[1] Renee-Claude Mercier[1], [1]Gilead Sciences, Inc.

Background: Bulevirtide (BLV) 2 mg once-daily (QD) is approved in the EU, United Kingdom, Switzerland, Russia, and Australia for the treatment of chronic hepatitis delta virus (HDV) in patients with compensated liver disease. BLV binds to the sodium taurocholate cotransporting polypeptide (NTCP) receptor, resulting in asymptomatic and transient elevations in bile acids (BAs). Evaluations exploring potential benefits of an increased 10 mg QD dose are in progress. This study evaluated the effect of severe hepatic impairment (HI) on the pharmacokinetics (PK), pharmacodynamics (PD), and safety of BLV 10 mg. **Methods:** This was a Phase 1, open-label, parallel-group, multiple-dose study in participants (pts) without HDV with severe HI (Child-Turcotte-Pugh class C, n = 8) and matched controls (MCs) with normal hepatic function (matched for age [± 10 years], sex, and body mass index [± 20%]; n = 8) who received BLV 10 mg subcutaneously QD for 6 days, with intensive serial sampling for BLV PK and PD (total BAs). Geometric least-squares mean ratios (GLSMRs) and 90% CIs of maximum plasma concentration (C_{max}; ng/mL) and the area under the time-vs-concentration curve over 24 hours (AUC_{24h}, ng·h/mL) or extrapolated to infinity (AUC_{inf}, ng·h/mL) were evaluated for PK; those of C_{max} (μM), AUC_{24h} (μM·h), and baseline-adjusted AUC (NetAUC; μM·h) were evaluated for total BAs. Safety was assessed by clinical laboratory tests and evaluation of adverse events (AEs). **Results:** After 6 days of BLV 10 mg QD dosing, PK exposures were similar in pts with severe HI and MCs (GLSMR [90% CI]: 1.14 [0.81, 1.61], 0.95 [0.73, 1.24], 0.95 [0.73, 1.24] for C_{max}, AUC_{24h}, and AUC_{inf}, respectively). Transient elevations in total BAs were observed on days 1 and 6 in both groups and returned to approximate predose levels within 24–48 h of dosing. After 6 days, the elevations in total BAs were higher in pts with severe HI (GLSMR [90% CI]: 1.76 [1.38, 2.25], 2.47 [1.88, 3.24], 1.44 [1.04, 2.01] for C_{max}, AUC_{24h}, and NetAUC, respectively). There were no Grade ≥3 treatment-emergent AEs (TEAEs), serious AEs, or AEs leading to BLV discontinuation. The TEAEs were mild, with no increased severity compared with the MCs. **Conclusion:** There were no differences in steady-state PK exposure or safety findings observed in pts with severe HI compared with MCs with normal hepatic function following 10 mg QD BLV dosing for 6 days. Baseline-adjusted elevations in total BAs at BLV steady-state were approximately 44% higher in pts with severe HI compared to MCs.



LLOQ was set at 1 ng/mL. PK samplings relative to BLV dose were taken on day 6 predose (≤30 minutes before dose) and at 0.5, 1, 1.5, 2, 3, 4, 6, 9, 12, 24 (day 7), and 48 (day 8) hours postdose
BLV, bulevirtide; HI, hepatic impairment; LLOQ, lower limit of quantitation; PK, pharmacokinetic; QD, once-daily.

2263 | ELEVATIONS IN TOTAL SERUM BILE ACIDS DURING BULEVIRTIDE TREATMENT ARE ASYMPTOMATIC AND NOT ASSOCIATED WITH ADVERSE EVENTS OF INTEREST IN PATIENTS WITH CHRONIC HEPATITIS DELTA

Pietro Lampertico[1] Soo Aleman[2] Tarik Asselah[3] Adrian Streinu-Cercel[4] Pavel Bogomolov[5] Viacheslav Morozov[6] Tatiana Stepanova[7] Stefan Lazar[8] Maurizia Brunetto[9] Sreenivasu Yalamanchili[10] Amos Lichtman[10] Mingyang Li[10] Renee-Claude Mercier[10] Dmitry Manuilov[10] Heiner Wedemeyer[11], [1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico and University of Milan, Milan, Italy, [2]Karolinska University Hospital/Karolinska Institutet, Stockholm, Sweden, [3]Hôpital Beaujon APHP, Université de Paris-Cité, INSERM UMR1149, Clichy, France, [4]NIID Prof Dr Matei Bals; University of Medicine and Pharmacy "Carol Davila", Bucharest, Romania, [5]M.F. Vladimirsky Moscow Regional Research and Clinical Institute, Moscow, Russian Federation, [6]LLC Medical Company Hepatolog, Samara, Russian Federation, [7]LLC Clinic of Modern Medicine, Moscow, Russian Federation, [8]Univ of Med & Pharm "Carol Davila" Bucharest; Inf & Trop Dis Hospital "Dr Victor Babes," Bucharest, [9]University Hospital of Pisa; Dept of Clinical and Experimental Medicine, University of Pisa, Pisa, I, [10]Gilead Sciences, Inc., [11]Hannover Medical School, Hannover, Germany

Background: Bulevirtide (BLV) inhibits hepatitis delta virus (HDV) entry by binding to the sodium taurocholate cotransporting polypeptide (NTCP) receptor, a bile acid (BA) transporter expressed in hepatocytes. As such, BLV treatment leads to increases in serum BAs, which are similar in mechanism to those observed with genetic NTCP deficiency without hyperbilirubinemia, pruritus, or jaundice. This analysis assessed the impact of BA level increases during BLV treatment on adverse events (AEs). **Methods:** Data from an integrated analysis of up to 96 weeks of BLV treatment in 199 patients with HDV who received BLV 2 mg (n = 49) or 10 mg (n = 150) monotherapy once daily in one Phase 2 study (MYR204; NCT03852433) and one Phase 3 study (MYR301; NCT03852719) were analyzed. AEs of interest included pruritus, skin disorders, eosinophilia, vitamin D deficiency (defined as below lower limit of normal on laboratory tests at any on-treatment visit), and cardiac disorders. On-treatment BA levels were compared between patients with and without AEs of interest. **Results:** Median (Q1, Q3) baseline BA levels were 12.2 (8.6, 17.8) and 10.1 (6.5, 16.3) μmol/L in BLV 2 and 10 mg groups, respectively. At week 96, change from baseline in median (Q1, Q3) BA levels were 3.1 (−2.8, 10.7) and 19.9 (7.3, 56.5) μmol/L, respectively. Overall, across both groups, 6% of patients maintained BA values within the normal range (ie, 0–10 μmol/L Russia site, 0–9.9 μmol/L other sites) at both the baseline and at week 96, 39% had values that increased from normal at baseline to high (ie, > 10 μmol/L Russia site, > 9.9 μmol/L other sites), 6% had values that decreased from high to normal, and 49% had values that remained high from baseline to week 96. While pruritus and eosinophilia are known effects of BLV treatment, BA levels were not related to these AEs (Figure). Alanine aminotransferase (ALT) levels did not correlate with BA levels: median (Q1, Q3) on-treatment BA levels were 36.4 (20.7, 75.4) and 31.0 (18.4, 55.5) μmol/L in visits with and without concurrent ALT increases, respectively. Total serum BA concentrations did not differ based on cirrhosis status: median (Q1, Q3) on-treatment BA levels were 31.7 (18.4, 62.9) and 31.5 (18.5, 53.5) μmol/L in patients with and without cirrhosis, respectively. **Conclusion:** Median total BA levels increased in a dose-dependent manner following BLV dosing. There was substantial on-therapy intra-patient variability in BA levels; however, no association was observed between BA levels and AEs.

2264 | DECLINING BURDEN OF ACUTE VIRAL HEPATITIS IN ADOLESCENTS AND ADULTS AGES 15-45 IN AFRICA, 1991-2021: A GLOBAL BURDEN OF DISEASE STUDY

Mohammed Youssef[1] Mohamad Elgozair[2] Lewis Roberts[3], [1]Hunt Regional Medical Center, [2]Danbury Hospital, CT, [3]Mayo Clinic Rochester

Background: Acute viral hepatitis remains a significant public health concern in Africa, particularly among younger adults. While global targets for hepatitis elimination have been set, understanding how the burden has changed within Africa is crucial to guide local responses and priorities. This study examines trends in incidence, mortality, and disability-adjusted life years (DALYs) from acute hepatitis A, B, C, and E in Africa between 1990 and 2021, with a focus on differences between males and females. **Methods:** We used data from the Global Burden of Disease (GBD) 2021 study to assess hepatitis burden among individuals aged 15–49. Trends in incidence (both total cases and rates per 100,000), deaths, and DALYs were analyzed across hepatitis types and by sex. Findings were summarized descriptively and visualized using time-series graphs. **Results:** The death rate from acute hepatitis decreased from 3.406 (95% CI 2.28-4.90) in 1991 to 1.03 (CI 0.78-1.35) in 2021. Gender specific data showed that the mortality rates in males and females in 1991 were 4.64 (CI 7.1-2.7) and 2.2 (CI 3.0-1.66) per 100,000 respectively. By 2021 the rates had decreased to 1.52 (CI 1.09-2.08) in males and 0.55 (CI 0.44-0.66) per 100,000 in females. Acute hepatitis B remained the leading cause of acute hepatitis-related mortality in adolescents between 15-49 with rates of 1.97 (CI 1.15-3.11) in 1991 and 0.73 (CI 0.5-1.01). Acute hepatitis A is the second leading cause of acute hepatitis related deaths, with rates of 0.94 (CI 0.55-0.94) per 100,000 in 1991 and 0.18 CI (0.43-0.10) in 2021. The DALY from acute viral hepatitis decreased from 195.8 (CI 133-279) in 1991 to 64.66 (CI 50.6-83.1) in 2021. The incidence rate decreased from 4164 CI (3347-5015) per 100,000 in 2023[LR1] to 3241.24 CI (2684.4-3907.5) in 2021. **Conclusion:** The burden of acute hepatitis decreased significantly over 30 years, in adolescents and adults between 15-49 in Africa. Hepatitis B remains a key contributor to mortality among young adults. Continued investment in prevention, vaccination, and gender-targeted interventions is essential to sustain these gains and achieve hepatitis elimination goals.

2265 | THE NUCLEOSIDE ANALOGUE NITD008 USED ALONE OR IN COMBINATION WITH RIBAVIRIN STRONGLY SUPPRESSES VIRAL REPLICATION IN IMMUNODEFICIENT HUMANIZED MICE STABLY INFECTED WITH THE HEPATITIS E VIRUS

Maura Dandri[1] Annika Volmari[1] Tassilo Volz[2] Florian Hinte[1] Marc Lütgehetmann[1], [1]University Medical Center Hamburg-Eppendorf, [2]University Medical Centre Hamburg-Eppendorf

Background: Hepatitis E virus (HEV) infection has an emerging clinical relevance for patients worldwide, but there is currently no approved antiviral therapy. For immunosuppressed people with chronic HEV, off-label treatment with ribavirin (RBV) is used in daily clinical practice, although it is effective in 80% of patients. Thus, there is an urgent need for effective antiviral drugs against HEV. The adenosine nucleoside analogue NIDT008 was shown to be effective in preclinical studies against a broad range of RNA viruses. The aim of this study was to evaluate the efficacy of NITD008 alone or in combination with ribavirin in HEV-infected human liver chimeric mice. **Methods:** Immunodeficient human-liver chimeric mice were infected with HEV (GT-1) via the co-housing fecal-oral route. After achieving stable viremia (median $1.5x10^7$ IU/ml HEV RNA), mice received either 20mg/Kg/day of NITD008 alone by oral gavage for up to 2 weeks, or 5mg/Kg NITD008 in combination with RBV (50mg/Kg), while other mice received mock treatment or RBV monotherapy. Viral changes were determined by qPCR in faeces and blood. Intrahepatic analyses (immunohistochemistry, RNA-ISH and qPCR) were performed at sacrifice. **Results:** NITD008 monotherapy effectively reduced fecal HEV loads (Δlog:-4log) already after 1 week of treatment. All mice had undetectable serum HEV titers (LloQ) after 7 days, while controls showed no decrease in fecal and serum titers. Intrahepatic analysis showed a Δlog:-2.5 reduction in HEV RNA levels in treated mice compared to controls after 14 days of treatment. RNA-ISH analysis confirmed the strong reduction of HEV-RNA-positive human hepatocytes in treated mice, whereas approximately 95% of human hepatocytes were positive in control animals. NITD008 administration did not induce ALT elevation. 11 days of combination therapy induced much stronger suppression of HEV RNA in faeces (Δlog:-5.02) then ribavirin monotherapy (Δlog:-1.08), despite using lower NITD008 amounts. **Conclusion:** This study demonstrates the efficacy and non-toxicity of NITD008 towards human hepatocytes in HEV infected humanized mice. NITD008 displayed more potent antiviral activity compared to ribavirin and combination regimens with ribavirin and lower NITD008 concentrations showed strong synergistic antiviral activity. The study suggests that HEV clearance may be achieved even in immunosuppressed patients by using and further developing this class of direct antiviral drugs.

2266 | SHIFTING EPIDEMIOLOGY OF HEPATITIS A AND ITS IMPACT ON UNVACCINATED ADOLESCENTS/ YOUNG ADULTS IN NORTH INDIA: A GEOSPATIAL ANALYSIS

Samagra Agarwal[1] Ayush Agarwal[1] Ginni Bharti[2] Sagnik Biswas[1] Rojaleen Das[2] Suneeta Meena[2] Baibaswata Nayak[1] . Shalimar[1], [1]Department of Gastroenterology and HNU, All India Institute of Medical Sciences, New Delhi, India, [2]Department of Laboratory Medicine, All India Institute of Medical Sciences, New Delhi, India

Background: Hepatitis A virus (HAV) may cause acute hepatitis rarely leading to acute liver failure (ALF). Most children in high endemicity zones are infected by 10 years of age, but access to improved drinking water and improved sanitation may shift epidemiology, making unvaccinated adolescents/ young adults more susceptible to HAV infection and paradoxically increasing the risk of ALF. While sero-surveys have indicated this epidemiological shift, direct clinical evidence of this change is lacking. **Methods:** In a retrospective hospital-based cohort study, we evaluated demographics of individuals with deranged liver enzymes tested for IgM HAV from January to June 2024 and assessed clinical outcomes of IgM HAV positive patients. Spatial analysis was performed for identifying HAV hotspots, and association of seropositivity with population density (kontur dataset 2023), access to clean water and sanitation (NFHS-5 database 2019-2021). Boruta algorithm was used to identify relevant features associated with seropositivity. **Results:** We identified 9996 unique individuals (median age 34 (IQR 25-50) years; 44.8% females) of whom 164 (1.64%) were IgM HAV positive; median age 13 (IQR 8-20) years. HAV positivity was concentrated in age-groups 5-10 yrs: 34/259(13.1%), 10-15 yrs: 42/283 (14.8%), 15-20 yrs (25/433; 5.8%) and 20-25 yrs (31/747; 4.2%). Elevated INR developed in 11, with ALF in 8 patients, of whom 4 succumbed to their illness, with 3 of 4 being older than 10 years. Most individuals were from Delhi and surrounding districts, with no hotspots (Figure 1) or seasonal trend. HAV infection was associated with higher population density [median 13730 (IQR: 6445 – 20451) vs 10310 (4492 – 18614) /km2; $p = 0.002$], but not with access to improved drinking water [99.8 (99.1-100)% vs 99.7 (99.1-100)%; $p = 0.32$] or improved sanitation [83.8 (76.8-84.5)% vs 79.7 (69.6-84.5)%; $p = 0.06$]. Boruta analysis identified being adolescent (age 10-25 years) and living in high population density areas as the most important factors associated with developing HAV infection. **Conclusion:** HAV hepatitis was common

beyond 10 years of age, indicating persistent susceptibility and increased risk of ALF and mortality. Adolescents living in high population-density areas were at maximum risk. Our results support the epidemiological shift of north Indian population to intermediate endemicity for HAV and highlight the need for universal HAV vaccination.

Background: Bulevirtide (BLV) monotherapy up to 144 weeks was safe and effective in patients with chronic hepatitis Delta (CHD) in the MYR-301 trial, however real-world data in patients with cirrhosis are lacking. **Methods:** Consecutive CHD patients with cirrhosis reaching week 144 (3 years) of BLV 2 mg/day monotherapy in the retrospective multicenter European study (SAVE-D) were included. Virological (HDV-RNA undetectable or $\geq$2-log decline *vs.* baseline), biochemical (ALT $<$40 U/L), combined response (biochemical + virological), adverse events and liver-related events were assessed. HDV RNA was tested locally. **Results:** Among 130 patients starting BLV monotherapy between September 2019 and April 2022, 78 patients with available data up to 144 weeks were enrolled: age 50 (IQR 40-58) years, 54% men, ALT 93 (57-145) U/L, liver stiffness measurement (LSM) 18.8 (14.1-26.8) kPa, platelets 83 (58-132) x 10^3/mm^3, 99% Child-A, 49% with varices, 6% HIV-positive, 9% with previous decompensation, 4% with active HCC, 100% on NUC. Baseline HBsAg levels and HDV-RNA were 3.8 (3.4-4.1) $\log_{10}$IU/mL and 5.2 (4.4-6.3) $\log_{10}$IU/mL, respectively. Following 144 weeks of BLV monotherapy, 69% patients achieved a virological response, 63% a biochemical response, 51% a combined response, 41% HDV RNA undetectability. 10 (13%) patients had $<$1 log HDV RNA decline *vs.* baseline, whereas 14

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(18%) achieved >1 but <2 log HDV RNA decline. 11 out of these 24 (46%) patients with a suboptimal response (< 2 Log HDV RNA decline) had ≥50% ALT decrease *vs.* baseline. During long-term BLV monotherapy, AST, GGT, IgG and AFP levels significantly declined, as well as LSM values and serological non-invasive tests of fibrosis (FIB-4, APRI score). No baseline predictors of HDV RNA undetectability at week 144 (baseline ALT, HBsAg levels HDV RNA levels, bile acids) were identified. Bile acids levels increased under BLV therapy, 19% of patients reported mild and transient pruritus, independently of bile acid levels. During 144 weeks of BLV treatment, de-novo HCC and ascites occurred in 2 and 3 patients, respectively. For 27 patients with available week 192 data (4 years), rates of virological (81%), biochemical (67%) and combined (56%) were comparable to week 144, while 33% had undetectable HDV RNA. **Conclusion:** A 3-year course of BLV monotherapy 2 mg/day is effective and safe in patients with HDV-related compensated cirrhosis also in real-world setting. Liver-related events were rare under BLV therapy.

2268 | DISEASE PROGRESSION AMONG COMMERCIALLY INSURED PATIENTS INFECTED WITH HEPATITIS DELTA VIRUS IN THE UNITED STATES

Robert Gish[1] Robert Wong[2] Chong Hoon Kim[3] Gary Leung[4] Ira Jacobson[5] Joseph Lim[6] Marvin Rock[7], [1]Robert G. Gish Consultants, LLC, San Diego, CA, USA; Hepatitis B Foundation, Doylestown, PA, USA, [2]Stanford University School of Medicine, Stanford, CA, USA, [3]HEOR—Global Value & Access, Gilead Sciences, Inc., Foster City, CA, USA;, [4]RWE—Epidemiology, Gilead Sciences, Inc., Foster City, CA, USA, [5]NYU Grossman School of Medicine, New York, NY, USA, [6]Yale University School of Medicine, New Haven, CT, USA, [7]HEOR—Global Value & Access, Gilead Sciences, Inc., Foster City, CA, USA

Background: Hepatitis delta virus (HDV) infection occurs as a coinfection with hepatitis B virus (HBV) and causes the most severe form of viral hepatitis. HDV leads to a greater risk of cirrhosis, hepatocellular carcinoma (HCC), liver transplant (LT), and mortality vs HBV monoinfection. Here, we compared the rate of disease progression by disease state in adults with HDV. **Methods:** A retrospective observational analysis of the PharMetrics database identified commercially insured patients aged ≥18 years with an HDV diagnosis within the study period (1/1/2006–5/31/2024). The index date was defined as the first HDV diagnosis claim between 1/1/2007 and 5/31/2023. Patients were required to have ≥12 months of continuous enrollment pre-index and 1 day post-index date. Disease progression from baseline (BL) to the next disease state was assessed using Kaplan-Meier curves and a multivariable Cox proportional-hazards regression model adjusting for patient characteristics. Disease states include noncirrhotic (NC), compensated cirrhosis (CC), decompensated cirrhosis (DCC), HCC, and LT. **Results:** Of the 126,380,914 patients identified within the database, 1,106 with HDV met the enrollment criteria, and 1,064 were analyzed after excluding patients with LT at BL. Overall, patients had a mean (SD) age of 48 (11.6) years. The proportions of patients within each disease state at BL were NC, 730/1,064 (69%); CC, 60/1,064 (6%); DCC, 205/1,064 (19%); HCC, 69/1,064 (6%). Compared to patients with HDV and NC disease at BL, those with BL CC demonstrated a higher rate of progression to DCC; those with BL DCC demonstrated a higher rate of progression to HCC and LT; those with BL HCC demonstrated a higher rate of progression to LT (log rank $P < .05$ for all). Further,

patients with BL HCC demonstrated a higher rate of progression to LT vs those with CC or DCC at BL (log rank $P < .05$ for both). Compared to patients with HDV and NC at BL, those with CC were at a higher risk of transitioning to DCC (hazard ratio [HR]: 1.92, 95% CI: 1.09–3.35, $P < .05$), those with DCC or HCC were at a higher risk of transitioning to LT (HR: 6.21, 95% CI: 2.09–18.45; HR: 180.67, 95% CI: 8.18–3,991.11, respectively; $P < .05$ for both). Patients with HDV and HCC at BL were also at a higher risk of transitioning to LT vs those with DCC at BL (HR: 8.27, 95% CI: 1.16–59.19, $P < .05$). **Conclusion:** These findings underscore the need for earlier identification, diagnosis, and treatment of HDV to mitigate future disease progression and associated burden of disease.

2269 | CLINICAL AND EPIDEMIOLOGICAL CHARACTERISTICS OF 92 HEPATITIS E PATIENTS

Lihua Yuan[1] Minghui Sun[1] Rui Hua[1] Yue Qi[1] Fang Xu[1] Hao Zhou[1], [1]The First Hospital of Jilin University, Changchun, China

Background: To investigate the clinical features and epidemiological characteristics of 92 sporadic Hepatitis E patients admitted to our hospital, and to compare the detection rates of Hepatitis E virus (HEV) in different specimens. **Methods:** Clinical data of 92 hospitalized Hepatitis E patients with positive anti-IgM antibodies from May 2023 to March 2025 at the First Hospital of Jilin University were collected. Hepatitis E virus nucleic acid was analyzed in blood and fecal specimens from 67 patients, and genotype testing was performed. Among them, 54 patients underwent urine antigen testing. Statistical analysis was conducted using SPSS 27.0. **Results:** Among them, there were 62 males (67%) and 30 females (33%),with 5 patients (5%) in the young group (age $\leq$40 years) and 87 patients (95%) in the middle-aged and elderly group (age $>$ 40 years). Cases were sporadic throughout the year, with a predominance in spring and winter (74%). 74 (80%) had simple infections, and 18 (20%) had overlapping infections or other liver diseases(hepatitis A, B, C, autoimmune liver diseases, etc.). Only 8 (9%) of the 92 hepatitis E patients were discharged automatically due to deterioration of condition (including 1 cases with liver cancer, 1 case with Hepatitis B cirrhosis, 1 case with Sjogren syndrome, and 3 cases with co-infections).The median hospital stay for the 74 patients with simple infections was 9 days. Patients with a hospital stay of $\geq$9 days were in Group A, and those with a hospital stay of $<$9 days were in Group B. Group A patients had lower levels of CHE, ALB, HDL-C, and PTA compared to Group B patients($P < 0.05$), while Group A patients had higher levels of TBIL, TBA, Scr, PT, and INR compared to Group B patients($P < 0.05$).Among the 67 patients, 43 (64%) were positive for blood nucleic acid,57 (85%) were positive for fecal nucleic acid, and 44 (81%) were positive for urine antigen. All patients had genotype 4 infection. **Conclusion:** Hepatitis E patients are mainly caused by genotype 4 hepatitis E virus infection, middle-aged and elderly patients, mainly in spring and winter. Co-infection with pathogens is a risk factor for disease progression and poor prognosis. Compared with blood and fecal nucleic acid detection, the positive rate of urine antigen is similar to that of fecal nucleic acid, but urine antigen detection is convenient, economical and has more diagnostic advantages.

2270 | LONAFARNIB AS FINITE TREATMENT FOR CHRONIC HEPATITIS D: LONG-TERM FOLLOW-UP DATA

Jeffrey Glenn[1], [1]Stanford University School of Medicine

Background: Hepatitis delta virus (HDV) infection leads to the most severe form of viral hepatitis. New treatment options are urgently needed. The farnesyl transferase inhibitor lonafarnib (LNF) may be an option for finite treatment as it possesses a dual mode of action: it interferes with virion assembly (Glenn et al Science 1992) and also has immunomodulatory properties (Lempp et al, Nat Commun 2019). The aim of this study was to assess if

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

finite treatment with a LNF-based regimen is able to prevent hard endpoints such as complications of liver disease and death from liver disease on long-term follow-up (LTFU). **Methods:** All patients subject to this study had received LNF-based treatment in two phase 2 (LOWR 1 and 2) and one phase 2 (LIFT) studies in Ankara (TR) and NIH (USA), respectively, and one phase 3 (DLIVR) study in Istanbul (TR). LOWR 1 and 2 studies contained 21 and 55 patients, respectively, the LIFT study 26 and the phase 3 Istanbul study contained 27 patients with a LNF-based treatment. Start date used for LTFU (median 79.5 months (0-134, n = 97) and survival analysis was EOT date of LNF-based treatment. End of follow-up (EOFU) was set to either the last date of data collection (March 2025), or the date of liver-related event, the start date of a new potential treatment against HDV or loss to follow-up. Short-term viral response (STVR) was defined as undetectable HDV RNA or a ³ 2 log decline of HDV RNA compared to baseline and biochemical response (BR) as ALT normalization at off treatment month 6. BR and VR were the co-primary endpoints. Cumulative probabilities of any event occurrence were estimated by the Kaplan-Meier method and compared with the log-rank test. Univariate and multivariate logistic regression models with forward Wald deletion were used to estimate the effect of various on- and off-treatment variables on clinical outcome. **Results:** STVR and BR was achieved in 12 patients. On LTFU none of these patients developed a clinical event in up to 10 years of follow up. Out of 85 patients without VR+BR, 17(20%) developed an event (Figure, $p < 0.05$ by the log rank test). **Conclusion:** Patients achieving a 2 log drop in HDV RNA from baseline and normal ALT at 6 months after stopping any finite lonafarnib-based treatment regimen have no major clinical events (liver decompensation, liver cancer, or death) in up to 10 years of follow-up.

2271 | LOW HEPATITIS D VIREMIA AND CIRRHOSIS BURDEN AMONG AFRICAN PATIENTS: A MULTICENTER PROSPECTIVE STUDY

Adriana Palom[1] Ariadna Rando-Segura[2] Tomás Balari[3] ROSA MARIA MORILLAS CUNILL[4] Adrià Rodríguez[5] Patricia Huelin[6] Carmen Lopez[7] Darly Salazar[8] Joana Villaverde[9] Indiana Jesús Abdo Sanmartino[10] José Castellote[3] Joan Carles Quer[5] Carles Aracil Blanch[6] Andrés Marco[10] Maria Buti[1], [1]Liver Unit, Hospital Universitari Vall d'Hebron, CIBERehd, Barcelona, Spain, [2]Microbiology Unit, Hospital Universitari Vall d'Hebron, CIBERehd, Barcelona, Spain, [3]Gastroenterology Department, Hospital Universitari de Bellvitge, Barcelona, Spain, [4]Gastroenterology Department, Hospital Universitari Germans Trias i Pujol, Badalona, Spain, [5]Gastroenterology Department, Hospital Universitari Joan XXIII, Tarragona, Spain, [6]Gastroenterology Department, Hospital Universitari Arnau de Vilanova, Lleida, Spain, [7]Gastroenterology Department, Hospital Universitari Doctor Josep Trueta, Girona, Spain, [8]Gastroenterology Department, Hospital de Tortosa Verge de la Cinta, Tortosa, Spain, [9]Gastroenterology Department, Hospital de Viladecans, Barcelona, Spain, [10]Group of infectious diseases in Prisons of Catalonia (GRUMIP), Barcelona, Spain

Background: Hepatitis D infection is a severe form of viral hepatitis, often leading to cirrhosis and liver failure. Its prevalence varies by geography and ethnicity, yet its distribution in Catalonia remains underexplored. This study examines the rate of HDV viremia across different ethnic groups in Catalonia, Spain. **Methods:** Multicenter prospective study that evaluated all anti-HDV positive patients detected in 15 months in the seven Catalan Health Institute laboratories. Demographic, epidemiological, clinical and laboratory data for all anti-HDV positive patients was recorded on a digital platform. HDV-RNA determination was centralized and quantified with an in-house RT-qPCR using the HDV-RNA WHO international standard. **Results:** From January 1, 2024, to March 31, 2025, a total of 215 anti-HDV-positive patients were identified; 128 Caucasian, 54 African, 10 Asian and 6 Hispanic. Table 1 shows the baseline characteristics from the two most prevalent groups. African patients were more often younger, had a lower percentage of cirrhosis and had more normal ALT levels and undetectable HDV-RNA. The multivariate analysis showed that older age and detectable HDV RNA were associated with a higher risk of cirrhosis while African ethnicity was strongly associated with a lower risk of cirrhosis compared to Caucasians (OR 0.12, $p < 0.001$). Moreover, among Caucasians, Eastern European patients (n = 43) had a higher proportion of detectable HDV-RNA (72% [31/43] vs. 26% [22/85], $p < 0.001$), and qHDV-RNA levels (median 5.0 (4.2–5.8) vs. 4.3 (3.8–4.8) log IU/mL ($p = 0.032$), than those from Western Europe. However, the proportion of cirrhosis was similar in Eastern and Western Europeans (18 [42%] vs 29 [34%], respectively) ($p = 0.439$). Among the 10 Asian patients, 4 (40%) were viremic and 2 (20%) had liver cirrhosis. No Hispanic patients presented detectable viremia or liver cirrhosis. **Conclusion:** African patients with HDV infection in Catalonia have a milder disease profile; characterized by lower viremia rates, lower cirrhosis prevalence, and younger age at diagnosis compared to other ethnic groups. These findings underscore the importance of considering ethnic background in the clinical assessment and management of HDV infection.

2272 | EVALUATING THE EFFICACY OF BULEVIRTIDE MONOTHERAPY IN SUPPRESSING HEPATITIS DELTA VIRUS (HDV) RNA AND ACHIEVING ALT NORMALIZATION: A SYSTEMATIC REVIEW AND META-ANALYSIS

Rohan Karkra[1] Joshua Pagán-Busigó[1] Mahinaz Mohsen[1] Michael Bebawy[1] Muhammad Hassaan Arif Maan[1] Paul Gaglio[1], [1]Rutgers New Jersey Medical School

Background: The Hepatitis D Virus (HDV), a defective virus requiring Hepatitis B surface antigen (HBsAg) to replicate, affects 10-20 million people globally. Patients with Chronic Hepatitis Delta (CHD) are at an increased risk of advanced hepatic fibrosis, cancer, and mortality, with an estimated 50,000 deaths every year. Peginterferon alpha has traditionally been used for therapy, but its effectiveness is variable. Bulevirtide, a novel antiviral drug for treating chronic Hepatitis D, was recently authorized in Europe. It blocks the Sodium Taurocholate Co-Transporting Polypeptide (NTCP) receptor on hepatocytes, preventing viral entry into liver cells. This meta-analysis will evaluate Bulevirtide monotherapy's efficacy in managing CHD. **Methods:** We conducted a comprehensive search of electronic databases – PubMed, Embase, and Cochrane to date to identify all trials and studies that investigated the efficacy of Bulevirtide, irrespective of dosing regimen, for CHD. Eligible studies were restricted to single-arm investigations reporting clinical outcomes. Three reviewers performed data extraction. Pooled proportions were calculated using a random-effects model, with heterogeneity assessed via the DerSimonian–Laird method. Doses were pooled to represent Bulevirtide as a therapeutic class. Analyses adhered to PRISMA guidelines, and the results were visually represented using forest plots. **Results:** A total of 9 studies were included, involving 390 patients. Statistical heterogeneity was insignificant ($p > 0.05$), supporting the consistency of findings across studies. The pooled proportion of patients achieving biochemical response (ALT normalization) was 54% (95% CI: 47%–62%, $p < 0.05$). The proportion of patients attaining undetectable HDV RNA was 24% (95% CI: 18%–31%, $p < 0.05$). 46% (95% CI: 32%-60%, $p < 0.05$) of patients had a sustained combined response, defined as either ≥ 2 log decrease in HDV RNA or undetectable RNA, with ALT normalization at follow-up, at least 6 months later. **Conclusion:** In this analysis, over half of the patients receiving Bulevirtide demonstrated biochemical improvement, and approximately one-quarter achieved virological suppression at the end of treatment. Close to 50% had a sustained combined response ≥ 24 weeks after treatment. Despite the absence of comparator arms, these findings suggest that Bulevirtide offers clinically meaningful benefits in chronic hepatitis D, a historically challenging disease with limited therapeutic options. Given the relatively recent introduction of Bulevirtide and the scarcity of head-to-head trials, these results underscore the drug's potential role in treatment algorithms. Larger, randomized controlled studies, including combinations with interferons, are warranted to establish its efficacy further and optimize its clinical application.

2273 | REAL-WORLD PERSISTENCY OF BULEVIRTIDE THERAPY IN CHRONIC HEPATITIS D PATIENTS IN GERMANY: A RETROSPECTIVE OBSERVATIONAL ANALYSIS

Dirk Nierhoff[1] Marianna Schwenken[2] Monika Weischenberg[2] Markus Cornberg[3] MEHTAP GUENDOGDU[2] Kyung min Kwon[4] AMANDA SINGER[4] MICHAEL MERTENS[4] Joerg Petersen[5], [1]University Hospital Cologne, [2]Gilead Sciences GmbH, [3]Hannover Medical School, [4]GILEAD SCIENCES, INC., [5]IFI Institute for Interdisciplinary Medicine Hamburg

Background: Bulevirtide (BLV) is the only approved therapy for the treatment of chronic hepatitis D (CHD) in the European Union. Administered as daily subcutaneous injections, BLV therapy should be continued as long as clinical benefit persists. Real world (RW) persistency is key to sustained outcomes. In 2020, Germany was the first country with availability of BLV for routine medical care, but RW persistency data are yet to be described. **Methods:** This retrospective, observational analysis used the German IQVIATM LRx prescription database (~80% of national statutory insurance coverage) to evaluate BLV persistency rates (PRs) in two cohorts: early (EC, 2020 – 2022 initiators, 24 months follow-up), and late (LC, 2023 initiators, 12 months follow-up). The rationale for selecting the two cohorts was based on assumed differences in clinical practice in Germany, historically prioritizing patients with higher disease burden for BLV initiation. Reasons for discontinuations were not captured. Data were stratified by demographics and comedication prescription (CP) (utilizing the Anatomical Therapeutic Chemical Classification – Level 3 (ATC3)). Persistency, defined as the probability of remaining on treatment, was estimated by Kaplan-Meier allowing therapy breaks of < 3 months. Predictors of 12-month PR were analyzed using logistic regression. **Results:** EC and LC included 219 and 87 patients, respectively. Baseline (BL) characteristics and CPs are shown in Table 1. In EC, the 12-months and 24-months PRs were 82%, and 73%, respectively. In LC, the 12-months PR was 79%. Nucleos(t)ide analogues (NUCs) were the most frequent CP at BL (66 – 68%) and during therapy (77 – 79%) in both cohorts. Pegylated Interferon alpha (Peg-IFN α) CP at BL was rare (1 – 2%) with no CP after 3 months of BLV-treatment. In pooled univariate analysis for preselected CPs at 12 months, NUCs during therapy were positively associated with persistency (OR = 7.78; 95% CI: 2.64 – 22.93; p < 0.001), while N02B analgesics /antipyretics were negatively associated (OR = 0.38; 95% CI: 0.19 – 0.79; p = 0.009). **Conclusion:** The current analysis demonstrated high real world BLV persistency, with 12-months rates of 79 – 82% and 24-months rate of 73% highlighting the sustained BLV use in clinical care. High persistency rates often serve as surrogate for overall clinical utility such as safety and effectiveness. RW associations with CPs such as NUCs were observed and require further validation.

Table 1:

		Early BLV cohort (EC)		Late BLV cohort (LC)	
Baseline (BL) characteristics	Parameter	Patients* count	Patients* share (%)	Patients* count	Patients* share (%)

2274 | EFFECT OF 48-WEEK BULEVIRTIDE THERAPY ON NON-INVASIVE MARKERS OF LIVER FIBROSIS IN PATIENTS WITH HBEAG NEGATIVE CHRONIC HEPATITIS B/D

Iliana Mani[1] Eleftheria Nasika[1] Alexandros Pelekanos[1] Vasilios Sevastianos[2] Vasilios Papadimitropoulos[1] Nikolaos Papadopoulos[1] Hariklia Kranidioti[1] Alexandra Alexopoulou[1] Ioannis Koskinas[1] Georgios Kontos[1] Melanie Deutsch[1] Emilia Hadziyannis[1] Spilios Manolakopoulos[1], [1]"Hippokration" General Hospital of Athens, [2]"Evangelismos" General Hospital of Athens

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Treatment with Bulevirtide (BLV) in chronic hepatitis B/D (CHB/D) results in biochemical (BR), virologic (VR) or combined response in a significant proportion of patients. However, there is limited knowledge regarding changes in non-invasive fibrosis tests (NITs) during treatment. Our aim was to explore the changes in NITs after 48 weeks of 2mg daily BLV. **Methods:** We included patients with CHB/D who completed 48 weeks of BLV and had available liver stiffness values (LS) measured by transient elastography at the beginning of treatment (T0) and 48 (± 8) weeks later (T1). The AST to Platelet Ratio Index (APRI) and Fibrosis-4 (FIB-4) scores were also calculated. Cirrhosis was diagnosed based on clinical or imaging findings or LS >10.0 kPa. BR and VR were defined as ALT ≤ 40 IU/l and a reduction of HDV-RNA by 2 $\log_{10}$, respectively. **Results:** Of 31 patients followed at our Unit, 19 patients [36.8% males, median age 53 (41-63 years] fulfilled the inclusion criteria and were included in the analysis. After 48 weeks of BLV, 47.4% had BR and 78.9% VR. The LS at T0 was 11.9 (8.0-18.2) vs 8.4 (6.5-12.3) kPa ($p<0.001$) at T1. Seventy-five percent of patients showed a reduction in LS, while for 8/19 the reduction was >2 kPa. At T0, LS was >10 kPa in 13/19 patients (68.4%) compared to 7/19 (36.8%) at T1 ($p=0.024$). The reduction in LS was greater for cirrhotics compared to non-cirrhotics {-6.5 [-9.8-(-0.4)] vs -0.35 (-1.4-0.5) kPa, $p=0.103$}. LS was non-significantly greater among patients who did or did not achieve VR {-5.8 [-9.7-(-0.8)] vs -0.2 [-0.5-(-0.2)] kPa, $p=0.333$] and those with or without BR {-5.8 (-9.7-0.25) vs -1.9 (-8.4-0.1) kPa, $p=0.394$]. The APRI showed a non-statistically significant decrease between T0 and T1 in the total population [1.29 (0.62-2.04) vs 0.62 (0.56-1.03), $p=0.155$]. However the change was statistically significant greater between those with and without BR {-0.99 [-4.31 - (-0.45) vs 0.14 (-0.38-0.59), $p=0.004$}, while it did not differ when based on VR ($p=0.230$). A non-statistically significant decrease was also observed for FIB-4. Changes in FIB-4 followed similar trends to those of APRI. No correlation was observed between the changes in LS and those of APRI ($r=-0.079$, $p=0.829$) or between LS and FIB-4 ($r=0.006$, $p=0.98$). However, changes in APRI and FIB-4 showed a strong correlation ($r=0.937$, $p<0.001$). **Conclusion:** Treatment with BLV for 48 weeks is associated with a reduction in the NIT's particularly in LS values by transient elastography. Changes in NIT's based on serology (APRI and FIB-4) are clearly related to the biochemical response; therefore the profile of biochemistry during treatment should be taken into account when evaluating progression / regression of liver disease with APRI or FIB-4.

2275 | SPECTRUM AND OUTCOMES OF HEPATITIS A VIRUS-ASSOCIATED ACUTE LIVER FAILURE: INSIGHTS INTO EXTRAHEPATIC MANIFESTATIONS AND ROLE OF EXTRACORPOREAL THERAPIES

Ayush Jain[1] Rakhi Maiwall[2] Chhagan Bihari[1] EkTA Gupta[3] Meenu Bajpai[2] Shiv Kumar Sarin[1], [1]ILBS, New Delhi, [2]Institute of Liver and Biliary Sciences, [3]ILBS New Delhi

Background: Hepatitis A virus (HAV) remains a leading cause of acute liver failure (ALF) in developing countries. While hepatic dysfunction is well recognized, the spectrum of extrahepatic manifestations is increasingly appreciated. This study aimed to characterize the clinical profiles, extrahepatic involvement, and outcomes of patients with HAV-related ALF, with a focus on the impact of extracorporeal therapies. **Methods:** A retrospective analysis was conducted on patients with HAV-associated ALF and cerebral edema admitted to the Institute of Liver and Biliary Sciences (ILBS), New Delhi, between April 2022 and April 2024. Patients were stratified into two groups: Group 1 (liver-dominant), fulfilling King's College Hospital (KCH) criteria for liver transplantation, and Group 2 (non–liver-dominant), not meeting KCH criteria but with significant extrahepatic organ involvement. Clinical, biochemical, and outcome variables were compared. **Results:** Of 82 ALF cases, 56 (68.3%) were attributed to HAV (mean age: 23.6 years; 64% male). Among these, 12 (21.8%) were liver-dominant (Group 1) and 44 (78.2%) were non–liver-dominant (Group 2). Group 1 had higher INR (4.48 $\pm$ 2.34 vs. 2.52 $\pm$ 1.07; $p=0.014$), while Group 2 had higher SOFA scores (8.25 $\pm$ 1.67 vs. 7.08 $\pm$ 1.62; $p=0.031$) and CRP levels (38.5 ± 19.2 vs 67.8 ± 42.4; $p=0.02$). Therapeutic plasma exchange (TPE) was performed in 66% (Group 1) and 65% (Group 2); continuous renal replacement therapy (CRRT) was required in 83% and 56%, respectively. Extrahepatic manifestations included renal dysfunction (42%), pulmonary involvement (39%), hemolysis (5.6%), cardiac injury (7.5%), pancreatitis (7.5%), non-edema-related neurological symptoms (7.4%), and hemophagocytic lymphohistiocytosis (HLH) in 16%. Group 2 had

higher mean and peak serum creatinine levels (1.92 ± 0.07 vs. 1.1 ± 0.8 mg/dL; 9.7 vs. 3.9 mg/dL; $p < 0.001$) and greater incidence of glomerulonephritis (58% vs. 33%; $p = 0.06$) and extrapulmonary ARDS (25% vs. 77%; $p = 0.03$). Despite greater extrahepatic involvement, Group 2 had better 28-day survival (84% vs. 41%; $p = 0.002$) and longer hospital stays (16.6 ± 14.3 vs. 12.2 ± 19.5 days; $p = 0.054$). Liver transplantation was performed more frequently in Group 1 (25% vs. 2.2%; $p = 0.028$). **Conclusion:** HAV-associated ALF exhibits a wide array of extrahepatic manifestations. Patients with non–liver-dominant HAV-related illness, despite greater multi-organ involvement, demonstrated better survival outcomes and favourable responses to extracorporeal therapies

2276 | A NEW NON-INVASIVE DIAGNOSTIC APPROACH: RESEARCH ON THE DIAGNOSTIC VALUE OF URINE HEV RNA/ ANTIGEN DETECTION IN HEPATITIS E

Haiying Zhang[1] Yuyuan Jia[2] Huiying Rao[2], [1]Peking University People's Hospital, [2]Peking University People's Hospital

Background: Hepatitis E virus (HEV) is the main cause of acute and chronic viral hepatitis. Hepatitis E virus (HEV) is known to be excreted through feces, but there is little research on its presence in urine. This study investigated the presence and dynamic changes of antigens (HEV Ag) in urine. **Methods:** Virus markers were detected in the urine and serum of acute and chronic HEV patients to evaluate the diagnostic utility of HEV Ag in predicting HEV infection outcomes. **Results:** HEV RNA and HEV Ag were continuously detected in the blood of 4 patients with chronic HEV infection, and HEV Ag was continuously detected in the urine. The dynamic change of HEV Ag in blood was consistent with the dynamic change of HEV RNA in blood. Among 41 patients with acute HEV, 97.56% (40/41) had HEV Ag detected in their urine, and the specificity of HEV Ag in urine was 100%. Among 63 patients with acute HEV, 93.65% (59/63) had HEV Ag detected in their serum, although 2 cases were negative for anti-HEV IgM. We also identified 24 patients with hepatitis E complicated with hematological diseases. Among them, 13 patients underwent bone marrow transplantation, including 8 patients who underwent haploid hematopoietic stem cell transplantation and 5 patients who underwent fully compatible bone marrow hematopoietic stem cell transplantation. All 24 patients had positive HEV RNA. 87.5% of the patients had positive serum HEV Ag. Only 19 patients had urine samples, and 100% of the patients had positive urine HEV Ag. **Conclusion:** Detecting HEV Ag in urine may have important value in diagnosing acute and chronic HEV infections and monitoring persistent infections.

2277 | THE IMPORTANCE OF INTERFERON AND WNT-RELATED SIGNALING PATHWAYS IN ACUTE HEPATITIS A: INSIGHTS FROM A MOUSE XENOGRAFT MODEL

Reina Sasaki-Tanaka[1] Tatsuo Kanda[2] Ryota Masuzaki[3] Hiroyuki Abe[1] Masaru Kumagai[1] Tomoaki Yoshida[1] naruhiro kimura[1] Takeshi Yokoo[1] Akira Sakamaki[1] Hiroteru Kamimura[1] Kenya Kamimura[4] Hiroaki Okamoto[5] Shuji Terai[1], [1]Division of Gastroenterology and Hepatology, Graduate School of Medical and Dental Sciences, Niigata, [2]Uonuma Institute of Community Medicine, Niigata University Medical and Dental Hospital, [3]NIhon University School of Medicine, [4]Department of General Medicine, Graduate School of Medical and Dental Sciences, Niigata University, [5]Department of Infection and Immunity, Jichi Medical University School of Medicine, Shimotsuke

Background: Hepatitis A outbreak was declared in Los Angeles County last year, and the case counts continued to climb throughout the early part of this year. However, no potent anti-HAV drugs are currently available in clinical use, and there are no easily accessible or practical *in vivo* models for HAV drug screening, especially HAV genotype (GT)-III. In this study, we established a HAV GT-IIIA *in vivo* model using BALB/cAJcl-nu/nu (nude) xenograft mice and treated with several medicines. Moreover, we investigated how HAV induces gut microbiota dysbiosis, which may contribute to its survival. **Methods:** 1) Human hepatoma cells were infected with HAV, then transplanted as xenografts into the back of nude mice, which were subsequently treated with mouse IFN. 2) HAV-RNA were measured by real-time RT-PCR in liver tissues, intestinal tissues, feces, sera and xenografts of the mice. 3) Tissues samples were evaluated by hematoxylin and eosin staining. 4) Serum aminotransferase protein levels were quantified by ELISA. 5) HAV-RNA in the infected mouse liver was investigated by *in situ* hybridization. 6) RNA-Seq was performed to identify transcripts specifically associated with HAV infection. 7) Proteomic analysis was performed to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

identify the proteome profile of the conditioned medium from HAV infected hepatocytes. 8) The composition of the gut microbiota was determined by sequencing the V3-V4 region of the 16S rRNA gene. **Results:** 1) There was no difference in body weight between HAV infected and uninfected mice. 2) HAV-RNA levels were detected in liver tissues, intestinal tissues, feces, sera, and xenografts. HAV-RNA levels tend to be inhibited in IFN treated xenograft mice. Hepatic necroinflammation was observed in the liver with a slight elevation of serum aminotransferase levels in HAV infected xenograft mice and serum aminotransferase levels were significantly inhibited in IFN treated xenograft mice. 3) RNA sequencing and proteome analysis showed that HAV infection altered Wnt-related signaling pathways. 4) Gut microecological dysregulation was observed in HAV infected xenograft mice. **Conclusion:** We have established and utilized an *in vivo* HAV GT-IIIA model for anti-HAV drugs screening. In this model, inflammation was observed histopathologically in the liver tissues and intestinal tissues where HAV-RNA was detected, and IFN treatment tends to inhibit quantitative HAV-RNA levels. The Wnt-related signaling pathways altered by HAV infection may contribute to gut microecological dysregulation in HAV infected xenograft mice.

2278 | PATIENT-REPORTED BURDEN AND HEALTH-RELATED QUALITY OF LIFE AMONG PATIENTS WITH HEPATITIS DELTA: RESULTS: FROM A REAL-WORLD STUDY IN EUROPE

Pietro Lampertico[1] Fritha Hennessy[2] Tia Pennant[2] Daniel Graham[2] Fraser Barrable[2] Caroline Burk[3] Chong Hoon Kim[3] Marvin Rock[3] Maria Buti[4], [1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico and University of Milan, Milan, Italy, [2]Adelphi Real World, Bollington, UK, [3]HEOR—Global Value & Access, Gilead Sciences, Inc., Foster City, CA, USA, [4]Hospital Universitario Vall d'Hebron, Barcelona; CIBEREHD del Instituto Carlos III, Madrid, Spain

Background: Evidence surrounding the impact of bulevirtide (BLV) on health-related quality of life (HRQoL) among patients with hepatitis delta virus (HDV) infection is limited. We aimed to describe the demographics and HRQoL outcomes of patients with HDV infection in a real-world setting who were treatment naïve or prescribed BLV. **Methods:** Data were drawn from the Adelphi Real World Hepatitis Disease Specific Programme™, a cross-sectional survey with retrospective data collection of physicians and their patients with HDV in France, Italy, Spain, and the UK from June 2024 to December 2024. Physicians consulting 4 patients with HDV diagnosis for routine care collected physician-reported patient demographics and patients' HRQoL impact via patient-reported outcome measures (PROMs). Each physician reported on 2 patients who were prescribed BLV and 2 patients with or without a prescribed treatment. Descriptive analyses focused on patients who received BLV monotherapy for ≥6 months (BLV mono ≥6 m) and treatment-naïve patients. Patients prescribed interferon monotherapy or combination therapy were excluded from the analysis. **Results:** Overall, 34 physicians (France, 10; Italy, 7; Spain, 12; UK, 5) reported data on 102 patients (France, 24; Italy, 20; Spain, 28; UK, 30). Mean (SD) patient age was 45 (15.3) years; 68% were male, and 73% were White. Mean (SD) time since HDV diagnosis was 4 (7.4) years. Half (n = 51) of patients were prescribed BLV monotherapy and 41% were treatment naïve (n = 42). Of the 51 patients prescribed BLV monotherapy, 37 (73%) were BLV mono ≥6 m patients. Mean (SD) Fatigue Severity Scale, 7-item (1–7 scale; higher scores indicate more fatigue) scores were 3.7 (1.75) and 3.9 (1.39) for BLV mono ≥6 m and treatment-naïve patients, respectively (Table). Mean (SD) Hepatitis B Quality of Life (HBQoL; 0–100 scale; higher scores indicate worse HRQoL) overall and HBQoL viral response scores were 36 (18.7) and 34 (18.4), respectively, for BLV mono ≥6 m patients and 45 (14.1) and 48 (19.0) for treatment-naïve patients. Mean (SD) EuroQoL 5-Dimension 5-Level (EQ-5D-5L; 0–1 scale; 1 represents the best health) and EQ-5D Visual Analog Scale (0–100 scale; 100 represents the best health) scores for BLV mono ≥6 m patients were 0.7 (0.26) and 66 (21.7), respectively, and 0.8 (0.18) and 73 (14.3) for treatment-naïve patients. **Conclusion:** Disease- and symptom-specific PROMs show that patients prescribed BLV monotherapy for ≥6 months have better HRQoL outcomes compared with patients not on HDV treatment. General measures of HRQoL, which may be less sensitive, show minimal differences between the groups.

Table. Patient-Reported HRQoL Among Patients With HDV Receiving BLV vs Treatment-Naïve Patients

HRQoL Measure	BLV Monotherapy ≥6 Months (n = 37)	Treatment-Naive (n = 42)
Disease- and symptom-specific PROMs		
FSS-7[a]	3.7 (1.75)	3.9 (1.39)
HBQoL[b] measures		
Overall	36 (18.7)	45 (14.1)
Viral response	34 (18.4)	48 (19.0)
Transmission	38 (24.0)	50 (21.0)
Psychological well-being	35 (21.0)	39 (18.0)
Anticipation anxiety	46 (25.7)	54 (17.2)
Vitality	35 (19.7)	39 (15.7)
Stigmatization	29 (22.2)	39 (18.7)
Vulnerability	34 (20.9)	46 (19.5)
General measures of HRQoL		
EQ-5D-5L[c]	0.7 (0.26)	0.8 (0.18)
EQ-5D VAS[d]	66 (21.7)	73 (14.3)

Values in table represent mean (SD). The *n* values indicate the overall group size; not all HRQoL measures include all patients.
[a]FSS-7 scale: 1-7, where higher scores indicate more fatigue. [b]HBQoL scale: 0-100, where 0 represents the best possible HRQoL. [c]EQ-5D-5L scale: 0-1, where 1 represents the best health the patient can imagine. [d]EQ-5D VAS scale: 0-100, where 100 represents the best health the patient can imagine.
BLV, bulevirtide; EQ-5D-5L, EuroQoL 5-Dimension 5-Level; EQ-5D VAS, EuroQoL 5-Dimension Visual Analog Scale; FSS-7, Fatigue Severity Scale, 7-item; HBQoL, Hepatitis B Quality of Life; HDV, hepatitis delta virus; HRQoL, health-related quality of life; PROM, patient-reported outcome measure.

Background: Hepatitis delta virus (HDV) displays wide genetic variability, with eight known genotypes differing in geographic distribution and clinical relevance. Understanding circulating genotypes is essential for improving diagnosis, anticipating disease progression, and optimizing treatment strategies. This study analyzes the genotype distribution of HDV in Spain using whole-genome sequencing (WGS) in patients with active infection. **Methods:** A retrospective observational study was conducted from August 2019 to June 2024 in Andalusia, Murcia, and the Canary Islands, including HDV RNA-positive patients. Following the launch of the national Delta Double Reflex (DDR) project, additional samples from other Spanish regions were incorporated. WGS was performed using overlapping primers and Illumina NextSeq 1000 technology. Genotypes were assigned by alignment with HDVdb references. Phylogenetic analysis, including only sequences with $>90\%$ coverage, was performed using the Neighbor-Joining method (MEGA software). Recombination was evaluated with RDP5.63. **Results:** A total of 151 patients were included; 52.3% were of Spanish origin. Median HDV RNA level was 4.9 log IU/mL (IQR: 3.9–6). Genotyping was successful in 144 cases (95.4%), with mean genome coverage of 98% (range 70–100%). Genotype 1 (G1) predominated (88.2%), mostly among Spanish-born patients. Genotype 5 (G5) was found in 15 cases (10.4%), exclusively in individuals from West Africa. One case (0.7%) of genotype 7 (G7) was identified in a patient from Equatorial Guinea, and one case (0.7%) of genotype 3 (G3) in a patient from Bolivia. Seven samples could not be genotyped due to low amplification or insufficient coverage. Phylogenetic analysis (140 sequences) showed that subgenotype 1d was identified in 86.6% of G1 cases, and subgenotype 5b in 64.3% of G5 cases. No recombination events were detected. **Conclusion:** Genotype 1 is the predominant HDV strain in Spain, particularly among native patients, while genotype 5 is restricted to individuals from West Africa. This study contributes to understanding the molecular epidemiology of HDV in Spain and supports the relevance of genotyping in HDV management and surveillance.

◆ 2280 | PREDICTING PORTAL HYPERTENSION SEVERITY USING THREE-DIMENSIONAL MR ELASTOGRAPHY-BASED MACHINE LEARNING MODEL IN PATIENTS WITH ADVANCED CHRONIC LIVER DISEASE

Ling Yang[1] Xiaolong Qi[1] Zhiying Wang[2] Chunli Li[2] He Zhu[3] Meng Yin[4] Chuan Liu[1] Wei Wang[3] Yan Wang[3] Xing Liu[3] Jie Chen[5] Dawei Yang[6] Bo Wei[5] Meng Niu[2] Bin Song[5] Zhenghan Yang[6] Hui Xu[6] Xinjun Han[6] Lixue Xu[6] Jingjing Liu[7] Yong Zhang[7] Jingliang Cheng[7] Michael Pavlides[8] Shenghong Ju[1] Qijun Wu[2] Yang Hou[2] Yu Shi[2], *[1]Zhongda Hospital, Southeast University, [2]Shengjing Hospital of China Medical University, [3]The Sixth People's Hospital of Shenyang, [4]Mayo Clinic, 200 First St SW, [5]Sichuan University West China Hospital, [6]Beijing Friendship Hospital, Capital Medical University, [7]The First Affiliated Hospital of Zhengzhou University, [8]Oxford NIHR Biomedical Research Centre, University of Oxford*

Background: Hepatic venous pressure gradient (HVPG) is the gold standard for assessing portal hypertension (PH) severity but is limited by its invasive nature. This study developed and validated machine learning models (MLMs) integrating three-dimensional magnetic resonance elastography (3D-MRE) and laboratory parameters to establish a noninvasive PH risk stratification system for patients with advanced chronic liver disease (ACLD). **Methods:** The multicenter study enrolled patients with ACLD undergoing HVPG measurements and dual-frequency (30Hz/60Hz) 3D-MRE with dual drivers (spleen/liver) from six independent institutions between 2022 and 2024. Viscoelastic parameters were extracted from 3D-MRE data, with MLMs trained and validated in a 7:3 cohort split based on viscoelastic and laboratory parameters. External validation included a prospective cohort (n = 85, 2015-2019 HVPG measurements) and a retrospective cohort (n = 631, 2012-2024 3D-MRE and endoscopy data). **Results:** The primary cohort (n = 172) showed comparable HVPG between training (n = 120, median 9.5 mmHg) and validation (n = 52, median 8 mmHg) sets. Two optimized MLMs emerged: the MRE model (splenic shear stiffness at 60Hz, liver shear stiffness at 60Hz, and splenic damping ratio at 30Hz) and MRE-combined clinical model (MRE-ig) (adding international normalized ratio [INR] and gamma-glutamyl transferase). Both showed exceptional performance for clinically significant PH (CSPH, i.e., HVPG ≥ 10mmHg: train-AUC: 0.990/0.990, validation-AUC: 0.957/0.961, HVPG ≥ 12

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

mmHg: train-AUC 0.978/0.982, validation-AUC: 0.961/0.967, HVPG ≥ 16mmHg: train-AUC: 0.949/0.964, validation-AUC: 0.937/0.942, and HVPG ≥ 20mmHg: train-AUC: 0.924/0.939, validation-AUC: 0.931/0.931), significantly outperforming transient elastography (AUC 0.792-0.840) and serum-based models, such as the 3P (platelet count, bilirubin, INR) or 3P+LSM models (AUC: 0.742~0.872) (mostly $p < 0.001$). Prospective validation confirmed robust performance (CSPH: 0.912/0.924, PH12: 0.864/0.887, PH16: 0.830/0.842, PH20: 0.821/0.826), significantly outperforming serum-based 3P models (CSPH: 0.805, PH16: 0.561, all $p < 0.001$), while retrospective analysis revealed strong correlation with the six-stage PH severity classification ($r = 0.732/0.756$, both $p < 0.0001$). Notably, in 341 non-cirrhotic/compensated cirrhosis patients, both models effectively identified patients who needed screening esophageal varices (VNT, AUC 0.858/0.864, both $p < 0.001$) (Figure 1). **Conclusion:** 3D-MRE-based MLMs offer a practical alternative to invasive HVPG measurements, enabling improved risk stratification and clinical decision-making for patients with advanced chronic liver disease.

◆ 2281 | A PROSPECTIVE RANDOMIZED CONTROLLED, OPEN LABELED, TWO ARM PILOT STUDY WITH BLINDED ENDPOINTS TO EVALUATE THE EFFICACY OF TORSEMIDE-SPIRONOLACTONE VERSUS FUROSEMIDE-SPIRONOLACTONE COMBINATION IN CIRRHOSIS PATIENTS WITH NEWLY DIAGNOSED ASCITES

Arun Valsan[1] Arathi Venu[1] Nipun Verma[2] Marva Abdul Khader[3] Shreya Haridas[3] Ruby Renji[3] Bonny Thankachan[3] Gowri Priya Nair[1] Zubair Mohamed[1] Sudhindran Surendran[1] Priya Nair[1] Anoop K Koshy[1] Nimitha Mohan[4] Yashowardhan Taparia[1] Dr George Eapen Puthusseril[1] Ajay Nathan[5] Ajay Duseja[6], [1]Amrita Institute of Medical Sciences, Kochi, [2]Postgraduate Institute of Medical Education and Research, Chandigarh, [3]Amrita School of Pharmacy, [4]Aster Medcity, Kochi, [5]INHS Sanjivani, [6]Postgraduate Institute of Medical Education & Research

Background: Ascites is the most common complication of liver cirrhosis, often associated with poor prognosis and reduced survival. In addition to salt restriction, diuretics such as furosemide and torsemide in combination with spironolactone are widely used to manage ascites in cirrhotic patients. However, comparative evidence on their efficacy in controlling ascites and safety remains limited. **Methods:** We conducted a prospective, open label, randomized trial with blinded endpoints assessment at a tertiary-care center between May 2024 and Apr 2025. Adult patients (> 18years) with cirrhosis and newly diagnosed ascites without SBP, poorly controlled diabetes, pregnancy or SIADH, were randomized to receive either Furosemide-Spironolactone (FS) or Torsemide-Spironolactone (TS). The patients were followed-up for a period of 28 days or until death or liver transplantation whichever occurred first. Laboratory investigations were done on days 0, 4 and weekly till day 28. Body weight and abdominal girth were recorded every 4 days as surrogate for ascites control. Dose modification was done based on the degree of ascites control as per the treating physician. The primary end point was to assess the efficacy of treatment in controlling ascites and secondary endpoints were treatment emergent adverse effects and survival.Mixed-effects model was used to compare parameters over time between the groups. **Results:** A total of 103 patients (FS-49,TS-54) were enrolled, with a mean age of 52 ± 9.2 years. The cohort was predominantly male (90%) with alcohol being the most common underlying etiology (54%). Both groups demonstrated a significant reduction in abdominal girth over time ($p < 0.001$), without significant group-time differences ($p = 0.999$). There was significant weight reduction

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

within each group ($p < 0.001$), without a significant interaction between group and time ($p = 0.843$). Dose escalation was required in 17.47% (18.36% vs 16.6%), while de-escalation was implemented in 43.68% (36% vs 50%) due to effective ascites control. The occurrence of muscle cramps (24.5% vs 20.3%, $p = 0.79$), hyponatremia (55.1% vs 53.7%, $p = 1.00$), hypokalemia (10.2% vs 11.1%, $p = 1.00$), hypomagnesemia (16.3% vs 20.3%, $p = 0.78$), incidence of AKI (22.4% vs 22.2%, $p = 1.00$) were similar in both groups. Liver transplantation was done in 2.04% patients in FS and 7.4% patients in TS group. There was no statistically significant difference in survival between the two groups, with a HR of 0.89 ($p = 0.87$). **Conclusion:** Both the FS and TS combinations were equally effective in achieving ascites control, with significant reductions in abdominal girth and mean body weight. No significant differences were observed between the groups in terms of efficacy, safety or survival. The findings suggest that both the regimens are equally effective and well tolerated for the management of new onset ascites.

◆ 2282 | POCUS-GUIDED FLUID RESUSCITATION COMPARING PLASMALYTE PLUS 20% ALBUMIN VS 5% ALBUMIN IN CIRRHOSIS WITH SEPSIS-INDUCED HYPOTENSION: A RANDOMIZED CONTROLLED TRIAL (ALPS PLUS)

Ayush Jain[1] Rakhi Maiwall[2] Harsh Vardhan Tevethia[3] Omkar Rudra[3] Prashant Agarwal[3] Chhagan Bihari[3] Guresh Kumar[3] Mradul Daga[1] Shiv Kumar Sarin[1], [1]ILBS, New Delhi, [2]Institute of Liver and Biliary Sciences, [3]ILBS New Delhi

Background: In critically ill cirrhosis patients (CIC) with sepsis-induced hypotension (SIH), 5% albumin, plasmalyte and 20% albumin have been evaluated for fluid resuscitation. Point-of-care ultrasound (POCUS) can guide fluid resuscitation and reduce the incidence of pulmonary complications. However, no study has evaluated 5%Albumin (5%Alb) versus plasmalyte combined with slow infusion of 20% albumin (P+Alb20) using a POCUS -guided fluid resuscitation strategy. **Methods:** CIC patients with SIH were randomized in a 1:1 open-label design to receive either 5%Alb (5 ml/kg bolus over 30 minutes, followed by 50 ml/hr) or PlasmaLyte (30 ml/kg bolus over 30 minutes, followed by 100 ml/hr) along with 20–40 g of 20% albumin. Subsequent fluid management was guided by hourly POCUS (including IVC variablility and lung USG) assessment for 3 hours. The primary outcome was achievement of a mean arterial pressure (MAP) > 65 mmHg without vasopressor support at 3 hours. **Results:** Baseline characteristics including MAP(mm of Hg) (58.55 ± 4.16 vs 59.48 ± 2.90; $p = 0.157$), arterial lactate(mmol/L) (2.37 ± 1.63 vs 2.58 ± 1.68; $p = 0.502$), SOFA score (9.00 ± 2.35 vs 8.87 ± 2.54; $p = 0.766$), MELD score (28.28 ± 9.98 vs 29.25 ± 9.54; $p = 0.589$), IVC diameter(mm) (14.61 ± 3.63 vs 15.14 ± 4.36; $p = 0.484$), and initial POCUS findings (all A pattern) were comparable between groups. Shock reversal rates at 3 hours (43.3% vs 54.2%; $p = 0.234$) and 24 hours (55.9% vs 67.9%; $p = 0.193$) were similar across both arms. Fluid volume(ml) administered by 3 hours was significantly greater in the P+Alb20 group (600.83 ± 242.77 vs 2202.54 ± 658.52; $p < 0.001$), whereas daily albumin dose was higher in the 5%Alb group (67.01 ± 20.03 vs 34.44 ± 9.64; $p < 0.001$). POCUS identified a higher incidence of B-lines at 3 hours in the 5% Alb group compared to the P+Alb20 group (28.3% vs 10%, $p = 0.01$). However, by 24 hours, the proportion of patients with B-lines was comparable between the groups (20% vs 15%, $p = 0.487$), and the

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

change in IVC measurements over time was similar in both groups. Time to norepinephrine initiation (in hours) (3.45 ± 4.47 vs 3.37 ± 3.50; $p = 0.960$) and cumulative dose of norepinephrine equivalents (1.83 ± 1.93 vs 1.30 ± 1.90; $p = 0.135$), changes in arterial lactate ($p = 0.336$), and requirement for renal replacement therapy (51.7% vs 47.5%; $p = 0.646$) were comparable. At 28 days, mortality (50% vs 43.3%; $p = 0.619$), incidence of hyperchloremic metabolic acidosis (23.3% vs 15.3%; $p = 0.26$), hypernatremia (10% vs 8.5%; $p = 0.774$), and respiratory distress (10% vs 11.6%; $p = 0.976$) were similar between groups. **Conclusion:** Plasmalyte combined with low-dose 20% albumin, guided by dynamic POCUS assessment, is as effective as 5% albumin for fluid resuscitation in cirrhosis with SIH. The POCUS allows tailored resuscitation and may lower the risk of pulmonary complications, highlighting its utility in critical care hepatology.

