Background: The prevalence of metabolic dysfunction-associated steatotic liver disease (MASLD) continues to rise in the pediatric population. Murine models indicate that stevia-derived sweeteners, particularly rabaudioside A, may improve hepatic steatosis and inflammation through modulation of adipogenesis and insulin resistance. These pre-clinical findings prompted us to test commercially available stevia-sweetened beverages as a practical dietary intervention for pediatric patients with MASLD. **Methods:** This pilot study evaluated the effects of daily consumption of a commercially available stevia-sweetened beverage in children and adolescents with biopsy proven metabolic dysfunction-associated steatohepatitis (MASH) over an 8-week intervention period. Eligible participants were 10-18 years old with ALT >45 IU/L, BMI >85th percentile, and fat >5% and kPa >2.0 on liver MR elastography. Participants were randomized into three groups: stevia-sweetened beverage consumption, water consumption, or standard of care nutrition counseling (RD). Our primary outcome measure was change in ALT after 8 weeks with secondary outcomes being liver fat and fibrosis measured by MR elastography, anthropomorphic measurements, and additional laboratory markers. Participants tracked beverage intake using sticker charts with weekly phone follow-up to assess adherence, which was defined as completion of at least 80% of the target intervention dose. **Results:** We prospectively randomized 20 patients (8 to the stevia group, 5 to the water group, and 7 to RD counseling). Due to adherence issues, patient drop-out, and missing data, the final data set included 6 participants from the stevia group, 4 from the water group, and 6 from the RD group. Paired t-test analysis demonstrated significant improvement in ALT levels pre- and post-intervention in the water group (–36.5 U/L; $p = 0.044$) but not in the stevia group (3.2 U/L; $p = 0.955$) or RD group (–35U/L; $p = 0.207$). Notably, weight and BMI showed an increase in the stevia group that trended towards significance (weight +1.2kg; $p = 0.051$; BMI +0.4 kg/m2; $p = 0.058$). **Conclusion:** Our findings from this small pilot study are consistent with prior research suggesting that nutrition counseling and water consumption may support improvements in hepatic enzyme levels in pediatric MASLD/MASH. Given the small sample size, larger adequately powered studies are needed to better define the role of stevia-sweetened beverages in MASLD management.

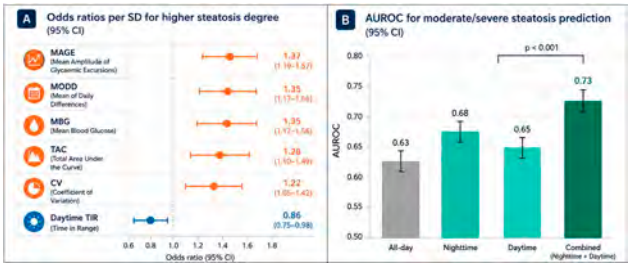
3585 | CONTINUOUS GLUCOSE MONITORING (CGM)-DERIVED GLYCAEMIC VARIABILITY METRICS ARE STRONGLY ASSOCIATED WITH HEPATIC STEATOSIS AND FIBROSIS IN MASLD- AN EVIDENCE REVIEW



Ashok Kumar Choudhury[1] Adhithya Mullath Ullas[2] Mirza Khalid Baig[3] Manoj Kumar Sharma[1] Shiv Kumar Sarin[2] Bishnupriya Sahoo[4] Sanghamitra Pati[5], [1]Institute of Liver and Biliary Sciences, [2]Institute of Liver and Billiary Sciences, [3]National Instiute of Technology, Rourkela, [4]SGT University Gurugram Haryana India, [5]ICMR Delhi

Background: MASLD affects nearly one-third of the global population. Glycaemic dysregulation is central to MASLD pathogenesis, yet hepatology practice relies primarily on static parameters i.e. HbA1c and fasting glucose. Continuous Glucose Monitoring (CGM) becoming the standard of diabetes care and may provide a non-invasive metabolic phenotyping tool to complement existing liver risk stratification like FIB-4 and VCTE. We aimed to synthesise current evidence evaluating associations between CGM-derived glycaemic metrics and hepatic steatosis and fibrosis. **Methods:** A structured emerging-evidence review was conducted of original studies reporting CGM-derived glycaemic metrics alongside validated hepatic endpoints including liver biopsy, MRI-PDFF, VCTE/FibroScan, ultrasound, and FIB-4. Eight eligible studies encompassing over 5,000 participants from type 2 DM and non-diabetic populations with CGM were identified. Liver disease assessment methods included liver biopsy (3 studies, including 2 using Brunt's histological classification), MRI-PDFF (1), VCTE/FibroScan (2), abdominal ultrasound (2), and FIB-4 index (1). Only studies with validated liver endpoints and original CGM or glucose-profiling data were included. **Results:** Across all eight studies, CGM-derived glycaemic variability metrics demonstrated consistent and independent associations with hepatic steatosis and fibrosis. The strongest evidence emerged from MRI-PDFF cohort ($n = 1,180$), where all-day mean amplitude of glycaemic excursions (MAGE) (OR 1.37, 95% CI 1.19–1.57), mean of daily differences (MODD) (OR 1.35, 95% CI 1.17–1.56), and mean blood glucose (OR 1.35, 95% CI 1.17–1.56) were independently associated with hepatic steatosis. Time-stratified analyses identified nighttime MODD as the strongest predictor of steatosis, while a combined nighttime and daytime CGM model achieved superior discrimination (AUROC 0.73) compared with all-day metrics alone (AUROC 0.63; $p < 0.001$). In biopsy-proven MASLD, 24-hour glucose level associated with 2.3-fold higher number of cases with advanced fibrosis ($p = 0.002$), while CGM-derived hyperglycaemia correlated with fibrosis severity

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(r = 0.65, p < 0.05) and identified three-fold more glucose intolerance than conventional testing. CGM uniquely detected postprandial reactive hypoglycaemia in 70% of MASLD patients. Across all studies, conventional glycaemic markers were insufficient to capture the dynamic glycaemic phenotypes most strongly associated with liver disease severity. **Conclusion:** Emerging evidence suggests that CGM-derived glycaemic variability metrics are closely associated with hepatic steatosis and fibrosis severity across MASLD populations. Prospective longitudinal studies are required to determine whether CGM metrics predict disease progression and treatment response in MASLD.

3586 | HEALTH-RELATED QUALITY OF LIFE IN MASLD/MASH TREATED WITH ESSENTIAL PHOSPHOLIPIDS SHOWS IMPROVEMENT IN FATIGUE AND ACTIVITY: CLDQ-MASH RESULTS FROM THE EXCEL RANDOMIZED TRIAL

Zobair Younossi[1] Maria Stepanova[2] Katarzyna Wielgus[3] Branko Popovic[4], [1]The Global NASH/MASH Council, [2]Center for Outcomes Research in Liver Diseases, Washington, District of Columbia, [3]Opella Healthcare, Warsaw, Poland, [4]Opella Healthcare, A. Nattermann & Cie. GmbH, Frankfurt am Main, Germany

Background: MASLD/MASH is associated with substantial impairment in health-related quality of life (HRQoL) and other patient-reported outcomes (PROs). Essential phospholipids (EPL) are widely used as adjunctive therapy in chronic liver diseases; however, their impact on MASH-specific PROs remain unestablished. This study evaluated the effect of adding EPLs to standard of care (SoC) on changes in CLDQ-MASH scores. **Methods:** EXCEL was a Phase 4, multicenter, double-blind, randomized, placebo-controlled study conducted in Germany and Poland (2022-2024). Adults with MASLD and metabolic comorbidities (type 2 diabetes, hyperlipidemia and/or obesity) were randomized 1:1 to EPL + SOC or placebo + SOC for 6 months. PROs were assessed using CLDQ-MASH (total score and 7 domains) at baseline, 3, 6, and 9 months (with 9-month assessment conducted after treatment discontinuation). In CLDQ-MASH, 4 of 7 domains retained a structure similar to CLDQ-NAFLD/NASH, 2 were reorganized and renamed, and 1 new domain (sleep) was added. The digestive symptoms and diet domain highlights MASH-specific burden, while the shared domain structure enables consistent HRQoL assessment and meaningful cross-disease comparisons. Change from baseline scores were analysed by the treatment arm and clinical subgroups. Proportions of HRQoL responders at 6 months (improvement of 0.3 or more on CLDQ-MASH domains) were calculated. **Results:** The modified intention-to-treat population included 165 patients (EPL: n = 82; placebo: n = 83) with comparable baseline characteristics. Across all post-baseline visits, both treatment arms demonstrated statistically significant within-group improvements across most CLDQ-MASH domains (p < 0.05). At 6 months, EPL showed greater improvement vs placebo in the CLDQ-MASH total score (+0.40 vs +0.26; LSMD: 0.14, SE: 0.09; p = 0.097) and the Fatigue domain (+0.55 vs +0.28; LSMD: 0.27, SE: 0.13; p = 0.046). At 9 months, activity scores also improved significantly in EPL group vs placebo (+0.45 vs +0.19; LSMD: 0.26, SE: 0.12; p = 0.038). Other CLDQ-MASH domains remained numerically greater with EPL at 6- and 9-month assessments. The proportion of fatigue responders was higher with EPL (59.8% vs. 44.6%, p = 0.051). Treatment effects were consistent across subgroups (CAP, triglycerides, sex, BMI). EPL treated patients with baseline CAP of at least 288 dB/m showed greater improvement in worry at 6 months vs placebo (LSMD: 0.32 (SE: 0.16), p = 0.049), and among male patients, EPL treatment was associated with greater improvement in fatigue (LSMD: 0.36 (SE: 0.18), p = 0.048). **Conclusion:** EPL added to SoC was associated with consistent, sustained improvements in HRQoL in MASLD/MASH patients, with greater improvements in fatigue and activity domains, suggesting additional benefits beyond SoC.

3587 | CLINICAL EVALUATION OF A ONCE-DAILY POLYHERBAL NUTRACEUTICAL ON LIVER FUNCTION IN HEALTHY ADULTS: A RANDOMIZED, PLACEBO-CONTROLLED STUDY

Benjamin Tillisch[1] Saumin Shah[2] Ghanashyam Patel[3], [1]Dose Daily, [2]Unity Trauma Center, [3]Eetho Brands (DBA: Dose Daily)

Background: Recent data suggest there may be a subclinical drift toward metabolic dysfunction of the liver, even among healthy individuals. This clinical study evaluated the efficacy and safety of a nutraceutical containing organic extracts of turmeric, dandelion, milk thistle, and ginger on liver function parameters in healthy participants. **Methods:** This was a randomized, placebo-controlled study. Healthy adults aged 18-60 years with liver function test values within upper normal limits were randomized 1:1 to receive the nutraceutical or placebo (60 mL) once daily for 90 days. Primary endpoint was change in liver function tests (alanine aminotransaminase [ALT], aspartate aminotransferase [AST], alkaline phosphatase [ALP], gamma-glutamyl transferase [GGT], bilirubin) from baseline to end of treatment (EOT). Safety was also evaluated. Intergroup and intragroup comparisons were analyzed using paired t-tests and analysis of covariance, respectively. **Results:** 108 participants enrolled; 54 randomized to each group. From baseline to EOT, mean levels of ALT, AST, ALP, GGT, and total bilirubin (primary endpoints) were significantly decreased with the nutraceutical ($p < 0.05$ for all) and significantly increased with placebo ($p < 0.05$). Mean improvements from baseline to EOT in each of these parameters was significantly greater with the nutraceutical than placebo ($p < 0.01$ for all). No adverse events were reported. **Conclusion:** Daily single-dose (60 mL) supplementation of this nutraceutical was safe and demonstrated significant improvements in liver function tests in healthy participants. These results suggest that the nutraceutical product may provide meaningful improvements in attenuating the progress of early signs of metabolic liver dysfunction in healthy individuals.

3588 | SINGLE CENTER RETROSPECTIVE EXPERIENCE EVALUATING THE EFFECTS OF BARIATRIC SURGERY ON METABOLIC ASSOCIATED STEATOHEPATITIS WITH FIBROSIS.

Teresa Del Rio Montesinos[1] Asma Siddique[1] Blaire Burman[2], [1]Virginia Mason Medical Center, [2]University of Washington

Background: Hepatic steatosis is now the leading cause of cirrhosis in the United States. The prevalence of metabolic-associated steatoliver disease (MASLD) and metabolic-associated steatohepatitis (MASH) is estimated to affect 25-30% of the population and is expected to double by 2030. Prevalence varies by race, ethnicity, and clinical setting, and due to its asymptomatic nature, MASLD is often underdiagnosed. Complications include fibrosis, cirrhosis, and hepatocellular carcinoma. Lifestyle changes are currently the only established means to prevent or regress the disease, though pharmacological and surgical interventions are available for treating MASH. This study aimed to evaluate the impact of bariatric surgery (gastric bypass and sleeve gastrectomy) on patients with MASH and fibrosis (stage 1 or higher, with stage 4 indicating cirrhosis). Our objectives were to assess the reduction in fibrosis stage or resolution of hepatic fibrosis post-surgery and to emphasize the role of sustained weight loss in decreasing steatohepatitis and fibrosis. **Methods:** Patients(100) were selected based on history of bariatric surgery (sleeve gastrectomy or RYGB), aged 18-65 and documentation of MASH with fibrosis at Virginia Mason Franciscan Health hospital in Seattle, WA. Reviewed MR elastography, liver biopsy and transient elastography prior to surgery with a documentation of fibrosis stage I or above. Patients identified with fibrosis, after the bariatric surgery a repeat MR elastography or transient elastography was done to assess the fibrosis score. Fibrosis score improved at least one stage or resolved completely. **Results:** Results showed 34 patients had MASH cirrhosis at different fibrosis stages all above F1. Out of the 34 patients, 52.9 % (18 patients) of patients had an improvement in fibrosis. Our findings show that bariatric surgery significantly improved hepatic fibrosis. On average, patients needed to lose 78 lbs within the first 9-12 months to observe a decrease in fibrosis stage. Notably, patients with compensated cirrhosis (stage 4 fibrosis) showed regression, with some reducing by two stages to no fibrosis. **Conclusion:** Even though bariatric surgery has proven to be one of the only therapies available to effectively reduce the fibrosis stage and even lead to complete resolution of liver fibrosis for patients suffering from fibrosis secondary to MASH, it does have significant complications and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

is considered an invasive procedure. Weight loss is not always maintained and, in many cases, patients regain the weight they had lost prior to surgery. Again, lifestyle changes; diet, exercise, and education of healthy habits the continued treatment even after surgery. While the primary treatment and prevention option is still lifestyle changes, bariatric surgery is a good resource to help improve fibrosis due to MASH.