◆ 2283 | SPLEEN STIFFNESS MEASUREMENT RELIABLY ASSESSES THE RESPONSE TO β-BLOCKER THERAPY (SPARE-B) FOR PRIMARY PROPHYLAXIS OF HIGH-RISK VARICES

Omkar Rudra[1] Jaifrin Daniel[1] Ayush Jain[1] SAURAV PAUL[1] Babu Lal Meena[1] VINOD ARORA[1] Akhil Deshmukh[1] Sherin Thomas[1] GURESH KUMAR[1] Manoj Sharma[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences

Background: HVPG is the gold standard for measurement of the presence and severity of portal hypertension. Clinically Significant Portal Hypertension (CSPH) is defined as HVPG $\geq$ 10 mmHg. Use of non-selective beta blockers (NSBB) has been associated with a positive effect on survival. Response to NSBB therapy is defined as a reduction of HVPG by 10% or to $\leq$ 12 mmHg. Non-invasive tests (NIT) to predict CSPH have been defined, but not assessed for predicting response to NSBB for primary prophylaxis. **Methods:** Patients $>$ 18 years of age with cirrhosis and small or large high-risk esophageal varices and no prior variceal bleed were enrolled. After a thorough assessment, carvedilol was initiated and titrated to the maximum tolerated dose within 7 days. Fibroscan, NIT and HVPG were performed at baseline and repeated after 4 weeks of maximum tolerated dose. NITs were evaluated to predict change in HVPG. **Results:** 130 patients were enrolled. 14 patients were lost to follow-up. 5 patients had a variceal bleed and 4 patients expired prior to follow-up. 107 patients analysed. 74 (69%) patients were HVPG responders and 33 (31%) were non-responders. HVPG at baseline was 17.5 ± 2.6 mmHg in non-responders and 16.8 ± 3.3 mmHg in responders ($p = 0.289$). MELD was comparable between the groups ($p = 0.990$). Mean dose of carvedilol was 18.5 ± 7.4 mg/day in non-responders and 20.2 ± 6.6 mg/day in responders ($p = 0.263$). Target heart rate achieved in 9 (27%) non-responders versus 19 (25%) responders ($p = 0.862$). At 5 weeks, HVPG was 16.7 ± 2.6 mmHg in non-responders and 13.6 ± 2.7 mmHg in responders ($p < 0.001$). SSM reduced by 18.8 ± 13.6 kPa in responders but had increased by 0.6 ± 10.9 kPa in non-responders. Reduction of SSM by $\geq$ 6kPa predicted HVPG response to carvedilol with 85% sensitivity, 84.8% specificity (AUROC 0.913). Reduction in LSM by $\geq$ 2kPa predicted HVPG response with 63% sensitivity and specificity and 68% accuracy. von-Willebrand factor (vWF) and vWF/ADAMTS ratio had an AUROC of 0.664 and 0.653 ($p = 0.007$ and 0.014 respectively). **Conclusion:** Change in SSM at 5 weeks can predict HVPG responders to carvedilol with good accuracy. A reduction of $\geq$6 kPa in SSM reliably reflects response to carvedilol and is a good alternative to repeat HVPG measurement for the primary prophylaxis of high-risk varices. [Trial Registration - NCT06050837]

◆ 2284 | PROTON PUMP INHIBITOR TO PREVENT RECURRENT BLEEDING EPISODES AND MORTALITY AFTER ENDOSCOPIC VARICEAL LIGATION FOR ACUTE VARICEAL BLEEDING IN PATIENTS OF LIVER CIRRHOSIS: A RANDOMIZED CONTROLLED TRIAL

ABHISHEK YADAV[1] HARSHAL S MANDAVDHARE[1] VISHAL SHARMA[1] JIMIL SHAH[1] ATUL SAROCH[2] VANEET JEARTH[1] JAYANTA SAMANTA[1] ANUPAM SINGH[1] SAROJ SINHA[1], [1]Department of Gastroenterology, Postgraduate Institute of Medical Education & Research, Chandigarh, [2]Department of Internal Medicine, Postgraduate Institute of Medical Education & Research, Chandigarh

Background: Acute variceal bleeding is a life-threatening decompensating event in the natural history of cirrhosis. Endoscopic variceal ligation (EVL) along with non-selective beta blockers or carvedilol are current standard of care for patients with acute esophageal variceal bleeding. Use of proton pump inhibitors (PPI) in post EVL period is more of a personal choice as various society guidelines do not recommend continuation of PPI after EVL owing to low quality of evidence to support their use. **Methods:** We conducted a single centre, outcome assessor blinded prospective randomized controlled trial where patients of liver cirrhosis with acute variceal bleeding were enrolled and those who underwent EVL were randomized into PPI or No-PPI group after EVL. Patients in the PPI group received Tab Esomeprazole 40 mg once a day in addition to the standard of care for all patients. Both groups were followed up at 2 weeks post index EVL to assess occurrence of rebleeding and a repeat upper gastrointestinal endoscopy (UGIE) was done to document presence or absence of post EVL ulcers, their number and size. All patients were again followed up at 3 months to assess development of recurrent bleeding, mortality and adverse effects like pain and dysphagia post EVL. Primary outcome was to compare the rate of recurrent bleeding between the 2 groups. Secondary outcomes were to assess the difference in mortality, number and size of post EVL ulcers and adverse effects in the form of pain and dysphagia post EVL **Results:** A total of 246 patients were screened between June 2023 to April 2024 and after exclusion, 147 patients were randomized to both the groups. Baseline parameters were comparable between both the groups. In the primary outcome, recurrent bleeding was significantly more in the no PPI group [23 (31.94%) vs 7 (10.45%), p-0.002]. Among the secondary outcomes, incidence of mortality was higher in the no-PPI group [15 (20.83%) vs 11 (16.42%), p-0.505]. All the deaths in the no-PPI group were related to rebleeding episode [15 (100%) vs 3 (27.27%), $p = 0.00011$]. Incidence of post EVL ulcers was significantly more in the no- PPI group [58 (89.23%) vs 21 (34.43%) respectively; $p < 0.001$]. Median post EVL ulcer number and size were also significantly higher in the no-PPI group [1 (IQR 1,2) vs 0 (IQR 0,1) ($p = < 0.001$); 6 mm (IQR 5,8) vs 5 mm (IQR 5,5.5) ($p = 0.001$) respectively]. At 2 weeks, chest pain was reported by 5 (7.69%) patients in no PPI group vs 1 (1.63%) patient in PPI group ($p = 0.11$). No patient reported dysphagia at 2 weeks. No patient reported chest pain or dysphagia at 3 months. **Conclusion:** Prescription of PPI after EVL in patients of liver cirrhosis with acute esophageal variceal bleeding is beneficial as it significantly decreases the recurrent bleeding episodes as well as mortality in such patients.

◆ 2285 | REVERSAL OF HEPATORENAL SYNDROME-ACUTE KIDNEY INJURY DOES NOT IMPACT LIVER TRANSPLANT RATES

Kavish Patidar[1] Andrew Allegretti[2] Giuseppe Cullaro[3] Sumeet Asrani[4] Stevan Gonzalez[5] Sanaz Cardoza[6] Richard Wu[6] Chandrashekhar Kubal[7] R. Todd Frederick[8], [1]Division of Gastroenterology and Hepatology, Houston Methodist Hospital, Houston, TX, USA, [2]Division of Nephrology, Massachusetts General Hospital, Boston, MA, USA, [3]Division of Digestive and Liver Diseases, Columbia University, New York, NY, USA, [4]Baylor University Medical Center, Baylor Scott and White, Dallas, TX, USA, [5]Baylor Simmons Transplant Institute, Fort Worth, TX, USA, [6]Mallinckrodt Pharmaceuticals, Bridgewater, NJ, USA, [7]Division of Transplant Surgery, Indiana University School of Medicine, Indianapolis, IN, USA, [8]California Pacific Medical Center, San Francisco, CA, USA

Background: Liver transplant (LT) is the definitive treatment for hepatorenal syndrome-acute kidney injury (HRS-AKI). Reversal of HRS-AKI may lower Model for End-Stage Liver Disease (MELD) score, which could impact LT access. We examined if HRS-AKI reversal impacts LT rates. **Methods:** This study analyzed a pooled cohort of patients with HRS-AKI enrolled in the Phase III CONFIRM (NCT02770716), REVERSE (NCT01143246), and OT-0401 (NCT00089570) clinical trials of terlipressin vs placebo. Patients were excluded if they met any of the following criteria at baseline: serum creatinine (SCr) ≥ 5 mg/dL, acute-on-chronic liver failure grade 3, or MELD score ≥ 35. The analysis cohort reflected the FDA label-specific population for terlipressin who are most likely to derive benefit from treatment. Patients were compared by baseline SCr (< 3 mg/dL vs ≥ 3 mg/dL) and by HRS reversal. The main outcome of interest was LT within 90 days. Rates of LT were compared across SCr and HRS reversal groups using Fine and Gray competing risks

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

regression, with death during follow-up considered as a competing risk. Cumulative incidence functions were generated, and differences between groups were assessed using Gray's test. **Results:** Among 207 patients included (terlipressin, n = 136; placebo, n = 71), 45 were listed for LT at baseline. In total, the cumulative incidence of LT by Day 90 was 23.9% (95% confidence interval [CI] 18.0–31.7). There was no difference in cumulative incidence of LT by Day 90 between terlipressin (24.1% [95% CI 17.9–32.4]) and placebo (23.5% [95% CI 15.1–36.5]) groups overall ($P = .926$) or compared by SCr ($P = .950$; Figure). There was no difference in cumulative incidence of LT by Day 90 between patients who achieved HRS reversal (23.4% [95% CI 16.8–32.8]) and those who did not (24.7% [95% CI 16.6–36.6]) ($P = .839$; Figure). After adjusting for age, sex, and MELD score, there was no difference in cumulative incidence of LT by Day 90 between patients who achieved HRS reversal (24.2% [95% CI 17.1–31.3]) and those who did not (23.6% [95% CI 17.7–29.4]) ($P = .701$; adjusted subhazard ratio, 1.03 [95% CI 0.85–1.82; $P = .918$]); likewise, no difference was observed in the subgroup of patients listed for LT at baseline ($P = .341$). **Conclusion:** In this pooled analysis, terlipressin treatment and achieving HRS reversal were not associated with lower cumulative incidence of liver transplant at 90 days. These findings support the use of terlipressin in appropriate candidates without concern for compromising timely access to liver transplant.

◆ 2286 | THE ASSOCIATION BETWEEN ALBUMIN ADMINISTRATION AT OUTPATIENT PARACENTESIS AND INCIDENT AKI HOSPITALIZATION IN A LARGE VETERANS AFFAIRS COHORT

Max Schechter[1] Marina Serper[2] Siqi Zhang[1] David Kaplan[1] Nadim Mahmud[3], [1]University of Pennsylvania, [2]University of Pennsylvania Health System, [3]Hospital of the University of Pennsylvania

Background: Guidelines recommend albumin infusion after paracenteses where more than 5 liters of ascites are removed. This recommendation, however, is based on small randomized controlled trials limited to a few centers. The current study aimed to evaluate if albumin infusion after outpatient paracentesis in patients with cirrhosis is associated with change in risk of hospitalization with acute kidney injury (AKI) and to further identify patient subgroups in which this association may vary. **Methods:** This was a retrospective cohort study using data from the Veterans Health Administration comprising 128 centers. All outpatient paracenteses in patients with established cirrhosis were identified. Detailed patient-level and paracentesis-related data were obtained, including a natural language processing-based approach to ascertain volume removal, as well as albumin administration per prior methods. Mixed-effects logistic regression was performed to evaluate the adjusted association between (1) albumin administration and (2) incident AKI hospitalization, accounting for key *a priori* covariates; an interaction between albumin administration and baseline creatinine category was also evaluated. **Results:** The analytic cohort comprised of 56,941 patients, 97.1% of which were male, 72.3% were white, with the most common etiology of liver disease being alcoholic liver disease at 32.9% followed by MASLD at 22.8%. The median MELD-Na score was 16 (IQR 11-20). The distribution of volume removal across all paracenteses is shown in Figure Panel A; albumin was administered in 17.0% of paracenteses. In adjusted analysis for the first

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

outcome, higher baseline creatinine (Cr) was associated with increased odds of albumin administration, for instance an OR 1.48 for Cr 1-2 (95% CI 1.35–1.62) and OR 3.10 for Cr >2 (95% CI 2.74–3.52) relative to Cr <1. In adjusted analysis for the second outcome, albumin administration was associated with reduced odds of AKI hospitalization (OR 0.67, 95% CI 0.55–0.82). A significant interaction between albumin administration and baseline Cr was identified such that albumin administration had a greater effect in reducing the probability of AKI hospitalization in patients with higher baseline creatinine ($p=0.01$) (Figure Panel B). **Conclusion:** Albumin administration after outpatient paracentesis was found to reduce the probability of hospitalization with AKI; this effect intensified in patients with higher creatinine at time of paracentesis.

◆ 2287 | A MACHINE LEARNING APPROACH TO NON-INVASIVELY PREDICT HEPATIC DECOMPENSATION IN ADVANCED CHRONIC LIVER DISEASE

Georg Kramer[1] Anders Hildeman[2] Caterina Tozzi[2] Roza Maghshood[2] Vinusha Kalatharan[3] Hyewon Nina Koo[2] Kinga Jastrzębska[2] Nils Svangård[2] Claire Donoghue[2] Benedikt Simbrunner[1] Mattias Mandorfer[1] Benedikt Hofer[1] Thomas Reiberger[1] Jan Oscarsson[2] Philip Ambery[2], [1]Medical University of Vienna, [2]AstraZeneca, [3]Astra Zeneva

Background: Clinically significant portal hypertension (CSPH, i.e. hepatic venous pressure gradient [HVPG] ≥ 10 mmHg) indicates compensated advanced chronic liver disease (cACLD) at risk of decompensation. Invasive HVPG measurement is the gold standard for CSPH assessment, needing non-invasive alternatives. We developed and validated the Cirrhosis Risk Identifier (CIRI) model – a machine-learning tool trained to predict first decompensation using 11 general demographic and routine laboratory parameters. CIRI's performance was benchmarked with HVPG and liver stiffness measurement (LSM) in an external validation cohort. **Methods:** cACLD patients were included from the U.S. Optum's de-identified Clinformatics® Data Mart Database (Optum® CDM) cohort and an external validation cohort, prospectively recruited in the VICIS study (Vienna, Austria). Event of interest was first hepatic decompensation (ascites, overt hepatic encephalopathy, variceal bleeding) with HCC and death as competing events. The cACLD and decompensating event diagnoses in the Optum® CDM cohort were identified using ICD 9/10 codes. **Results:** In the Optum® CDM collective, we trained CIRI on 25,531 patients and validated it in an independent set of 18,852. The leading etiology in the Optum® CDM validation cohort was metabolic dysfunction-associated steatotic liver disease (MASLD) (34%), with a median MELD of 8 (IQR 6-11), and a median follow-up of 47 (IQR 18-102) months. The VICIS cohort included 216 patients with predominantly viral hepatitis (25%) and alcohol-related liver disease (22%), with a median MELD of 9 (IQR 8-12) and median follow-up of 70 (IQR 54-88) months. The CIRI model showed high time-dependent AUROCs for predicting decompensation at 1 and 2 years (Optum® CDM: 0.821, 0.819; VICIS: 0.846, 0.803), comparable to HVPG (0.837, $p=0.993$; 0.817, $p=0.955$) and outperforming LSM ($p=0.002$; $p=0.006$) in the VICIS cohort. In Fine-Gray competing risk regression analysis adjusted for non-selective beta-blocker intake, CIRI was independently linked to a higher decompensation risk (Optum® CDM: adjusted subdistribution hazard ratio [aSHR]: 1.67, $p<0.001$; VICIS: 2.25, $p<0.001$). **Conclusion:** The machine-

learning-based CIRI model showed robust prognostic performance and effective risk stratification in cACLD patients. Its predictive accuracy was confirmed in both a large U.S. and a European validation cohort, where CIRI's discrimination of decompensation risk was comparable to that of HVPG, thus highlighting its potential future utility as a non-invasive tool to identify "at-risk" cACLD patients.

◆ 2288 | PREDICTION OF INCIDENT OVERT HEPATIC ENCEPHALOPATHY USING MEASURES OF MINIMAL HEPATIC ENCEPHALOPATHY: THE PRO-MHE STUDY

Akash Roy[1] Uttkarsh Bhattad[2] Awanish Tewari[1] Nikhil Sonthalia[1] Shardhya Chakroborty[1] Nipun Verma[3] Anand Kulkarni[4] Madhumita Premkumar[3] Uday Ghoshal[1] Rajender Reddy[5] Mahesh Goenka[1], [1]Apollo Hospitals, [2]Apollo Hospitals,Kolkata, [3]PGIMER, Chandigarh, [4]AIG, Hospitals, [5]University of Pensylvania

Background: Psychometric hepatic encephalopathy score (PHES) is the gold standard for diagnosing minimal hepatic encephalopathy (MHE) and may predict incident overt hepatic encephalopathy (OHE). However, it is cumbersome, thus mandating increased use of simpler tests, such as EncephalApp (Stroop), QuickStroop, and Animal Naming Test (ANT). While these tests are good surrogates for MHE, their role in predicting OHE remains unclear. We aimed to ascertain the predictive performance of MHE scores for incident OHE. **Methods:** Stable outpatients without baseline or recent ($\leq$3 months) OHE were prospectively recruited to undergo PHES, Stroop, Quickstroop, and ANT. For MHE diagnosis at baseline, area under the receiver operating curves (AUROC) were generated using PHES as the gold standard ($\leq$-5 cut-off as prior validated local norm). Patients were followed up for at least six months to assess incident OHE as the primary outcome, and predictors were analyzed using Cox proportional hazards regression. To reduce dimensionality and avoid overlap among cognitive metrics, an exploratory principal component analysis (PCA) was conducted using Stroop and ANT to generate a composite measure of cognitive dysfunction ($PC_{Stroop-ANT}$) and assessed for OHE prediction. **Results:** 153patients [54(46-61) years), females 21%, MELD,10 (9-12), prior OHE 11.1%, CTP A/B 46.4%/48.4%) were enrolled. At baseline, 74(48.4%) had MHE by PHES. Stroop, Quickstroop, and ANT had an AUROC of 0.81 (0.74-0.87), 0.79 (0.72-0.85), and 0.65 (0.57-0.73), respectively, for MHE. Twenty-nine (19%) developed OHE on follow-up. On univariable Cox regression, Stroop [(HR, 1.03, (1.01-1.05), $p = < 0.01$] and PHES [0.74(0.65-0.85), $p = < 0.01$] but not ANT [0.89(0.77-1.01, $p = 0.08$)] predicted OHE. On multivariable analysis adjusted for MELD, only PHES was independently predictive of OHE (aHR,0.76(0.66-0.890)[Stroop, 1.00 (0.99-1.00), ANT,1.01(0.89-1.2)]. Only PHES was associated with all-cause non-elective hospitalization [0.84 (0.76-0.92), $p < 0.01$]. The composite cognitive score ($PC_{Stroop-ANT}$) was significantly associated with incident OHE (aHR: 1.48; 95% CI: 1.17–1.89; $p = 0.001$), and was only marginally inferior to PHES alone (Model Information criteria Akaike/Bayesian: PHES,267.7/273.8, $PC_{Stroop-ANT}$278.9/285). **Conclusion:** Among the various MHE tests, PHES most strongly predicts incident OHE. While individually simpler tests of Stroop, Quickstroop, and ANT are not as predictive, an exploratory composite measure, $PC_{Stroop-ANT,}$ closely approximates prediction by PHES.

◆ 2289 | EFFICACY AND SAFETY OF LOW-DOSE VERSUS CONVENTIONAL DOSE ALBUMIN FOR PREVENTION OF ACUTE KIDNEY INJURY IN CIRRHOSIS AND HIGH-RISK SPONTANEOUS BACTERIAL PERITONITIS: A RANDOMIZED CONTROLLED TRIAL

SAURAV PAUL[1] Manoj Kumar Sharma[2] Rakhi Maiwall[2] Shiv Kumar Sarin[2] Priyanka Saha[3] Babu Lal Meena[4] Omkar Rudra[4], [1]Institute of Liver and Bilary Sciences, Delhi, India, [2]Institute of Liver and Biliary Sciences, Delhi, India, [3]All India Institute of Medical Sciences, Delhi, India, [4]Insititute of Liver and Biliary Sciences, Delhi, India

Background: Patients with cirrhosis and high-risk spontaneous bacterial peritonitis (SBP) are prone to acute kidney injury (AKI), and albumin infusion can reduce this risk. However, conventional dosing often leads to infusion-related complications such as circulatory overload, and evidence for lower or individualized dosing is limited. This study evaluated the efficacy and safety of low-dose versus conventional-dose albumin for preventing new-onset or progressive AKI in this high-risk population. **Methods:** This randomized, open-label, non-inferiority trial at a tertiary center in northern India enrolled adults with cirrhosis and high-risk SBP (bilirubin >4 mg/dL and/or creatinine >1 mg/dL). Patients were randomized to receive either conventional (1.5 g/kg on day 1; 1.0 g/kg on day 3) or low-dose albumin (1.0 g/kg on day 1; 0.5 g/kg on day 3), infused as 20% solution over 18–24 hours. Analyses followed the intention-to-treat principle. The primary outcome was AKI onset or progression by day 4; secondary outcomes included SBP resolution, circulatory overload, biomarker changes, and mortality at days 7, 28, and 90. **Results:** Of the 263 patients screened for spontaneous bacterial peritonitis (SBP), 168 met the inclusion criteria and were randomized to receive either conventional-dose albumin (Group I, $n=83$) or low-dose albumin (Group II, $n=85$). Median ages were similar between groups (49 years [IQR: 43–58] vs. 50 years [IQR: 43–56]; $p=0.21$). The predominant causes of cirrhosis were alcohol-related liver disease (Group I: 47%; Group II: 51.8%) and non-alcoholic steatohepatitis (Group I: 39.8%; Group II: 34.1%). Most patients were Child-Pugh Class C (Group I: 73.5%; Group II: 70.6%; $p=0.78$), with comparable median MELD scores (24 [IQR: 22–29] vs. 24 [IQR: 20–28]; $p=0.21$). Circulatory overload occurred significantly more often in the conventional-dose group on both day 1 (81.9% vs. 31.8%) and day 3 (86.7% vs. 5.9%; $p<0.001$). Among patients without baseline AKI, new-onset AKI rates were similar (16.1% vs. 22.2%; $p=0.786$). However, among those with baseline AKI, progression occurred in 26.9% of Group I compared to 6.8% of Group II ($p=0.011$), favoring the low-dose group. Mortality and SBP resolution rates did not differ significantly between groups. **Conclusion:** This study demonstrated that low-dose albumin was non-inferior to conventional-dose albumin for new onset or progression of AKI among high-risk patients with SBP, while resulting in significantly reduced infusion-related complications. These findings suggest for adopting individualized, tolerance-guided albumin dosing strategies in the management of cirrhosis patients with high risk SBP. Clinical trial: gov (identifier: NCT06026267) Keywords: Spontaneous bacterial peritonitis, Acute kidney injury, Low dose albumin, Conventional dose albumin, Randomized controlled trial

◆ 2290 | IMPACT OF CIRRHOTIC CARDIOMYOPATHY AND CARDIOMETABOLIC RISK ON HEPATIC DECOMPENSATION AND SURVIVAL IN PATIENTS WITH CIRRHOSIS

Madhumita Premkumar[1] Kamal Kajal[2] Manhal Izzy[3] Prerna Sharma[2] Anchal Sandhu[2] Bhupendra Sihag[2] Ajay Bahl[2] Ankur Gupta[2] Jasvinder Nain[2] Ajay Duseja[1] Anand Kulkarni[4] Ashwani Sood[2] Arka De[2] K Rajender Reddy[5], [1]Postgraduate Institute of Medical Education & Research, [2]PGIMER, [3]Vanderbilt University Medical Center, [4]Asian Institute of Gastroenterology, [5]University of Pennsylvania

Background: Left ventricular diastolic dysfunction (LVDD) and Cirrhotic cardiomyopathy (CCM) are under-recognized, while not uncommon, in patients with advanced liver disease. Herein, we aimed to assess, in those with cardiometabolic risk factors,

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

changes in cardiac function, hepatic decompensation events, and survival based on the etiology of cirrhosis. **Methods:** Prospective patients with cirrhosis of any etiology between January 2020 and January 2025 presenting to the outpatient liver clinic were screened with transthoracic echocardiography (TTE). speckle tracking, and tissue Doppler imaging for presence of LVDD as per 2020 CCM consortium criteria; ischemic heart disease, porto-pulmonary hypertension, valvular heart disease, anemia, and hepatocellular carcinoma were exclusions. Assessments were done every 6m; clinical and survival data, TTE and cardiac imaging, and biomarkers (NT-proBNP, aldosterone, norepinephrine) were collected. **Results:** Of 749 patients with cirrhosis enrolled (77.7%men, 50.4 ± 11.4y, with mean MELD-Na 20.7 ± 5.6), 32.4% with DM-2, 16.4% with hypertension, 9.% obese, with etiology being 245(32.7%), 209(27.9%), 91(12.1%), (171,22.8%), and (33,4.4%) due to alcohol-associated disease(ALD), metabolic-dysfunction associated steatotic liver disease(MASLD), Met-ALD, chronic viral hepatitis and autoimmune etiology respectively. Of them, 255(34%) met criteria for CCM (grades II-III LVDD), with increased prevalence in patients with MASLD (31%) and MetALD (65%). Overall, 270(36%), 184(24.6%), 121(16.2%), 142(19%) had no LVDD, or grades I, II,III LVDD, respectively, with 32(4.3%) being indeterminate for diastolic function. In patients with CCM, liver decompensation events were more frequent, with recurrence of ascites (18% vs 4.7%), hepatic encephalopathy (7.4% vs 1.4%,), HRS-AKI (28.9% vs 5.3) and variceal bleeding (13.3% vs 3.7%, $P < 0.001$) (Figure 1) The overall mortality at 90-days (13.3% vs 2.4%, $p < 0.001$) and 1 year(18%vs 12.4%, $P = 0.047$) was higher in patients with CCM, On multivariable regression for competing risks of deaths vs TIPS/transplantation, CCM (SHR1.3, 95%CI-1.2-1.7,$P = 0.034$), and MELDNa (SHR 1.14, 95%1.04-1.2,$P < 0.001$) predicted mortality at 1 year, independent of age, gender, diabetes, and disease etiology. (A) Table 1: Baseline characteristics, cardiometabolic risk factors and spectrum of cardiac dysfunction based on etiology and severity of cirrhosis, with outcomes on follow up.(B) and (C) Survival Plots for patients with and without CCM at 90 days /1 year (D) Sankey plot-outcomes **Conclusion:** Consistent with prior reports from the United States and EU, CCM is prevalent in approximately 1/3 rd of patients with advanced liver disease from the Indian subcontinent and is associated with increased risk of hepatic decompensation and 1 year mortality independent of age, gender, DM-2 and etiology of liver disease. Recognition of CCM may help in modifying care.

◆ 2291 | REDUCED RISK OF HEPATIC DECOMPENSATION AND OVERALL MORTALITY IN PATIENTS WITH COMPENSATED CIRRHOSIS AND STATIN THERAPY: A PROPENSITY SCORE-MATCHED ANALYSIS OF A POPULATION BASED COHORT OF 14,034 ADULTS

Monica Tincopa[1] Abdallah Hussein[2] Bisher Sawaf[3] Yusuf Hallak[3] Sana Rabeeah[3] Mohammed Abu-Ramaileh[3], [1]University of California, San Diego, [2]Al-Quds University, [3]University of Toledo

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Statin use is often avoided in cirrhosis due to hepatotoxicity concerns. However, emerging data suggests a potential clinical benefit of statins in compensated cirrhosis. The aim of this study was to assess the impact of statin therapy on risk of hepatic decompensation, hepatocellular carcinoma (HCC) and overall mortality in a large population-based cohort. **Methods:** Using a large, federated electronic health based (EHR) database (TriNetX), we identified patients with compensated cirrhosis using ICD-10 codes. Statin users were defined as individuals taking statins at any dose for at least 1 year. Statin users were propensity score-matched 1:1 using demographics, labs, BMI, alcohol use, medical comorbidities, cirrhosis etiology, beta-blocker, opioid, and benzodiazepine use. Outcomes assessed at 1 and 4 years included composite hepatic decompensation [ascites, variceal bleeding, hepatic encephalopathy (HE), hepatorenal syndrome (HRS), spontaneous bacterial peritonitis (SBP) or hepatocellular carcinoma (HCC)]. Secondary outcomes included individual decompensation outcomes and overall mortality. **Results:** After matching, 14,034 patients were included in each group for 1-year outcomes, and 13,853 for 4-year outcomes. Statin use was associated with significantly lower 1-year rates of composite hepatic decompensation (6.4% vs. 9.8%; OR: 0.64; 95% CI: 0.58–0.70; $p < 0.0001$) and overall mortality (4.5% vs. 8.5%; OR: 0.51; 95% CI: 0.46–0.57; $p < 0.0001$) (Table 1a). At 4 years, the statin group continued to show reduced risk of composite hepatic decompensation (10.8% vs. 14.8%; OR: 0.70; 95% CI: 0.65–0.75; $p < 0.0001$) and overall mortality (14.6% vs. 20.8%; OR: 0.65; 95% CI: 0.61–0.69; $p < 0.0001$) (Table 1b). Statin use was particularly associated with reduced rates of ascites and portal hypertension, though not with reduced risk of HCC. **Conclusion:** In a large population-based propensity score-matched cohort of patients with compensated cirrhosis, statin therapy was associated with significantly lower rates of hepatic decompensation and overall mortality at 1 and 4 years of follow-up. These data suggest potential preventative benefit of statin therapy in adults with compensated cirrhosis that should be further assessed in future randomized clinical trials.

Table 1a. Outcome over one year

Outcome	Statin Group (n=14,034)	Control Group (n=14,034)	Odds Ratio (95% CI)	p-value

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Poor physical fitness (PhysFit), including frailty/sarcopenia, is highly prevalent in advanced chronic liver disease (AdvCLD) and significantly increases morbidity and mortality in liver transplant (LT) waitlisted candidates. Prehabilitation, the optimization of a candidate's physiologic reserve through a lifestyle intervention prior to surgery, improves PhysFit in LT candidates. In May/2024, Northwestern's Comprehensive Transplant Center opened a Prehabilitation Clinic for patients undergoing evaluation or waitlisted for LT. Herein, we present our first-year experience, highlighting clinical outcomes and improvements in PhysFit metrics among LT candidates. **Methods:** Frailty was assessed with the liver frailty index (LFI) and cardiorespiratory fitness with the 6-minute walk test (6MWT). At each visit, all patients were seen by a nurse practitioner, a dietician, two exercise professionals, and one hepatologist. An individualized exercise and dietary prescription was provided, and adherence monitored through phone calls and clinic visits every 2-6 weeks. Paired t-test was used for comparisons. **Results:** A total of 43 patients (age 63 $\pm$ 7, male 63%) were referred for frailty during a 1-year period, and 38 attended the clinic (70% during evaluation phase) for a median of 2 visits (32% attended $\geq$3 visits). Most patients had steatotic liver disease (35% ALD, 19% MASLD, 16% MetALD), and all were decompensated (ascites 94%, encephalopathy 72%) with a MELDNa of 17 $\pm$ 7; falls were reported by 36%. A total of 17 patients underwent LT: 6 newly waitlisted and 10 reactivated, following improvement of their PhysFit metrics; 1 inpatient who could not attend the clinic also underwent LT. Seven patients died (6 pre-LT, 1 post-LT) and none of them engaged with the program or showed adherence with recommendations. There were no differences in LFI at baseline between patients who were alive (4.98 $\pm$ 0.57) or deceased (5.01 $\pm$ 0.55) at the end of follow-up. Improvement in PhysFit metrics during prehabilitation is shown in *Table*. **Conclusion:** We successfully optimized 16 frail patients with AdvCLD who were initially deemed ineligible for LT, enabling them to meet listing criteria. Transplant approval was contingent upon sustained engagement in prehabilitation, observed physical resilience, and clinically meaningful improvement in objective physical fitness measures—defined as a $\geq$0.4-point reduction in LFI or an increase of $\geq$30 meters in 6MWT. While implementing LT prehabilitation is challenging, LFI and 6MWT trajectories offer actionable guidance for exercise and dietary interventions. While our findings are encouraging, they underscore the need for validation through a randomized controlled trial.

All (n=24)	Baseline	Second Visit	Difference	p-value
LFI	4.95 ± 0.62	4.79 ± 0.68	0.15	0.33
6MWT (m)	222 ± 72	230 ± 78	-7	0.58
Transplant (n=11)	**Baseline**	**Second Visit**	**Difference**	**p-value**

◆ 2293 | ALLOPURINOL USE IS ASSOCIATED WITH DECREASED INCIDENCE OF HEPATIC DECOMPENSATION AND OVERALL MORTALITY AMONG ADULTS WITH COMPENSATED CIRRHOSIS: A POPULATION-BASED PROPENSITY-MATCHED COHORT STUDY OF 10,716 INDIVIDUALS

Monica Tincopa[1] Bisher Sawaf[2] Mohammad Al Hayek[3] Yusuf Hallak[4] Shahem Abbarh[5] Mohammed Beshr[6] Mohammed Elhadi[7] Mohammed Abu-Rumaileh[4], [1]University of California, San Diego, [2]Univeristy of Toledo, [3]Damascus University, [4]University of Toledo, [5]MedStar, [6]Sana'a University, [7]Korea University

Background: Recent studies highlight the potential role of allopurinol in reducing incident hepatic decompensation in compensated cirrhosis given its anti-inflammatory and anti-oxidant properties. The aim of this study was to evaluate the association of allopurinol use with incidence of hepatic decompensation and overall mortality in patients with compensated cirrhosis in a large, population-based propensity-matched cohort. **Methods:** Using a large electronic health-based database (TriNetX), we identified patients with compensated cirrhosis using ICD-10 codes. Allopurinol use was defined as having received allopurinol during $\geq$ five visits or hospital stays before follow-up and on or after cirrhosis diagnosis. Allopurinol use was assessed at: any dose, 100 mg and 300 mg. 1:1 propensity-score matching was done using demographics, labs, BMI, alcohol use, medical comorbidities, cirrhosis etiology, beta-blocker, opioid, benzodiazepine and statin use. The primary outcome was the incidence of composite hepatic decompensation [ascites, variceal bleeding, hepatic encephalopathy (HE), hepatorenal syndrome (HRS) or spontaneous bacterial peritonitis (SBP)]. Secondary outcomes included individual decompensation outcomes, hepatocellular carcinoma (HCC), and overall mortality. Outcomes were assessed at 6, 12, and 18 months. **Results:** After propensity-score matching, each group in the any dose exposure included 5358 patients, 2124 in each group for 100 mg, and 1020 in each group for 300 mg. At 18 months, statistically significantly lower incidence of hepatic decompensation was seen in the overall allopurinol

exposure cohort (OR: 0.77; 95% CI: 0.70-0.84), the 100 mg cohort (OR: 0.66; 95% CI: 0.57 to 0.76), and 300 mg cohort (OR: 0.76, 95% CI: 0.62 to 0.94). Allopurinol exposure was associated with a decreased incidence of esophageal variceal bleeding (OR: 0.71 95% CI: 0.55 to 0.92), ascites (OR: 0.77 95% CI: 0.69 to 0.84), HE (OR: 0.76 95% CI: 0.63 to 0.92), SBP (OR: 0.61 95% CI: 0.46 to 0.80), and overall mortality (OR: 0.86 95%% CI: 0.77 to 0.96) compared to the control group (Figure). **Conclusion:** In a propensity-score matched analysis of a large national database, individuals with compensated cirrhosis and allopurinol use had significantly lower risk of hepatic decompensation and overall mortality. These findings suggest that allopurinol may play a potential role in managing cirrhosis. Future randomized clinical trials are needed to confirm these findings.

◆ 2294 | RIFAXIMIN MONOTHERAPY REDUCES THE RISK OF NEW-ONSET HEPATIC ENCEPHALOPATHY AND MORTALITY COMPARED TO LACTULOSE MONOTHERAPY IN COMPENSATED CIRRHOSIS: A REAL-WORLD PROPENSITY-MATCHED STUDY

Himsikhar Khataniar[1] Renuka Verma[2] Kaitlyn Gernhard[1] Daniel Huynh[3] Leandro Sierra[4] Nabeeha Mohy-ud-din[1] Nikki Duong[5], [1]Allegheny General Hospital, [2]UNLV, [3]University of Washington, [4]Cleveland Clinic Foundation, [5]Stanford University

Background: Lactulose is the first-line therapy for hepatic encephalopathy (HE), but its real-world efficacy is often limited by the side effect profile (flatulence, nausea, diarrhea). Although rifaximin has shown benefit as an adjunct, less is known regarding its efficacy to prevent new-onset HE as monotherapy. Post hoc analyses from trials suggest rifaximin may be a superior alternative in decompensated patients, but real-world comparative data in patients with compensated cirrhosis are lacking. **Methods:** This is a retrospective cohort study using the TriNetX US Collaborative Network. Adult patients aged 18–90 years with cirrhosis and preserved hepatic function (defined by MELD surrogate labs: INR <1.5, bilirubin <1.9 mg/dL, creatinine <1.3 mg/dL, and albumin >3.5 g/dL) who initiated rifaximin or lactulose monotherapy between January 2010 and December 2023 were included. Individuals with any prior hepatic decompensation—including overt hepatic encephalopathy (OHE), ascites, or variceal bleeding—were excluded to specifically evaluate the incidence of new-onset OHE. Propensity score matching using 59 covariates generated two well-balanced cohorts ($N=1814$). Outcomes were assessed up to one year. Primary outcomes were new-onset HE and all-cause mortality. Secondary outcomes included major adverse liver events (MALO), progression to decompensated cirrhosis, all-cause hospitalization, hepatocellular carcinoma (HCC), and liver transplantation (LT). **Results:** At 1 year, new-onset OHE was lower with rifaximin (1.0% vs. 2.1%; HR 0.48, 95% CI 0.27–0.84; $p=0.009$; NNT 91). All-cause mortality was lower in the Rifaximin cohort (5.0% vs. 7.4%; HR 0.67, 95% CI 0.51–0.88; $p=0.003$). Rifaximin had lower rates of MALO (11.6% vs. 16.3%; HR 0.70, $p=0.002$), decompensations (6.9% vs. 8.8%; HR 0.78, $p=0.048$), and hospitalizations (6.1% vs. 10.0%; HR 0.62, $p=0.004$). No significant differences were seen in HCC (1.1% vs. 1.3%; HR 0.84; $p=0.59$) or LT (0.6% vs 0.6%; HR 1.26; $p=0.65$). **Conclusion:** In this large, multicenter real-world analysis of patients with compensated cirrhosis and no prior decompensation, rifaximin monotherapy reduced the risk of new-onset hepatic encephalopathy by almost 50% as well as all-cause mortality compared to lactulose. Additionally, rifaximin was associated with fewer liver-related complications and hospitalizations. These findings support a re-evaluation of rifaximin as potential first-line therapy for HE prevention due to the poor tolerability of lactulose, though costs and insurance approval may be limit widespread access.

◆ 2295 | LATENT CLASS ANALYSIS (LCA) IDENTIFIES DISTINCT ASCITES PHENOTYPES ASSOCIATED WITH CLINICAL OUTCOMES AND WITH IMPLICATIONS FOR TARGETED THERAPY IN PATIENTS WITH DECOMPENSATED CIRRHOSIS AND ASCITES

Giuseppe Cullaro[1] Andrew Allegretti[2] Kavish Patidar[3] Jennifer Lai[4] Elizabeth Verna[5], [1]Columbia University Irving Medical Center, [2]MGH, [3]Houston Methodist Hospital, [4]University of California San Francisco, [5]Columbia University Medical Center

Background: Ascites results from complex pathophysiologic mechanisms including portal hypertension, systemic vasodilation, and renal dysfunction. Traditional classifications—dependent on the degree or responsiveness to treatment—inadequately capture the heterogeneity of underlying mechanisms. We hypothesized that LCA could identify distinct phenotypes with differing clinical profiles and treatment implications. **Methods:** We performed LCA on 776 decompensated cirrhosis participants with ascites from two centers. 7 parameters were included: systolic blood pressure (SBP), portal vein thrombosis (PVT) status, platelet count (plt), albumin, total bilirubin, eGFR, and ascites grade. Continuous variables were modeled as deciles. We used a cross-validation approach with 80/20 split (derivation/validation) stratified by center. Optimal model selection was guided by BIC values and clinical interpretability. We assessed class-specific clinical characteristics and outcomes, including acute kidney injury (AKI) and transplantation through competing risk analysis. **Results:** LCA identified three distinct phenotypes: Class 1 "Kidney-Metabolic" (25%): characterized by highest albumin median(q1-q3): 3.80(3.40-4.10) g/dL, lowest bilirubin: 0.9(0.6-1.2) mg/dL, highest SBP: 131(116-150) mmHg, highest plts: 135(105-188) K/μL, and greatest burden of ≥ Stage 3b CKD (21%); Class 2 "Vasodilatory" (47%): distinguished by lowest albumin: 2.90(2.50-3.30) g/dL, highest bilirubin: 4.8 (3.0-8.3) mg/dL, lowest SBP: 115(104-127) mmHg, and intermediate burden of ≥ Stage 3b CKD (11%); Class 3 "PVT" (28%): exhibiting intermediate values with moderate albumin: 3.30(2.90-3.60) g/dL, intermediate bilirubin: 1.9(1.5-2.6) mg/dL, intermediate SBP: 124(112-139) mmHg, but notably highest PVT burden (27%), lowest plts: 58(46-73) K/μL, and lowest burden of ≥ Stage 3b CKD (8%) (Figure 1). In competing risk analysis, Class 2 demonstrated significantly higher cumulative incidence of AKI compared to Class 1 (sHR: 3.5, 95CI: 2.0-6.0) and higher rates of liver transplantation (sHR: 3.0, 95CI: 2.1-4.1), while Class 3, as compared to Class 1, showed no significant difference in AKI risk (sHR: 0.9, 95CI: 0.4-1.8) or transplantation (sHR: 1.0, 95CI: 0.7-1.6) (Figure 1). 4.6% of patients showed overlapping phenotypes, suggesting concurrent pathophysiological processes, without any significant differences in AKI ($p = 0.7$) or waitlist outcomes ($p = 0.4$) when compared to those with clear phenotypes. **Conclusion:** Our LCA reveals three clinically distinct ascites phenotypes with varying pathophysiologic mechanisms, crucial for therapy selection. The "Vasodilatory" phenotype (lower SBP) may benefit from vasoconstrictive therapies, while the "Kidney-Metabolic" phenotype (higher SBP, lower eGFR) may benefit from renoprotective interventions. This framework enables personalized treatment for cirrhotic patients with ascites.

◆ 2296 | DYSPHAGIA IMPAIRS HEALTH-RELATED QUALITY OF LIFE IN PATIENTS WITH CHRONIC LIVER DISEASE

Takao Miwa[1] Tatsunori Hanai[1] Itsuki Hayashi[1] Shinji Unome[1] Kenji Imai[1] Atsushi Suetsugu[1] Koji Takai[1] Masahito Shimizu[1], [1]Gifu University Hospital

Background: Dysphagia refers to the dysfunction or deterioration of swallowing and is usually a multidimensional syndrome rather than a localized disease specific to the oropharynx. Many patients with chronic liver disease (CLD), especially those with older age, malnutrition, and sarcopenia, can be at high risk for complications of dysphagia. However, very few studies have been conducted on the prevalence, clinical characteristics, and impact on outcomes of dysphagia in patients with CLD. This study aimed to reveal the prevalence and characteristics of dysphagia in patients with CLD and its association with health-related quality of life (HRQOL). **Methods:** This cross-sectional study included outpatients with CLD in Gifu University Hospital. Dysphagia, sarcopenia risk, malnutrition risk, and HRQOL were assessed using the Eating Assessment tool-10 (EAT-10), SARC-F, Royal Free Hospital-Nutrition Prioritizing Tool (RFH-NPT), and Chronic Liver Disease Questionnaire (CLDQ), respectively. Dysphagia and low HRQOL were based on EAT-10 ≥ 3 and CLDQ overall score < 5, respectively. Factors associated with dysphagia and low HRQOL were assessed using the logistic regression model. **Results:** Of the 335 outpatients with CLD, patients with dysphagia, at risk of sarcopenia, and at risk of malnutrition were, 33 (10%), 51 (15%), and 68 (20%), respectively. The median CLDQ overall score was 5.55, and 103 (31%) were diagnosed with low HRQOL based on a CLDQ overall score < 5. Patients with dysphagia were older, had lower liver functional reserve, were at higher risk for sarcopenia and malnutrition, and showed lower CLDQ overall score (median, 4.41 vs. 5.69; $p < 0.001$) than in those without. After adjustment, SARC-F (odds ratio [OR], 1.24; 95% confidence interval [CI], 1.02–1.50; $p = 0.029$) and RFH-NPT (OR, 1.71; 95% CI, 1.04–2.81; $p = 0.034$) scores were independently associated with dysphagia in patients with CLD. EAT-10 (OR, 1.17; 95% CI, 1.04–1.30; $p = 0.008$) and SARC-F (OR, 1.37; 95% CI, 1.18–1.59; $p < 0.001$) scores were also independently associated with low HRQOL. In addition, patients with dysphagia alone had significantly lower CLDQ score than those with sarcopenia risk alone ($p = 0.040$; Figure 1). **Conclusion:** Dysphagia was prevalent in approximately 10% of patients with CLD and was associated with a risk of sarcopenia and malnutrition. Furthermore, dysphagia was related to HRQOL in patients with CLD.

◆ 2297 | MICROBIOLOGICAL PROFILE OF BACTERIAL INFECTIONS IN PATIENTS WITH CIRRHOSIS OVER TIME: A 20-YEAR TERRITORY-WIDE STUDY

Jie Cai[1] Terry Cheuk-Fung Yip[2] Grace Lai-Hung Wong[2] Vincent Wong[2] Grace Lui[2] Jian Sun[3] Jimmy Che-To Lai[2], [1]Southern Medical University; The Chinese University of Hong Kong, [2]The Chinese University of Hong Kong, [3]Southern Medical University

Background: Antimicrobial resistance (AMR) complicates the management of bacterial infections in cirrhosis, while detailed microbiology data remain scarce. This study aimed to characterise the microbiological landscape of bacterial infections in patients with cirrhosis and assess their impact on mortality. **Methods:** All admissions of adult patients with cirrhosis between 2001-2021 were identified using a territory-wide database in Hong Kong. Temporal trends in bacteriology and AMR patterns were assessed using joinpoint regressions. In vitro non-susceptibility to empirical antibiotics recommended by the European Association for the Study of the Liver was evaluated across specimen types. The survival status of all patients at their last admissions was assessed, and patient-based multivariable logistic regressions were conducted. **Results:** A total of 173,725 admissions from 17,685 patients were included in the study, among which 18,513 admissions from 7,638 patients had positive cultures, involving 24,110 samples, 27,982 isolates and 21,394 episodes. Gram-negative bacteria predominated (69.3%), but their proportion decreased from 2010 to 2021 (annual percent change [APC] -0.6%, 95% CI: -1.8 to -0.1). Multidrug-resistant (MDR) organisms were isolated in 34.1% of episodes, with a significant rise during 2001-2006 (APC 6.8%, 95% CI: 3.0 to 17.7). A heterogeneous increase in drug-resistant bacteria was observed. The total number (and prevalence of resistance among the same organism) of methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, third-generation cephalosporins-resistant *Enterobacterales*, carbapenem-resistant *Enterobacterales*, carbapenem-resistant *Pseudomonas aeruginosa* and carbapenem-resistant *Acinetobacter* episodes was 1,484 (60.4%), 20 (0.8%), 3,122 (28.7%), 135 (1.4%), 119 (6.2%) and 254 (40.5%), respectively. Amoxicillin/clavulanic acid showed comparable *in vitro* resistance rates to third-generation cephalosporins in community-onset infections. MDR infections during admissions (adjusted odds ratio [aOR] 1.55, 95% CI: 1.26-1.93, $p < 0.001$) and a history of two (aOR 1.65, 95% CI: 1.37-2.00, $p < 0.001$) or more (aOR 2.75, 95% CI: 2.28-3.32, $p < 0.001$) infection episodes per year were independently associated with increased in-hospital mortality. **Conclusion:** AMR is rising in patients with cirrhosis. Multidisciplinary effort is crucial to combat AMR and manage bacterial infections in cirrhosis.

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Current models of disease progression (i.e. Baveno stages) propose a monotonic progression of portal hypertensive complications starting with ascites; however, clinically many patients present outside this schema. We hypothesize that patients with cirrhosis due to metabolic dysfunction [MASLD], cholangitis [CS], or viral hepatitis [VHEP]) progress slowly, allowing for venous remodeling while cirrhosis due to alcohol [ETOH] increases portal pressure rapidly leading to variceal rupture and/or symptomatic ascites. Here we examine how participants with cirrhosis of various etiologies first decompensate in three large biobanks, the UK Biobank, the All of Us Research Program, and The Michigan Genomics Initiative. **Methods:** Patients were included at time of first cirrhosis diagnosis using ICD codes. We defined decompensation as new diagnosis of ascites, encephalopathy (HE), or bleeding varices (BV) using ICD codes and/or their treatment procedure codes based on validated criteria. We excluded individuals that had decompensation codes before their inclusion date or if they had abnormal albumin, platelets or bilirubin within 12 months prior to inclusion date. To estimate venous remodeling, we used codes for non-bleeding varices (V). We limited our analyses to individuals with a single etiological cause of cirrhosis. We carried out a Fine Gray competing risk analysis in R 4.4.0. **Results:** A total of 3,361 patients were included (AoU n = 1,750, MGI n = 387, UKBB n = 1,124) with a mean follow up of 4.0 years comprising a total of 13,444 person years of follow up. Patients were an average age of 61 years old at cirrhosis diagnosis, 48% female, and 74.1% of European ancestry. Etiology of liver disease was 31.1% ETOH, 39.2% MASLD, 15.0% CS, and 14.7% VHEP. At the end of follow up, 1,035 (30.8%) patients experienced their first decompensation, with ascites in 447 (13.3%), HE in 197 (5.9%), V in 354 (10.5%), and BV in 37 (1.1%). ETOH cirrhosis more commonly presented with ascites and variceal bleeding as first decompensation while patients with CS, MASLD, and VHEP experienced higher early V formation prior to decompensation (Figure). Individuals with ETOH decompensated more than other causes in all categories (all $P < 0.05$). **Conclusion:** Our results suggest that decompensation pattern is influenced by the liver disease etiology. These findings support our hypothesis that rapidly progressing liver diseases like ETOH exceed compensatory venous remodeling to cause ascites and variceal bleeding more than slowly progressive liver diseases (CS, MASLD, VHEP). Future work can examine genetic predictors of venous remodeling to personalize care for patients with portal hypertension.

◆ 2299 | ROTATIONAL THROMBOELASTOMETRY-GUIDED BLOOD COMPONENT ADMINISTRATION VERSUS STANDARD OF CARE IN PATIENTS WITH CIRRHOSIS AND COAGULOPATHY UNDERGOING INVASIVE PROCEDURES (RECIPE): FINAL RESULTS: FROM A MULTI-CENTRE AUSTRALIA-WIDE RANDOMISED CONTROLLED TRIAL (RCT)

Natasha Janko[1] William Kemp[2] Simone Strasser[3] Marcus Robertson[4] Fadak Mohammadi[3] Rohit Sawhney[1] Avik Majumdar[5] Karen Waller[3] Gerry MacQuillan[6] Thomas Goodwin[2] Paul Gow[5] Chris Hogan[5] Harshal Nandurkar[2] Ammar Majeed[2] Stuart Roberts[7], [1]Eastern Health, [2]Alfred Health, [3]Royal Prince Alfred, [4]Peninsula Health, [5]The Austin, [6]Sir Charles Gairdner Hospital, [7]Alfred Hospital

Background: Prophylactic transfusion of blood products remains common before invasive procedures in patients with cirrhosis. We assessed the efficacy and safety of a ROTEM-based algorithm to guide prophylactic transfusions in subjects with cirrhosis and coagulopathy. **Methods:** This single-blinded, multicentre RCT conducted at six Australian sites included adults with cirrhosis and coagulopathy (INR value or platelet count requiring pre-procedural correction as per

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

local practice) scheduled for invasive procedures. Patients were randomized 1:1 to receive ROTEM-guided transfusions or standard of care (SOC) with stratification by bleeding risk (high vs low), INR ($<$/2), and platelet count ($<$/30$\times 10^9$/L). The primary outcome was the proportion of procedures requiring prophylactic blood product transfusion; secondary outcomes included procedure-related bleeding, thrombosis, transfusion-related complications, length of stay and mortality. **Results:** 114 patients were screened with 57 randomised (28 in ROTEM, 29 in SOC). 44 (77%) were high bleeding risk procedures: 13 dental procedures, 10 liver biopsies (7 percutaneous, 3 trans-jugular), 4 other solid organ biopsies, 4 trans-jugular intrahepatic portosystemic shunts, 4 abdominal surgeries, 4 endoscopic or image-guided hepatobiliary procedures, 3 radiological hepatocellular carcinoma treatments, one hip replacement, one muscle biopsy. Baseline demographics, coagulation profile and types of procedures were similar between the two groups. Prophylactic blood products were given before 20 procedures in the ROTEM group compared with 28 in SOC (71% vs. 97%, $p < 0.01$). The median volume of total blood components transfused was significantly lower in the ROTEM compared to SOC group (325 ml *vs.* 570ml, $p = 0.03$). The pattern of blood product usage differed between the groups, with less FFP and more cryoprecipitate given in the ROTEM group compared to SOC (see Table 1). There was no difference in procedure-related bleeding (1 ROTEM *vs.* 2 SOC, $p = 0.60$; no recorded major bleeding), thrombosis, transfusion-related complications, length of stay or mortality between the two groups. **Conclusion:** ROTEM-guided management significantly reduced blood product use in patients with cirrhosis undergoing invasive procedures without increasing bleeding risk or adverse outcomes. Future studies should refine ROTEM thresholds to enhance transfusion efficiency and patient safety.

Table 1. Comparison of blood product prophylaxis between the two groups

	ROTEM	SOC	p-value
Proportion of procedures where prophylaxis given,n (%)			
Any blood product	20 (71)	28 (97)	**0.009**
Fresh frozen plasma (FFP)	8 (29)	19 (66)	**0.005**
Platelets	7 (25)	14 (48)	0.069
Cryoprecipitate	10 (36)	3 (10)	**0.022**
Volume (ml) of prophylactic blood component transfused, median (interquartile range IQR)			
Total blood product	325 (0-570)	570 (285-570)	**0.031**
FFP	0 (0-285)	285 (0-570)	**0.002**
Platelets	0 (0-135)	0 (0-270)	0.133
Cryoprecipitate	0 (0-325)	0 (0-0)	**0.032**

Background: Patients with cirrhosis experience highly variable disease trajectories, and there remains a critical need to identify, at the earliest possible stage, those most likely to progress to liver transplantation. To address this, we constructed a random survival forest algorithm that combines routinely obtained laboratory results with three novel derived metrics—age-normalized enzyme ratios, binary indicators of treatment response, and a unified severity index—to predict transplant-free survival and to surface the most influential prognostic variables. **Methods:** Using a de-identified dataset from a tertiary-care center, we selected adult cirrhosis cases and extracted key variables: age, total bilirubin, serum glutamic–oxaloacetic transaminase, serum albumin, validated comorbidity scores, and recorded treatment histories. We then generated three engineered features: liver enzyme ratios adjusted for patient age; binary flags denoting documented response to therapy; and a composite score reflecting overall disease severity. Missing continuous values were imputed with the mean, and categorical gaps were filled with the mode. The cohort was split 80:20 into training and held-out test sets. A random survival forest of 100 trees was trained using the sksurv package, with hyperparameters (split rule and minimum node size) optimized via five-fold cross-validation. Model performance was evaluated by the concordance index, and risk stratification was visualized through Kaplan–Meier survival curves. Finally, we employed permutation importance to rank the predictors of time until transplant. (Figure 1,2,3,4) **Results:** On the training data, the model achieved a concordance index of 0.94 and maintained strong performance on the test set with a concordance index of 0.82. Permutation analysis identified age, bilirubin levels, and serum glutamic–oxaloacetic transaminase as the three most impactful predictors of transplant risk.

Patients were categorized into low-, intermediate-, and high-risk strata, comprising 29 percent, 37 percent, and 34 percent of the cohort, respectively. Median transplant-free survival times were 2,450 days for the low-risk group, 1,520 days for the intermediate group, and 890 days for the high-risk group. Kaplan–Meier curves for each stratum showed statistically significant separation (log-rank $p < 0.001$), confirming the model's ability to discriminate among risk tiers. **Conclusion:** The proposed random survival forest model delivers high discriminative accuracy in stratifying cirrhosis patients by transplant risk, with clear differences in median transplant-free survival across risk groups (log-rank $p < 0.001$). Integrating engineered features with conventional laboratory measures offers a promising avenue for personalized guidelines on transplant referral timing. Prospective external validation is warranted to establish clinical applicability and generalizability.

◆ 2301 | UNDERSTANDING THE IMPACT OF CIRRHOSIS ETIOLOGY ON RISKS OF COMPLICATION, REGIONAL PATTERNS, AND TRENDS OVER TIME IN THE UNITED STATES

Arun Jesudian[1] Patrick Gagnon-Sanschagrin[2] Rebecca Burne[2] Anaïs Lemyre[2] Nathan Gobeil[2] Kana Yokoji[2] Tom Cornwall[2] Olamide Olujohungbe[3] Annie Guérin[2] Shweta Kiran Shah[3], [1]Weill Cornell Medicine, [2]Analysis Group, Inc., [3]Bausch Health

Background: Cirrhosis often leads to serious complications, with risk and prognosis varying by etiology. Understanding regional and temporal patterns is critical to identifying high-risk populations, guiding care, and informing future public health strategies. **Methods:** This retrospective cohort study using Komodo Research Data (2016-2023) included adults with cirrhosis. Newly diagnosed patients with cirrhosis were followed from an index date – defined as diagnosis onset or earliest complication (ascites, overt hepatic encephalopathy (OHE), varices with/without bleeding) – until the earliest of: end of continuous enrollment, liver transplant, secondary malignant neoplasm of liver, death, or end of data availability. Complications were descriptively reported for all patients and stratified by etiologies (alcohol-associated liver disease [ALD], metabolic dysfunction-associated steatohepatitis [MASH], viral hepatitis, or other/unspecified). Time to first complication after the index date was assessed using Kaplan-Meier methods. The geographic distribution of etiologies was described by U.S. region. Finally, trends in etiology were projected by linear extrapolation of patterns observed from 2017 to 2022 through 2030. **Results:** In total, 110,359 adults with cirrhosis (median age: 60 years; 55.5% male; 56.9% identified as White; median follow-up: 23.5 months) were included in the study. Of those, 34.7% had ALD, 22.8% MASH, 13.8% viral hepatitis, and 28.8% other or unspecified etiologies. Higher prevalence of ALD cirrhosis was observed in Midwest (6.9% above national average, Panel A); viral hepatitis-related cirrhosis in West (24.3% above national average; Panel B), and MASH in the South (8.7% above national average). By 36 months, 62.3% (95% CI: 62.0–62.6) of all patients developed a complication, with the highest rate observed in patients with ALD (84.6%; 95% CI: 84.2–85.0) and the lowest in patients with viral hepatitis (41.5%; 95% CI: 40.7–42.4; Panel C). The first complication observed was most commonly ascites (63.6%), followed by varices without bleeding (27.2%), OHE (14.6%), and varices with bleeding (8.5%; Panel D). Based on trends observed from 2017 to 2022, the proportion of incident cirrhosis attributable to viral hepatitis in 2030 is expected to decline by 78.5% relative to 2023, driven by a steep decline in cases due to hepatitis C. In the same period, the proportion of new cirrhosis cases due to ALD and MASH in 2030 is projected to increase by 12.0% and 17.7%, respectively. **Conclusion:** Cirrhosis etiology is a strong determinant of complication risk, with notable geographic variation across the U.S. The growing prevalence of ALD and MASH etiologies associated with the highest risk suggests a shift toward a more clinically severe cirrhosis population. These findings underscore the need for continued research to understand the evolving burden and its implications for clinical outcomes.

◆ 2302 | METABOLIC AND CARDIOVASCULAR EFFECTS OF ZIBOTENTAN AND DAPAGLIFLOZIN IN PATIENTS WITH CIRRHOSIS: A RANDOMIZED PLACEBO-CONTROLLED 6-WEEK STUDY

Kristin Fiorino[1] phil ambery[1] Jan Oscarsson[1] Lynsey Corless[2] Emma Wijkmark[1] Agata Oruba[1] Eric Lawitz[3], [1]AstraZeneca, [2]Hull University Teaching Hospitals, [3]Texas Liver Institute, University of Texas Health San Antonio

Background: Endothelin-1 is a strong vasoconstrictor linked to intrahepatic vasoconstriction and portal hypertension (PH) in cirrhosis. Endothelin receptor antagonists (ERAs) can potentially lower PH but often cause fluid retention. Sodium-glucose co-transporter 2 inhibitors (SGLT2i) may normalize extracellular water volume. This phase 2b study examined effects of zibotentan (zibo), a selective ERA as monotherapy or combined with dapagliflozin (dapa), a selective SGLT2i, verses placebo (pbo) on different measures of fluid retention and safety biomarkers. **Methods:** Patients with clinically significant PH (CSPH) with compensated or decompensated cirrhosis (MELD <15 and Child Pugh score <10) were randomized to receive 5 mg zibo/10 mg dapa (n = 24), 5 mg zibo (n = 25), or placebo (n = 24) in a 6-week double-blind study. Key measures included body weight, total body water, loop diuretic use, adverse events (AEs) of fluid retention, systolic and diastolic blood pressures (SBP, DBP). Exploratory objectives included changes in eGFR, AST, ALT, MELD score, and liver stiffness. **Results:** Seventy-two treated patients with mean age of 60.8 years, 70.8 % males, 30.6% type 2 diabetes, 30.6% decompensated. Main etiology was alcoholic liver disease (47.2%) or metabolic dysfunction–associated steatotic liver disease (34.7%), with mean MELD and Child-Pugh scores of 8.4 and 5.8, respectively. Comparing zibo/dapa to zibo alone change from baseline over 6 weeks, estimated differences were: body weight -1.72 kg (90% CI: −2.82, −0.62), body fat -1.45 kg (90% CI: -2.48, −0.43), and body water -0.3 L (90% CI: −1.10,0.49). Difference in blood pressure change from baseline for zibo/dapa vs pbo were SBP -11.9 mmHg (90% CI: −17.7, −6.1); DBP-2.5 mmHg (90% CI: −17.7, −6.1). For zibo vs. pbo: SBP -10.8 mmHg (90% CI: −14.1, −7.6), DBP-4.3 mmHg (90% CI: −7.4, −1.1). In both zibo arms, median transaminase reductions were greater (2.5-4.5 U/L) than pbo (-0.5-0 U/L). Most AEs were mild/moderate, the most common being headache. One unrelated case of hepatitis E, 4 SAEs, and 6 subjects withdrew. No observed DILI events. **Conclusion:** Six weeks of treatment with both zibo/dapa and zibo alone were well tolerated, with no significant difference in fluid retention-related events between the active arms. Dapagliflozin may mitigate fluid retention associated with a lower dose of zibo. Both active treatment groups lowered blood pressure and transaminase levels.

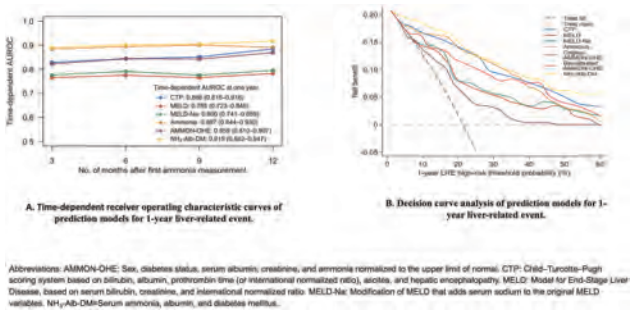
◆ 2303 | DEVELOPMENT OF A NEW MODEL TO PREDICT HOSPITALIZATION FOR LIVER-RELATED EVENTS: THE SOLIDARITY-DAM (DIABETES, ALBUMIN, AMMONIA) SCORE

Gayathry Morvil[1] Pooi Ling Loi[1] Xuan Han Koh[1] Daniel Lim[1] Chin Kimg Tan[1] YU JUN WONG[1] Jessica Tan[1] Andrew Boon Eu Kwek[1] Tiing Leong Ang[1] Marianne De Roza[2] Hiang Keat Tan[3] Chanda Ho[3] Jason Chang[3] Prema Raj Jeyaraj[3] Rahul Kumar[1], [1]Changi General Hospital, [2]Sengkang General Hospital, [3]Singapore General Hospital

Background: Predicting liver-related events (LREs) in cirrhosis is crucial. Traditional scoring models like MELD and CTP perform poorly due to incomplete pathophysiological integration and a shift in the etiological curve towards MASLD. New models, such as AMMON-OHE, are limited to predicting HE and mortality, not LREs. We developed and validated a new DAM (Diabetes, Albumin, aMmonia) model for predicting hospitalisation due to LRE. **Methods:** A total of 280 consecutive patients with cirrhosis were enrolled. Baseline and periodic data were collected on biochemical, clinical, demographic, and radiological parameters. Patients were then followed up prospectively for the primary endpoints, which were a composite of hospitalization within one year for new or worsening ascites, variceal bleeding, HE, or bacterial infection (LRE). Cox proportional hazards regression was used to derive a prognostic index (PI) for 1-year LRE. TRIPOD+AI guidance and decision curve analysis were carried out to interrogate the performance characteristics of competing models. Model discrimination was assessed by estimating the time-dependent area under the receiver operating characteristic curve (AUROC) at 90, 180, 270, and 360 days from study enrolment. **Results:** Most patients were male (60.7%) with a mean age of 66.1 ± 10.3 years. MASLD was the most common etiology (43.7%). Median CTP and MELD were 6 (IQR: 5-7) and 8 (IQR: 6-11). Overall, 60 (21.4%) developed LRE at one year, and 23 (8.2%) died. The PI of DAM for 1-year LRE was PI = 0.0247×ammonia (μmol/L)-0.126×albumin (g/L)+0.755×DM. The model-estimated baseline 1-year LRE-free survival was $\hat{S}_0(1y) = 0.904$. The DAM model outperformed others (AMMON-OHE, CTP, MELD, MELD-Na; Figure 1). AMMON-OHE predicted LRE with a time-dependent AUROC of 0.859 (CI: 0.810-0.907), outperforming MELD ($p = 0.014$) but similar to CTP (p = NS), underestimating LRE. Best prediction for LRE was achieved by the DAM (Diabetes, Albumin, aMmonia) model, yielding an AUROC of 0.915 (CI: 0.882 -0.947) and Brier score of 0.075 (CI: 0.038-0.119). A 1 g/L increase in albumin correlated with a 12% lower hazard of 1-year LRE (HR 0.88, 95% CI 0.85 to 0.92; $P < 0.001$). Patients with DM showed a 2.1 times higher hazard rate for 1-year LRE (HR 2.13, 95% CI 1.25 to 3.63; $P = 0.006$). Each 10 μmol/L rise in ammonia linked to a 28% higher hazard rate of 1-year LRE (HR 1.28, 95% CI 1.19 to 1.38; $P < 0.001$). **Conclusion:** We developed and internally validated a new LRE prediction model, the DAM (Diabetes, Albumin, aMmonia), which outperforms others. External validation is needed.



A. Time-dependent receiver operating characteristic curves of prediction models for 1-year liver-related event.

B. Decision curve analysis of prediction models for 1-year liver-related event.

Abbreviations: AMMON-OHE: Sex, diabetes status, serum albumin, creatinine, and ammonia normalized to the upper limit of normal. CTP: Child–Turcotte–Pugh scoring system based on bilirubin, albumin, prothrombin time (or international normalized ratio), ascites, and hepatic encephalopathy. MELD: Model for End-Stage Liver Disease, based on serum bilirubin, creatinine, and international normalized ratio. MELD-Na: Modification of MELD that adds serum sodium to the original MELD variables. NH_3-Ab-DM=Serum ammonia, albumin, and diabetes mellitus.

◆ 2304 | THE HEPATORENAL HIT: NATIONWIDE TRENDS IN CHRONIC LIVER DISEASE AND ACUTE KIDNEY INJURY RELATED MORTALITY IN THE U.S. (1999–2023)

Simran Joshi[1] MANJEET GOYAL[2] Muhammad Faizan Ali[3] Husnain Ahmad[4] Susan Feldman[5] Muhammad Khan[6] Muhammad Rahim[4] Salman Attari[7] Sherif Eltawansy[8] Saman Javid[9] Preethi Jagannath[10] Mayssaa Hoteit[11], [1]Yale New Haven Health/Yale University School of Medicine, [2]Cleveland Clinic Akron General, [3]Jinnah Postgraduate Medical Center, [4]Shalamar Medical and Dental College, [5]University of South Carolina/ Prisma health, [6]Bacha Khan Medical College, [7]Asian Institute of Medical Sciences, [8]Jersey Shore University Medical Center, [9]CMH Kharian Medical College, [10]Mayo Clinic Arizona, [11]Yale New Haven Heath/Yale University School of Medicine

Background: Chronic Liver Disease (CLD) remains a major cause of morbidity and mortality in the United States, often progressing to advanced stages with systemic complications. Among these, Acute Kidney Injury (AKI) is a frequent and serious complication, markedly increasing the risk of in-hospital mortality and adverse outcomes in CLD patients. Despite its clinical significance, national trends in mortality associated with comorbid CLD and AKI have not been well characterized. This study examines 25-year trends in CLD and AKI–related mortality among U.S. adults, with a focus on demographic and regional disparities. **Methods:** Mortality data from the CDC WONDER database (1999–2023) were analyzed using Joinpoint regression to assess CLD and AKI-related deaths among U.S. adults aged 25 and older. Age-adjusted mortality rates (AAMRs) per million were calculated, along with the average annual percent change (AAPC) and corresponding 95% confidence intervals (CI). **Results:** AKI among individuals with CLD accounted for 104,609 deaths in adults aged 25 years and older. Between 1999 and 2023, the overall AAMR surged from 0.79 to 4.26 with an AAPC of 7.79 (95% CI 7.17- 8.5, $p < 0.000001$). Males consistently exhibited higher mortality rates than females (AAMR; 2.34 vs 1.27) however, the trajectory of increase was steeper in females (AAPC: 8.75; 95% CI 8.11- 9.55) as compared to males (AAPC: 7.07; 95% CI 6.42- 7.85) both with $p < 0.000001$). Among the racial groups, American Indian or Alaska Native (AI/AN) had the highest AAMR (6.74) followed by Hispanics (2.60), Non-Hispanic (NH) White (1.70) and NH Black individuals (1.66). NH Asian had the lowest mortality among all races (AAMR; 0.93). AI/AN experienced the sharpest rise (AAPC: 8.901; 95% CI 7.53- 10.87), followed by White population (AAPC: 8.42 95% CI 7.81- 9.19), Asians (AAPC: 5.91; 95% CI 0.64- 11.83), Hispanics (AAPC: 5.88; 95% CI 5.17- 6.72), Blacks (AAPC: 5.61; 95% CI 4.93- 6.43) and NH Asians (AAPC: 3.11; 95% CI 1.74- 4.86). The Midwest experienced the highest increase in mortality (AAPC: 7.98; 95% CI: 7.23–8.91), followed by the West (7.96), South (7.75), and Northeast (5.84). States with the highest AAMRs were Oklahoma (12.04), New Mexico (9.09), and South Dakota (8.70). Rural areas had higher AAMRs than urban areas (1.55 vs. 1.51) and a steeper rise in mortality (AAPC: 7.07 vs. 5.03). Individuals aged ≥ 75 had the highest mortality (AAMR: 3.52), followed by those aged 45–74 (2.70), and < 45 (0.53). However, the sharpest increase was in the younger population (AAPC: 8.81), followed by older (7.69) and middle-aged adults (7.29). **Conclusion:** CLD and AKI-related mortality has escalated over the past 25 years with the most notable increases observed in AI/AN, females, Whites, young adults, rural areas and in the Midwest region. These disparities emphasize the urgent need for targeted intervention and care to address the growing mortality burden, especially among vulnerable populations

◆ 2305 | STAGE-SPECIFIC DRIVERS OF CLINICAL PROGRESSION IN ADVANCED CHRONIC LIVER DISEASE

Benedikt Simbrunner[1] Georg Semmler[1] Marta Bofill Roig[1] Elias Meyer[1] Lorenz Balcar[1] Mathias Jachs[1] Lukas Hartl[1] Benedikt Hofer[1] Georg Kramer[1] Paul Thoene[1] Christian Sebesta[1] Nina Dominik[1] Bernhard Scheiner[1] Philipp Schwabl[1] Albert Stättermayer[1] Michael Trauner[1] Thomas Reiberger[1] Mattias Mandorfer[1], [1]Medical University of Vienna

Background: Different pathophysiological mechanisms contribute to the progression of advanced chronic liver disease (ACLD). We investigated the clinical trajectory of ACLD in a contemporary cohort and evaluated biomarkers reflecting key pathophysiological mechanisms for their stage-specific prognostic value. **Methods:** We prospectively recruited 464 ACLD patients at hepatic venous pressure gradient (HVPG) measurement between 2017 and 2021 (VICIS; NCT03267615; see figure, panel 1). Clinical states at baseline and follow-up were defined as compensated ACLD (cACLD), first decompensation, further decompensation/ACLF (acute-on-chronic liver failure; combined), liver-related death (LRD), and recompensation (see figure, panel 2). Multistate modeling was used to investigate the risk of stage transitions during follow-up (median: 29 months). The association of biomarkers for portal hypertension (HVPG), endothelial dysfunction (VWF), liver fibrogenesis (ELF), liver function (MELD/albumin/bile acids), systemic inflammation (CRP/IL-6/procalcitonin), and circulatory dysfunction (proBNP/copeptin) with stage transitions was evaluated. **Results:** In cACLD, 12% developed first decompensation at 24 months, 3.2% further decompensation/ACLF, 2.1% LRD; and 1.1% recompensation after decompensation (see figure, panel 3). In decompensated cirrhosis, 19% developed further decompensation/ACLF, 6.3% LRD while 8.8% achieved recompensation. Among patients with further decompensation at baseline, 33% experienced LRD and 3.0% recompensation at 12 months.

Portal hypertension, endothelial dysfunction, fibrogenesis, and liver function were indicative of progression in cACLD, shifting towards SI and liver function in decompensated cirrhosis, with the additional contribution of circulatory dysfunction in further decompensation (see figure, panel 4). HVPG and albumin provided independent prognostic information in cACLD, CRP in decompensated cirrhosis, and copeptin in further decompensation. **Conclusion:** Targeting PH should be prioritized in cACLD, while modulating systemic inflammation and circulatory dysfunction is crucial for preventing disease progression in decompensated cirrhosis. Precision medicine based on individual biomarker profiles could optimize patient outcomes in future clinical trials.

2306 | IMPAIRED COGNITION AND A HISTORY OF HEPATIC ENCEPHALOPATHY ARE ASSOCIATED WITH DISORDERED SLEEP AS MEASURED BY SHORT TERM MONITORING WITH COMMERCIAL WEARABLE TECHNOLOGY

Jessica Siguencia[1] Ziyu Liu[1] Brian McSteen[1] Olivia Blocker[1] Jialin Gao[1] Avesh Thuluvath[2] Elizabeth Verna[2] Ana Krieger[1] Himel Mallick[1] Robert Brown[1] Adam Buckholz[1], [1]Weill Cornell Medicine, [2]Columbia University Irving Medical Center

Background: Hepatic encephalopathy (HE) is common in cirrhosis but is often difficult to diagnose and assess longitudinally due to its dynamic nature and the subjective nature of gold standard cognitive assessment tools. Patients with both covert (CHE) and overt (OHE) HE often report disturbed sleep. We hypothesized that cognitive impairment and/or HE would be associated with objectively worse measured sleep when tracked by a commercial wearable device. **Methods:** We enrolled patients with cirrhosis and longitudinally monitored sleep for 6 months. For this study, we included participants with complete baseline cognitive assessment by Psychometric Hepatic Encephalopathy Score (PHES) and sleep data for at least 14/28 days after enrollment, analyzing the first 14 consecutive days recorded per participant. A PHES $\leq$ -4 was considered abnormal cognition. Primary comparison groups were those with vs. without impaired cognition at baseline, and those with a history of OHE or therapy for HE at enrollment compared to those without. Assessed sleep metrics included total sleep time, REM sleep duration, sleep efficiency (%SE), time in bed/time in bed variability and sleep midpoint/midpoint variability. A mixed effects model (MEM), log transformed where applicable, assessed outcomes, with primary analysis adjusting for age, gender, BMI and MELD. **Results:** Of 117 participants, 81 met adherence criteria, with 1134 baseline sleep nights analyzed. Patients with impaired cognition at enrollment had significantly reduced nightly time in bed (463 vs 495 min, $p = 0.01$) and REM sleep (64.4 vs 81.4 min, $p = 0.01$) (A, B). In MEM adjusted for age, gender, BMI, and MELD score, the association remained significant for both reduced time in bed ($\beta =$ -.594, $p = 0.01$) and REM ($\beta =$ -14.1, $p = 0.03$). Measured %SE was similar between groups. There was no difference in nightly REM time among those with a history of OHE compared to those without. In the adjusted MEM, sleep midpoint was numerically later in those with compared to without OHE history (4:21 vs 4:51, $p = 0.07$) (C), but there was significantly higher variability in sleep midpoint in those with prior OHE ($\beta = 0.25$, $p < 0.001$). In a subgroup analysis including only those with normal baseline cognition, there remained increased midpoint variability among those with a history of OHE compared to those without ($\beta = 0.19$, $p = 0.003$) (D). **Conclusion:** In cirrhosis, impaired cognition at baseline was associated with reduced REM and nightly time in bed, while a history of diagnosed encephalopathy, even if treated or covert, was associated with increased variation in sleep midpoint. A stable sleep midpoint is a marker of circadian health, and high variation has been associated with circadian rhythm dysfunction. Reduced REM may be more associated with sleep physiology or fragmentation. Further studies developing sleep as a biomarker and circadian dysfunction as a therapeutic target for HE should be considered.

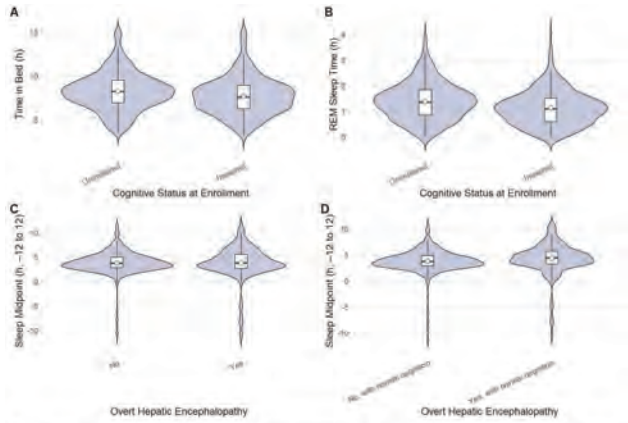

Figure. Violin plots showing distribution of analyzed nights and reduced measured time in bed **(A)** and REM sleep duration **(B)** among those with impaired cognition (CHE or OHE) at enrollment. Additionally, violin plots demonstrating distribution of sleep measured sleep midpoint, which showed higher variability among those with any history of overt hepatic encephalopathy **(C)**, even among those with normal enrollment cognition **(D)**. All differences were significant at p<0.01.

2307 | GROWTH HORMONE AS A DISEASE-MODIFYING THERAPY IN CIRRHOSIS: INTEGRATING MUSCLE, LIVER, AND IMMUNE AXIS REPAIR

Parminder Kaur[1] Nipun Verma[2] Pratibha Garg[3] Pinaki Dutta[2] Gaurav Sharma[2] Naveen Kalra[2] Sunil Taneja[2] Ajay Duseja[3] Virendra Singh[4], [1]Post Graduate Institute of Medical education and Research, [2]Post Graduate Institute of Medical Education and Research, Chandigarh, India, [3]Postgraduate Institute of Medical Education & Research, [4]Punjab Institute of Liver and Biliary Sciences, Mohali, Punjab, India

Background: Perturbed growth hormone (GH) - insulin-like growth factor (IGF-1) axis is linked to complications and mortality in cirrhosis. We evaluated the impact of GH therapy on complication-free survival (CFS), malnutrition, neutrophil function, and hepatic regeneration in patients with decompensated cirrhosis (DC). **Methods:** In a single-centre, parallel-group, open-label trial, 92 DC patients were randomized to standard medical therapy (Group A: SMT) (n = 46) or GH+SMT (Group B) (n = 46). GH was administered subcutaneously daily at 2 IU/day for 12 months, with dosing titration based on IGF-1 levels. Primary end point was CFS. Secondary end points were assessment of GH-IGF1 (by CLIA), malnutrition (muscle mass – CT-SMI, muscle function – handgrip strength), hepatic growth factors (hepatocyte growth factor: HGF, augmenter of liver regeneration: ALR - ELISA), and cell death makers (apoptosis: M30, total cell death: M65 – ELISA), neutrophil function (oxidative burst – ROS production and phagocytic capacity – flow cytometry). Patients achieving normal IGF-1 levels were classified as IGF-1 responders. Causal tree analysis was used to identify subgroups with maximum benefit. **Results:** Median age of patients was comparable (50.0 vs 45.5, p = 0.600) and 96.7% were males. Median MELD score was comparable in both (14.7 vs 14.8, p = 0.685). GH+SMT significantly improved 12-month CFS (HR: 0.58, p = 0.035; RR: 0.69, p = 0.021; NNT = 4.2) with a stronger effect in the per-protocol (HR: 0.46, p = 0.007) and IGF-1 responders (HR: 0.18, p = 0.001). Overall survival was better in per-protocol (HR:0.19, p = 0.027). Incidence of ACLF significantly reduced in GH+SMT comapred to SMT (2.4% vs 22.3%, p = 0.004). MELD score improved significantly in only GH+SMT (p = 0.015). IGF-1 levels (%ΔIGF-1: 79.3 vs 0.0, p < 0.001), muscle mass (%ΔSMI: 11.8 vs 1.2, p = 0.006), muscle strength (%ΔHGS: 4.8 vs 0.0, p = 0.017), frailty (%ΔLFI: –7.0 vs –0.2, p = 0.001) improved significantly along with reduction in circulating myostatin levels (%Δ: –27.8 vs –8.8, p < 0.001). Hepatic growth factor levels increased (%ΔHGF: 7.5 vs 1.2; ALR: 32.8 vs 5.2, p < 0.05 both), alongside reduced cell death markers (M30: –17.7 vs –11.6, p = 0.026; M65: –25.4 vs –14.0, p < 0.05 both). Neutrophil function improved with reduced resting ROS (%Δ: –56.1 vs 5.1, p = 0.009) and enhanced phagocytosis (%Δ: 35.2 vs –6.6, p = 0.03); with trend in oxidative index (%Δ: 14.6 vs –16.3, p = 0.179). No significant changes were observed in SMT. No HCC or grade ≥ 3 adverse events occurred with GH. Best treatment benefit was observed in patients with MELD < 16 and IGF-1 < 54, and albumin ≥ 3.7. **Conclusion:** GH therapy is a novel, multimodal, disease-modifying strategy that reduces the risk of ACLF and complications in cirrhosis, acting through improvements in muscle mass, immune function, and liver regeneration. Further studies are needed to optimise GH administration, enhance IGF-1 response, and validate multimodal improvement in cirrhosis.

2308 | DYNAMIC HEPATIC SEGMENTAL NETWORKS: A NOVEL IMAGING EARLY-WARNING SYSTEM FOR CIRRHOSIS DECOMPENSATION

Wang Zixing[1], [1]Peking University People's Hospital

Background: Alterations in inter-segmental communication networks – driven by fibrotic bridging, vascular shunting, and metabolic dysfunction – serve as latent biomarkers for impending cirrhotic decompensation. However, the dynamic hepatic connectomes and its role in signaling decompensation remain unexplored. **Methods:** Study Cohort □Inclusion: Cirrhotic patients (with/without HCC) from our medical center (2022–2025) undergoing gadoxetic acid-enhanced upper abdominal MRI with ≥5 imaging phases (non-contrast, arterial, portal venous, equilibrium, delayed). □Exclusion: Poor image quality, honeycombing, macrocysts/large masses, uncorrected inter-sequence misalignment. □Study outcome: Cirrhosis decompensation (including ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, variceal bleeding, sepsis, hepatorenal syndrome, jaundice, or other clinically determined decompensation events, whichever occurs first). Imaging Acquisition Dynamic contrast-enhanced T1-weighted MRI using a GE Discovery 750 3.0T or Siemens Prisma 3.0T scanner with standardized axial acquisition (FOV = 38 cm), performed prior to and following intravenous injection of 0.1–0.2 mL/kg gadoxetic acid disodium (Bayer AG, Germany). Hepatic Segmental Division Liver partitioned into 8 segments (I-VIII, Couinaud classification). Representative slices: □Upper hepatic level: Middle/right hepatic veins (or fissures if veins indistinct), ensuring analyzable Segment I. □Splenic vein level: Right portal vein branch as reference if indistinct. □All sequences registered to portal venous phase (Phase 2) with manual correction when needed. MR Feature Quantification □ROI selection: Circular ROIs placed centrally in Segments I–VIII, avoiding vessels and lesions □Feature extraction: 837 radiomic features per segment extracted via PyRadiomics (first-order, GLCM, GLDM, GLSZM, NGTDM, wavelet features). □Feature screening: Phase 2 average values across segments showed both statistical and clinical differences between compensation and decompensation states, leading to their selection for network construction. Dynamic Network Analysis □Network construction: Sliding window (window size = 3 phases) applied to build topological networks. Inter-segmental connectivity quantified by Pearson correlation, with sparsity controlled at 0.2. □Network metrics: Small-worldness (sigma, clustering, path length), modularity, hub distribution, nodal centrality (degree, strength, betweenness, closeness, eigenvector). Clinical Value Evaluation Patients stratified into low/medium/high-risk groups by network features. Decompensation prediction assessed via Cox regression (Hazard Ratios, HRs). **Results:** Limited Predictive Value of Aggregate Radiomics Among 426 scans (224 [52.6%] pre-decompensation ≥30 days), only 2/837 average features across Segments I-VIII showed clinically (|fold change| > 2.5) and statistically significant differences between decompensation and compensation states. This underscores the critical need to account for spatial heterogeneity and segmental interactions. Inter-Segmental Network Remodeling in Decompensation Significant network reorganization was observed in decompensated compared to compensated livers within the arterial-portal venous-equilibrium window. This included an increase in modularity (indicating functional fragmentation: 0.066 vs. 0.038), sigma (reflecting heightened randomness: 1.514 vs. 1.434), and a decrease in path length (suggesting impaired information transfer efficiency: 0.786 vs. 0.818); all $P < 0.05$. Decentralization of Hub Nodes Signifies Hepatic Network Instability Segment V dominated the liver network in compensation (20% hub prevalence, consistent with its anatomical centrality). Decompensation triggered hub redistribution: Peripheral Segments II-V & VII-VIII: 12–15%; Marginal Segments I & VI: 8–10%. This indicate collapse of compensatory network. Segment I Centrality as an Effective Risk Gauge The betweenness centrality of Segment I (measure of its information-bridging role) predicted decompensation risk: 18.2%, 54.2%, and 83.3% in low, medium and high risk stratus, respectively. High-risk groups showed significantly elevated HRs for onset of ascites, hepatic encephalopathy and variceal bleeding; all $P < 0.05$. The findings were robust in sensitivity analyses (demographics and scanner-independent). **Conclusion:** This study pioneers a dynamic network paradigm for cirrhosis prognostication, shifting from isolated segmental biomarkers to system-level monitoring. The arterial-portal-equilibrium phase offers a critical window for detecting connectome-driven decompensation signals, with Segment I centrality emerging as a clinically important predictor.

2309 | REAL-WORLD TREATMENT PATTERNS AND UTILIZATION OF ALBUMIN AMONG PATIENTS WITH CIRRHOSIS AND ASCITES IN THE UNITED STATES

Cristina Coll-Ortega[1] Rahul Rajkumar[2] Thomas Ardiles[3] Peter Nelson[3] Jonathan Lilley[2] Apeksha Shenoy[2] Miquel Barceló[1] Dermot Whyms[4] Fiona McCarthy[4] Elisabet Viayna[1], [1]Grifols, Sant Cugat del Vallès, Spain, [2]Boston Strategic Partners, Inc., Boston, MA, USA, [3]Grifols, Shared Services North America, Research

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Triangle Park, NC, [4]Grifols Worldwide Operations Ltd, Dublin, Ireland

Background: Decreases in serum albumin play a central role in the development and worsening of several complications of decompensated cirrhosis, including ascites, spontaneous bacterial peritonitis (SBP), and hepatorenal syndrome-acute kidney injury (HRS-AKI). Human albumin (HA) infusions are commonly used in accordance with clinical guidelines—for example, after large-volume paracentesis (LVP), alongside antibiotics for SBP, or in combination with vasoconstrictors for HRS-AKI. However, patterns of HA use beyond these established indications remain poorly characterized. This study evaluates HA utilization among patients with decompensated cirrhosis and ascites in the United States. **Methods:** US adult patients with ICD-10-coded cirrhosis and concurrent ascites (loop or potassium-sparing diuretic use) who received ≥1 albumin infusion between Jan 2021–Dec 2023 were identified in the TriNetX database. Demographics, clinical characteristics, and treatment patterns (dosing, setting, and frequency) were examined, including the use of HA for cirrhosis-related complications in alignment with AASLD guidelines and international expert consensus. **Results:** A total of 18,937 adult patients were identified, with a median age of 59.0 years (IQR 49.0, 67.0) and 56.7% male. Alcohol-associated liver disease was the most common etiology of cirrhosis (65.0%). The median Charlson Comorbidity Index was 4.0 (IQR 3.0, 6.0). At identification (index of ascites diagnosis or diuretic receipt), patients had a MELD-3 score of 20.0 (IQR 15.0, 26.0) and a Child-Pugh score of 9.0 (IQR 8.0, 11.0). HA was administered primarily in the inpatient setting (90.8%), predominantly for LVP for ascites (59.0%), HRS-AKI (60.6%), and SBP (16.4%). Among patients with available dosing data (n = 5,562), the median per-encounter average albumin dose was 1.8 g/kg (IQR 0.6, 5.5) overall. Over 75% of patients received the vast majority of infusions (≥80%) acutely in a single care setting (inpatient or outpatient). HA use beyond AASLD guideline-recommended indications (e.g., LVP, SBP, or HRS-AKI), was less frequent. **Conclusion:** This real-world study highlights that HA use in the US remains largely acute and confined to inpatient care, primarily for guideline-based indications such as LVP, HRS-AKI, and SBP. Use across care settings was highly siloed, with minimal continuity into the outpatient setting, and limited adoption beyond well-established indications.

Table 1: Use of albumin across cirrhosis-related complications/events and infusion-related characteristics by care setting

Treatment Characteristics	Overall Cohort (N = 18,937)	Inpatient Setting[a] (N = 17,195)	Outpatient Setting[b] (N = 5,129)
Albumin use for complications/events based on both AASLD guidelines and international expert consensus			
Large-volume paracentesis (LVP), n (%)	11,564 (61.2%)	10,150 (59.0%)	3,693 (72.0%)
Hepatorenal syndrome-Acute kidney injury (HRS-AKI), n (%)	10,485 (55.4%)	10,413 (60.6%)	235 (4.6%)
Spontaneous bacterial peritonitis (SBP), n (%)	2,840 (15.0%)	2,813 (16.4%)	67 (1.3%)
Albumin use beyond guideline-based indications			
Hepatic encephalopathy (HE), n (%)	4,626 (24.4%)	4,525 (26.3%)	213 (4.2%)
Hyponatremia, n (%)	13,573 (71.7%)	13,256 (77.1%)	1,010 (19.7%)
Septic shock, n (%)	3,146 (16.6%)	3,129 (18.2%)	21 (0.4%)

2310 | HEPATIC RECOMPENSATION AND PREDICTIVE FACTORS AFTER EUS-GUIDED THERAPY OR TIPS IN PATIENTS WITH DECOMPENSATED CIRRHOSIS

Chenyue Zhang[1] You Deng[1] Weina Lu[2] Xinyan Zhao[1] Yu Wang[1] Peng Li[3] Jidong Jia[1] Junxiong Wang[3] Fuliang He[1], [1]Liver Research Center, Beijing Friendship Hospital, Capital Medical University, [2]Center of Liver Disease, Shijiazhuang fifth hospital, Shijiazhuang, China, [3]Department of Gastroenterology, Beijing Friendship Hospital, Capital Medical University

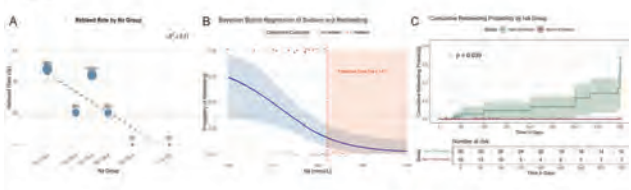
Background: Gastric fundus variceal bleeding (GFVB) is a life-threatening complication of portal hypertension and a major trigger of acute decompensation in cirrhosis. Both endoscopic ultrasound (EUS)-guided therapy and transjugular intrahepatic portosystemic shunt (TIPS) are effective for hemorrhage control, although each carries distinct risks and clinical implications. Hepatic recompensation, defined as a state of clinical and biochemical recovery, has emerged as a meaningful therapeutic endpoint. However, the long-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

term rates of recompensation following EUS or TIPS remain unclear in patients with prior decompensation. Identifying real-world outcomes and potential predictors of recompensation may inform individualized secondary prevention strategies. **Methods:** We conducted a retrospective single-center study including 119 cirrhotic patients with at least one episode of GFVB and evidence of hepatic decompensation, treated between December 2017 and October 2024. Patients received either EUS-guided therapy (n = 56) or TIPS (n = 63). Hepatic recompensation was defined as the absence of decompensating events within one year. We compared recompensation rates and changes in liver function parameters between groups. Given the high rebleeding rate in the EUS group (26.8%, 15/56) and the high incidence of hepatic encephalopathy (HE) in the TIPS group (36.5%, 23/63), we performed univariate and multivariate logistic regression to identify risk factors. Binomial Curve and restricted cubic spline modeling were used to explore the optimal threshold of serum sodium. **Results:** At baseline, patients in the TIPS group had higher proportions of Child-Pugh class B/C (74.6% 47/63 vs. 42.9% 24/56, $p = 0.001$), portal vein thrombosis (61.9% 39/63 vs. 23.2% 14/56, $p < 0.001$), and ≥ 3 prior bleeding episodes (61.9% 39/63 vs. 14.3% 8/56, $p < 0.001$). Hepatic recompensation was achieved in 68% (81/119) of the overall cohort, with no significant difference between groups (EUS 67.9% 38/56 vs. TIPS 68.3% 43/63, $p > 0.999$). After a median follow-up period of 18.5 months (IQR 6–24), TIPS patients showed significantly higher total bilirubin (40.1 vs. 18.8 μmol/L, $p < 0.0001$), lower albumin (31.2 vs. 31.7g/L, $p < 0.0001$), and worsened Child-Pugh scores (median 8 vs. 7, $p < 0.001$). In the EUS group, no significant changes were observed in total bilirubin or Child-Pugh score ($p > 0.05$), while albumin levels improved significantly (from 32 to 33.8 g/L, $p = 0.005$). No independent predictors of HE were identified in the TIPS group. In contrast, in the EUS group, serum sodium emerged as an independent predictor of rebleeding. Sodium levels ≥ 141 mmol/L were associated with a significantly lower rebleeding risk [OR(95% CI): 0.82 (0.66–0.98), p = 0.041]. **Conclusion:** Both EUS and TIPS led to high rates of hepatic recompensation in GFVB. In the EUS group, higher serum sodium independently predicted lower rebleeding risk, Na 141 is a good cut-off.

Figure 1



(A) bubble plot demonstrated a strong linear correlation (R^2=0.71); (B) analysis confirmed a non-linear relationship; (C) Stratified analysis revealed a threshold effect at 141 mmol/L, with significantly lower cumulative rebleeding rates over 2 years in the ≥141 mmol/L subgroup (log-rank p=0.039)

2311 | CONTEMPORARY NATURAL HISTORY OF COMPENSATED CIRRHOSIS: RESULTS: FROM THE POPULATION-BASED INDIANA CIRRHOSIS COHORT

Maaz Arif[1] Eric Orman[1] Lauren Nephew[1] Marwan Ghabril[1] LaKeisha Boyd[1] Yang Li[1] James Slaven[1] Naga Chalasani[1] Archita Desai[1], [1]Indiana University

Background: Contemporary real-world data on longitudinal trajectories of decompensation in patients with cirrhosis are lacking. We investigated a statewide cohort to characterize the contemporary natural history of patients with compensated cirrhosis. **Methods:** The Indiana Cirrhosis Cohort (ICC) was constructed digitally using the Indiana Network for Patient Care, a well-recognized, statewide health information exchange with manual validation of cirrhosis diagnosis. The ICC consists of 13,264 adults diagnosed with cirrhosis between 2018 and 2020; of whom 10,398 had compensated cirrhosis (study cohort). Baseline demographics, comorbidities, and cirrhosis-related characteristics were extracted. Outcomes were initial decompensation event [IDE: ascites, hepatic encephalopathy (HE), variceal bleeding (VB), or multiple concurrent events (MCE; 2+ events occurring within 30days)], hepatocellular carcinoma (HCC), liver transplant (LT), and death. Kaplan–Meier and log-rank tests assessed LT-free survival (TFS); multivariable logistic regression identified predictors of IDE. **Results:** The study cohort is described in the Figure. The median age was 61 years (IQR:53-68), 51% were male, and 86% were White. The most common etiologies were MASH (33%), viral hepatitis (25%), and alcohol-related liver disease (ALD, 21%). Baseline median MELD3.0 score was 11 (IQR:9 – 16). IDE or HCC occurred in 43% (n = 4,496) during a median follow-up of 4.4 years (IQR:2.7-5.8). Initial event was ascites in 34% (n = 1,515), HE in 34% (n = 1,531), MCE in 16% (n = 719), HCC in 12% (n = 550) and VB in 4% (n = 181). Time to IDE was 1.7 to 1.9 years from cirrhosis diagnosis. In a model fitted with age, sex, race, insurance, etiology, alcohol use disorder, and a categorical MELD 3.0 score, modeled as a binary variable (≥ 15 vs. < 15), an event was more likely in males vs. females (aOR 1.10, p = .02), in those with ALD vs. MASH (aOR 2.45, p < .001), and those with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

MELD3.0 ≥ 15 vs. < 15 (aOR 1.41, p < .001). Comorbid conditions were not significantly associated with decompensation/HCC. After IDE or HCC, median TFS ranged from 1.35 years (HCC) and 1.61 years (MCE) to 3.56 years (VB) and significantly differed by first event type on all pairwise comparisons, except between HCC and MCE (*log-rank* $p < 0.05$; Figure). **Conclusion:** In this contemporary, real-world cirrhosis cohort, decompensation or HCC occurs frequently within 3–5 years of initial diagnosis, with risk factors extending beyond MELD 3.0. The first decompensating event is not merely descriptive—it is prognostic, with outcomes shaped by both event phenotype and concurrent presentations, reinforcing the need for a dynamic model of cirrhosis progression, early risk stratification, and individualized care.

Variables	Study Cohort (N=10,398)

2312 | COMPARISON OF STANDARD-DOSE REPEATED BOLUS INJECTION VS. LOW-DOSE CONTINUOUS INTRAVENOUS INFUSION OF TERLIPRESSIN FOR ACUTE ESOPHAGEAL VARICEAL BLEEDING IN PATIENTS WITH LIVER CIRRHOSIS: A PROSPECTIVE MULTICENTER RANDOMIZED TRIAL

Hyung Joon Yim[1] Seong Hee Kang[1] Taehyung Kim[2] Moon Young Kim[3] Seul Ki Han[3] Yeon Seok Seo[2] Sun Young Yim[2] sang gyune kim[4] Seong Kyun Na[5] Hanah Lee[6] Eileen Yoon[7] Jae Young Jang[8] Young-Sun Lee[9] Young Kul Jung[1] Ji Hoon Kim[9], [1]Korea University Ansan Hospital, [2]Korea University Anam Hospital, [3]Yonsei University Wonju Severance Hospital, [4]Soon Chun Hyang University Bucheon Hospital, [5]Inje University Sangye Paik Hospital, [6]Chung Ang University Hospital, [7]Hangyang University Hospital, [8]Soon Chun Hyang University Seoul Hospital, [9]Korea University Guro Hospital

Background: Acute esophageal variceal bleeding (AVB) is one of the most serious complications of liver cirrhosis. For the emergent management of variceal bleeding, administration of a vasoconstrictor is essential for hemostasis together with endoscopic variceal ligation (EVL). Standard-dose repeated bolus injection (SDRBI) of terlipressin 4-6 times daily is most widely employed before and after EVL, but the adverse effects of terlipressin cannot be overlooked. To minimize the ischemic side effect, low-dose continuous infusion (LDCI) of terlipressin has been proposed for hepatorenal syndrome in patients with liver cirrhosis. However, data from prospective comparisons between the two methods for AVB are sparse. This study aims to compare the safety and efficacy of the two methods for the management of AVB. **Methods:** This study is a randomized controlled trial to compare SDRBI and LDCI of terlipressin in patients with AVB. A total of 125 patients were enrolled and randomly assigned to the SDRBI group (n = 63, 1 mg bolus injection every 6 hours after initial 2 mg of terlipressin) or LDCI group (n = 62, 2 mg/day of terlipressin infusion) after EVL. Patients with gastric varices on the fundus, failure of initial endoscopic therapy, or advanced hepatocellular carcinoma were excluded. **Results:** The baseline characteristics of the patients were not significantly different. Re-bleeding incidence after initial successful EVL was observed for 5 days. The success rate of maintaining hemostasis was 98.4% in both groups (Crude odd ratio = 0.98 [0.06-6.09], P = 0.991). One patient died in the SDRBI group. Decrease of Hb more than 3 g/dL or adjusted blood requirement index over 0.75 to maintain Hb > 8.0 g/dL were observed in 7 patients (11.1%) in the SDRBI and 9 (14.5%) in the LDCI group (P = 0.763), respectively, without newly developed hematemesis or melena. The overall incidence of gastrointestinal, cardiovascular, metabolic, or neurologic adverse events was significantly higher in the SDRBI group than in the LDCI group during 5 days (P < 0.05). **Conclusion:** Compared with SDRBI, LDCI of terlipressin shows comparable efficacy and better safety for managing AVB in patients with liver cirrhosis.

2313 | OUTCOMES OF TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS) CREATION PRIOR TO SURGERY IN PATIENTS WITH CIRRHOSIS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Archit Garg[1] Mehak Bassi[1] Aashi Garg[2] Aadhithyaraman Santharaman[1] Abhishek Chouthai[1] Marcella Pimpinelli[1] umesh bhagat[3] Arkady Broder[1], [1]Saint Peter's University Hospital, [2]Boston University School of Public Health, [3]Cleveland Clinic, Cleveland

Background: Patients with cirrhosis undergoing surgery have higher rates of morbidity and mortality. Transjugular intrahepatic portosystemic shunt (TIPS) placement prior to surgery has shown favorable postoperative outcomes. The objective of our study was to compare the outcomes of TIPS versus no TIPS prior to surgery in cirrhotic patients. **Methods:** e searched multiple databases including Medline, Web of Science, Cochrane Library, Pubmed, Embase and conference proceedings from inception through November 2024 for articles reporting outcomes of TIPS vs no TIPS in cirrhotic patients undergoing surgical intervention. We studied liver failure, hepatic encephalopathy, postoperative ascites, mortality rates and blood transfusion requirements. Standard meta-analysis methods were employed using the random-effects model, and heterogeneity was studied by I2 statistics. **Results:** We analyzed 7 retrospective studies involving 561 subjects. 255 patients (70.56% males and mean age 58.13 years) in the TIPS group and 306 subjects (67.32% males and mean age 62.57 years) in the TIPS group. Postoperative ascites was significantly lower in TIPS group, 53.1% [CI 41.2-65.0%; I2 = 0.0%] compared to no TIPS group, 89.4% [CI 55.1-123.8%; I2 = 80.7%] with RR 0.46 [0.26-0.81; p 0.023]. TIPS were associated with lower incidence of hepatic encephalopathy, 49.0% [CI 38.9-59.1%; I2 = 15.0%] compared to no TIPS 58.3% [CI 38.9-77.8%; I2 = 73.9%]; RR 0.72 [0.56-0.93; p 0.022]. The pooled rate of liver failure was 40.9% [CI 34.9-46.8%; I2 = 0.0%] in TIPS group and 47.8% [10.3-85.3%; I2 = 84.1%] in no TIPS group with RR 0.52 [0.25-01.09; p 0.068]. The infection rates were comparable between the two groups, 7.3% [CI 41.6-73.0%; I2 = 62.6%] with TIPS and 58.3% [CI 38.9-77.8%; I2 = 73.9%] with no TIPS; RR 0.87 [0.40-1.89; p 0.673]. Intraoperative blood transfusion requirement was 53% [CI 42.6-63.5%; I2 = 6.6%] with TIPS and 51.5% [CI 33-70%; I2 = 73.6%] with no TIPS; RR 1.11 [0.69-1.78; p 0.585]. The pooled postoperative blood transfusion requirement was 48.7% [CI 23.7-73.8%; I2 = 61.4%] in TIPS group and 50.0% [CI 4.9-95.1%; I2 = 94.8%] in no TIPS group with RR 0.71 [0.31-1.63; p 0.330]. The bleeding complication rate with TIPS and no TIPS was 40.2% [CI 7.5-88.0%; I2 = 76.2] and 53.1% [CI 12.2-94.0%; I2 = 88.1%] respectively, RR 0.66 [0.03-13.88; p 0.692]. The overall mortality rate was 45.6% [CI 33.2-57.9; I2 = 54.7%] with TIPS compared to 54.5% [CI 38.9-70%; I2 = 82.4%] with no TIPS; RR 0.70 [0.44-1.09; p 0.095]. Further results are summarized in Table 1. **Conclusion:** Based on this meta-analysis, TIPS demonstrated significantly lower rates of hepatic encephalopathy (49% vs 58.3%) and ascites (53.1% vs 89.4%) compared to those who did not undergo TIPS prior to surgery. There was no significant difference in mortality rates. Preoperative TIPS can be considered as a bridge prior to surgery to lower the rates of postoperative adverse events.

Outcomes	Pooled rates (95% Confidence Interval), I2		Risk Ratio (95% CI); I2%; Studies	p-value
	TIPS	No TIPS		
Intraoperative Blood Transfusion	53.0% (42.6-63.5%); 6.6%	51.5% (33.0-70.0%); 73.6%	1.11 (0.69-1.78); 1.5%; 5 studies	0.585
Post-Op Blood Transfusion	48.7% (23.7-73.8%); 61.4%	50.0% (4.9-95.1%); 94.8%	0.71 (0.31-1.63); 64.5%; 4 studies	0.330
Liver Failure	40.9% (34.9-46.8%); 0.0%	47.8% (10.3-85.3%); 84.1%	0.52 (0.25-1.09); 2.7%; 4 studies	0.068
Hepatic Encephalopathy	49.0% (38.9-59.1%); 15.0%	58.3% (38.9-77.8%); 73.9%	0.72 (0.56-0.93); 0.0%; 6 studies	0.022
Postoperative Ascites	53.1% (41.2-65.0%); 0.0%	89.4% (55.1-123.8%); 80.7%	0.46 (0.26-0.81); 15.2%; 4 studies	0.023
Infectious Complications	57.3% (41.6-73.0%); 62.6%	60.1% (36.5-83.7%); 86.4%	0.87 (0.40-1.89); 60.8%; 6 studies	0.673
Bleeding Complications	40.2% (-7.5-88.0%); 76.2%	53.1% (12.2-94.0%); 88.1%	0.66 (0.03-13.88); 83.8%; 3 studies	0.614

2314 | COAGULATION PARAMETERS WITH ALBUMIN IN DECOMPENSATED CIRRHOSIS (COPA-D): AN OPEN-LABEL RANDOMIZED CONTROL TRIAL

Omkar Rudra[1] Ayush Jain[1] SAURAV PAUL[1] Jaifrin Daniel[1] Babu Lal Meena[1] VINOD ARORA[1] Chhagan Bihari[1] Varsha Shasthry[1] Jaswinder Maras[1] Imran Khan[1] Satyakam Pandey[1] Manoj Sharma[1] GURESH KUMAR[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences

Background: Human albumin solution (HAS) has multiple indications in decompensated cirrhosis (DC); long-term administration serves as a disease-modifier. Cirrhosis is a state of dysregulated coagulation. Whether HAS infusion alters coagulation parameters and has clinical relevance was prospectively and dynamically studied in a randomised clinical trial. **Methods:** DC patients (>18yr.) with serum albumin ≤2.5 g/dl, were randomized to standard-of-care (SOC) plus albumin (Gr. A) or SOC arm (Gr. B). Those in albumin arm received daily 20% HAS to raise serum albumin ≥3 g/dl along with standard medical treatment (SMT). Those in SOC arm received SMT without HAS. Coagulation was assessed by a battery of tests and rotational thromboelastometry (ROTEM) at day 0, 1 and 3. Clinical bleeding events were recorded for 3 days. **Results:** 120 DC patients were enrolled; 9 [3 (7%) in albumin, 6 (12%) in SOC] were excluded as they required urgent coagulation correction for therapeutic interventions. 98 patients (albumin-50, SOC-48) with complete follow-up is analysed per-protocol. Baseline parameters including MELD score (17.2±4.9 in albumin vs 17.2±4.7 in SOC; p=0.970) was comparable. Mean dose of albumin received was 55.8 gram on day 0, 39.4 gram on day 1, 30 gram on day 2 and 23.6 gram on day 3. 60% patients received full prescribed dose of albumin and 63% achieved target albumin levels. After HAS infusion, albumin arm compared to SOC arm showed increase in clotting time (CT) of the extrinsically activated thromboelastometric test (EXTEM) {increase by 36% vs. reduction by 5.5%, p <0.001}, clot formation time (CFT) EXTEM {increase by 53% vs. decrease by 1%, p<0.001} by day 3. In albumin arm, EXTEM A10, A20 reduced by 13% and 12.8% versus increase by 2.8% and 0.2% in SOC arm {p<0.001 for both}. The maximum clot firmness (MCF) EXTEM reduced by 8% in albumin arm vs.0.8% in SOC, p=0.003. Fibrinogen-based thromboelastometry (FIBTEM) showed 38% reduction in A10 and A20 in albumin arm versus an increase by 8.5% and 5% respectively in the SOC arm {p<0.001 for both}. MCF FIBTEM showed a 39% reduction with albumin and 4% increase in SOC {p<0.001}. INR increased by 7.3% with albumin and 1.8% in SOC {p = 0.029}. No clinically significant muco-cutaneous or spontaneous bleeding developed in any of the patients. **Conclusion:** HAS in standard doses causes significant derangement in ROTEM-based coagulation parameters within 24-72 hours in patients with decompensated cirrhosis. Deranged coagulation indices may pose clinical challenges if patients receive regular albumin infusions during hospitalizations. Monitoring of coagulation by ROTEM and clinical bleeding events is advisable in DC patients receiving HAS. [Trial registration - NCT05937048]

2315 | CORRELATION OF RACE-NEUTRAL GLOMERULAR FILTRATION RATE ASSESSMENT IN LIVER DISEASE (GRAIL 2.0) WITH HEPATORENAL SYNDROME-ACUTE KIDNEY INJURY REVERSAL IN PATIENTS RECEIVING TERLIPRESSIN

R. Todd Frederick[1] Kavish Patidar[2] Giovanna Saracino[3] Richard Wu[4] Sanaz Cardoza[4] Melissa Thompson Bastin[4] Sumeet Asrani[3], [1]California Pacific Medical Center, San Francisco, CA, USA, [2]Division of Gastroenterology and Hepatology, Houston Methodist Hospital, Houston, TX, USA, [3]Baylor University Medical Center, Baylor Scott and White, Dallas, TX, USA, [4]Mallinckrodt Pharmaceuticals, Bridgewater, NJ, USA

Background: Hepatorenal syndrome-acute kidney injury (HRS-AKI) is a life-threatening but potentially reversible condition that occurs in patients (pts) with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

decompensated cirrhosis and ascites. Terlipressin (terli), the only FDA-approved therapy for adult pts with HRS-AKI, can reverse HRS and improve kidney function. While pts with low baseline serum creatinine (SCr) tend to respond more favorably to terli, SCr alone is a poor estimate of kidney dysfunction in pts with cirrhosis for assessment of optimal initiation of terli. GRAIL 2.0, a recently validated race-neutral equation in pts with cirrhosis designed to estimate glomerular filtration rate (GFR), has shown improved performance in predicting true GFR compared with CKD-EPI 2021. **Methods:** Pts with available baseline characteristics needed to calculate GRAIL 2.0 and CKD-EPI 2021 were pooled from the Phase III OT-0401 (NCT00089570), REVERSE (NCT01143246), and CONFIRM (NCT02770716) studies of terli versus placebo in pts with HRS-AKI. Estimated GFR (eGFR) was calculated using GRAIL 2.0 and CKD-EPI 2021. The main outcome of interest was HRS reversal. Scatter plots were constructed to visualize the relationship between eGFR calculations, treatment with terli, and clinical outcomes. **Results:** Among evaluable pts (terli, n = 323; placebo, n = 238), GRAIL 2.0-based eGFR identified HRS responders over a broader range of eGFR compared to CKD-EPI 2021. More pts in the 25th and 50th percentiles (low eGFR) by GRAIL 2.0 achieved HRS reversal than with CKD-EPI 2021 (Figure A). The variance of GRAIL 2.0-based eGFR was smaller, providing a more precise estimate than with CKD-EPI 2021 across terli and placebo groups (Figure B). **Conclusion:** GRAIL 2.0 identified more pts with HRS reversal despite lower eGFR compared with CKD-EPI 2021. Additionally, GRAIL 2.0 estimated GFR with smaller variance, suggesting greater consistency and potentially greater precision. However, GRAIL 2.0-based assessment did not enhance overall ability to predict terli response. Notably, our study population had already received substantial exogenous albumin and exhibited near normal serum albumin levels at enrollment, which could negatively influence GRAIL 2.0 performance. These results suggest that HRS reversal, while more common in pts with lower baseline SCr, may not be due entirely to a higher baseline eGFR and that other patient characteristics or factors may be contributing to response. Further validation of GRAIL 2.0 should be conducted in pts with advanced cirrhosis.

2316 | CHARACTERIZATION AND PROGNOSTIC IMPLICATIONS OF BIOMARKERS OF SYSTEMIC INFLAMMATION AND PORTAL HYPERTENSION ACROSS DISTINCT STAGES OF CIRRHOSIS

Georg Kramer[1] Dalila Costa[2] Benedikt Hofer[1] Ana Frias[2] Ricardo Silvestre[2] Joana Camoesneves[2] Joao Belmiro Martins[2] Kerstin Zinober[1] Vlad Taru[1] Mathias Jachs[1] Lukas Hartl[1] Lorenz Balcar[1] Christian Sebesta[1] Marlene Hintersteininger[1] Paul Thöne[1] Nina Dominik[1] Georg Semmler[1] Benedikt Simbrunner[1] Michael Trauner[1] Mattias Mandorfer[1] Carla Rolanda[2] Thomas Reiberger[1], [1]Medical University of Vienna, [2]University of Minho

Background: Systemic inflammation (SI) and portal hypertension (PH) are prominent drivers of disease progression in cirrhosis. In this study, we analyzed stage-specific differences of surrogates of PH/endothelial dysfunction (von Willebrand Factor Antigen [vWF]) and SI (Interleukin-6 [IL6]) in compensated (CC), decompensated (DC) and recompensated (RC) cirrhosis and their prognostic value for disease progression or regression. **Methods:** Patients with cirrhosis were prospectively enrolled at two tertiary centers (Vienna, Austria, and Braga, Portugal) between 01/2017 and 12/2023 and underwent measurement of IL-6 and vWF. Biomarker levels were compared cross-sectionally across CC, DC and RC. In CC, the primary endpoint was first hepatic decompensation. In DC, progression was defined as a composite endpoint comprising further decompensation or acute-on-chronic liver failure, while regression was defined as achieving recompensation (as per Baveno VII). Prognostic value of IL-6 and vWF was evaluated using uni- and multivariable Fine-Gray competing risks regression models, adjusted for MELD. **Results:** Among the 394 included patients (mean age 59.3 ± 10.6 years; 66.6% male; alcohol-related liver disease (ALD) in 65.7%), 88 patients (22.3%) had CC, 57 (24.5%) RC and 249 (63.2%) DC. MELD did not differ significantly between CC and RC (median 9 [IQR: 7-11] vs. 9 [IQR: 8-11], p = 0.845) but was significantly higher in DC (12 [IQR: 10-15], p < 0.001). IL6 levels

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

were numerically lowest in RC (6.3 vs. CC: 8.7 pg/mL, $p = 0.194$) and highest in DC (21.4 pg/mL, $p < 0.001$ vs. CC/RC). A similar pattern was observed for vWF, which was comparable in CC (median: 211%) and RC (median: 192%, $p = 0.503$ vs. CC), yet significantly elevated in DC (median: 307%; $p < 0.001$ vs. CC/RC). During a median follow up of 24 (IQR: 14-32) months, 23 (26.1% of CC) patients experienced first decompensation, 70 (28.1% of DC) patients had disease progression and 45 (19.8% of DC with abstinent ALD or cured/suppressed viral hepatitis) achieved recompensation. In CC, IL-6 (subdistribution hazard ratio [SHR]: 1.03, $p = 0.010$) and vWF (SHR: 1.01, $p = 0.014$) were associated with first decompensation in univariable analysis, yet did not remain significant predictors after adjusting for MELD. In DC, IL-6 (adjusted SHR [aSHR]: 1.09, $p < 0.001$) and vWF (aSHR: 1.04, $p = 0.031$) remained independent risk factors for disease progression. Neither IL-6 nor vWF predicted recompensation. **Conclusion:** Surrogates of SI and PH are markedly elevated in DC and both, IL-6 and vWF, predict disease progression independently of liver function (MELD). In CC, IL-6 and vWF were also associated with the occurrence of first hepatic decompensation. Notably, recompensated patients tended to have lower levels of SI than those with CC, possibly reflecting disease trajectory.

2317 | CACHEXIA IS AN INDEPENDENT PREDICTOR OF MORTALITY IN PATIENTS WITH CIRRHOSIS

Takao Miwa[1] Goki Suda[2] Ryosuke Tateishi[3] Tatsunori Hanai[4] Masatsugu Ohara[2] Yasuhiro Hagiwara[3] Shinji Unome[4] Kazuya Okushin[3] Mina Nakagawa[5] Naoya Sakamoto[2] Masahito Shimizu[4], [1]Gifu University Hospital, [2]Hokkaido University, [3]The University of Tokyo, [4]Gifu University, [5]Science Tokyo Hospital

Background: Cachexia is a systemic response syndrome characterized by disabling wasting during disease progression. We hypothesized that the diagnosis of cachexia can stratify the risk of mortality independent of liver functional reserves by reflecting devastating condition of cirrhosis. Furthermore, it is necessary to clarify whether cirrhosis is a predisposing condition for cachexia. This study aimed to elucidate factors associated with cachexia in patients with cirrhosis and to examine the impact of cachexia on patient survival. **Methods:** This multicenter cohort study included patients with cirrhosis admitted to two distinct institutes in Japan. Cachexia was diagnosed according to the criteria proposed by the Asian Working Group for Cachexia assessing weight loss, body mass index, anorexia, handgrip strength, and C-reactive protein. Factors associated with cachexia and the prognostic impact of cachexia were assessed using logistic regression and Cox proportional hazards regression, respectively. **Results:** Of the 723 patients enrolled (median [interquartile range] age, 71 [64–77] years; 456 [63%] were male; and 390 [54%] had viral hepatitis), 200 (28%) met the criteria for cachexia diagnosis, with the prevalence increasing with Child–Pugh class from A (17%) to B (40%) and C (66%). Multivariable logistic regression analysis revealed that age and indices of liver function reserve, including Child–Pugh score (adjusted odds ratio, 1.59; 95% confidence interval

[CI], 1.43–1.76; $p < 0.001$), were associated with cachexia, whereas sex, etiology of cirrhosis, and complications with hepatocellular carcinoma were not. During a median follow-up period of 3.2 years, 264 (37%) patients died. Patients with cachexia had significantly lower survival rates than those without cachexia (overall survival rates at 1-, 3, and 5 years: 75%, 53%, and 43% vs. 92%, 76%, and 66%) (Figure 1). Multivariable Cox regression analyses showed that cachexia was independently associated with increased mortality (adjusted hazard ratio, 1.59; 95% CI, 1.24–2.12; $p < 0.001$), along with factors related to liver function, hepatocellular carcinoma, and alcohol-associated liver disease as the etiology. **Conclusion:** Cachexia is associated with poor liver function in patients with cirrhosis and is an independent prognostic factor.

2318 | PREDICTING CARDIOVASCULAR OUTCOMES AFTER TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS) USING MACHINE LEARNING: AN ALTA GROUP STUDY

Shoma Bommena[1] Lisa VanWagner[2] Elizabeth Verna[3] Justin Boike[4] Kanti Kolli[5] Bartley Thornburg[6] Adnan Said[7] Catherine Frenette[8] Aparna Goel[9] Jennifer Lai[5] Sumeet Asrani[10] Consuelo Soldevila-Pico[11] Mary Thomson[12] Arun Jesudian[13] Adam Deising[14] Sonali Paul[15] Douglas Simonetto[16] Erin Spengler[17] Mehnush Hameie[6] Cynthia Padilla[6] Dyanna Gregory[2] Mike Fallon[1], [1]University of Arizona, [2]University of Texas Southwestern Medical Center, [3]Columbia University Medical Center, [4]Northwestern Memorial Hospital/ Northwestern University, [5]University of California San Francisco, [6]Northwestern University, [7]University of Wisconsin School of Medicine and Public Health, [8]Gilead Sciences, Inc., [9]Stanford University Medical Center, [10]Liver Consultants of Texas, [11]University of Florida, [12]University of Minnesota, [13]Weill Cornell Medicine, [14]Scripps Clinic, [15]University of Chicago Medical Center, [16]Mayo Clinic Rochester, [17]University of Wisconsin

Background: Cardiovascular complications after TIPS are associated with adverse outcomes; yet, identifying patients at risk remains challenging. Prior studies primarily focused on predictors of heart failure (HF), without comprehensively evaluating a broader spectrum of cardiovascular events (CVEs). Validated machine learning (ML) models for predicting these outcomes are also lacking. We assessed whether a ML model using baseline clinical data from a large multicenter prospective cohort could predict post-TIPS CVEs in patients with cirrhosis. **Methods:** Advancing Liver Therapeutic Approaches in Portal Hypertension (ALTA) is a multicenter prospective study across 13 U.S. centers of adults ($\geq$18 years) scheduled for TIPS from 7/2019 to 1/2025. Participants with TIPS for any indication without prior liver transplantation (LT) were included in this analysis. The primary outcome was post-TIPS CVE, defined as decompensated HF, myocardial infarction, cardiac arrest, arrhythmia requiring intervention, or stroke. We assessed the association between CVEs and all-cause mortality using competing risk analysis, with LT as a competing event. ML models, including Elastic Net, Least Absolute Shrinkage and Selection Operator, Random Forest (RF), Gradient Boosting Machine, and Support Vector Machine, were developed and internally validated. The training set included 635 participants and testing set 157. Model performance was assessed via 5-fold cross-validation, with area under the receiver operating characteristic curve (AUROC) as the primary metric. **Results:** We included

792 participants (median age 59.2 years; 57.3% male, 75% Caucasian, 21% Hispanic). Median MELD was 10.9. Over median follow-up of 262 days, 64 participants (8.1%) developed post-TIPS CVEs; 8 (1.0%) had HF requiring hospitalization. Participants with CVEs were older and had higher MELD, more ascites, impaired renal function, and more cardiovascular risk factors. Mortality was significantly higher among those with CVEs (43% vs.17%, $P < 0.001$; Fig.1a), with a 1.5-fold increased sub-hazard for death after adjusting for MELD and TIPS indication (sHR 1.5, 95% CI 1.01-2.3). Among ML models, RF showed the highest predictive performance for post-TIPS CVEs, with an AUROC of 0.811 (95% CI, 0.74-0.93; Fig.1b) and 86% accuracy. Top predictors included renal dysfunction and history of HF, valvular disease, or atrial fibrillation. **Conclusion:** In this large US cohort, CVEs occurred in 8.1% of participants and were independently associated with increased post-TIPS mortality. ML models, particularly RF, showed high specificity in predicting post-TIPS CVEs using readily available clinical variables, especially renal dysfunction and cardiac history. Ongoing work incorporating echocardiographic features and external validation aims to enhance predictive performance, enabling more accurate pre-TIPS cardiovascular risk stratification and informed patient selection.

2319 | TRAINING AND VALIDATION OF THE PHASE ANGLE (PA)/C-REACTIVE PROTEIN (CRP) INDEX (PAC-I) AS A NOVEL NON-INVASIVE TOOL ACCURATELY PREDICTING SARCOPENIA AND FURTHER DECOMPENSATION EVENTS REQUIRING HOSPITALIZATIONS IN MASLD-RELATED DECOMPENSATED CIRRHOSIS

Mario Romeo[1] Fiammetta Di Nardo[1] Annachiara Coppola[1] Giuseppina Martinelli[1] Claudio Basile[1] Carmine Napolitano[1] Paolo Vaia[1] Alessandro Federico[1] Marcello Dallio[1], [1]University of Campania Luigi Vanvitelli

Background: Phase Angle (PA) represents a Bioelectrical impedance analysis (BIA)-assessable marker of sarcopenia, accurately predicting hospitalizations in advanced chronic liver disease (ACLD). Systemic inflammation severely burdens sarcopenia and, simultaneously with clinically significant portal hypertension (CSPH), constitutes the main driver of decompensation. Considering the high prevalence of sarcopenia in Metabolic dysfunction-associated Steatotic Liver Disease (MASLD) ("sarcopenic obesity" paradox), we evaluated the accuracy of the PA/C-reactive-protein (CRP) index (PAC-I) in predicting sarcopenia and 3-month further liver-related events (LREs)-determining hospitalizations in MASLD decompensated-ACLD (dACLD). **Methods:** Between December 2022 and January 2024, 50 MASLD-dACLD patients were consecutively enrolled, collecting baseline anthropo-biochemical, nutritional (BIA), and clinical [including Liver Stiffness Measurement (LSM) and varices severity] data. EWGSOP2 criteria diagnosed sarcopenia. Patients were followed up, and further LRE-determining

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

hospitalizations in the subsequent 3 months were recorded. Between March 2024 and January 2025, 40 MASLD-dACLD patients were enrolled [validation cohort]. **Results:** PA values inversely correlated with LSM [R: -0.711, $p < 0.0001$] and with CRP [-0.945, p:0.001], emerging as significantly higher in $\geq$F2 varices-affected patients ($p < 0.0001$). Multivariate analysis identified PAC-I (HR: 1.178, p: 0.03), CRP (HR: 1.112, p: 0.02), and CSPH (HR: 1.221, $p < 0.0001$) as variables associated with decompensation. ROC analysis showed a superior accuracy of PAC-I (AUC:0.843) compared to PA alone (AUC:0.721) and CRP alone (AUC:0.592) in predicting sarcopenia, as well as the superiority of PAC-I (AUC: 0.893) compared with LSM (0.814), PA (0.717), and CRP (0.581) (all $p < 0.05$) in predicting 3-month further LREs' occurrence, identifying PAC-I < 2.35 as the best cut-off. Consistently, dACLD patients showing baseline PAC-I < 2.35 presented a higher risk [HR: 2.287, p:0.032] of further LREs (Figure 1). The superiority of PAC-I in predicting sarcopenia [AUC PAC-I: 0.821, AUC PA: 0.709, AUC CRP: 0.611; all $p < 0.001$] and further LREs at 3 months [AUC PAC-I: 0.852, AUC LSM: 0.792, AUC PA: 0.711, AUC CRP: 0.572; all $p < 0.0001$] was confirmed in the validation cohort. **Conclusion:** In MASLD-dACLD, PAC-I represents a useful noninvasive tool in predicting sarcopenia and liver-related hospitalizations.

2320 | SYSTEMATIC LITERATURE REVIEW AND META-ANALYSIS OF THE CARDIOVASCULAR EFFECTS OF TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT CREATION

Wali Badar[1] Ramzy Khabbaz[1] Kashif Osmani[2] Sarah Shalaby[3] Anna Baiges[3] Juan Carlos Garcia-Pagan[3] Ron Gaba[1], [1]University of Illinois at Chicago, [2]University of Illinois-Chicago, [3]Hospital Clinic of Barcelona

Background: To characterize the cardiovascular (CV) effects of transjugular intrahepatic portosystemic shunt (TIPS) through systematic literature review and meta-analysis. **Methods:** A systematic literature review was performed using PubMed from inception through April 2025. The search strategy was: (Transjugular intrahepatic portosystemic shunt[Title]) OR Transjugular intrahepatic portosystemic[Title] OR Transjugular intrahepatic shunt[Title] OR Transjugular shunt[Title] OR TIPS[Title]) AND (Heart[Title] OR Cardiac[Title] OR Cardiovascular[Title] OR Mitral[Title] OR Atrial[Title] OR Ventricular[Title] OR Pulmonary[Title] OR Systemic[Title]) AND (Effects[Title] OR Changes[Title] OR Impact[Title] OR Survival[Title] OR Mortality[Title] OR Function[Title] OR Parameters[Title] OR Decompensation[Title] OR Follow-up[Title] OR Outcomes[Title]). Eligible articles were English language studies >5 patients reporting CV outcomes after TIPS. Outcome measures included hemodynamic changes, CV index alterations, CV decompensation, and mortality. Continuous outcomes were compared using the random effects method for meta-analysis. Statistical analysis was performed using R Studio 3.6.1. **Results:** Thirty-two articles with 4,452 patients met inclusion criteria. In 17 articles with 2,201 patients, right atrial pressure (RAP) significantly increased vs. baseline (+5.2 mm Hg, 95% CI: 4.0-6.3; $P < 0.001$). In 22 articles with 1,231 patients, cardiac output (CO) (+1.9 L/min, 95% CI: 1.1-2.7), cardiac index (CI) (+1.0 L/min/m2, 95% CI: 0.6-1.4), pulmonary artery pressure (PAP) (+8.6 mm Hg, 95% CI: 4.1-13.1), pulmonary capillary pressure (PCWP) (+5.7 mm Hg, 95% CI: 2.1-9.3), and E/A ratio (+0.2, 95% CI: 0.1-0.4) significantly increased vs. baseline ($P < 0.001$-0.006), but were not different $\geq$3 months post-TIPS ($P > 0.05$). Pre-TIPS portosystemic pressure gradient (PPG), RAP, PAP, and PCWP, and post-TIPS PPG and RAP, were higher when TIPS was performed under general anesthesia compared to moderate sedation ($P < 0.001$-0.004). In 8 articles with 1,914 patients, pooled incidence of symptomatic heart failure was 9%. In 10 articles with 1,967 patients, 1-year mortality rate was 30%. Diastolic dysfunction was associated with increased 1-year post-TIPS mortality (OR: 2.85, $P = 0.013$). In 5 articles with 413 patients, 9% of all post-TIPS mortality was attributable to cardiac decompensation. **Conclusion:** Transient CV changes occur after TIPS and may result in cardiac decompensation and mortality.

2321 | SARCIRAM: A PILOT STUDY ON THE IMPACT OF HYDROXIRAM D SUPPLEMENTATION ON SARCOPENIA IN PATIENTS WITH LIVER CIRRHOSIS

Paolo Gallo[1] Dafne Marcelli[1] Lucrezia Santoro[1] Valentina Flagiello[1] Francesca Terracciani[1] Andrea Falcomatà[1] Antonio Picardi[1] Umberto Vespasiani-Gentilucci[1], [1]Medicina Clinica ed Epatologia Campus Biomedico di Roma

Background: Background & Aims: Sarcopenia is a common complication of chronic liver disease and is associated with poor prognosis. Emerging evidence supports the role of branched-chain amino acids (BCAAs) and their metabolite β-hydroxy-β-methylbutyrate (HMB) in sarcopenia. The SARCIRAM pilot trial evaluated Hydroxiram D (BCAAs, calcium HMB, vitamin D) on sarcopenia progression in MASLD-related cirrhosis. **Methods:** In this single-center, open-label, randomized (1:1) pilot study, adults with compensated MASLD-related cirrhosis (Child-Pugh A) were assigned to receive Hydroxiram D twice daily plus standard care or standard care alone for 6 months. Bioelectrical impedance analysis measured fat- free mass (FFM), phase angle (PA), and appendicular skeletal muscle mass index (ASMM/h²). Ultrasound assessed quadriceps thickness index, cross-sectional rectus index, psoas height-to-width ratio, and diaphragm excursion. Muscle function was tested by handgrip strength (HGS) and 4 m walk test (4mWT). Within-group changes were analysed with paired-sample t-tests; between-group differences with baseline-adjusted ANCOVA. **Results:** Forty patients were randomized; 32 completed the study. Exclusions included five lost to follow-up, two with hepatocellular carcinoma detected at baseline, and one statistical outlier. Baseline anthropometric characteristics, age, sex, laboratory data and muscle parameters were comparable between groups (all $p > 0.05$). After 6 months, the adjusted mean change in FFM was –1.89 kg in the Hydroxiram D group versus –2.69 kg in controls ($p = 0.431$). PA changed by +0.20° versus –0.34° ($p = 0.242$), and ASMM/h² by –0.28 versus –0.44 kg/m² ($p = 0.343$), respectively. Although these between-group differences did not reach statistical significance, Hydroxiram D was associated with trends toward smaller declines in FFM and ASMM/h² and an increase in PA. Between-group differences in muscle function [ΔHGS +2.36 kg vs +1.80 kg ($p = 0.700$) and Δ4mWT –0.142 m/s vs –0.210 m/s ($p = 0.290$)] were not significant; however, within-group analysis showed a significant HGS improvement in the Hydroxiram D group ($p = 0.044$) and a greater decline in 4mWT in controls ($p = 0.004$). No significant changes were observed in ultrasound-derived indices or laboratory parameters. No safety concerns or adverse events were reported. **Conclusion:** Six months of Hydroxiram D supplementation was associated with improved muscle strength and physical performance in patients with compensated MASLD-related cirrhosis,
alongside favorable trends in nutritional status and muscle mass preservation. These pilot data support further investigation in larger, adequately powered trials to confirm efficacy and assess long-term clinical and functional outcomes in cirrhosis-related sarcopenia.

University, [2]The Second Affiliated Hospital of Chongqing Medical University

Background: Malnutrition is a prevalent complication in cirrhosis patients, significantly impacting prognosis. Existing prognostic models for cirrhosis inadequately address the impact of nutritional factors. This study aimed to identify key nutritional indicators associated with prognosis and develop a nomogram-based predictive model. **Methods:** Clinical data of 53 hospitalized cirrhosis patients admitted to the Second Affiliated Hospital of Chongqing Medical University (Feb 2023–Feb 2025) were analyzed. Body mass index (BMI), prognostic nutritional index (PNI), geriatric nutritional risk index (GNRI), Model for End-Stage Liver Disease (MELD), MELD-Na, and MELD 3.0 scores were calculated. Blood samples underwent non-targeted metabolomics to screen marker metabolites based on MELD 3.0. Patients were followed up at 3 months, 6 months, 1 year, and 2 years to record survival rates, adverse liver events, and complications. Univariate Cox regression ($P < 0.2$ threshold) identified prognostic indicators, which were entered into least absolute shrinkage and selection operator (LASSO) regression with 10-fold cross-validation to optimize the λ parameter and avoid overfitting. Multivariate Cox regression ($P < 0.05$) selected independent predictors for nomogram construction. Model performance was evaluated via AUC, C-index, calibration curves, and decision curve analysis (DCA). **Results:** Multivariate analysis identified PNI, esophageal-gastric variceal bleeding, and neutrophil count as independent risk factors. The nomogram assigned scores as follows: −7 points per 2-unit PNI increase, +48 points for variceal bleeding (0 if absent), and +5 points per 1×10^9/L neutrophil increase. The model showed a C-index of 0.8698. For 3-month and 1-year outcomes, AUC values were 0.8820 [95% CI (0.7787, 0.9852), $P < 0.001$] and 0.8860 [95% CI (0.7952, 0.9769), $P < 0.001$], surpassing MELD (0.8059, 0.7163), MELD-Na (0.8230, 0.7802), and MELD 3.0 (0.8525, 0.8116). Calibration curves showed close agreement between observed and predicted mortality. DCA revealed significantly higher net benefit than traditional models, validating robust predictive capability. **Conclusion:** The nomogram integrating PNI, variceal bleeding, and neutrophil count demonstrated superior prognostic performance for cirrhosis compared to traditional models, enabling more objective, comprehensive, and accurate clinical evaluation.

2323 | HIGHER RISK OF FIRST ACUTE VARICEAL BLEEDING (AVB) IN MASLD DECOMPENSATED ADVANCED CHRONIC LIVER DISEASE PATIENTS (DACLD) RECEIVING CARVEDILOL-BASED PRIMARY PROPHYLAXIS: A MATTER OF INSULIN RESISTANCE. IS IT TIME TO PERSONALIZE PREVENTION STRATEGIES OF AVB ACCORDING TO THE ETIOLOGY?

Mario Romeo[1] Fiammetta Di Nardo[1] Carmine Napolitano[1] Paolo Vaia[1] Simone Olivieri[1] Claudio Basile[1] Giuseppina Martinelli[1] Alessandro Federico[1] Marcello Dallio[1], [1]University of Campania Luigi Vanvitelli

Background: In the *panorama* of chronic liver disease disorders, Metabolic dysfunction-associated Steatotic Liver Disease (MASLD) is dramatically supplanting viral etiologies worldwide. The recently published "CAVARLY trial" has demonstrated the superiority of combining variceal band ligation (VBL) with non-selective beta-blocker administration (NSBB) compared to each strategy alone for the primary prophylaxis of acute variceal bleeding (AVB) in patients with decompensated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

advanced chronic liver disease (dACLD) and high-risk varices (HRV). Notably, the monotherapy group receiving carvedilol exhibited a higher AVB incidence, highlighting a significant proportion of NSBB-not hemodynamically responding individuals among MASLD patients. Consistently, type 2 diabetes mellitus (T2DM) and obesity have already been demonstrated to impair the hemodynamic response to NSBB, thus predisposing to hepatic decompensation. However, the impact of the dysmetabolic etiology in conditioning the effectiveness of NSBB- and VBL-based strategies in preventing the first AVB in dACLD with HRV has never been systematically investigated. **Methods:** From July 2022 to April 2024, we consecutively enrolled and followed over 12 months, 76 (35 viral-related and 41 MASD-related) dACLD individuals presenting HRV. Patients received carvedilol-based primary prophylaxis (32 MASLD; 28 viral-related), reserving VBL for NSBB-intolerant subjects (9 MASLD; 7 viral-related). Baseline anthropometrical, biochemical, and clinical data were collected. NSBB-compliance was monitored by arterial pressure measurements and a self-compiled diary. **Results:** Unlike patients undergoing VBL, in the carvedilol-receiving group, MASLD patients showed a significantly higher rate of AVB compared to the viral-related CLD individuals (HR: 2.806, p: 0.027). Cox regression analysis [adjusted for sex, age, Child-Pugh, body mass index (BMI), and endoscopic varices features] revealed obesity (aHR: 1.781, p:0.002), T2DM (aHR: 2.541, p:0.001), C-reactive protein (aHR:1.72, p:0.001), and Homeostasis Model Assessment for Insulin Resistance (aHR: 2.112, $p < 0.0001$) as the variables significantly associated with this outcome (Figure 1). **Conclusion:** In the Era of Precision Medicine, personalizing the first AVB-prevention strategy for dACLD patients with HRV according to CLD etiology represents an urgent need.

2324 | A MACHINE LEARNING MODEL TO REDUCE UNNECESSARY PARACENTESIS FOR SBP EXCLUSION HAS EXCELLENT PERFORMANCE IN A RECENT NATIONWIDE CIRRHOSIS COHORT

Jacqueline O'Leary[1] Jasmohan Bajaj[2] Scott Silvey[2] Nilang Patel[2] Heather Patton[3] Timothy Morgan[4] Sofia Jakab[5] Shari Rogal[6], [1]Dallas VAMC, [2]Virginia Commonwealth University, [3]VA San Diego Healthcare, [4]VA Long Beach Healthcare System, [5]West Haven VA, [6]University of Pittsburgh

Background: Lack of timely paracentesis to exclude spontaneous bacterial peritonitis (SBP) leads to poor outcomes. A machine learning (ML) model developed using demographics & blood tests from the Veterans Affairs Corporate Data Warehouse (VA-CDW) during pre-COVID era (2009-19) had excellent negative predictive value (NPV) for SBP. During/post-pandemic, there was disruption of inpatient/outpatient care. Aim: Validate a ML model to exclude SBP using clinical variables in cirrhosis inpatients enrolled after 2020. **Methods:** The derivation ML model included admitted Veterans with cirrhosis who received timely paracentesis between 2009-2019 (Fig 1A). We studied a similar cohort of patients 2020-2023 without prior SBP, and key variables were used to calculate SBP risk on admission using the established ML model. Predicted probabilities were assessed for overall calibration and NPV at thresholds of $<5\%$, $<10\%$, and $<15\%$ risk. Cohort characteristics were summarized between SBP/no-SBP groups, and compared to the 2009-19 derivation cohort used to train the ML model. Decision-curve analysis was applied in order to measure the potential net benefit of the ML model over a paracentesis-for-all scenario. **Results:** From 2020-2023, we identified 4192 Veterans (15.0% w/SBP) who met the inclusion criteria. SBP patients were significantly older, with lower BMI, less likely to have alcohol cirrhosis, and were more likely to be on SBPPr (Fig 1C). SBP pts. had higher total WBC, neutrophil%, platelets, INR, BUN, potassium, temperature on admission, and lower Hgb, eosinophil%, AST, ALP, eGFR, CO2, and blood pressure on admission. Compared to the pre-COVID derivation cohort ($n = 9643$, Figure 1A), these pts had significantly lower Hgb, AST, ALT, bilirubin, eGFR, CO2, and higher neutrophil/eosinophil%, platelets, INR, and albumin, although absolute differences were minor. Model validation: We found high NPVs of 93.6% [89.6%-96.4%] (219/234 pts. correctly predicted SBP-negative) at the $<5\%$ risk threshold, 92.0% [90.6%-93.3%] (1647/1791 correct) at the $<10\%$ threshold, and 90.9% [89.7%-91.9%] (2523/2777 correct) at the $<15\%$ threshold. Sensitivities were also high at the three risk levels (97.6%/77.1%/59.7%) indicating low false

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

negativity rate. Predicted probabilities ranged from 2.8%-88.8% and were well-calibrated (brier score = 0.119, slope: 0.891, $p = 0.639$), implying that the predicted risk was similar to the true SBP risk over all levels. Decision curve analysis demonstrated superiority of the ML model over a paracentesis-for-all strategy (Fig 1B). **Conclusion:** In a nationwide cohort of Veterans with cirrhosis, a machine learning model derived in the pre-COVID era using routinely collected variables without paracentesis had excellent NPV, sensitivity, calibration & decision curve support to exclude SBP in a current cohort. Using this robust model could reduce the need for unnecessary paracentesis by excluding those unlikely to have SBP.