3589 | INTEGRATING A PHYSICAL ACTIVITY PLAYBOOK INTO MULTIDISCIPLINARY MASLD CARE INCREASES PHYSICAL ACTIVITY OVER 6 MONTHS

Hannah Mohr[1] Breianna Hummer-Bair[2] Kofi Clarke[3] Britney Fitzgerald[3] Samantha Garcia[3] Karen Krok[4] Heather Tressler[3] Nataliya Smith[5] Kyra VanKirk[6] Jonathan Stine[1], [1]Penn State College of Medicine, [2]Pennsylvania State University, [3]Division of Gastroenterology & Hepatology, Penn State Health Milton S. Hershey Medical Center, [4]Penn State Milton S. Hershey Medical Center, [5]Pennsylvania State University, College of Medicine, [6]College of Medicine, Penn State Health Milton S. Hershey Medical Center, Hershey PA, USA

Background: Lifestyle intervention in metabolic dysfunction-associated steatotic liver disease (MASLD) requires scalable physical activity (PA) assessment and behavior support. However, clinics often lack standardized workflows. We aimed to determine if implementation of a standardized workflow that embeds screening, brief intervention and referral to treatment can help adults with at-risk MASH increase weekly moderate-to-vigorous PA. **Methods:** Using the Screening, Brief Intervention, and Referral (SBIRT) framework, we developed and implemented the MASLD Physical Activity Playbook in a multidisciplinary MASLD clinic. The playbook includes three questionnaires (American College of Sports Medicine (ACSM) Physical Activity Vital Sign, MASLD Barriers to Exercise Survey, Duke Activity Status Index) to assess current PA level, PA barriers and facilitators and functional capacity followed by education with the ACSM MASLD PA handout. In some cases, the Playbook was coupled with a personalized exercise prescription. Change in moderate-to-vigorous PA was measured six months after implementation. **Results:** A total of n = 29 adults with at-risk MASH were included (mean age 58 years, 55% female, mean BMI 34.8 kg/m$^{2)}$. At baseline, 56% of patients had a fibrosis level of F2 or greater as measured by Vibration Controlled Elastography (FibroScan). At baseline, mean PAVS was 101.6 min/week (± 124 min/week) of moderate-to-vigorous PA. At 6-month follow-up, mean PAVS increased to 223 min/wk (mean change +122.1 min/wk, p = 0.011). The proportion of patients meeting ACSM PA guidelines increased from 24.1% to 41.3%, though this did not reach statistical significance (p = 0.07). Exercise barriers decreased and functional capacity (DASI) increased after intervention, though neither reached statistical significance. Exploratory outcomes including weight, aspartate aminotransferase (AST), alanine aminotransferase (ALT), hemoglobin A1c (HbA1c), and Fibrosis-4 scores (FIB-4) show decreasing trends but did not reach statistical significance at this sample size. **Conclusion:** A brief, standardized PA Playbook integrating screening, education, and individualized exercise prescription, where necessary, can be feasibly implemented into routine MASLD care and is associated with a significant increase in moderate-to-vigorous PA at 6 months. These findings support further implementation and evaluation of the PA playbook within MASLD care settings to confirm efficacy and assess impact on hepatic outcomes.

Figure 1: Exposure to PA Playbook leads to a meaningful increase in physical activity in those with MASLD/MASH

3590 | MANAGING MASH AND CARDIOMETABOLIC COMORBIDITIES: THE IMPLICATIONS OF SPECIALTY-NUANCED TREATMENT DECISIONS

Lizy Gill[1] Ramya Logendra[1] Ayse Levent[1] Rhoda Schmuecking[1], [1]Ipsos

Background: Metabolic dysfunction-associated steatohepatitis (MASH) and associated cardiometabolic conditions are major causes of morbidity and mortality. The care pathway for MASH patients involves a multidisciplinary approach that often results in referrals and complex diagnostic and treatment processes, driven by comorbidities. **Methods:** Data are from the Ipsos Syndicated MASH Therapy Monitor, an online medical chart review and physician perceptual study including 646 physicians in the US (212), Germany (170), Japan (114) and China (150) treating MASH patients, collected between Feb-Apr 2026. Participants consisted of primary care physicians (PCPs), diabetologists/endocrinologists and gastroenterologists/hepatologists and were screened for caseload. Physicians reported on 2450 MASH patients in the US (727), Germany (551), Japan (422) and China (750) seen in the last 3 months. **Results:** When aggregating regional data, cardiometabolic conditions have a strong influence on MASH treatment decisions for hepatologists, endocrinologists and PCPs. Across these specialties, over 81% of MASH treatment decisions are reported to be strongly influenced by Type 2 Diabetes (T2D), >61% by hypertension, and >71% by dyslipidemia/hyperlipidemia/hypercholesterolemia. In contrast, gastroenterologists specialising in both liver and non-liver conditions report lower influence rates; T2D 67%, hypertension 39%, dyslipidemia 45%.This divergence extends beyond comorbidity influence on MASH treatment management, to physicians' prioritisation of conditions treated. While most gastroenterologists do manage MASH and cardiometabolic conditions concurrently, a subset prioritise managing MASH *over* the cardiometabolic conditions. Specifically, 16% of gastroenterologists prioritise managing MASH over T2D, compared to only 5-6% among other specialties. For hypertension, 22% prioritise MASH management over hypertension, versus ≤10% in other specialties. **Conclusion:** This specialty-based fragmentation suggests there's a divergence in MASH patient care; that gastroenterologists appear to be taking a more liver-specific approach while hepatologists, endocrinologists and PCPs are treating more holistically along with MASH. By prioritising MASH over cardiometabolic conditions, this liver-centric approach taken by gastroenterologists may potentially limit the benefits of addressing comorbidities on disease progression. Ultimately, this specialty-based fragmentation may compromise optimal patient outcomes and suggests the need for standardised, multidisciplinary approaches to MASH care that balance hepatic and metabolic therapeutic targets.

3591 | MULTIDISCIPLINARY CARE SIGNIFICANTLY IMPROVES WEIGHT LOSS OUTCOMES IN MASLD COMPARED TO STANDARD HEPATOLOGY CARE: A REAL-WORLD COHORT STUDY

Tolga Gidener[1] Saumya Srivastava[2] Lisa Yanek[3] Tyrus Vong[4] Victor Arahirwa[5] Alexandra Strauss[1] Arunkumar Krishnan[6] Selvi Rajagopal[7] Yuval Pinto[7] James Hamilton[8] Tinsay Woreta[9], [1]Division of Gastroenterology and Hepatology, Johns Hopkins University School of Medicine, Baltimore, [2]Section of Digestive Diseases, Yale School of Medicine, New Haven, CT, USA, [3]Division of General Internal Medicine, Department of Medicine, Johns Hopkins University School of Me, [4]Division of Gastroenterology and Hepatology, Johns Hopkins University School of Medicine, Baltimore., [5]Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA, [6]Department of Medicine, Wake Forest University School of Medicine, Charlotte, North Carolina, USA, [7]Division of General Internal Medicine, Johns Hopkins University School of Medicine, [8]Johns Hopkins University, [9]Johns Hopkins University School of Medicine

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: The 2023 AASLD Practice Guidance recommends a multidisciplinary approach for the management of MASLD. However, data comparing outcomes between multidisciplinary and standard hepatology care remains limited. In June 2020, our institution established the Healthful Eating, Activity and Weight Program (HEAWP), a multidisciplinary clinic staffed by obesity medicine physicians, hepatologists, an endocrinologist, and bariatric surgeons, with psychology and nutrition collaboration. Patients undergo evaluation with an obesity medicine physician assessing nutrition, sleep, mood, medications, and physical activity in addition to Hepatology evaluation. Individualized goals are established, with frequent follow-up for support with behavior change and treatment. We aimed to evaluate the impact of this multidisciplinary clinic on clinical outcomes in patients with MASLD. **Methods:** Adults with MASLD seen in the HEAWP vs. standard hepatology clinics between 2020-2025 were identified using our liver disease Precision Medicine Analytics Platform. Baseline characteristics were compared between groups using Chi-squared or Fisher's exact tests and student's t-tests or Wilcoxon tests. Changes in weight, ALT, and liver stiffness measurement (LSM) by transient elastography (TE) were assessed using paired Wilcoxon tests. Multivariable regression models assessed changes in weight adjusted for GLP-1 receptor agonist use. **Results:** 103 patients with MASLD were identified in the HEAWP clinic cohort, and 1,050 patients in the standard hepatology cohort. Compared to the hepatology cohort, patients in the HEAWP cohort were more likely to be prescribed semaglutide (43% vs 25%) and tirzepatide (31% vs 17%). At 12 months, patients in the HEAWP cohort had substantially greater weight loss compared to those receiving standard hepatology care (-5.61 kg vs. -0.6 kg; $p = 0.02$). The mean percent body weight reduction in the HEAWP cohort reached –6.1% at 12 months, compared to only -0.7% in the standard hepatology cohort. After adjustment for usage of GLP-1 medications, the difference in weight loss at 12 months (-4.5 kg [95% CI -7.98, -1.04]) remained statistically significant between the two cohorts. Change in ALT and LSM by TE did not significantly differ between cohorts, likely due to small sample sizes. **Conclusion:** In this real-world comparison of multidisciplinary versus standard hepatology care for MASLD, patients managed in a multidisciplinary clinic achieved substantially greater weight loss, even after adjustment for GLP-1 receptor agonist use. Our findings highlight the promise of multidisciplinary care models for achieving clinically meaningful weight loss in patients with MASLD. In our model, hepatologists collaborating with obesity medicine physicians who provided comprehensive, individualized care led to significant weight loss benefits beyond pharmacotherapy alone.

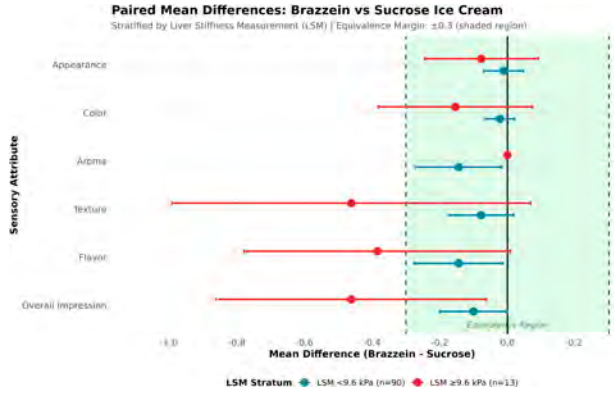
3592 | BRAZZEIN-SWEETENED ICE CREAM SHOWS HIGH ACCEPTANCE IN MASLD PATIENTS ACROSS LIVER FIBROSIS SEVERITY



Vasily Isakov[1] Alexei Goncharov[2] Armida Sasunova[2], [1]Federal Research Center of Nutrition and Biotechnology, [2]Federal Research Center of Nutrition, Biotechnology & Food Safety

Background: Sugar reduction is a key dietary target in metabolic dysfunction-associated steatotic liver disease (MASLD), but acceptable sugar-reduced foods are needed to support adherence. Brazzein is an intensely sweet natural protein with potential for sugar replacement, but sensory data in clinically characterized MASLD patients, including those with significant liver fibrosis, are limited. **Methods:** In a double-blind, randomized, two-period crossover sensory study, 103 adults with MASLD evaluated iso-sweet vanilla ice cream sweetened with brazzein or sucrose. Overall impression and sensory attributes, including appearance, color, aroma, taste, and texture, were rated on 5-point hedonic scales. Consumption of each 100 g portion was measured. Liver fibrosis was assessed by vibration-controlled transient elastography. Exploratory analyses compared sensory responses by liver stiffness measurement (LSM), with LSM ≥ 9.6 kPa used to define advanced fibrosis. **Results:** Fourteen participants had F3/F4 fibrosis. Overall acceptance was very high for both products: 96.1% for brazzein and 98.1% for sucrose. Mean portion consumption was also high and did not differ significantly between formulations: 98.01% for brazzein vs 99.61% for sucrose; mean difference −1.60% (95% CI −3.64 to 0.44; $p = 0.122$). Liver stiffness was the only significant predictor of consumption, with each 1 kPa increase in LSM associated with a 0.81% lower intake ($\beta = -0.812$; 95% CI −1.432 to −0.193; $p = 0.012$). In exploratory interaction analysis, the effect of sweetener on overall

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

impression varied by LSM category (LR $\chi^2 = 12.26$; $p = 0.002$). In participants with LSM < 9.6 kPa, paired mean differences for all sensory attributes remained within the prespecified ±0.3 practical-equivalence margin. In contrast, among participants with LSM ≥ 9.6 kPa, confidence intervals were wider and several attributes extended beyond this margin, including texture, taste, and overall impression, with mean differences numerically favoring sucrose. Nevertheless, acceptance remained >95% across LSM strata. **Conclusion:** Brazzein-sweetened ice cream showed very high short-term acceptability and near-complete consumption in MASLD patients. Patients with higher liver stiffness consumed slightly less ice cream overall and showed greater uncertainty in sensory equivalence, but acceptance remained high. These findings support further evaluation of brazzein-containing sugar-reduced foods in MASLD, including adequately powered studies in patients with advanced fibrosis.

3593 | NUTRITIONAL STRATEGIES IN MASLD: A SCOPING REVIEW

Pranav Ramamurthy[1] Tejashree Rajhans[2], [1]University of Massachusetts Chan Medical School, [2]N/A

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects over 30% of adults globally and is now the leading indication for liver transplantation. Nutrition remains foundational to management, even in the wake of pharmacologic advances such as resmetirom and incretin-based therapies. However, substantial heterogeneity exists in guideline recommendations and real-world effectiveness remains limited by poor adherence and lack of standardized protocols. **Methods:** We conducted a comprehensive review of randomized controlled trials, systematic reviews, and international guidelines (EASL-EASD-EASO 2024, AASLD 2023, AACE/AASLD 2022) to evaluate dietary interventions for MASLD. Outcomes included histologic improvement, non-invasive biomarker changes, weight loss and cardiometabolic parameters. **Results:** Weight loss targets are consistent across guidelines: ≥5% reduces steatosis, ≥7%-10% improves MASH, and ≥10% promotes fibrosis regression. However, fewer than 10% of patients maintain ≥10% loss at five years.Among dietary patterns, the Mediterranean diet demonstrates the most robust evidence. A 2025 network meta-analysis of 37 RCTs confirmed significant reductions in body weight (-2.4 kg), BMI (-0.7 kg/m²), waist circumference (-1.6 cm), and ALT (-4.0 IU/L) versus control, with effects amplifying with caloric restriction. Time-restricted feeding (16:8 or 5:2 protocols) shows promise for insulin sensitivity and hepatic fat reduction, potentially independent of weight loss, though histologic data are absent. Low-carbohydrate and ketogenic diets achieve rapid steatosis reduction but raise concerns regarding sustainability, LDL elevation and safety in cirrhosis.Plant-based proteins confer metabolic advantages through favorable gut microbiome effects and reduced trimethylamine N-oxide generation, while processed red meats exacerbate inflammation and iron dysregulation. Coffee consumption (≥3 cups/day) is associated with improved liver-related outcomes.Critical evidence gaps include: (1) no dietary approach has demonstrated superiority for fibrosis regression in adequately powered trials with histologic endpoints; (2) adherence rates fall below 50% beyond 12 months; (3) pediatric and lean MASLD populations remain understudied; (4) social determinants of nutrition access receive insufficient guideline attention; (5) optimal integration with pharmacotherapy (resmetirom, GLP-1 RAs) is undefined. **Conclusion:** Nutrition interventions for MASLD require personalization beyond macronutrient ratios to incorporate eating patterns, timing, protein quality and behavioral support. Future research must prioritize durable adherence strategies and integration with emerging pharmacotherapy. Multidisciplinary delivery incorporating registered dietitians, behavioral therapists and digital health tools represents the optimal implementation framework.