2325 | IMPACT OF BACTERIAL INFECTION ON CLINICAL OUTCOMES IN PATIENTS WITH ACUTE DECOMPENSATION: REAL-WORLD EVIDENCE INSIGHTS

Javier Fernandez[1] Yacine Hajji[2] Jonel Trebicka[3] Thierry Artzner[4] William Bernal[5] Joan Claria[6] Lise Lotte Gluud[7] Jennifer Lai[8] Jacqueline O'Leary[9] Pierre-Emmanuel Rautou[10] Debbie Shawcross[11] Bart Staels[12] Florence Wong[13] Cristina Sánchez-Garrido[14] Eva Usón-Raposo[14] Carol Addy[15] Maxime Anné[2] Stéphanie Ferreira[2] Dean Hum[15] Jérémy Magnanensi[2] Pierbruno Ricci[2] Katharina Staufer[16] Arun Sanyal[17] Richard Moreau[18] Jasmohan Bajaj[17] Paolo Angeli[19], [1]Hospital Clinic, IDIBAPS and CIBEREHD, Barcelona, Spain, [2]Genfit S.A., [3]University Hospital Münster, Münster, Germany, [4]Hôpitaux Universitaires de Strasbourg, Strasbourg, France, [5]King's College Hospital, [6]Hospital Clínic-IDIBAPS, CIBERehd, University of Barcelona, Barcelona, Spain, [7]Hvidovre Hospital, Hvidovre, Denmark, [8]University of California, San Francisco, United States, [9]University of Texas, Southwestern, Dallas, United States, [10]Université Paris-Cité, INSERM, Paris, France, [11]Kings College London, London, United Kingdom, [12]University Lille 2, [13]University of Toronto, [14]European Foundation for the Study of Chronic Liver Failure, Barcelona, Spain, [15]GENFIT CORP, [16]Versantis AG (GENFIT Group), Zurich, Switzerland, [17]Virginia Commonwealth University, [18]European Foundation for the Study of Chronic Liver Failure (EF CLIF), [19]University of Padova

Background: Acute decompensation (AD) of liver cirrhosis is associated with an increased risk of acute-on-chronic liver failure and short-term mortality. It is characterized by the acute development or worsening of ascites, gastrointestinal bleeding (GB), and/or hepatic encephalopathy (HE). Additionally, bacterial infections (BI) contribute to precipitating or aggravating decompensation but it remains controversial whether BI needs to be regarded as an AD event on its own. Using real-world data, we assessed the impact of BI on patient (pts) outcomes either alone or in combination with other AD events. **Methods:** All hospitalizations of pts with chronic liver disease associated with at least one AD event recorded on the date of admission between January 2023 and April 2025 in Komodo's Healthcare Map US real-world database were included. Hospitalizations were categorized by types of AD events (ascites, GB, HE) recorded during the hospital stay, accounting for BI reported within 48h after admission. Mortality at 90/180d, liver transplant-free survival at 90d, and rate of re-hospitalization within 90d for the occurrence of an additional AD event were compared between categories of hospitalization with or without BI using fold changes (FC) with 95% confidence intervals. **Results:** The data from 118,457 hospitalizations in 82,741 pts were analyzed (male: 59%, mean age at admission: 55y, median duration of hospitalization: 5d). BI was reported within 48h after admission in 48% of hospitalizations. During the hospital stay, ascites was the most common event (44%), followed by GB (32%), and HE (16%). In 29% of hospitalizations, BI was the only event. GB or BI alone were associated with the lowest 90/180d mortality (3/4% and 4/5% respectively) while HE or ascites alone showed higher rates (7/10%

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and 8/12%, respectively). Overall, mortality increased with the number of different types of AD events (1-4) experienced during hospital stay (90d: 5, 10, 18, 28%; 180d: 7, 13, 21, 31%). Pts admitted with BI and reporting of any other single type of AD event during their hospital stay had higher 90d mortality rate than pts with the same type of AD event recorded but without BI at admission: FC = 1.4 [1.3, 1.4] (11 vs 8%) for ascites, 1.7 [1.5, 1.9] (12 vs 7%) for HE and 2.3 [2.2, 2.5] (7 vs 3%) for GB. Irrespective of the number of different types of AD events reported during hospitalization, BI at admission did not impact the rate of re-hospitalization (FC: 0.9-1.1) but increased 90d (FC: 1.4-2.3) and 180d (FC: 1.2-2.0) mortality. Experiencing all 4 types of AD events resulted in a transplant-free survival rate of 70% vs 83% without the presence of BI at admission. **Conclusion:** While BI alone was associated with low risk of mortality and re-hospitalization, experiencing BI in addition to any other AD event consistently increased mortality rates. These findings support considering BI as an aggravating factor in pts with AD (ascites, GB, and/or HE), rather than an AD event on its own.

VAMC, [3]McGuire Veterans Affairs Medical Center, [4]Central Virginia VA Healthcare System, [5]Hunter Holmes McGuire VA Medical Center

Background: Cirrhosis is linked with poor nutrition, which could partly be due to anorexia & coexistent end-stage renal disease (ESRD). Taste & smell perception affect appetite but their role in pts with cirrhosis and ESRD are unclear. Aim: Define taste & smell perception in pts with cirrhosis ± ESRD & impact on eating. **Methods:** Healthy controls (Ctrls) & outpts with cirrhosis, ESRD only & both cirrhosis+ESRD underwent taste & smell tests, cognitive testing using (PHES, high = better, Stroop, lower = better) & SAS questionnaire for olfactory impact on life (high = worse). Patients with past/current COVID-19, dentures, current/recent alcohol or tobacco use were excluded. We used WETT taste test which studies sweet, sour, salty, brothy & bitter taste, while smell was tested using the NIH Olfactory toolbox system. Quality-of-life (QOL) testing was performed using Sickness Impact Profile (SIP high = worse) which has physical & psychosocial domains & one specifically for eating. Taste & smell results were compared between groups & correlated with eating SIP. Multi-variable analysis for eating SIP/taste/smell testing was performed using demographics, disease type, medications & cognitive testing **Results:** We enrolled 94 subjects [24 ctrl, 40 cirrh (20 comp/decomp), 20 ESRD only & 10 cirrhosis+ESRD]. Controls were younger & were free of diabetes; gender was similar. Diabetes trended higher in ESRD groups. Taste and smell: Ctrls had the best taste discrimination while cirrhosis & ESRD pts were similar. All taste sensations were more impaired in diseased vs controls, but sweet, sour & bitter tastes were most affected. Diseased groups admitted to more impact of smell-related impairment on the SAS questionnaire. Correct taste identification was linked with correct smell identification ($r = 0.5, p < 0.001$). Diabetes did not affect taste or smell results. QOL: QOL was worst in decomp cirrhosis, ESRD and both vs controls and comp cirrhosis. Eating portion of SIP was poor in all diseased groups and worst in pts with both cirrhosis+ESRD; this correlated with subjective impact of smell impairment (Fig B). Cognition: PHES, Stroop were best in ctrls & worsened with disease; worst in cirrhosis+ESRD pts. PHES linked with taste while Stroop linked with smell (Fig C/D). Multivariable analysis: For eating SIP, higher total SAS ($t = 0.3$, $p = 0.001$), advancing disease (1.04, $p = 0.05$) and age (1.0, $p = 0.05$) were contributory. For smell percentile Stroop was negatively ($t = -0.2$, $p = 0.005$), while age and taste ($p = 0.05$ each) were positively contributory while for taste age ($t = -0.2$, $p = 0.02$), PHES (0.6, $p = 0.03$) and smell performance (0.1, $p = 0.04$) were significant. **Conclusion:** Smell and taste impairments affect ability to eat in cirrhosis, which worsens with coexistent end-stage renal disease. Cognitive impairment are correlated with smell and taste impairment. Focusing on smell and taste improvement could beneficially impact nutrition and reduce sarcopenia.

Figure A	Healthy (n=24)	Comp cirrhosis (n=20)	Decomp Cirrhosis (n=20)	ESRD only (n=20)	Cirrhosis & ESRD (n=10)	P value (all groups)

2327 | DEVELOPMENT AND VALIDATION OF AN AMBULATORY ADMINISTRATIVE FRAILTY INDEX FOR PATIENTS WITH CIRRHOSIS

Lucia Calthorpe[1] Jessica Rubin[2] Catherine Lee[1] Garrett Roll[2] Sandy Feng[1] Jennifer Lai[1], [1]University of California San Francisco, [2]University of California, San Francisco

Background: Frailty is highly prevalent among patients with cirrhosis and is strongly associated with health outcomes. While numerous tools have been developed to assess frailty in administrative data, they are not specific to patients with cirrhosis, nor have they been developed against gold standard measures of physical frailty. **Methods:** Adult ambulatory patients listed for liver transplantation with in-person frailty assessments were identified from a single center from 2017 to 2024. Frailty was assessed with the Liver Frailty Index (LFI). The electronic health record was searched to identify all ICD-10 codes associated with inpatient, outpatient, and emergency department encounters for the two years prior to in-person frailty assessment. Codes with a frequency > 50 (n = 143) were considered for inclusion in the model. The cohort was randomly split into training

and validation sets (65% and 35% respectively), and lasso regression was used to select ICD-10 codes which predict LFI. Model performance was assessed in the validation cohort in terms of discrimination (AUC) and calibration (observed vs. expected outcomes). **Results:** Among 2419 patients, 63% were male, with a median age of 60, and 18.5% were frail by LFI. Patients had an average of 19 ICD-10 codes associated with their inpatient and outpatient encounters in the two years prior to their in-person LFI assessment. Lasso regression was used to generate the cirrhosis administrative frailty index (CAFI). We identified 30 codes which predict LFI > 4.5 with an AUC of 0.72. In comparison, the commonly used Hospital Frailty Risk Score predicted LFI with an AUC of 0.58. The CAFI was associated with pretransplant mortality and delisting secondary to illness (OR = 1.40, 95% CI: 1.18, 1.66). **Conclusion:** We developed the cirrhosis administrative frailty index, the first ICD-based frailty tool built to predict an in-person gold standard frailty metric. While numerous administrative frailty indices have been developed and correlate strongly with outcomes like in-hospital mortality, they correlate poorly with physical frailty (e.g., Fried Frailty Index, chair stands, falls). An administrative frailty index for ambulatory patients with cirrhosis will facilitate population-level research to understand the burden of frailty among patients with cirrhosis and quantify its impact on healthcare utilization and outcomes. Further, it will allow researchers to account and adjust for frailty in large-scale data analysis.

Figure 1. Area under the ROC for CAFI as compared to HFRS in predicting LFI, Validation cohort (n=827)

2328 | RISK FACTORS FOR INFECTION AFTER TIPS

Shannon Sanda[1] John Martens[1] M. Katherine Dokus[2] Bandar Aljudaibi[1], [1]University of Rochester Medical Center, [2]University of Rochester

Background: Transjugular intrahepatic portosystemic shunt (TIPS) is a crucial intervention for complications of portal hypertension. While effective, TIPS procedures carry a risk of complications, with infection being a significant concern contributing to prolonged hospital stays, increased healthcare costs, and poor outcomes in an already vulnerable cirrhotic population. Despite the known risk, specific patient characteristics and procedural indications that independently predispose individuals to infection after TIPS are not fully elucidated. **Methods:** This was a retrospective cohort study of 293 adult patients who underwent TIPS placement at a single center (Mar 2011 – July 2020). The primary outcome was the occurrence of any infection within 30 days post-TIPS, confirmed by clinical diagnosis, culture results, or need for antimicrobial therapy. Univariate analyses were performed to compare characteristics between patients with and without 30-day infection. A multivariate backwards stepwise logistic regression was then completed to identify independent predictors of 30-day infection. **Results:** Among 293 patients, 59 (20.1%) developed infections: Pneumonia (31%), undifferentiated sepsis (28%), urinary tract infection (16%), bacteremia (12%), spontaneous bacterial peritonitis (5%), cellulitis (3%), fungemia (2%), tracheitis (2%), and viral infection (2%). The mean age was 56.6 years and 36% were female. The univariate predictors of infection included female sex (49.2% vs. 32.5%; p = 0.018), initial TIPS vs. revision (96.6% vs. 82.1%; p = 0.005), higher MELD-Na (median 20 vs. 17; p < 0.001), elevated Child-Pugh scores (p = 0.035), and variceal bleeding indication (45.8% vs. 20.9%; p < 0.001). Multivariate analysis identified independent predictors: diabetes (OR = 1.9, 95% CI:1.1–3.8; p = 0.019), variceal bleeding indication (vs. ascites; OR = 2.1, 1.1–3.8; p = 0.012), and MELD score (OR = 1.03 per unit; 1.03–1.12; p < 0.001). **Conclusion:** Diabetes, variceal bleeding as the TIPS indication, and higher MELD scores independently predict 30-day post-TIPS infection. These findings underscore the need for enhanced pre-procedural risk stratification and targeted antimicrobial prophylaxis in high-risk cohorts. Future studies should validate preventive strategies.

2329 | PATHOMECHANISTIC BIOMARKERS LINK BACTERIAL TRANSLOCATION TO ENDOTHELIAL DYSFUNCTION AND HEPATIC FIBROGENESIS ACROSS DIFFERENT STAGES OF CIRRHOSIS

Vlad Taru[1] Georg Kramer[1] Benedikt Silvester Hofer[1] Tammo Tergast[2] Kerstin Zinober[1] Katharina Regnat[1] Nina Dominik[1] Christian Sebesta[1] Paul Thöne[1] Lorenz Balcar[1] Michael Schwarz[1] Lukas Hartl[1] Mathias Jachs[1] Michael Trauner[1] Philipp Schwabl[1] Mattias Mandorfer[1] Barbara Kistler[3] Peng Sun[3] Stefan Kauschke[3] Thomas Reiberger[1] Benedikt Simbrunner[1], [1]Medical University of Vienna, [2]Hannover Medical School, [3]Boehringer Ingelheim Pharma GmbH & Co.KG, Biberach

Background: Liquid biomarkers may reflect specific pathomechnisms of cirrhosis including bacterial translocation (BT), macrophage activation, systemic inflammation, endothelial dysfunction, and fibrogenesis, but their dynamics across disease stages and specific etiologies remain unclear. **Methods:** Patients with advanced chronic liver disease were prospectively included in the Vienna Cirrhosis Study (VICIS). Ten pre-selected biomarkers were analyzed by ELISA and compared between compensated (CC), decompensated (DC) cirrhosis patients and liver-healthy controls (HC), as well as across alcohol-related (ALD) vs. viral hepatitis B and C (VIRAL) vs. metabolic dysfunction-associated (MASH) cirrhosis etiologies. Multivariable linear regression models were used to evaluate the independent association between biomarkers (log10-transformed), adjusted for liver disease severity. **Results:** Forty HC and 200 patients, comprising 100 CC (MELD: 10 [4]; HVPG: 13 [9]) and 100 DC (MELD: 14 [8]; HVPG: 19 [6]) were included. The main etiology was ALD in 106 (53%) patients, followed by MASH in 45 (22.5%), VIRAL in 41 (20.5%) and others in 8 (4%). BT, indicated by increased circulating levels of LPS-binding protein (LBP) was already increased in CC and peaked in DC (HC vs. CC vs. DC: 5.8 [1.8] vs. 7.0 [2.8] vs. 7.7 [4.8] µg/mL, $p = 0.002$). Soluble CD14 (sCD14), an LPS co-receptor that activates toll-like receptor 4 (TLR4), was elevated in DC compared to CC (1.93 [0.77] vs. 1.56 [0.47] µg/mL, $p < 0.001$). In DC patients, sCD14 levels correlated with LBP (Spearman's rho = 0.50, $p < 0.001$), and this association was consistent across all etiologies, supporting a key role of BT-driven TLR4 activation in DC. Systemic inflammation (IL-6 and TNF-α) was more pronounced in DC than in CC and correlated with sCD14 (IL-6: rho = 0.43; TNF-α: rho = 0.45; both $p < 0.001$). Notably, sCD14 was independently associated with markers of endothelial dysfunction (von Willebrand factor antigen, VWF) and liver fibrogenesis (tissue inhibitor of metalloproteinases 1, TIMP1; and Enhanced Liver Fibrosis [ELF] test) when adjusted for HVPG and MELD (VWF: $\beta = 0.139$, $p = 0.003$; TIMP1: $\beta = 0.254$, $p = 0.002$; ELF: $\beta = 0.04$, $p = 0.012$). **Conclusion:** Biomarkers reflecting inflammation, BT and macrophage activation are elevated in patients with DC, regardless of the underlying etiology. Increased sCD14 levels in DC suggest a contribution of BT-driven innate immune activation to endothelial dysfunction and fibrogenesis during cirrhosis progression.

2330 | BIOELECTRICAL IMPEDANCE ANALYSIS PROVIDES NOVEL INSIGHTS INTO FACTORS ASSOCIATED WITH SARCOPENIA IN DECOMPENSATED CIRRHOSIS

Somaya Albhaisi[1] Jennifer Dodge[1] Diana Segura[1] Norah Terrault[1] Ani Kardashian[1], [1]University of Southern California

Background: Sarcopenia predicts poor outcomes in cirrhosis. Optimal assessment and modifiable risk factors remain ill-defined. Bioelectrical impedance analysis (BIA), specifically phase angle (PA) and appendicular skeletal muscle index (SMI), offers a non-invasive, objective assessment. Our study investigated factors associated with sarcopenia in outpatients with decompensated cirrhosis. **Methods:** We performed a cross-sectional analysis of 134 adults with decompensated cirrhosis evaluated for liver transplant (July 2023-present) from a single-center prospective cohort. Sarcopenia was assessed using BIA-derived PA ($\leq$5.6° in males, $\leq$5.4° in females) and SMI ($\leq$11.1 kg/m^2 in both sexes). Multivariable linear regression evaluated associations of demographic, clinical, and socioeconomic factors with PA and SMI, adjusting for sex, BMI, MELD-3.0, ascites grade, and cirrhosis etiology. Locally weighted scatterplot smoothing (lowess curves) was used to visualize the association between BMI and sarcopenia and derive potential BMI thresholds with the optimal BMI threshold confirmed in linear regression (i.e. highest adjusted R-squared). **Results:** Of 134 participants, median age was 55 years, 56% were male, 72% were Hispanic, median MELD was 16, and median BMI was 29. Major cirrhosis etiologies were ALD (49%) and MASH (25%); 49% were married, 29% unemployed, and 52% had income 25,000/year. Sarcopenia prevalence was high overall (PA: 96%, mean PA 4.2 [SD 0.9]; SMI: 94%, mean SMI 8.1 [SD 1.7]); highest among Hispanics (PA: 98%, SMI: 96%). Multivariable analysis showed female sex ($\beta = -0.52$, $p < 0.001$), MASH ($\beta = -0.46$, $p = 0.006$), moderate/severe ascites ($\beta = -0.39$, $p = 0.012$), and higher MELD ($\beta = -0.04$, $p = 0.005$) were independently associated with lower PA. Female sex ($\beta = -1.32$, $p < 0.001$) and Hispanic ethnicity ($\beta = -0.65$, $p < 0.001$) were associated with lower SMI. Higher BMI was strongly associated with higher PA ($\beta = 0.03$ per 1-unit BMI increase, $p = 0.027$) and greater SMI ($\beta = 0.18$, $p < 0.001$). Lowess curves showed a linear relationship between BMI and SMI (Fig 1A) and an inflection point in BMI on PA (Fig 1B). An optimal BMI threshold of 26 kg/m^2 was identified above which BMI had a protective effect on PA ($\beta = 0.05$, $p = 0.004$); in other words, each 1-unit BMI increase above 26 kg/m^2 was associated with a 0.05 PA increase. **Conclusion:** Sarcopenia prevalence is high in decompensated cirrhosis. Female sex, liver disease severity, and MASH were independently associated with poorer muscle quality. Female sex and Hispanic ethnicity were also independently associated with lower muscle mass. Higher BMI, particularly $\geq$26 kg/m², was protective against sarcopenia. These findings underscore the need for targeted interventions to mitigate sarcopenia in this vulnerable population, especially for women and Hispanics, and highlight the need for nuanced nutritional and functional assessments beyond BMI.

Figure 1. Association of BMI with (A) skeletal muscle index (SMI) and (B) Phase Angle (PA)

2331 | COMBINATION OF CARVEDILOL AND ENDOSCOPIC VARICEAL LIGATION IS SUPERIOR TO CARVEDILOL ALONE FOR PRIMARY PROPHYLAXIS OF VARICEAL BLEEDING IN HIGH-RISK CIRRHOTICS: A RANDOMIZED CONTROLLED TRIAL

Premashis Kar[1] JataShankar Kumar[2] Pabitra Sahu[2], [1]Max Superspecialty Hospital, Vaishali, Ghaziabad, India, [2]Max SuperSpeicalty Hospital, Vaishali, Ghaziabad, India

Background: Primary prophylaxis against variceal hemorrhage in cirrhosis typically involves non-selective beta-blockers (NSBBs) or endoscopic variceal ligation (EVL). Carvedilol, a potent NSBB with α1-blocking activity, has shown superior portal pressure reduction compared to propranolol. However, its efficacy in combination with EVL in preventing first variceal bleed in high-risk cirrhotic patients remains inadequately studied. **Methods:** This single-center, open-label, randomized controlled trial enrolled 80 cirrhotic patients(July 2022–July 2023) with large varices or red color signs and no history of prior bleeding. Patients were randomized 1:1 to receive either (1) carvedilol alone or (2) carvedilol plus serial EVL until variceal eradication. The primary outcome was first variceal bleed within 1 year. Secondary outcomes included all-cause mortality, hospitalization for bleeding, and adverse events. **Results:** 72 patients (n = 36 per group) completed follow-up. First variceal bleeding occurred in 8.3% in the EVL+carvedilol group versus 25.0% with carvedilol alone (p = 0.041). All-cause mortality was significantly lower in the combination group (11.1% vs 27.8%, p = 0.048).Fewer hospitalizations due to bleeding were observed in the EVL+ carvedilol group (5.5% vs 22.2%, p = 0.031). Adverse event rates were similar between groups. **Conclusion:** Among cirrhotic patients with high-risk varices, combining EVL with carvedilol significantly reduces first variceal bleeding and mortality compared to carvedilol monotherapy. This dual-modality approach may represent a superior prophylactic strategy in selected high-risk populations.

2332 | PROTON PUMP INHIBITOR USE AND RISK OF HEPATIC ENCEPHALOPATHY IN CIRRHOTIC PATIENTS: A META-ANALYSIS OF OBSERVATIONAL STUDIES

Anwar Uddin[1] Madia Ahad[1] Sujay Edavalapati[2] Savanna Thor[1], [1]Suny Downstate Medical Center, [2]Emory University

Background: Hepatic encephalopathy (HE), a common complication of cirrhosis, contributes to cognitive dysfunction, reduced quality of life, and higher healthcare utilization. Proton pump inhibitors (PPIs) are frequently prescribed, often beyond evidence-based indications. Observational studies have linked PPI use to increased HE risk, possibly due to altered gut microbiota, infections, or intestinal permeability changes. Findings vary. This meta-analysis aimed to quantify the association between PPI use and HE in cirrhotic patients using adjusted effect estimates from observational data. **Methods:** A meta-analysis of observational studies was performed. Included studies reported adjusted odds ratios (ORs) or hazard ratios (HRs) assessing the association between PPI use and hepatic encephalopathy in adult cirrhotic patients. Data extracted: study design, population characteristics, outcome definitions, exposure classification, and adjusted effect sizes with 95% confidence intervals (CIs). Pooled ORs were calculated using a random-effects model (DerSimonian–Laird). Heterogeneity was assessed using I^2 and τ^2. Publication bias was evaluated via funnel plot with visual inspection for asymmetry. **Results:** Four observational studies (n = 169,090 cirrhotic patients) were included: two case-control, one prospective cohort, and one retrospective Medicare cohort. HE definitions varied, minimal, overt, and incident HE during follow-up. The pooled odds ratio for HE in PPI users was 3.48 (95% CI: 1.65–7.34), with high heterogeneity (I^2 = 88.7%, τ^2 = 0.3583). Zhu et al.'s inpatient study showed the largest effect; Tapper et al.'s Medicare cohort the smallest. Variability in setting, outcome definitions, and exposure classification likely contributed. Funnel plot showed asymmetry; smaller studies reported stronger effects. This meta-analysis shows a significant association between PPI use and HE in cirrhosis. Direction and magnitude were consistent despite heterogeneity. The indications for PPI use were not readily apparent on these studies. Given PPIs are often used in patients with gastrointestinal bleeding (GIB) and GIB is a risk factor for development of hepatic encephalopathy, it is possible that this may be a reason for the associated increased risk; thus, further prospective studies are needed to characterize this association. **Conclusion:** PPI use in cirrhotic patients was associated with increased odds of hepatic encephalopathy across four observational studies. The pooled effect estimate was statistically significant, with substantial between-study heterogeneity. Differences in study design, population setting, and outcome definitions may explain the observed variability. Future studies using

prospective designs, standardized definitions of hepatic encephalopathy, and rigorous confounder adjustment will be necessary to further characterize this association.

2333 | AGE AS A PREDICTOR OF POST-TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT HEPATIC ENCEPHALOPATHY

Mohamed Eldesouki[1] Ahmed Ibrahim[2] Ali khalifa[3] Ahmed Salem[4] Mohammed Youssef[5] Hazem Abosheaishaa[6] Kamran Qureshi[3] Wing-Kin Syn[3], [1]New York Medical College at Saint Michael Medical Center, [2]Digestive Disease and research center, Medical University of South Carolina, [3]Saint Louis University School of Medicine, [4]Maimonides Medical Center, [5]Hunt regional medical center, [6]Mount Sinai/Queen hospital

Background: Age is a known risk factor for adverse outcomes in various medical conditions, but its role as a predictor of complications following transjugular intrahepatic portosystemic shunt (TIPS) procedures, particularly hepatic encephalopathy (HE), remains unclear. Therefore, we aimed to evaluate the impact of age on 90-day post-TIPS outcomes, including HE, gastrointestinal (GI) bleeding, infections, hospital readmissions, and all-cause mortality. **Methods:** We used the TriNetX database to examine adult patients ($\geq$ 18 years) who underwent a TIPS procedure (2010-2025), stratified into two cohorts: those $>$70 years and those $<$70 years. Groups were propensity matched based on age, sex, race/ethnicity, cardiometabolic risk factors, medications (diuretics, beta-blockers), MELD, and Child-Pugh scores. Diagnoses, procedures, and medication use were extracted using ICD-9/10-CM, ICD-10-PCS, CPT®, and RxNorm codes. The primary outcome was incident HE, while secondary outcomes included mortality, GI bleeding, infections, and readmissions. **Results:** A total of 18,443 cirrhotic patients who underwent TIPS, including 6,090 patients $>$ 70 years (3,506 $>$ 75 years) were identified. Before matching, younger patients had a higher frequency of variceal hemorrhage (44% vs. 28%, $p < 0.001$), and ascites (45% vs. 41%, $p < 0.001$) compared to those $>$ 70 years, as well as higher bilirubin, ALT, and AST. After matching, 5,585 pairs were well-balanced. The mean age in the older group was 72 $\pm$ 6 years vs. 49 $\pm$ 12 years in the younger group. The majority of patients in both cohorts were White males and were evenly matched regarding cardiometabolic risk factors, and liver disease severity. Alcohol-associated cirrhosis was the most common underlying etiology of cirrhosis, followed by MASH-related cirrhosis, and viral hepatitis-associated cirrhosis. At 90 days post-TIPS procedure, the older cohort had significantly higher rates of HE (27% vs. 25%, $p = 0.02$) and all-cause mortality rates (11% vs. 7%, $p < 0.001$), as compared to the younger group. However, there were no significant differences in hospital readmissions, infections, or GI bleeding between both groups. Finally, a Cox proportional hazard model analysis demonstrated that older age was independently associated with a higher risk of developing HE after TIPS. Elevated bilirubin levels and INR (markers of more severe liver disease) were also significant predictors of increased risk of HE post-TIPS. **Conclusion:** Advanced age appeared to be a significant predictor of poorer outcomes following TIPS, particularly regarding hepatic encephalopathy and mortality. However, there were no significant differences in the incidence of infection or GI bleeding between groups. These findings highlight that tailored post-TIPS management strategies, particularly focused on HE prevention and treatment in older adults, are warranted.

Table 1. Demographic and clinical features in TIPS (stratified by age)

Baseline characteristics	Before propensity score matching			After Propensity score matching

2334 | ALBUMIN INFUSION MEDIATED INCREASE IN STRUCTURAL AND FUNCTIONAL MODIFICATION CAN EXACERBATE LIVER INJURY IN DECOMPENSATED CIRRHOSIS

jaswinder singh Maras[1] Omkar Rudra[2] neha sharma[2] Babu Mathew[2] Sanju Yadav[2] Shiv Kumar Sarin[2], [1]NSTITUTE OF LIVER AND BILIARY SCIENCES, [2]institute of liver and biliary science

Background: Human albumin solution (HAS) is widely used for managing various complications in decompensated cirrhosis (DC), with long-term infusion considered a disease-modifying intervention. However, the impact of infused albumin on the structural and functional dynamics including advance oxidation of protein along with Ischemia modification of circulating albumin and its correlation with disease severity remains insufficiently explored and was studied in an RCT in DC patients [Trial registration - NCT05937048]. **Methods:** Decompensated cirrhosis patients aged ≥ 18 years with serum albumin ≤ 2.5 g/dL were allocated to two groups. Group A received standard-of-care (SOC) plus daily 20% HAS to maintain serum albumin ≥ 3 g/dL, along with standard medical therapy (SMT). Group B received SOC and SMT alone. High-resolution mass spectrometry and biochemical assays assessed albumin modifications at baseline, Day 1, and Day 3. Inflammatory markers (IL-6, TNF-α, CRP) and clinical parameters (MELD score, ABIC, AGE, IMA, AOPP) were also measured. **Results:** Baseline level of all albumin modification (Native, cysteinylated, Sulfinylated, Sulfonylated C-Truncated, Nitrosylated, Acetylated and Carbamylated Albumin) were comparable between Group A and Group B respectively. Albumin infusion by Day 3 significantly increased native albumin by 5 folds ($p < 0.05$) in Group A along with significant increase in Sulfonylated albumin (pro-inflammatory) by 3 folds, Carbamylated albumin (5.2 folds; pro-inflammatory) and acetylated albumin (4 folds; known for reduction of bilirubin binding $p < 0.05$) as compared to Group B. Increase in pro-inflammatory and dysfunctional albumin phenotype by Day 3 in Group A significantly correlated with increase in Advance Glycosylated End products (AGE; >2Folds), Ischemia Modified albumin (IMA, IMAr; >2Folds), Advance oxidation proteins products (AOPP >2Folds) levels, MELD score (>2Folds,$p < 0.045$) and CRP levels (>2FC,$p < 0.05$) respectively. Interestingly the levels of ABIC (albumin binding capacity) was significantly decreased in Group A as compared to Group B (>2FC, $p < 0.05$) suggesting decrease in albumin functionality and also suggestive of increase in liver severity in Group A respectively. Day-3 increase in carbamylated albumin documented the highest diagnostic efficiency of AUC $>$ 0.89 $p < 0.05$ for prediction of pro-inflammatory conversion of albumin in DC patients. **Conclusion:** Standard-dose human albumin solution (HAS) induces pro-inflammatory structural and functional changes in circulating albumin. Elevated carbamylated albumin levels serve as an indicator for this pro-inflammatory shift. Monitoring albumin carbamylation is recommended in decompensated cirrhosis patients receiving HSA

2335 | IMPACT OF FRAILTY ON CLINICAL OUTCOMES AMONG HOSPITALIZED PATIENTS WITH HEPATORENAL SYNDROME: A NATIONWIDE ANALYSIS FROM 2018–2022

Daniel Gonzalez Mosquera[1] Maria Mateo Chavez[2] Mariana Nunes Ferreira[1] Sakina Paracha[1] Carolina Gonzalez Mosquera[3] Juan Martinez-Ortega[1] Yassine Kilani[4] Cynthia Victor-Prophete[1], [1]New York Health + Hospitals | Lincoln–Weill Cornell Medical College affiliate, New York, USA, [2]Knowledge and Research Evaluation Unit, Mayo Clinic, Rochester, Minnesota, USA., [3]Universidad Católica Santiago de Guayaquil, Ecuador, [4]Washington University in St. Louis, Saint Louis, Missouri, USA

Background: Hepatorenal syndrome (HRS) is a life-threatening complication of advanced liver disease

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

characterized by rapid renal dysfunction and high inpatient mortality. While frailty has emerged as a key prognostic factor in chronic liver disease, its impact on hospitalized patients with HRS remains unclear. We aimed to evaluate the association between frailty and inpatient outcomes in HRS hospitalizations using a nationally representative database. **Methods:** We conducted a retrospective cohort study using the National Inpatient Sample (NIS) from 2018 to 2022 to identify adult hospitalizations with a principal diagnosis of HRS. Frailty was assessed using the Hospital Frailty Risk Score (HFRS), categorized as low (<5), intermediate (5–15), and high (>15). Descriptive analyses were performed to estimate unadjusted incidence rates of in-hospital outcomes. Multivariable logistic and linear regression models were used to determine adjusted odds ratios (aOR) and 95% confidence intervals (CI), controlling for demographics, comorbidity index, income, insurance and hospital-level variables. **Results:** A total of 18,315 HRS hospitalizations were identified, with 29.9% classified as low frailty (n = 5,480), 67.7% intermediate (n = 12,390), and 2.4% high frailty (n = 445). Descriptive analysis showed an increasing trend of adverse outcomes with higher frailty scores, including in-hospital mortality (17.8% low vs. 29.2% high), ICU admission (6.1% vs. 20.2%), respiratory failure (5.2% vs. 20.2%), and sepsis (1.8% vs. 15.7%). LOS and total hospital charges also increased with frailty (mean LOS: 7.1 vs. 13.6 days; charges: $83,711 vs. $166,273; $p<0.001$ for all comparisons). Adjusted regression analysis revealed that high frailty was independently associated with higher mortality (aOR: 2.02 [1.20–3.40], $p=0.008$), ICU admission (aOR: 4.41 [2.37–8.16], $p<0.001$), respiratory failure (aOR: 4.40 [2.37–8.16], $p<0.001$), sepsis-related complications (aOR: 10.01 [4.57–21.95], $p<0.001$), and cerebrovascular accident (aOR: 7.18 [1.47–35.10], $p=0.015$). LOS costs also remained significantly elevated in the high frail adjusted models (aOR: 7.09 [4.51 – 9.67], $p<0.001$). **Conclusion:** Our study reveals a substantial association between higher frailty scores and adverse clinical outcomes among HRS-related hospitalizations. These findings highlight the importance of frailty assessment in managing patients with hepatorenal syndrome, emphasizing the need for targeted interventions and resource allocation for frail individuals to improve outcomes and reduce healthcare burden. Incorporating the Hospital Frailty Risk Score into clinical workflows may enhance risk stratification and guide personalized management strategies for this high-risk population.

Portugal, [12]Liver Unit, Hospital Clínic de Barcelona, Barcelona, Spain, [13]Department of Medical and Surgical Sciences, University of Bologna, Bologna, Italy, [14]Hospital Universitario Virgen Macarena, Sevilla, Spain, [15]Hospital Universitario Costa del Sol, Marbella, Spain

Background: Removal of the primary aetiological factor ('cure') may result in hepatic recompensation in patients with decompensated cirrhosis. This study assessed aetiology-specific differences in the incidence of recompensation and its impact on transplant-free survival. **Methods:** In this multicentre Baveno-endorsed study, patients with decompensated cirrhosis due to alcohol-related liver disease (ALD), hepatitis B (HBV) or hepatitis C (HCV) were included at time of aetiological treatment (abstinence or start of antiviral treatment) until December 2022. According to Baveno VII, recompensation was defined by (i) resolution of ascites and hepatic encephalopathy, (ii) no variceal bleeding for 1 year, and (iii) improved hepatic function. Alcohol relapse or viral reinfection/relapse led to censoring. **Results:** Among 1793 included patients (68.6% male; median age: 57 years), the underlying aetiology was ALD in 35.3% (n = 633), HBV in 35.6% (n = 639) and HCV in 29.1% (n = 521). Baseline MELD was highest in ALD (median: 17, IQR: 13-21), followed by HBV (median 13, IQR: 11-17) and HCV (median: 11, IQR: 9-14) ($p < 0.001$). Over a median follow-up of 54.6 months, 662 patients (36.9%) achieved recompensation. The overall 3-year cumulative incidence of recompensation was 34.0%, with 28.8% in ALD, 35.5% in HBV and 37.6% in HCV. Nevertheless, the aetiology was not significantly linked to the likelihood of recompensation after accounting for MELD, age and sex with an adjusted subdistribution hazard ratio of 1.010 (95% CI: 0.478-2.135; $p = 0.980$) for HBV vs. ALD and 1.228 (95%CI: 0.477-3.163; $p = 0.670$) for HCV vs. ALD. During the study period, 617 patients died: n = 123 in ALD (19.4%), n = 278 in HBV (43.5%) and n = 216 in HCV (41.5%). At 5 years, the cumulative incidence of all-cause mortality was 32.8% overall, with 19.2% in ALD, 47.7% in HBV and 29.9% in HCV. After adjusting for MELD, age and sex, recompensation (included as time-varying covariate) was associated with a significantly reduced risk of all-cause mortality across all aetiologies. Specifically, in ALD the adjusted hazard ratio was 0.223 (95%CI: 0.111-0.449; $p < 0.001$), in HBV 0.511 (95%CI: 0.304-0.860; $p = 0.011$) and in HCV 0.566 (95%CI: 0.417-0.769; $p < 0.001$). **Conclusion:** The incidence of hepatic recompensation is comparable between ALD, HBV and HCV after accounting for disease severity at baseline. Recompensation improves transplant-free survival across all treatable aetiologies.

2337 | READMISSION RATES FOR PATIENTS WITH CIRRHOSIS IN SASKATOON

Sushila Pathak[1], [1]University of Saskatchewan

Background: Cirrhosis is a major global health burden, causing over 1.5 million deaths annually. In the U.S., cirrhosis-related deaths rose by 65% between 1999 and 2016. In Canada, prevalence is projected to double by 2040, driven by increasing rates of alcohol-associated liver disease (ALD) and metabolic-associated steatotic liver disease (MASLD). Hospitalizations are frequently due to complications of portal hypertension such as ascites, variceal hemorrhage, hepatic encephalopathy (HE), and hepatorenal syndrome (HRS). Identifying predictors of readmission and mortality is critical to improving outcomes. **Methods:** We conducted a retrospective cohort study of 768 adult patients hospitalized with cirrhosis at Royal University Hospital and St. Paul's Hospital in Saskatoon, Saskatchewan, Canada (2016–2022). Patients with hepatocellular carcinoma or receiving palliative care were excluded. Data included demographics, etiology, MELD-Na, Child-Pugh class, complications, length of stay (LOS), discharge status, and readmissions at 30, 60, 90, and > 90 days. Univariate and multivariate analyses were used to identify predictors of 30-day readmission. Mortality was analyzed by complication type and burden. **Results:** The 30-day readmission rate was

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

23.4%, with 44.4% readmitted beyond 90 days. ALD was the leading etiology (49.7%), followed by MASLD and hepatitis C. LOS increased with MELD-Na category (<15, 15–20, >20), ranging from 7.0 to 12.0 days. Patients with MELD-Na >20 had the highest 30-day readmission rate (31.0%, $p=0.0099$). On multivariate analysis, higher Child-Pugh class was an independent predictor of 30-day readmission ($p=0.018$). Mortality was strongly associated with complication burden: patients with ≥ 4 complications had a 1-year mortality of 59.3%. HRS ($p<0.0001$) and HE ($p=0.021$) were the strongest individual predictors of death. ALD and mixed ALD/HCV etiologies were associated with higher readmission and mortality rates. **Conclusion:** In this Canadian dual-centre cohort, cirrhosis-related readmissions and mortality were highest in patients with advanced liver disease, multiple complications, and alcohol-related etiologies. HRS and HE were the most lethal complications. These findings support the need for risk-based discharge planning, outpatient follow-up, and integrated care models targeting high-risk subgroups.

Readmission Rates for Patients with Cirrhosis in Saskatoon

2338 | MEASURED SLEEP QUALITY AND CONSISTENCY ARE ASSOCIATED WITH IMPAIRED QOL AND SLEEP FUNCTION IN PATIENTS WITH CIRRHOSIS

Olivia Blocker[1] Ziyu Liu[1] Brian McSteen[1] Jessica Siguencia[1] Jialin Gao[1] Avesh Thuluvath[2] Elizabeth Verna[3] Ana Krieger[1] Himel Mallick[1] Robert Brown[1] Adam Buckholz[1], [1]Weill Cornell Medicine, [2]Columbia University Irving Medical Center, [3]Columbia Medical Center

Background: Many patients with cirrhosis report poor sleep quality, but formal assessment is rarely performed in clinical practice, making diagnosis and intervention difficult. Wearable devices offer a non-invasive, longitudinal method to track and characterize sleep but are understudied in this population. We hypothesized that worse measured short-term sleep would be associated with reduced patient reported sleep quality and overall quality of life (QoL). **Methods:** A prospective cohort of patients with cirrhosis were enrolled from 8/2023-5/2025. At baseline we collected clinical, laboratory, and survey data including the Pittsburgh Sleep Quality Index (PSQI) and the Chronic Liver Disease Questionnaire (CLDQ), where PSQI ≥ 5 and CLDQ <5 represented poor sleep and poor QoL, respectively. Sleep was longitudinally tracked for 6 months with a commercial wearable, the Oura Ring. We analyzed the first 14 recorded nights among participants with $\geq$ 14 nights of sleep data within 28 days of enrollment. Sleep data included total sleep time (TST), REM and deep sleep time, sleep efficiency (%SE), bedtime variability, wake after sleep onset (WASO), and sleep midpoint. Multivariable mixed effects models adjusting for age, gender, CTP score, and BMI were used to evaluate associations between objective and subjective measures of sleep quality and QoL. **Results:** Of 117 enrolled participants, 83 had ≥ 14 full nights of analyzable Oura data (n = 1162 nights). Among these, 73% had PSQI ≥ 5 and 55% CLDQ <5. Mean CTP scores were higher in those who reported poor sleep by PSQI (7.0 vs. 5.9, $p=0.03$), as well as lower QoL by CLDQ (7.1 vs 6.2, $p=0.049$). Mean TST was 388 minutes, with 75 min REM, 66 min deep sleep, 98 min WASO and 80% SE, with a mean sleep midpoint at 3:31 AM. Compared to those reporting good sleep, participants with poor sleep had Lower % SE (–4.9%, CI: –8.0 to –1.8, $p = 0.002$) Later average sleep midpoint (3:51 AM vs. 2:49 AM, $p < 0.001$) and Greater night-to-night variability in sleep midpoint (7.96 vs. 5.32 hours, $p < 0.001$), Higher %SE and lower WASO were associated with improved overall QoL. These associations remained significant in mixed-effects models adjusting for age, gender, BMI, and CTP score, except for WASO, which approached significance ($p = 0.056$). **Conclusion:** Impaired sleep efficiency and sleep consistency measured over a short period, 14 days, were associated with reduced QoL and self-reported sleep quality in cirrhosis. These findings suggest the clinical potential of wearable technology to identify sleep-related impairment and improve clinical monitoring in liver disease care. Later sleep midpoints and more variability in sleep period timing have been associated with circadian rhythm dysfunction, which may offer a therapeutic target for future studies to improve sleep and wellbeing in cirrhosis.

2339 | DIRECT ORAL ANTICOAGULANTS VERSUS ENOXAPARIN FOR PORTAL VEIN THROMBOSIS IN CIRRHOSIS WITHOUT HCC:A REAL-WORLD COMPARATIVE STUDY

Mohamed Nadeem[1] *Shilpa Junna*[2] *Archana Kharel*[1], [1]*Cleveland Clinic Foundation,* [2]*Cleveland Clinic*

Background: Direct oral anticoagulants (DOACs) are increasingly used for managing portal vein thrombosis (PVT) in cirrhotic patients without hepatocellular carcinoma, but comparative real-world data are limited. We compared clinical outcomes in cirrhotic patients receiving apixaban, rivaroxaban, or enoxaparin. **Methods:** Adult cirrhotic patients with PVT initiating apixaban (n = 2,259), rivaroxaban (n = 442), or enoxaparin (n = 6,262) were identified from the TriNetX database. Propensity score matching balanced demographic, clinical, and laboratory characteristics. Outcomes included a primary composite of ascites, hepatic encephalopathy (HE), spontaneous bacterial peritonitis (SBP), hepatorenal syndrome (HRS), variceal bleeding, and all-cause mortality. Secondary outcomes included individual components of the primary composite, liver transplantation, transjugular intrahepatic portosystemic shunt (TIPS) placement, and intestinal ischemia. Patients with hepatocellular carcinoma (HCC) were excluded. Outcomes were assessed using odds ratios (OR), 95% confidence intervals (CI), and two-sided p-values. **Results:** Demographic and clinical characteristics of our study population can be found in Table 1. After matching, the primary composite was noted to occur similarly between apixaban and rivaroxaban cohorts, (60.8% vs 59.2%; OR 1.07, 95% CI [0.82–1.40], p = 0.63) and there was no significant difference in risk of variceal bleed. Use of apixaban was associated with higher liver transplant rates (12.7% vs 5.7%; OR 2.42, 1.48–3.96, p < 0.001), but lower events of intestinal ischemia (9.1% vs 14.7%; OR 0.58, 0.38–0.88, p = 0.009), when compared to use of rivaroxaban. Compared to enoxaparin, apixaban significantly reduced the primary composite outcome (59.1% vs 72.5%; OR 1.82, 1.60–2.06, p < 0.001), all-cause mortality (21.4% vs 39.7%; OR 2.43, 2.13–2.77, p < 0.001), and incidence of variceal bleeding (19.9% vs 24.9%; OR 1.33,1.16–1.53, p < 0.001). Liver transplant rates were similar between apixaban and enoxaparin cohorts (11.9% vs 11.8%; OR 0.98, 0.82–1.18, p = 0.853). Compared to patients on rivaroxaban, those on enoxaparin had an increased risk of primary composite outcome (67.2% vs 58.8%; OR 1.44, 1.09–1.89, p = 0.01), and all-casue mortality (31.9% vs 25.1%; OR 1.40, 1.04–1.88, p = 0.025), and no significant difference in risk of variceal bleeding (25.3% vs 21.4%; p = 0.175). Additional findings are outlined in Table 2. **Conclusion:** In cirrhotic patients with PVT, DOACS demonstrated superior effectiveness and safety—markedly lowering hepatic decompensation, intestinal ischemia, and all-cause mortality—compared with enoxaparin. These findings support DOACs as the preferred anticoagulation strategy for this population.

2340 | POPULATION-LEVEL PATTERNS OF RECOMPENSATION IN CIRRHOSIS AND THEIR IMPACT ON MELD-NA TRAJECTORIES

Anna Goebel[1] Siqi Zhang[2] Marina Serper[3] David Kaplan[2] Nadim Mahmud[1], [1]Hospital of the University of Pennsylvania, [2]University of Pennsylvania, [3]University of Pennsylvania Health System

Background: Cirrhosis has traditionally been viewed as a progressive, unidirectional disease advancing from compensation to decompensation. However, emerging preliminary data support the concept of recompensation, wherein patients with decompensated cirrhosis can achieve a return to a compensated state. Understanding the frequency and biochemical markers of recompensation at the population level may have important implications for prognostication and disease management. This study aimed to characterize recompensation across distinct etiologies of liver disease and to evaluate longitudinal changes in MELD-Na trajectories among recompensated versus non-recompensated patients. **Methods:** This was a retrospective cohort study using data from the Veterans Health Administration. Patients with established cirrhosis due to MASLD, ALD, MetALD, HCV, or ALD+HCV who experienced an incident decompensation were included. Decompensation was identified based on paracentesis data, use of medications (diuretics, lactulose, rifaximin), and documented variceal bleeding. From the time of decompensation, patients were followed for up to 18 months. Recompensation was defined as the absence of paracentesis or decompensation-related medications for at least 12 consecutive months, with status also assessed at 18 months. MELD-Na trajectories were compared between recompensated and non-recompensated patients using linear regression. **Results:** A total 20,119 patients with cirrhosis and incident decompensation were included; the majority were MASLD (10,509), followed by HCV (7,376), ALD (5,919), MerALD (3,214), and ALD+HCV (2,101). There were significant differences in observed recompensation rates at 12 and 18 months across etiologies of liver disease (each $p < 0.001$), with HCV demonstrating the highest recompensation rates and ALD the lowest. For instance, 18% of patients with HCV had recompensation through 18 months, versus 12.4% MASLD and 11.7% ALD (Table 1). In comparing patients who remained recompensated through 18 months versus not, there were significant differences in MELD-Na trajectories. Significant declines in median MELD-Na were observed in recompensated patients (beta -0.34/month, $p = 0.04$), while there was no significant change in non-recompensated patients (beta -0.12/month, $p = 0.12$; Figure 1). **Conclusion:** Recompensation was observed across steatotic liver disease phenotypes and in HCV-related cirrhosis within this population-level dataset, with rates varying by etiology. Patients who achieved recompensation showed a significant decline in MELD-Na over time, supporting its association with measurable biochemical improvement. These results highlight recompensation as a clinically meaningful outcome and support the need for further investigation into its role as a prognostic marker and treatment target.

2342 | HIGHER PLATELET COUNTS DEFINE A LOW-RISK SUBGROUP AMONG RECOMPENSATED HBV CIRRHOSIS: A PROPENSITY-MATCHED COHORT STUDY

Bingqiong Wang[1] Zhiying He[1] Xiaoning Wu[2] shuai xia[1] Zhongjie Hu[3] Chunqing Zhang[4] Yanqin Hao[5] YongFeng Yang[6] Yan Huang[7] Wei Rao[8] Jing Wang[9] Xiaojuan Ou[1] Jialing Zhou[1] Ping Li[10] Jidong Jia[1] Hong You[11], [1]Liver Research Center, Beijing Friendship Hospital, Capital Medical University, [2]University of Michigan Medical Center, [3]Department of Critical Care Medicine of Liver Disease, Beijing YouAn Hospital, Capital Medical Unive, [4]Department of Gastroenterology, Provincial Hospital Affiliated to Shandong First Medical University, [5]Department of Infectious Diseases, The First Hospital of Shanxi Medical University, [6]Liver Disease Department, the Second Hospital of Nanjing, Affiliated to Medical School of South East, [7]Department of Liver and Infectious Diseases, Xiangya Hospital Central South University, [8]Division of Hepatology, Liver Disease Center, the Affiliated Hospital of Qingdao University, [9]Depatment of Gastroenterology, The Second Affiliated Hospital of Baotou Medical College, [10]Department of Hepatology, Tianjin Second People's Hospital, [11]Capital Medical University

Background: Recompensation could be achieved by effective etiological treatment in patients with HBV-related decompensated cirrhosis. However, it remains unclear whether the clinical prognosis of those who achieve recompensation is comparable to that of patients with compensated cirrhosis who have never experienced decompensation. **Methods:** Patients with HBV-related cirrhosis treated with first-line nucleos(t)ide analogues were enrolled from two cohorts: a retrospective cohort with treatment-naïve decompensated cirrhosis; a prospective cohort with treatment-naïve HBV-related compensated cirrhosis. Participants were classified into 2 groups: (1) compensated group, (2) recompensated group according to Baveno VII criteria. Propensity score matching (1:1) matched recompensated patients at their recompensation time point to compensated patients at 1 year of antiviral therapy. The primary outcomes included overall survival, liver-related mortality, incidence of decompensation, and hepatocellular carcinoma (HCC). Kaplan-Meier analysis and Cox proportional hazards models were used to compare outcomes between groups. **Results:** A total of 223 patients with recompensated cirrhosis and 859 patients with compensated cirrhosis following one year of anti-HBV treatment were enrolled in this study. After propensity score matching, well-balanced cohorts were obstained. During a median follow-up of 45.0 months (IQR: 31.0–53.0), patients with recompensated cirrhosis had a significantly higher risk of developing decompensation and HCC compared to those with compensated cirrhosis (HR = 1.95, 95%CI:1.29-2.95 for re-decompensation; HR = 3.38, 2.27-5.02 for HCC; Figure 1a). Subgroup analyses indicated that neither the type of initial decompensating event nor albumin levels at recompensation adequately discriminate patients with favorable prognoses (HR = 1.90-3.69 for HCC, HR = 2.05-3.74 for re-decompensation, compared with compensated cirrhosis; Figure 1b). Notably, among recompensated patients with higher platelet counts ($\geq 100\times10^9$/L), the risks of HCC and subsequent decompensation was comparable to those observed in patients with compensated cirrhosis (HCC: HR = 1.03, 95%CI: 0.43-2.49, $P = 0.944$; re-decompensation: HR = 0.86, 95%CI: 0.38-1.95, $P = 0.718$). **Conclusion:** Among patients with HBV-related cirrhosis who

achieving recompensation, those with higher levels of platelet counts demonstrate a promising prognosis similar to that of compensated cirrhosis. However, the remaining patients remain at elevated risk for subsequent decompensation and HCC.

Figure 1a. Cumulative incidence of liver related events in recompensated and compensated patients after recompensation or one year of antiviral therapy.

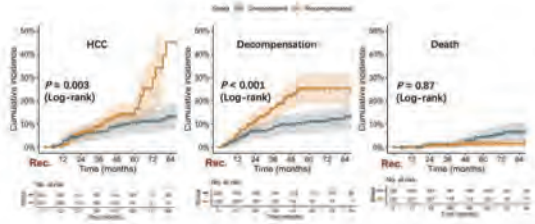

Figure 1b. Forest plot of hazard ratios of decompensation risk in recompensated vs compensated cirrhosis across different stratifications. Stratified by first decompensation type: Ascites and Bleeding. Stratified by serum albumin level. Stratified by platelet count.

2343 | SPLEEN AND LIVER SSI-SHEAR WAVE ELASTOGRAPHY ACCURATELY ASSESS THE RISK FOR CLINICALLY SIGNIFICANT PORTAL HYPERTENSION – THE PROSPECTIVE AIXPLORE STUDY

Christian Sebesta David Bauer[1] Mathias Jachs[1] Lukas Hartl[1] Michael Schwarz[1] Lorenz Balcar[1] Benedikt Hofer[1] Nina Dominik[1] Georg Kramer[1] Paul Thoene[1] Bernhard Scheiner[1] Albert Friedrich Stattermayer[1] Benedikt Simbrunner[1] Till Schöchtner[1] Friedrich Haimberger[1] Nicolas Balutsch[1] Michael Trauner[1] Mattias Mandorfer[1] Thomas Reiberger[1], [1]Medical University of Vienna

Background: Liver stiffness (LSM) and spleen stiffness (SSM) are closely correlated with the hepatic venous pressure gradient (HVPG), which is the minimal invasive reference standard for diagnosing clinically significant portal hypertension (CSPH; defined as HVPG $\geq$10 mmHg). Measurements of LSM, SSM, and related scores or models can be used to non-invasively estimate the risk of CSPH. **Methods:** In the prospective AIXPLORE study, 103 patients with compensated advanced chronic liver disease (cACLD) — 64% of whom had CSPH — were enrolled between July 2020 and August 2023. LSM and SSM were measured using 2D shear-wave elastography from SuperSonic Imagine (SSI). We evaluated: (i) the correlation of LSM and SSM with HVPG, (ii) optimal reliability criteria, and (iii) the diagnostic accuracy (AUC) of the measurement methods and multivariable models, including the resulting diagnostic gray zones and their accuracy for CSPH prediction. **Results:** The optimal reliability criterion for LSM was an interquartile range to median ratio (IQR/Median) $\leq$0.30 (met in 82.5% of cases), and for SSM a standard deviation $<$15 kPa (met in 70.9%). Both LSM and SSM showed good predictive value for identifying CSPH (AUCs $>$0.79). Multivariable models combining SSI-based LSM and SSM (the Anticipate-SSI model) with platelet count (PLT, used for LPS-SSI) significantly narrowed the diagnostic gray zone and achieved excellent discriminatory performance (AUCs $>$0.90). **Conclusion:** SSI-based measurements of spleen and liver stiffness allow for accurate non-invasive diagnosis of CSPH, particularly when applying the defined reliability criteria. Combined models incorporating SSI-SSM, SSI-LSM, and platelet count deliver the highest diagnostic precision while minimizing diagnostic uncertainty.

2344 | PROGNOSTIC PERFORMANCE OF THE ENHANCED LIVER FIBROSIS (ELF) TEST IN PATIENTS WITH ADVANCED CHRONIC LIVER DISEASE

Georg Kramer[1] Benedikt Simbrunner[1] Benedikt Hofer[1] Nina Dominik[1] Lorenz Balcar[1] Lukas Hartl[1] Mathias Jachs[1] Michael Schwarz[1] Christian Sebesta[1] Georg Semmler[1] Paul Thoene[1] Philipp Schwabl[1] Michael Trauner[1] Mattias Mandorfer[1] Thomas Reiberger[1], *[1]Medical University of Vienna*

Background: The enhanced liver fibrosis (ELF) test based on serum biomarkers was initially developed for fibrosis staging. This study aimed to evaluate its prognostic utility in a tertiary care cohort of patients with compensated (cACLD) and decompensated (dACLD) advanced chronic liver disease. **Methods:** Patients enrolled in the prospective VICIS study (NCT03267615) who underwent hepatic venous pressure gradient (HVPG), liver stiffness measurement (LSM) and ELF testing were included. Individuals were grouped as cACLD or dACLD (ascites, overt hepatic encephalopathy, variceal bleeding). In cACLD, the primary outcome was first hepatic decompensation. For dACLD, the composite outcome for disease progression (DP) included further decompensation, acute-on-chronic liver failure (ACLF) or liver-related death. Prognostic performance was evaluated using multivariable Fine-Gray competing-risks regression models, adjusting for age, sex, HVPG and body mass index. **Results:** Among 573 patients (230 cACLD, 343 dACLD), alcohol-related liver disease (ALD) was the leading etiology (44.7%). Median ELF (12.00 vs. 10.79, $p < 0.001$) and HVPG (19 vs. 11 mmHg, $p < 0.001$) were significantly higher in dACLD. Over a median follow-up of 18.7 months, first decompensation occurred in 51 cACLD patients (22%), while 168 dACLD patients (49%) experienced LRE. In cACLD, ELF yielded time-dependent area under the receiver operating characteristic curves (td-AUROCs) of 0.765 (1 year) and 0.754 (2 years) for first decompensation. Moreover, ELF was independently associated with decompensation (adjusted subdistribution hazard ratio [aSHR]: 1.35, $p = 0.002$). Stratification using ELF separated high risk patients (≥ 11.1) from medium-risk (10.1–11.09 vs. ≥ 11.1, Gray's test $p = 0.006$) and lower-risk (< 10.1 vs. ≥ 11.1, $p < 0.001$) ACLD groups. In dACLD, ELF showed moderate discrimination for DP (td-AUROCs: 0.585 and 0.649 at 1 and 2 years). ELF remained an independent predictor of DP (aSHR: 1.15, $p = 0.008$). Risk stratification differentiated high-risk (≥ 14.0) from medium-risk (12.5–13.9 vs. ≥ 14.0, $p = 0.003$) and lower-risk (< 12.5 vs ≥ 14.0, $p < 0.001$) groups, albeit with less balanced distribution than in cACLD. **Conclusion:** The ELF test is a valuable prognostic tool both in cACLD and dACLD. ELF effectively predicts first decompensation in cACLD and disease progression in dACLD patients, respectively, and thereby facilitates individualized risk stratification and selection of appropriate, potentially intensified therapies.

2345 | PROGNOSTICATION OF LIVER DISEASE PATIENTS VIA ARFI-BASED LIVER STIFFNESS MEASUREMENT USING THE WFUMB &LDQUO;RULE-OF-4&RDQUO; ALGORITHM

Christian Sebesta[1] Mathias Jachs[1] Lukas Hartl[1] Michael Schwarz[1] Lorenz Balcar[1] Benedikt Hofer[1] Nina Dominik[1] Georg Kramer[1] Paul Thoene[1] Bernhard Scheiner[1] Albert Friedrich Stattermayer[1] Benedikt Simbrunner[1] Till Schöchtner[1] Nicolas Balutsch[1] Friedrich Haimberger[1] Michael Trauner[1] Mattias Mandorfer[1] Thomas Reiberger[1] David Bauer[1], [1]Medical University of Vienna

Background: Liver stiffness measurement (LSM) using Acoustic Radiation Force Impulse (ARFI) technology represents a valuable tool for assessing liver disease severity. The recently proposed "rule-of-4" offers a comprehensive framework: values ≥ 13 kPa suggest advanced chronic liver disease (ACLD), while measurements > 21 kPa indicate a high likelihood of clinically significant portal hypertension (CSPH), which is associated with an elevated risk for liver-related events (LRE). **Methods:** We conducted a prospective study including 127 individuals with chronic liver disease who underwent ARFI-LSM via 2D-shear wave elastography (Aixplorer® Ultimate) and same-day hepatic venous pressure gradient (HVPG) measurements. Three groups were stratified based on LSM: < 13 kPa, 13–21 kPa, and > 21 kPa. All patients were followed for LRE defined by hepatic decompensation or liver-related death. Cumulative incidence of LRE was assessed using competing risk analysis across the three ARFI-based risk groups. **Results:** Among the participants, 17 (13.4%) had LSM values < 13 kPa (non-ACLD), 28 (22.0%) had values between 13 and 21 kPa (ACLD), and 82 (64.6%) had values > 21 kPa (CSPH). Median HVPG values increased progressively across the groups: 5 [IQR: 4-7] mmHg, 10 [8-12] mmHg, and 17 [12-20] mmHg, respectively, with corresponding CSPH prevalences of 11.8% in the < 13 kPa group, and 90.2% in the > 21 kPa group. Over a 12-month follow-up LREs occurred in 0% of non-ACLD, 7.1% of ACLD, and in 26.8% of the CSPH groups ($p = 0.007$). HVPG demonstrated the highest accuracy for predicting LREs (AUC: 0.79). ARFI-LSM and vibration-controlled transient elastography (VCTE) showed comparable performance (AUCs: 0.71 and 0.74, respectively; $p = 0.386$). Competing risk analysis showed LRE rates of 0%, 8%, and 30% for the three ARFI groups. **Conclusion:** Applying ARFI-LSM within the "rule-of-4" framework offers a non-invasive method to estimate liver disease progression and the risk of LRE. Patients with LSM values ≥ 13 kPa are at increased risk for LRE, with risk markedly elevated above 21 kPa. These findings support the broader integration of ARFI-LSM for liver disease prognostication.

2346 | NOVEL THERAPEUTIC STRATEGY FOR PORTOPULMONARY HYPERTENSION TARGETING PORTOSYSTEMIC SHUNTS

Tsuyoshi Ishikawa[1] Aika Kirihara[1] Natsuko Nishiyama[1] Daiki Kawamoto[1] Ryo Sasaki[1] Tatsuro Nishimura[1] Taro Takami[1], [1]Yamaguchi University Graduate School of Medicine

Background: Portosystemic shunt (PSS) development is considered to be a major risk factor for portopulmonary hypertension (PoPH), and reportedly contributes to PoPH onset through pulmonary arterial pressure elevation by increasing pulmonary arterial blood flow due to hyperdynamic state progression and pulmonary vascular resistance following humoral factor-mediated pulmonary vasoconstriction. However, there have been no studies on PSSs as a therapeutic target for PoPH. We previously reported a suggestive case in which PSS occlusion by balloon-occluded retrograde transvenous obliteration (BRTO) for refractory encephalopathy could successfully control pathophysiology of existing PoPH in alcoholic decompensated cirrhosis (J Vasc Interv Radiol. 2024). According to our case, the present study aimed to investigate changes in pulmonary arterial hemodynamics as well as those in systemic hemodynamics and humoral factors by PSS occlusion in patients with portal hypertension. **Methods:** Of patients who underwent BRTO at our hospital by November 2024, 25 patients who underwent transthoracic echocardiography (TTE) both before and after the procedure were enrolled in this retrospective study. Tricuspid valve systolic pressure gradient (TRPG) and cardiac output (CO) measured by TTE and blood levels of endothelin-1 (ET-1) and 5-hydroxytryptamine (5-HT) pre- and at 1month post-BRTO were statistically analyzed. **Results:** BRTO decreased TRPG in 20 of 25 patients (80%), and the postoperative reduction was statistically significant (24.9 ± 10.9 to 22.4 ± 9.6 mmHg, $p < 0.01$). In addition, following the procedure, ET-1 levels were significantly reduced (1.37 ± 0.79 to 1.13 ± 0.64 pg/mL, $p < 0.05$), and 5-HT levels showed a decreasing trend (51.6 ± 32.6 to 46.5 ± 27.1 ng/mL, $p = 0.10$). The CO was also significantly decreased postoperatively (5.3 ± 1.2 to 4.9 ± 0.7 L/min, $p < 0.05$). The maximum diameter of PSSs was the only preoperative parameter showing a significant difference between 20 patients with decreased TRPG and 5 patients with non-decreased TRPG (17.4 ± 4.6 vs. 11.8 ± 5.3 mm, $p < 0.05$), and the optimal cutoff value by receiver operating characteristic curve analysis was 12.17 mm (AUROC, 0.780; sensitivity, 90%; specificity, 60%). **Conclusion:** BRTO can control PoPH pathogenesis via both hemodynamic-related and humoral factor-related mechanisms. In addition, novel therapeutic strategy for PoPH can be expectedly developed with the prediction of TRPG reduction using the maximum diameter of PSSs.

2347 | RIFAXIMIN MONOTHERAPY IS SUPERIOR TO LACTULOSE MONOTHERAPY IN REDUCING THE RISK OF HEPATIC ENCEPHALOPATHY RECURRENCE: INSIGHTS FROM A SUBGROUP ANALYSIS BY BASELINE CHARACTERISTICS

Jasmohan Bajaj[1] Robert Rahimi[2] Christopher Allen[3] Zeev Heimanson[3] Kris Kowdley[4], [1]Virginia Commonwealth University, [2]Baylor University Medical Center, [3]Salix Pharmaceuticals, [4]Liver Institute Northwest

Background: Lactulose monotherapy is recommended as secondary prophylaxis after an initial overt HE (OHE) episode, with rifaximin added when subsequent episodes occur. However, non-lactulose–based management approaches may be required due to patient nonadherence or tolerability issues (eg, GI adverse events leading to dehydration/electrolyte imbalances and precipitating OHE, as well as issues with lactulose dosing/volume/unpleasant taste). The aim was to assess the impact of baseline parameters on the risk of OHE recurrence in patients treated with rifaximin monotherapy vs lactulose monotherapy. **Methods:** Data were pooled post hoc from 2 randomized trials (1 phase 3 double-blind; 1 phase 4 open-label) of 270 adults with cirrhosis and a history of OHE occurrence in the previous 6 months (currently in remission [Conn score ≤1]). Analysis included patients treated for up to

6 months with rifaximin 550 mg twice daily (ie, rifaximin monotherapy) or placebo plus lactulose (titrated [2-3 soft stools/d]; ie, lactulose monotherapy). The primary efficacy endpoint in both trials was time to first breakthrough OHE episode (Conn score ≥ 2). Patients were subgrouped by select baseline demographic/clinical characteristics. **Results:** 125 and 145 patients were treated with rifaximin monotherapy and lactulose monotherapy, respectively. The median (range) age in rifaximin vs lactulose groups was 58 y (32-83 y) vs 57 y (21-78 y); 60.0% vs 68.3% were male; 51.2% vs 46.2% were Child-Pugh (C-P) class B; and median Model for End-Stage Liver Disease score was 12 for both. Overall, significantly fewer patients treated with rifaximin monotherapy had an OHE episode vs lactulose monotherapy, with a 60% reduction in risk of a breakthrough OHE episode during 6 months of treatment (hazard ratio, 0.40; 95% CI, 0.26-0.62 [Table]). When analyzed by baseline parameters, rifaximin monotherapy was superior to lactulose monotherapy for all subgroups evaluated, except C-P class B or C and >2 HE episodes during previous 6 months (Table). The number needed to treat with rifaximin vs placebo to prevent an OHE episode was 4 for the overall population and ranged from 2 to 4 for the subgroups, showing significant differences between the 2 treatments. **Conclusion:** Rifaximin monotherapy demonstrates superior efficacy compared with lactulose monotherapy in reducing the risk of OHE recurrence in patients with cirrhosis and a history of OHE across a diverse range of demographic and baseline clinical characteristics.

2348 | THE EFFECT OF HEPATIC ENCEPHALOPATHY SERUM ON THE FIRING PATTERNS OF PRIMARY RAT NEURONS

David Yardeni[1] Daniel Kimhi[2] Ohad Etzion[1] Shira Knafo[2], [1]Soroka University Medical Center, [2]Ben-Gurion University of the Negev

Background: Hepatic encephalopathy (HE) ranges from minimal HE where patients show subtle cognitive and behavioral changes, to overt HE with asterixis, disorientation, lethargy, and ultimately coma. Its mechanism is incompletely understood, however assumed to be connected to gut-derived toxins. Multielectrode arrays (MEA) are special tissue culture plates containing a grid of small electrodes embedded in the bottom of each well and are used to record extracellular action potentials from neuronal cells cultured directly on top of the recording electrodes. Simultaneous recording of spiking activity from multiple spatial locations within a culture allows for the interrogation of population-wide firing activity, and understanding of how network dynamics may be altered in disease states. We aimed to investigate the effects of HE serum on the firing patterns of primary rat neurons (PRN) using a MEA. **Methods:** Cortical PRN cultures were grown on 16x24-electrode MEA dishes. Serum samples from 6 healthy donors and 4 patients with cirrhosis exhibiting clinical or laboratory signs suggestive of HE (Grade I–II HE) were applied to a separate neuronal culture that had established baseline activity. Spiking, bursting, and network connectivity patterns were recorded (Figure 1,a). **Results:** Recorded neuronal activity demonstrated comparable spike rates (Figure 1, b). However, HE serum significantly reduced burst frequency (c), shortened burst duration (d), decreased spikes per burst (e), and disrupted synchrony, as shown by lower cross-correlation values. **Conclusion:** This pilot study demonstrates that HE serum induces reproducible and quantifiable alterations in PRN function over time possibly contributing to cognitive impairment in HE.