3594 | LIFESTYLE MODIFICATION IN EARLY NON-ALCOHOLIC FATTY LIVER DISEASE: A META-ANALYSIS AND SUBGROUP COMPARISON OF EXERCISE AND DIET INTERVENTIONS

Chanpreet SIngh[1] Prince Shah-Riar[2] Nimish Thakral[3] Asif Zamir[4] Theodore Pettle[1] Valeska Balderas[1] Bipneet Singh[5], [1]South Texas Health System-Universal Health Services, [2]DHR Health, [3]University of Kentucky Medical Center, [4]DHR Hospital, [5]Univeristy of Ketuncky

Background: Non-alcoholic fatty liver disease (NAFLD) is the most prevalent chronic liver disease globally and a growing public health burden. In the absence of approved pharmacologic therapies, structured lifestyle interventions are the cornerstone of management. This meta-analysis evaluates the effectiveness of physical exercise and dietary modification in reversing key clinical and biochemical markers of early-stage NAFLD, with a subgroup analysis comparing their differential impacts. **Methods:** A systematic search of PubMed, ScienceDirect, Cochrane Library, ClinicalTrials.gov, Google Scholar, and PLOS ONE was conducted. Fourteen randomized controlled trials (RCTs) involving adult patients with NAFLD were included. Interventions consisted of either structured physical exercise or a controlled diet, compared to usual care. Primary outcomes included liver enzymes [AST, ALT], insulin resistance (HOMA-IR), and body mass index (BMI). Results were pooled using mean differences (MD) with 95% confidence intervals (CI). Subgroup analysis was performed to evaluate biomarker-specific effects by intervention type. **Results: Exercise Subgroup:** Significantly reduced AST (MD: -4.48; CI: -4.82 to -4.14), ALT (MD: -5.43; CI: -5.91 to -4.94), HOMA-IR (MD: -0.29; CI: -0.35 to -0.23), and BMI (MD: -0.66; CI: -0.74 to -0.58). **Diet Subgroup:** Reduced AST (MD: -4.28; CI: -5.09 to -3.48), ALT (MD: -5.04; CI: -5.91 to -4.16), and BMI (MD: -0.76; CI: -0.81 to -0.70), but did not significantly affect HOMA-IR (MD: -0.08; CI: -0.17 to 0.01). Both interventions improved overall quality of life and physical fitness. **SubgroupAnalysis:** As illustrated in Figure 1 and Figure 2, exercise uniquely improved insulin resistance, while both interventions demonstrated comparable benefits in liver enzymes and BMI. These findings suggest distinct metabolic advantages of exercise in NAFLD reversal. **Conclusion:** Structured exercise and dietary interventions significantly improve metabolic and hepatic outcomes in early NAFLD. Exercise appears to offer broader benefits, particularly in insulin sensitivity, supporting its prioritization in personalized lifestyle protocols. These findings may inform updated NAFLD guidelines and support integration of structured exercise into first-line management.

3595 | WITH NO LYSINE KINASE 1 (WNK1) FORMS CONDENSATES WITH GLYCOLYTIC TRIOSEPHOSPHATE ISOMERASE 1 (TPI1) IN HEPATIC STELLATE CELLS TO PROMOTE MOUSE AND HUMAN LIVER FIBROSIS

Zeba Firdaus[1] Alexander Washington[1] Jasper Solverson[1] Luke Doskey[1] Vijay Shah[2] Patrick Starlinger[1] Gina Razidlo[1] Matthew Schellenberg[1] Enis Kostallari[2], [1]Mayo Clinic, [2]Mayo Clinic Rochester

Background: Platelet-derived growth factor B (PDGF)-mediated hepatic stellate cell (HSC) activation is a hallmark of liver fibrosis. HSC activation is accompanied by increased glycolysis to meet high energy demands. However, the signaling leading to this metabolic shift, subsequent HSC activation, and liver fibrosis remains unclear and is the focus of this study. **Methods:** Primary human HSCs and mouse liver tissues were analyzed by chemical genetics, western blot, or immunofluorescence. Liver fibrosis was induced by carbon tetrachloride (CCl_4) or high-fat, choline-deficient, amino acid-defined (HF-CDAA) diet. Human precision-cut liver slices (PCLS) were obtained from patient liver resections. **Results:** We identified with no lysine kinase 1 (WNK1) as a new kinase promoting HSC proliferation and migration (TLM 2025). Chemical genetics, a method we described to identify direct substrates of kinases (TLM 2025), detected triose phosphate isomerase 1 (TPI1), a glycolytic enzyme, as a novel WNK1 substrate. PDGF increased the formation of WNK1 condensates (3-fold, $n = 3$, $p < 0.05$), a liquid-liquid phase separation entity. PDGF also enhanced the TPI1-WNK1 co-localization in these condensates (4-fold, $n = 3$, $p < 0.05$). Functionally, TPI1 knockdown reduced PDGF-mediated glucose consumption (4-fold, $n = 4$, $p < 0.05$), HSC proliferation (EdU incorporation, 3-fold, $n = 3$, $p < 0.05$) and migration (transwell assay, 2.3-fold, $n = 3$, $p < 0.05$). Condensate inhibition using 1,6-hexanediol reduced HSC proliferation (3-fold, $n = 3$, $p < 0.05$) and migration (2.3-fold, $n = 3$, $p < 0.05$). These results suggest that WNK1-TPI1 interaction in condensates contributes to HSC activation. *In vivo*, HSC-specific WNK1 deletion in *Wnk1*$^{\Delta HSC}$ mice reduced liver fibrosis compared to *Wnk1*$^{fl/fl}$ controls as evidenced by Sirius-red staining, collagen 1 (COL1), COL3, and α-smooth muscle actin protein levels, both in CCl_4 (4-fold, 2.8-fold, 3-fold, and 5-fold, respectively, $n = 5$ mice/group, $p < 0.05$) and HF-CDAA diet (4-fold, 3-fold, 4-fold, and 2-fold, respectively, $n = 3$-5 mice/group, $p < 0.05$) models. Finally, activated phospho-WNK1 increased 5-fold in human cirrhotic liver tissues compared to healthy controls ($n = 3$, $p < 0.05$) and WNK1 pharmacological inhibition reduced COL1 expression (3-fold, $n = 3$, $p < 0.05$) in human cirrhotic PCLS. **Conclusion:** Together, these results identify WNK1-TPI1 axis as a novel mechanism promoting liver fibrosis in mouse and human liver tissues, that can be pharmacologically targeted.

Background: Over the past 2 decades, alcohol consumption in the United States has increased considerably. Previous work demonstrated that alcohol-associated liver disease (ALD) mortality increased from 2017 to 2020 and accelerated during the COVID-19 pandemic. However, it is unclear how these trends have evolved following the pandemic. We aimed to examine ALD-related mortality in the United States from 2014 to 2024. **Methods:** Using national data from the Centers for Disease Control and Prevention, we examined ALD-related mortality rates from 2014 to 2024. ALD-related deaths were defined as the presence of an ICD-10 code for ALD (K70) listed as the underlying cause of death. We determined the annual age-adjusted mortality rates stratified by sex and race/ethnicity and crude age-cohort mortality rates stratified by sex. We performed a Joinpoint analysis to examine annual percent change (APC) and average annual percent change (AAPC) in ALD mortality, stratified by sex. **Results:** ALD mortality rates increased from 2014-2024 with an AAPC of 3.46 (1.72-5.68; $p < 0.01$) and a significant change-point identified in 2021. From 2014 to 2021, ALD mortality increased nearly every year across age, sex, and race/ethnicity. Mortality was highest among American Indian, Hispanic, and White individuals and ages 55 to 64 years. From 2014-2021, the overall APC was 7.04 (5.02-14.2; $p < 0.01$). By sex, the 2014-2021 APC was 6.40 (4.36-14.36; $p < 0.01$) among males and 8.25 (6.24-12.86; $p = 0$) among females. ALD mortality peaked in 2021 with age-adjusted rates of 18.70 per 100,000 (95% CI 18.45-18.95) among males and 8.55 per 100,000 (95% CI 8.39-8.73) among females. While there was no significant trend in AAPC or APC following 2021, there was a relative decrease in ALD mortality rates observed among both sexes. The overall AAPC 2020-2024 was -1.68 (1.98-0.34; $p = 0.34$); -2.2 (-6.82-1.58; $p = 0.22$) among males and -0.76 (-4.13-2.43; $p = 0.66$) among females. The overall APC 2021-2024 was -4.42 (-14.16-1.83; $p = 0.16$); -4.91 (-15.81-1.48; $p = 0.12$) among males and -3.59 (-12.2-2.04; $p = 0.23$) among females. Furthermore, from 2021 to 2024, ALD mortality decreased nearly every year across age and race/ethnicity. **Conclusion:** ALD mortality steadily rose from 2014-2019 and experienced a significant acceleration during the COVID-19 pandemic. However, one year following the onset of the pandemic, ALD mortality peaked. From 2021, a non-significant trend towards a decline in ALD mortality was observed across sexes and nearly all ages and races/ethnicities.

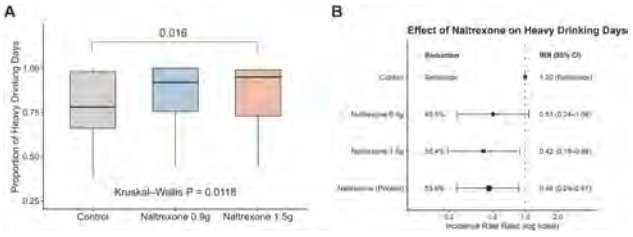
3597 | EFFICACY AND SAFETY OF NALTREXONE IMPLANT IN PATIENTS WITH MILD ALCOHOL-ASSOCIATED LIVER DISEASE: A POST HOC SUBGROUP ANALYSIS OF A MULTICENTER, RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED PHASE II TRIAL



Yi-Zhou Jiang[1], [1]China-Japan Friendship Hospital

Background: Naltrexone is an established pharmacological therapy for alcohol use disorder (AUD); however, evidence in patients with alcohol-associated liver disease (ALD), particularly those with early-stage disease, remains limited. Long-acting formulations may improve adherence and treatment outcomes, but data on implantable naltrexone in this population are lacking. We aimed to evaluate the efficacy and safety of naltrexone implant in patients with mild ALD. **Methods:** This study represents a post hoc subgroup analysis of a multicenter, randomized, double-blind, placebo-controlled phase II trial (ClinicalTrials.gov identifier: NCT07014644). Adult patients with AUD who met predefined criteria for mild ALD at baseline were included. Participants were randomized to receive

naltrexone implant (0.9 g or 1.5 g) or placebo and followed for 24 weeks. The primary endpoint was the proportion of heavy drinking days (PHDD). Secondary endpoints included abstinence-related outcomes and breath alcohol concentration. Safety was assessed by treatment-emergent adverse events. **Results:** Among 149 participants with mild ALD, naltrexone implant was associated with a significant reduction in PHDD at week 24, with the greatest effect observed in the 1.5 g group. In regression analyses, naltrexone treatment was associated with a clinically meaningful reduction in the incidence rate of heavy drinking days compared with placebo. Secondary outcomes showed consistent trends favoring naltrexone but did not reach statistical significance. Breath alcohol concentration analyses suggested that the treatment effect was more pronounced early after implantation and attenuated over time. Naltrexone implant was generally well tolerated, with no increase in serious adverse events or evidence of hepatotoxicity. **Conclusion:** In this post hoc subgroup analysis, naltrexone implant was associated with reduced heavy drinking and demonstrated an acceptable safety profile in patients with mild ALD. These findings support the potential role of implantable naltrexone as a novel adherence-optimizing strategy in early-stage ALD and warrant confirmation in prospective, adequately powered studies.

3598 | INOSITOL HEXAPHOSPHATE PROTECTS AGAINST METABOLIC ASSOCIATED STEATOHEPATITIS IN MICE VIA THE PI3K/AKT/PLA2G2A SIGNALING PATHWAY

Zhao Chen[1] Huiying Rao[1], [1]Peking University Hepatology Institute

Background: Recently, inositol hexakisphosphate (Phytic acid, IP6), primarily extracted from plants, possess anti-oxidative and anti-tumor effects. However, whether it can alleviate MASH remains unclear. This study aimed to explore the preventive and therapeutic effects and mechanisms of IP6 on MASH phenotypes and the alteration of metabolomics and transcriptomic profiles in MASH mice. **Methods:** A western diet combined with low doses of CCl4 (WD/CCl4) was used to induce MASH in mice and evaluate the protective effects of IP6. Additionally, the effects of IP6 and in vitro using free fatty acid (FFA)-treated HepG2 cells and activated hepatic stellate cells were investigated. Assessments of transcriptomics, metabolomics, and lipidomics analyses were conducted to explore potential molecular mechanisms. Furthermore, the involvement of the PI3K/Akt/PLA2G2A signaling pathway was examined through in vivo and in vitro experiments, including molecular docking, PLA2G2A overexpression assays, and measurements of key fibrotic markers (α-SMA and COL-1) and lipid accumulation. **Results:** The results showed that pretreatment with IP6 significantly reduced obesity, fibrosis and lipid accumulation, alleviated insulin resistance, and prevented hyperglycemia in MASH mice. IP6 also alleviated free fatty acid (FFA)-induced lipid accumulation in HepG2 cells. Transcriptomics analysis of the liver revealed that IP6 reversed MASH-related transcriptomic changes, suppressing the expression of pro-fibrotic, pro-inflammatory, and lipid-metabolic genes. Integrated metabolomics and lipidomics revealed that the preventive effect of IP6 against MASH was mediated through the rectification of disordered glycerophospholipid metabolism. Mechanistically, both in vivo and in vitro experiments showed that IP6 inhibited MASH-induced elevation of PI3K and Akt phosphorylation. Molecular docking suggested a strong binding affinity between AKT and PLA2G2A. Importantly, in vitro overexpression of PLA2G2A completely abolished IP6-mediated inhibition of lipid accumulation and the expression of key fibrotic markers (α-SMA and COL-1). Collectively, these findings indicate that IP6 modulates glycerophospholipid metabolism through the PI3K/Akt/PLA2G2A signaling pathway in MASH. **Conclusion:** Our findings demonstrate that IP6 protects against MASH by inhibiting the PI3K/Akt signaling pathway, thereby downregulating PLA2G2A expression and improving glycerophospholipid homeostasis in hepatocytes, which provides novel insights into MASH treatment.