2349 | HIGH-FIDELITY NATURAL LANGUAGE PROCESSING MODEL FOR AUTOMATED EXTRACTION OF RADIOLOGIC BIOMARKERS TO STUDY CIRRHOSIS OUTCOMES

Peiyun Ni[1] Prasanna Challa[1] Robert Wilechansky[2] Eric Przybyszewski[1] Brooke Rice[1] Emad Salman Shaikh[3] Maryam Ibrahim[1] Lauren Smith[1] Enoch Chung[1] Allison Carroll[1] Oluwafemi Balogun[1] Sway Chen[1] Gregory Fricker[1] Rebecca Liu[1] Tracey Simon[1], [1]Massachusetts General Hospital, [2]Oregon Health & Science University, [3]Brigham and Women's Hospital

Background: Radiological findings are key biomarkers for cirrhosis prognosis but remain underutilized due to unstructured reports and resource-heavy image analysis. Many deep learning models, while powerful, suffer from non-interpretable “black-box” features that hinder clinical adoption. We address these gaps with a natural language processing (NLP) framework that automates accurate extraction of imaging biomarkers from free-text radiology reports, enabling risk-stratified analysis of liver decompensation and 30-day hospitalization. **Methods:** We conducted a retrospective multicenter cohort study of 19768 adult patients with compensated cirrhosis from the Mass General Brigham healthcare system, from 1990 to 2024. The Clinical Longformer NLP model with data augmentation by Llama 3.1 was trained to extract 16 predefined imaging biomarkers of cirrhosis severity and portal hypertension from abdominal imaging reports (CT, US, MRI). NLP performance was manually validated in 1252 radiology reports. These validated features subsequently informed a Cox regression model to evaluate rates of incident major liver decompensation events and 30-day hospitalizations, among patients with compensated cirrhosis. **Results:** For all cirrhosis-related imaging features, the NLP algorithm yielded positive predictive values and sensitivity from 83.3% to 100%, with all negative predictive values between 97.9% and 100% (Table 1). Among 19768 patients with compensated cirrhosis, imaging features associated with higher rates of decompensation events included splenomegaly (HR 1.22, 95% CI 1.17-1.27), varices (HR 1.09, 95% CI 1.03-1.16), any ascites (HR 1.58, 95% CI 1.50-1.66), presence of TIPS (HR 1.36, 95% CI 1.17-1.58), abnormal venous flow (HR 1.19, 95% CI 1.08-1.31), and thrombus (HR 1.51, 95% CI 1.39-1.64). Any ascites (HR 1.62, 95% CI 1.44-1.82) and thrombus (HR 1.31, 95% CI 1.09-1.59) were also associated with higher rates of 30-day hospitalization (Table 2). **Conclusion:** The validated NLP algorithm enables accurate, automatic identification of key features of cirrhosis from radiology reports. In a large cohort of patients with compensated cirrhosis, presence of any ascites and thrombus on imaging are associated with higher rates of liver decompensation and 30-day hospitalization.

Table 1: Performance characteristics of natural language processing algorithm for identification of radiologic features in cirrhosis in test set (*n* = 188)

Feature	Accuracy %	Sensitivity/recall %	Specificity %	PPV*/Precision %	NPV* %	F_1 score	Support

2350 | ENDOSCOPIC ULTRASOUND GUIDED LIVER BIOPSY AND PORTAL PRESSURE GRADIENT MEASUREMENT COMPARED TO THE TRANSJUGULAR APPROACH: A RANDOMIZED CONTROLLED TRIAL

Amine Benmassaoud[1] Ali Bessissow[1] Gordan Samoukovic[1] Philip Wong[1] Xun Zhao[1] Marc Deschenes[1] Giada Sebastiani[1] Tatiana Cabrera[1] David Valenti[1] Louis-Martin Boucher[1] Jean-Pierre Pelage[1] Karl Muchantef[1] Andres Cardenas[2] Mary Anne Givis[1] Sheryl White[1] Guillaume Bousquet-Dion[1] Catherine Waked[3] Jeremie Jacques[1] Elham Rahme[1] Olivia Geraci[3] Myriam Martel[3] Alan Barkun[1] Chelsea Maedler-Kron[1] yen-I Chen[1], [1]McGill University Health Centre, [2]Institut de Malalties Digestives i Metaboliques, [3]Research institute-McGill University Health Centre

Background: The transjugular (TJ) technique is the gold standard to simultaneously evaluate portal hypertension and liver fibrosis, with the hepatic venous pressure gradient (HVPG) and liver biopsy (LB), respectively. Recently, Endoscopic Ultrasound (EUS) has emerged as a novel approach capable of measuring portal pressure gradient (PPG) and performing LB. We hypothesize that EUS will yield higher-quality LB than TJ and also provide consistent PPG measurements. To date, no randomized controlled trial (RCT) has compared EUS to TJ. **Methods:** This single center RCT included adults evaluated for liver fibrosis and portal hypertension. Participants were randomly assigned to EUS or TJ for simultaneous PPG and LB. The TJ technique was performed as per standard of care (low-dose midazolam, 18G TJ-LB system, and balloon-occlusion HVPG). EUS was performed under conscious sedation with ketamine and low-dose midazolam. EUS-PPG was done using a 25G needle (EchoTip Insight, Cook Medical) and LB with a 19G needle (Acquire, Boston Scientific). The primary endpoint was the proportion of high-quality LB (AASLD criteria: $\geq$25mm total aggregate length and $\geq$11 complete portal tracts using 2 or 3 passes) with consistent PPG (duplicate or triplicate measures within $\leq$1mmHg). Secondary endpoints included technical success (obtaining a LB and PPG), procedure time, LB- and PPG-related outcomes, adverse events (AE, ASGE grading at day 7) and patient satisfaction (patient sedation satisfaction instrument, PSSI). We conducted an intent-to-treat analysis, reporting n (%) and mean (SD), with statistical significance defined as a two-tailed p-value ≤ 0.05. **Results:** A total of 58 patients were randomized, 29 to EUS and 29 to TJ (56.6 [14.7] years old, 37.9% female, 50% MASLD, 67.2% cirrhosis). The primary endpoint was met in 24 (82.8%) for EUS vs 12 (41.4%) for TJ ($p < 0.01$). Technical success occurred in 26 (90.0%) for EUS vs 28 (96.6%) for TJ ($p = 0.61$). The procedure time was 20.7 (4.8) minutes for EUS and 48.8 (14.0) minutes for TJ ($p < 0.01$). Mean total aggregate length was EUS: 117 (83.7) mm vs TJ: 29.2 (9.5) mm ($p < 0.01$), complete portal tracts per specimen: EUS: 29.2 (18.7) vs TJ: 11.2 (5.8) ($p < 0.01$), longest core: EUS: 25.3 (17.1) mm vs TJ: 13.6 (3.8) mm ($p < 0.01$), number of passes: EUS: 2.1 (0.3) vs TJ: 2.3 (0.5) ($p = 0.02$). Consistent PPG was obtained in 26 (89.7%) for EUS vs 17 (58.6%) for TJ ($p < 0.01$). All AEs were mild, including 2 (6.9%) for EUS and 3 (10.3%) in TJ. As per PSSI, total patient satisfaction with sedation was higher for EUS ($p < 0.01$). **Conclusion:** While both procedures had similar technical success and safety profile, EUS is superior to TJ for the simultaneous acquisition of high-quality LB, consistent PPG, and patient satisfaction with sedation. In the well-selected cases, EUS is therefore preferable to TJ, paving the way for a significant shift in practice.

2351 | PREDICTORS AND SIGNIFICANCE OF ELEVATED LIPASE IN PATIENTS UNDERGOING EXPEDITED LIVER TRANSPLANT EVALUATION

Peyton Crest[1] Francis Yao[1] Chris Freise[1] John Roberts[1] Nghiem Ha[1], [1]University of California, San Francisco

Background: Serum lipase is a common but non-specific marker for pancreatitis and may be elevated in extra-pancreatic conditions. Among patients undergoing expedited liver transplant evaluation, lipase elevations are frequent yet unclear in significance. Accurate interpretation is crucial to avoid listing delays or unnecessary interventions. We aimed to identify predictors of clinically significant lipase elevation and assess its association with radiographic (RP) or intraoperative (IOP) pancreatitis. **Methods:** Retrospective cohort study of adults undergoing expedited liver transplant evaluation between 1/2020 and 3/2025 with elevated lipase ($\geq$78 U/L) within 14 days of pre-transplant, listing, or deferral/decline. RP was defined as imaging evidence of peripancreatic inflammation, necrosis, or fluid collections. IOP was defined as gross evidence of inflammation, necrosis, firmness, or surrounding saponification. Logistic regression identified predictors of clinically significant elevated lipase $\geq$3xULN and RP/IOP. **Results:** Among 178 patients, 47% were male with median age of 56; etiologies included alcohol-associated (43%), metabolic-associated (17%), viral hepatitis (14%), and cholestasis-associated (5%). Of these, 90 (51%) were transplanted, 40 (22%) waitlisted and 48 (27%) deferred/declined—primarily for psychosocial (19%), frailty (15%), or comorbidities (6%). Deferred/declined were younger (median age 53 vs 58 years, $p = 0.01$) and more likely to have alcohol-associated disease (67% vs 35%, $p < 0.001$). Independent predictors of lipase $\geq$3xULN were acute liver failure/Status 1A (OR 4.11, 95%CI 1.49-11.34) and GI-related infection (OR 2.03, 95%CI 1.02-4.01), after adjusting for age, alcohol-associated, kidney function, and MELD. While lipase $\geq$3xULN was not associated with RP/IOP, lipase $\geq$5xULN was predictive of RP/IOP (OR 6.92, 95%CI 2.04-23.52), and remained significant after adjusting for age, alcohol-associated, kidney function, MELD, and GI-related infection (OR 6.32, 95%CI: 1.78-22.47). **Conclusion:** Among patients undergoing expedited liver transplant evaluation, acute liver failure with Status 1A and GI infections predict lipase $\geq$3xULN, though not radiographic/intraoperative pancreatitis. However, lipase levels $\geq$5xULN may serve as a threshold for identifying individuals at increased risk for clinically relevant pancreatitis. These findings can guide interpretation of elevated lipase in transplant candidates and inform risk stratification and management.

Table 1. Univariable and multivariable logistic regression model for clinically significant lipase elevation (≥3xULN).

2352 | ELECTIVE TIPS AND KIDNEY FUNCTION: PROSPECTIVE ASSESSMENT OF EGFR TRAJECTORIES AND IMPACT ON CLINICAL OUTCOMES IN THE ADVANCING LIVER THERAPEUTIC APPROACHES (ALTA) STUDY GROUP

Giuseppe Cullaro[1] Michael Fallon[2] Pallav Kolli[3] Bartley Thornburg[4] Lisa VanWagner[5] Justin Boike[6] Elizabeth Verna[7], [1]Columbia University Irving Medical Center, [2]Banner Health, [3]UCSF, [4]Northwestern University, [5]University of Texas Southwestern Medical Center, [6]Northwestern Memorial Hospital/Northwestern University, [7]Columbia University Medical Center

Background: Transjugular Intrahepatic Portosystemic Shunt (TIPS) is widely used for portal hypertension complications, yet its effects on kidney function, particularly long-term outcomes, remain incompletely characterized. We examined longitudinal eGFR changes after TIPS creation and explored relationships between kidney parameters and clinical outcomes. **Methods:** The Advancing Liver Therapeutic Approaches in Portal Hypertension (ALTA) study is a multi-center prospective cohort study across 13 U.S. centers of adults ($\geq$18 years) who were scheduled for TIPS between 7/19-1/25. We included 522 subjects with 3-month post-TIPS creatinine data. CKD-EPI 2021 eGFR changes from baseline to 1, 3, 6, and 12 months post-TIPS were analyzed using linear mixed effects models. Subjects were categorized as "improved" ($>$10% increase), "stable" (within $\pm$10%), or "declined" ($>$10% decrease) based on baseline-to-3-month eGFR change. We assessed associations, including baseline eGFR and eGFR response, with hospitalizations with hepatic encephalopathy (HE) and, for those with ascites, number of paracenteses during 12-month

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

follow-up. **Results:** Among these 522 subjects, mean baseline eGFR was 79.2 ± 27.9 mL/min/1.73m². eGFR significantly increased at 1 and 3 months post-TIPS (84.0 ± 29.2, mean improvement 5.2 mL/min/1.73m², $p < 0.001$), with attenuated but sustained benefits at 6 and 12 months (Figure 1). Response distribution: 31% improved, 54% stable, 10% declined. The improved group had significantly lower baseline eGFR (69.6 ± 21.6 vs 84.4 ± 30.0 vs 80.7 ± 26.3 mL/min/1.73m² for improved, stable, and declined groups, $p < 0.001$) and greater Stage 3 CKD (37% v. 27%, $p < 0.001$). Factors associated with eGFR trajectory in univariable analyses included baseline eGFR (B = -0.01 ml/min/month, $p < 0.001$) and hepatorenal syndrome (HRS-AKI) history (B = 1.2 ml/min/month, $p < 0.001$). In the final multivariable model, only baseline eGFR (B = -0.01 ml/min/month, $p = 0.001$), HRS-AKI history (B = 0.9 ml/min/month, $p = 0.02$), and Asian race (B = -3.3 ml/min/month, $p = 0.01$). Only the baseline eGFR ($r = -0.01$, $p = 0.04$), but not the eGFR change over 12-months ($r = 0.01$, $p = 0.64$), was significantly correlated with the number of hospitalizations with HE over the 12-months after TIPS. Among the 249 (48%) subjects with ascites as an indication for TIPS, baseline eGFR ($r = -0.10$, $p < 0.001$), but not eGFR changes post-TIPS correlated with post-TIPS paracentesis requirements ($r = -0.02$, $p = 0.68$). **Conclusion:** TIPS creation is associated with early kidney function improvement, particularly in subjects with moderate baseline renal dysfunction. Baseline eGFR, but not eGFR improvement post-TIPS, was associated with post-TIPS hospitalizations with HE, and among those with ascites as a primary indication, baseline eGFR—not eGFR improvement—predicts need for post-TIPS paracenteses. These findings help inform the natural history of kidney function after elective TIPS creation.

2353 | NECROTIZING FASCIITIS IN CIRRHOSIS: A PROSPECTIVE STUDY OF CLINICAL FEATURES AND OUTCOMES COMPARED TO NON-CIRRHOTIC PATIENTS

Mallikarjun Patil[1] Harisimha Godha[1] Praveen Nanjeshi Gowda[1] Harshad Devarbhavi[1], [1]St. John's Medical College, Bengaluru

Background: Cirrhosis-associated immune dysfunction predisposes patients to severe bacterial infections, including necrotizing fasciitis (NF)—a rapidly progressive and life-threatening soft tissue infection. NF in cirrhotic patients is frequently under-recognized early due to non-specific clinical features. While early surgical intervention is crucial, data comparing NF in cirrhotic vs. non-cirrhotic patients are limited and mostly retrospective. This prospective study aimed to evaluate differences in clinical presentation, microbiological profiles, and outcomes in patients with and without cirrhosis. **Methods:** This prospective observational study included all consecutive adult patients diagnosed with NF in both cirrhotic and non-cirrhotic at tertiary care university hospital. Diagnosis of NF was based on clinical, surgical, and histopathological criteria. Patients were stratified based on the presence of cirrhosis. Data on demographics, clinical features, laboratory parameters, microbial isolates, and outcomes were recorded. Cirrhosis severity was classified using Child-Pugh and MELD scores. ACLF was defined by APASL criteria. Statistical comparisons were performed using t-tests or Wilcoxon rank-sum tests, with $p < 0.05$ considered significant. **Results:** The demographic and clinical characteristics of patients are shown in Table 1. Eighty-eight patients were included (35 with cirrhosis, 53 without). Alcohol was the predominant cause of cirrhosis (74%). Cirrhotic patients presented at a younger age (mean 48 vs. 55 years, $p = 0.008$), and 34% had ACLF. Mortality was significantly higher in the cirrhosis group (45.7% vs. 18.8%, $p = 0.006$), as was the incidence of shock (42% vs. 15%, $p = 0.008$). Gram-negative organisms were predominant in cirrhosis (60% vs. 4%, $p < 0.001$). All patients underwent surgical debridement and one third in both groups required re-intervention (range,1-3) and skin grafting. **Conclusion:** NF in cirrhosis presents earlier, is commonly caused by gram-negative organisms, and carries significantly higher morbidity and mortality. High clinical vigilance and early surgical debridement are

Background: Patients with cirrhosis are at risk of developing drug-resistant organisms (DRO) infections which can lead to poor outcomes. A recent study indicated that rifaximin could increase this risk, especially with daptomycin (dapto). There are global variations in rifaximin use & DRO prevalence. Aim: Determine the predictors of DROs in a global cohort of cirrhosis inpatients with infections and focus on pre-admission rifaximin. **Methods:** CLEARED consortium enrolls cirrhosis inpatients globally (FigA). Data re: pre-admission demographics, cirrhosis severity, complications, and medications on admission are recorded. We included those with infections either on admission or during the hospitalization only. The primary outcome was DROs (Vancomycin resistant Enterococcus (VRE), MRSA, carbapenem/fluroquinolone resistance), whether admission rifaximin was related & country-income level variations were studied. Logistic regression for DRO emergence was performed. **Results:** 7821 pts, of which 2823 had infections were enrolled (Fig B). 345 (12%) had DROs & 800 (28%) were on rifaximin. Mean age was 55 yrs with 63% men with mostly alcohol (42%) etiology were included. 24% were from LMICs, 44% UMIC & 32% HICs. Most had ascites (69%), 48% were on lactulose, 55% on diuretics, 16% on SBP prophylaxis & 44% on PPIs. Rifaximin use was highest in LLMICs, lowest in UMICs & intermediate in HICs ($p < 0.0001$). More males were on rifaximin (69 vs 61%), as well more people with alcohol (48 vs 40%) & MASH (22 vs 16%), while it was lower in HBV (10 vs 20%). Pts on rifaximin had more advanced cirrhosis with ascites (81 vs 63%), prior HE (63 vs 19%), AKI (34 vs 15%) prior infections (40 vs 26%). They had ↑admit MELDNa (26 vs 22, $p < 0.0001$) & WBC (8.5 vs 7.5, $p < 0.0001$). Dapto use was similar (1.9 vs 1.3%, $p = 0.29$). DROs (Fig C): Those with DRO were less likely to be men, have HBV, & more with MASH, lactulose/rifaximin use, & AKI. Country-incomes were similar. More DRO pts had dapto use (5.2 vs 1.0%, $p < 0.0001$). DROs resulted in higher in-hospital (29 vs 17%, $p < 0.0001$) & 30-day mortality (37 vs 27%, $p < 0.001$). Rifaximin and DROs crude/multivariable comparisons: No differences in VRE (2.1 vs 1.3, $p = 0.13$), MRSA (1.2 vs 1.3%, $p = 0.94$), fluoroquinolones (3.8 vs 3.6%, $p = 0.86$) was seen; carbapenem resistance was higher (4.4 vs 2.2%, $p = 0.003$) with rifaximin. On Multivariable analysis (Fig D) however, rifaximin was not significant; alcohol & HBV etiology linked with lower while MELD-Na was associated with higher DRO. **Conclusion:** 12% of inpatients with cirrhosis and infections had DROs which were associated with high mortality but were not different between country income types. Rifaximin pre-admission did not affect DROs in general or VRE specifically when adjusted on logistic regression. Daptomycin was used in $< 2\%$ of patients and unaffected by rifaximin. Rifaximin use is not associated with DRO emergence in a global cohort of inpatients with cirrhosis.

2356 | PREVALENCE AND CLINICAL OUTCOMES OF RECOMPENSATION IN DECOMPENSATED CIRRHOSIS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Xin En Goh[1] May Xuan Goh[2] Vincent L Chen[3] Guadalupe Garcia-Tsao[4] Juan Gonzalez-Abraldes[5] Yu Jun Wong[6], [1]Yong Loo Lin School of Medicine, National University of Singapore, Singapore, [2]Yong Loo Lin School of Medicine, NUS, [3]Division of Gastroenterology & Hepatology, University of Michigan, Ann Arbor, Michigan, USA, [4]Section of Digestive Disease, Yale University School of Medicine, New Haven, USA, [5]Liver Unit, Division of Gastroenterology, University of Alberta, Edmonton, Canada, [6]Department of Gastroenterology & Hepatology, Changi General Hospital, Singapore

Background: Patients with decompensated cirrhosis may experience recompensation following effective

etiological cure. However, the prevalence and clinical outcomes of decompensated patients who achieved recompensation remains unclear. We performed a systematic review and meta-analysis to determine the prevalence and clinical outcomes in decompensated patients who achieved recompensation. **Methods:** We systematically searched PubMed and EMBASE from inception to include all studies of patients with decompensated cirrhosis who achieved recompensation, evaluated the prevalence of clinical outcomes, specifically death and hepatocellular carcinoma (HCC), and compared them to patients who did not achieve recompensation. The primary outcome was the pooled prevalence of recompensation, and secondary outcomes included HCC occurrence and death. To improve precision of our analysis on the prognostic impact of recompensation, we applied a strict definition of recompensation, requiring both etiological cure and absence of liver decompensating events for one year, and minimum follow-up of two years. **Results:** A total of 26 studies encompassing 8,261 patients with decompensated cirrhosis were analyzed. The overall pooled prevalence of recompensation was 32% (95% CI: 24-41%). Recompensation prevalence was the highest among viral-related cirrhosis 46% (95%CI: 37-55%), followed by alcohol-related cirrhosis 21% (95%CI: 15-28%), and other etiologies 15% (95%CI: 2-37%). The pooled prevalence of recompensation was also higher in studies with lower median MELD (<15) and smaller sample sizes ($p<0.05$), but was not influenced by publication type or risk of bias. Over a median follow-up ranging from 2 to 8 years after recompensation, patients achieving recompensation had lower odds of HCC occurrence (OR: 0.60, 95%CI: 0.40-0.91, 6 studies) and death (OR: 0.34, 95%CI: 0.19-0.61, 5 studies). The clinical benefit of recompensation did not significantly differ between studies using the standard versus the expanded Baveno-VII criteria. Despite achieving recompensation, further decompensating events occurred in 13% (95%CI: 5%-23%). **Conclusion:** Recompensation occurred in approximately a quarter of decompensated cirrhosis patients who achieved etiological control. Recompensation was associated with a lower risk of death and possibly HCC, suggesting that recompensation could represent a clinically meaningful endpoint in patients with decompensated cirrhosis undergoing etiological treatment.

2357 | EFFICACY OF INTRAVENOUS ALBUMIN FOR MANAGEMENT OF CELLULITIS AMONG PATIENTS WITH LIVER CIRRHOSIS

Chetan Saner[1] Arun Vaidya[1] Akash Shukla[1], [1]Seth GS Medical College & KEM Hospital

Background: Cellulitis is one of the major bacterial infections in cirrhosis. Albumin is beneficial in spontaneous bacterial peritonitis but there is no data on efficacy of albumin in patients with cirrhosis and cellulitis. **Methods:** We conducted a open label study on adult patients with cirrhosis and new-onset cellulitis. One arm received Standard Medical Therapy (SMT) along with 20% albumin (20g/d) for 5 days and the other arm received SMT alone. Same antibiotics protocol was followed in both arms. The primary outcomes included 30-days mortality and time to cellulitis resolution (judged by an independent blinded investigator). Secondary outcomes were improvement in renal function, duration of hospital stay, improvement in CTP and MELD scores and requirement of surgical intervention. **Results:** A total 60 patients were included; 30 in each arm. Baseline characteristics were comparable in both arms. Duration of cellulitis resolution was significantly shorter in the albumin arm (median 6 vs. 8 days, $p=0.003$). The 30 days mortality was similar (6.7% vs. 10%, $p=0.64$). Overall hospital stay was significantly shorter in the albumin arm (8 vs 10 days, $p=0.01$). Decrease in serum creatinine at day 5, improvement in CTP and MELD score sat day 5 were comparable in both arms. There was a trend towards higher surgical intervention the SMT arm (36.7% vs. 16.7%, $p=0.08$). **Conclusion:** Intravenous albumin in patients with cirrhosis and cellulitis was associated with faster resolution of cellulitis and shorter hospital stay, without any difference in mortality.

Baseline Characteristics

Parameters	SMT + Albumin Arm	SMT Arm	P Value	Parameters	SMT + Albumin Arm	SMT Arm	P Value
Demographics				Lab Parameters on Day1			
Age (Median, IQR)	44 (40.75 – 53)	49.5 (40.5 – 56.25)	0.23	Total Leucocyte Count	16000 ± 10000	14000 ± 7100	0.37
Gender (Male)	25 (86.67%)	25 (83.33%)	0.72	Total Bilirubin	7.90 ± 3.93	5.87 ± 3.45	0.06
Etiology of Cirrhosis (Alcohol)	23 (76.67%)	21 (70%)		Serum Albumin	2.81 ± 0.35	2.74 ± 0.43	0.22
Site of Cellulitis				Creatinine	1.89 ± 0.63	1.82 ± 0.57	0.28
Right Lower Limb	16 (53.33%)	12 (40%)		INR	2.12 ± 0.66	2.02 ± 0.58	0.5
Left Lower Limb	8 (20%)	14 (46.67%)		CTP	12 (9.5 – 13)	13.5 (13, 14)	0.11
Bilateral Lower Limb	6 (20%)	4 (13.33%)		MELD	24 (22 – 27)	29 (27, 31)	0.22

Outcomes

Parameters	SMT + Albumin Arm	SMT Arm	P Value
Time to Resolution (Days)	6 (5 – 7.75)	8 (7 – 9)	0.003
Length of Hospital Stay (Days)	8 (6 – 10)	10 (9 – 11)	0.01
Need for Surgical Intervention	5	11	0.08
Need of RRT	4	2	0.39
Δ Creatinine	0.35 ± 0.56	-0.30 ± 1.27	0.18

2358 | A SIMPLE SCORE OF SARCOPENIC OBESITY PREDICTS ALL-CAUSE MORTALITY IN PATIENTS WITH CIRRHOSIS

Yuteng Yang[1] Tingyang Wei[1] Zixing Wang[1] Rui Huang[2], [1]Peking University People's Hospital, Peking University Hepatology Institute, [2]Peking University People's Hospital

Background: Sarcopenic obesity (Sa-O) is linked to poor prognosis in liver cirrhosis (LC), and Computed Tomography (CT)-based body composition parameters offer diagnostic value of Sa-O. This study aimed to evaluate the incidence, predictors, and prognostic impact of Sa-O on all-cause mortality in cirrhotic patients. **Methods:** This retrospective cohort included patients diagnosed with cirrhosis from November 2008 to September 2022. Sa-O was defined via L3-level CT as skeletal muscle index (SMI) <42 cm²/m² (men) or <38 cm²/m² (women) with visceral adipose tissue area (VATA) >100 cm². Clinical data was collected via medical records. The primary outcome was all-cause mortality. Predictors were identified using univariable and multivariable analyses. A nomograph was developed and the total points formed the ABAH (Age-BMI-Alcohol-Hypertension) score by the predictors. Subgroups analysis was conducted to calculate the hazard ratio of death (HR) by categorized ABAH level (low: <100, medium: 100-130, high: >130). **Results:** Among 769 patients (60.1% male; 45.5% ≥ 60 years; median follow-up duration: 1557 days), 281(36.5%) was diagnosed as Sa-O. Multivariable analysis identified age ≥ 60 years (OR 1.813, 95% CI 1.210-2.718, P = 0.0040), obesity and overweight (BMI ≥ 28 kg/m²: OR 0.076, 95% CI 0.018-0.317, P = 0.0011; 24-28 kg/m²: OR 0.650, 95% CI 0.442-1.001, P = 0.0352), alcoholic liver disease (OR 1.685, 95% CI 1.078-2.634, P = 0.0220), and hypertension (OR 1.801, 95% CI 1.184-2.739, P = 0.0059) as independent predictors of Sa-O. The average probability of Sa-O was respectively 8.4% (low), 18.7% (medium) and 30.5% (high), with an increasing trend (P = 0.0260). Subgroups analysis in cirrhotic patients with sarcopenic obesity found ABAH (medium vs. low: HR 1.53, 95% CI, 1.12-2.09, P = 0.007; high vs. low: HR 1.72, 95% CI, 1.22-2.42, P = 0.002) having predictive value for all-cause mortality. In females, both medium ABAH (HR 1.90, 95% CI 1.13-3.17, P = 0.015) and high ABAH (HR 1.97, 95% CI 1.12-3.45, P = 0.018) significantly increased mortality compared to the low ABAH, whereas in males (HR 1.60, 95% CI 1.03-2.47, P = 0.035) and viral hepatitis subgroup (HR 2.10, 95% CI 1.18-3.74, P = 0.012), only high ABAH showed a significant effect. Other high-risk subgroups included patients with multiple liver disease etiologies (medium vs. low: HR 3.92, 95% CI 1.37-11.20, P = 0.049; high vs. low: HR 3.94, 95% CI 1.24-12.50, P = 0.011), ascites (medium vs. low: HR 1.46, 95% CI 1.01-2.12, P = 0.046; high vs. low ABAH: HR 1.69, 95% CI 1.13-2.54, P = 0.011), and decompensated cirrhosis (medium vs. low: HR 1.43, 95% CI 1.00-2.04, P = 0.050; high vs. low ABAH: HR 1.62, 95% CI 1.10-2.38, P = 0.014) (Figure 1). **Conclusion:** Sa-O in cirrhotic patients was associated with Age, BMI, Alcoholic etiology, and Hypertension, the new ABAH score being predictive of their all-cause mortality.

2359 | STATIN USE IN LIVER TRANSPLANT CANDIDATES WITH DECOMPENSATED CIRRHOSIS: A MULTICENTER SAFETY ANALYSIS

Rishaan Sharma[1] John McMichael[1] Xaralambos Zervos[2] Kalyan Bhamidimarri[2] Nicholas Ruthmann[1] Omar Sims[1] William Carey[1] Shilpa Junna[1], [1]Cleveland Clinic Foundation, [2]Cleveland Clinic Florida

Background: Despite evidence of liver-specific benefits, statin use in patients with decompensated cirrhosis is often avoided due to concerns about complications such as rhabdomyolysis. This may increase cardiovascular risk and overlook potential hepatoprotective effects. We evaluated the safety of statin therapy in liver transplant (LT) candidates with decompensated cirrhosis. **Methods:** This multicenter retrospective study (Cleveland Clinic OH & FL) included 4,906 adult LT candidates listed between January 2000 and October 2023. Statin users (n = 277, 5.6%) had active prescriptions for ≥ 60 days prior to and after listing; non-users

(n = 4,629, 94.4%) served as controls. Patients with acute liver failure or re-transplantation were excluded. Outcomes included hepatic complications, rhabdomyolysis, and major adverse cardiovascular events (MACE) within 1 year post-listing. Hospital encounters were reported per 100 patients. Wilcoxon rank sum, Pearson's Chi-square, and Fisher's exact tests were used for comparisons. **Results:** The median age of the cohort was 64.0 years, 61.6% were male, with a median BMI of 27.9 and MELD 3.0 score of 12.2 at listing. Rates of hospital encounters per 100 patients were lower in statin users for variceal bleeding (2.68 vs. 6.05, p = 0.004), but higher for hepatic encephalopathy (89.7 vs. 58.6, p = 0.001). Rates were similar for ascites (118.4 vs. 124.6, p = 0.421), spontaneous bacterial peritonitis (SBP) (8.71 vs. 8.48, p = 0.912), and rhabdomyolysis (1.34 vs. 0.32, p = 0.097), which was rare. MACE rates at 1-year post-listing were not significantly different between groups (4.3% vs. 2.5%, p = 0.086). **Conclusion:** In this large multicenter cohort of LT candidates with decompensated cirrhosis, statin use was not associated with increased risk of rhabdomyolysis, cardiovascular events, or most liver-related complications. Statin users had lower rates of variceal bleeding, though higher rates of hepatic encephalopathy were observed. These findings support the overall safety of statin use in this population and highlight the need for further prospective studies.

Outcome	[ALL] n= 4,906	Statin users (n=277 (5.6%))	Non-statin users (n=4,629 (94.4%))	p-value
Overall Demographics Median [25th;75th]				
Age	64.0 [55.0;71.0]	67.0 [61.0;72.0]	63.0 [54.0;70.0]	<0.001
BMI	27.9 [24.3;32.3]	29.6 [26.2;34.4]	27.8 [24.2;32.2]	<0.001

2360 | EVALUATION OF SARCOPENIA-RELATED MUSCLE DECLINE IN PATIENTS WITH LIVER CIRRHOSIS FOR REHABILITATION

Hiroyuki Abe[1] Hiroteru Kamimura[1] Suguru Miida[1] Hiroki Maruyama[1] Saori Endo[1] Hitoshi Yoshiji[2] Masahito Shimizu[3] Takumi Kawaguchi[4] Tetsuya Tsuji[5] Shuji Terai[1], [1]Niigata University, [2]Nara Medical University, [3]Gifu University, [4]Kurume University, [5]Keio University

Background: Liver disease is a representative cause of secondary sarcopenia, and liver cirrhosis (LC) complicated by sarcopenia is associated with poor prognosis. Therefore, controlling sarcopenia progression is crucial. This study aimed to analyze factors related to muscle mass decline using the skeletal muscle index at the third lumbar vertebra (L3-SMI; cm²/m²), a representative indicator of sarcopenia. We establish and validate a predictive model for muscle mass decline in LC patients. **Methods:** This multicentered retrospective study included 612 LC patients (375 males; mean age: 70 years) from four facilities who underwent annual CT imaging, including the pelvis, over five years. L3 SMI (Skeletal Muscle Index) (cm²/m²) is calculated by dividing the skeletal muscle area at the L3 vertebral level (cm²) by the square of the individual's height (meters). L3-SMI was measured annually, and factors related to muscle mass decline were analyzed. A linear regression model predicting L3-SMI at year five (SMI_5) based on L3-SMI at year one (SMI_1) was developed using our institution's data and validated using external data from three other facilities. **Results:** For the predictive model derived from data on 175 patients, we validated its accuracy using a dataset of 343 patients from three other institutions. The model's performance was assessed using the root mean squared error (RMSE) and the coefficient of determination (R^2 score). Patients were categorized by Child-Pugh score (A: n = 466, B: n = 135, C: n = 11). The average annual decline rates in L3-SMI were significantly steeper in Child C patients (-1.79 ± 1.92 cm²/m²/year) than in Child A (-0.99 ± 0.70 cm²/m²/year, p = 0.002). A multiple regression analysis yielded the following predictive formula: SMI_5 = -1.194 + 0.731SMI_1 - 2.609 (male) + 0.081BMI - 0.033*age - 4.077 (Child B) - 23.085 (Child C) Validation with data from 343 external patients demonstrated high accuracy (R^2 = 0.0079; root mean squared error [RMSE] = 24.9328). In addition to factors significantly associated with SMI, males tended to have significantly higher SMI

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

values than females (regression coefficient: 6.829, P value < 0.01), higher albumin values tended to have higher SMI values (regression coefficient: 1.179, P value < 0.01), and SMI values with loop diuretics were lower than those without (regression coefficient: -1.025, P value < 0.01). The same results were also observed for Child-Pugh diuretics (regression coefficient: -1.275, P value < 0.01). **Conclusion:** This study identified a significant correlation between liver functional reserve (Child-Pugh score) and the rate of muscle mass decline, with worse liver reserve associated with accelerated muscle loss. The developed model accurately predicts future L3-SMI values based on current L3-SMI,age, BMI, and Child-Pugh score. These findings support the potential for personalized hepatic rehabilitation protocols targeting sarcopenia in LC patients.

2361 | INCIDENCE, RISK FACTORS, AND OUTCOMES OF MAJOR ADVERSE KIDNEY EVENTS IN PATIENTS WITH DECOMPENSATED CIRRHOSIS

Rakhi Maiwall[1] Sumeet Asrani[2] Gnana Kavitha[1] Neha Chauhan[1] Chhagan Bihari[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences, [2]Baylor University Medical Center, part of Baylor Scott & White Health

Background: Patients with cirrhosis have significant hemodynamic alterations and require continuous medications, predisposing them to the development of major adverse kidney events (MAKE). However, limited studies have evaluated risk factors for MAKE in cirrhosis **Methods:** We investigate a large retrospective cohort of decompensated cirrhosis (n = 3708) patients, from index hospitalization, risk factors for development of MAKE at 1 year. MAKE was defined as a composite of ≥25% decline in eGFR, development of de-novo chronic-kidney-disease (CKD) stage ≥3 or CKD progression (≥50% reduction in eGFR compared with baseline) or new haemodialysis or death. eGFR was measured every 3-6 months. Competing risk survival analysis was performed to identify risk factors of MAKE. **Results:** Patients {mean age 48 ± 15 years, 86% males, MELDNa 24 ± 10, eGFR 92.23 ± 51.54 ml/m^2, alcohol-related liver disease (ALD) in 38.5% } admitted with decompensated cirrhosis, 20% without acute kidney injury (no AKI 76.5%, CKD (32% CKD) or AKI on CKD (29%) while CKD without AKI (2.9%) were followed for a median of 220 days (IQR 198-354). Altogether, 63% developed MAKE (50% showed eGFR decline, 31% developed de-novo CKD, 15% had CKD progression, 38% required dialysis), 28% died while 5% and 2% underwent LT or TIPS respectively. MAKE was an independent predictor of mortality (HR 1.25, 95% CI 1.08-1.46). On multivariable analysis, patients with AKI on CKD had the highest risk (HR 2.42, 2.12-2.76), followed by CKD without AKI (HR 1.76, 1.45-2.14) while presence of AKI alone (sHR 0.96, 0.86-1.08) ref (no AKI or CKD), sepsis (sHR 1.82, 1.62-2.05), refractory ascites (sHR 1.79, 1.59-1.99) higher leucocyte counts (sHR 1.02, 1.001-1.03) and MELDNa (sHR 1.03, 1.02-1.04) were risk factors for MAKE. Patients with MAKE had more frequent hospitalizations (OR 3.84, 3.53-4.17), new episodes of AKI (OR 1.87, 1.53-2.30), hepatic encephalopathy (OR 1.38, 1.17-1.63) and worsening of ascites (OR 5.03, 4.33-5.84). Cystatin C was available in 436 patients and was found to be an independent risk factor for MAKE (sHR 1.74,1.54 -1.97). **Conclusion:** MAKE develops in almost two-thirds of patients with decompensated cirrhosis which is associated with higher risk of major adverse liver outcomes and mortality. Patients with background CKD and those with risk factors of MAKE should be closely monitored with biomarkers or eGFR equations for institution of appropriate therapeutic interventions for prevention and consideration of an early liver transplant.

Digestive and Liver Diseases, Columbia University Irving Medical Center, New York, NY, [2]Mailman School of Public Health, Columbia University, New York, NY, [3]Division of Gastroenterology and Hepatology, Weill Cornell Medicine, New York, NY, [4]Department of Population Health Sciences, Weill Cornell Medicine, New York, NY

Background: Frailty is strongly associated with mortality in cirrhosis and may be exacerbated by decreased physical activity as liver disease progresses. Digital wearable technology, such as Oura™ rings, present a potential strategy to longitudinally monitor physical activity. We used Oura rings to study the association between severity of liver disease, frailty and physical activity in patients with cirrhosis. **Methods:** Adults with cirrhosis were prospectively enrolled at two centers in New York City from 8/2023-5/2025 and provided with an Oura ring for 6 months. Frailty was measured in a subset of patients using the Liver Frailty Index (LFI: grip, chair stands and balance testing). Daily total steps from each patient were extracted from the 1st month after enrollment. Data from the first 14 days in which the patient wore the ring $\geq$ 90% of the day were analyzed. Linear mixed effects models were used to estimate the association between daily total steps, indicators of liver disease severity (MELD, Child-Turcotte-Pugh Score [CTP], history of ascites, hepatic encephalopathy [HE] and variceal hemorrhage) and frailty. **Results:** Of the 111 enrolled participants, 109 had $\geq$ 1 day with $\geq$ 90% wear-time within the first month after enrollment; 50% were male, the mean age was 55.1 ($\pm$11.2) years and the most common etiologies of cirrhosis were alcohol-associated liver disease (35%) and metabolic dysfunction-associated steatotic liver disease (33%). The mean MELD was 10.6 ($\pm$4.8); 53% were CTP A, 33% CTP B and 14% CTP C, while 52% were decompensated. Among participants who underwent baseline LFI, mean LFI was 3.61 ($\pm$0.62). After adjusting for sex and age, a 1-point increase in MELD was associated with a 4% decrease in daily step count (95% CI: -2%, -7%, $p<0.01$) (Figure 1). Compared to CTP A, CTP B (-32%, 95% CI: -12%, -48%, $p<0.01$) and CTP C (-55%, 95% CI: -34%, -69%, $p<0.01$) were inversely associated with daily step count, as was a history of ascites (-40%, 95% CI: -48%, -12%, $p<0.01$) or HE (-27%, 95% CI: -44%, -4%, $p=0.03$). A 1-point increase in LFI was associated with an estimated 37% decrease in daily step count (95% CI: -57%, -7%, $p=0.04$) after adjusting for age, sex and MELD score. **Conclusion:** Physical activity measured by digital wearable technology is significantly associated with severity of liver disease and frailty in patients with cirrhosis. These findings demonstrate the potential for Oura rings to track physical activity in patients with cirrhosis and potentially even monitor response to frailty interventions and predict progression of both frailty and liver disease.

2363 | REAL-WORLD COMPARATIVE OUTCOMES OF TERLIPRESSIN USE IN HEPATORENAL SYNDROME: A PROPENSITY SCORE-MATCHED ANALYSIS OF U.S. HOSPITALIZED PATIENTS

Romelia Barba[1] Khawaja Hassam[2] Ana Marenco-Flores[3] Natalia Rojas-Amaris[3] Daniela Goyes[4] Denisse Rubio Cruz[3] Leo Yamaguchi[1] Kanak Das[1] Hakan Akin[1] Michael Curry[3], [1]Texas Tech University, [2]Lahey Hospital and Medical Center, [3]Beth Israel Deaconess Medical Center, [4]Yale School of Medicine

Background: Hepatorenal syndrome–acute kidney injury (HRS-AKI) is a life-threatening but reversible complication of cirrhosis. Terlipressin, a vasopressin analog, is FDA-approved and guideline-recommended for HRS-AKI, yet trials (OT-0401, REVERSE, CONFIRM) did not demonstrate a mortality benefit, likely due to limited power and inclusion of patients with advanced disease. Real-world data are needed to assess its effectiveness and safety in U.S. clinical practice. **Aim:** To evaluate real-world outcomes of terlipressin versus standard therapy in hospitalized adults with HRS-AKI. **Methods:** We conducted a retrospective cohort study using the TriNetX U.S. Collaborative Network, a federated research platform aggregating de-identified

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

electronic health record data from multiple healthcare organizations. Among 13,888 hospitalized adults with HRS from September 14, 2022, through May 2025, 378 patients treated with terlipressin were 1:1 propensity score-matched to 378 patients receiving albumin and/or norepinephrine, midodrine, or octreotide. Matching included MELD 3.0 variables: serum sodium, creatinine, total bilirubin, INR, and albumin. Outcomes within 90 days included mortality, dialysis, liver transplant, and recurrent HRS. Odds ratios (OR), hazard ratios (HR), and Kaplan-Meier analyses were used. **Results:** After matching, mortality was slightly lower in the terlipressin group compared to controls (38.4% vs. 40.2%; OR 0.93, 95% CI 0.69–1.24; $p = 0.60$), as was dialysis initiation (24.1% vs. 26.7%; OR 0.87, 95% CI 0.63–1.21; $p = 0.40$), though neither reached statistical significance. In contrast, terlipressin-treated patients had higher rates of liver transplantation (17.7% vs. 7.4%; OR 2.67, 95% CI 1.69–4.29; $p < 0.001$) and recurrent HRS (49.7% vs. 35.2%; OR 1.82, 95% CI 1.36–2.44; $p < 0.001$). Kaplan-Meier analysis showed increased hazards for both recurrent HRS (HR 1.60, 95% CI 1.28–1.99; $p < 0.001$) and transplant (HR 2.63, 95% CI 1.69–4.09; $p < 0.001$) in the terlipressin group. **Conclusion:** In this multi-center matched cohort, terlipressin was not associated with significant reductions in mortality or dialysis, which is consistent with findings from prior trials. Higher transplant and recurrent HRS rates may reflect greater illness severity, treatment timing, or differential access to transplant. Due to de-identified data, site-level variation and practice patterns could not be assessed. Additionally, competing risks (e.g., death prior to transplant) were not formally modeled, which may influence the interpretation of non-fatal outcomes. These findings underscore the complexity of real-world terlipressin use and the need for prospective studies to clarify its role and guide MELD policy recalibration in transplant-listed patients.

2364 | PLASMA AMMONIA LEVELS OVER THE COURSE OF A HOSPITALISATION FOR OVERT HEPATIC ENCEPHALOPATHY

Davide Erminelli[1] Chiara Mangini[2] Dario Gapeni[2] Lisa Zarantonello[2] Sara Montagnese[2], [1]University of Padova, Department of Medicine, [2]University of Padova

Background: The diagnostic and prognostic role of ammonia in the assessment of Overt Hepatic Encephalopathy (OHE) remains debated. The aim of the present study was to assess the time-course of ammonia levels during an OHE-related hospitalisation in relation to OHE duration/severity and the length of hospitalisation. **Methods:** All patients admitted to the Liver Unit, Padova University Hospital (Italy) between January 2021 and July 2024 with a verified discharge diagnosis of OHE were included ($n = 104$; 77% males, 72 ± 11 years). Clinical and laboratory indices, including ammonia levels prior to admission/after discharge (time frame: ± 6 month from hospitalisation) and during the hospitalisation (average of 3 measurements, up to 10) were recorded, along with duration of hospitalisation, precipitants, ongoing ammonia-lowering and psychoactive treatment. **Results:** Over the studied time frame, 58 (56%) patients had a single OHE hospitalisation while 20 (19%) had 2-7 OHE hospitalisations. Of the 104 hospitalisations, 31 (30%) were for grade II, 66 (63%) grade III and 7 (7%) grade IV OHE. Of the 58 single hospitalisations, 23 (40%) were for grade II, 33 (57%) for grade III and 2 (3%) for grade IV OHE. Ammonia levels increased progressively and significantly with increasing OHE grade (II: 118 ± 47 μmol/L; III: 155 ± 62 μmol/L; IV: 219 ± 65 μmol/L; $p < 0.001$, grade II vs grade III and IV, $p < 0.05$ and $p < 0.01$ respectively). Ammonia levels prior to admission/after discharge (87 ± 35 μmol/L and 79 ± 42 μmol/L, respectively) were significantly lower than those on admission (148 ± 63 μmol/L; $p < 0.0001$, Figure 1A). Hospitalisations for grade IV OHE were longer (12.3 ± 6.5 days) than those for grade III (5.8 ± 4.8 days $p < 0.01$). Lower levels of ammonia on admission were found in patients qualified as not fully recovered on discharge (124 ± 60 μmol/L) and those on chronic treatment with psychoactive drugs (117 ± 57 μmol/L) compared to their counterparts (155 ± 63 μmol/L, $p < 0.05$; 158 ± 62 μmol/L, $p < 0.01$ respectively). All the above held true when analyses were restricted to the 58 single hospitalisations (Figure 1B). **Conclusion:** OHE presence and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

severity correlated both with ammonia levels and with the duration of hospitalisation. Ammonia on admission was significantly higher to baseline ammonia levels prior to admission and after discharge. Incomplete recovery and chronic treatment with psychoactive drugs were associated with lower ammonia levels, suggesting confounding in the expression of OHE phenotype.

2365 | ULTRASOUND MUSCULAR THICKNESS-BASED MODEL TO IDENTIFY SARCOPENIA IN PATIENTS WITH PORTAL HYPERTENSION (PH): A CROSS-SECTIONAL SINGLE-CENTER OBSERVATIONAL STUDY

Martina Lucà[1] Lorenzo Argiento[1] Giulia Tosetti[1] Valentina Cardone[1] Sofia Ridolfo[1] Edoardo Acquati[1] Francesco Cicchetti[1] Edon Xhepa[1] Matilde Pavan[1] Chiara Grilli[1] Pierpaolo Biondetti[1] Salvatore Alessio Angileri[1] Simona Stella[2] Gianpaolo Carrafiello[1] Pietro Lampertico[1], [1]Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, [2]Occupational Health Unit, Foundation IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy

Background: Sarcopenia is a prevalent complication in cirrhosis (affecting 40–70% of patients) and an independent predictor of poor outcomes. Although CT imaging is the diagnostic gold standard, its use is limited by cost, radiation, and availability. Therefore, reliable, reproducible, and non-invasive tools are needed for routine sarcopenia screening and follow-up. **Methods:** This cross-sectional, single-center study included consecutive outpatients with cirrhotic or non-cirrhotic PH who had recent abdominal CT scans. Ultrasound (US) assessment of muscle thickness was performed at four sites—biceps brachii (BB), rectus abdominis (RA), rectus femoris (RF), and thigh muscles (TM)—by two blinded, trained operators. Clinical, anthropometric, biochemical, and nutritional data were collected. Sarcopenia was defined by CT using EASL/AASLD-endorsed L3 skeletal muscle index (L3-SMI) cut-offs. Associations between sarcopenia and clinical or US parameters were analyzed. **Results:** A total of 102 patients were enrolled (median age 61, 63% male, 84% cirrhotic, median BMI 25.7 kg/m²). Sarcopenia prevalence was high in both cirrhotic and non-cirrhotic PH patients (54.1% vs. 61.5%, $p = 0.58$), without significant sex-related differences. Among the parameters evaluated, US-RF thickness and BMI showed the strongest inverse correlations with sarcopenia: OR 0.79 (95% CI: 0.69–0.91, $p < 0.01$) and OR 0.80 (95% CI: 0.63–0.91, $p < 0.01$), respectively. Based on these findings, a sex-specific model was developed, combining BMI with US-RF thickness. The model showed best performance in cirrhotic men and in women overall, using BMI thresholds of 28.6 kg/m² for men and 21.7 kg/m² for women, with US-RF thickness cut-offs of 15 mm and 10 mm, respectively. These cut-offs yielded good diagnostic accuracy, with an overall AUC of 0.78. Intra- and inter-operator reproducibility of US measurements was excellent (ICC > 0.95). **Conclusion:** Ultrasound assessment of muscle thickness, especially when integrated with BMI, appears to be a reliable, non-invasive, and reproducible bedside method for identifying sarcopenia in patients with portal hypertension. Future studies on larger, sex-stratified cirrhotic cohorts are warranted to assess its prognostic value.

2366 | INTERPRETING SPLEEN STIFFNESS MEASUREMENT: THE ROLE OF TECHNICAL RELIABILITY CRITERIA IN CLINICAL DECISION-MAKING

Elizabeth Williams[1] Regina Weber[1] Archita Desai[1] Raj Vuppalanchi[1], [1]Indiana University

Background: The interquartile range to median ratio (IQR/M) is a widely accepted reliability criterion for liver stiffness measurement (LSM), where values ≤10% are considered very reliable, 10–30% reliable, and > 30% unreliable in cases with ≥10 valid measurements.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

However, equivalent criteria have not been established for spleen stiffness measurement (SSM). This study aimed to evaluate the utility of IQR/M as a reliability metric for SSM and its impact on diagnostic accuracy in detecting esophageal and/or gastric varices. **Methods:** In this cross-sectional study, 170 patients underwent 220 paired SSM and upper endoscopy exams within six months. SSM was measured using vibration-controlled transient elastography (FibroScan 630 Expert). We assessed the diagnostic accuracy of SSM $>$ 50 kPa —a threshold aligned with the Baveno VII guideline for high-risk varices—across varying IQR/M levels. **Results:** SSM and endoscopy were performed on the same day in 55 patients, with a median interval of 1.2 months (IQR 0–3). The median patient age was 60 years (range 20–83), with 55.3% male and 90% White. Common liver disease etiologies included metabolic dysfunction-associated steatotic liver disease (33.5%) and alcohol-associated liver disease (22.9%). Mean platelet count was $116 \pm 91 \times 10^3/\mu L$, INR 1.3 ± 0.5, and MELD score 12 ± 4. The prevalence of SSM $>$ 50 kPa was 68%, with only 6.7% meeting the unreliability criteria of IQR/M $>$ 30%. Without applying reliability criteria, the presence of varices was accurately identified in 125 patients (83.3%). When applying IQR/M $\leq$ 30%, diagnostic accuracy increased to 86.4% (121/140). Stricter thresholds (IQR/M $\leq$20% and $\leq$10%) were associated with lower diagnostic accuracy (Table 1). **Conclusion:** In patients with suspected portal hypertension and SSM $>$ 50 kPa, unreliable measurements (IQR/M $>$30%) were rare (6.6%). Applying IQR/M $\leq$ 30% as a reliability threshold modestly improved diagnostic accuracy for detecting varices. However, using more stringent thresholds paradoxically reduced diagnostic performance, suggesting that while reliability criteria enhance confidence, overly restrictive cutoffs may exclude valid clinical data.

Table 1. Diagnostic Accuracy of Spleen Stiffness Measurements in Identifying Esophageal and/or Gastric Varices Based on Interquartile Range/Median

	IQR/M ≤ 30% (n=140)	IQR/M > 30% (n=10)	P-value	Accuracy	IQR/M ≤ 20% (n=116)	IQR/M > 20% (n=34)	P-value	Accuracy	IQR/M ≤ 10% (n=69)	IQR/M > 10% (n=81)	P value	Accuracy
			0.001	84.7%			0.005	75.3%			0.048	53.3%
SSM > 50 kPa + Varices, n (%) Accurate	121 (86.4)	4 (40.0)			102 (87.9)	23 (67.6)			62 (89.9)	63 (77.8)		
SSM > 50 kPa + No Varices, n (%) Inaccurate	19 (13.6)	6 (60.0)			14 (12.1)	11 (32.4)			7 (10.1)	18 (22.2)		

IQR/M: Interquartile Range (IQR)/Median (M)

2367 | PREDICTORS OF POST TIPS PERSISTENT ASCITES

JAYASHREE BISWAS[1] Shiv Kumar Sarin[2] VINOD ARORA[3] AMAR MUKUND[2] YASHWANT PATIDAR[4], [1]INSTITUTE OF LIVER AND BILIARY SCIENCES, NEW DELHI, INDIA, [2]Professor, [3]Associate Professor, [4]Associate Professor, ILBS

Background: TIPS is used to lower portal pressure in refractory ascites. However, a proportion of patients require therapeutic paracentesis despite adequate portal pressure reduction and on optimum tolerable diuretic dose. This study investigated factors responsible for 'post-TIPS ascites persistence". **Methods:** EMRs of patients who underwent TIPS for refractory ascites over 5 years were reviewed. Ascites persistence was defined as the need for paracentesis $>$1 month post-TIPS despite max tolerable dose of diuretics and no shunt stenosis defined as angiographic evaluation of greater than 50% stenosis, PSG $>$12 mmHg or Doppler criteria. Follow-up: 1 month post-TIPS, then every 3 months. Patients needing paracentesis were evaluated for cardiac, renal, or shunt-related causes. Data included: Pre-TIPS labs and echo, TIPS procedure details, Post-TIPS outcomes SPSS v30; paired t-test, univariate and multivariate regression. $p<0.05$ significant. **Results:** 384 patients underwent TIPS placement during this period. TIPS placement due to variceal bleed (n=96), Budd-Chiari Syndrome (n=65) or miscellaneous reasons (n=6) or received liver transplant (n=32) or had incomplete data (n=185) were excluded. Finally, 107 patients were taken for assessment and follow-up Patients requiring therapeutic paracentesis after one month of TIPS (Group A) were compared with those who did not require tapping (Group B). Mean age Group A [n=39 (36.4%)] 53.05 $\pm$ 11.03 and Group B [n=68 (63.6%)] 53.14 $\pm$ 13.35 was comparable. Median MELD in group A was higher than group B {17.05 $\pm$ 5.14 vs.14.75 $\pm$ 4.13, p= 0.016} along with CTP score {8.82 $\pm$ 1.57 vs 7.95 $\pm$ 1.33, p 0.004}. The pre-TIPS cardiac ECHO parameters in Gr. A vs. B {RA dimension pre-TIPS 34.08 $\pm$ 5.31 vs 32.90 $\pm$ 6.71, p 0.35}, E/e' ratio Group A vs Group B {pre and post TIPS 8.46 $\pm$ 2.10 vs 6.6 $\pm$ 4.85 p 0.31, 8.96 $\pm$ 2.00 vs 8.08 $\pm$ 4.20 p values 0.11} were not statistically significant. Baseline Plasma Renin Activity had a mean of 11.80 $\pm$ 1.47 in the entire TIPS cohort, NT Pro BNP 967.51 $\pm$ 238.10 taking log into account. Pre and Post-TIPS plasma renin levels (p=0.04) were significantly higher in group A, possibly contributing to ascites recurrence. MELD, CTP, serum ALT, total protein, haemoglobin, and LA dimension were variables considered in univariate analysis. Multivariate analysis- MELD and CTP were the only variables contributing to post-TIPS ascites persistence. Post-TIPS, RA Pressure increased from 4.95 $\pm$ 3.24 to 9.44 $\pm$ 3.81 (p-value $<$0.01) in Group A. Portal Pressure reduction was significant in both groups (p-value $<$0.01) The average stent diameter in Group A patients was 8mm compared to group B, where 10mm stent was placed. **Conclusion:** Post-TIPS ascites persisting beyond 1 month, can be attributed to higher MELD, and CTP score, higher

baseline PRA and or smaller diameter stent that may attribute to delayed ascitic fluid mobilization as one of the factors for therapeutic paracentesis, despite optimum portal pressure reduction.

2368 | UNDERUTILIZATION OF STATINS IN YOUNGER CIRRHOTIC PATIENTS DESPITE HEPATOPROTECTIVE BENEFITS: A PROPENSITY-MATCHED REAL-WORLD STUDY

Mohammad Adam[1] Fatima Elmustafa[2] Abdellatif Ismail[3] Abdelhaleem Sideeg[4] John Helzberg[5] Ashwani Singal[6], [1]University of Missouri - Kansas City School of Medicine, Kansas City, MO, [2]Henry Ford Health System, Warren, MI, [3]University of Maryland Medical Center Midtown Campus, Baltimore, MD, [4]Virginia Mason Medical Center, Seattle, WA, [5]University of Missouri-Kansas City, Saint Luke's Liver transplant Program, [6]University of Louisville

Background: Despite historical concerns regarding hepatotoxicity, emerging evidence suggests statins may offer hepatoprotective effects in patients with cirrhosis. Using real-world data from a large, multicenter electronic health record network, we evaluated the association between statin use and liver-related outcomes. **Methods:** We conducted a retrospective cohort study using the TriNetX US Collaborative Network. Adults (≥18 years) with alcoholic or unspecified cirrhosis were categorized into statin-exposed and statin-naïve groups. Propensity score matching (1:1) was performed based on demographics, comorbidities, and labs. Outcomes included hepatocellular carcinoma (HCC), liver decompensation (ascites, hepatic encephalopathy, variceal bleeding, spontaneous bacterial peritonitis, hepatorenal syndrome), and liver transplantation (LT). Hazard ratios (HRs) with 95% confidence intervals (CIs) were calculated. **Results:** Before matching, statin users (n = 239,120) were older (mean age: 64.2 vs. 56.3) and had more comorbidities than non-users (n = 488,690). After matching, yielding 136,091 patients per group, baseline characteristics were balanced. Statin users had a lower risk of HCC (HR 0.66; 95% CI: 0.64–0.69; p < 0.001) and liver decompensation (HR 0.70; 95% CI: 0.68–0.71; p < 0.01). Transplant-free survival was similar (HR 1.02; p = 0.14). **Conclusion:** In this large real-world cohort, statin use was associated with a reduced risk of HCC and liver decompensation in patients with cirrhosis. These findings suggest that statin therapy should not be discouraged and may, in fact, be encouraged for its hepatoprotective benefits, particularly in younger cirrhotic patients.

2369 | RISING SEPSIS-RELATED MORTALITY IN CIRRHOTIC PATIENTS IN THE UNITED STATES (1999–2020): A CDC WONDER ANALYSIS

Corinne Caissie[1] Simran Joshi[2] Saman Javid[3] Gaurav Sharma[4] Laksh Kumar[5] Aseef Rehman[6] Faizan Saqib[7] Sardar Noman Qayyum[8] Revathi Rajendran[9] Muhammad Faizan Ali[10] Preethi Jagannath[11] Marquise Soto[12] Jeevin Singh Sandhu[13] Matthew Manoj[14], [1]Yale New Haven Health, Brigeport Hospital, CT, [2]Yale New Haven Health, Bridgeport Hospital, [3]CMH Kharian Medical College, Kharian, Pakistan, [4]JNU Medical College, Jaipur, [5]Shaheed Mohtarma Benazir Bhutto Medical College, Lyari, [6]University College of Medicine and Dentistry, Lahore, Pakistan, [7]House Officer, CMH Kharian, [8]Bacha Khan Medical College, Mardan, Pakistan, [9]Sri Lalithambigai Medical College and Hospital, [10]Jinnah Postgraduate Medical Center, [11]Mayo Clinic, Rochester, MN, [12]Massachusetts General Hospital, Boston, MA, [13]Methodist Dallas Medical Center, Dallas, TX, [14]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Background: Patients with cirrhosis are at elevated risk for sepsis due to profound immune dysfunction, impaired hepatic clearance, and increased gut permeability. Sepsis—a dysregulated host response to infection leading to life-threatening organ dysfunction—remains a major contributor to mortality in this population. Monitoring long-term mortality

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

trends is critical to understanding disease burden and informing targeted clinical interventions. **Methods:** We conducted a retrospective, population-based study using age-adjusted mortality data from the CDC Wide-ranging Online Data for Epidemiologic Research (WONDER) database to assess trends in sepsis-related deaths among individuals with cirrhosis in the United States from 1999 to 2020. Joinpoint regression analysis was applied to identify statistically significant inflection points in mortality trends. Annual percent change (APC) and corresponding 95% confidence intervals were calculated to quantify temporal shifts. **Results:** The analysis revealed two distinct mortality trends. From 1999 to 2009, sepsis-related mortality among cirrhotic patients remained relatively stable (APC: 0.07; $p > 0.05$). In contrast, the period from 2009 to 2020 demonstrated a significant upward trajectory (APC: 4.03; $p < 0.05$), indicating a substantial increase in sepsis-associated deaths. This shift suggests a worsening clinical outlook for cirrhotic patients in the context of systemic infection over the last decade. **Conclusion:** The observed rise in sepsis-related mortality in patients with cirrhosis underscores an urgent need for improved surveillance, early detection, and management strategies tailored to this high-risk group. Potential contributors include increasing cirrhosis prevalence, evolving microbial resistance, suboptimal care pathways, and delayed diagnosis. Future research should focus on identifying modifiable risk factors and developing evidence-based protocols to reduce mortality and improve outcomes in cirrhosis-associated sepsis.

2370 | OVERALL MORTALITY TRENDS IN LIVER CIRRHOSIS AND GASTROINTESTINAL HEMORRHAGE (1999–2020)

Corinne Caissie[1] Simran Joshi[1] Saman Javid[2] Gaurav Sharma[3] Laksh Kumar[4] Sushrut Ingawale[5] Preethi Jagannath[6] Marquise Soto[7] Jeevin Sandhu[8] Matthew Manoj[9], [1]Yale New Haven Health, Bridgeport Hospital, CT, [2]CMH Kharian Medical College, Kharian, Pakistan, [3]JNU Medical College, Jaipur, [4]Shaheed Mohtarma Benazir Bhutto Medical College, Lyari, [5]Quinnipiac University Frank H. Netter MD School of Medicine / St. Vincent's Medical Center, Bridgepo, [6]Mayo clinic, Rochester, MN, [7]Massachusetts General Hospital, Boston, MA, [8]Methodist Dallas Medical Center, [9]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA

Background: Liver cirrhosis and gastrointestinal (GI) hemorrhage remain significant contributors to morbidity and mortality in the United States. Understanding long-term mortality trends is essential for informing public health strategies and resource allocation. Our objective is to evaluate national trends in mortality from liver cirrhosis and GI hemorrhage in the U.S. between 1999 and 2020 using joinpoint regression analysis. **Methods:** Age-adjusted mortality rates were obtained from the CDC WONDER database. Joinpoint regression modeling was used to identify statistically significant changes in temporal trends. Annual Percent Changes (APCs) and corresponding 95% Confidence Intervals (CIs) were calculated for each trend segment. **Results:** From 1999 to 2007, mortality from liver cirrhosis and GI hemorrhage declined significantly, with an APC of –4.97% (95% CI: –7.04 to –3.69; $p = 0.004$). This trend reversed between 2007 and 2018, with a modest, non-significant increase in mortality (APC = +1.85%, 95% CI: –0.65 to 3.00; $p = 0.080$). A marked and statistically significant increase was observed from 2018 to 2020, with an APC of +12.70% (95% CI: 4.29 to 17.36; $p < 0.000001$), indicating a concerning resurgence in mortality in recent years. **Conclusion:** Following a period of improvement from 1999 to 2007, mortality from liver cirrhosis and GI hemorrhage plateaued and then rose sharply beginning in 2018. This recent surge

2371 | RIFAXIMIN USE IS ASSOCIATED WITH REDUCED MORTALITY AND HOSPITALIZATIONS IN CIRRHOTIC PATIENTS: A GLOBAL COHORT STUDY

Mohamad Mahdi Osman[1] Mohamad-Noor Abu-Hammour[1] Walid Hazem[2] Leandro Sierra[1] Omar Sims[1] Dian Chiang[3], [1]Cleveland Clinic Foundation, [2]University Hospitals, [3]Cleveland Clinic

Background: Lactulose and Rifaximin with or without lactulose are recommended therapy for prevention of recurrent hepatic encephalopathy (HE) in patients with cirrhosis. While rifaximin is often added as adjunct therapy, it is sometimes used alone in patients who are intolerant to lactulose. This retrospective study evaluates the effectiveness of rifaximin monotherapy versus lactulose monotherapy using a large global database. **Methods:** Using the TriNetX research network, we identified adult patients with cirrhosis and hepatic encephalopathy who were prescribed either rifaximin or lactulose alone. The rifaximin cohort included 1,737 patients, and the lactulose cohort included 12,950 patients. After 1:1 propensity score matching based on demographics, liver function tests, comorbidities, and MELD components, 1,734 matched pairs were analyzed. The primary composite outcome was recurrent HE and all-cause mortality. Secondary outcomes included all-cause hospitalizations, spontaneous bacterial peritonitis (SBP), and HE. **Results:** Rifaximin monotherapy was associated with a significantly lower risk of the primary composite outcome compared to lactulose monotherapy, driven largely by a reduction in all-cause mortality (HR 0.689; 95% CI 0.603–0.786; p = 0.003). Rifaximin also significantly reduced all-cause hospitalizations (HR 0.456; 95% CI 0.405–0.514; p = 0.045). While SBP was less frequent in the rifaximin group (HR 0.285; 95% CI 0.152–0.532), this difference did not reach statistical significance (p = 0.762). There was no significant difference in rates of HE (HR 1.045; 95% CI 0.940–1.160). **Conclusion:** In this large real-world cohort, rifaximin monotherapy was associated with reduced mortality and hospitalization rates compared to lactulose monotherapy in cirrhosis patients with hepatic encephalopathy, despite similar rates of recurrent HE. These findings suggest that rifaximin monotherapy may be superior to lactulose monotherapy in this population. Further risk stratification of HE patients and pharmacoeconomic study may help individualize treatment approach to prevent recurrent HE.

2372 | COMPARATIVE OUTCOMES OF CIRRHOSIS ETIOLOGIES: A PROPENSITY SCORE–MATCHED ANALYSIS OF ALCOHOLIC VS NON-ALCOHOLIC CIRRHOSIS

Yazan Al Jabiri[1] Mohammad Aldiabat[1] Sura Issa[2] Thabet Qapaja[1] Kamran Qureshi[3] Wing-Kin Syn[3], [1]Washington university in saint louis, [2]Jordan university, [3]Saint Louis University School of Medicine

Background: Cirrhosis represents the terminal stage of chronic liver disease, yet clinical outcomes vary by etiology. While some analyses have contrasted single etiologies against all others combined, there remains a paucity of head-to-head comparisons across specific causes. This study aimed to compare long-term outcomes of several distinct cirrhosis etiologies—each matched to alcoholic cirrhosis (AC)—using a large real-world electronic health record dataset. **Methods:** We performed a retrospective cohort study using TriNetX, a US Collaborative Network comprising 69 tertiary institutions, to identify adults with cirrhosis due to autoimmune hepatitis (AIH); biliary diseases (BD) including primary biliary cholangitis and primary sclerosing cholangitis; chronic hepatitis B (CHB); chronic hepatitis C (CHC); metabolic dysfunction-associated steatotic liver disease (MASLD); and genetic metabolic liver diseases (GMLD) including Wilson disease, hemochromatosis, and alpha-1 antitrypsin deficiency. Each etiology was propensity score–matched 1:1 to AC based on demographics, MELD components, liver enzymes, and prior complications. Outcomes were assessed over 10 years and included hepatic encephalopathy (HE), hepatorenal syndrome (HRS), ascites, spontaneous bacterial peritonitis (SBP), upper gastrointestinal bleeding (UGIB), transjugular intrahepatic portosystemic shunt (TIPS), portal hypertension, hepatic vein thrombosis (HVT), portal vein thrombosis (PVT), hospitalization, emergency department (ED) visits, liver transplantation (LT), hepatocellular carcinoma (HCC), and a composite outcome. Results are presented as hazard ratios (HRs) with 95% confidence intervals (CIs) and p-values. **Results:** Compared to AC, CHB and CHC had the most favorable profiles, showing lower risks of HE, ascites and hospitalization, though both had increased HCC risk (CHB: HR 2.873, $p < 0.001$; CHC: HR 2.634, $p < 0.001$). AIH and BD were associated with improved composite outcomes but showed elevated risks of HVT (AIH: HR 2.030, $p = 0.018$; BD: HR 2.084, $p = 0.002$), PVT (AIH: HR 1.261, $p = 0.005$; BD: HR 1.588, $p < 0.001$), and LT (AIH: HR 1.584, $p < 0.001$; BD: HR 2.274, $p < 0.001$). MASLD-related cirrhosis showed worse outcomes, including HE (HR 1.050, $p < 0.001$), UGIB (HR 1.259, $p < 0.001$), TIPS (HR 1.541, $p < 0.001$), HCC (HR 1.764, $p < 0.001$), LT (HR 2.488, $p < 0.001$), PVT (HR 1.820, $p < 0.001$), and HVT (HR 1.831, $p < 0.001$). GMLD-related cirrhosis showed better outcomes across most endpoints, though it was associated with increased HVT (HR 3.298, $p = 0.003$) and HCC (HR 1.326, $p < 0.001$). **Conclusion:** In this large cohort study, non-alcoholic cirrhosis etiologies were associated with more favorable outcomes than AC. Conversely, MASLD-related cirrhosis was linked to worse prognosis across multiple complications. These findings support etiology-specific risk stratification and emphasize the need for tailored management strategies in cirrhosis care.