4001 | ◆ PREDICTORS OF FUNCTIONAL CURE AMONG PATIENTS WITH LOW HBSAG LEVELS: RESULTS OF THE SIGNAL STUDY

Sanam Tabataba Vakili[1] Grishma Hirode[2] Andrew Mendlowitz[2] Leila Amiri[1] Aaron Vanderhoff[2] Saima Naim[1] Adam Gehring[3] Scott Fung[3] Jordan Feld[4], [1]Toronto Centre for Liver Disease, University Health Network, Canada, [2]Toronto Centre for Liver Disease, University Health Network, Canada;Viral Hepatitis Care Network,UHN, [3]University Health Network, [4]Toronto General Hospital

Background: Lower hepatitis B surface antigen (HBsAg) levels are a well-established predictor of higher rates of functional cure, defined as HBsAg loss. However, whether there are additional predictors among chronic hepatitis B (CHB) patients with already low HBsAg levels remains unknown. We aimed to examine factors associated with HBsAg loss among patients with low HBsAg levels and HBV DNA below treatment thresholds. **Methods:** Cohort study of CHB patients with ≥1 qHBsAg measurement ≥0.05 IU/mL between 2010-2022. We compared characteristics of patients with and without HBsAg loss in the total cohort at the first qHBsAg measurement (baseline), and in subgroups who had ≥1 instance of HBsAg ≤10 and ≤100 IU/mL with HBV DNA ≤1000 IU/mL at first occurrence, regardless of duration in that state, treatment or phase of infection. Cumulative incidence and factors associated with HBsAg loss were analyzed using survival analysis methods. **Results:** Among the total cohort of 8239 patients (mean age 48 years, HBsAg 2.6 $\log_{10}$ IU/mL, HBV DNA 3.4 $\log_{10}$ IU/mL, median ALT 29 U/L, 56% male, 81% Asian, 76% HBeAg-neg, 7% cirrhosis), 558 had HBsAg loss with a 5-year cumulative probability of 3.3% over a mean follow-up of 6.1 years. Among the subgroup of 2230 patients with HBsAg ≤100 IU/mL and HBV DNA ≤1000 IU/mL (mean age 54 years, HBsAg 1.1 $\log_{10}$ IU/mL, HBV DNA 1.5 $\log_{10}$ IU/mL, median ALT 24 U/L, 64% male, 83% Asian, 90% HBeAg-neg, 13% cirrhosis), 522 had HBsAg loss with a 5-year cumulative probability of 19% over a mean follow-up of 7.4 years. Asian race (aHR 0.7) and presence of cirrhosis (aHR 0.7) were associated with lower rates of HBsAg loss ($p < 0.05$). Among the subgroup of 1288 patients with HBsAg ≤10 IU/mL and HBV DNA ≤1000 IU/mL (mean age 54 years, HBsAg 0.1 $\log_{10}$ IU/mL, HBV DNA 1.5 $\log_{10}$ IU/mL, median ALT 23 U/L, 63% male, 81% Asian, 92% HBeAg-neg, 11% cirrhosis), 516 had HBsAg loss with a 5-year cumulative probability of 40% over a mean follow-up of 7.3 years. After achieving this state, no factors remained significant on adjusted regression. **Conclusion:** Our results highlight that in addition to HBsAg levels, race and cirrhosis status are important predictors of HBsAg loss among patients who achieve HBsAg ≤100 IU/mL and HBV DNA ≤1000 IU/mL even once. Once HBsAg levels fall below 10 IU/mL, the probability of HBsAg loss is high enough that no clinical factors further predict clearance. These factors can help prioritize patients for curative treatment regimens.

4002 | SUSTAINED DECLINE OF SERUM QHBSAG DURING LONG-TERM NUCLEOS(T)IDE ANALOGS THERAPY IN CHRONIC HEPATITIS B: A 7-YEAR TRAJECTORY ANALYSIS

Shuyan Chen[1] Siru Zhao[2] Tongtong Meng[1] Xinyu Zhao[1] Xiaoqian Xu[1] Xiaoning Wu[1] Jialing Zhou[1] Xinyan Zhao[1] Xiaojuan Ou[1] Jidong Jia[1] Zhizhen Hu[3] Yameng Sun[1] Rong Fan[2] Hong You[1], [1]Beijing Friendship Hospital, Capital Medical University, [2]Department of Infectious Diseases, Nanfang Hospital, Southern Medical University, [3]Hansoh Pharmaceutical Group Co, Ltd, Shanghai, China

Background: Quantitative hepatitis B surface antigen (qHBsAg) is the critical predictor of functional cure in chronic hepatitis B (CHB). However, the long-term dynamics of qHBsAg during nucleos(t)ide analogues (NUCs) therapy, particularly in treatment-naïve patients, remain unclear. This study aimed to elucidate the longitudinal trajectory of serum qHBsAg in treatment-naïve CHB patients undergoing 7 years of NUCs monotherapy. **Methods:** Treatment-naïve CHB patients who initiated NUCs monotherapy treatment were enrolled from three different cohorts. Baseline and serial on-treatment qHBsAg levels were prospectively collected over 7 years of continuous antiviral therapy. **Results:** A total of 1465 CHB patients with longitudinal qHBsAg data over 7 years of antiviral therapy were included. The cohort was predominantly male (75%), with a mean age of 42 years. At baseline, 53.0% (n = 777) were HBeAg-positive, 48.1% (n = 705) had cirrhosis, and the median qHBsAg level was 1993.0 IU/mL at baseline. In patients with baseline qHBsAg > 3000 IU/mL (n = 532, 36.3%), the median qHBsAg level declined from 6233.6 IU/mL to 3154.9 IU/mL during the first year, followed by a further decrease from 2971.1 IU/mL to 1509.5 IU/mL over the subsequent 6 years. The probability of achieving qHBsAg ≤ 3000 IU/mL was 22.7% at year 1, rising gradually to 64.2% by year 7. In patients with baseline qHBsAg ≥ 1000 ~ 3000 IU/mL (n = 483, 33.0%) and ≥ 100 ~ 1000 IU/mL (n = 376, 25.6%), median levels decreased from 1828.6 IU/mL (baseline) to 639.10 IU/mL (year 7), and from 468.9 IU/mL (baseline) to 229.0 IU/mL (year 7), respectively. These longitudinal qHBsAg trajectories were consistent regardless of HBeAg status or cirrhosis. In patients with baseline HBsAg > 3000 IU/mL, multivariable analysis identified detectable HBV DNA at year 2 as an independent factor associated with reduced likelihood of achieving qHBsAg ≤ 3000 IU/mL (HR, 0.611; 95% CI, 0.403-0.925; P = 0.020). **Conclusion:** During 7 years of NUCs monotherapy, serum qHBsAg levels declined progressively in treatment-naïve CHB patients. Notably, those with baseline qHBsAg > 3000 IU/mL exhibited a rapid decline in the first year, followed by a slow but overall declining trend over the next 6 years.

4003 | IMPACT OF METABOLIC AND VIRAL FACTORS ON SIGNIFICANT LIVER FIBROSIS IN TREATMENT-NAÏVE PATIENTS WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE AND CHRONIC HEPATITIS B: A CROSS-SECTIONAL STUDY OF 562 LIVER BIOPSIES

Weihua Cao[1] Yao Xie[1] Minghui Li[1], [1]Beijing Ditan Hospital, Capital Medical University

Background: The coexistence of metabolic dysfunction-associated steatotic liver disease (MASLD) and chronic hepatitis B (CHB) is increasingly recognized, but the independent drivers of significant liver fibrosis in this dual-aetiology population remain unclear, especially in treatment-naïve patients. This study aimed to identify independent metabolic and viral risk factors for significant fibrosis (F ≥ 2) using liver biopsy as the gold standard. **Methods:** A cross-sectional study was conducted on 562 treatment-naïve patients with concurrent MASLD and CHB confirmed by liver biopsy. All patients underwent clinical, laboratory, and transient elastography assessments. Liver fibrosis was staged according to the Metavir system (F0–F4). Significant fibrosis was defined as Metavir F ≥ 2. Univariate and multivariable logistic regression analyses were performed to identify independent risk factors for significant fibrosis. Subgroup analyses were performed by stratifying patients according to HBeAg status (for metabolic factors) and BMI < 25 vs. ≥ 25 kg/m² (for viral factors). Interaction was formally tested using product terms. **Results:** Among the 562 treatment-naïve patients with concurrent MASLD and CHB (mean age 42.53 ± 9.87 years, 72.95% male), 192 (34.2%) had significant liver fibrosis (Metavir F ≥ 2). Compared with patients at F0-1, those with significant fibrosis had significantly higher BMI, higher prevalence of diabetes mellitus and dyslipidemia, lower platelet count, higher LSM value, and a lower proportion of HBeAg positivity (all P < 0.05) in Table 1. Multivariable logistic regression identified that higher BMI (OR = 1.173, 95% CI: 1.082–1.525, P < 0.001), HBeAg negative status (OR for HBeAg positivity = 0.624, 95% CI: 0.421–0.925, P = 0.019), lower platelet count (OR = 0.994, 95% CI: 0.991–0.997, P < 0.001), lower prothrombin time activity (PTA) (OR = 0.979, 95% CI: 0.962–0.996, P = 0.014), and higher liver stiffness measurement (LSM) (OR = 1.344, 95% CI: 1.191–1.516, P < 0.001) were independent risk factors for significant fibrosis, while conventional metabolic and viral parameters such as diabetes, dyslipidemia, HBV DNA, and HBsAg lost their independent significance after adjustment in Table 2. Subgroup analyses showed that the effect of BMI on fibrosis was significant only in HBeAg (-) patients (P for interaction = 0.009) in Table 3, and the effect of HBeAg negative status on fibrosis in Table 4 was significant only in patients with BMI < 25 kg/m² (P for interaction = 0.02), indicating effect modification by HBeAg status and BMI, respectively. **Conclusion:** In treatment-naïve CHB-MASLD patients, high BMI, HBeAg negativity, low PLT, low PTA, and elevated LSM are independent risk factors for significant fibrosis, with metabolic factors and HBeAg negativity driving progression, supporting early risk stratification based on metabolic and virological parameters.

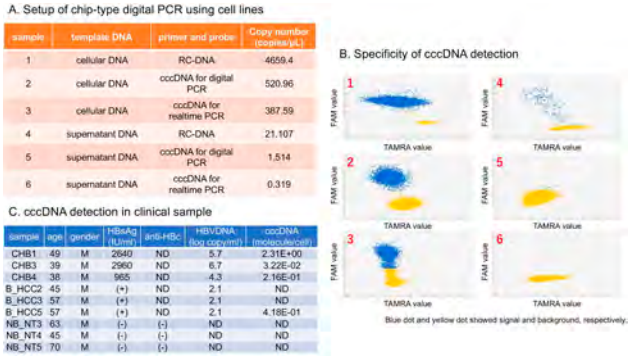
4004 | DEVELOPMENT OF A SIMPLE METHOD FOR MEASURING HBVCCCDNA USING CHIP-BASED DIGITAL PCR



Yoshiki Murakami[1] Takahide Niijima[2] Yoshihiko Yano[3] Takashi Honda[4] Tomohiro Umezu[2] Masahiko Kuroda[2], [1]Tokyo Medical Univesity/Asahi University, [2]Tokyo Medical University, [3]Kobe University, [4]Nagoya University Graduate School of Medicine

Background: A major technical challenge in hepatitis B virus (HBV) research is the selective detection of covalently closed circular DNA (cccDNA) from the more abundant relaxed circular DNA (rcDNA). Because these DNA species share overlapping HBV genomic sequences, conventional PCR can amplify both, limiting cccDNA-specific quantification without laborious pretreatment. We developed a chip-based digital PCR method for simple detection and quantification of HBV cccDNA without enzymatic digestion pretreatment. **Methods:** QuantStudio chip-based digital PCR was used. Primers were designed to flank the HBV direct repeat region, and a probe was designed to recognise the PCR product. Genomic DNA from Hep38.7-tet cells, which contain one cccDNA molecule per cell, was used as the template. RNase P, present as two copies per cell, served as an internal control to calculate cccDNA copies per cell. We also analyzed liver biopsy tissue from 4 cases of chronic hepatitis B (CHB) treated at Kobe University Hospital, 7 cases of HBV-positive

hepatocellular carcinoma (BHCC), 3 cases of non-cancerous tissue (NBNT) derived from HCC without HBV infection. **Results:** HBV cccDNA was quantified directly from cell-derived genomic DNA without digestion of single-stranded or gapped DNA. No cccDNA signal was detected in cell culture supernatant DNA, which lacks cccDNA, indicating selective discrimination from rcDNA-dominant samples. In cell-derived DNA, both cccDNA and rcDNA were detected, allowing evaluation of intracellular HBV DNA species. This assay detected the number of cccDNA copies per cell in liver biopsy tissue and resected material after RNase P treatment. As a result, the cccDNA copy number was measured in 3 out of 4 cases of chronic hepatitis B (CHB), 1 out of 7 cases of hepatocellular carcinoma (BHCC), and 0 out of 3 cases of non-B hepatitis (NBNT). **Conclusion:** This chip-based digital PCR method enables simple quantification of HBV cccDNA distinct from rcDNA. Unlike droplet-based digital PCR, which requires enzymatic removal of non-cccDNA species, this method omits this step, simplifying workflow and reducing cost and DNA loss. RNaseP-based cell number correction enables absolute quantification of cccDNA copies per cell, supporting applications in HBV reactivation risk assessment, treatment monitoring and drug development endpoints.

4005 | DYNAMIC CHANGES IN HBSAG OUTPERFORM HBV RNA IN PREDICTING RESPONSE TO PEGIFN-α ADD-ON THERAPY IN NUCLEOS(T)IDE ANALOGUE-EXPERIENCED PATIENTS WITH CHRONIC HEPATITIS B

Ziyu Zhang[1] Minghui Li[2], [1]Beijing Ditan Hospital affiliated Capital Medical University, [2]Capital Medical University Affiliated Beijing Ditan Hospital

Background: HBV RNA has been considered a surrogate marker of HBV covalently closed circular DNA (cccDNA) transcriptional activity; however, its predictive value for treatment response during PegIFN-α add-on therapy in nucleos(t)ide analogue (NA)-experienced patients with chronic hepatitis B (CHB) remains unclear. This study aimed to compare the predictive performance of HBV RNA and dynamic HBsAg changes for treatment response. **Methods:** A total of 295 NA-experienced patients with CHB who received PegIFN-α add-on therapy on the basis of ongoing NA treatment were retrospectively enrolled. The primary endpoint was an HBsAg decline $\geq$1 log IU/mL at week 48. Correlations between HBV RNA and virological markers were analyzed. Receiver operating characteristic (ROC) curve analysis and logistic regression analysis were performed to evaluate the predictive value of HBV RNA and dynamic HBsAg changes for treatment response. **Results:** At baseline, HBV RNA was positively correlated with HBsAg ($r = 0.597$, $P < 0.001$), HBV DNA ($r = 0.590$, $P < 0.001$), and HBeAg ($r = 0.792$, $P < 0.001$). At week 48, 28.52% (73/256) of patients achieved an HBsAg decline $\geq$1 log IU/mL. The magnitude of HBsAg decline at weeks 12 and 24 was significantly greater in responders than in non-responders (both $P < 0.001$), whereas HBV RNA clearance and HBV DNA clearance showed no significant predictive value (both $P > 0.05$).ROC analysis demonstrated that the area under the curve (AUC) of HBsAg decline at week 12 for predicting week-48 response was 0.815, which further increased to 0.879 at week 24. Multivariate logistic regression analysis identified an HBsAg decline $\geq$1 log at week 24 as an independent predictor of week-48 response (OR = 491.509, $P < 0.001$). **Conclusion:** HBV RNA may reflect HBV transcriptional activity but has limited value in predicting treatment response to PegIFN-α add-on therapy. In contrast, early on-treatment dynamic changes in HBsAg demonstrated superior predictive performance and may serve as an important marker for individualized treatment strategies in NA-experienced patients with CHB.

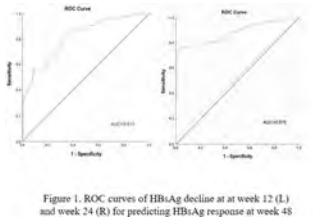

Figure 1. ROC curves of HBsAg decline at at week 12 (L) and week 24 (R) for predicting HBsAg response at week 48

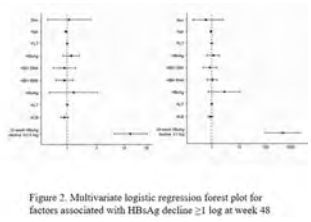

Figure 2. Multivariate logistic regression forest plot for factors associated with HBsAg decline ≥1 log at week 48

4006 | MIDKINE GENE EXPRESSION IS ASSOCIATED WITH FIBROTIC PROGRESSION IN CHRONIC HEPATITIS B PATIENTS

Shasha Li[1] Meng Yi[2] Olivia Mezzetti[3] Thien Nguyen[3] Min Xu[3] Shuhan Li[2] Ning Jiang[4] Jing Xu[4] Yufeng Gao[5] Shilin Li[2] Raymond Chung[3] Limin Chen[2] Jiabin Li[5] Xiaoqiong Duan[2] Wenyu Lin[3], [1]The Second People's Hospital of Fuyang City, China, [2]Chinese Academy of Medical Sciences and Peking Union Medical College, [3]Massachusetts General Hospital, Harvard Medical School, [4]The Second People's Hospital of Fuyang City, [5]The First Affiliated Hospital of Anhui Medical University

Background: Chronic hepatitis B (CHB) is a leading cause of liver cirrhosis and hepatocellular carcinoma (HCC). Blood-based biomarkers have been proposed as an alternative to liver biopsy for noninvasive liver disease assessment. We sought to identify the genes significantly associated with the occurrence of hepatic fibrosis in CHB patient peripheral blood mononuclear cells (PBMCs) and preliminarily explore their regulatory mechanisms. **Methods:** We recruited 104 patients with confirmed chronic HBV infection, 79 patients in the inactive carrier stage of chronic HBV (CHBV-I) and 25 patients with advanced fibrotic CHB (CHB-F), from The Second People's Hospital of Fuyang City. We also recruited 33 healthy subjects (HC) with no history of HBV infection. We selected 16 genes that are associated with liver fibrosis-related pathways and examined the transcriptional profiling of these genes in PBMCs from CHB patients. Midkine (MDK) expression was assessed in HepAD38 cells with or without tetracycline (to inhibit HBV replication), uninfected and HBV-infected NTCP-HepG2 cells, pAAV-HBV1.2 carrier mice, and HBV transgenic (HBV-Tg) mice. MDK siRNA and recombinant MDK supplementation was used to determine its role in pro-fibrotic gene expression. **Results:** We identified 14 regulated genes in PBMCs from CHB patients. Six of these genes (MDK, AFP, VCAM1, AEBP1, LOXL2 and IGFBP7) were significantly upregulated in PBMCs from CHBV-I and CHBV-F patients compared to the HC group. The expression of MDK and AFP were also significantly increased in CHBV-F patients compared to CHBV-I patients. We observed a significant moderate positive correlation between the expression of MDK, VCAM1, AFP, LOXL2 and the progression of CHB-I and CHB-F, while CREB1 and FBN1 were negatively correlated with CHB-I and CHB-F progression. We also found that HBV infection significantly increased MDK expression in HBV-infected NTCP-HepG2 cells, precision-cut liver slices (PCLS) and mouse models. Knockdown of MDK significantly suppressed the induction of pro-fibrotic gene expression by TGF-β1, while MDK recombinant protein increased pro-fibrotic gene expression. **Conclusion:** We found that advanced chronic hepatitis B is associated with increased MDK in PBMCs. MDK is a multifunctional secreted protein which can be induced by TGF-β1 and promotes fibrosis. These findings suggest that MDK could be used as a biomarker in PBMCs for CHB-induced liver fibrosis and as a possible target for therapeutic intervention.

4008 | LIMITED CLINICAL UTILITY OF BASELINE HBV DNA TESTING IN PATIENTS UNDERGOING AUTOLOGOUS STEM CELL TRANSPLANTATION

Sanam Tabataba Vakili[1] Leila Amiri[1] Lauren Finlay[2] Christine Chen[2] Michael Crump[2] Scott Fung[3] Jordan Feld[4], [1]Toronto Centre for Liver Disease, Toronto General Hospital, University Health Network, Toronto, Can, [2]Princess Margaret Cancer Centre, University Health Network, Toronto, Canada, [3]University Health Network, [4]Toronto General Hospital

Background: Hepatitis B virus (HBV) reactivation is a recognized complication of autologous stem cell transplantation (auto-SCT), particularly after prior HBV exposure. International guidelines recommend serologic screening before transplantation, but the role of baseline HBV DNA testing, particularly in HBsAg-negative patients, remains unclear. We evaluated the clinical utility of baseline HBV DNA testing in auto-SCT candidates. **Methods:** We conducted a retrospective study of adults undergoing autologous stem cell transplantation at the University Health Network, Toronto, from 2017-2022. Baseline HBV serology (HBsAg, anti-HBc, anti-HBs) and HBV DNA testing results were reviewed. HBV DNA testing was performed in HBsAg-positive and anti-HBc-positive patients, and selectively in isolated anti-HBs-positive patients with unclear vaccination history. Antiviral prophylaxis was routinely used in HBsAg-positive and anti-HBc-positive patients, but not in isolated anti-HBs-positive patients. Patients were categorized as HBsAg-positive, HBsAg-negative/anti-HBc-positive, isolated anti-HBs-positive, or triple-negative. HBV DNA results, antiviral prophylaxis, liver biochemistry, and HBV-related outcomes were assessed. **Results:** Among

1,600 patients (60% male, median age 60.5 years [IQR 53.2–66.2]), most undergoing auto-SCT for multiple myeloma and lymphoma, baseline serologic profiles were HBsAg-positive in 18 patients, HBsAg-negative/anti-HBc-positive in 134, isolated anti-HBs-positive in 393, and triple-negative in 1,055 (Table 1). HBV DNA testing was performed in 298 patients (18.6%). Among tested patients, HBV DNA was detectable in 10/18 (55.6%) HBsAg-positive patients, 15/131 (11.5%) anti-HBc-positive patients, and 4/142 (2.8%) isolated anti-HBs-positive patients, while no triple-negative patients had detectable HBV DNA. Three additional HBV DNA–positive patients could not be classified because of missing baseline serology. In anti-HBc-positive patients, detectable HBV DNA was low level or intermittent and did not alter antiviral management, as all received prophylaxis based on serologic status alone. Among isolated anti-HBs-positive patients, HBV DNA levels were very low (< 10–50 IU/mL), and none developed HBV-related hepatitis or transplant-related hepatic complications. **Conclusion:** Routine baseline HBV DNA testing demonstrated limited clinical utility in auto-SCT candidates beyond standard HBV serologic screening. HBV DNA results did not alter management in anti-HBc-positive patients and had very low diagnostic yield in isolated anti-HBs-positive and triple-negative individuals. These findings support limiting routine HBV DNA testing to HBsAg-positive patients. In immunosuppressed patients with unexplained ALT elevation, repeat HBsAg testing remains important, particularly in those with humoral immune dysfunction. **HBV DNA testing; auto-SCT; HBV reactivation**

Table 1. Baseline HBV DNA positivity by serologic group in auto-SCT candidates (2017–2022)

HBV serologic group	Total patients, n	Underwent HBV DNA testing, n (%)	HBV DNA positive, n (%) among those tested	HBV DNA negative, n
HBsAg-positive	18	18 (100.0%)	10 (55.6%)	8
HBsAg-negative/anti-HBc-positive	134	131 (97.8%)	15 (11.5%)	116
Isolated anti-HBs-positive	393	142 (36.1%)	4 (2.8%)	138
Triple-negative	1,055	7 (0.7%)	0 (0.0%)	7
Total	1,600	298 (18.6%)	29 (9.7%)	269

Footnote: Percent HBV DNA positivity is calculated among patients who underwent HBV DNA testing within each serologic group. Overall, 32 patients had at least one detectable HBV DNA result; 3 could not be assigned to a serologic group because of missing baseline serology and are therefore not included in the group-specific patient counts.

4009 | LONGITUDINAL QHBSAG TRAJECTORIES PREDICT FUNCTIONAL CURE IN CHRONIC HEPATITIS B: A LARGE REAL-WORLD STUDY

Leila Amiri[1] Sanam Tabataba Vakili[2] Aaron Vanderhoff[3] Andrew Mendlowitz[4] Grishma Hirode[4] Saima Naim[2] Adam Gehring[5] Scott Fung[5] Jordan Feld[5], [1]University Health Network, [2]Clinical Research Coordinator, [3]Community Outreach Coordinators, [4]Research Fellow, [5]Clinical Research Staff – Hepatology

Background: Chronic hepatitis B remains a major cause of cirrhosis and hepatocellular carcinoma worldwide. Functional cure, defined as hepatitis B surface antigen (HBsAg) loss, is rare but associated with favorable long-term outcomes. While quantitative HBsAg (qHBsAg) is a promising biomarker, the value of longitudinal qHBsAg trajectories compared with single measurements and other routine biomarkers has not been well defined. We aimed to identify longitudinal biomarkers predictive of HBsAg loss. **Methods:** We conducted a cohort study of patients with chronic hepatitis B followed at the Toronto Centre for Liver Disease between 2010 and 2022 with ≥ 2 visits and ≥ 6 months follow-up. Longitudinal qHBsAg trajectories were modeled using the longitudinal discriminant analysis (LoDA) framework proposed by Fan et al. (GOLDEN Rule, 2024). Separate mixed-effects models were fitted for patients with and without HBsAg loss. We evaluated whether HBV DNA and ALT improved prediction beyond qHBsAg alone. **Results:** Among 7338 patients with chronic hepatitis B (median age 48.1 years, 56.2% male, 82.2% Asian, median follow-up 84.1 months), 552 (7.5%) achieved HBsAg

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

loss. The LoDA-based longitudinal qHBsAg-only model demonstrated excellent predictive performance for HBsAg loss (AUC 0.965, 95% CI 0.953–0.975; sensitivity 94.2%; specificity 96.4%) and identified patients a mean of 21.2 months before HBsAg loss. Addition of HBV DNA and ALT did not meaningfully improve predictive performance, as no model improved the AUC by more than 0.0004 beyond longitudinal qHBsAg alone.Compared with a single baseline qHBsAg measurement, the longitudinal model showed significantly greater discrimination for HBsAg loss (AUC 0.965 vs 0.830; DeLong $p < 0.001$), with the greatest improvement observed among patients with baseline qHBsAg > 10000 IU/mL (AUC 0.985 vs 0.420). Using the optimal LoDA threshold defined by the Youden index, 768 (10.5%) patients were classified into the predicted HBsAg loss group and 6570 (89.5%) into the predicted non-loss group, with 5-year cumulative HBsAg loss rates of 27.6% versus 0.4%, respectively.Among 1044 patients with baseline qHBsAg >10000 IU/mL, the predicted likelihood of HBsAg loss increased from 0.4% in patients with minimal qHBsAg decline (< 1 $\log_{10}$; $n = 751$) to 8.8% with moderate decline (1–2 $\log_{10}$; $n = 194$) and 61.6% among those with large decline (≥ 2 $\log_{10}$; $n = 99$). **Conclusion:** Longitudinal qHBsAg trajectories accurately predicted functional cure nearly two years before HBsAg loss and substantially outperformed single baseline qHBsAg measurements, particularly among patients with high baseline qHBsAg levels. Addition of HBV DNA and ALT provided minimal incremental predictive value beyond longitudinal qHBsAg alone. These findings support serial qHBsAg monitoring as a clinically applicable approach for early functional cure prediction and patient stratification in chronic hepatitis B.

4010 | QUANTITATIVE HBSAG LEVELS AND POTENTIAL ELIGIBILITY FOR FUTURE FUNCTIONAL CURE THERAPIES AMONG NUCLEOS(T)IDE ANALOGUE–TREATED AND UNTREATED INDIVIDUALS WITH CHRONIC HEPATITIS B IN ALBERTA, CANADA

Carla Coffin[1] Stephen Congly[1] Brendan Lethebe[1] Mayur Brahmania[1] Laura Stinton[1] Matthew Sadler[1] Karen Doucette[2] Conar O'Neil[2] Vanessa Meier-Stephenson[2] Robert Bailey[3] Mang Ma[2] Carlos Moctezuma-Velazquez[2] Jordyn Vienneau[1] Pam Crotty[1] Carmen Charlton[4], [1]University of Calgary, [2]University of Alberta, [3]Bailey Health Clinic, [4]Provincial Laboratory for Public Health

Background: Quantitative hepatitis B surface antigen (qHBsAg) is an important biomarker for refining chronic hepatitis B management and identifying individuals who may be eligible for future finite functional cure therapies. We used linked laboratory and administrative health data to evaluate qHBsAg levels and longitudinal trends among untreated and nucleos(t)ide analogue (NA)-treated individuals with chronic hepatitis B in Alberta. **Methods:** Linked administrative health data were used to identify individuals with hepatitis B who underwent qHBsAg testing using the Abbott ARCHITECT assay between 2015 and 2023. Laboratory results were linked with clinical encounter and medication dispensing records to compare baseline and follow-up qHBsAg levels among NA-treated and untreated individuals. **Results:** A total of 6,507 unique individuals with qHBsAg testing were identified. Median age was 46.3 years, and 44.2% were female. At baseline, defined as the index qHBsAg measurement, 1,404 (21.6%) individuals were receiving NA therapy, of whom 210 (39.7%) were HBeAg positive. Among NA-treated individuals, median HBV DNA was 10 IU/mL (IQR 10–18), and median qHBsAg was 1,463 IU/mL (IQR 361–4,508). In comparison, among 5,103 untreated individuals, 294 were HBeAg positive (11.5%; $p < 0.001$), median HBV DNA was significantly higher at 176 IU/mL (IQR 5.2–2,608; $p < 0.001$), and median qHBsAg was 2,264 IU/mL (IQR 30-4,851; $p = 0.279$).Follow-up qHBsAg data were available for 4,058 individuals, including 1,094 NA-treated and 2,964 untreated individuals. Median follow-up qHBsAg was 772 IU/mL overall, 832 IU/mL in the NA-treated group, and 660 IU/mL in the untreated group. The most recent follow-up was a median of 5.4 years after index HBsAg

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

test for NA-treated individuals (n = 2003) and 3.8 years for untreated individuals (n = 2055). In the NA treatment group, qHBsAg levels were < 100 IU/mL in 481 (24.0%), ≥ 100–1000 IU/mL in 591 (29.5%), ≥ 1000–3000 IU/mL in 388 (19.4%), and ≥ 3000 IU/mL in 543 (27.1%). Among untreated individuals, corresponding values were 810 (39.4%), 299 (14.5%), 283 (13.8%), and 663 (32.3%), respectively. **Conclusion:** In this large cohort of individuals with chronic hepatitis B in Alberta, more than half of those with follow-up qHBsAg testing had levels < 1,000 IU/mL, including 53.5% of NA-treated individuals and 53.9% of untreated individuals. An additional 16.5% overall had qHBsAg levels between 1,000 and 3,000 IU/mL when last tested. These findings suggest that a significant proportion of people living with hepatitis B in Alberta are potentially eligible for future functional cure therapies.