2373 | POINT-OF-CARE ULTRASOUND-BASED VOLUME STATUS METRICS AS PREDICTORS OF HEPATORENAL SYNDROME–ACUTE KIDNEY INJURY IN HOSPITALIZED PATIENTS WITH CIRRHOSIS: A PROSPECTIVE COHORT STUDY

Daniel Alvarez Suneet Waghmarae[1] Kelsie Pereyra-Bencosme[1] Nicholas Samel[2] Ashley Choi[2] Paola Mejia[1] Zoe Verzani[3] Abhilash Koratala[4] Benjamin Galen[1] Brett Fortune[5], [1]Montefiore Medical Center/Albert Einstein College of Medicine, [2]Albert Einstein College of Medicine, [3]Weill Cornell Medicine, [4]Montefiore Medical Center/Albert Einstein College of Medicine/Medical College of Wisconsin, [5]Montefiore Medical Center

Background: Hepatorenal syndrome–acute kidney injury (HRS-AKI) was traditionally thought to result solely from renal vasoconstriction driven by splanchnic vasodilation and reduced effective circulating volume in cirrhosis. Recent evidence, however, suggests a multifactorial etiology that includes subclinical to overt cardiac dysfunction—the so-called hepatocardiorenal syndrome—as well as congestion-related renal impairment. Point-of-care ultrasound (POCUS) is increasingly used to assess systemic congestion and has been validated in patients with heart failure, but its role in cirrhosis remains underexplored. We evaluated whether POCUS-derived volume metrics—including ultrasound-estimated jugular venous pressure (uJVP), venous excess ultrasound (VExUS) score (integrating portal, hepatic, and renal vein Doppler), inferior vena cava (IVC) parameters, and lung B-line burden—predict the development of HRS-AKI in hospitalized patients with decompensated cirrhosis. **Methods:** We conducted a prospective observational study of 37 hospitalized patients with decompensated cirrhosis, including three readmissions treated as separate subjects, yielding 40 observations. All underwent comprehensive POCUS on admission, including uJVP (via internal jugular distension), IVC diameter and collapsibility, VExUS score, and lung B-line burden. Patients were monitored for HRS-

AKI during hospitalization. HRS-AKI was defined as a creatinine rise of ≥ 0.3 mg/dL within 48 hours or ≥ 50% within 7 days, without response to diuretic withdrawal and albumin (1g/kg) for two days. **Results:** The cohort had a median age of 54; 63% were male, 68% Hispanic, and 68% had alcohol-associated liver disease. At admission, median MELD 3.0 was 23, median MAP was 79 mm Hg, and median creatinine was 0.92 (Table). Fourteen (35%) developed HRS-AKI. Compared to those without HRS-AKI, affected patients had significantly higher uJVP (mean 10.63 cm vs 7.89 cm, $p = 0.043$) and a trend toward higher VExUS scores: 25% of patients with HRS-AKI had a VExUS score ≥ 1, compared to 8.6% in those without ($p = 0.2$). IVC assessment was limited due to poor acoustic windows. Lung B-line burden did not differ between groups ($p = 0.9$). **Conclusion:** Higher uJVP and elevated VExUS scores—markers of right-sided filling pressure and venous congestion—may serve as early predictors of HRS-AKI in cirrhosis. These findings suggest underlying hemodynamic disturbances, such as reduced effective circulating volume, since venous congestion can impair the organ afterload, ultimately reducing organ perfusion. While not all associations reached statistical significance due to limited sample size, effect size trends were notable. POCUS-based volume assessment may aid in early risk stratification for HRS-AKI and warrants validation in larger cohorts.

2374 | CIRRHOSIS AS AN INDEPENDENT RISK FACTOR FOR MORTALITY IN HOSPITALIZED PATIENTS WITH ASPIRATION PNEUMONIA: A NATIONWIDE INPATIENT SAMPLE (NIS) STUDY

Angelin Raju[1] Anish Jomy[2] Aashish Anunaya[1], [1]Texas Health Resources HEB/ Denton, [2]Methodist Richardson Medical Center

Background: Aspiration pneumonia (AP) is a known complication in patients with multiple comorbidities, yet its interplay with cirrhosis remains under-characterized. This study aims to assess the burden, demographics, outcomes, and resource utilization among hospitalized patients with AP and coexisting cirrhosis using data from the NIS. **Methods:** Using NIS datasets (2018-2022), we identified admissions for AP with Cirrhosis vs without cirrhosis using relevant International Classification of Diseases(ICD), Tenth Revision codes. We compared the demographics, comorbidity burden (Elixhauser index), in- hospital outcomes and related comorbidities between the two groups. **Results:** Out of the 33,905,592 weighted adult hospitalizations, 678,739 had aspiration pneumonia, of which only 1.9% ($n = 13,035$) had cirrhosis. Cirrhotic cohorts were significantly younger (mean age 66 vs 73 years), males (66% vs 57%), higher Elixhauser comorbidity burden (98.9% vs 83.1%) and had higher proportions of Hispanic and Native American individuals than non-cirrhotic cohort (all $p < 0.001$). In-hospital mortality was higher in patients with cirrhosis (unadjusted odds ratio ≈1.52, $p < 0.001$). After adjusting for confounders, cirrhosis remained an independent predictor of mortality (design-based F-test, adjusted odds ratio[AOR] = 1.37, $p < 0.001$), alongside older age and higher comorbidity burden. Female sex was associated with slightly reduced mortality risk; race was not statistically significant in the adjusted model. Cirrhotics had longer LOS (+1.1 days, $p = 0.053$) and higher unadjusted hospital charges (+$23,800), though not significant after adjustment. Heptic Encephalopathy was significantly higher in cirrhotic cohort (11.9% vs 0.17%; AOR≈ 44, $p < 0.001$) but lower adjusted odds for dysphagia(AOR 0.65, $p < 0.001$), GERD(AOR 0.85, $p = 0.001$), PEM(AOR = 0.869, $p = 0.003$); suggesting potential confounding. **Conclusion:** In this large, nationally representative

study, cirrhosis was present in a small subset (1.9%) of patients hospitalized with aspiration pneumonia but was independently associated with significantly increased in-hospital mortality, even after adjusting for demographic and clinical confounders. Cirrhotic patients exhibited a higher burden of comorbidities, were younger, and more likely to belong to Hispanic or Native American populations. While cirrhosis was associated with markedly higher rates of hepatic encephalopathy-nearly 44-fold increased odds-it was paradoxically linked to lower adjusted odds of dysphagia, GERD, and PEM, suggesting possible diagnostic or coding bias. These findings underscore the need for heightened clinical vigilance and targeted management strategies in cirrhotic patients hospitalized with aspiration pneumonia.

2375 | BELAPECTIN MAINTAINS A FAVORABLE TREND IN REDUCING VARICEAL DEVELOPMENT OVER 36 MONTHS IN MASH CIRRHOSIS: RESULTS: FROM THE NAVIGATE TRIAL

Eric Lawitz[1] *Mazen Noureddin*[2] *Naga Chalasani*[3] *Raj Vuppalanchi*[4] *Edward Mena*[5] *Nadege Gunn*[6] *Zainab Abbas*[7] *Khurram Jamil*[8] *Naim Alkhouri*[9], [1]*Texas Liver Institute, University of Texas Health San Antonio, TX,* [2]*Houston Methodist Hospital,* [3]*Indiana University Medical Center,* [4]*Indiana University School of Medicine,* [5]*California Liver Reasearch Institiute,* [6]*Impact Research Institute,* [7]*St Mary,* [8]*Galectin Therapeutics,* [9]*Summit Clinical Research*

Background: Variceal development in patients with MASH cirrhosis and portal hypertension reflects disease progression and risk of decompensation. The NAVIGATE trial (NCT04365868) previously reported a statistically significant reduction in new varices at 18 months in the per-protocol population treated with belapectin 2 mg/kg LBW. This analysis reports outcomes at 36 months among subjects who completed the long-term follow-up. **Methods:** NAVIGATE is a Phase 2b/3 randomized, placebo-controlled trial of intravenous belapectin (2 mg/kg or 4 mg/kg LBW) administered bi-weekly in patients with MASH cirrhosis and portal hypertension without baseline varices. Endoscopies were performed at baseline, 18 months, and 36 months and were centrally read by multiple reviewers. The per-protocol (PP) population at 36 months included 57 subjects who completed 18 months of blinded therapy with evaluable endoscopy data. Subjects were stratified by type 2 diabetes mellitus (T2DM) status at baseline. The cumulative incidence of new varices was assessed using the Cochran-Mantel-Haenszel (CMH) test. **Results:** At 36 months, the per-protocol population included 57 subjects across three cohorts; placebo($n = 20$), 2mg ($n = 23$),4mg ($n = 14$). Incidence of new varices was 23.4%, 12.4% and 16.7% respectively in placebo, 2 and 4 mg cohorts. The cumulative trend observed in belapectin 2mg cohort at 18 months was maintained, with statistical significance for the 2 mg/kg group ($p = 0.04$ vs. placebo). The 4 mg/kg group showed no significant difference ($p = 0.24$). No new safety findings were observed at 36 months. Incidence of major adverse clinical events (MACE) was comparable across treatment arms, with a median follow-up of 24 months. **Conclusion:** In MASH cirrhosis with portal hypertension, belapectin 2 mg/kg continued to show a favorable trend in reducing new varices through 36 months in the per-protocol population. These findings show a continuous and sustained effect thru 36 month and support the long-term potential of galectin-3 inhibition for variceal prevention in patients with MASH cirrhosis and portal hypertension.

2376 | MICRONUTRIENT DEFICIENCIES IN PATIENTS WITH CIRRHOSIS: A CONTEMPORARY EVALUATION

Melinda Wang[1] Kathy Pariani[1] Fawzy Barry[1] Dorothea Kent[1] Jennifer Lai[1], [1]University of California San Francisco

Background: Despite the well-established relationship between micronutrient deficiencies and cirrhosis, little is known of micronutrient deficiencies among ambulatory cirrhosis patients awaiting liver transplant (LT). We aimed to characterize micronutrient deficiencies among cirrhosis patients awaiting LT and assess their association with frailty, a complication with high morbidity and mortality. **Methods:** Ambulatory adult patients with cirrhosis awaiting LT from 6/2024-3/2025 were tested for micronutrient deficiencies with a parsimonious panel in clinical practice. Multivariable modeling was used to assess the association between frailty and micronutrient deficiencies. **Results:** Of 154 patients, median (IQR) age was 60 (50-66) years and 66 (43%) were women. Median MELD 3.0 (IQR) was 17 (12-22) and 40 (26%) were frail. Micronutrient deficiencies were common, especially of zinc, vitamin D/E/B12, and selenium (Figure). Compared to patients who were not frail, frail patients were more likely to have vitamin E deficiency ($p = 0.01$). Frail patients had a 3.26 increased odds of vitamin E deficiency on multivariable analysis (95%CI 1.46-7.28, $p = 0.004$). **Conclusion:** Deficiencies of zinc, vitamin D/E/B12, and selenium are common in patients with cirrhosis awaiting LT and may represent a pragmatic panel of micronutrients to send in clinical practice. Vitamin E deficiency, in particular, was associated with frailty. In light of prior studies demonstrating that vitamin E supplementation improves sarcopenia and frailty in older adults, vitamin E supplementation may represent an important component of a multi-pronged approach to reversing frailty in cirrhosis patients.

2377 | DIET-FED HAMSTERS AS A MODEL OF MASH CIRRHOSIS-ASSOCIATED WEIGHT LOSS WITHOUT THE USE OF TOXINS FOR HIGH-THROUGHPUT IN VIVO SCREENING

Joanne Hsieh[1] Shengping Wang[1] Linda Chio[1] Ian Driver[1] Jingshu Chen[1] Christopher Carrico[1] Daniel Fuentes[1] Vinay Kartha[1] Hikaru Miyazaki[1] Arnav Gupta[1] Dimitry Popov[1] Smitha Shambhu[1] Gayathri Donepudi[1] Carmen Le[1] Jessica Nonora[1] Sophia Ruiz[1] Juana Cruz Sampedro[1] Chris Towne[1] Martin Borch Jensen[1] Francisco LePort[1], [1]Gordian Biotechnology

Background: Sarcopenia and osteopenia often co-occur with MASH and cirrhosis. An FGF21 analogue recently showed both antifibrotic and bone mineral density (BMD)-reducing effects in compensated MASH cirrhosis. There is a need for therapies that reduce fibrosis without compromising muscle mass or bone health, but discovery is limited by the tendency of diet-fed mouse models to progress to HCC rather than cirrhosis. **Methods:** Golden Syrian hamsters were given a “free choice” high fat, cholesterol, and fructose diet or chow, and 10% fructose water or plain water. AAV8 was delivered and livers were collected after 37 weeks then analyzed by single-nucleus RNA-Seq (snRNA-Seq). In a high-throughput *in vivo* screen, Gubra-Amylin (GAN) diet-fed mice were administered >100 barcoded AAV8 interventions. Hepatocyte responses were assessed by snRNA-Seq. **Results:** Hamsters displayed heterogeneous responses to the free choice diet, with lower body weight associated with more severe porto-portal fibrosis. In fibrotic livers, expression gradients of the periportal marker *Hal* and pericentral marker *Slco1b3* aligned, and hepatocytes showed upregulation of purine catabolism genes (*Nt5c2*, *Entpd5*) and steroid excretion transporters (*Abcc3*). Hepatocytes in severe fibrosis expressed the cholangiocyte markers *Sox9* and *Krt19*, indicating a biphenotypic hepatocyte state. AAV8 effectively transduced both zonated and biphenotypic hepatocytes. In the mouse screen, myotrophic IGF-1 overexpression suppressed purine breakdown genes, while spliced XBP-1 to mimick ER stress enhanced them. TGFBR2 overexpression induced steroid catabolism genes, suggesting a mechanistic link between fibrosis, sarcopenia, and osteopenia. FGF21 overexpression did not affect steroid catabolism pathways but rather reduced

genes involved in the provision of micronutrients such as calciferol to peripheral tissues, suggesting its BMD-reducing effects are dissociated from liver fibrosis effects. The screen identified an overexpression candidate that increased micronutrient provision gene expression. When delivered as a saturating gene therapy to GAN-fed mice (62 weeks), this candidate reduced serum CK-18, TIMP1, and osteopontin while increasing body weight. **Conclusion:** In hamsters, 37 weeks of the free choice diet led to loss of hepatocyte zonation and acquisition of cholangiocyte-like features, paralleling changes seen in human cirrhosis. These aberrant hepatocytes remained transducible by AAV8, enabling parallelized *in vivo* screening. Differential gene expression analysis from this hamster model informed identification of a gene therapy candidate that mitigated fibrosis-related weight loss in MASH.

2378 | LIVER STIFFNESS AS A PREDICTOR OF MYOPENIA AND FUNCTIONAL MUSCLE DECLINE IN ADVANCED LIVER DISEASE: A CALL FOR REFINED DIAGNOSTIC CUTOFFS

Lourianne Nascimento Cavalcante[1] Aloma Campeche-Leão[2] Ana Clara Batista[2] Monalisa Reis Arruda[2] Rosangela Passos[2] Lais Garcez[2] Helma Cotrim[3], *[1]Universidade Federal Bahia; Virginia Commonwealth University, [2]Universidade FEderal da Bahia, [3]University Hospital Professor Edgar Santoss*

Background: Transient elastography is widely used to assess liver fibrosis. However, few studies have examined the correlation between liver stiffness and indicators of muscle mass and function, and specific data on populations with advanced liver disease remain scarce. This study aimed to investigate whether liver stiffness (VCTE) and its categorization, including platelet levels, could serve as predictors of myopenia and declines in muscle function in patients with advanced liver disease. **Methods:** Patients aged 18 years or older with chronic liver disease and portal hypertension were included in this study. Liver stiffness was assessed using transient elastography with controlled vibration (VCTE, FibroScan®), analyzed as a continuous variable and categorized into groups: Group 1 (<15 kPa and platelets $\geq 150{,}000/mm^3$); Group 2 (≥ 15 kPa and platelets $<150{,}000/mm^3$); and Group 3 (≥ 25 kPa). Muscle parameters included Upper Arm Muscle Circumference (UAMC) and Handgrip Strength (HGS). The results were compared with established literature cutoffs (men: UAMC <24.2 cm and HGS <27 kgf; women: UAMC <21.5 cm and HGS <16 kgf). Linear and multiple logistic regression models were adjusted for covariates. **Results:** A total of 132 patients were included and categorized:Group 1 ($n=50$, 37.9%); Group 2 ($n=55$, 41.7%); and Group 3 ($n=27$, 20.5%). In the sex-stratified analysis, women had a median UAMC of 20.8 cm and median HGS of 15.8 kgf, values below the literature cutoffs (21.5 cm and 16 kgf). Among men, the medians were 24.8 cm and 26.8 kgf, with lower percentiles indicating impairment. In the adjusted linear model, each 1 kPa increase in liver stiffness was associated with a 0.45 kgf reduction in HGS (95%CI: –0.60 to –0.30; $p < 0.001$) and a 0.30 cm reduction in UAMC (CI: –0.42 to –0.18; $p < 0.001$). The coefficient for male sex was –1.10 (95% CI: –3.15 to 0.95; $p = 0.453$), indicating that although men had higher mean values, sex-adjusted effects did not alter the robustness of muscle predictors. In categorical analysis, Group 2 showed an average reduction of 3.0 kgf in HGS (95%CI: –4.5 to –1.5; $p < 0.001$) and 1.5 cm in UAMC (95%CI: –2.3 to –0.7; $p < 0.001$), while Group 3 exhibited reductions of 7.5 kgf and 3.0 cm, respectively ($p < 0.001$ for both). **Conclusion:** Liver stiffness is a significant predictor of myopenia and functional muscle impairment, independent of sex. Data suggest that in patients with advanced liver disease, median values in the most severe group (Group 3: UAMC 20.2 cm and HGS 18.3 kgf) fall below established cutoffs, indicating that current diagnostic methods may underestimate muscle impairment. Revising cutoffs and adopting an integrated approach—considering functional and compositional parameters alongside liver disease severity—are recommended for improved risk stratification and clinical management.

2379 | CHARACTERIZATION OF CIRRHOSIS-RELATED COMPLICATIONS IN A NATIONALLY REPRESENTATIVE DATABASE OF ELECTRONIC HEALTH RECORDS

James Haddad[1] Adnan Said[1] Askar Safipour Afshar[1] Anoop Mayampurath[1] Majid Afshar[1] Matthew Churpek[1], [1]University of Wisconsin School of Medicine and Public Health

Background: Compensated cirrhosis can progress to life-threatening complications. Previous studies are limited due to the fragmentation of data sources, small sample sizes, and lack of national representation. We conducted a retrospective cohort study using a national dataset to characterize adults with cirrhosis and the timing and types of subsequent liver-related events. **Methods:** Adults with a first diagnosis of compensated cirrhosis (index date) between January 2015 and May 2024 were identified using ICD-10 codes in Epic Cosmos, a longitudinal dataset comprising >300 million patient records. Patients who developed a complication or received a liver transplant within 90 days of diagnosis were excluded. Subsequent occurrence of decompensation (variceal bleeding, encephalopathy, ascites, liver failure without encephalopathy), transplant, or hepatocellular carcinoma (HCC) was retrieved from diagnostic or procedural coding. Death dates were captured if recorded in patients' health records. Patients without an event were censored in May 2025. Cumulative-incidence functions were estimated using the Aalen–Johansen method. **Results:** Among 548,999 patients meeting inclusion criteria, the median age at first recorded cirrhosis diagnosis was 64 years (IQR 55-72), and 53.6% were male (Table 1). Median time to liver-related event or censoring was 2.3 years (IQR 1.2–4.2). First event was decompensation in 112,533 (20.5%), HCC in 11,426 (2.1%), transplantation in 79 (<0.1%), and death in 90,443 (16.5%). Median time from index to first decompensation was 1.4 years (IQR 0.7–2.7). Among patients who decompensated, 57,079 (50.7%) developed ascites, 14,729 (13.1%) liver failure without encephalopathy, 13,168 (11.7%) hepatic encephalopathy, 8,247 (7.3%) variceal bleeding, and 19,310 (17.2%) had multiple decompensation types. Of those who decompensated or developed HCC, 3,238 (2.6%) later underwent liver transplantation. At 1, 3, and 5 years, cumulative incidence estimates (accounting for censorship) were 7.9%, 18.3%, and 24.4% for any hepatic decompensation; 0.7%, 1.7%, and 2.5% for HCC; and 8.7%, 14.7%, and 18.9% for death. **Conclusion:** In this national retrospective study, we found that 20.5% of patients with cirrhosis progressed to decompensation, with ascites being the most frequent event, and 2.1% developed HCC. Among those who decompensated, 75% did so within 2.7 years of initial cirrhosis diagnosis, highlighting a critical window for preventative intervention.

Table 1: Characteristics and outcomes of patients diagnosed with cirrhosis in a national cohort (N = 548,999)

Sex		**First Outcome**	
Male	294,268 (53.6%)	Decompensation	112,533 (20.5%)
Female	254,692 (46.4%)	Hepatocellular Carcinoma	11,426 (2.1%)
Race		Transplantation	79 (<0.1%)
White	398,407 (72.6%)	Death	90,443 (16.5%)
Black	56,879 (10.4%)	**First Decompensation Etiology**	
Asian	9,946 (1.8%)	Ascites	57,079 (50.7%)
American Indian/Alaska Native	3,747 (0.7%)	Liver failure without encephalopathy	14,729 (13.1%)
Native Hawaiian or Pacific Islander	635 (0.1%)	Hepatic encephalopathy	13,168 (11.7%)
Multiracial	55,909 (10.2%)	Variceal bleeding	8,247 (7.3%)
Other/unknown	23,476 (4.3%)	Multiple decompensation etiologies	19,310 (17.2%)

2380 | INCIDENCE OF HEPATORENAL SYNDROME IN THE HOSPITALIZED U.S. PEDIATRIC POPULATION (2019–2023): A RETROSPECTIVE REAL-WORLD HEALTHCARE DATABASE ANALYSIS

Xingyue Huang[1] Mary Panaccio[1] Sanaz Cardoza[1] Eva Tarau[1] Peggy Rooney[1] Chris Pappas[2] Jonathan Lilley[3] Rahul Rajkumar[3], [1]Mallinckrodt Pharmaceuticals, Bridgewater, NJ, USA, [2]Orphan Therapeutics, LLC, Longboat Key, Florida, USA, [3]Boston Strategic Partners, Inc., Boston, MA, USA

Background: Hepatorenal syndrome (HRS) is a rare and serious complication of severe liver disease characterized by marked impairment of kidney function. While HRS is well documented in adults, its incidence in children remains unclear, largely due to absence of standardized and published diagnostic criteria specific to pediatrics. **Methods:** Pediatric patients (<18 years) hospitalized with HRS were identified in the Premier database (Jan 2019–Dec 2023) using ICD-10 code K76.7 at admission and stratified by age, sex, and race. Concomitant chronic liver disease (CLD) and biliary atresia (BA) were evaluated using ICD-10 codes. National projections were calculated using discharge weights from the American Hospital Association. **Results:** Of 6,069,353 pediatric hospitalizations between 2019 and 2023, there were 90 admissions with an HRS diagnosis (0.0015%); 54.4% being female, and median age was 7.0 years (IQR 1.0, 14.0). Adolescents (12–17 years) accounted for the largest proportion (35.6%), followed by neonates/infants (0–<2 years; 27.8%). By race/ethnicity, 34.4% were White, 30.0% were Hispanic, and 21.1% were Black; notably, Black and Hispanic patients together

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

accounted for over 50% of encounters overall and among infants and adolescents. Medicaid was the most common payer (62.2%), followed by managed care (12.2%) and commercial insurance (7.8%). Most cases (87.8%) were associated with concomitant CLD, including cirrhosis, while 12.2% had both CLD/cirrhosis and BA, which occurred predominantly (81.8%) in the neonate/infant age group. Over one-third of all pediatric HRS admissions resulted in in-hospital mortality (n = 33). Projected national estimates resulted in 251 pediatric HRS admissions during the 5-year study period, averaging 50.2 admissions per year (range: 39–75), with a consistent age group distribution across years. **Conclusion:** Based on U.S. data from 2019 to 2023, an estimated 50 pediatric HRS hospitalizations occured annually (range: 39–75), highlighting the rarity of this serious complication of advanced liver disease. Adolescents were most frequently affected, and CLD—including cirrhosis—was the predominant underlying etiology. Black and Hispanic patients accounted for over half of all encounters, particularly among infants and adolescents, highlighting potential disparities in disease burden that warrant further investigation. These findings provide national context on the incidence and associated mortality of pediatric HRS and may help inform future recognition and management strategies.

Table 1: Observed and projected annual incidence of hepatorenal syndrome (HRS) in pediatric patients stratified by age, race, and sex

Pediatric Admissions with HRS (N=90 patients)					
	Overall, n (%)	Neonates/Infants, (0–<2 years)	Early Childhood, (2–<6 years)	Middle Childhood, (6–11 years)	Adolescents, (12–17 years)
Age and Year, n (row%)

2381 | IT IS COST-EFFECTIVE TO SCREEN AND TREAT PATIENTS WITH DEMENTIA FOR UNDIAGNOSED HEPATIC ENCEPHALOPATHY

Vinay Jahagirdar[1] Leroy Thacker[1] Michael Weissberger[1] Peter Boling[1] Jasmohan Bajaj[1], [1]Virginia Commonwealth University

Background: Cognitive impairment in older adults is frequently attributed to dementia. However, with the aging cirrhosis population & overlapping risk factors and symptoms between the conditions, approximately 10% of patients with dementia could have reversible but unrecognized hepatic encephalopathy (HE). Also, other cirrhosis complications (HCC/ascites) could be neglected in these patients. Aim: Evaluate cost-effectiveness of screening & treating patients with dementia for HE using FIB-4 ± GI consults. **Methods:** A decision-analytic cost-effectiveness model was developed to evaluate 7 strategies for HE detection and treatment & cirrhosis management (preventing/treating HCC, ascites) in dementia. These included: (1) no screening; (2–3) Empiric treatment using lactulose/rifaximin for those with a positive FIB-4 screen suggestive of cirrhosis; (4–5) hepatology referral and targeted therapy with lactulose/rifaximin for those with a positive FIB-4 screen suggestive of cirrhosis; and (6–7) empiric treatment of all dementia patients with lactulose/rifaximin. Transition probabilities across health states (dementia, cirrhosis with or without HE, recovery) and state-specific costs were based on predefined clinical assumptions based on published data. Outcomes included cumulative costs, quality-adjusted life years (QALYs), and incremental cost-effectiveness ratios (ICERs) over a 1-year cycle. **Results:** *Status quo* model projected $1.505 million cost & 45 QALYs (Figure). The most cost-effective approach was FIB-4 screening followed by GI consult and lactulose treatment (Strategy 4), which yielded 53 QALYs at a reduced cost of $1.472 million (ICER: $2.78 million/QALY). The most cost-saving approach was empiric lactulose treatment for all individuals with dementia (Strategy 6), which achieved

91.875 QALYs at $1.478 million (ICER: $1.6 million/QALY) but this would not be acceptable to providers or patients. Strategies involving rifaximin, either focused therapy or treat-all were substantially more costly with less favourable cost-effectiveness. **Conclusion:** Using focused GI/hepatology consults and lactulose therapy in patients with dementia and high FIB-4 was the most cost-effective strategy. This approach allows for the identification and management of potentially reversible cognitive impairment due to HE as well as preventing and managing HCC, ascites, and other cirrhosis complications. These findings support incorporating liver disease assessment into the diagnostic evaluation of cognitive decline, particularly in populations at risk for cirrhosis.

	Cumulative Cost ($100k)	Cumulative QALY	$ per QALY	ICER
Strategy 1: Do nothing	$1505	45	3,344,444	—
Strategy 2: FIB-4 + Lactulose	$1480.723	53	2,793,827	-303,462.50
Strategy 3: FIB-4 + Rifaximin	$1476.454	18.7	7,895,476	108,539.90
Strategy 4: FIB-4 + GI + Lactulose	$1472.498	53	2,778,299	-406,271.00
Strategy 5: FIB-4 + GI + Rifaximin	$1467.574	18.7	7,847,989	142,304.20
Strategy 6: Treat All with Lactulose	$1478.250	91.875	1,608,980	142,304.20
Strategy 7: Treat All with Rifaximin	$2002.600	52	3,851,154	7,108,571.00

2382 | RECOMBINANT HUMAN ADAMTS13 ATTENUATES LPS-INDUCED ACUTE KIDNEY INJURY AND RENAL MICROANGIOPATHY IN MICE WITH LIVER CIRRHOSIS VIA CLEAVAGE OF VWF

Kosuke Kaji[1] NORIHISA NISHIMURA[1] Shinya Sato[1] Tadashi Namisaki[1] Hitoshi Yoshiji[1], [1]Department of Gastroenterology, Nara Medical University

Background: Hepatorenal syndrome (HRS) has a poor prognosis among the complication of liver cirrhosis, yet treatment options are limited. Thrombotic microangiopathy with accumulation of von Willebrand factor (vWF) due to decreased a disintegrin and metalloproteinase with thrombospondin motifs 13 (ADAMTS13), a cleaving enzyme of vWF, has been reported to contribute to the pathogenesis of acute kidney injury (AKI) in liver cirrhosis. This study investigated the effect of recombinant human ADAMTS13 (rhADAMTS13) on acute kidney injury using a mouse model of HRS. **Methods:** To generate a mouse model of HRS (AKI-C mice), C57BL/6J mice received intraperitoneal administration of carbon tetrachloride (CCl_4) (0.5 ml/kg, twice a week) for eight weeks, subsequent administration of a double dose of CCl_4 (1.0 ml/kg) after 72 hrs, followed by intraperitoneal injection of LPS from *Klebsiella pneumonia* (6 mg/kg) after 24 hrs. AKI-C mice were subsequently injected intraperitoneally with saline as vehicle or rhADAMTS13 (10 μg/mouse equivalent to 2800 U/kg) 24 and 48 hrs after LPS administration and sacrificed 72 hrs later. Normal control mice received administration of saline instead of CCl_4, LPS and rhADAMTS13. Serological, histological and molecular analyses were performed to assess the effect of rhADAMTS13 on liver and kidney injuries in AKI-C mice. Tissue blood flow was also measured using a laser Doppler tissue blood flow meter to evaluate differences between the groups. **Results:** AKI-C mice showed a marked liver dysfunction as well as renal dysfunction with elevated serum level of AKI including Kidney Injury Molecule 1 (KIM-1), osteopontin and neutrophil gelatinase-associated lipocalin (NGAL). Plasma ADAMTS13 activity was reduced, and vWF antigen levels were increased. A decrease in blood flow in the liver and kidney tissues was also observed. In the rhADAMTS13-treated mice, plasma ADAMTS13 activity was increased, vWF antigen levels were decreased, and liver and kidney blood flow were improved as comoared to AKI-C mice. As a result, liver and kidney injuries were significantly alleviated. Furthermore, in the rhADAMTS13-treated mice, macrophage (F4/80-positive) infiltration and the increased expression of inflammatory cytokines observed in the AKI-C mice were suppressed. Accumulation of oxidative stress (4-HNE-positive) was also reduced. In addition, the deposition of CD41a-positive microthrombi in kidney tissues seen in the AKI-C mice was significantly suppressed in the rhADAMTS13-treated mice. This group also showed an increased expression of angiogenesis markers (Vegf) and a decreased expression of vascular inflammation markers (Vcam1, Icam1, Sele, Selp). **Conclusion:** Administration of rADAMTS13 may improve inflammation, oxidative stress, and reduced blood flow in liver and kidney, thereby mitigating HRS.

2383 | WHEN THE MIND MEETS THE LIVER: A REAL-WORLD LOOK AT MOOD AND MORTALITY IN CIRRHOSIS

Muhammad Ali Ibrahim Kazi Qetevan Gvazava[1] Siraj Ahmad[2] Zurabi Lominadze[3] Maia Tavadze[1], [1]Anne Arundel Medical Center, [2]Aga Khan University, [3]Baltimore VA Medical Center

Background: Cirrhosis is a progressive liver disease associated with high morbidity and mortality, often leading to complications such as ascites, hepatic encephalopathy, and liver failure. Beyond physical symptoms, cirrhosis significantly impacts patients' quality of life, contributing to fatigue, disability, and social isolation. Mood disorders, including major depressive disorder (MDD) and stress-related conditions, are common in patients with chronic liver disease. These psychiatric conditions may worsen clinical outcomes through poor adherence, increased inflammation, and reduced engagement in care. Despite their prevalence, the effect of mood disorders on cirrhosis outcomes remains unclear. This study uses real-world data from the TriNetX network to assess whether mood disorders are associated with increased complications, lower transplant rates, or higher mortality in cirrhotic patients. **Methods:** We conducted a retrospective cohort study using TriNetX, a global federated health research network with de-identified electronic medical record data. Patients with cirrhosis were categorized into two cohorts: those with comorbid mood disorders (Cirrhosis + MDD) and those without (Cirrhosis – MDD). Propensity score matching (1:1) was performed based on demographics, cardiovascular, neurologic, pulmonary, renal, gastrointestinal, malignancy, and behavioral health conditions. Outcomes assessed in this study included key cirrhosis-related complications such as variceal bleeding, ascites, spontaneous bacterial peritonitis (SBP), hepatic encephalopathy, and hepatorenal syndrome. In addition to these complications, liver transplantation and all-cause mortality were also evaluated as primary clinical endpoints. **Results:** The matched analysis revealed that patients in the Cirrhosis + Mood disorder group experienced significantly worse outcomes compared to the Cirrhosis without mood disorder group across all endpoints: · Esophageal/Gastric Varices: RR 1.19 [95% CI: 1.17–1.21]; $p < 0.001$ · Ascites: RR 1.13 [95% CI: 1.11–1.14]; $p < 0.001$ · Spontaneous Bacterial Peritonitis (SBP): RR 1.40 [95% CI: 1.35–1.45]; $p < 0.001$ · Hepatic Encephalopathy: RR 1.52 [95% CI: 1.48–1.56]; $p < 0.001$ · Hepatorenal Syndrome: RR 1.34 [95% CI: 1.29–1.39]; $p < 0.001$ · Liver Transplantation: RR 1.76 [95% CI: 1.71–1.81]; $p < 0.001$ · All-Cause Mortality: RR 1.06 [95% CI: 1.05–1.07]; $p < 0.001$ **Conclusion:** Cirrhotic patients with mood disorders experience worse clinical outcomes compared to those without, including higher rates of hepatic decompensation and mortality. They were also more likely to get a liver transplant as well. The study is limited by reliance on coded data, absence of data on treatment for depression (e.g., SSRIs, SNRIs, CBT), and lack of psychiatric severity assessment. These findings highlight the need for integrated psychiatric and hepatologic care and further prospective studies.

2384 | MUSCLE COMPOSITION MATTERS: MRI-BASED MYOSTEATOSIS STRONGLY CORRELATES WITH PHYSICAL FUNCTION IN CIRRHOSIS

Maria Rydfjord[1] Mohammad Siddiqui[2] Olof Dahlqvist Leinhard[3] Pontus Henriksson[4] Geneva Roache[2] Amon Asgharpour[2] Vaishali Patel[2] Mikael Forsgren[3] Danielle Kirkman[2], [1]Linköping University; AMRA Medical AB, [2]Virginia Commonwealth University, [3]AMRA Medical AB; Linköping University, [4]Linköping University

Background: Muscle fat infiltration (MFI), as a measurement of myosteatosis, is increasingly recognized as a predictor of functional decline in patients with liver cirrhosis, contributing to frailty and poor transplant outcomes. Traditionally, sarcopenia is assessed by identification of low muscle mass, but emerging evidence emphasizes also assessing MFI due to its links with strength, mobility, and endurance. Muscle volume z-score (MVZ), a standardized measure of muscle volume independent of sex and body size, has been developed to define sarcopenia and is associated with decreased mobility and adverse outcomes. This study examined the relationship between magnetic resonance imaging (MRI) derived muscle composition

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

and standardized physical function tests in patients with decompensated cirrhosis. **Methods:** In this prospective study at Virginia Commonwealth University, USA, 26 patients (20 females) with decompensated cirrhosis undergoing liver transplant evaluation completed standardized physical function tests: 6-minute walk test (6MWT), Timed Get-Up-and-Go (GUG), gait speed (GS), sit-to-stand repetitions (STS), and isometric knee extensor strength (KES). AMRA® Researcher was used to measure thigh fat free muscle volume (FFMV), MVZ based on FFMV, and MFI based on MRI. Spearman correlation was used to evaluate associations between muscle composition and functional tests. Correlation strength was interpreted as weak ($\rho < 0.30$), moderate ($\rho = 0.30$-0.59), or strong ($\rho \geq 0.60$). **Results:** Higher MFI was strongly associated with poorer performance across multiple domains: reduced 6MWT distance ($\rho = -0.846$), slower GUG ($\rho = 0.77$), and fewer STS repetitions ($\rho = -0.642$), all $p < 0.001$ (Fig). MFI also showed a moderate correlation with slower GS ($\rho = 0.525$, $p = 0.007$), but was not significantly correlated with KES. Lower FFMV was strongly associated with reduced isometric KES ($\rho = 0.714$, $p < 0.001$), and moderately associated with 6MWT ($\rho = 0.42$, $p = 0.033$) and GUG time ($\rho = -0.489$, $p = 0.012$). Lower MVZ was moderately correlated with shorter 6MWT distance ($\rho = 0.426$, $p = 0.030$), slower GUG ($\rho = -0.51$, $p = 0.009$), and reduced isometric KES ($\rho = 0.584$, $p = 0.011$). Neither MVZ nor FFMV was associated with STS or GS. **Conclusion:** MFI, more than muscle volume alone, strongly predicts functional impairment in patients with decompensated cirrhosis. MFI correlated strongly with endurance and mobility measures, but not isolated strength measures, suggesting that MFI reflects broader physiological limitations. FFMV correlated more strongly with strength, highlighting its role in force generation. Despite a limited sample size, the wide range of functional performance supports generalizability. MRI-based muscle composition measurements may improve early identification of functional decline and enable targeted, preventative interventions to preserve function and enhance transplant readiness.

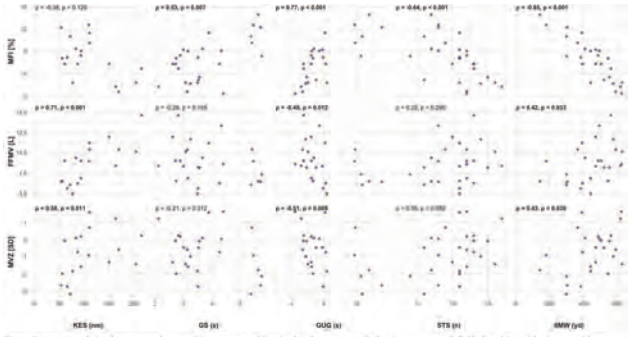

Figure. Spearman correlations between muscle composition measures and functional performance tests. Each point represents an individual participant. Muscle composition was assessed using (row 1) anterior thigh muscle fat infiltration [%], (row 2) fat free muscle volume of the anterior thigh [L], and (row 3) muscle volume Z score [SD]. Functional tests included knee extension strength (KES), gait speed (GS), get-up-and-go (GUG), sit-to-stand repetitions (STS), and six-minute walk distance (6MW. Each plot displays the Spearman correlation coefficient (ρ) and p-value.

2385 | THE ROLE OF LIVER STIFFNESS IN ASSESSING THE SEVERITY OF PORTAL HYPERTENSION AND STRATIFYING LONG-TERM PROGNOSIS: A COMPARISON OF VIRAL AND NON-VIRAL ETIOLOGIES

Tatsuro Nishimura[1] Tsuyoshi Ishikawa[1], [1]Yamaguchi University Graduate School of Medicine

Background: The hepatic venous pressure gradient (HVPG) is one of the most useful tools for diagnosing the severity of portal hypertension (PH) and evaluating the risk of cirrhotic complications. Clinically significant portal hypertension (CSPH) is defined as HVPG $\geq$10 mmHg, severe portal hypertension (SPH) as HVPG $\geq$12 mmHg, and very severe portal hypertension (VSPH) as HVPG $\geq$16 mmHg. However, since HVPG measurement is invasive, it is necessary to develop a non-invasive alternative to its measurement. This study aimed to evaluate the correlation between liver stiffness (LS) and HVPG by etiology, and to examine the long-term prognosis. **Methods:** 111 patients with portal hypertension who underwent HVPG and LS at our hospital were enrolled in this retrospective study. The patients were separated into two groups, the viral group (n = 54, mean age: 66.3 years, male/female: 23/31, etiology of HBV/HCV: 4/50) and the non-viral group (n = 57, mean age: 63.9 years, male/female: 36/21, etiology of alcohol/MASH: 41/16). (Study1) The correlation between HVPG and LS in both groups was analyzed. (Study2) The best cutoff values defining CSPH, SPH and VSPH were examined. (Study3) Survival analysis was performed using the best cutoff value defined in Study 2. **Results:** Child-Pugh scores

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

were not significantly different between the viral and non-viral groups (6.5 vs. 6.9, $p = 0.21$), while HVPG (11.1 vs. 12.9 mmHg, $p < 0.05$) and LS (25.1 vs. 29.5 kPa, $p < 0.05$) were significantly higher in the non-viral group. Fibrosis assessment markers such as type 4 collagen 7s and FIB4 index were also significantly higher in the non-viral group ($p < 0.05$). In addition, when LS was compared according to the severity of PH, it was significantly higher in the non-viral group in all CSPH, SPH and VSPH ($p < 0.01$). (Study 1) Correlation analysis showed a strong correlation between HVPG and LS in both the viral ($r = 0.68$, $p < 0.01$) and non-viral ($r = 0.68$, $p < 0.01$) groups. Significant correlations were also maintained in both groups for SPH and VSPH, which indicate severe PH. The cutoff values of CSPH, SPH and VSPH by LS were 20.6 kPa (AUROC: 0.78), 23.0 kPa (AUROC: 0.85) and 30.1 kPa (AUROC: 0. 92). On the other hand, the cutoff values for the non-viral group were 27.0 kPa (AUROC: 0.82), 30.4 kPa (AUROC: 0.81) and 35.3 kPa (AUROC 0.89). The cutoff values of LS at each HVPG level were significantly higher in the non-viral group. Survival analysis between the three groups based on HVPG and LS showed significant differences in MST in both groups ($p < 0.05$). **Conclusion:** LS represents a useful non-invasive surrogate marker for HVPG in cases of PH. The cutoff value of LS for CSPH, SPH and VSPH must be set for each etiology. LS may stratify survival and predict long-term prognosis similarly to HVPG.

2386 | PREDICTORS OF ASCITES RESOLUTION IN PATIENTS WITH HEPATITIS C CIRRHOSIS AFTER ETIOLOGICAL CURE

Daniela Goyes[1] Anahita Rabiee[1] Nicolas Chong Lugon[1] Catherine Mezzacappa[1] David Kaplan[2] Tamar Taddei[1] Guadalupe Garcia-Tsao[1], [1]Yale University, [2]University of Pennsylvania

Background: Ascites is, by far, the most common decompensating event in cirrhosis. With etiological treatment of cirrhosis, ascites may resolve, no longer requiring diuretics, and this is one of the Baveno VII criteria defining cirrhosis "recompensation". Identifying predictors of ascites resolution could enhance prognostication and help refine the definition of cirrhosis recompensation. **Methods:** Retrospective cohort study of Veterans with HCV-related cirrhosis who achieved sustained virologic response (SVR) after direct-acting antiviral (DAA) therapy and who had ascites on abdominal imaging (ultrasound, computed tomography, or magnetic resonance) within six months prior to DAA initiation. Ascites (and absence of ascites) was determined via natural language processing (NLP) of imaging reports. Baseline was defined as DAA initiation. We excluded patients with hepatocellular carcinoma, heart failure, or chronic kidney disease at baseline, died within 24 weeks of DAA initiation, and those without follow-up imaging. The primary outcome was ascites resolution defined as absence of ascites, off diuretics, 12-18 months post-DAA initiation. Bivariate analyses were used to assess the associations between baseline parameters and ascites resolution. Variables with p value < 0.20 were included in a multivariable logistic regression model predicting resolution of ascites. **Results:** Of the 693 patients with available imaging 12-18 months after completing DAA treatment, 241 (35%) had resolution of ascites, 162 (23%) had no ascites but remained on diuretics, and 290 (42%) continued to have ascites (200 on diuretics and 90 off). Patients with ascites resolution had higher albumin and platelet count, and lower bilirubin and INR at baseline (Table 1). On multivariable analysis, the factor most strongly associated with ascites resolution was higher baseline serum albumin (OR 0.71, 95% CI 0.52–0.96). In contrast, baseline grade 2/3 ascites (versus grade 1) (OR 2.02, 95% CI 1.41–2.89), history of hepatic encephalopathy (OR 1.48, 95% CI 1.00–2.19), and variceal hemorrhage (OR 2.47, 95% CI 1.70–3.58) were associated with lower odds of ascites resolution. **Conclusion:** Resolution of ascites was observed in 35% of patients with HCV cirrhosis who achieve SVR after DAAs. Baseline serum albumin was the strongest predictor of ascites resolution.

Table 1. Cohort characteristics at baseline (initiation of DAA)

	Overall n = 693	Ascites resolution n = 241	No ascites resolution n = 452
Age, median [IQR]	60 [56, 64]	61 [57, 65]	60 [56, 64]
Male, n (%)	667 (96.2)	232 (96.3)	435 (96.2)

Background: Acute kidney injury (AKI) is a common complication in decompensated cirrhosis, significantly increasing morbidity and mortality. However, the impact of pre-existing chronic kidney disease (CKD) on AKI outcomes in this population remains unclear. Using a large international cohort, we investigated how pre-existing CKD influences AKI outcomes in hospitalized patients with decompensated cirrhosis. **Methods:** We analyzed data from patients with decompensated cirrhosis and AKI enrolled in the International Club of Ascites GLOBAL-AKI study, a prospective, international observational study spanning 65 centers across 5 continents. Patients were categorized as AKI alone or AKI-CKD based on the absence or presence of pre-existing CKD. CKD was defined by an estimated glomerular filtration rate <60 mL/min for ≥ 3 months prior to AKI onset. Multivariable logistic regression and competing risk models were used to identify the independent factors associated with AKI resolution and 28-day mortality. **Results:** Among 1,456 patients with AKI, 239 (16.4%) had pre-existing CKD. Compared to AKI alone patients, AKI-CKD patients were older (64

vs 57 years; $p < 0.01$), were more likely to have MASLD (44% vs 22%; $p < 0.01$), hypertension (57% vs 34%; $p < 0.01$), diabetes (53 vs 32%; $p < 0.01$), higher serum creatinine at baseline (1.5 vs 0.9 mg/dL; $p < 0.01$) and at AKI diagnosis (2.4 vs 1.8 mg/dl; $p < 0.01$), but lower MELD-Na score (24 vs 27; $p < 0.01$). AKI-CKD patients more often had AKI stage 1 at diagnosis (68 vs 51%; $p < 0.01$) and were less likely to have hypovolemic AKI (54% vs 60%) and hepatorenal syndrome-AKI (15.9% vs. 18%), while the prevalence of acute tubular necrosis phenotype was higher (15.4% vs. 14.7%) compared to AKI alone patients ($p = 0.01$) (Figure). AKI-CKD patients had significantly lower rates of AKI resolution (52 vs 60%, $p = 0.02$), but lower cumulative incidence of 28-day mortality (42% vs 50%, $p = 0.02$), compared to AKI alone patients. On multivariable analyses, AKI-CKD patients had lower odds of AKI-resolution (OR 0.53, 95%CI 0.38-0.73, $p < 0.01$), without a significant difference in risk for 28-mortality (sHR 0.76, 95%CI 0.56-1.03, $p = 0.08$). **Conclusion:** In patients with decompensated cirrhosis, pre-existing CKD significantly reduces AKI resolution rates without increasing short-term mortality risk, highlighting the need for tailored management strategies. These findings emphasize the importance of stratifying patients based on pre-existing CKD status in future clinical trials evaluating AKI interventions in cirrhosis.

2388 | SEX-SPECIFIC EFFECT OF ESTRADIOL ON CHOLESTATIC LIVER CIRRHOSIS AND PORTAL HYPERTENSION

Fabian Schachteli[1] Sabine Klein[1] Robert Schierwagen[1] Maximilian Joseph Brol[1] Jonel Trebicka[1] Frank Erhard Uschner[1], [1]Department of Medicine B, University Hospital Münster, Münster, Germany

Background: Sex-specific differences have been observed in the etiology, clinical progression and therapeutic response of patients with chronic liver disease. Estradiol (E2) exerts its effects not only through the nuclear receptor alpha (ERα) but also via the G protein-coupled estradiol receptor (GPER). However, the role of GPER in liver cirrhosis with portal hypertension remains unclear. **Methods:** Cholestatic liver cirrhosis was induced in male rats via bile duct ligation (BDL). Female rats underwent BDL combined with either ovariectomy or a sham operation. The animals received one of the following: (i) a single dose of E2, (ii) an acute dose of a phosphodiesterase-5 inhibitor (PDE-5-I), (iii) a combination of both, or (iv) placebo. Portal and systemic hemodynamics were measured and the expression levels of E2 receptors and components of the nitric oxide (NO) signaling pathway (eNOS, PDE-5, VASP, p-VASP) were analyzed in liver and aorta using Western blot and qPCR. **Results:** In male BDL rats, E2 had no effect on hemodynamics, ER expression, or PDE-5-I efficacy. In female BDL rats, ovariectomy resulted in increased hepatic portal vascular resistance (HpVR), reduced hepatic GPER expression and decreased hepatic NO signaling activity, compared with non-ovariectomized females. Furthermore, ovariectomized females exhibited lower systemic vascular resistance and higher levels of GPER and ERα in the aorta. PDE-5-I significantly reduced portal pressure (PP) in female BDL rats but was ineffective after ovariectomy. Notably, E2 substitution in ovariectomized BDL rats significantly reduced HpVR and PP, while restoring PDE-5-I responsiveness. **Conclusion:** Estradiol deficiency after ovariectomy aggravates portal hypertension in female rats with cholestatic cirrhosis. Estradiol reverses this effect through activation of the cGMP-NO pathway. Combining estradiol substitution therapy with PDE-5 inhibition could represent a potential treatment strategy for postmenopausal women with portal hypertension.

2389 | ALBUMIN IN THE MANAGEMENT OF HEPATORENAL SYNDROME-ACUTE KIDNEY INJURY (HRS-AKI): IS THERE EVER TOO MUCH?

Florence Wong[1] Nicodemus Ong[2], [1]University of Toronto, [2]University Health Network

Background: Albumin (alb) at a dose of 20-40g/day is recommended as an adjunct therapy for HRS-AKI. Recent concerns of alb causing respiratory failure in patients (pts) with HRS-AKI have caused unease with excess alb use in these pts. Aim: to assess the outcomes of HRS-AKI pts who received more than the recommended daily alb dose. **Methods:** Retrospective study of all inpatients fulfilling the diagnostic criteria of HRS-AKI between Jan 2020 to Apr 2023 collected demographics, lab results, AKI treatment & course, admission outcomes and follow-up for 6Ms. Pts with alb dose of $\leq$50g/day were compared to those with $>$50g/day. **Results:** 195 pts (age 62 ± 12 yrs; male: 66%; MELD-Na: 27 ± 7) with 230 HRS-AKI events were identified. Group (Grp) A (alb $\leq$50g/day: 145 pts with 169 HRS-AKI events) had similar demographics as Grp B (alb $>$50g/day: 50 pts with 61 HRS-AKI events) except Grp B had a higher baseline serum creatinine (sCr) (102 ± 52 vs. Grp A $= 90 \pm 31$μmol/L, $p = 0.048$). HRS-AKI in Grp B was mostly precipitated by infections (46% vs.26.6% in Grp A) and less so by fluid shifts/loss (23% vs. 27% in Grp A) ($p = 0.025$). HRS-AKI stage distribution was similar at diagnosis between the 2 Grps. At peak sCr, significantly more Grp B pts reached stage 3 (59%), whereas 50% of Grp A pts remained in stage 1 HRS-AKI ($p < 0.0001$). 62.3% of Grp B pts fulfilled the old definition of type 1 HRS (vs.23.7% in Grp A, $p < 0.0001$). All Grp B pts received a mean of 66 ± 14g alb/day for a total of 8.1 ± 6.4days (total dose = 540 ± 379g), vs. a mean of 44 ± 10g alb/day ($p < 0.0001$) for a total of 4.7 ± 4.4days ($p < 0.0001$) (total dose = 221 ± 193g, $p < 0.0001$) in Grp A. Pts in Grp B received either midodrine (62%), octreotide (71%) or norepinephrine (28%), vs. 33%, 38%, and 16% respectively in Grp A. 65% of all Grp A pts had a complete response vs. 43% in Grp B ($p = 0.004$), mostly from stages 1 & 2 HRS-AKI. There was no difference in the HRS-AKI response for stage 3 between the Grps ($p = 0.554$). 3% of Grp A and 4% of Grp B pts developed respiratory failure ($p = 0.808$). Grp B patients had a

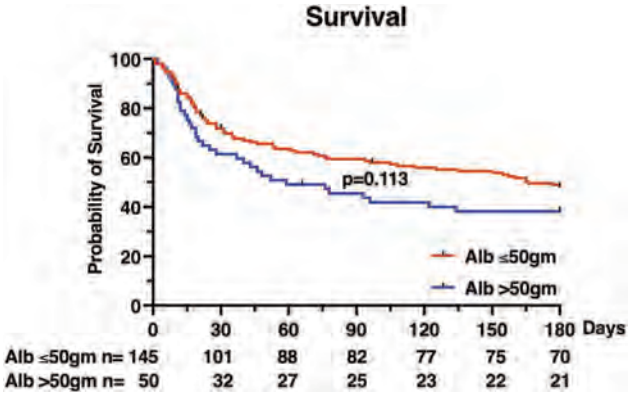
higher discharge MELD-Na (28 ± 9 vs. 24 ± 10 in Grp A, p = 0.002). There was no difference in length of hospital stay, readmission rate, or recurrent AKI in both Grps. Survival was the same (Figure). **Conclusion:** Pts with higher baseline sCr whose HRS-AKI is triggered by infection may need more than recommended alb dose, as they tend to have more severe AKI. The use of higher dose of alb may prevent a more serious outcome without causing respiratory compromise.



Disclosures: Florence Wong: Mallinckrodt: Consultant, Mallinckrodt Pharmaceutical Inc: Grant/Research Support, River 2 Renal: Consultant, Sequana Medical: Consultant, sequana Medical: Grant/Research Support, Inventiva: Grant/Research Support, Inventiva: Consultant, Nicodemus Ong: Nothing to Disclose

2390 | ASCITIC NEUTROPHIL COUNT AT INITIAL PARACENTESIS IS ASSOCIATED WITH ADVERSE OUTCOMES IN CIRRHOSIS

Alp Kahveci[1] *Melis Celdir*[2] *Tomohiro Tanaka*[3],
[1]*University of Iowa Caver College of Medicine,*
[2]*University of Iowa Carver College of Medicine,*
[3]*University of Iowa School of Medicine*

Background: Spontaneous bacterial peritonitis (SBP) is the most common source of infection in patients with cirrhosis and is a frequent precipitant of hepatic decompensation. While diagnosis is based on ascitic fluid neutrophil count, the prognostic significance of ascites neutrophil count (ANC) itself at initial paracentesis remains uncertain. **Methods:** We analyzed a cohort of patients with cirrhosis who underwent paracentesis at a tertiary healthcare center in the US Midwest between January 2015 and December 2024. The primary outcome was 90-day mortality; the secondary outcome was the development of SBP. Patients were stratified by ANC at the time of paracentesis (<125 cells/mm^3 vs. ≥ 125 cells/mm^3, defined as ascitic neutrophilia), and a Cox proportional hazards (PH) model was used to adjust for demographic and clinical confounders. Cumulative incidences of SBP and the composite outcome of death, liver transplant (LT), or TIPS placement were assessed using Gray's test, treating each as a competing risk for the other. **Results:** This retrospective cohort study included 1,053 patients. No significant demographic differences were noted other than white patients who were more likely to have an ANC < 125 cells/mm^3 (90.5% vs 84.2%, p = 0.017). Of the 1,053 patients, 269 died within 90 days. The 90-day mortality rate was higher in those with ascitic neutrophilia (39.1% vs. 24.6%, p = 0.012). In multivariable Cox PH model, ascitic neutrophilia remained an independent predictor of 90-day mortality (HR 1.77, 95% CI 1.18-2.64), alongside older age and lower BMI. Cumulative incidence of SBP was also higher amongst those with ascitic neutrophilia (7.2% vs. 4.0%) though it did not reach statistical significance (p = 0.18; Gray's test) and death, LT or TIPS were significantly higher in those with ascitic neutrophilia (40.6% vs. 27.7%, p = 0.012; Gray's test). **Conclusion:** An elevated neutrophil count in ascitic fluid at the index paracentesis is independently associated with increased 90-day mortality in patients with cirrhosis, and it may indicate a higher risk of developing SBP. This finding supports its utility not only as a diagnostic marker for current SBP but also as a prognostic indicator of adverse outcomes.

2391 | IMPACT OF INTRAVENOUS ALBUMIN ADMINISTRATION ON CLINICAL OUTCOMES AFTER VARICEAL HEMORRHAGE IN PATIENTS WITH CIRRHOSIS: A RANDOMIZED CONTROLLED TRIAL

Sagnik Biswas[1] Shubham Mehta[2] Shekhar Swaroop[1] Arnav Aggarwal[1] Sarthak Saxena[1] Shubham Jain[1] Samagra Agarwal[1] Shivanand Gamanagatti[1] . Shalimar[1], [1]All India Institute of Medical Sciences, New Delhi, [2]All India Institute of Medical Sciences

Background: Systemic inflammation plays a significant role in influencing clinical outcomes after variceal bleeding independent of the severity of underlying liver disease. Despite having anti-inflammatory and antioxidant properties, limited data exists on the efficacy of intravenous human albumin administration in improving clinical outcomes (overall survival, prevention of new onset organ failures [encephalopathy, renal failure] or spontaneous bacterial peritonitis [SBP]) after variceal bleeding in patients with cirrhosis. **Methods:** Consecutive patients with cirrhosis (Child-Pugh class B and C) with hypoalbuminemia (<3.5 g/dL) and esophageal variceal bleeding were randomized to receive either standard medical therapy (SMT) or SMT along with intravenous human albumin administration (40g per day) for 3 consecutive days after primary hemostasis. Hepatic venous pressure gradient (HVPG) was measured on day-1 and-3 of admission. Primary outcome was a composite of new onset renal failure, SBP, hepatic encephalopathy (HE) and all-cause mortality at 6 weeks. Secondary outcomes included 5-day treatment failure rate and need for rescue therapy. **Results:** From December 2022 to October 2024, 136 patients were randomized, of whom 123 patients received the allocated interventions (SMT: 63 patients, SMT+albumin: 60 patients). The median Child-Pugh score was 9 (8-10) and the model for end stage liver disease score was 14.8 (11.7-19.7). Alcohol use was the leading cause of cirrhosis (69/123 patients, 56.1%) with a male predominance (108, 87.8%). The median change in serum albumin levels (on day 3 as compared to day 1) among patients receiving SMT+albumin was higher (0.5 [0.2-0.8]) as compared to those receiving SMT (0 [-0.3 to 0.2]; $p<0.01$). However, patients receiving SMT +albumin had similar composite rates of HE, SBP, renal failure and all-cause mortality at 6 weeks (8 [13.3%, 95% CI: 5.9%-24.6%]) as compared to SMT alone (11 [17.5%, 95% CI: 9.1%-29.1%]; $p=0.53$). There were no differences in the rates of 5-day rebleeding (SMT alone: 3 [4.8%, 95% CI: 1.0%-13.3%] versus SMT+albumin: 5 [8.3%, 95% CI:2.7%-18.4%]; $p=0.42$) and mortality (SMT alone: 1 [1.6%, 95% CI: 0.04%-8.5%] versus SMT + albumin: 1 [1.7%, 95% CI: 0.04%-8.9%]; $p=0.97$) between the two groups. The median change in HVPG on day 3 compared to day 1 (SMT alone: 0 [-2 to +1.5] versus SMT+albumin: 0 [-2 to +2]; $p=0.41$) was also similar between both groups. Rescue therapy in the form of transjugular intrahepatic portosystemic shunt was required in 2 (3.2%, 95% CI: 0.4%-11.0%) patients in the SMT alone group as compared to 3 (5%, 95% CI: 1.0%-13.9%) patients in the SMT+albumin group ($p=0.61$). **Conclusion:** Intravenous albumin use is safe after an episode of variceal bleeding in patients with cirrhosis, but does not contribute to reduction in 6-week mortality or prevention of new onset SBP/organ failures [CTRI/2022/10/046898].

2392 | ENDOSCOPIC VARICEAL LIGATION ALONE OR IN COMBINATION WITH NON-SELECTIVE BETA BLOCKERS FOR SECONDARY PROPHYLAXIS IN CHILDREN WITH NON-CIRRHOTIC PORTAL HYPERTENSION- A RANDOMIZED CONTROL TRIAL

Srinivas Srinidhi Vadlapudi[1] Anshu Srivastava[1] Anil Kumar Singh[1] Ujjal Poddar[1] Moinak Sen Sarma[1] Prabhaker Mishra[1], [1]Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India

Background: Non-cirrhotic portal hypertension (NCPH) is the predominant cause of portal hypertension (PHT) and variceal bleed (VB) in children in the east. Baveno VII consensus recommends use of non-selective beta blockers (NSBB) with endoscopic variceal ligation (EVL) for secondary prophylaxis of esophageal VB (EVB). However, the role of NSBB in children with NCPH is not clearly established. Hence, the study was undertaken to address this issue. **Methods:** In this prospective randomized control trial (pilot study), consecutive children (age 2-17 years) of NCPH with VB were enrolled (September 2020-2023) and followed up for a year. Patients with contraindication for NSBB, large gastric varix (F3), prior endotherapy or shunt surgery were excluded. Randomization was done by computer generated random number tables. Subjects underwent 3 weekly EVL till variceal eradication followed by 3 monthly endoscopies for recurrence of varices (EVL done if $>/=$ grade 2 varix). Patients in EVL+NSBB arm were started on long acting propranolol (1-3mg/kg/day) targeting a 25% reduction in heart rate. Splenic artery resistivity index (RI) was measured by

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

doppler to assess response to NSBB. Outcome measures included proportion of patients having rebleed (early-prior to variceal eradication or late- after variceal eradication), recurrence of esophageal varices (EV), change in gastric varices (GV), portal hypertensive gastropathy (PHG), tolerability and compliance to NSBB. **Results:** Seventy patients (9.2 ± 4.2 years, EVL = 36, EVL+NSBB = 34, extra hepatic portal venous obstruction [n = 64], non-cirrhotic portal fibrosis [n = 3], congenital hepatic fibrosis [n = 3]) were enrolled. Baseline characteristics were similar in the 2 groups. Patients got a dose of 1.6 ± 0.5 mg/kg of NSBB. There was no difference in overall rebleeding (16.1% *vs.* 12.5%, p = 0.73), early (9.1% *vs.* 12.1%, p = 1) or late rebleed (6.9% *vs.* 0%, p = 0.49) or the number of sessions needed for variceal eradication (3[1-9] *vs.* 3[1-10], p = 0.4) between the groups. Addition of NSBB was associated with significantly higher increase in RI, lower recurrence rate or need for further endotherapy of EV, maintained platelet counts and trend towards higher resolution of GV at 1year follow-up (table). There was no effect of NSBB on PHG. Four (11.8%) patients were non-compliant to NSBB and 4 (11.8%) did not achieve target heart rate due to hypotension (settled with reducing the dose of the drug). **Conclusion:** Addition of NSBB to EVL does not affect the rebleeding rate but reduces the recurrence or need for further endotherapy of EV in follow-up, maintains platelet count and downgrades GV in children with NCPH and EVB. NSBB are safe and well tolerated in children.

Table: Comparison between EVL and EVL+NSBB arms at baseline and at 1 year

2393 | TERLIPRESSIN USE LEADS TO A SIGNIFICANTLY REDUCED CREATININE AMONG HOSPITALIZED PATIENT WITH HEPATORENAL SYNDROME WHEN COMPARED WITH MIDODRINE/OCTREOTIDE IN A REAL-WORLD EXPERIENCE

Tanvi Goyal[1] David Kaplan[2] Jonathan Nahas[1],
[1]University of Pennsylvania, Penn Medicine, [2]University of Pennsylvania

Background: Hepatorenal syndrome (HRS) is a costly and often fatal complication of end-stage decompensated cirrhosis. Terlipressin (T) is the first FDA-approved treatment for HRS. Limited randomized controlled trial data showed superior outcomes for terlipressin relative to the prior off-label standard of care, midodrine/octreotide (MO). The objective of this study was to evaluate the efficacy of T relative to MO in a real-world setting. **Methods:** We performed a retrospective cohort study utilizing medical records review of inpatients admitted to our health system with a diagnosis of HRS in the 18 months prior to T formulary approval (January 2022-June 2023) and the 18 months following its introduction (July 2023-December 2024). Patients admitted at our main hospital, a tertiary referral and liver transplant center, were identified. [JN1] We collected laboratory values 48 hours prior to initiation of HRS therapy, at the time of initiation, 48 hours after initiation, and at maximal change in kidney function, length of stay (LOS) on medical floor and intensive care unit (ICU) and need for renal replacement therapy (RRT). We used non-parametric statistics and chi-square tests to compare demographic characteristics and the outcomes of interest. Linear and logistic regression models were evaluated to assess the association of treatment assignment and outcomes adjusting for key baseline covariates. **Results:** There were a total of 88 patients, with 59 in the MO cohort and 29 in the T cohort. Among patients admitted at our main hospital, 36 were in the MO cohort and 25 in T. At baseline, admission median creatinine was higher for the MO group, but at the start of HRS therapy, there were no significant differences in median creatinine or mean MELD-Na between the groups (Table 1). Post-treatment, patients in the T group demonstrated a significant improvement in creatinine, compared with a creatinine rise in the MO cohort. Patients in the T group had significantly higher rates of HRS reversal. Additionally, patients in the T group required fewer days of HRS treatment, and among those at our main hospital,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

had a lower fraction of inpatient days spent in ICU. There was also a trend towards decreased need for RRT in the T cohort. **Conclusion:** Among patients with HRS in a real-world clinical setting, T was associated with a greater improvement in creatinine and reversal of HRS, with a trend towards decreased need for RRT when compared to MO. Patients in the T group also required fewer days of HRS therapy and had less fractional time spent in ICU. Future work will compare the hospitalization costs of T versus MO to evaluate the cost-effectiveness of terlipressin in clinical practice.

2394 | ULTRASOUND LOCALIZATION MICROSCOPY FOR DIAGNOSIS OF CLINICALLY SIGNIFICANT PORTAL HYPERTENSION: A PROSPECTIVE MULTICENTER STUDY

Wei Zhang[1] Chuan Liu[2] Yanping Ma[1] Yingchun Yuan[3] Xinde Gong[4] Xia Chen[5] Renmei Wu[6] Jia Li[7] Xiaolong Qi[2] Jie Ren[1], [1]The Third Affiliated Hospital of Sun Yat-sen University, [2]1.Liver Disease Center of Integrated Traditional Chinese and Western Medicine, Department of Radiolo, [3]General Hospital of Ningxia Medical University, [4]TaiHe Hospital (Affilated Hospital Of HuBei University Of Medcine), [5]Department of Ultrasound, The First Affiliated Hospital of USTC, Division of Life Sciences and Medic, [6]Suining Central Hospital, [7]Zhongda Hospital Southeast University

Background: Currently, hepatic venous pressure gradient (HVPG) remains the gold standard for diagnosing clinically significant portal hypertension (CSPH), but its use is restricted by invasiveness and accessibility. This multicenter study aims to apply ultrasound localization microscopy (ULM) to visualize and quantify hepatic microvasculature in cirrhotic patients, evaluating its potential in non-invasive CSPH diagnosis. **Methods:** This study enrolled patients aged 17 to 80 with clinical diagnosis of cirrhosis who underwent HVPG measurement between April 2024 and November 2024 based on clinical needs. Exclusion criteria included prior hepatosplenic surgery, TIPS, SonoVue allergy, hypovolemia, and HVPG contraindications. After informed consent, patients underwent ULM, with data acquisition in the portal phase. Real-time imaging was performed, followed by offline quantitative analysis of microvessel functional and morphological parameters. HVPG $\geq$ 10 mmHg was considered the gold standard for diagnosing CSPH. The Mann-Whitney U test was used to compare microvessel parameters between the CSPH and non-CSPH groups. Spearman correlation analysis assessed the correlation between microvessel parameters and HVPG values. Simple and multiple linear regression models evaluated independent predictors of HVPG. receiver operating characteristic curve was used to assess the diagnostic performance of microvessel parameters in identifying CSPH. **Results:** A total of 29 patients were enrolled, including 21 males, with an average age of 51 (range: 28-70) years. Among them, 12 had alcoholic cirrhosis (including 2 co-infected with hepatitis B), 11 had hepatitis B cirrhosis, 1 had non-alcoholic steatohepatitis, 2 had autoimmune hepatitis, and 3 had primary biliary cirrhosis. Eight patients were diagnosed with CSPH, and 3 were non-CSPH. Compared to the non-CSPH group, the CSPH group exhibited lower vessel density (VD) (57.8 $\pm$ 11.3 vs. 42.2 $\pm$ 4.7, $p = 0.001$) and perfusion index (PI) (12.7 $\pm$ 1.3 vs. 8.7 $\pm$ 1.4, $p = 0.002$). Moderate correlations were observed both between VD and HVPG ($r = -0.70$, $p < 0.001$), and between PI and HVPG ($r = -0.57$, $p = 0.001$). VD was an independent predictor of HVPG ($r^2 = 0.52$). The diagnostic performance of VD for CSPH (AUC = 0.98, $p = 0.01$) was higher than that of the CSPH risk score (AUC = 0.59, $p = 0.54$). **Conclusion:** ULM-based microvessel parameters were proposed with good diagnostic consistency for HVPG measurement.