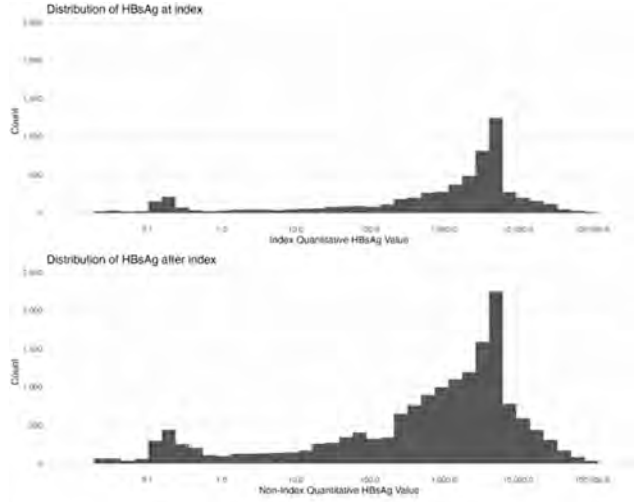

Figure 1. Distribution of quantitative hepatitis B surface antigen (qHBsAg) levels at index (top panel; n=6,507) and most recent follow-up (bottom panel; n=4,058) among individuals with chronic hepatitis B in Alberta. qHBsAg values (IU/mL) are displayed on a logarithmic scale.

4011 | HIGH FREQUENCY OF SERUM HEPATITIS B SURFACE ANTIGEN (HBSAG) < 3000 IU/ML AND THE ASSOCIATED FACTORS IN US PATIENTS WITH CHRONIC HEPATITIS B VIRUS (HBV) INFECTION

Ke-Qin Hu[1] Kim Huynh[2] Tung Huynh[3], [1]University of California, Irvine, [2]Fairmont Preparatory Academy, [3]University of California Irvine Medical Center

Background: Studies demonstrated a low serum HBsAg level is associated with spontaneous HBsAg clearance and treatment-induced HBV functional cure. However, the actual frequency of low HBsAg level is unknown in US patients with chronic HBV infection. The present study assessed the distribution of serum HBsAg level, the frequency of HBsAg < 3000 IU/mL and the associated factors in US patients with chronic HBV infection. **Methods:** A single center retrospective study on 74 cases with chronic HBV infection, regular follow-up (f/u) in our liver clinic, UCI Health, and HBsAg quantitative tests (Immunometric Immunoassay with cut off value of 0.05 IU/mL, sensitivity > 99.9%, and specificity of 99.4%, QUEST) every 6 months for a total 36 months. The data were collected by chart review; Chi square test and likelihood ratio test were used for statistical analysis. **Results:** In 74 cases, the mean age was 55 year old; 63 (85.1%), > 40 years; 36 (48.6%), males; 68 (91.9%), Asian; 47 (63.5%), on HBV treatment; 31 (41.9%) had history of perinatal transmission; 7 (9.5%), stage 3-4 liver fibrosis by shear wave elastography; 8 (11.8%), HBeAg+; 27 (62.8%), pre-core mutation (PCM); 21 (56.8%), basal core promotor (BCP) mutation. HBV genotype distribution was A = 3 (6.4%); B = 32 (68%); C = 9 (19.1%); D = 2 (4.3%); and H = 1 (2.1%); 29 (46%), baseline HBV DNA < 2000 IU/mL. The baseline distribution of HBsAg level was > 10000 = 5 (6.8%), 5000-10000 = 4 (5.4%); 3000-5000 = 1 (1.4 %), 1000-3000 = 17 (23%), 500-1000 = 11 (14.9%), 100- 500 = 19 (25%); < 100 IU/mL = 17 (23%). Baseline HBsAg < 3000 was seen in 64 (85.5%); < 500 IU/mL, 36 (48.6%). During follow-up, 4 (12.9%) had rising; 21 (67.7%) stable; and 6 (19.4%), down trending HBsAg level. The Chi Square test showed that baseline HBsAg < 3000 was significantly associated with Asian ethnicity (89.7% vs. 50%, P = 0.006), HBeAg- (50% vs. 10%, P = 0.003), PCM+ (100% vs. 62.5%, P = 0.001), end of f/u HBsAg < 1000 (98 % vs. 55.6%, P = 0.0006), and < 500 IU/mL (100% vs. 73.5%, P = 0.002), but not associated with gender (P = 0.927), age (P = 0.624),

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

transmission mode (P = 0.896), BMI ≥ 25 (P = 0.655), liver fibrosis (P = 0.272), BCP mutation (P = 0.416), and HBV treatment history (P = 0.452). Multivariable analysis by Likelihood Ratio Test showed baseline HBsAg < 3000 IU/mL was associated with PCM+ (P = 0.005) and end of f/u HBsAg < 1000 IU/mL (P = 0.017), independent of HBeAg- (P = 0.436) and HBV treatment history (p = 0.721). **Conclusion:** This study revealed that in our single center cohort of 74 US patients with chronic HBV infection, as high as 85.5% have serum HBsAg level < 3000 IU/mL, that is associated with HBV PCM+ and end of f/u HBsAg level < 1000 IU/mL, independent of HBeAg status and HBV treatment history during 3-years follow-up. Our data support the clinical utility and value of HBsAg quant test in identifying the patients who may need only definitive course of HBV treatment and could be benefited by upcoming innovative treatment, such as bepirovirsen for HBV functional cure.

4012 | PREDICTING LIVER-RELATED OUTCOMES USING WHO-RECOMMENDED APRI CUTOFFS: A MULTICENTER COHORT STUDY OF THAI CHB PATIENTS

Pimsiri Sripongpun[1] Chitchai Rattananukrom[2] Huttakan Navadurong[3] Kessarin Thanapirom[4] Kanokwan Pinyopornpanish[5] Supot Nimanong[6] Apichat Kaewdech[1] Sakkarin Chirapongsathorn[7] Chalermrat Bunchorntavakul[8] Chanunta Hongthanakorn[9] Sith Siramolpiwat[10] Abhasnee Sobhonslidsuk[11] Sarita Ratana-Amornpin[11] Watcharasak Chotiyaputta[6] Sombat Treeprasertsuk[4] Teerha Piratvisuth[1], [1]Prince of Songkla University, [2]Khon Kaen University, [3]Navamindradhiraj University, [4]Chulalongkorn University, [5]Chiang Mai University, [6]Siriraj Hospital, [7]Phramongkutklao Hospital and College of Medicine, [8]Rajavithi Hospital, [9]Bhumibol Adulyadej Hospital, [10]Thammasart University, [11]Ramathibodi Hospital

Background: The World Health Organization (WHO) guidelines expand chronic hepatitis B (CHB) treatment criteria, recommending the AST-to-Platelet Ratio Index (APRI) as a primary noninvasive test in resource-limited settings where vibration-controlled transient elastography (VCTE) is unavailable. While APRI is validated to cross-sectionally identify significant fibrosis (SF; ≥ F2), data remains limited regarding the prognostic value of WHO-recommended cutoffs (< 0.5 for excluding SF, ≥ 0.5 for diagnosing SF, and > 1.0 for diagnosing cirrhosis; corresponding to VCTE thresholds of 7 and 12.5 kPa). We aimed to evaluate the long-term prognostic performance for liver-related events (LREs) of these WHO-recommended APRI cutoffs in CHB patients. **Methods:** This multicenter retrospective cohort study utilized data from the Gastroenterological Association of Thailand (GAT) Fibroscan registry, including CHB patients who underwent VCTE between 2014 and 2026 across six tertiary centers. Patients with incomplete data for APRI calculation, or follow-up < 6 months were excluded. Patients were stratified by baseline APRI: < 0.5, 0.5–1.0, and > 1.0. The primary outcome was LREs, defined as a composite of hepatocellular carcinoma and/or hepatic decompensation (ascites, variceal bleeding, encephalopathy). Long-term outcomes were analyzed using Kaplan-Meier curves, log-rank tests, and multivariable Cox regression adjusted for age and sex. **Results:** Of 437 eligible patients (mean age 52.6 ± 11.8 years; 50.8% female), 371 (84.9%)/ 43 (9.8%)/ 23 (5.3%) were categorized into APRI ≤ 0.5, > 0.5–1.0, and > 1.0, respectively. Median VCTE-measured liver stiffness in each stratum was 5.6 (IQR 4.5–7.4), 12.0 (IQR 8.1–16.4), and 17.9 (IQR 9.2–25.6) kPa, respectively. The WHO APRI categories significantly discriminated LRE development as shown in Figure (p < 0.001). The 5-year LRE-free survivals were 97.2%, 90.3%, and 78.3% for the APRI < 0.5, 0.5–1.0, and > 1.0 groups, respectively. In a multivariable analysis, the WHO-recommended APRI strata were independently associated with LRE risk, with an adjusted hazard ratio (aHR) of 3.21 (95%CI 0.98-10.51, p = 0.05) for the 0.5–1.0 group, and aHR 11.93 (95%CI 3.90-36.51, p < 0.001) for the > 1.0 group. **Conclusion:** The WHO-recommended APRI cutoffs effectively stratify the long-term risk of LREs in CHB patients, demonstrating strong prognostic utility. These baseline thresholds offer critical clinical value for risk-stratification and intensive surveillance or treatment initiation in resource-limited settings. While lacking granular data on serial HBV DNA, HBeAg status, or specific antiviral therapy due to the nature of a retrospective registry, our findings provide a crucial, real-world body of evidence validating the long-term prognostic sustainability of this simplified, WHO-endorsed public health strategy.

4013 | MONTH-1 POST-CESSATION HBV DNA OUTPERFORMS END-OF-TREATMENT HBSAG IN PREDICTING HEPATITIS FLARE AFTER TDF/TAF CESSATION IN HBEAG-NEGATIVE CHRONIC HEPATITIS B

Yen-Chun Liu[1] Rachel Wen-Juei Jeng[1] Rong-Nan Chien[1], [1]Chang Gung Memorial Hospital, Linkou medical center

Background: Hepatitis flares after discontinuation of tenofovir disoproxil fumarate (TDF) or tenofovir alafenamide (TAF) may occur rapidly, predominantly within the first 6 months after treatment cessation. Early identification of patients at risk for imminent flare is critical for safe off-therapy monitoring. We evaluated whether HBV DNA measured at 1 and 3 months after TDF/TAF cessation predicts subsequent hepatitis flare in HBeAg-negative chronic hepatitis B (CHB). **Methods:** HBeAg-negative CHB patients who discontinued TDF or TAF after sustained virological suppression, defined as consecutive undetectable HBV DNA measurements at least 6 months apart, were included. After treatment cessation, patients underwent monthly monitoring during the first 3 months and every 3 months thereafter during the first year. Off-therapy hepatitis flare was defined as ALT $\geq$5×ULN with HBV DNA $\geq$2000 IU/mL. Predictive performance of month 1 and month 3 HBV DNA after cessation and end-of-treatment (EOT) HBsAg, was assessed using AUROC analysis. Kaplan-Meier analysis compared cumulative flare incidence by Youden index-derived HBV DNA cutoffs. **Results:** Among 83 HBeAg-negative CHB patients who discontinued TDF or TAF, median age was 55 years, 84% were male, and 78% had genotype B. Median pretreatment HBV DNA and EOT HBsAg levels were 6.6 and 2.4 $\log_{10}$ IU/mL, respectively. During a median follow-up of 5.0 years, 48 patients (56%) developed off-therapy hepatitis flare, with a median time to flare of 14 weeks. Flares clustered early after cessation: 17, 32, 38 patients flared within 3, 6, 12 months, respectively, and 84% of the first-year flares occurred within the first 6 months. Month-1 HBV DNA outperformed EOT HBsAg in predicting 3-month flare, with AUROCs of 0.825 versus 0.474, respectively; p = 0.007. Month-1 HBV DNA also predicted 6-month flare, with an AUROC of 0.716, compared with 0.460 for EOT HBsAg. Using 2.5 $\log_{10}$ IU/mL as the optimal month-1 HBV DNA cutoff, cumulative flare incidence was higher in patients with HBV DNA $\geq$2.5 versus <2.5 $\log_{10}$ IU/mL at 3 months and 6 months: 31% versus 0% and 52% versus 14%, respectively; log-rank p < 0.01. For predicting 3-month flare, this cutoff identified all flare cases, yielding a sensitivity and NPV of 100%, with a specificity of 43.9% and PPV of 31.5%. Month-3 HBV DNA further improved prediction of 6- and 12-month flare, with AUROCs of 0.888 and 0.876, respectively. **Conclusion:** In HBeAg-negative CHB patients after TDF/TAF cessation, month-1 HBV DNA outperformed EOT HBsAg in predicting early off-therapy hepatitis flare. A month-1 HBV DNA level <2.5 $\log_{10}$ IU/mL identified patients at low risk for imminent 3-month flare, while levels $\geq$2.5 $\log_{10}$ IU/mL may warrant closer early monitoring. Month-3 HBV DNA further refined prediction of 6- and 12-month flare, supporting individualized post-cessation surveillance.

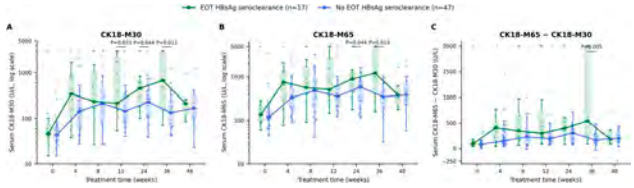
4014 | ON-TREATMENT CK18-M30 AND CK18-M65 DYNAMICS REFLECT HEPATOCYTE DEATH PATTERNS ASSOCIATED WITH END-OF-TREATMENT HBSAG SEROCLEARANCE IN CHRONIC HEPATITIS B



Xinyue Meng[1] Jing Zhao[1] Jianxia Dong[1] Pengxuan Wu[1] Shan Ren[1] Xinyue Chen[1] Sujun Zheng[1], [1]First Department of Hepatology, Beijing YouAn Hospital, Capital Medical University, Beijing, China

Background: Peg-IFN α-based therapy can induce HBsAg seroclearance in selected patients with chronic hepatitis B (CHB), but the treatment-phase biological

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

events associated with HBsAg loss remain incompletely defined. CK18-M30 reflects caspase-cleaved CK18 and is commonly considered an apoptosis-related marker, whereas CK18-M65 reflects total CK18 release. We aimed to investigate whether on-treatment CK18 dynamics were associated with end-of-treatment HBsAg seroclearance. **Methods:** We analyzed 64 CHB patients who received 48 weeks of peg-IFN α-based therapy. The primary endpoint was HBsAg seroclearance at week 48. Serum CK18-M30 and CK18-M65 were measured longitudinally at baseline and during treatment. CK18-M65 − CK18-M30 was calculated as an exploratory indicator of non-M30 CK18 release. CK18 trajectories were compared between patients with and without end-of-treatment HBsAg seroclearance using Mann–Whitney U tests at each time point and repeated-measures models. **Results:** Seventeen patients achieved HBsAg seroclearance at week 48, whereas 47 did not. Baseline CK18-M30 and CK18-M65 levels did not differ significantly between the two groups. During therapy, patients who achieved end-of-treatment HBsAg seroclearance showed more pronounced increases in CK18 markers, with separation mainly emerging between weeks 12 and 36. At week 36, CK18-M30 was higher in the seroclearance group than in the non-seroclearance group (670.8 vs. 133.5 U/L, $P = 0.011$), as was CK18-M65 (1209.0 vs. 349.2 U/L, $P = 0.013$). The most pronounced difference was observed for CK18-M65 − CK18-M30(538.2 vs. 167.4 U/L, $P = 0.005$). Repeated-measures analysis further supported distinct on-treatment CK18 trajectories between the two groups. After accounting for ALT and AST, CK18-M65 and CK18-M65 − CK18-M30 remained informative, suggesting that CK18 dynamics were not fully captured by aminotransferase changes alone. **Conclusion:** In CHB patients receiving peg-IFN α-based therapy, end-of-treatment HBsAg seroclearance was associated with distinct on-treatment CK18 dynamics, particularly increased CK18-M65 and CK18-M65 − CK18-M30 during the mid-treatment phase. These findings suggest that CK18-based markers may provide complementary information on hepatocyte death patterns associated with peg-IFN α-induced HBsAg seroclearance.

4015 | ASSAY-DEPENDENT CATEGORICAL DIVERGENCE OF LOW-LEVEL HBSAG REACTIVITY IN CHRONIC HEPATITIS B POST-CLEARANCE SURVEILLANCE

Haishi Wu[1] Zhiliang Gao[1] Na Gao[1], [1]Sun Yat-sen University Third Affiliated Hospital

Background: As more chronic hepatitis B patients approach or achieve HBsAg seroclearance, very low-level HBsAg reactivity is increasingly encountered across surveillance. Whether commercial HBsAg platforms remain categorically concordant near their lower analytical range, and how often residual low-level reactivity remains observable in samples already classified as clinically cleared, are not well characterized in real-world surveillance. **Methods:** We retrospectively analyzed 885 samples from 329 chronic hepatitis B patients at a tertiary center across two surveillance-relevant settings: (1) 145 low-titer samples for comparison of four commercial HBsAg assays (Abbott, Roche, Mindray, Autobio; hereafter Assays 1–4, respectively); and (2) 740 archived follow-up samples from 275 patients with documented HBsAg seroclearance (defined a priori by Assay 2 HBsAg < 0.05 IU/mL in routine care), retrospectively re-tested with the four conventional assays and an ultrasensitive qualitative HBsAg assay. Sample stratification by HBsAg concentration used quantitative values from one of the four conventional assays as a within-cohort scale. No assay was treated as a reference standard; sensitivity, specificity, PPV, and NPV were not calculated. **Results:** Among 145 low-titer samples, Assays 1 and 2 were reactive in all 145, Assay 3 in 141 (97.2%), and Assay 4 in 124 (85.5%). Categorical agreement across the four platforms ranged from 85.5% to 100%, with the lowest agreement in comparisons involving Assay 4. Divergence was concentration-dependent and most pronounced at the lower analytical range: among samples within the lowest HBsAg stratum (< 0.1 IU/mL, n = 7), Assay 4 was reactive in 1 and Assay 3 in 6, despite categorical reactivity by Assays 1 and 2 in all 7; within the 0.1-0.5 IU/mL stratum (n = 77), reactivity by the four assays ranged from 62 to 77. Pairwise Spearman correlation across platforms remained high (rho 0.92-0.95), confirming that strong quantitative correlation coexisted with categorical divergence near the lower analytical range. Among the 740 clinically cleared samples, low-level conventional HBsAg reactivity was uncommon (range 0–3.6% across the four platforms; Assay 2, the cohort-defining assay, was reactive in 0/740 as expected). The ultrasensitive HBsAg assay was reactive in 138/740 samples (18.6%), including 108/740 samples (14.6%) with no reactivity by any conventional platform. **Conclusion:** Conventional HBsAg platforms diverge categorically

near the lower analytical range despite strong quantitative correlation, and a measurable subset of clinically cleared samples retains low-level reactivity visible only under extended-range testing. Across surveillance of chronic hepatitis B patients approaching or after HBsAg seroclearance, platform choice materially shapes the observable analytical window.

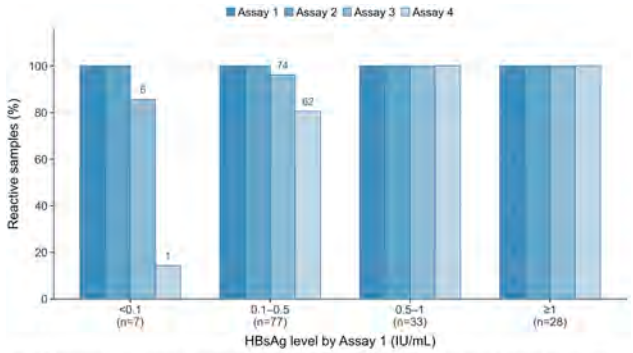

Figure 1. Categorical reactivity of four conventional HBsAg assays (Assay 1, Abbott; Assay 2, Roche; Assay 3, Minilray; Assay 4, Autobio) across low-titer concentration strata (n=145). Reactivity was assessed at each platform's routine clinical cutoff. Samples were stratified by quantitative HBsAg values from one of the conventional assays, used solely as a within-cohort scale rather than as a reference standard. Numbers above non-100% bars indicate the count of reactive samples in that stratum.

4016 | HIV COINFECTION ALTERS THE RELATIONSHIP BETWEEN QHBSAG AND PLASMA HBV PGRNA IN HBEAG-POSITIVE CHRONIC HEPATITIS B

Tetiana Pozniak[1] Alip Ghosh[2] Gaayathri Krishnan[2] Shyam Kottilil[2] Lydia Tang[3], [1]Institute of Human Virology University of Maryland, [2]Institute of Human Virology, University of Maryland School of Medicine, [3]University of Maryland, Baltimore

Background: Globally, chronic hepatitis B (CHB) is a leading cause of cirrhosis and hepatocellular cancer. Eliminating or silencing covalently closed circular DNA (cccDNA), the transcriptional template responsible for persistent hepatitis B virus (HBV) infection, is a goal of CHB cure. Direct measurement of intrahepatic cccDNA requires liver biopsy, highlighting the need for non-invasive biomarkers of cccDNA activity to guide CHB cure strategies. Currently, reduction in quantitative hepatitis B surface antigen (qHBsAg) is a key endpoint in CHB cure studies; however, circulating HBsAg may derive from both cccDNA and integrated HBV DNA. In contrast, pregenomic RNA (pgRNA) is transcribed exclusively from cccDNA and therefore represents a promising biomarker of cccDNA activity. HIV coinfection with CHB may alter HBV transcriptional activity and potentially affect interpretation of biomarkers used in CHB cure studies. We therefore developed a pgRNA assay and evaluated the effect of HIV coinfection on the relationship between qHBsAg and pgRNA in people with HBeAg positive CHB. **Methods:** Plasma samples from adults with HBeAg-positive CHB with and without HIV coinfection were analyzed. All participants were HBV virally suppressed on nucleos(t)ide analogue (NUC) antivirals. Participants with HIV coinfection were also HIV RNA suppressed on antiretroviral therapy containing two NUCs active against HBV. A quantitative qPCR assay for plasma HBV pgRNA quantification was developed and standardized using an in-house HBV plasmid clone generated from HepG2.2.15-derived HBV DNA. qHBsAg was quantified from serum by Chemiluminescent Immunoassay (Ig Biotechnology, CA). **Results:** Plasma samples from 13 patients with HIV/CHB and 12 with CHB monoinfection were analyzed. pgRNA was quantifiable in all samples (mean ± SD, 2.50 ± 1.06 log U/μL). HBV pgRNA levels were positively correlated with qHBsAg (mean ± SD, 3.5 ± 1.07 log U/mL) in all HBeAg-positive patients with HIV/CHB coinfection receiving NUC ($P = 0.0189$). No significant correlation was observed among patients with CHB monoinfection. **Conclusion:** Using a newly developed quantitative plasma pgRNA assay, we demonstrate persistent cccDNA transcriptional activity despite HBV suppression and further show that HIV coinfection influences relationships between qHBsAg and pgRNA. Detectable pgRNA in all participants supports ongoing cccDNA activity as a major barrier to CHB cure with NUC therapy alone. HIV coinfection altered the relationship between quantitative HBsAg and pgRNA, reflecting differing contributions of cccDNA and integrated HBV DNA-derived HBsAg production. In people with HIV/CHB, qHBsAg may remain a useful biomarker of active cccDNA transcription for monitoring responses in CHB-cure studies.

4017 | SERUM HBV RNA KINETICS AND TREATMENT RESPONSE IN PATIENTS WITH CHRONIC HEPATITIS B RECEIVING NUCLEOS (T)IDE ANALOGUE THERAPY

Jian Wang[1] Ye Xiong[2] Shaoqiu Zhang[1] Hongpan Xu[1] Juan Xia[1] Xiaomin Yan[1] Yuxin Chen[1] Rui Huang[1] Chao Wu[1], [1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, [2]Nanjing Drum Tower Hospital Clinical College of Nanjing University of Chinese Medicine

Background: Serum HBV RNA reflects intrahepatic cccDNA transcriptional activity in chronic hepatitis B (CHB). We explored the serum HBV RNA kinetics and treatment response in patients with CHB receiving

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

nucleos(t)ide analogue (NA) therapy. **Methods:** This retrospective study included treatment-naïve CHB patients initiating NA therapy. Serum HBV RNA was detected at baseline and during NA treatment, which was quantified using the Cobas HBV RNA real-time PCR assay on the Cobas 6800 Systems (Roche Diagnostics), with a lower limit of quantification of 10 copies/mL. We explored the association of HBV RNA with virologic (VR, HBV DNA undetectable), and serologic (SR, HBeAg clearance) and combination (CR, HBeAg clearance and HBsAg < 3000 IU/ml) response. **Results:** A total of 654 patients were included, of whom 51.8% were HBeAg-positive. HBeAg-positive patients (vs. HBeAg-negative) had higher baseline HBV RNA levels (6.3 vs. 2.3 $\log_{10}$ copies/mL, $P < 0.001$). Baseline HBV RNA (aOR: 0.505, 95%CI: 0.355-0.719, $P < 0.001$) and HBeAg-positive status (aOR: 0.346, 95%CI: 0.138-0.869, $P = 0.024$) were significantly associated with undetectable HBV RNA at week 48 of treatment. The 5-year cumulative incidence of VR, SR and CR were significantly higher in patients who had a greater HBV RNA decline (> 1 $\log_{10}$ copies/mL) at weeks 12, 24, and 48 of treatment in HBeAg-positive patients. On-treatment HBV RNA decline at weeks 12, 24, and 48 were independently associated higher chance of achieving VR, SR, and CR in such patients. **Conclusion:** Higher baseline HBV RNA and HBeAg-positive status were significantly associated with lower chance of undetectable HBV RNA in CHB with NA treatment. Early on-treatment decline (> 1 $\log_{10}$ copies/mL) in serum HBV RNA is associated with VR, SR and CR in HBeAg-positive CHB patients receiving NA therapy. Serum HBV RNA may help guide individualized treatment strategies for patients with CHB.

4018 | ASSOCIATIONS OF AI-BASED HISTOLOGIC ASSESSMENT WITH SURROGATE MARKERS OF LIVER DISEASE SEVERITY AMONG PERSONS WITH CHRONIC HEPATITIS

Fahmida Haque[1] Veronica Locker[2] Haoyue Zhang[1] Sushant Patkar[1] Zahra Sarrafan-Chaharsoughi[2] Stephen Hewitt[1] Barbara Rehermann[2] Peter Choyke[1] Stephanie Harmon[3] Devid Kleiner[1] Baris Turkbey[1] Marc Ghany[4], [1]NCI, NIH, [2]NIDDK, NIH, [3]NCI,NIH, [4]NIH/NIDDK

Background: Liver biopsy remains the gold standard for histologic assessment in chronic hepatitis B (CHB), but Histologic Activity Index (HAI) scoring is subjective and prone to inter-observer variability. We evaluated the performance of two previously developed artificial intelligence (AI)-based classification models for assessing hepatic inflammation and fibrosis by comparing AI-derived scores with pathologist-assigned HAI scores and established clinical markers of disease severity, including alanine aminotransferase (ALT), aspartate aminotransferase (AST), aspartate aminotransferase-to-platelet ratio index (APRI), and Fibrosis-4 index (FIB-4). **Methods:** Liver biopsies of CHB patients with pathologist-assigned Knodell scores were categorized for inflammation as none/mild (0–6), moderate (7–12), and severe (13–18), and for fibrosis as none (F0), portal fibrosis (F1), bridging fibrosis (F3), and cirrhosis (F4). H&E-stained and Masson's trichrome-stained slides were used to train AI models that rely on pathology foundation model features and slide-level weakly supervised classification techniques to predict inflammation and fibrosis severity, respectively. Agreement between AI and pathologist scores was assessed using weighted Cohen's kappa (κ) with bootstrapped 95% confidence intervals (CI). Spearman correlation coefficients (ρ) were used to evaluate associations between histologic scores and clinical markers. Differences across severity classes were assessed using Wilcoxon rank-sum tests, with statistical significance defined as $p < 0.05$. **Results:** A total of 342 biopsies from 205 patients and 282 biopsies from 147 patients were used for assessment of inflammation and fibrosis, respectively. AI and pathologist's assessments showed substantial agreement for inflammation ($\kappa = 0.73$, 95% CI: 0.68–0.78) and fibrosis ($\kappa = 0.60$, 95% CI: 0.55–0.65). AI-predicted inflammation severity correlated strongly with ALT ($\rho = 0.69$, 95% CI: 0.62–0.74) and AST ($\rho = 0.72$, 95% CI: 0.66–0.77), and was comparable to correlations between pathologist's scores with ALT ($\rho = 0.71$, 95% CI: 0.64–0.76) and AST ($\rho = 0.72$, 95% CI: 0.66–0.76). For fibrosis, AI-predicted severity correlated significantly with APRI ($\rho = 0.44$, 95% CI: 0.33–0.53) and FIB-4 ($\rho = 0.34$, 95% CI: 0.22–0.45). In contrast, pathologist-assessed fibrosis correlated more strongly with FIB-4 ($\rho = 0.46$, 95% CI: 0.35–0.55), while the association with APRI ($\rho = 0.37$, 95% CI: 0.27–0.47) was lower. Significant differences across AI- and pathology-assessed inflammation and fibrosis severity classes were observed for all clinical markers ($p < 0.05$). **Conclusion:** AI-derived histologic scoring demonstrated clinically meaningful associations with established surrogates of liver disease severity, supporting its potential role as an objective complement to pathological and clinical evaluation.