2395 | HEPATOLOGISTS' EXPERIENCE IN USING TERLIPRESSIN FOR TREATMENT OF HEPATORENAL SYNDROME-ACUTE KIDNEY INJURY

Prutha Shah[1] Rachel White[2] Morgan Elias[1] Rebecca Loh[3] Jonathan Fenkel[3] John Knorr[1] David Sass[3] Sarah Yeager[3] Jamie Schulte[3] Richard Kalman[1], [1]Jefferson Einstein Philadelphia Hospital, Philadelphia PA, [2]Sidney Kimmel Medical College, Philadelphia PA, [3]Thomas Jefferson University Hospital, Philadelphia PA

Background: Hepatorenal Syndrome-Acute Kidney Injury (HRS-AKI) is a complication of advanced liver disease. In September 2022, the FDA approved terlipressin + albumin for treating adults hospitalized with HRS-AKI. This study explores transplant hepatologists' experiences using the drug since its approval. **Methods:** A ten-question Qualtrics survey collected demographic data and assessed provider comfort, adverse effects, success rates, and optimal usage of terlipressin. The survey was distributed to 17 transplant hepatologists at two major liver transplant centers in Philadelphia, PA: Thomas Jefferson University Hospital and Jefferson Einstein Philadelphia Hospital. This study was IRB-exempt, voluntary, and responses were anonymized. Data analysis was conducted with Microsoft Excel. **Results:** Twelve transplant hepatologists responded to the survey (response rate 71%). Of the respondents, 83% found success with terlipressin 1/3 of the time, 17% found success 2/3 of the time, and none reported complete success or failure. Regarding adverse effects, 93% reported seeing hypoxia. Abdominal pain was the only other reported adverse reaction. When asked if the benefit outweighs the risks, 33% of providers said "it depends on the patient", 42% reported "most of the time", 25% reported "some of the time", and none reported "never" or "always". When asked about the minimum level of care, 75% of providers said the step-down unit, and 25% of providers answered the general medical floor. 58% of providers are less likely to prescribe terlipressin if the patient is listed for transplant, 8% are more likely, and 33% reported that transplant listing did not influence their decision. Providers with over 11 years of experience reported greater comfort using terlipressin than those with less than 10 years ($p < 0.05$) (Figure 1). Cost consideration influenced prescribing decisions for 8% of respondents. **Conclusion:** This study highlights transplant hepatologists' early experiences with terlipressin, showing success rates consistent with clinical trials. It underscores the need for targeted training for providers early in their careers and suggests further research to optimize usage. Our results confirm that despite the side effects and imperfect efficacy, transplant hepatologists at our centers believe there is a role for terlipressin in the treatment of HRS-AKI. Future research should explore experiences at other hospitals and identify specific patient populations who would benefit the most. Continued evaluation is critical to improving patient outcomes with this novel therapy.

2396 | POST-POLYPECTOMY BLEEDING IN PATIENTS WITH CIRRHOSIS: A SYSTEMATIC REVIEW OF RISK, PREDICTORS, AND PROCEDURE-RELATED FACTORS

Sajid Jalil[1] Talal Bhatti[2] Mohammad Adam[3] Chencheng Xie[4] Ashwani Singal[5], [1]Stanford University, [2]Northwell Health Center for Liver Diseases and Transplantation, [3]University of Missouri - Kansas City School of Medicine, [4]Avera McKennan Hospital, [5]University of Louisville

Background: Patients with cirrhosis are considered at increased risk for post-polypectomy bleeding (PPB) due to coagulopathy, portal hypertension, and associated comorbidities. However, the frequency and predictors of bleeding, especially in the modern era of optimized endoscopic practice, remain incompletely characterized. This systematic review aims to quantify the incidence of immediate and delayed PPB in cirrhotic patients, evaluate procedure- and patient-level predictors, and propose practical implications for clinical endoscopy. **Methods:** This systematic review was conducted in accordance with the PRISMA 2020 guidelines. A comprehensive literature search was performed in databases for articles published up to April 2025. Retrospective or prospective studies in adults with a diagnosis of cirrhosis and undergoing colonoscopy were selected. Of these, those reporting outcomes on PPB, immediate (IPB) defined as intra-procedural or delayed (DPB) defined as bleeding within 30-d of procedure. Data were extracted on patient demographics, liver disease severity (Child-Pugh class, MELD, INR, platelet count), procedural characteristics (polypectomy technique, polyp size, number, location), and clinical outcomes (IPB and DPB, transfusion, hospitalization). Reported odds ratios (ORs) for bleeding predictors were collected when available. A formal meta-analysis was not conducted due to considerable heterogeneity across studies. **Results:** A total of five retrospective cohort studies, encompassing 4,345 cirrhotic patients, met inclusion criteria (Table). IPB occurred in 6.3–7.5%, and DPB in 0.3–5.9% of cirrhotic patients in comparison to the risk of 30-day PPB rate of $< 0.5\%$ in general population. Risk of significant bleeding (defined as requiring hospitalization or transfusion) was rare (0.3–2.0%). Risk factors for PPB from different studies included Child-Pugh B/C (OR: 19.7), decompensated cirrhosis (OR: 1.65), ascites (OR: 2.82), polyp size $\geq$ 10 mm (OR: 1.087 to 8.3). Prolonged INR was associated with increased risk of IPB ($r = 0.61$) and low platelet counts (below 50,000) was associated with DPB ($r = -0.58$). Colonoscopy with endoscopic mucosal resection (EMR) was associated with higher rates of IPB and DPB compared to snare polypectomy. Aspirin use was not associated with increased bleeding risk. Use of antiplatelets (e.g. clopidogrel) within 5 days was associated with increased risk of DPB (RR = 2.42). **Conclusion:** Rates of PPB in cirrhotic patients is higher compared to general population (6.1% vs. $< 1\%$). The use of EMR should be coupled with prophylactic strategies in high-risk patients. Careful patient selection using liver severity markers (Child-Pugh, platelet count, INR), lesion size, and polypectomy type can enable safe endoscopic practice. Future prospective studies should validate bleeding risk tools and assess the role of prophylactic clipping, cold resection techniques and hemostatic optimization.

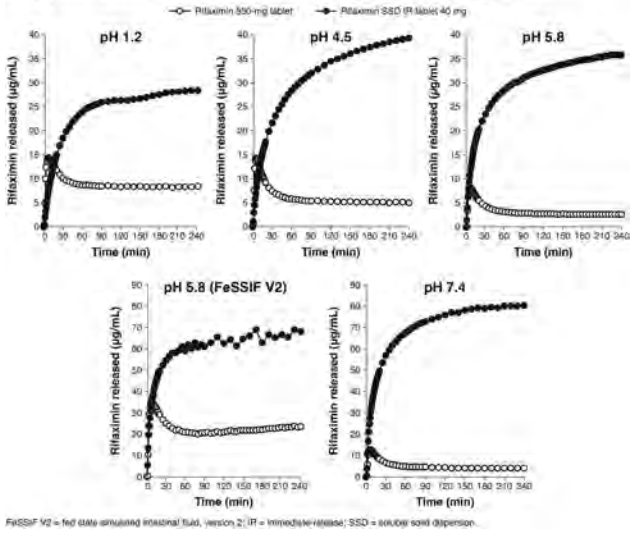
2397 | ENHANCED RIFAXIMIN DRUG RELEASE ACROSS GASTROINTESTINAL TRACT PH CONDITIONS WITH SOLUBLE SOLID DISPERSION (SSD) IMMEDIATE-RELEASE (IR) TABLETS: A COMPARATIVE IN VITRO STUDY VERSUS RIFAXIMIN 550 MG TABLET FORMULATION

Jasmohan Bajaj[1] RK Pillai[2] Sateesh Kandavilli[2] Saurabh Mishra[2] Christopher Allen[3] Arun Sanyal[1], [1]Virginia Commonwealth University, [2]Bausch Health US, LLC, [3]Salix Pharmaceuticals

Background: The current rifaximin 550-mg tablet is largely water insoluble and relies on small intestine bile acids (BA) to maximize solubility. Low intestinal BA levels in cirrhosis may reduce GI bioavailability. New formulations are needed to increase the applicability of rifaximin therapy across a wider range of cirrhosis/hepatic encephalopathy severity. Rifaximin SSD IR tablet 40 mg (SSD IR40) was designed to increase aqueous solubility of the rifaximin molecule throughout the lumen and minimize the need for BA. This is clinically important for patients with cholestasis/cirrhosis. The aim was to compare the in vitro dissolution profiles of rifaximin 550 mg and rifaximin SSD IR40 across a simulated range of fluid pH exposures likely to occur during GI transit. **Methods:** Dissolution rates of rifaximin 550 mg and rifaximin SSD IR40 were determined in 5 media to simulate portions of the GI tract (pH 1.2 [stomach], pH 4.5 [duodenum], pH 5.8 [small intestine], pH 5.8 [fed state simulated intestinal fluid, ver 2 (FeSSIF V2); small intestine], and pH 7.4 [colon]). Each test (N = 6) was conducted in 500 mL of medium at selected pH and maintained at 37 °C and 75 rpm (USP Apparatus 2 paddle method) for 240 min, with monitoring using an in situ UV fiber-optic 10-mm probe at λ_{max} = 325 nm (Opt-Diss 410, Distek, Inc). **Results:** The rifaximin release profile for both formulations is shown in the Figure. At 1 hour, for rifaximin SSD IR40 vs rifaximin 550 mg, there was a 2.7-, 4.9-, 9.1-, 2.8-, and 13.3-fold higher concentration of rifaximin at pH 1.2, 4.5, 5.8, 5.8 (FeSSIF V2), and 7.4, respectively. At 4 hours, there was a 3.4-, 7.7-, 13.6-, 2.9-, and 18.7-fold higher rifaximin concentration at pH 1.2, 4.5, 5.8, 5.8 (FeSSIF V2), and 7.4, respectively. Rifaximin 550-mg tablet dissolution was significantly enhanced at pH 5.8 in the presence of BA (FeSSIF V2 vs phosphate buffer pH 5.8); rifaximin SSD IR40 dissolution was not impacted. **Conclusion:** During exposure to pH conditions considered clinically relevant within segments of the lower GI tract, an ≈3- to 19-fold greater increase in rifaximin release was observed and sustained over time with rifaximin SSD IR40 vs rifaximin 550 mg. BA did not impact rifaximin SSD IR40 dissolution rate. These data support that rifaximin SSD IR may provide higher luminal bioavailability of rifaximin at a lower dosage throughout the lower GI tract vs the current rifaximin 550-mg tablet. Thus, rifaximin SSD IR40 may overcome low BA availability issues observed in cirrhosis progression.

Figure. Comparative Dissolution Profile of Rifaximin SSD IR Tablet 40 mg Versus Rifaximin 550-mg Tablet Across Various pH Values and FeSSIF V2 Medium Containing Bile Salts



FeSSIF V2 = fed state simulated intestinal fluid, version 2; IR = immediate-release; SSD = soluble solid dispersion.

2398 | VASCULAR GEOMETRIC MODEL FOR PREDICTING PORTAL PRESSURE GRADIENT IN PATIENTS WITH CIRRHOSIS

Ling Yang[1] Jiawei Zhang[1] Yechong Huang[2] Jiaqi Gu[1] Xiaolin Wang[3] Chuan Liu[3] Shaoting Zhang[2] Xiaolong Qi[3], [1]Zhongda Hospital, Medical School, Southeast University, [2]SenseTime Research, Shanghai, [3]Zhongda Hospital, Southeast University

Background: Measurement of the portacaval pressure gradient (PPG) is a crucial step in evaluating portal pressure in patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) procedures. However, PPG assessment is limited by its invasive nature. Based on the inspiration provided by our previous study, we further explored the feasibility of non-invasively predicting PPG by utilizing 64 vascular geometric parameters derived from preoperative contrast-enhanced CT scans in patients scheduled for TIPS surgery. **Methods:** A retrospective cohort study was conducted from January to September 2024 across six university-affiliated medical centers, enrolling 39 patients scheduled for TIPS surgery. Invasive PPG measurements before TIPS surgery (PPG_Before) were obtained for all participants as the reference standard. We developed a comprehensive pipeline for the calculation of 64 geometric parameters from raw DICOM data using Python 3.6.1, encompassing data preprocessing, vessel segmentation, and vascular tree construction. Multivariate regression, logistic and linear regression analyses were used to identify predictive features. For clinical stratification, patients were dichotomized using a 20 mmHg PPG threshold - an established indicator for variceal rebleeding risk. **Results:** The cohort had a median age of 52.0 years (IQR 46.0–64.0), with 74.4% males (n = 29). Baseline PPG_Before measurements were available for 37 patients (mean 22.76 ± 6.12 mmHg). Logistic regression identified the main portal vein branch length as a particularly robust predictor during the portal venous phase (OR = 1.138, 95% CI: 1.016-1.275, $p < 0.05$). Linear regression models further established moderate but statistically significant correlations for both aortic phase vessel tortuosity (R = 0.437) and subbranch diameter (R = 0.348) with measured PPG_Before values. These findings informed the development of our convolutional neural network-derived predictive algorithm: PPG_{AI} = -0.175 × (Aorta_Average vessel tortuosity) + 0.149 × (Aorta_Subbranch diameter) + 0.130 × (Pv_Main branch length) - 1.657. The model achieved 83.8% accuracy in classifying patients above/below the 20 mmHg threshold. Through receiver-operating characteristic analysis, we established a clinically actionable cutoff value of PPG_{AI} = -0.3313, where values below this threshold indicated low rebleeding risk (negative predictive value = 90.0%), while values above suggested elevated risk requiring closer monitoring (positive predictive value = 81.5%). This stratification demonstrated good concordance with invasive PPG measurements (R = 0.576, $p < 0.001$), suggesting robust clinical utility for rebleeding risk assessment (Figure 1). **Conclusion:** In conclusion, the study proposed a PPG calculation model using anatomical imaging features, which may serve as a substitute for invasive PPG measurement.

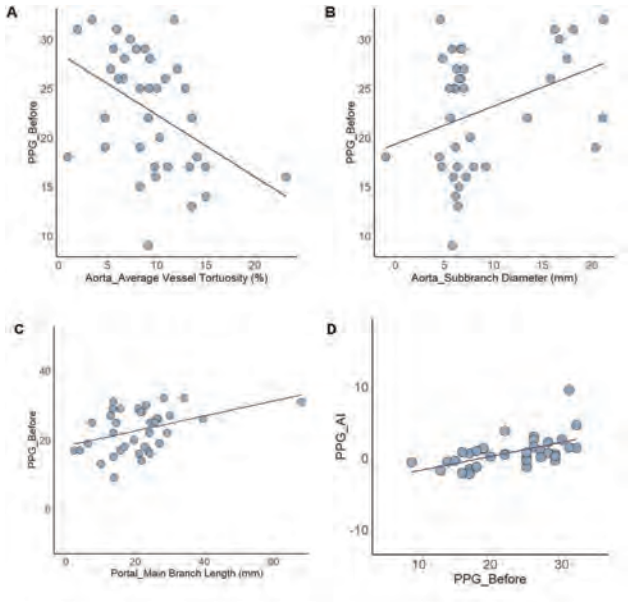

Figure 1: A-C: Scatter plot of average vessel tortursity, subbranch diameter in arterial phase and main branch length in portal phase and correlation with PPG_Before in linear regression. D: Scatter plot of PPG_AI and PPG_Before.

Womans University College of Medicine, [3]Chosun University Hospital, [4]Hallym University Dongtan Sacred Heart Hospital, [5]Kang Buk Samsung hospital, [6]Kangbuk Samsung Hospital

Background: It is unclear whether the risk of infection is different between chronic liver disease (CLD) without cirrhosis, compensated cirrhosis and decompensated cirrhosis. This study aimed to investigate the risk of serious infection and mortality in patients with compensated cirrhosis and decompensated cirrhosis. **Methods:** This study was conducted on 1,699,159 patients with CLD from the Korean National Health Insurance Service between 2009 and 2021. Serious infection was defined as acute meningitis, acute osteomyelitis, bacteremia, pneumonia, pyelonephritis, serious gastrointestinal infection, skin and soft tissue infections, spontaneous bacterial peritonitis, or COVID-19 infection. The primary outcome was all-cause mortality stratified by serious infection episodes (0, 1, and ≥ 2). We compared the development of serious infection, the admission of intensive care unit (ICU), and mortality between CLD without cirrhosis, compensated cirrhosis and decompensated cirrhosis. **Results:** The mean age of patients was 57.4 years, with 55.6% being men. Among them, the proportion of CLD without cirrhosis, compensated cirrhosis, and decompensated cirrhosis was 77.5% (N = 1,317,468), 17.5% (N = 296,617), and 5.0% (N = 85,074), respectively. During follow-up, there were 336,602 episodes of serious infections, with pneumonia being the most common, followed by serious gastrointestinal infection, pyelonephritis, and bacteremia. Mortality rates were 3.94, 41.58, and 114.03 per 1,000 person-years in patients with 0, 1, and ≥ 2 serious infections, respectively. Multivariable analysis indicated that adjusted hazard ratios (aHRs) for mortality were 6.04 (95% confidence interval [CI]: 5.96-6.13) for one infection and 13.40 (95% CI: 13.20-13.60) for ≥ 2 infections, compared to no infections. Compared to CLD without cirrhosis, the development of serious infection was higher in compensated cirrhosis (aHR: 1.99, 95% CI:1.97-2.02), and decompensated cirrhosis (aHR: 3.31, 95% CI:3.26-3.37). **Conclusion:** Patients with CLD exhibited a trend of increased mortality dependent on the number of serious infections and the degree of disease severity of CLD ranging from CLD without cirrhosis, compensated cirrhosis, and decompensated cirrhosis. Decompensated cirrhosis has more than 3-fold risk of infection than CLD without cirrhosis.

2400 | REAL-WORLD OUTCOMES FOLLOWING TERLIPRESSIN USE IN HEPATORENAL SYNDROME: A MULTI-CENTER U.S. EHR ANALYSIS

Romelia Barba[1] Khawaja Hassam[2] Ana Marenco-Flores[3] Natalia Rojas-Amaris[3] Pojsakorn Danpanichkul[4] Daniela Goyes[5] Gloria Erazo[1] Zeyad Elharabi[1] Leo Yamaguchi[1] Kanak Das[1] Hakan Akin[1] Michael Curry[3], [1]Texas Tech University, [2]Lahey Hospital and Medical Center, [3]Beth Israel Deaconess Medical Center, [4]Texas Tech University Health Sciences Center, [5]Yale School of Medicine

Background: Hepatorenal syndrome–acute kidney injury (HRS-AKI) is a life-threatening but potentially reversible complication of cirrhosis characterized by rapid deterioration in kidney function. Terlipressin, a vasopressin analog, is FDA-approved (in combination with albumin) for the treatment of adult patients with HRS and is recommended as first-line therapy for HRS-AKI in recent AASLD and EASL guidelines. Despite demonstrated efficacy in clinical trials, real-world comparative data on terlipressin use remain limited in U.S. practice. **Aim:** To evaluate real-world outcomes in patients with HRS treated with terlipressin using a large multi-institutional electronic health record (EHR) database. **Methods:** We conducted a retrospective, single-arm outcomes analysis using the TriNetX U.S. Collaborative Network, a federated platform aggregating de-identified EHR data—including diagnoses, procedures, medications, labs, and outcomes—from 68 U.S. healthcare organizations. Adults (≥ 18 years) diagnosed with HRS who received terlipressin on or after September 14, 2022, were included. The date of terlipressin initiation served as the index event. Risk and Kaplan-Meier survival analyses were performed for all-cause mortality, dialysis initiation, liver transplantation, and recurrent HRS, assessed at 30, 60, 90, and 180 days. Competing risks (e.g., death before transplant) were not formally modeled. **Results:** A total of 380 patients were identified (mean age 54.5 years; 59% male; 74.7% White). Within 30 days, 30% had died, 21.3% initiated dialysis, 17.4% underwent liver transplantation, and 42.6% experienced recurrent HRS. These risks increased modestly at 60 days (36%, 23.4%, 21%, and 48.7%, respectively) and again by 90 days (38.4%, 24%, 22%, and 49.7%). At 180 days, 40.5% had died, 25.5% started dialysis, 24.2% underwent transplant, and 51.1% had recurrent HRS. Kaplan-Meier analysis showed the steepest risk increase in the first 30 days (Figure 1). The 180-day survival probabilities were 53.1% for overall survival, 66.0% dialysis-free, 61.4% transplant-free, and 36.6% HRS-free. Median time to event dropped below 50% only for recurrent HRS (43 days). **Conclusion:** In this real-world, multi-center cohort of adults with HRS treated with terlipressin,

nearly half experienced death or recurrent HRS within six months, and one in four required dialysis or liver transplantation. These findings highlight the high acuity of the HRS population and suggest that while terlipressin may reverse renal dysfunction, it does not alter the underlying trajectory of advanced liver disease. Real-world data such as ours is essential to complement trial results and guide treatment decisions in this complex population. Limitations include the inability to model competing risks and the lack of site-level data, which may influence transplant-related outcomes.

2401 | REAL-WORLD TREATMENT PATTERNS AND OUTCOMES AMONG HOSPITALIZED U.S. ADULTS WITH HEPATORENAL SYNDROME-ACUTE KIDNEY INJURY TREATED WITH TERLIPRESSIN

Alfred Barritt IV[1] Robert Wong[2] Kavish Patidar[3] Nisha Wadhwani[4] Jonathan Lilley[4] Rahul Rajkumar[4] Xingyue Huang[5] Mary Panaccio[5], [1]University of North Carolina School of Medicine, Chapel Hill, NC, [2]Stanford University School of Medicine, Palo Alto, CA, USA, [3]Houston Methodist Hospital, Houston, TX, [4]Boston Strategic Partners, Inc., Boston, MA, USA, [5]Mallinckrodt Pharmaceuticals, Bridgewater, NJ, USA

Background: Hepatorenal syndrome–acute kidney injury (HRS-AKI), is a life-threatening complication of advanced liver disease marked by rapid renal decline. This study examined early real-world use and outcomes of terlipressin, a vasopressin analogue recently approved in the U.S. to improve kidney function in adults with HRS. **Methods:** We identified adults hospitalized with HRS-AKI who received terlipressin for ≥ 2 consecutive days between Sep 2022–Feb 2025 using the Premier Healthcare Database. We evaluated treatment patterns and outcomes, including HRS reversal, which were also assessed among patients with alcohol-associated liver disease (ALD) and those on the liver transplant waitlist. Diagnoses, medication use, and outcomes were identified using ICD-10, National Drug Codes, and billing data. **Results:** We identified 285 patients [median age 56.0 years (IQR 47.0, 66.0), 63.5% male], of whom 68.1% were hospitalized at large-volume health systems (500+ beds). Most patients were White (64.2%), and Medicare was the most common payer type (33.0%). ALD was the most common cirrhosis etiology (70.5%). Overall median time to terlipressin initiation was 4.0 days (IQR 2.0, 8.0). First-line treatment included terlipressin (22.5%), same-day midodrine and octreotide (26.0%), or norepinephrine (3.2%). The remaining 48% received midodrine or octreotide monotherapy, or other combination therapies. In-hospital mortality was 16.8%, with 16.5% discharged to hospice and 45.6% discharged home. Median length of stay was 16 days (IQR 10.0, 27.0). Renal replacement therapy was required in 26.3% of patients. Among 36 patients with available SCr data, HRS reversal, defined as post-treatment SCr to ≤ 1.5 mg/dL, was achieved in overall 52.8% of patients, with median SCr declining from 2.2 mg/dL (IQR 1.7, 3.1) to 1.2 mg/dL (IQR 1.0, 1.4). HRS reversal was more frequent in ALD patients (60.7%) than in non-ALD patients (25.0%). Among those on the transplant waitlist, 75.0% achieved reversal compared with 50.0% of those not listed. **Conclusion:** In this real-world HRS cohort treated with terlipressin, most were managed at high-volume centers and had underlying ALD. Although terlipressin was infrequently used first-line, meaningful rates of HRS reversal were observed, particularly in ALD. With nearly half of all patients discharged home and in-hospital mortality under 20%, these findings highlight the potential for terlipressin to improve renal function and overall clinical outcomes–reinforcing the importance of early recognition and treatment.

2402 | COMPARATIVE VALIDATION OF PROGNOSTIC MODELS FOR TRANSPLANT-FREE SURVIVAL IN TIPS: THE ADVANCING LIVER THERAPEUTIC APPROACHES IN PORTAL HYPERTENSION (ALTA) STUDY

Ludovic Saba[1] Justin Boike[2] Michael Fallon[3] Pallav Kolli[4] Bartley Thornburg[2] Elizabeth Verna[5] Adnan Said[6] Carrie Frenette[7] Aparna Goel[8] Jennifer Lai[4] Sumeet Asrani[9] Giuseppe Joseph Morelli[10] Nicholas Lim[11] Arun Jesudian[12] Adam Deising[13] Sonali Paul[14] Douglas Simonetto[15] Margarita German[16] Dyanna Gregory[1] Mehnush Hameie[17] Cynthia Padilla[17] Lisa VanWagner[18], [1]UT Southwestern Medical Center, [2]Northwestern Memorial Hospital/Northwestern University, [3]University of Arizona, [4]UCSF, [5]Columbia University Medical Center, [6]University of Wisconsin School of Medicine and Public Health, [7]Gilead Sciences, [8]Stanford University, [9]Liver Consultants of Texas, [10]University of Florida, [11]University of Minnesota, [12]Weill Cornell Medicine, [13]Scripps Clinic, [14]University of Chicago Medical Center, [15]Mayo Clinic Rochester, [16]University of Wisconsin, [17]Northwestern University, [18]University of Texas Southwestern Medical Center

Background: Despite advances in transjugular intrahepatic portosystemic shunt (TIPS) technique and patient selection, short-term mortality still varies widely (9-80% depending on patient characteristics). Prognosis is usually guided by MELD-based or Child-Turcotte-Pugh (CTP) scores, yet newer models derived in non-US based populations – the Freiburg Index of Post-TIPS Survival (FIPS) and the Modified TIPS Score (MOTS) – may offer better discrimination. We aimed to comparatively validate prognostic models for post-TIPS mortality in a large prospective multicenter US-based cohort. **Methods:** Advancing Liver Therapeutic Approaches in Portal Hypertension (ALTA) is a multi-center prospective cohort study across 13 US centers of adults (≥18 years) who were scheduled for TIPS between 7/2019-1/2025. Those who underwent successful TIPS creation with complete data for modeling were included in this analysis. Descriptive statistics were summarized using t-tests and ANOVA, or Chi-squared and Fisher, as appropriate. Fine and Gray competing risk models were fitted to evaluate time to death with transplant treated as a competing event and covariates

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(sex, race/ethnicity, TIPS indication and urgency, portal-hypertension cause, transplant intent) held constant. Six candidate scores – MELD, MELD-Na, MELD-3.0, CTP, FIPS and MOTS – were evaluated. Discrimination for transplant-free survival (TFS) at 30, 90, 180 and 365 days was assessed using area under the receiver operating characteristic curves (AUROC). **Results:** A total of 501 subjects (mean age 56.7 years, 43.1% female, 80.6% White, 20.8% Hispanic) were included with mean follow up 427 days. Median (IQR) MELD was 11.4 (9.3-14.5), MELD-Na 13.1 (9.9-17.1), and MELD-3.0 13.6 (10.2-17.2). The 3 MELD-based scores provided the strongest and most consistent associations with death: each point increase in MELD-3.0 raised the instantaneous hazard by 7 % (HR 1.07, $p = 0.002$), and MELD-Na and original MELD produced similar effects (HR 1.06, $p = 0.003$ and 0.006, respectively). CTP score was also significant (HR 1.24, $p = 0.026$) but, because it spans only 5–15 points, offered less patient-level discrimination (i.e., ability to separate higher from lower-risk individuals). MOTS met significance (HR 1.50, $p = 0.032$), while FIPS was not associated with mortality ($p = 0.25$). MELD-3.0 and MELD yielded the highest 30 and 90-day AUROCs, but all 6 scores converged ≈0.78 by 1 year (Figure). In stratified analyses by cirrhosis status, sex, race and ethnicity, only MELD-3.0 and/or MELD-Na significantly predicted mortality. **Conclusion:** In a large contemporary US-based prospective cohort of TIPS recipients, MELD scores showed the most consistent hazard associations with short-term death post-TIPS across multiple subgroups. These findings suggest MELD-based scores remain reliable short-term guides. Additional studies are needed to improve risk discrimination for longer term survival post-TIPS.

University, [6]Columbia University Medical Center, [7]University of Wisconsin School of Medicine and Public Health, [8]Gilead Sciences, [9]Stanford University Medical Center, [10]Liver Consultants of Texas, [11]University of Florida, [12]University of Minnesota, [13]Weill Cornell Medicine, [14]Scripps Clinic, [15]University of Chicago Medical Center, [16]Mayo Clinic Rochester, [17]University of Wisconsin, [18]University of Texas Southwestern Medical Center

Background: TIPS is a key intervention for portal hypertension, and MELD-based scores are widely used to assess procedural risk. While they were developed to predict post-TIPS mortality, they also predict mortality in cirrhosis. Their ability to distinguish TIPS-attributable deaths (TAD) from non-attributable deaths (TNAD) remains unclear. We aim to evaluate this distinction. **Methods:** Advancing Liver Therapeutic Approaches in Portal Hypertension (ALTA) is a multi-center prospective cohort study across 13 U.S. centers of adults ($\geq$18 years) who were scheduled for TIPS between 7/2019-1/2025. Those who underwent successful TIPS creation with complete data for modeling were included; those with unknown cause of death were excluded. A committee of interventional radiologists and hepatologists adjudicated deaths as TIPS-related (TAD) or non-attributable (TNAD) by unanimous agreement. Fine-Gray subdistribution hazard models were used to assess associations between MELD scores and TAD/TNAD. TAD/transplant and TNAD/transplant were treated as competing risks in the TNAD and TAD models, respectively. **Results:** A total of 609 participants (mean age 57.2 years; 44.3% female; 82.2% White; 20.6% Hispanic) were included. TNAD group was older (67.4 vs. 61.8 years, $p = 0.02$); other demographics were similar between groups. Mean follow-up was 398 days. Overall post-TIPS mortality was 17.1% ($n = 104$), with 26.9% ($n = 28$) attributable to TIPS. Most common causes of TAD death were multiple organ system failure (28%), renal failure (14%), and cardiovascular and infection (11% each). TNAD were infection (18%), multiple organ system failure (14%), and malignancy (12%). Time to death was shorter in TAD vs. TNAD (110.6 vs. 366.1 days; $p < 0.001$). In adjusted models, all MELD scores were significantly associated with overall mortality and TAD but not associated with TNAD (Table). In stratified analyses, MELD variants were associated with increased risk of TAD in females, non-Hispanics, TIPS done for ascites, and patients with cirrhotic portal hypertension. Traditional MELD was associated with increased risk of TAD in patients in alcohol-associated cirrhosis. MELD-Na was associated with increased risk of TAD in patients with noncirrhotic portal hypertension. **Conclusion:** In this large multicenter study, MELD scores predicted overall and TIPS-attributable mortality, but not non-TIPS-related deaths. These findings suggest that MELD-based risk stratification specifically reflects vulnerability to TIPS-related complications rather than general post-procedure mortality. Risk assessment tools should account for this distinction to better guide TIPS candidacy and counseling.

Table. Subdistribution hazard ratios (95% CI) for MELD score variants stratified by clinical characteristics among TIPS recipients

	MELD		MELD-Na		MELD 3.0	
	TAD	TNAD	TAD	TNAD	TAD	TNAD
Overall	**1.10 (1.05, 1.16)**	1.02 (0.98, 1.06)	**1.10 (1.04, 1.16)**	1.02 (0.98, 1.06)	**1.10 (1.04, 1.18)**	1.03 (0.99, 1.07)

2404 | PHASE 1, SINGLE-ASCENDING DOSE RESULTS: FROM THE PHIN-001 STUDY OF PHIN-214 IN COMPENSATED AND DECOMPENSATED PATIENTS WITH CIRRHOSIS

Douglas Simonetto[1] Naim Alkhouri[2] Ethan Weinberg[3] Christina Lindenmeyer[4] Gary Reiss[5] Eric Lawitz[6],
[1]Mayo Clinic Rochester, [2]Summit Clinical Research, [3]University of Pennsylvania, [4]Cleveland Clinic, [5]Tandem Clinical Research, [6]Texas Liver Institute

Background: Portal hypertension is a key driver of decompensation in cirrhosis patients, yet effective chronic pharmacologic interventions are limited. PHIN-214 is a novel vasopressin analogue exhibiting partial V1a receptor agonism, reduced V2 activity, and a broad therapeutic index, that is being developed for subcutaneous, once daily self-injection for out-patient management of portal hypertension and associated complications. **Methods:** PHIN-001 (NCT05490888) is an ongoing phase 1 dose-optimization study evaluating single and multiple doses of PHIN-214 in adults with Child-Pugh (CP) A and B cirrhosis. Primary objectives include safety, tolerability, pharmacokinetic, and pharmacodynamic assessments. **Results:** Fifteen (15) subjects, 8 men and 7 women, were treated across eight (8) single-ascending dose levels. The subjects were mostly CP-A (73%) with a mean MELD-Na score of 10 (range 6-14) and an average age of 56 (range 42-72). Overall exposure to PHIN-214 and PHIN-156 (the active PHIN-214 metabolite) appear dose-proportional. PHIN-214 was generally well tolerated with a safety profile consistent with on-target V1a engagement. Possibly or likely drug-related adverse events included injection site blanching, abdominal pain/cramping, diarrhea, hematochezia and hypertension. An asymptomatic decrease in serum sodium was observed in all cases with a mean decrease of 6.2 (mmol/L) (95% CI: 4.6, 7.8) and mean minimum of 133 mmol/L (95% CI: 131.6, 134.4). Evidence of potential clinical benefit was demonstrated by improved estimated glomerular filtration rate (eGFR) in all subjects, irrespective of CP classification or baseline eGFR. Mean eGFR rose 40.2% within 12 hours (95% CI: 28–52.5%) and was sustained up to 24 hours in most cases. A strong positive correlation ($r > 0.80$, $P < 0.01$) was observed between PHIN-156 and eGFR improvement, particularly at higher doses. The single ascending dose phase of the study is complete; the multi-ascending dose phase is now enrolling to assess safety and sustained benefit with 28-day once daily dosing. **Conclusion:** A single subcutaneous dose of PHIN-214 was safe, well tolerated and showed a physiologic profile consistent with V1a activation. Early signs of clinical activity as evidenced by improvement in eGFR and a strong correlation with PHIN-156 exposure support continued development of PHIN-214 as a once-daily, self-administered treatment for portal hypertension in cirrhosis. Complete single-dose and emerging multi-dose data will be presented.

2405 | BARIATRIC SURGERY IS ASSOCIATED WITH REDUCED RISK OF HEPATIC DECOMPENSATION AND IMPROVED SURVIVAL IN OBESE PATIENTS WITH CIRRHOSIS: A PROPENSITY-MATCHED TRINETX STUDY

Archana Kharel[1] Umesh Bhagat[1] Islam Mohamed[2] Mohamed Nadeem[1] Prabhat Kumar[3] Raseen Tariq[3], [1]Cleveland Clinic Foundation, [2]The Cleveland Clinic Foundation-Fairview hospital, [3]VCU health, Richmond

Background: Obesity often coexists with chronic liver disease and cirrhosis, yet the impact of bariatric surgery on decompensation remains unclear.We aimed to see whether bariatric surgery lowers decompensation risks in obese cirrhotic adults, using real-world data. **Methods:** We queried the TriNetX Research Network (101 healthcare organizations) to identify adults ($\geq$ 18 years) with a diagnosis of cirrhosis (ICD-10: K74 or K70.3) and obesity (E66) between Jan 1, 2010 and Apr 28, 2025. Patients with prior liver transplant, hepatic or gastric malignancy, or pregnancy were excluded. Two cohorts were defined: (1) those undergoing bariatric surgery (n = 4,411) and (2) non-surgical controls without weight loss intervention (n = 234,617). After 1:1 propensity score matching on age, sex, race, labs (Na, INR, total bilirubin), BMI, and comorbidities, 4,286 patients were retained per group. Outcomes assessed over a 3-year follow-up included ascites (R18), variceal bleeding (I85.01/I85.11), spontaneous bacterial peritonitis (SBP, K65.2), hepatocellular carcinoma (HCC, C22), hepatorenal syndrome (HRS, K76.7), and hepatic encephalopathy (HE, K72.9). **Results:** Following propensity score matching, the final study included 8,572 patients (4,286 per group). The cohorts were well-balanced in terms of age (mean 50 $\pm$ 12.2 years), sex (71.4% female), and metabolic comorbidities (94.9% with endocrine/metabolic disease). Post-matching standardized differences for all variables were < 0.01, indicating excellent covariate balance. During a 3-year follow-up, patients in the bariatric surgery group experienced significantly fewer liver-related decompensation events compared to those without any intervention. Ascites developed in 9.1% of the bariatric group versus 19.0% in the control group (HR 2.49, 95% CI 2.20–2.81; $p < 0.001$). Spontaneous bacterial peritonitis occurred in 0.8% vs 2.9% (HR 4.45, 95% CI 3.03–6.53; $p < 0.001$), and variceal bleeding was reduced among surgical patients (0.5% vs 2.9%; HR 6.38, 95% CI 4.09–9.96; $p < 0.001$). Other significant differences included a reduced incidence of hepatic encephalopathy in the bariatric cohort (4.2% vs 12.5%; HR 3.56, 95% CI 3.00–4.21; $p < 0.001$), hepatocellular carcinoma (1.8% vs 3.9%; HR 2.43, 95% CI 1.86–3.19; $p < 0.001$), and hepatorenal syndrome (0.9% vs 3.0%; HR 4.04, 95% CI 2.80–5.82; $p < 0.001$). Kaplan–Meier analysis showed significantly higher event-free survival across all outcomes in the bariatric cohort, three year event free survival were notably higher for ascites (89.6% vs 77.3%), HE (95.0% vs 84.6%), and HCC (97.9% vs 95.2%). **Conclusion:** Among patients with cirrhosis and obesity, bariatric surgery is associated with significantly reduced risk of hepatic decompensation with ascites, encephalopathy, variceal bleeding, and HCC. These findings suggest a possible disease-modifying role of metabolic surgery in selected cirrhotic populations and support prospective evaluation.

Figure 1:Bariatric surgery was associated with significantly lower 3-year cumulative risk for multiple complications:

Outcome	Non-intervention Cohort (%)	Bariatric Cohort (%)	Hazard Ratio (95% CI)	p-value
Ascites	19.0	9.1	2.49 (2.20–2.81)	<0.001
Variceal Bleed	2.9	0.5	6.38 (4.09–9.96)	<0.001
SBP	2.9	0.8	4.45 (3.03–6.53)	<0.001
HCC	3.9	1.8	2.43 (1.86–3.19)	<0.001
HRS	3.0	0.9	4.04 (2.80–5.82)	<0.001
HE	12.5	4.2	3.56 (3.00–4.21)	<0.001

2406 | TARGETING THE HIDDEN RISK: RIFAXIMIN LOWERS THE RISK OF NEW ONSET OF HEPATIC ENCEPHALOPATHY IN PATIENTS WITH HEPATOCELLULAR CARCINOMA AND SPLENORENAL SHUNT RECEIVING LENVATINIB

Takumi Kawaguchi[1] Shigeo Shimose[1] Hideki Iwamoto[2] Takashi Niizeki[1] Tomotake Shirono[1] Etsuko Moriyama[1], [1]Kurume University School of Medicine, [2]Iwamoto Internal Medicine Clinic

Background: Lenvatinib effectively inhibits tumor angiogenesis and growth of hepatocellular carcinoma (HCC), leading to an improvement in prognosis. However, hepatic encephalopathy (HE) is a serious adverse event of lenvatinib that requires discontinuation of the medication. Rifaximin is a minimally absorbed oral antimicrobial agent, which reduces the risk of recurrence of HE in patients with liver cirrhosis. The aim of this study is to investigate risk factors for HE in patients with HCC receiving lenvatinib. We also explored the usefulness of rifaximin for preventing HE and the dosage of lenvatinib. **Methods:** This is a two-center retrospective observational cohort study. We enrolled 216 patients with HCC receiving lenvatinib. HE was diagnosed according to the presence of asterixis and/or mental symptoms from disorientation through the coma. Before the initiation of LEN, patients with hyperammonemia ($\geq$80 μg/dL) were treated with oral rifaximin at a dose of 1,200 mg/day. The incidence of HE was evaluated (observational period 480 [1-3,657] days). The dosage of lenvatinib was assessed by relative dose intensity (RDI). A decision-tree algorithm was constructed to reveal the profiles associated with HE. **Results:** The incidence of HE was 8.8%. There was no significant difference in age, sex, BMI, and tumor stage between the HE and non-HE groups. Although there was no significant difference in blood ammonia level between the two groups, the prevalence of splenorenal shunt was significantly higher in the HE groups compared to the non-HE group. A multivariate analysis demonstrated that a splenorenal shunt was identified as an independent risk factor for HE (HR 16.4, 95%CI 5.2-52.6, $P < 0.001$). Decision-tree analysis revealed that, in the patients with splenorenal shunt and ALBI grade 2, HE occurred in 66.6% of the patients with no refaxmin. In contrast, 16.6% developed HE in the patients with rifaximin. Furthermore, the prevalence of RDI $>$70% was 20.0% and 66.7% in the patients with no rifaximin and rifaximin, respectively. **Conclusion:** Splenorenal shunt was an independent risk factor for HE in patients with HCC receiving lenvatinib. Moreover, rifaximin prevented HE and contributed to sufficient dosage of lenvatinib in patients with HCC, splenorenal shunt, and ALBI grade 2. Thus, rifaximin may be beneficial for the management of HCC patients receiving lenvatinib, especially in HCC patients with splenorenal shunt and hepatic dysfunction.

2407 | TIMING MATTERS: COMPARATIVE ANALYSIS OF EARLY VS. LATE TIPS IN VARICEAL BLEED MANAGEMENT

Het Patel[1] Hammad Liaquat[2], [1]St. Luke's University Healthcare Network, [2]St Luke's University Healthcare Network

Background: Acute variceal bleeding is a life-threatening complication of portal hypertension in cirrhosis. Despite initial endoscopic and pharmacologic therapy, some patients require early or rescue Transjugular Intrahepatic Portosystemic Shunt (TIPS) to control bleeding and prevent rebleeding. The goal of this study is to identify the outcomes associated with delayed TIPS in acute variceal bleed. **Methods:** This is a retrospective cohort study using National Inpatient Sample data including adult patients hospitalized between 2019 and 2022 with history of cirrhosis and presenting with acute variceal bleed. The study compares patients who underwent early TIPS (between Day 0 and Day 2) to late TIPS (from Day 3 and onward) and assessed risk factors including demographics, chronic medical conditions and inpatient complications. Statistical analyses were all performed using STATA software. **Results:** Of the 11,740 patients with cirrhosis presenting with a variceal bleed, a majority of patients were males, however gender was not associated time of TIPS ($p > 0.05$). In general, the patients who underwent late TIPS were on average older (56.6 vs. 54.9 years old, $p < .05$). There was no statistical significance of race on time of TIPS ($p < 0.05$). Of the other comorbidities assessed in Table 1, we found later TIPS in patient with congestive heart failure (OR = 0.706 (0.521-0.958)), end-stage renal disease (OR = 0.447 (0.231-0.863)), obesity (OR = 0.792 (0.639-0.980)), cancer (OR = 0.648 (0.437-0.962)), and Charlson Comorbidity Index (CCI) of 7 or more (OR 0.522

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(0.392-0.696)). Patients with a CCI lower than 3 were more likely to have early TIPS (OR = 1.312 (1.111-1.550)). As outlined in Table 2, a statistically significant greater rate of mechanical ventilation and mortality was seen patients with early TIPS; there was no difference in the number of patients requiring blood transfusion ($p > 0.05$). Patients with later TIPS has greater average length of stay 12.2 days versus 7.4 days for earlier TIPS ($p < 0.05$). **Conclusion:** Our study showed that patients with later TIPS although associated with greater length of stay and cost, was associated with lower mortality and may potentially indicate the benefits of postponed TIPS. Furthermore, these patients who underwent late TIPS also had greater comorbidities. Our retrospective study may find this greater mortality correlation in early TIPS as it may potentially represent a more critical presentation and further studies are necessary to explore the benefits of delayed TIPS.

Table 1: Demographics and Comorbidities

	Early TIPS (n = 7,365)	Late TIPS (n = 4,375)	p value	Odds Ratio (95% Confidence Interval)
Mean Age, years	54.9	56.5	0.001	-

2408 | EPIDEMIOLOGY AND OUTCOMES OF SYSTEMIC MYCOSES IN HOSPITALIZED PATIENTS WITH CIRRHOSIS: A 5-YEAR NATIONAL INPATIENT SAMPLE ANALYSIS

David Maundu[1] Mohamed Omar[1] Daly Al-Hadeethi[1] Clark Kulig[2] William Salyers[1] Nathan Tofteland[3], [1]University of Kansas, Wichita, [2]Presbyterian-St. Luke's Transplant Center, [3]University of Kansas Medical Center

Background: Patients with cirrhosis are prone to numerous complications, chief among them being infections. Although bacterial infections in this cohort have been well studied, there is a paucity of data on the impact of fungal infections in this population. We sought to establish the prevalence of different fungal infections in hospitalized patients with cirrhosis and the associated inpatient outcomes. **Methods:** We analyzed the National Inpatient Sample (NIS) across five years (2018-2022) to identify adult hospitalizations with a primary diagnosis of cirrhosis using validated ICD-10 codes. Subsequently, fungal infections were identified using diagnostic codes for systemic mycoses. Outcomes of interest included in-hospital mortality, length of stay (LOS), and total hospital cost. Survey-weighted logistic and linear regressions adjusted for demographics, comorbidities, ICU-level care, and hospital characteristics. Statistical analysis was done using STATA version 18. **Results:** Among an estimated 4.4 million weighted cirrhosis hospitalizations, 2.3% had a fungal infection. These patients had significantly increased mortality (15.2% vs. 6.7%), longer LOS (13.9 vs. 6.7 days), and greater costs resulting from admission ($192,567 vs. $93,218). Fungal infection was independently associated with increased adjusted odds of mortality (aOR 1.50, 95% CI 1.42–1.59), longer LOS ($\beta = 0.56$, $p < 0.001$), and higher costs ($\beta = 0.54$, $p < 0.001$). Subgroup analysis demonstrated that the association with mortality was still significant even when accounting for elective (aOR 2.46) and non-elective (aOR 2.23) admissions. **Conclusion:** Systemic mycoses are associated with markedly worse outcomes in this cohort of hospitalized cirrhotic patients. This underscores the need for early recognition and aggressive management, even in elective admissions, in this cohort, to reduce the burden of fungal-related morbidity and mortality.

2409 | VALIDATING THE URINARY CHLORIDE DIPSTICK AS A POTENTIAL BIOMARKER FOR PREDICTING DECOMPENSATION IN PATIENTS WITH CIRRHOSIS

Susan Fischer[1] Britt van Ruijven[2] Govert Veldhuijzen[3] Annarein Kerbert[1] Michael Klemt-Kropp[4] Tom Gevers[2] Anton Jan Zonneveld[1] Minneke Coenraad[1] Kirill Basiliya[1], [1]Leiden University Medical Center, [2]Maastricht UMC+, [3]Gelre Ziekenhuizen, [4]Noordwest Ziekenhuisgroep

Background: Easily applicable biomarkers to predict acute decompensation in patients with cirrhosis is an unmet need. While reduced urinary sodium excretion reflects disease severity in patients with cirrhosis, it is not feasible for routine use outside clinical settings. Urinary chloride excretion can be easily measured using a dipstick. This study examines the correlation between dipstick-measured urine chloride and urinary sodium/chloride concentrations, and explores its potential as a predictive biomarker for future decompensation in cirrhosis. **Methods:** In this prospective multicenter cohort study, consecutive hospitalized adult patients with cirrhosis were enrolled from four Dutch hospitals. A single urine sample was collected for dipstick-based chloride measurement with simultaneous laboratory analysis of urinary sodium and chloride. Clinical data were recorded at inclusion, with prospective follow-up at 3 months to assess the occurrence of acute decompensation and mortality. Primary outcome was the correlation between dipstick and lab-based urine electrolytes, secondary outcome was the predictive value of dipstick-measured chloride for acute decompensation of cirrhosis. **Results:** A total of 100 patients (62% male), were included. Median age was 64 years [IQR 53-70] and median MELD score was 13 [8-19]. At enrollment, 49 patients (49%) were acutely decompensated. Dipstick-measured urinary chloride in all patients showed strong positive correlations with laboratory urinary chloride concentration (Spearman's $\rho = 0.801$, $p < 0.001$) and urinary sodium concentration ($\rho = 0.757$, $p < 0.001$). Among patients with available follow-up data (n = 62), 21 patients (34%) developed a new decompensating event within 90 days. Seven patients (11%) died, all due to acute-on-chronic liver failure (ACLF). In univariate logistic regression, both urine sodium concentration and dipstick chloride concentration <50 mmol/L were associated with an increased risk of decompensation within 90-days (OR 6.00, CI 1.71-21.03 and OR 3.81, CI 1.09–13.37 respectively). **Conclusion:** Dipstick-measured urinary chloride concentration strongly correlates with laboratory urinary sodium and -chloride concentration, and low laboratory urinary sodium concentration and dipstick-measured urinary chloride concentration are associated with an increased risk of new decompensation in patients with cirrhosis. Given its simplicity, low-costs and non-invasive properties, urine chloride dipstick testing may serve as a practical tool for early risk stratification in the outpatient setting. Further clinical trials are warranted to evaluate the role of dipstick-measured urinary chloride-guided therapy in patients with cirrhosis.

2410 | COMPARATIVE OUTCOMES FOLLOWING AKI VERSUS NON-AKI HOSPITALIZATIONS IN PATIENTS WITH DECOMPENSATED CIRRHOSIS: AN ANALYSIS OF POST-DISCHARGE TRAJECTORIES

Chip Bowman[1] Giuseppe Cullaro[1] Elizabeth Verna[2], [1]Columbia University, [2]Columbia University Medical Center

Background: Acute kidney injury (AKI) complicates 20-50% of liver disease hospitalizations, yet comparative post-discharge outcome data remain limited. Gaps persist regarding differential impacts of AKI versus non-AKI hospitalizations on paracentesis requirements, readmission patterns, transplant rates, and renal recovery trajectories, significantly limiting evidence-based post-discharge care. **Methods:** We conducted a retrospective cohort study of 422 hospitalizations among liver transplant candidates at Columbia University. Baseline values (7-365 days before admission) were obtained from the EHR: serum creatinine (sCr), total bilirubin (Bili), INR, albumin, sodium, and ascites severity from imaging. AKI was defined as a $\geq$50% creatinine (sCr) increase during hospitalizations from baseline sCr. We identified 211 AKI hospitalizations and propensity matched to 211 non-AKI hospitalizations based on baseline sCr/Bili, INR, albumin, sodium, and ascites severity, length of stay (LOS), and age. Cox regression evaluated rates of 90-day readmission, binomial regression assessed 90-day number of large-volume paracenteses (LVPs), competing risk analysis evaluated transplant rates accounting for death, and linear mixed-effects modeling examined post-discharge sCr trajectories. **Results:** Compared to non-AKI hospitalizations, AKI hospitalizations had longer LOS (12v10 days), lower baseline Bili (3.1v3.7 mg/dL), higher peak sCr (2.7v1.4 mg/dL), and higher sCr at discharge (1.8v1.2 mg/dL) ($p < 0.05$ for all). Groups were otherwise similar for baseline sCr, INR, albumin, sodium, MELD3.0, ascites grade, need for paracentesis during hospitalization, discharge Bili, INR, sodium, and ascites grade ($p > 0.05$ for all). Post-discharge there were no differences in paracentesis frequency (IRR 0.5, $p = 0.1$) or 90-day readmission rates (HR 0.9, $p = 0.7$). Competing risk analysis revealed AKI hospitalizations reduced transplant probability (SHR 0.63, $p = 0.007$) while increasing mortality risk (SHR 1.59, $p = 0.04$). Longitudinal mixed-effects modeling showed no differences in sCr trajectory but sustained sCr elevations in the AKI group at 7-day ($\beta = 0.5$, $p = 0.004$) and 90-day ($\beta = 0.4$, $p = 0.021$). **Conclusion:** Among patients with decompensated cirrhosis, AKI hospitalizations are linked to lower transplant rates, higher mortality, and persistent renal dysfunction despite similar post-discharge

care utilization. These findings suggest AKI during hospitalization as a high-risk subgroup that may benefit from targeted post-discharge interventions to improve outcomes.

2411 | IN-HOSPITAL OUTCOMES AFTER PCI IN PATIENTS WITH CIRRHOSIS: A CONTEMPORARY NATIONWIDE INPATIENT SAMPLE ANALYSIS (2016–2022)

Abdullah Hafeez[1] Omar Alkasabrah[1] Ritu Tated[2] Siddharth Agrawal[1] Kriti Soni[3] Hritvik Jain[4] Faiza Jajja[1] Muhammad qasim Chaudhry[1] Sadia Rekhum[5] Tanuj Sharma[6], [1]NYMC/Landmark Medical Center, [2]New York Medical College, [3]MD, [4]All India Institute of Medical Sciences, Jodhpur, India, [5]Rahbar Medical And Dental College, [6]NYMC/Landmark Medical College

Background: Cirrhosis complicates the management of coexisting coronary artery disease, present in up to 37% of affected patients. Its coagulopathic and hemodynamic challenges raise concerns about the safety of percutaneous coronary intervention (PCI). Despite advances in hepatology and cardiology, large-scale, contemporary data on PCI outcomes in patients with cirrhosis remain limited **Methods:** We conducted a retrospective cohort study using the National Inpatient Sample (NIS) from 2016 to 2022, identifying adult patients ($\geq$18 years) who underwent PCI using ICD-10-PCS codes. Cirrhosis was identified via validated ICD-10-CM codes. The primary outcome was in-hospital mortality. Secondary outcomes included atrial fibrillation, heart failure, bleeding complications, and respiratory failure. Multivariable logistic regression was performed adjusting for age, sex, race, comorbidities, and hospital characteristics. **Results:** Of the 3,134,735 patients who underwent PCI between 2016 and 2022, 23,005 (0.73%) had a diagnosis of liver cirrhosis. Patients with cirrhosis were more likely to have comorbidities such as diabetes mellitus (64.6% vs. 51.2%), anemia (33.3% vs. 13.9%), chronic kidney disease stage $\geq$4 (29.6% vs. 17.1%), and coagulation disorders (22.6% vs. 6.3%) compared to those without cirrhosis. They also had significantly longer hospital stays (7.6 vs. 3.9 days, $P<0.001$) and were more frequently admitted to teaching hospitals. After multivariable adjustment, cirrhosis was independently associated with higher odds of in-hospital mortality (OR 1.28, 95% CI 1.22–1.37, $P<0.001$), atrial fibrillation (OR 1.09, 95% CI 1.06–1.13, $P<0.001$), heart failure (OR 1.27, 95% CI 1.23–1.31, $P<0.001$), and bleeding complications (OR 1.29, 95% CI 1.23–1.36, $P<0.001$). Although a lower odds ratio was observed for respiratory failure, this is likely attributable to selection bias, overlapping diagnostic codes, or inherent limitations of administrative data, rather than a true protective effect. **Conclusion:** In this large, nationally representative analysis, cirrhosis was independently associated with worse in-hospital outcomes following PCI, underscoring the need for liver-specific risk stratification and individualized, targeted pre-procedural planning in this high-risk population.

Table 1. Baseline Characteristics and In-Hospital Outcomes of PCI Patients With and Without Cirrhosis

Variable	No Cirrhosis (%)	Cirrhosis (%)	P value
Baseline Characteristics

2412 | RECOMPENSATION IMPROVE SURVIVAL AND REDUCES FURTHER DECOMPENSATION IN A NATIONWIDE COHORT OF PATIENTS WITH ACUTE VARICEAL BLEEDING

May Xuan Goh[1] Alyssa Sim[2] Ian Yang Liew[2] Xin En Goh[3] Guan Wee Wong[4] Wei Rong Benjamin Tay[4] Pik Eu Jason Chang[5] Poh Hui Wee[5] Margaret Teng[6] Sophia Delu Lin[6] Garrett Kang[7] Guadalupe Garcia-Tsao[8] Juan Gonzalez-Abraldes[9] Yu Jun Wong[10], [1]Yong Loo Lin School of Medicine, NUS, [2]Department of Gastroenterology & Hepatology, Tan Tock Seng Hospital, Singapore, [3]Yong Loo Lin School of Medicine, National University of Singapore, Singapore, [4]Division of Gastroenterology & Hepatology, Department of Medicine, Ng Teng Fong General Hospital, Si, [5]Department of Gastroenterology & Hepatology, Singapore General Hospital, Singapore, [6]Division of Gastroenterology & Hepatology, National University Hospital, Singapore, [7]Department of Gastroenterology & Hepatology, Sengkang General Hospital, Singapore, [8]Section of Digestive Disease, Yale University of Medicine, New Haven, USA, [9]Liver Unit, University of Alberta, Edmonton, Canada, [10]Department of Gastroenterology & Hepatology, Changi General Hospital, Singapore

Background: The natural history and clinical impact of recompensation following acute variceal bleeding (AVB) remains poorly understood. We aimed to evaluate the predictors and prognostic impact of recompensation in AVB patients. **Methods:** A nationwide cohort of well-characterized hospitalized AVB patients (2015 to 2020) were followed up (PMID:38381716). Patients with prior AVB or prior HCC were excluded. Primary predictor was recompensation, defined by the Baveno-VII (B7) criteria. Additionally, expanded Baveno-VII (eB7) criteria were evaluated for patients on low-dose diuretics and/or lactulose/rifaximin for 12 months. Landmark analysis was performed to compare the clinical outcomes after index AVB episode, with and without recompensation, by setting time zero at 1 year post AVB. **Results:** From 989 patients with AVB, 377 patients without prior AVB or HCC were included for analysis. 37% presented with more than 1 decompensating events at index AVB. While half of the cohort (53%) had potentially curable etiology of cirrhosis (28% were viral; 25% were alcohol), only 82 (22%) achieved etiological cure within a year of AVB. Among those achieving etiological cure, 32 (39%) achieved recompensation by B7 criteria, and 41 (50%) achieved recompensation by eB7 criteria. Predictors for achieving recompensation by B7 were a lower MELD score, lower bilirubin and higher albumin at index AVB. However, serum albumin at index AVB was the only independent predictors for both B7- and eB7-recompensation criteria in multivariable analysis. In landmark analysis, etiological cure after AVB was associated with a significantly lower risk of mortality, particularly when recompensation was achieved (Figure 1). Etiological cure also reduce further decompensation in patients presented with more than 1 decompensating events at index AVB. Importantly, recompensation was not only associated with a significantly less further decompensating events (HR: 0.43, 95%CI: 0.23-0.82), but also significantly better survival (HR: 0.50, 95%CI: 0.28-0.91). **Conclusion:** In this large cohort of patients with index AVB with predominantly viral-related cirrhosis, etiological cure leads to recompensation in nearly half of the patients at 1 year post AVB. Importantly, recompensation was associated with less further decompensating events and better survival, highlighting that recompensation is an achievable and clinically meaningful endpoint in patients with decompensated cirrhosis.

Figure 1

Risk of death after AVB in patients with and without achieving etiological cure and recompensation (B7)

2413 | CONCORDANCE BETWEEN BAVENO VII RECOMMENDATIONS AND REAL-WORLD PRACTICE IN THE MANAGEMENT OF PORTAL HYPERTENSION IN CIRRHOSIS: A NATIONWIDE AUDITEW SUBMISSION

LUCY MEUNIER Christophe Bureau[1] Georges-Philippe Pageaux[2] Dominique Thabut Damais[3] Margaux Delhomme[2], [1]CHU Toulouse, [2]CHU Montpellier, [3]CHU La Pitié

Background: Portal hypertension (PH) is a key driver of liver-related morbidity and mortality in cirrhotic patients. The Baveno VII consensus provides structured recommendations to improve outcomes, but their application is complex due to the integration of multiple parameters, which may lead to practice variability and underutilization of evidence-based strategies. This study aimed to assess adherence to Baveno VII guidelines in clinical practice and to evaluate whether an automated decision-support tool could enhance compliance. **Methods:** A web-based, anonymous national survey was disseminated to French hepatogastroenterologists on April 20, 2025. The survey included 13 clinical vignettes representing core Baveno VII scenarios. For each vignette, participants selected a management strategy for three decision points: PH risk stratification, indication for upper gastrointestinal endoscopy, and initiation of primary prophylaxis using non-selective beta-blockers (NSBBs) or endoscopic variceal ligation. **Results:** A total of 100 physicians from 13 French regions completed the survey, comprising 22 residents, 28 general gastroenterologists without hepatology specialization, and 50 hepatology specialists. Across 3,900 individual decisions, overall adherence to Baveno VII was 59% (2,322 correct responses). Discordance was observed in 34% of PH stratification decisions, 42% of endoscopy indications, and 45% of prophylactic treatment decisions. Notably, 46% of endoscopies were performed without guideline-based indication, while 31% were omitted when recommended. NSBBs were incorrectly prescribed in 53% of scenarios where not indicated, and inappropriately withheld in 10% of cases where they were warranted (figure 1). The highest discordance rates (mean 52 ± 7.8%) were observed in scenarios involving intermediate-to-high liver stiffness in conjunction with thrombocytopenia. **Conclusion:** Adherence to Baveno VII recommendations remains suboptimal, particularly in complex cases requiring the integration of multiple clinical parameters. An automated clinical decision-support system could help standardize care, reduce unnecessary procedures, and enhance the management of portal hypertension in cirrhosis.

2414 | IMPACT OF CIRRHOSIS ON OUTCOMES IN ACUTE CHOLECYSTITIS: A NATIONWIDE ANALYSIS

Angelin Raju[1] Anish Jomy[2] Aashish Anunaya[1], [1]Texas Health Resources HEB/ Denton, [2]Methodist Richardson Medical Center

Background: This study used the Nationwide Inpatient Sample(NIS) to assess how liver cirrhosis(LC) affects outcomes in acute cholecystitis. Due to altered physiology, coagulopathy, and immunosuppression, LC may worsen risks of mortality, organ dysfunction, sepsis, surgical needs, and healthcare use. **Methods:** We performed a retrospective study of adult patients with Acute Cholecystitis (AC) utilizing the NIS database from 2018 to 2022. We compared AC outcomes in patients with and without LC. The primary outcome was all-cause inpatient mortality. Secondary outcomes were the length of stay (LOS), healthcare cost utilization, incidence of acute kidney injury (AKI), sepsis and surgical procedures. Statistical analyses were performed using STATA, version 19.5. Multivariable logistic and linear regression models were used to estimate adjusted odds ratios (AOR) for key outcomes, controlling for age, sex, race, and comorbidities (Elixhauser index). **Results:** From 2018 to 2022, 948,105 adult patients underwent AC admissions. Among the patients, 923,315 (97.4%) had AC without LC, and 24,790 (2.6%) had AC with LC. Cirrhotic patients were older (mean age 61.6 vs 56.6), more likely male (57% vs 43%), white (64.7% vs 60.3%) and had higher comorbidity burden (Elixhauser category 3: 89.6% vs. 42.1%)[all $p < 0.001$].Also they had a significantly higher likelihood of in-hospital mortality (AOR: 1.45, 95% CI: 1.11–1.90, $p = 0.006$), surgical interventions like Cholecystectomy (AOR: 1.34, $p = 0.012$) and Cholecystostomy (AOR: 1.12, $p = 0.023$). Odds of AKI (AOR: 0.75, $p < 0.001$) and healthcare utilization cost (-$3,544, $p = 0.001$) was lower even though unadjusted values were higher. Cirrhotic had longer

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

LOS (+1.5 days) and increased sepsis (3.57% vs. 1.78%) though not significant after adjustment. A non-significant trend toward lower use of ERCP was observed in cirrhotic (AOR: 0.79, p = 0.137). **Conclusion:** In this national cohort of adults hospitalized with acute cholecystitis from 2018 to 2022, cirrhotic patients represented a small but clinically significant high risk group with older, predominantly male, white and a greater comorbidity burden. After adjustment, cirrhosis was independently associated with increased odds of in-hospital mortality, and were more likely to undergo surgical interventions, including cholecystectomy and cholecystostomy. While cirrhosis was linked to longer hospital stays and higher rates of sepsis, these associations were not statistically significant after adjustment. Also a decreased incidence of AKI and healthcare costs was found in cirrhotic after adjustment even though it was higher when unadjusted. A non-significant decrease in ERCP may reflect over procedural risk in cirrhotics such as bleeding, infection, or hepatic decompensation. These findings highlight the need for tailored management strategies to optimize outcomes in cirrhotic patients with AC.

2415 | SECONDARY SPONTANEOUS BACTERIAL PERITONITIS PROPHYLAXIS IS ASSOCIATED WITH A HIGHER RATE OF SBP RECURRENCE IN NON-CIRRHOTIC PATIENTS: A PROPENSITY-MATCHED ANALYSIS USING A NATIONWIDE EMR DATABASE

Mohammed Aloqaily[1] Pinghsin Hsieh[2] Ahmad Abdulraheem[3] Omar Abureesh[4] Ahmed El Sabagh[3] Rashid Abdel-Razeq[5] Abdulla Massad[6] Alexander Rabadi[7], [1]University of Maryland medical system Midtown Campus, [2]University of Maryland Midtown Campus, [3]MedStar Georgetown Washington Hospital Center, [4]Staten Island University Hospital, [5]Cleveland Clinic Foundation, [6]University of Texas Medical Branch, [7]McLaren Health Care

Background: Spontaneous bacterial peritonitis (SBP) is a life-threatening infection commonly associated with cirrhosis. However, SBP may also occur in non-cirrhotic patients, where its recurrence risk and the role of prophylactic antibiotics remain unclear. We aimed to assess the effectiveness of prophylactic antibiotics in preventing recurrent SBP and improving survival in non-cirrhotic patients using real-world data. **Methods:** We conducted a retrospective cohort study using the TriNetX Research Network, a global federated research database comprising de-identified electronic health records and ICD-10-CM coding, encompassing electronic health records from 102 healthcare organizations. Adult patients with no prior diagnosis of cirrhosis who survived their first SBP between October 2015 and October 2022 were identified. Two cohorts were defined: those who started on secondary SBP prophylaxis 1–4 months post-SBP and those who did not. The two cohorts were matched using propensity scores on 16 clinical and demographic variables. Outcomes included SBP recurrence, all-cause mortality, and liver transplantation, assessed over a 2-year follow-up window starting 30 days post-SBP episode. **Results:** We identified 4,169 patients who survived their first SBP episode. And 444 of them (10.7%) were prescribed secondary SBP prophylaxis. After propensity score matching, 440 patients in each cohort were compared. A significantly higher risk of recurrent SBP (OR 2.28; 95% CI: 1.55–3.37; p < 0.001) was observed in those who received prophylactic antibiotics (20.2%) vs those who didn't (10.0%). Kaplan-Meier analysis confirmed significantly worse SBP-free survival in the prophylaxis group (p = 0.001). No significant difference was observed in mortality (33.0% vs 28.9%; p = 0.189) or overall survival (p = 0.720).

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

Liver transplantation was rare but occurred only in the prophylaxis group (2.3% vs 0%; p = 0.001). **Conclusion:** In this large, multicenter cohort of non-cirrhotic SBP patients, the use of prophylactic antibiotics was associated with a significantly higher risk of recurrent SBP, with no observed survival benefit. These findings question the utility of prophylactic antibiotics in this population and underscore the need for targeted strategies for SBP management in non-cirrhotic patients rather than extrapolation from cirrhotic SBP paradigms

Table 1. Clinical Outcomes After Propensity Score Matching (N=440 per group)

Outcome	Prophylaxis (%)	No Prophylaxis (%)	OR [95% CI]	p-value
SBP	20.2	10.0	2.28 [1.55–3.37]	<0.001
All-Cause Mortality	33.0	28.9	1.21 [0.91–1.61]	0.189
Liver Transplantation	2.3	0.0	—	0.001

2416 | NON-INVASIVE PREDICTION MODELS OF FIRST HEPATIC DECOMPENSATION IN COMPENSATED ADVANCED CHRONIC LIVER DISEASE – A SYSTEMATIC REVIEW AND META ANALYSIS

Angus Jeffrey[1] James Chen[2] Andrew Chin[1] Emmanuel Tsochatzis[3] Avik Majumdar[4] Luis Calzadilla Bertot[5] Michael Wallace[1] Gary Jeffrey[1] Leon Adams[6], [1]Sir Charles Gairdner Hospital, Perth, Australia, [2]Fiona Stanley Hospital, Perth, Australia, [3]UCL Institute for Liver and Digestive Health and Sheila Sherlock Liver Unit, Royal Free Hospital, [4]Department of Hepatology, The Austin Hospital, Melbourne, [5]The University of Western Australia, Perth, Australia, [6]University of Western Australia

Background: Non-invasive prediction models (NITs) provide an accessible alternative to invasive measures such as hepatic venous pressure gradient in predicting decompensation in cACLD. This review aims to critically appraise available data to determine the accuracy of NITs in identifying patients with cACLD who are at increased risk of decompensation. **Methods:** This systematic review and meta-analysis was conducted from all published articles until February 2025. Studies were included if they evaluated performance of a NIT (defined as two or more individual non-invasive markers that had been combined into a prognostic model). Studies were excluded if analysis was not done on a cACLD population in isolation, such as studies examining only singular prognostic markers (e.g. baseline liver stiffness in isolation). Summary data was extracted from published reports consisting of the c-statistic and/or AUROC and model calibration. This review was registered with PROSPERO (CRD42024608001). **Results:** Of 5,643 articles, 29 were included consisting of 47,469 participants with cACLD. The articles described 38 prognostic models; 12 new prognostic models, and the application of 26 models developed for outcomes other than decompensation in cACLD. Random effects meta-analysis found models developed and validated in cACLD provide the best prediction, including the SAVE score (summary c-statistic 0.87, 95% CI 0.82-0.93) and ABC score (0.85, 0.80-0.89). Of note both of these models had unclear risk of bias and each were studied in only 2 cohorts. Models assessed in a larger number of cohorts (> 10) tended to be validation of existing models of fibrosis or liver-related outcomes, with only ALBI-FIB-4 (c-statistic 0.73, 95% CI 0.71-0.76) being developed in a cohort of cACLD patients with more than 10 validation cohorts, outperforming the other well validated (> 10 cohorts) models with a low risk of bias. Existing models of fibrosis or liver-related outcomes developed in non-cACLD cohorts (e.g. MELD, CPS) are not suitable for use as a prognostic test in cACLD. There was limited validation and calibration of all models. Sensitivity analysis found that method of cACLD diagnosis (invasive vs non-invasive) had a large influence on heterogeneity across all models, improving from high to low/moderate ($< I^2 < 50\%$) when HVPG or liver biopsy was used to define cACLD. Models that incorporated LSM had a higher prognostic performance (c-statistic 0.82, 95% CI 0.79-0.85, $I^2 = 78\%$) compared to those that didn't (0.69, 0.68-0.71, $I^2 = 98\%$, $p < 0.001$). **Conclusion:** cACLD specific NITs offer the best option in predicting decompensation, and future studies should focus on robust validation, calibration and external validation with standardised endpoints to ensure that

models are reliable for guiding clinical practice in applicable populations. Five scores meet a minimum minimally acceptable diagnostic criteria of 0.8 (SAVE, ABC, LSPS, PH Risk Score, CHESS-ALARM).

2417 | EXERCISE AND NUTRITION INTERVENTIONS FOR SARCOPENIA IN CIRRHOSIS: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS OF RANDOMIZED CONTROLLED TRIALS

Roongruedee Chaiteerakij[1] Soe Thiha Maung[1] Sirinda Kittiprachakul[1] Solaphat Hemrungrojn[1] Sarissa Rangkla[1], [1]Chulalongkorn University

Background: Sarcopenia is highly prevalent and associated with poor outcomes in cirrhotic patients. We aimed to evaluate the efficacy of exercise, protein supplementation, and branched-chain amino acid (BCAA) supplementation in treating cirrhotic sarcopenia. **Methods:** We conducted systematic review and meta-analysis of randomized controlled trials (RCTs). PubMed, Embase, Scopus and the Cochrane library were searched from the database inception until March 2024 for RCTs of exercise, protein supplementation, and/or BCAA supplementation on improving at least one of the sarcopenia features: muscle mass, muscle strength and physical performance. Differences in post- and pre-intervention changes between intervention and control arms were calculated as a standardized mean difference (SMD), with 95% confidence interval (CI). A network meta-analysis (NMA), component NMA, pairwise meta-analysis (PW-MA) were performed. **Results:** 23 RCTs were included in the meta-analysis. There were 1624 participants, with 977 (60.2%) males and a mean age of 56.4 years (SD: 7.1) The PW-MA, NMA and CNMA revealed that exercise significantly increased muscle mass, while protein or BCAA supplementation alone had no significant effects on muscle mass. Combined exercise with protein and BCAA supplementations had the greatest effect on increasing muscle mass (SMD 2.12; 95%CI: 0.59–3.65). Exercise with BCAA/protein supplementation also significantly increased muscle mass. A subgroup analysis by exercise type, aerobic exercise significantly improved muscle mass ($p < 0.05$), whereas combined aerobic and resistance exercises did not show significant effects compared to the non-exercise groups. By PW-MA, exercise significantly improved physical performance versus control (SMD 1.43; 95%CI: 0.63–2.17; $p < 0.01$; $I^2 = 59\%$) and exercise plus protein supplementation was superior to protein alone (SMD 0.66; 95%CI: 0.26–1.06; $p = 0.001$; $I^2 = 0\%$). By the systematic review, the effects of BCAA supplementation on muscle strength was inconclusive. **Conclusion:** Combining exercise with protein and BCAA supplementation demonstrated the greatest effects on increasing muscle mass, suggesting it is the most effective strategy for treating sarcopenia in cirrhotic patients. Nutritional supplementation alone does not enhance muscle mass. Further well-designed studies are needed to identify the most effective type of exercise.

2418 | ASCITES PRESSURE ACCOUNTS FOR PATIENT REPORTED MEASURES AND IS A MELD-INDEPENDENT PREDICTOR OF ONE YEAR OUTCOMES AFTER PARACENTESIS

Nikhilesh Mazumder[1] Max Macgregor[2] Elliot Tapper[3] Anna Lok[3], [1]University of Michigan Hospitals and Health Centers, [2]University of Michigan, [3]University of Michigan Medical Center

Background: Therapeutic paracentesis is commonly used for symptom relief in patients with large volume ascites. While this event is known to portend poor 1-year outcomes for patients, it is unclear at the time of paracentesis which patients will ultimately undergo Transjugular Intrahepatic Portosystemic Shunt placement (TIPS), liver transplantation (LT), or die. Earlier recognition of patient trajectory may allow for earlier triage to appropriate treatment course. **Methods:** We prospectively enrolled patients with portal hypertensive ascites (SAAG > 1.1) undergoing therapeutic paracentesis in our ambulatory paracentesis unit. We excluded patients with prior LT, TIPS, or stage 4 or worse chronic kidney disease. We measured patient symptoms and relief using a validated questionnaire (Ascites Symptom Index-7, ASI-7) and directly measured ascites opening pressure (OP) at the start of paracentesis using an open-ended manometer. The primary outcome was time to first event (death, TIPS, or LT) using Fine-Gray competing risk methodology with censoring at one year or study end. Demographic and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

clinical variables on the day of paracentesis were recorded. **Results:** 236 procedures were included in the study among 75 unique patients observed for an average of 143 days for a total of 33,972 patient-days. On the day of procedure, the average age was 60 years, 73 (30.9%) were female, with alcohol (n = 81; 34.3%) and MASLD (n = 98; 41.5%) the most common etiologies of liver disease. The average MELD 3.0 score was 16.4, OP was 14.1 cmH_2O, with 45.3% of patients reaching the primary outcome: 35 (14.8%) died prior to TIPS or transplant, 30 (12.7%) underwent TIPS, and 42 (17.8%) underwent LT without TIPS. Among patients who ultimately underwent TIPS or LT, OPs were higher (16.6 and 15.9 cmH_2O, respectively) compared to patients who died or had no event (12.5 and 13.5 cmH_2O, $p = 0.001$). When adjusted for age and MELD 3.0, patients with greater difficulty moving due to ascites (sHR 1.64, $p = 0.007$), or trouble breathing while walking (sHR 1.60, $p = 0.004$) were more likely to have received TIPS on follow up. In competing risk analyses adjusted for age and MELD 3.0, higher OP but not patient symptoms remained a significant predictor for survival, TIPS, or LT (sHR 0.87, $p = 0.001$ per cm H_2O). **Conclusion:** Pressure measurement was a MELD independent predictor of patient outcomes and can account for symptom assessment in patients undergoing paracentesis. Patients presenting for symptom relief via therapeutic paracentesis without high abdominal pressures may have a worse prognosis. Future analyses would facilitate identification of patients who may benefit from earlier transplant or TIPS referral using this bedside measurement of ascites pressure.

2419 | SPLENIC STIFFNESS MEASUREMENT AS A NONINVASIVE MARKER FOR MONITORING DOSE OF CARVEDILOL IN CIRRHOTIC PATIENTS WITH HIGH RISK VARICES

Virendra Singh[1] Nitesh Bassi[1] Amandeep Singh[1] Jahnvi Dhar[1] sandeep kaur toor[1] Himanshu Gupta[1] Upasna Rajput[1] Rashmeet Brar[1] Brahmjot Kaur[1], [1]Punjab Institute of Liver and Biliary Sciences, SAS Nagar, India

Background: Non-selective beta-blockers (NSBBs), are recommended for prophylaxis of variceal bleeding in patients with cirrhosis and high risk varices (HRV). Recent studies indicate that splenic stiffness measurement (SSM) is a reliable, non-invasive alternative to invasive methods such as hepatic venous pressure gradient (HVPG) and crude methods like blood pressure. SSM effectively assesses hemodynamic response to NSBB therapy used for primary prophylaxis of HRV and reduction in SSM of 10% or more (SSM responders) demonstrates excellent accuracy in identifying HVPG responders. **Methods:** We prospectively studied consecutive patients with cirrhosis, aged 18-60 years, who were candidates for NSBBs for primary variceal bleeding prophylaxis. Patients were evaluated at our department before starting NSBB, then monthly for three months. Patients were started on carvedilol dose 6.25 mg and titrated to 25 mg per day according to tolerability and SSM change. Correlation between delta changes of SSM by using transient elastography with carvedilol dosage was performed. **Results:** Thirty patients were analyzed from the initial group of 65 patients considered for the study (median age 48 years, 80% Males). Patients who were intolerant to carvedilol and having active hepatic insult were excluded. Most common etiology was alcoholic liver disease (80%), followed by Hepatitis C (10%), MASLD (5%), and hepatitis B (5%). Out of the patients who achieved a $\geq$ 10% SSM reduction at 3 months, 14(46.6%) were on a daily dose of 12.5 mg carvedilol, 4(13.33%) on 6.25 mg, and 6(20%) on 25 mg carvedilol daily. Notably, 6 (20%) patients were SSM non responder to carvedilol even at the 25 mg daily dose. Sixty percent of patients were SSM responders even at daily carvedilol doses of $\leq$12.5 mg. This highlights the utility of SSM in effectively monitoring carvedilol treatment, thereby preventing the administration of unnecessary higher dosages and avoiding potential adverse events. **Conclusion:** Splenic stiffness measurement is a non-invasive marker for monitoring the dose of carvedilol

2420 | A PANEL OF SYSTEMIC INFLAMMATION BIOMARKERS PREDICTS THE COURSE OF DECOMPENSATED CIRRHOSIS TOWARDS RECOMPENSATION OR FURTHER DECOMPENSATION

Dalila Costa[1] Benedikt Hofer[1] Georg Kramer[1] Ana Frias[2] Ricardo Silvestre[2] Joana Camões Neves[3] João Belmiro Martins[2] Kerstin Zinober[1] Vlad Taru[1] Georg Semmler[4] Benedikt Simbrunner[4] Mattias Mandorfer[4] Carla Rolanda[2] Thomas Reiberger[4], [1]Vienna Hepatic Hemodynamic Lab, Division of Gastroenterology and Hepatology, Department of Medicine, [2]Life and Health Sciences Research Institute (ICVS), University of Minho, [3]Gastroenterology Department, Braga Hospital, [4]Medical University of Vienna

Background: Patients with decompensated cirrhosis are at high risk for further decompensation (FDC) and liver-related death, however, some may achieve recompensation (ReC). Since systemic inflammation (SI) represents a central disease-driving mechanism in cirrhosis, we investigated a broad panel of SI biomarkers and their dynamics across the course of patients with DC. **Methods:** A two-center, prospective cohort of cirrhosis outpatients evaluated between 01/2017 and 12/2023 were stratified at baseline (BL) as compensated (CC), decompensated (DC) and recompensated (ReC) cirrhosis. At baseline and follow-up (FU: minimum of $\geq$ 6-months), surrogates of portal hypertension (PH) and an SI biomarker panel (bead-based immunoassay) were evaluated. In DC, progression was defined as a composite endpoint comprising further decompensation or ACLF, while regression was defined as achieving recompensation. **Results:** A total of 280 cirrhosis patients (median age: 60.1 years; 68.2% men; main etiology: ALD 68.2%) with a median follow-up of 23.0 months were included. At BL, 73 (25.7%) showed CC, 166 (59.2%) DC and 41 (15.1%) ReC. MELD (DC: 12 vs. CC: 9 v ReC: 8; $p < 0.001$), multiple SI biomarkers (IL6, IL8, IL10, IFNy, IL1b, MCP1, IL12p70, IL23 and IL33 pg/mL vs CC/ReC, p-values all < 0.05) and PH surrogates such as VWF (DC: 313 vs. CC: 214 vs ReC: 175%; $p < 0.001$) were significantly higher in DC vs. CC/ReC, respectively. HVPG was significantly lower in recompensated patients (DC: 19 mmHg vs CC:13 vs ReC: 9 mmHg; $p = 0.001$) in comparison to CC and DC. There were no significant differences within SI markers between CC and ReC patients. Among 127 DC patients, $n = 29$

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

(22.8%) progressed to FDC with significantly increasing MELD (12 vs. 14; $p = 0.002$) and SI biomarker levels (IL10, IFNa2, IFNy, IL17A, IL8, IL33; paired p-values all < 0.05). There were no significant differences in VWF levels and HVPG. In turn, $n = 27$ (22.3%) of DC patients achieved recompensation with significant decreases in MELD (14 vs 11; $p = 0.05$), in HVPG (18 vs 13 mmHg; $p = 0.006$), VWF (283 vs 217 %; $p = 0.004$) and in SI biomarkers (IL6 and IL8 all $p < 0.05$). **Conclusion:** Patients with DC show not only impaired liver function and PH but also pronounced pro-inflammatory state. Importantly, with progression to further decompensation or regression to recompensation, we found significant dynamics in SI biomarkers paralleling liver disease surrogates (MELD, HVPG). The prognostic value of SI biomarker dynamics seems promising and further validation of their value to define cirrhosis disease states seems warranted.

2421 | SUBOPTIMAL BETA BLOCKER TITRATION IN PORTAL HYPERTENSION: INSIGHTS FROM THE SVASTA STUDY USING WEARABLE-DERIVED RESTING HEART RATE

Gautham Pranesh[1] Alisha Chaubal[2] HARDIK SHAH[2] Ameet Mandot[3] AMRIK SHAH[4] Ramesh Vangal[4] Shyam Kottilil[5] Mani Subramanian[6] SAMIR SHAH[2], [1]SensEarly, [2]Nanavati Max Super Speciality Hospital, [3]Gleneagles Hospital, [4]Sensearly Inc, [5]University of Maryland, [6]TLC

Background: Non-selective beta blockers (NSBBs) are used to reduce portal hypertension and reduce variceal bleeding in patients with advanced liver disease. However, a significant propotion of patients (~40-60%) do no achie guideline-directed titration targets, defined as $\geq 25\%$ reduction in resting heart rate (RHR) or a RHR target of 55-60 bpm. The further risk of adverse events remains high due to episodic nature of clinical visits and lack of monitoring. **Methods:** The Prospective Observational Study To evaluate Biomarkers of Metabolic Dysfunction Among Patients with Liver Failure (SVASTA study, CTRI/2022/09/045668) was an observational study conducted at a tertiary liver transplant center in western India. Fifty-six patients with advanced liver disease were enrolled, of whom 50 used Garmin Vivosmart wearables for continuous RHR monitoring and attended at least three clinic visits over a 6-month period. NSBB dose titration was assessed retrospectively based on wearable-derived daily RHR trends, blood pressure at clinical visits and chart-reviewed data. **Results:** Beta blockers were prescribed in 28/50 patients (56%) predominantly in the compensated and decompensated cirrhosis cohorts. 17/28 (60.7%) did not meet guideline-defined titration targets throughout the period of observation. Among these, 2/17 had dose-limiting hypotension whereas 15/17 (88.2%) patients had potential for further titration. Missed titration opportunities were primarily due to wide spacing of visits (typically every 2 to 3 months). Event rates over the time of observation were higher in the inadequately titrated group (35.3%) compared to the adequately titrated group (27.3%). **Conclusion:** Despite widespread use, NSBBs are frequently sub-optimally titrated in real-world practice due to limitations in accurate monitoring and reliance on visit-based care. Most patients with inadequate titration had physiological capacity for NSSB dose escalation. Continuous RHR monitoring using wearables may offer a scalable solution for optimizing titration for improving clinical outcomes in patients with portal hypertension.

Piyawat Komolmit[1] Kessarin Thanapirom[1], [1]King Chulalongkorn Memorial Hospital

Background: Liver and spleen stiffness measurement (LSM and SSM) are currently tools for ruling out high-risk varices (HRV) in patients with chronic liver disease. However, their utility has not yet been established in patients with hepatocellular carcinoma (HCC). Moreover, the optimal cut-off values for LSM and SSM using two-dimensional shear wave elastography (2D-SWE) require further investigation. This study aims to evaluate the performance of 2D-SWE-based LSM and SSM in predicting HRV and acute decompensation (AD) in HCC patients, and to validate the Baveno VI and VII criteria in HCC patients. **Methods:** We prospectively enrolled patients with HCC at Chulalongkorn University Hospital, Bangkok, Thailand, from June 2023 to March 2025. Patients underwent EGD, LSM and SSM by TE (Fibroscan, Echosens) and 2D-SWE (Supersonic Imaging). AD, including ascites, spontaneous bacterial peritonitis, variceal bleeding, and hepatic encephalopathy, was recorded during a one-year follow-up period. Optimal cutoffs for predicting HRV were identified by maximizing the negative predictive value (NPV) with a sensitivity $> 90\%$. The Baveno VI and VII criteria were evaluated using LSM by TE and platelet count. **Results:** Overall, 163 patients with HCC were enrolled, with 12 (7.4%) Barcelona-Clinic Liver Cancer (BCLC) 0, 66 (40.5%) BCLC A, 59 (36.2%) BCLC B and 26 (16%) BCLC C, respectively. The most common causes of HCC were HBV (47.9%) and HCV (22.1%). HRV was present in 20.9% ($n = 34$) of patients. LSM and SSM evaluated by TE and 2D-SWE exhibited significant ability to detect HRV (AUROC = 0.68-0.73, $p < 0.05$). Using 2D-SWE, an LSM cutoff of 23.2 kPa yielded 91% sensitivity and a 95% NPV for predicting HRV, avoiding 39.3% unnecessary EGD with an HRV missing rate of 4.7%. An SSM cutoff of 27.5 kPa using 2D-SWE yielded 91% sensitivity and 92% NPV, avoiding 22.1% EGD with an HRV missing rate of 8.3%. The Baveno VI criteria avoided 26.4% EGD with 2.9% missed HRV, while the Baveno VII criteria avoided 55.8% with 14.7% missing rate. After a 1-year follow-up, 16 patients (9.8%) developed AD. Baseline 2D-SWE-based LSM had a good accuracy (AUROC = 0.80, 95%CI: 0.69-0.91, $p \leq 0.001$) in predicting AD. Multivariate analysis revealed that LSM by 2D-SWE (adjusted OR (aOR) = 1.05, 95%CI: 1.00-1.09, $p = 0.05$), portal vein invasion (aOR = 5.49, 95%CI: 1.22-24.76, $p = 0.03$), and albumin-bilirubin (ALBI) score (aOR = 5.89, 95%CI: 1.70-20.38, $p = 0.005$) were independent factors associated with AD. **Conclusion:** LSM by 2D-SWE could safely avoid unnecessary EGD with a low HRV miss rate comparable to that of the Baveno VI criteria in HCC patients. Furthermore, 2D-SWE-based LSM may serve as a useful predictor of AD.

2423 | LOWER BMI AND SNARE POLYPECTOMY ARE ASSOCIATED WITH A HIGHER RATE OF POSTPOLYPECTOMY BLEEDING IN PATIENTS WITH CIRRHOSIS

Brian Yan[1] Jonathan Weng[1] Sarah Chen[1] Anderson Huang[1] Ki Jung Lee[1] Olivia Hofheinz[2] Raffi Karagozian[1], [1]Tufts Medical Center, [2]Tufts University School of Medicine

Background: As cirrhosis mortality decreases, more patients with cirrhosis are undergoing screening colonoscopies. Few studies exist on the safety of colonoscopy with polypectomy in patients with cirrhosis. This study aims to investigate the rates of colonoscopy complications in patients with cirrhosis and identify risk factors that may be associated with postpolypectomy bleeding (PPB). **Methods:** We performed a single-center retrospective study of patients with cirrhosis who underwent colonoscopy with polypectomy between 2017 and 2024 at a tertiary care center. Complications including immediate PPB, delayed PPB, perforation, death, need for pressors, intubation, blood transfusion, and hospitalization were recorded to 1-week follow-up. Clinical characteristics of patients with PPB were compared to those who did not have PPB. Polyp characteristics including size, morphology, histology, and removal method were also recorded. Data analysis was conducted using *t* tests and chi-square tests. **Results:** We reviewed 135 colonoscopies with 394 polypectomies. The mean age of the patient population was 63.82 years (SD = 11.29) and consisted of 80 (59.26%) males. Forty-three (31.85%) colonoscopies were complicated by immediate PPB and four (2.96%) by delayed PPB. Six (4.44%) required hospitalization, three (2.22%) blood transfusion, and two (1.48%) pressors and intubation. No cases of perforation or death occurred. Colonoscopies complicated by bleeding ($n = 47$) were compared to those with no bleeding ($n = 88$). Lower BMI, higher INR, and oral anticoagulant use were associated with increased risk of bleeding ($p = 0.03$) [Table 1]. There was no statistically significant difference between bleeders and non-bleeders regarding presence of esophageal varices, antiplatelet use, albumin or platelet levels, MELD 3.0 score, Child-Pugh

class, or ASA physical status. Of the 394 polyps, 61 (15.48%) bled and 333 (84.52%) did not bleed after removal. Removal by cold or hot snare polypectomy was associated with a higher risk of bleed compared to removal by cold biopsy forceps ($p < 0.01$). Among morphologies, polyps that were flat/semi-sessile or pedunculated were more likely to bleed ($p < 0.01$). Furthermore, adenomatous polyps had an increased risk of bleeding compared to non-adenomatous polyps ($p = 0.04$). The mean size of bleeding polyps was 7.24 mm (SD = 4.08) compared to 4.36 mm (SD = 2.69) for non-bleeding polyps ($p < 0.01$). **Conclusion:** Colonoscopy with polypectomy appears safe in patients with cirrhosis. Immediate PPB was the most common complication. Lower BMI, higher INR, and oral anticoagulant use were associated with higher risk of bleeding. There was no difference in albumin or platelet levels, MELD 3.0 score, Child-Pugh class, or ASA physical status between bleeding and non-bleeding groups. Polyps that bled after removal were often larger in size, adenomatous, flat/semi-sessile or pedunculated, or removed by snare polypectomy.

Table 1: Characteristics of patients and polyps stratified by bleeding status

Patient Characteristic	Non-Bleeding (n=88)	Bleeding (n=47)	*P* value
Age (years)	64.14 ± 10.01	63.23 ± 13.47	0.69
Gender (male)	47 (53.41%)	33 (70.21%)	0.06
BMI (kg/m²)	31.09 ± 8.87	28.35 ± 5.49	**0.03**
ASA			0.20
II	5 (5.68%)	1 (2.13%)	
III	73 (82.95%)	38 (80.85%)	
IV	10 (11.36%)	8 (17.02%)	
Total bilirubin (mg/dL)	1.31 ± 1.82	1.60 ± 1.51	0.32
Albumin (g/dL)	3.39 ± 0.73	3.29 ± 0.68	0.42
Platelets (K/μL)	153.43 ± 64.64	152.55 ± 86.47	0.95
INR	1.19 ± 0.23	1.30 ± 0.33	**0.03**

2424 | VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY AS A NON-INVASIVE PREDICTOR OF SARCOPENIA IN CIRRHOSIS: ESTABLISHING A THRESHOLD FOR RISK STRATIFICATION

Lourianne Nascimento Cavalcante[1] Aloma Conceição Campeche-Leão[2] Ana Clara Batista[2] Rosangela Passos[2] Lais Garcez[2] Monalisa Reis Arruda[2] Helma Cotrim[3], [1]Universidade Federal Bahia; Virginia Commonwealth University, [2]Universidade Federal da Bahia, [3]University Hospital Professor Edgar Santoss

Background: Sarcopenia is a significant complication of cirrhosis, associated with poor prognosis and increased morbidity and mortality. Traditional diagnosis involves assessing body composition and muscle strength; however, non-invasive methods for early identification remain limited, particularly when the cut-offs come from different population. Emerging studies suggest that liver stiffness, measured through vibration-controlled transient elastography (VCTE, FibroScan®), may reflect systemic changes, including muscle loss. This study aimed to evaluate the association between liver elastography and sarcopenia in cirrhotic patients and identify optimal cutoff points for risk stratification. **Methods:** Liver stiffness was assessed using VCTE (in kPa). Sarcopenia was defined by muscle mass parameters (Mid-Arm Muscle Circumference and SaRC-CALF score), handgrip strength (by dynamometry), and nutritional assessment (GLIM score). Associations were explored using logistic regression analysis, and ROC curves were constructed to determine optimal elastography cutoff points for sarcopenia and nutritional outcomes, validated through bootstrap analysis. **Results:** A total of 132 cirrhotic patients were analyzed, of whom 16.7% (n = 22) had sarcopenia. Sarcopenic patients exhibited significantly higher liver stiffness values than non-sarcopenic patients (27.1 ± 4.2 kPa vs. 22.8 ± 3.8 kPa, $p < 0.001$). Multivariate analysis confirmed that MELD-Na (OR: 1.20; 95% CI: 1.05–1.38), advanced Child-Pugh classification (Class C vs. A OR: 3.0; 95% CI: 1.50–5.99; Class B vs. A OR: 1.80; 95% CI: 1.10–2.95), and muscle markers (OR: 2.5; 95% CI: 1.30–4.80) were independent predictors of elevated liver stiffness. ROC analysis identified a cutoff of 25.2 kPa as the optimal threshold for discriminating sarcopenia (AUC = 0.81 [0.78–0.84]; sensitivity = 78%; specificity = 74%; $p < 0.001$). Similar cutoffs were

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

established for handgrip strength (24.0 kPa; AUC = 0.78 [0.75–0.81]; p = 0.002), myopenia (23.5 kPa; AUC = 0.76 [0.73–0.79]; p < 0.001), and severe malnutrition (≥ 24.7 kPa; AUC = 0.79 [0.76–0.82]; p < 0.001). Confidence intervals obtained through bootstrap analysis reinforced the robustness of these findings. **Conclusion:** Liver elastography may serve as a reliable non-invasive marker for sarcopenia, enabling early risk stratification in cirrhotic patients. Liver stiffness values above 25 kPa should be considered indicative of greater muscular and nutritional impairment, potentially aiding clinical decision-making and guiding therapeutic interventions.

2425 | USING FIB-4 TO UNCOVER UNDIAGNOSED CIRRHOSIS IN PATIENTS WITH DEMENTIA: A QUALITY IMPROVEMENT INITIATIVE

Vinay Jahagirdar[1] Michael Weissberger[1] Jawaid Shaw[1] Dan Park[1] Peter Boling[1] Jasmohan Bajaj[1], [1]Virginia Commonwealth University

Background: Dementia and hepatic encephalopathy (HE) can present with overlapping cognitive symptoms, particularly in older adults. Undiagnosed cirrhosis in patients with dementia may result in missed opportunities to identify and treat HE, a reversible contributor to cognitive impairment. National data suggest that 5-10% of patients with dementia may have unrecognized cirrhosis based on elevated Fibrosis-4 (FIB-4) scores. This QI project aimed to identify such patients in a geriatric cohort using FIB-4 as a non-invasive screening tool. **Methods:** We reviewed charts of patients with dementia seen in a geriatric clinic at a quaternary academic medical center. Patients with a known diagnosis of cirrhosis were excluded. FIB-4 scores were calculated using lab values (ALT, AST, platelets) collected near the time of dementia diagnosis. For those over 65, age was capped at 65 in the FIB-4 formula to avoid overestimation. A FIB-4 score > 2.67 was used to flag high risk for advanced fibrosis. Detailed chart reviews were conducted in these patients to identify risk factors and rule out alternative explanations. Kruskal-Wallis test was used for continuous variables and Chi-square test for categorical variables. P-value < 0.5 was considered statistically significant. **Results:** Of 470 charts reviewed, 451 had lab data for FIB-4 calculation. The cohort was predominantly female (70%), with 58% having moderate-to-severe dementia. Alzheimer's dementia was the most common subtype (47%). 53 patients (11.8%) had FIB4 > 2.67, with a median score of 3.3 (IQR 1.1). Compared to those with FIB-4 ≤ 2.67, they had higher rates of severe dementia (40% vs 15%, p < 0.0001), more frequent use of memantine and donepezil, and greater likelihood living in assisted living facilities (47% vs 18%, p < 0.0001). Comorbidities in FIB-4 ≥ 2.67 included diabetes (72%), obesity (23%), alcohol use disorder (9%) and hepatitis C (6%). Imaging findings were suggestive of chronic liver disease in 9.4%. Four patients were excluded due to alternative causes of thrombocytopenia (hematological malignancies, chemotherapy use). The geriatrics team was notified about the remaining 49 patients for further evaluation, with follow up plans individualized to include hepatology consultation, empiric lactulose therapy, or continued observation. **Conclusion:** In this ambulatory geriatric dementia cohort, 11% of patients had elevated FIB-4 scores, suggesting possible undiagnosed cirrhosis. These patients exhibited more severe cognitive decline, higher dependency & other risk factors for chronic liver disease (alcohol, metabolic syndrome, viral hepatitis). Clinicians caring for older adults with dementia should maintain a high index of suspicion for cirrhosis and can consider incorporating FIB-4 screening into dementia care to identify HE as a reversible and treatable cause of cognitive dysfunction.

2426 | REAL WORLD MULTI-CENTER EVALUATION OF THE USE OF TERLIPRESSIN FOR HRS-AKI IN THE UNITED STATES

Prutha Shah[1] Brooklyn Baylis[2] Morgan Elias[1] John Knorr[1] Sarah Yeager[3] Jonathan Fenkel[3] David Sass[3] Rebecca Loh[3] Jamie Schulte[3] Richard Kalman[1], [1]Jefferson Einstein Philadelphia Hospital, Philadelphia PA, [2]Thomas Jefferson University Hospital, Philadelphia, pA, [3]Thomas Jefferson University Hospital, Philadelphia PA

Background: According to various international guidelines, terlipressin, in combination with albumin, is the preferred treatment for Hepatorenal Syndrome-Acute Kidney Injury (HRS-AKI). Although terlipressin has shown benefits in reversing HRS and avoiding renal replacement therapy (RRT), its side effect profile and high financial cost have limited its utilization in the United States since FDA approval in 2022. This study aims to characterize real-world utilization of terlipressin at two tertiary academic medical centers in the U.S. **Methods:** This retrospective evaluation reviewed the efficacy, safety, and cost utilization of terlipressin in adults between the time of formulary addition starting 1/1/23 through 11/30/24. Efficacy and safety outcomes mirrored those of the FDA-approved CONFIRM trial, including verified HRS reversal (two consecutive serum creatinine (SCr) measurements of 1.5 mg/dL or less at least 2 hours apart up to day 14 and survival without RRT for at least an additional 10 days) and safety endpoints. **Results:** A total of 39 patients were included. Patients were male (62%), aged 55 $\pm$ 11.9 years, with alcohol use as the primary cause of cirrhosis (49%). Prior to terlipressin use, midodrine and octreotide were used in 71% of the patients. At the time of terlipressin initiation, median MELD 3.0 was 34 $\pm$ 6, with a baseline SCr of 2.87 $\pm$ 0.7 mg/dL. The average duration of terlipressin was 3.3 $\pm$ 3.3 days. Terlipressin was continued beyond day four in 12 patients (30.7%), 7 of whom had a dose increase. Albumin was continued for an average of 2.5 $\pm$ 3.1 days while on terlipressin, with an average total daily dose of 31 $\pm$ 27g per day. Verified HRS reversal occurred in 7/39 patients (17%), all with a SCr $\leq$ 3mg/dL. Liver transplant occurred in 35% of patients at a mean of 9.8 $\pm$ 10 days after terlipressin initiation. Death within 90 days occurred in 15/39 patients (38%). Adverse events occurred in 19/39 patients (48%), leading to discontinuation of terlipressin in 18/19 patients. Respiratory failure was the most common adverse effect in 14/39 (35%), with a mean time to onset of 2.9 $\pm$ 3.7 days. The average cost per patient for the terlipressin treatment course was $14,084.96 USD. **Conclusion:** In this real-world review of tertiary academic medical centers in the U.S., HRS reversal was similar to the outcomes in the CONFIRM trial (31% compared to 39%); however, verified HRS reversal was lower (17% in the present study vs. 32% in CONFIRM). Adherence to the institutional formulary guidelines was met for this high-cost, newly FDA-approved therapy and should continue to guide appropriate patient selection.

Table 1. Efficacy and safety outcomes

	Terlipressin (n = 39)
Efficacy Endpoints	
Verified reversal of HRS* – no. (%)	7 (17.9)
Competing Event¥	4 (10.3)
HRS Reversal** – no. (%)	12 (30.8)
Competing Event	4 (10.3)
Recurrence of HRS after reversal within 90 days (n=12) – no. (%)	7/12 (58.3)
Requirement of renal replacement therapy within 30 days – no. (%)	15 (38.4)
Underwent liver transplant – no. (%)	14 (35.8)
Death within 90 days – no. (%)	15 (38.4)
Safety Endpoints	
Occurrence of Adverse Event – no. (%)	19 (48.7)

*Verified HRS Reversal - two consecutive serum creatinine measurements of 1.5 mg per deciliter or less at least 2 hours apart and survival without renal-replacement therapy for at least 10 days after the completion of treatment
**HRS Reversal - any serum creatinine level of 1.5 mg per deciliter or less during the first 14 days
¥ Competing Event – liver transplant and/or death before patient could be evaluated for clinical success or failure

2427 | IS TIME LIVER? COMPARING OUTCOMES OF EARLY VERSUS LATE PARACENTESIS IN PATIENTS WITH ADVANCED CHRONIC LIVER DISEASE (ACLD)

Nisha Sanghani[1] Samuel Levine[1] Nishanth Eluri[1] Het Patel[1] Peyton Fair[2] Rana Moawad[2] Vishal Patel[1], [1]St. Luke's University Health Network, [2]Temple/St. Luke's School of Medicine

Background: Patients with advanced chronic liver disease (ACLD) decompensated by ascites are at risk for spontaneous bacterial peritonitis (SBP). Prior studies have shown that early diagnostic paracentesis (within 12 to 24 hours) for SBP detection is associated with lower in-hospital mortality rates, shorter lengths of hospital stay, and a reduced incidence of acute kidney injury (AKI) when compared to that of delayed diagnostic paracentesis. This study aims to investigate the current "time to diagnostic paracentesis" and differences in outcomes based on timing in patients with history of ACLD presenting with ascites at one hospital system. **Methods:** A retrospective chart review was performed on adult patients with history of ACLD, admitted at St. Luke's, Bethlehem Campus between 2021 and 2024 who received a paracentesis during their hospital stay. This study compared outcomes between paracentesis in 12 hours, 12-24 hours, and greater than 24 hours. Encounters for therapeutic paracentesis and paracentesis without subsequent fluid

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

analysis were excluded. All statistical analyses were performed with Stata software. **Results:** Of the 317 encounters, 211 met inclusion criteria. 29% had a diagnostic paracentesis within 12 hours, 29% had one between 12-24 hours, and 42% had one greater than 24 hours after ascites detection. Diagnostic paracentesis after 24 hours of ascites detection had the longest length of hospital stay at 8.5 days compared to 6 days in the within 12-hour group and 5 days in the 12-24 hour group (p = 0.025). Diagnostic paracentesis within 12 hours compared with one after 12 hours resulted in a lower incidence of AKI (p-value = 0.032). There was no difference in incidence of ICU stay, 90-day mortality, and 30-day readmission when comparing all three groups. **Conclusion:** This study demonstrates that delaying diagnostic paracentesis in patients with ACLD presenting with ascites leads to an increased length of hospital stay and a higher incidence of AKI. Longer hospital stays are undesirable, as they can lead to increased risk of hospital-acquired infections, higher morbidity, increased in-hospital mortality, and increased healthcare costs. Likewise, AKIs often have long term effects including development of chronic kidney disease and increased risk of cardiovascular events and mortality. This research can be further utilized to create an algorithm at this hospital system for all ACLD patients presenting with ascites to receive a diagnostic paracentesis within 12-24 hours of ascites detection.

Table 1: Demographics and characteristics on presentation compared across time of diagnostic paracentesis start.

Factor	Overall	12 hours of ascites	24 hours of ascites	> 24 hours of ascites	p-value

2428 | A LARGE LANGUAGE MODEL (LLM) APPROACH FOR SCREENING LITERATURE AND DRAFTING SYSTEMATIC REVIEWS AND META-ANALYSES USING THE EFFICACY OF CARVEDILOL ON DECOMPENSATION AND MORTALITY COMPENSATED CIRRHOSIS AS A MOTIVATING EXAMPLE

Yuntao Zou[1] Iris Kim[2] Mi-Ok Kim[2] Jin Ge[2], [1]UCSF, [2]University of California, San Francisco

Background: Systematic reviews and meta-analyses entail extensive manual effort for screening articles, constructing analysis and drafting, which LLMs may excel at. This study investigates whether LLMs could emulate a previously written meta-analysis regarding whether carvedilol reduces decompensation and mortality in patients with compensated cirrhosis. **Methods:** We identified 1,077 articles from PubMed, Cochrane, and EMCASE regarding the clinical question. We used protected health information-compliant GPT-4o to filter and screen articles, which was compared with manual screening. We then embedded the filtered articles via retrieval augmented generation into GPT-4o and drafted portions of a systematic review and meta-analysis manuscript. Each section of the manuscript (Introduction, Methods, Results, and Discussion) was independently generated 100 times and evaluated using predefined criteria. **Results:** Of the 1,077 articles, 374 (34.7%) were duplicates across multiple databases. We tested several prompt engineering methods to improve performance: 1) N-shot prompting; 2) Detailed clarifications for inclusion and exclusion criteria; 3) Emphasis on specific details relevant to article selection; 4) Streamlining prompts. Of the 703 unique articles, GPT-4o achieved a sensitivity of 93% (95% CI: 66-100%) and specificity of 96% (95% CI: 94-97%) compared to manual review. LLM screening required 30M tokens (~$82.5) and 2 hrs compared to 62 hrs for manual review. In manuscript drafting: 1. For Introduction and Methods, 100% of drafts met the quality criteria (e.g., generating background, rationale, evidence gap, and study objective). 2. For **Results:** 0% of drafts met quality criteria (e.g., including study selection summary, outcome synthesis, and graphical analyses). Notably, GPT-4o was unable to extract or synthesize numerical and tabular data from constituent articles, resulting in incorrect or incomplete outcome reporting. 3. For Discussion: 89% of drafts included the correct structural components (e.g., principal findings, comparison with

prior literature, limitations, relevance, and future directions). The drafted discussion sections, however, were based on inaccurate results and therefore were unusable. **Conclusion:** LLM shows high utility in automating the early phases of systematic reviews, particularly in screening abstracts and drafting Introduction and Methods sections. LLMs were insufficient for data extraction and result synthesis to draft Results and Discussion sections.

2429 | ENDOSCOPIC ULTRASOUND (EUS)-GUIDED PORTAL PRESSURE GRADIENT MEASUREMENT: CLINICAL USEFULNESS INCLUDING ASSESSMENT OF ACUTE RESPONSE TO PROPRANOLOL

Rafael Romero-Castro[1] Victoria Jimenez-Garcia[1] Isabel Carmona-Soria[1] Lourdes Grande-Santamaria[1] Paula Fernandez-Alvarez[1] Maria Tous-Romero[1] Enrique Silva Albarellos[1] Patricia Ruiz-Cordero[1] Javier Garcia-Perez[1] Manuel Rodriguez-Tellez[1] Angel Caunedo Alvarez[1], *[1]Virgen Macarena University Hospital*

Background: Portal hypertension is the main driver for complications in liver diseases. Portal pressure gradient can be assessed by Endoscopic Ultrasound (EUS). We report our experience on EUS-guided portal pressure gradient measurement (EUS-PPGm). **Methods:** Prospective study of patients referred for EUS-PPGm using a 25G dedicated needle was used. A 19G FNA needle was used for EUS-guided bilobar liver biopsy (EUS-BLB). Following baseline EUS-PPGm, 0.15 mg/kg of body weight, propranolol was administered intravenously by continuous infusión and the EUS-PPGm repeated 15 minutes later. **Results:** EUS-PPGm was performed in 70 patients. Indications: Assessment of metabolic associated steatotic liver disease in morbid obese patients: 43. Portal hypertension (PH): 20. Evaluation for curative therapy in hepatocellular carcinoma (HCC): 3. Acute response to intravenous propranolol: 4. Additional procedures were also performed in the same endoscopic session: Fifty-one (73%) EUS-BLB, 3 band ligation for esophageal varices and 1 EUS-guided coil therapy for gastric varices. EUS-PPGm was successfully obtained in 63/70 patients (90%). In 12/43 cases of morbid obese patients (28%) the EUS-PPGM was >6 mmHg in patients without varices nor fibrosis on EUS-BLB. In patients with morbid obesity, there was a statistically significant difference in the S3 score of steatosis in the group of portal hypertension (33%) in comparison with the no portal hypertension group (4%) [figure]. Patients were treated accordingly with the results of EUS-PPGm. There was observed a significant reduction of PPG in 2 patients treated with intravenous propranolol [10.5 mmHg to 4.75 mmHg (22%) and 10 mmHg to 2 mmHg (20%), respectively]. In the other two the PPG was normal, avoiding chronic use of beta-blockers. In 7 cases (10%) EUS-PPGm was not obtained. For rapid breathing movements (1 case) and for non-reliable pressure measurements (6 cases). In one case the 25G needle passed in close proximity to the hepatic artery. We experienced difficulty in punction the hepatic and the portal vein in one and two cases, respectively. In one case the 25G needle failed to transverse the liver capsule. Mean time to obtain EUS-PPGm 24 ± 2 minutes for EUS-BLB 17 ± 2 minutes and for combined EUS-PPGm plus EUS-BLB 45 ± 2 minutes. Three adverse events were observed. One mild epigastric pain 2 day after EUS-PPGm combined with EUS-BLB, one self-limited bleeding from the cardias and one atrial fibrillation. **Conclusion:** EUS-PPGm, even combined with EUS-BLB, seems safe, providing relevant clinical information. A notewhorty proportion of morbid obese patients were precociously diagnosed of portal hypertension by EUS-PPGm in early reversible stages without liver fibrosis on EUS-BLB. Acute response to intravenous propranolol can be obtained with EUS-PPGm.

2430 | ENHANCED EARLY DETECTION OF HEPATOCELLULAR CARCINOMA USING THE GALAD SCORE IN VIETNAMESE CIRRHOTIC PATIENTS: A PROSPECTIVE–RETROSPECTIVE COHORT STUDY

Thong Vo[1], [1]University Medical Center Ho Chi Minh City

Background: Hepatocellular carcinoma (HCC) remains a major global health burden and is often diagnosed at advanced stages due to limitations in current surveillance tools. While ultrasound and alpha-fetoprotein (AFP) are widely used, their sensitivity for early-stage HCC remains suboptimal, particularly in high-risk cirrhotic populations. The GALAD score, which integrates gender, age, and three serum biomarkers (AFP, AFP-L3, and PIVKA-II), has emerged as a promising diagnostic tool for early HCC detection. This study aimed to evaluate the diagnostic accuracy of the GALAD score in Vietnamese patients with cirrhosis and to assess its association with tumor characteristics. **Methods:** A combined prospective and retrospective cohort study was conducted at the University Medical Center Ho Chi Minh City from January 2018 to May 2021. We enrolled 196 adult patients with cirrhosis, including 102 with HCC and 94 without. Cirrhosis was confirmed by biopsy or non-invasive criteria (APRI $\geq$2, FibroScan $\geq$12.5 kPa, or MRE $\geq$5.9 kPa). All patients underwent contrast-enhanced CT or MRI and quantitative testing of AFP, AFP-L3, and PIVKA-II within three months of imaging. The GALAD score was calculated using a validated formula. Diagnostic performance was assessed by ROC analysis, and the optimal cutoff was identified by the Youden index. Associations between GALAD score and tumor size, number, and location were evaluated. **Results:** The mean GALAD score was significantly higher in HCC patients (2.5; 95% CI: -2.43–11.09) than in non-HCC patients (-2.46; 95% CI: -6.15–2.04; $p < 0.001$). At the optimal cutoff of -0.518, the GALAD score demonstrated an AUROC of 0.91 (95% CI: 0.86–0.94), with 87.25% sensitivity and 82.98% specificity—outperforming all individual biomarkers (AFP, AFP-L3, and PIVKA-II) with statistically significant differences (all $p < 0.001$). The GALAD score showed a moderate correlation with tumor size ($r = 0.44$; $p < 0.001$), and was significantly higher in patients with multiple tumors compared to those with solitary lesions ($p = 0.0081$). No significant correlation was found between GALAD score and tumor location. **Conclusion:** The GALAD score demonstrates excellent diagnostic performance for HCC detection in Vietnamese patients with cirrhosis and correlates with tumor burden. Its integration into routine surveillance protocols may enhance early detection and risk stratification of HCC, particularly in resource-limited settings where imaging sensitivity is constrained.

2431 | PREDICTIVE ACCURACY OF MELD 3.0 AND MELD-NA SCORES FOR MORTALITY AND REBLEEDING AFTER ENDOSCOPIC HEMOSTASIS IN CIRRHOSIS-ASSOCIATED VARICEAL HEMORRHAGE: A MULTICENTER STUDY

Shinya Yokoyama[1] Takashi Honda[1] yoji ishizu[1] Norihiro Imai[2] Takanori Ito[1] Kenta Yamamoto[1] Tomoyuki Tsuzuki[3] Masanao Nakamura[1] Hiroki Kawashima[1], [1]Nagoya University, [2]Nagoya University Graduate School of Medicine, [3]Toyota Kosei Hospital

Background: Acute variceal hemorrhage (AVH) is a life-threatening complication of cirrhosis, carrying substantial risks of mortality and rebleeding. Various scoring systems, including the Model for End-Stage Liver Disease (MELD), MELD-Na, Child-Pugh, and the newly introduced MELD 3.0 scores, have been proposed for outcome prediction in patients with liver diseases including cirrhosis, yet their comparative performance in long-term prognosis following AVH remains to be clarified. We aimed to evaluate which score best predicts mortality and rebleeding in patients with cirrhosis who achieve successful endoscopic hemostasis for AVH. **Methods:** This retrospective, multicenter study included 168 patients with cirrhosis who underwent successful endoscopic treatment including band ligation and glue injection for AVH of the esophagus and stomach between 2013 and 2023. Time-dependent receiver operating characteristic (ROC) analysis was performed to assess each score's predictive accuracy for mortality from day 30 to day 1080 post-AVH. Kaplan–Meier curves with log-rank tests compared survival in high- vs. low-score groups. Cox proportional hazard models identified independent

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

mortality predictors. Rebleeding was analyzed using a competing risk model, with Fine–Gray models incorporating death or variceal retreatment as competing events. **Results:** Median age was 66 years (interquartile range: 53–75), and 117 (69.6%) patients were men. Seventy-nine (47.0%) were classified as Child-Pugh class B and 42 (25.0%) as class C. MELD 3.0 consistently demonstrated the highest time-dependent ROC performance (average area under the curve: 0.789), remaining above 0.8 for up to 18 months after AVH. Patients with MELD 3.0 $\geq$15 had significantly worse survival (median 113 vs. 1750 days; hazard ratio [HR]: 2.71, 95% confidence interval [CI]: 1.68–4.37). Other independent mortality predictors included hepatocellular carcinoma (HR: 3.55, 95% CI: 2.05–6.14) and red blood cell transfusion (HR: 2.04, 95% CI: 1.15–3.62). In contrast, only a high MELD-Na score significantly predicted rebleeding (HR: 1.99, 95% CI: 1.17–3.39), showing a higher cumulative incidence of rebleeding in that group. Neither MELD 3.0, MELD, or Child-Pugh scores effectively stratified rebleeding risk. **Conclusion:** MELD 3.0 and MELD-Na scores are valuable non-invasive tools for predicting long-term mortality and rebleeding, respectively, in patients with cirrhosis after successful AVH hemostasis. These scoring systems can aid clinical decision-making by identifying high-risk individuals for intensive monitoring or intervention. Prospective studies are warranted to validate these findings and optimize post-bleeding management strategies.

Time-dependent receiver-operating characteristic analysis for the MELD, MELD 3.0, MELD-Na, and Child-Pugh scores at the time of initial acute variceal hemorrhage, plotting the area under the curve (AUC) for predicting mortality of every 30 days from 30–1080 days after successful endoscopic hemostasis of acute variceal hemorrhage

2432 | SAFETY OF TESTOSTERONE SUPPLEMENTATION IN MEN WITH CIRRHOSIS AND HYPOGONADISM: A PROPENSITY SCORE-MATCHED STUDY FROM A MULTINETWORK STUDY

Tinsae Tsegaye Anebo[1] Laith Alomari[1] Karecia Byfield[1] Phuuwadith Wattanachayakul[1] Ghideon Ezaz[1],
[1]Thomas Jefferson University

Background: Hypogonadism is a prevalent condition among men with cirrhosis, often leading to significant adverse clinical outcomes such as muscle wasting, decreased bone density, fatigue, sexual dysfunction, and a reduced quality of life. Testosterone supplementation has been explored as a potential therapy to counter these effects, but concerns regarding its safety, particularly about cardiovascular risks, and potential exacerbation of hepatic complications. This study aims to assess the safety and clinical outcomes of testosterone supplementation in men with cirrhosis and hypogonadism, providing insight into its potential benefits and risks. **Methods:** We used the US Collaborative Network-TriNetX database to identify male patients with an index diagnosis of cirrhosis and subsequent hypogonadism with and without testosterone supplementation between 2012 and 2024. Cohort comparability was achieved through 1:1 propensity score matching based on age and ethnicity. We evaluated the following outcomes censored at 12 years: all-cause mortality, hospitalization, anemia, SBP, HCC, variceal bleeding, ascites, hepatic encephalopathy, new-onset type 2 diabetes, sarcopenia, malnutrition, new myocardial infarction, and new stroke. Generalized linear models were used to measure the association, and estimates were presented as risk ratios/hazard ratios and 95% confidence intervals. A p-value of <0.05 was considered significant. **Results:** We used the US Collaborative Network-TriNetX database to identify male patients with an index diagnosis of cirrhosis and subsequent hypogonadism with and without testosterone supplementation between 2012 and 2024. Cohort comparability was achieved through 1:1 propensity score matching based on age and ethnicity. We evaluated the following outcomes censored at 12 years: all-cause mortality, hospitalization, anemia, SBP, HCC, variceal bleeding, ascites, hepatic encephalopathy, new-onset type 2 diabetes, sarcopenia, malnutrition, new myocardial infarction, and new stroke. and 95% confidence intervals. A p-value of < 0.05 was considered significant. **Conclusion:** These findings suggest that testosterone supplementation in men with cirrhosis appears to be safe, with no increased risk of major adverse events such as myocardial infarction or stroke. While it does not significantly impact overall survival, it may help mitigate certain cirrhosis-related complications, particularly reducing the risk of ascites and potentially alleviating muscle loss. Further research is needed to confirm these findings and evaluate the long-term safety and efficacy of testosterone therapy in this population. The decision to initiate treatment should be carefully individualized, considering potential benefits and risks.

Table 1-Clinical Outcomes

Clinical Outcome	HR	95% CI	P-value

2433 | BASELINE CHARACTERISTICS AND IN-HOSPITAL OUTCOMES OF PATIENTS WITH CIRRHOSIS UNDERGOING CORONARY ARTERY BYPASS GRAFTING (CABG): A SEVEN-YEAR ANALYSIS FROM THE NATIONAL INPATIENT SAMPLE

Omar Alkasabrah[1] Abdullah Hafeez[1] Ritu C. Tated[2] Siddharth Agrawal[1] Radhe Shah[3] Kriti Soni[4] Jatin Thukral[1] Mutaz Kalas[5] Ismail Elkhattib[6] Tanuj Sharma[1], [1]NYMC/Landmark Medical Center, [2]New York Medical College, [3]Beth Israel Deaconess Medical Center, [4]SUNY Upstate Medical University, [5]Texas Tech University Health Science Center EL Paso, [6]University of Nebraska

Background: Cirrhosis is associated with multisystem dysfunction that may increase perioperative risk in cardiac surgery patients. Coronary artery bypass grafting (CABG) remains a cornerstone therapy for advanced coronary disease, yet cirrhosis introduces physiological vulnerabilities that may alter procedural outcomes. We aimed to explore how cirrhosis influences postoperative complications and mortality in patients undergoing CABG. **Methods:** We conducted a retrospective cohort study using the National Inpatient Sample (2016–2022). Demographic, clinical, and hospital variables were compared, and multivariable logistic regression was used to assess the adjusted odds of in-hospital complications, controlling for comorbidities and institutional characteristics. The primary outcome was in-hospital mortality. Secondary outcomes included atrial fibrillation, cardiogenic shock, need for mechanical ventilation, and bleeding complications. **Results:** Among 1,296,455 CABG hospitalizations, 10,410 (0.8%) involved patients with cirrhosis. Compared to patients without cirrhosis, the cirrhosis population was younger and more likely to be male (77.7% vs. 75.7%). They had higher rates of diabetes (65.9% vs. 59.7%), anemia (26.5% vs. 16.4%), CKD (23.9% vs. 18.1%), alcohol use (22.5% vs. 3.2%), and coagulopathy (20.3% vs. 6.8%) ($p < 0.001$ for all). Cirrhotics also had longer hospital stays (12.5 vs. 9.8 days, $p < 0.001$) and higher total charges. In adjusted models, cirrhosis was associated with significantly increased in-hospital mortality (5.76% vs. 2.41%; aOR 2.194, 95% CI 2.004–2.401, $p < 0.001$), cardiogenic shock (aOR 1.067, 95% CI 1.023–1.114, $p = 0.002$), need for mechanical ventilation (aOR 1.107, 95% CI 1.038–1.181, $p = 0.002$), atrial fibrillation (aOR 1.047, 95% CI 1.004–1.092, $p = 0.032$), and bleeding complications (aOR 1.257, 95% CI 1.205–1.310, $p < 0.001$). **Conclusion:** Cirrhosis independently doubles the risk of mortality following CABG and significantly increases bleeding and cardiorespiratory complications. Cirrhosis contributes to physiologic fragility that complicates surgical recovery. These results highlight the need for careful risk assessment and multidisciplinary management in patients with chronic liver disease undergoing cardiac surgery.

Background: Chronic liver disease (CLD)-related thrombocytopenia limits the feasibility of invasive procedures. Recombinant human thrombopoietin (rhTPO) has demonstrated a favorable safety in clinical application without hepatotoxicity. In this study, we assessed the efficacy and safety of rhTPO in patients with CLD-related thrombocytopenia undergoing elective invasive procedures. **Methods:** This multicenter, randomized(2:1), double-blind, parallel-group, placebo-controlled study was conducted in 41 centers and enrolled adult Chinese patients with CLD-related thrombocytopenia (platelet count $<50\times10^9$/L). Eligible subjects were randomized to receive either rhTPO (15,000 IU) or placebo once daily for a maximum of 5 or 7 days. Treatment was discontinued if platelet counts $>50\times10^9$/L and increased by $>10\times10^9$/L from baseline (Figure 1). The invasive surgery were performed within 1 week after the end of treatment. The primary endpoint was the proportion of subjects with sustained platelet counts $\geq50\times10^9$/L from 24 hours before surgery to 7 days post-surgery, without requiring emergency bleeding management(including whole blood, red blood cells, platelets, plasma, or cryoprecipitate transfusion). **Results:** A total of 120 subjects were randomized, with 80 receiving rhTPO and 40 receiving placebo. By day 7 following surgery, the primary endpoint was met in 85.00% of subjects treated with rhTPO (95%CI: 75.26%–92.00%), compared with 12.50% of placebo-treated subjects (95%CI: 4.19%–26.80%), yielding a statistically significant difference of 72.21% (95%CI: 59.55%–84.86%, stratified Cochran-Mantel-Haenszel test, $p < 0.0001$, Figure 2a). At the preoperative assessment, 92.50% of subjects in the rhTPO group (95% CI: 84.39%-97.20%) achieved platelet counts $\geq50\times10^9$/L compared with 20.00% in the placebo group (95% CI: 9.05%-35.65%), with a statistically significant difference ($p < 0.0001$, Figure 2b). rhTPO markedly reduced the platelet transfusion, with 92.50% of rhTPO-treated patients (95% CI: 84.39%-97.20%) avoiding transfusion, *vs.* only 25.00% in the placebo group (95% CI: 12.69%-41.20%), yielding a significant between-group difference ($p < 0.0001$, Figure 2c). In addition, the median duration of platelet counts $\geq50\times10^9$/L was prolonged to 21 days in the rhTPO group (95% CI: 20–23), *vs.* 3 days in the placebo group (95% CI: 2–4), with a stratified hazard ratio of 0.38 ($p = 0.0007$, Figure 3). Regarding the safety, similar results of treatment-emergence adverse events (TEAEs) were found in rhTPO-treated (81.25%) and placebo-treated subjects (87.50%). Treatment-related TEAEs occurred in 12.5% of subjects in both the rhTPO and placebo groups. No treatment-related serious adverse events were observed. **Conclusion:** rhTPO is effective and well tolerated in the patients enrolled in this study and could be used as a viable therapeutic option for CLD-related thrombocytopenia in patients undergoing elective invasive procedures.

2435 | EARLY MODULATION OF INR AND MELD AFTER REGENERATIVE MACROPHAGE THERAPY IS ASSOCIATED WITH FAVOURABLE CLINICAL OUTCOMES AT THREE-YEAR FOLLOW-UP

Paul Brennan[1] Jose Meseguer-Ripolles[2] Thomas Manship[3] Alison Glover[4] Debbie Troland[5] Iain MacPherson[1] Catriona Graham[6] Rhona Aird[5] Scott Semple[7] David Morris[8] Alasdair Fraser[4] Chloe Pass[4] Neil McGowan[4] Marc Turner[4] Lynn Manson[4] Neil Lachlan[9] John Dillon[1] Alastair Kilpatrick[5] John Campbell[2] Francesca Moroni[10] Clifford Brass[11] Lara Campana[2] Jonathan Fallowfield[8] Stuart Forbes[8], [1]University of Dundee, [2]Resolution Therapeutics Ltd, [3]Royal Infirmary of Edinburgh, [4]Scottish National blood Transfusion Services, [5]Centre for Regenerative Medicine, University of Edinburgh, [6]Wellcome Trust CRF, University of Edinburgh, [7]Centre for Cardiovascular Science, University of Edinburgh, [8]University of Edinburgh, [9]Glasgow Royal Infirmary, [10]University of Aberdeen, [11]Brass Pharma Consulting LLC

Background: The Phase 2 MATCH study demonstrated that autologous regenerative macrophage cell therapy (RMT) enhanced overall, and transplant-free survival at 3 years in patients with advanced cirrhosis compared to a well-matched standard of care (SoC) control population (SoC: 3 transplant, 8 deaths; vs cell treatment: 2 deaths at 3-year follow-up; Fig.1A). Preclinical models have established a link between regenerative macrophages and anti-inflammatory, and anti-fibrotic functions that facilitate liver regeneration. In patients, improved regeneration should restore the liver's synthetic capacity, ensuring long-term clinical benefits. However, no direct correlation between clinical outcomes and early biomarker measurements of liver function have been established to substantiate the RMT mode of action elucidated in preclinical models. **Methods:** In this study, we investigated the correlation between long-term clinical benefits (transplant-free survival and overall survival) at three years post-treatment and early modulation (90 days post-treatment) of clinical markers of liver synthetic function, such as INR (International Normalised Ratio), and a validated prognostic score associated with overall survival, MELD (Model for End-Stage Liver Disease). **Results:** Directional changes in INR and MELD at 90 days post-therapy were associated with transplant-free survival at three years. For instance, INR exhibited a positive predictive value (PPV) of 0.5, and a strong negative predictive value (NPV) of 0.96 in the cell treatment group, with clinical non-responders (i.e., the two patients who died within the 3-year FU period) not demonstrating any INR improvement at 90 days (Fig.1B). Further, delta MELD at 90 days showed a PPV of 0.29 and a NPV of 1, indicating an increase in MELD score for both clinical non-responders compared to baseline in the cell treatment group (Fig. 1C). **Conclusion:** This is the first dataset to demonstrate that RMT administration is associated with early changes in biomarkers associated with liver function (INR; dMELD), which appear to correlate with better survival in patients with advanced cirrhosis. The primary statistical limitation of this study is the low number of clinical non-responders in the cell treatment group (n = 2). Further follow-up of this cohort will offer additional insights into the relationship between longer-term outcomes of RMT and early modulation of circulating biomarkers.

2436 | COMPARATIVE OUTCOMES OF RESPIRATORY SYNCYTIAL VIRUS VACCINATION AND INFECTION IN HOSPITALIZED PATIENTS WITH ADVANCED LIVER DISEASE

Adil Fazir[1] Katherine Cooper[2] Ami Patel[3] Deepika Devuni[2], [1]University of Massachusetts Chan Medical School, [2]University of Massachusetts, [3]Univeristy of Massachusetts

Background: Viral respiratory infections in patients with cirrhosis are associated with increased morbidity and mortality. Vaccinations are a widely used preventative measure aimed at mitigating these negative outcomes. The incidence of RSV infection and real-world outcomes of RSV vaccination is not well explored in chronic liver disease. **Methods:** This retrospective analysis of patients was completed using TriNetX. We created a base population of adults with a healthcare examination from 5/1/2023-10/31/2024. Patients were categorized as either having cirrhosis or not having cirrhosis (controls). We first reported the incidence proportion, or cumulative incidence, and prevalence (%) of RSV infection in patients with cirrhosis, with a focus on differences by sex, ethnicity, obesity, COPD and asthma. Next, to assess the effect of vaccination on the risk of RSV infection, we compared RSV infection from 11/1/2024-5/1/2025 in patients with cirrhosis who received the vaccine from 5/1/2023-10/31/2024 to RSV infection from 11/1/2024-5/1/2025 in patients with cirrhosis who did not receive the RSV vaccine. Incidence proportions were compared using relative risks ratio with 95% confidence intervals. **Results:** A total of 70,671 participants with cirrhosis were identified of which 6,977 received the RSV vaccine and 65,305 did not. The cumulative incidence of RSV infection in patients with cirrhosis was 0.21% and the prevalence was 0.77%, compared to 0.07% and 0.24% in controls, respectively. In the cirrhosis cohort, incidence of RSV was higher in patients who also had obesity (0.24% vs 0.16%, RR 1.50, 95% CI (1.02, 2.20), p = 0.038), COPD (0.31% vs 0.18%, (RR 1.72, 95%CI (1.17, 2.53) p = 0.006) or asthma (0.30% vs 0.18%, RR 1.67, 95% CI (1.12-2.49) p = 0.012) and was trended toward higher in females vs. males (0.22% vs. 0.18%, RR 1.22, 95% CI 0.88-1.69, p = 0.24) and in Hispanics vs. Non-Hispanics (0.30% vs. 0.22%, RR 1.30, 95% CI 0.79-2.12, p = 0.30). The incidence of RSV infection did not differ in cirrhosis participants with and without vaccination (0.19% vs. 0.20%, RR 0.98, 95% CI 0.57-1.68, p = 0.94). Similar findings were observed in patients without liver disease (0.08% vaccinated vs. 0.07% unvaccinated, RR 1.11, 95% CI 0.96-1.28, p = 0.15). **Conclusion:** In this large nationally representative sample, the incidence of RSV infection was elevated in cirrhosis compared to those without liver disease. Within patients with cirrhosis, the incidence was elevated in those who also had COPD, obesity or asthma. Importantly, the incidence did not differ in those with and without the RSV vaccine, however this may be limited by the short term follow up of 1 cold/flu cycle. Additional research and long-term data are needed to further assess the benefit of the RSV vaccine in patients with chronic liver disease.

	Total patients	Incident cases	Incident proportion	Relative risk
Cirrhosis + Obesity	36,853	76	0.24	1.50 (1.02, 2.20) P = 0.038
Cirrhosis without Obesity	30,964	40	0.16	
Cirrhosis + COPD	16,400	40	0.31	1.72 (1.17, 2.53) p=0.006
Cirrhosis without COPD	51,417	72	0.18	
Cirrhosis + Asthma	14,429	35	0.30	1.67 (1.12-2.49) p =0.012
Cirrhosis without Asthma	53,388	77	0.18	
Cirrhosis + RSV vaccine	6,977	12	0.19	0.98, 95% CI 0.57-1.68, p=0.94
Cirrhosis without RSV vaccine	65,305	101	0.20	
Control + RSV vaccine	301,633	209	0.08	1.11, 95% CI 0.96-1.28, p = 0.15
Control without RSV vaccine	4,427,240	2,297	0.07

2437 | ORAL CHOLATE CHALLENGE TEST CHARACTERIZES FUNCTIONAL DIFFERENCES BETWEEN CHILD-PUGH A5 AND A6

Naga Chalasani[1] Mitchell Shiffman[2] Timothy Morgan[3] Michael Leise[4] Michael McRae[5] Joanne Imperial[6] Gregory Everson[7], [1]Indiana University Medical Center, [2]Bon Secours Mercy Health, [3]VA Long Beach Healthcare System, [4]Mayo Clinic Rochester, [5]Custom DX Solutions LLC, [6]HepQuant, LLC, [7]HepQuant

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

Background: Liver function in patients with Child-Pugh (CP) A cirrhosis may vary from normal to severe functional impairment and shunting. Staging disease severity in patients with CP A cirrhosis is important for clinical decisions regarding further diagnostic testing, treatment, or follow-up interval. We used the oral cholate challenge test results to characterize and compare patients with CP A5 and A6. **Methods:** Subjects were enrolled in two US prospective studies linking the oral cholate challenge test results to endoscopic findings. Test parameters were quantified from 20- and 60-min concentrations of orally administered d4-cholate. Serum was analyzed for cholate concentrations by LC-MS/MS. A disease severity index (DSI) and portal systemic shunting (SHUNT%) were calculated. We combined data from subjects with CP A cirrhosis from two studies: SHUNT-V ($n = 238$) and HALT-C ($n = 216$). Standard laboratory values included albumin, alkaline phosphatase, ALT, AST, bilirubin, INR, and platelet count. **Results:** Subjects were age 56 ± 11 years, BMI 32 ± 7 kg/m^2, 86% overweight, 54% obese, 61% male, 84% White race, and 13% Hispanic ethnicity. Etiologies included hepatitis C (61%), MASLD/MASH (25%), and alcohol-associated liver disease (8%). Out of 454 subjects, 128 (28%) had small esophageal varices (EV), and 48 (11%) had large EV. Demographics were similar between CP A5 and A6; subjects with CP A6 were more likely to have hepatitis C ($p = 0.018$) and less likely to have MASLD/MASH ($p = 0.008$); laboratory values and MELD scores were significantly worse for CP A6 ($p < 0.001$), except ALT ($p = 0.449$); subjects with CP A6 were more likely to have large EV (23%) compared to CP A5 (8%) ($p = 0.0001$). Oral cholate challenge test parameters showed significantly worse function and shunting (Figure 1) in subjects with CP A6 (DSI, 25.2 ± 7.9; SHUNT%, 43.8% ± 16.7%) versus CP A5 (DSI, 19.8 ± 6.4; SHUNT%, 33.0% ± 12.4%) ($p < 0.0001$). For the detection of large EV on endoscopy, AUROCs for DSI (0.82) and SHUNT% (0.83) were significantly higher than CP score (0.63) ($p < 0.0001$). **Conclusion:** Patients with CP A6 cirrhosis have worse hepatic function and more portal-systemic shunting than patients with CP A5 cirrhosis. The oral cholate challenge test allowed characterization of functional differences in CP A5 versus A6 and was more predictive for EV than CP score. Given the heterogeneity within the CP classification, the cholate challenge test may be useful clinically in staging disease severity.

2438 | BILE CAST NEPHROPATHY IN CIRRHOSIS: CLINICAL PROFILE, BIOCHEMICAL PATTERNS, AND PROGNOSTIC IMPACT

Hrudya.[1] Harshad Devarbhavi[2] Mallikarjun Patil[2], [1]St. Johns Medical College and Hospital, [2]St.John's Medical College, Bengaluru, India

Background: Bile Cast Nephropathy (BCN), a bile pigment-induced tubular injury in the setting of hyperbilirubinemia, is increasingly recognized as a distinct cause of acute kidney injury (AKI) in cirrhotic patients. Its pathogenesis is multifactorial, but its clinical impact remains underexplored. This study compared clinical features, liver disease severity, biochemical

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2025 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, Inc. Unauthorized reproduction of this article prohibited.

parameters, and short-term mortality in cirrhotic patients with BCN versus those with non-BCN AKI. **Methods:** In this combined retrospective and prospective observational study at a tertiary center, 203 cirrhotic patients with AKI were categorized into Bile AK (n = 102) and Non-Bile AK (n = 101) groups based on clinical and biochemical criteria. A presumptive diagnosis of BCN was made using the presence of bile-stained urinary casts, hyperbilirubinemia, and unexplained renal dysfunction. Data on demographics, liver disease etiology, bilirubin, creatinine, INR, MELD and CTP scores, and 3-month mortality were analyzed. Statistical tests included chi-square and independent t-tests, with $p < 0.05$ as significant. **Results:** Bile AK patients were younger (43.3 ± 9.1 vs. 53.7 ± 11.3 years; $p = 0.001$) and more likely to have alcohol-related liver disease (94.1% vs. 73.3%; $p = 0.003$). ACLF was predominant in Bile AK (39.2% vs. 5.0%), while DCLD was more common in Non-Bile AK (90.1%). Bile AK was associated with significantly higher total bilirubin (25.5 ± 8.3 vs. 7.2 ± 8.9 mg/dL), direct bilirubin (17.2 ± 5.7 vs. 4.6 ± 6.2 mg/dL), creatinine (2.83 ± 1.60 vs. 2.42 ± 1.34 mg/dL), INR (2.56 ± 1.60 vs. 1.92 ± 1.39), and MELD scores (36.0 ± 5.9 vs. 24.2 ± 9.2) (all $p < 0.05$). Three-month mortality was significantly higher in Bile AK (72.5% vs. 33.7%; $p < 0.001$), though time to death was similar (1.28 ± 0.86 vs. 1.40 ± 0.84 months; $p = 0.498$). **Conclusion:** BCN is a severe AKI subtype in cirrhosis, linked to greater hepatic dysfunction, higher bilirubin burden, and significantly worse short-term outcomes. Early recognition is critical for risk stratification and targeted management.

2439 | FINERENONE IN THE MANAGEMENT OF PORTAL HYPERTENSION AND ASCITES

Butros Fakhoury[1] Leandro Sierra[2] Eyad Abdulrazzak[3], [1]Virginia Commonwealth University, [2]Cleveland Clinic Foundation, [3]Beth Israel Deaconess Medical Center

Background: Finerenone, is a selective non-steroidal mineralocorticoid receptor antagonist (MRA), with anti-inflammatory and antifibrotic effects that has demonstrated clinical benefits in chronic kidney disease and heart failure. Compared to spironolactone, Finerenone may offer several advantages in patients with cirrhosis, including greater antifibrotic efficacy, improved potency for ascites management, and fewer hormonal side effects due to its high receptor selectivity. This study evaluates the impact of Finerenone versus spironolactone on recurrent ascites, acute kidney injury (AKI), hyperkalemia, and hormonal adverse effects (gynecomastia and erectile dysfunction) in patients with cirrhosis and ascites. **Methods:** This retrospective cohort study used the TriNetX US Collaborative Network to identify adult patients with cirrhosis and ascites who received either finerenone or spironolactone between January 1, 2021, and January 1, 2025. The index date was defined as the first prescription of MRA prescription. Propensity score matching (PSM) was performed based on demographics, comorbidities, ascites- and portal hypertension–related medications, and baseline MELD laboratory values. Outcomes were evaluated from 1 month to 1 year after the index date. Outcomes included recurrent ascites, acute kidney injury, hyperkalemia, and hyperandrogenic side effects (gynecomastia or erectile dysfunction). **Results:** After PSM, 98 patients were included in each group with a median follow-up of 1 year. Finerenone was associated with a lower risk of recurrent ascites compared to spironolactone (18.6% vs. 30.9%; HR 0.48, 95% CI 0.27–0.87; $p = 0.013$). No significant differences were observed in the risks of AKI (32.0% vs. 28.9%; HR 0.93, 95% CI 0.56–1.55; $p = 0.786$), hyperkalemia (32.0% vs. 30.9%; HR 0.89, 95% CI 0.53–1.45; $p = 0.940$), or hyperandrogenic side effects (10.3% vs. 10.3%; HR 1.61, 95% CI 0.47–5.52; $p = 0.362$). **Conclusion:** In this multi-institutional US cohort, finerenone was infrequently used for ascites management in cirrhotic patients. However, after matching, finerenone was associated with a lower risk of recurrent ascites compared to spironolactone, without increased risk of AKI or hyperkalemia. These findings suggest that finerenone may offer a viable alternative for ascites management in cirrhosis patients. Larger prospective studies are warranted to confirm these findings.

Table.1 Baseline Characteristics Before and after propensity score matching

Variable	Before PSM					After PSM