4019 | STUDY ON THE DYNAMIC CHANGES OF HBV RNA AND ITS PREDICTIVE VALUE FOR EARLY EFFICACY IN TREATMENT-NAÏVE PATIENTS WITH CHRONIC HEPATITIS B RECEIVING PEGIFNα-2B COMBINED WITH NAS

Xinxin Li[1], [1]Department of Hepatology Division 2, Beijing Ditan Hospital

Background: To investigate the dynamic changes of serum hepatitis B virus ribonucleic acid (HBV RNA) and its predictive value for early treatment response in treatment-naïve patients with chronic hepatitis B (CHB) receiving pegylated interferon α-2b (PegIFNα-2b) combined with nucleos(t)ide analogues (NAs). **Methods:** A total of 132 treatment-naïve CHB patients with positive HBV RNA who visited Beijing Ditan Hospital from December 2023 to December 2024 were enrolled. All patients received PegIFNα-2b combined with NAs for 48 weeks. Serum samples were collected at baseline and at weeks 12,24, 36, and 48 of treatment to detect HBV RNA, HBV DNA, hepatitis B surface antigen (HBsAg), and alanine aminotransferase (ALT). Spearman correlation analysis, Logistic regression, receiver operating characteristic (ROC) curve, and Kaplan-Meier survival analysis were employed to evaluate the correlation between HBV RNA and various indicators, as well as its predictive value for 48-week treatment outcomes. **Results:** At week 48 of treatment, the rates of HBV RNA undetectability, significant HBsAg decline (>1 $\log_{10}$ IU/mL), and HBeAg seroconversion were 59.85%,42.42%, and 4.92%, respectively. HBV RNA showed significant positive correlations with HBV DNA at all time points (r = 0.18–0.63, all P < 0.05), with the strongest correlation with HBsAg at week 24 (r = 0.563, P < 0.01), and with ALT only at baseline and week 12. Baseline, week 12, and week 24 HBV RNA levels were significantly negatively associated with HBV RNA undetectability at week 48(OR = 0.543–0.658, all P < 0.01), but showed no significant predictive value for significant HBsAg decline. The median time to HBV RNA undetectability was 36 weeks in the rapid decline group, compared to 48 weeks in the slow decline and plateau groups; however, the differences among the three groups were not statistically significant (P > 0.05). **Conclusion:** HBV RNA declined continuously during combination therapy and correlated with HBV DNA and HBsAg dynamics, although more slowly than HBV DNA. Baseline, week 12, and week 24 HBV RNA levels independently predicted week 48 HBV RNA undetectability, while week 12 HBV RNA also predicted HBeAg seroconversion. Patients with rapid HBV RNA decline at week 24 achieved earlier RNA clearance than slow-decline groups. High viral load HBeAg-positive patients showed lower HBV RNA and HBV DNA clearance rates, but no significant differences in HBeAg seroconversion, HBsAg decline, or functional cure.

4020 | INTERPRETABILITY-GUIDED FEATURE ENGINEERING FOR COMPACT, ACCURATE MULTI-OUTCOME PROGRESSION RISK STRATIFICATION IN CHRONIC HEPATITIS B

Shu Su[1] Huiyi Zhang[2] Qingxian Song[2] Jun Yuan[3], [1]Second Affiliated Hospital of Chongqing Medical University, [2]The Second Affiliated Hospital of Chongqing Medical University, [3]Chongqing Medical University

Background: Clinical artificial intelligence (AI) often encounters a trade-off between predictive performance and interpretability. Most existing predictive tools prioritize statistical performance over clinical transparency, relying on post-hoc explanations that fail to guide targeted feature optimization. This study aims to develop an interpretability-driven framework for accurate and interpretable prediction of hepatitis B progression. **Methods:** A total of 36,024 hospitalized CHB patient records were enrolled in this retrospective observational study. We constructed an interpretable machine learning framework integrating SHAP-based main effect quantification and pairwise interaction analysis, and adopted a two-stage modeling strategy of feature dimensionality reduction and clinical interaction augmentation. Different from traditional post-model interpretation, this study embedded interpretability analysis into the feature engineering process to screen core clinical indicators and synergistic feature combinations, finally developing simplified and interaction-enhanced multi-outcome predictive models for CHB non-progression, liver cirrhosis, and hepatocellular carcinoma (HCC). **Results:** The proposed modeling framework achieved strong discriminatory performance, with AUCs of 0.930, 0.900, and 0.905 for predicting disease non-progression, liver cirrhosis, and hepatocellular carcinoma (HCC) at the patient level, respectively. SHAP analyses identified distinct stage-specific biomarker contributions and synergistic interaction patterns across three CHB progression endpoints. AFP predominantly predicted HCC risk, while platelet-related indicators served as core predictors for cirrhosis progression, demonstrating clear outcome-specific feature heterogeneity. Our interpretability-guided feature engineering yielded a compact 15-feature simplified model, which retained promising predictive performance with only a small average AUC reduction of 0.014 compared with the original 78-feature baseline model. Further embedding validated feature interactions effectively elevated HCC predictive sensitivity to 0.700 without compromising specificity. **Conclusion:** This study proposed an interpretability-guided feature optimization paradigm for CHB progression prediction. Embedding interpretability analysis into the early modeling stage avoids the limitations of passive post-hoc interpretation, enabling the construction of compact, high-performance, and clinically transparent multi-outcome models. This framework provides a practical, scalable strategy for individualized risk stratification and clinical decision-making for CHB patients.

4021 | DYNAMICS IN CONTROLLED ATTENUATION PARAMETER (CAP) PROVIDE INCREMENTAL PREDICTIVE VALUE FOR PROGNOSIS IN ON-TREATMENT CHB PATIENTS WITH SIGNIFICANT FIBROSIS AND CIRRHOSIS

Xiaowei Ai[1] Mengyang Zhang[1] Shuyan Chen[1] Xinyu Zhao[1] Jialing Zhou[1] Tongtong Meng[1] Bingqiong Wang[1] Chenglin Sun[1] Xiao Han[1] Yankun Gao[1] Xiaoning Wu[1] Yameng Sun[1] Hong You[2], [1]Liver Research Center, Beijing Friendship Hospital, Capital Medical University, [2]Capital Medical University

Background: The coexistence of hepatic steatosis and CHB is increasingly common in clinical practice, leading to a growing focus on the prognosis of this dual-burden population. Although the controlled attenuation parameter (CAP) has been widely used to quantify hepatic steatosis in CHB patients, the prognostic value of longitudinal changes in CAP remains unknown. This study aimed to evaluate whether dynamic changes in CAP are associated with liver-related events (LREs) in on-treatment CHB patients with significant fibrosis and cirrhosis. **Methods:** CHB patients with significant fibrosis or cirrhosis before antiviral treatment were included in this prospective cohort. CAP was used to assess hepatic steatosis. LREs were defined as hepatic decompensations, hepatocellular carcinoma (HCC), liver transplantation, or liver-related death. Joint models were employed to analyze associations between CAP trajectory and risk of LREs. **Results:** A total of 573 CHB patients were followed for a median of 6.9 years, during which 51 LREs occurred, including 26 cases of hepatic decompensations and 33 cases of HCC. We evaluated 5,967 individual VCTE

assessments. CAP-dynamics independently predicted LREs (per 10 dB/m increase aHR: 0.86, 95% CI: 0.78 - 0.96, P = 0.006). After adjusting for LSM-dynamics, CAP-dynamics remained an independent protective factor for LREs (per 10 dB/m increase aHR: 0.85, 95% CI: 0.77 - 0.95, P = 0.005), hepatic decompensations (per 10 dB/m increase aHR: 0.79, 95% CI: 0.68 - 0.91, P = 0.001), and HCC (per 10 dB/m increase aHR: 0.85, 95% CI: 0.75 - 0.96, P = 0.011).Among 355 patients with clinically diagnosed cirrhosis before treatment, with 3350 individual measurements, CAP-dynamics remained independently associated with LREs (per 10 dB/m increase aHR: 0.87, 95% CI: 0.78 - 0.97, P = 0.015).Multivariate joint model integrating CAP and LSM dynamics, improved predictive performance compared to LSM alone, with the 7-year AUROC increasing from 0.70 to 0.75. A CAP being greater than 236 dB/m over time was associated with a reduced risk of LREs (aHR: 0.69, 95% CI: 0.55-0.85, P < 0.001) **Conclusion:** Among on-treatment CHB patients with significant fibrosis or cirrhosis, a longitudinal decline in CAP was associated with a higher risk of LREs. Regular monitoring of CAP can improve prognostic value beyond LSM alone.

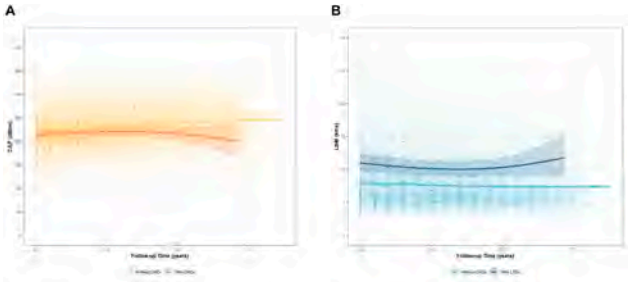

Fig.1 VCTE trajectories in patients with and without LREs. Individual VCTE measurements over time (dots), individual VCTE trajectories (shaded lines), and the population average VCTE trajectory (solid lines) before the development of LREs. Trajectories are color-coded by LREs status (light orange and light blue: without LREs; dark orange and dark blue: with LREs). (A) CAP; (B) LSM. Abbreviations: LSM, liver stiffness measurements; CAP, controlled attenuation parameter; LREs, liver-related events.

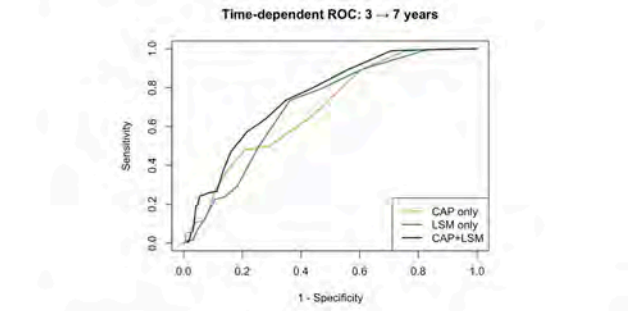

Fig.2 Time-dependent ROC curves for joint models using VCTE collected up to year 3 to predict LREs at year 7. CAP only: Joint model analysis for CAP-dynamics; LSM only: Joint model analysis for LSM-dynamics; CAP+LSM: multivariable Joint model analysis for both CAP-dynamics and LSM-dynamics. 4022 | COMPARATIVE ACCURACY OF BLOOD-BASED BIOMARKERS: FIB-4, APRI, AND SAFE SCORE FOR IDENTIFYING SIGNIFICANT FIBROSIS IN PATIENTS WITH CHRONIC HEPATITIS B

Pimsiri Sripongpun[1] Chitchai Rattananukrom[2] Huttakan Navadurong[3] Kessarin Thanapirom[4] Kanokwan Pinyopornpanish[5] Supot Nimanong[6] Apichat Kaewdech[1] Sakkarin Chirapongsathorn[7] Chalermrat Bunchorntavakul[8] Chanunta Hongthanakorn[9] Sith Siramolpiwat[10] Abhasnee Sobhonslidsuk[11] Sarita Ratana-Amornpin[11] Watcharasak Chotiyaputta[6] Sombat Treeprasertsuk[4] Teerha Piratvisuth[1], [1]Prince of Songkla University, [2]Khon Kaen University, [3]Navamindradhiraj University, [4]Chulalongkorn University, [5]Chiang Mai University, [6]Siriraj Hospital, [7]Phramongkutklao Hospital and College of Medicine, [8]Rajavithi Hospital, [9]Bhumibol Adulyadej Hospital, [10]Thammasart University, [11]Ramathibodi Hospital

Background: International hepatology society guidelines recommend antiviral therapy for viremic chronic hepatitis B (CHB) patients with significant liver fibrosis (SF; ≥F2). Although liver stiffness measurement via vibration-controlled transient elastography (VCTE) is widely accepted as the standard noninvasive test for treatment decisions, its accessibility remains limited in many CHB-endemic regions. We aimed to validate the diagnostic performance of blood-based biomarkers, specifically FIB-4, APRI, and SAFE score, in identifying SF among patients with CHB. **Methods:** As part of the Gastroenterological Association of Thailand (GAT) Fibroscan registry, this multicenter retrospective study included patients with CHB who underwent VCTE between 2014 and 2026 across six centers in Thailand. Patients with unreliable VCTE results or incomplete data for FIB-4, APRI, or SAFE score calculations were excluded. Laboratory results obtained within 3 months of the index VCTE were analyzed. The reference standard for SF diagnosis was defined as a VCTE-measured liver stiffness ≥7 kPa. Diagnostic performance was evaluated using the area under the receiver operating characteristic curve (AUROC), with the DeLong test used for comparisons. Specificities at established cutoffs were also calculated. **Results:** A total of 459 CHB patients were eligible for analysis. The median age of the cohort was 53 years (IQR 44–61), and 51.2% were male. Patients with SF were

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

significantly older, had higher BMIs, higher prevalence of diabetes, and higher values of FIB-4, APRI, and SAFE than those without SF. The SAFE score yielded the highest AUROC at 0.764 (95% CI 0.719–0.809), which was non-significantly higher than APRI (AUROC 0.754, 95% CI 0.708–0.801, p = 0.626) but significantly superior to FIB-4 (AUROC 0.695, 95% CI 0.646–0.744, p < 0.001) as shown in Figure. At recommended cutoffs, the specificities of SAFE ≥100, APRI >0.5, and FIB-4 >1.3 for diagnosing SF were 92.5%, 94.3%, and 65.6%, respectively. **Conclusion:** Both APRI and SAFE outperform FIB-4 in diagnosing SF among Thai CHB patients, offering high specificity to rule in treatment candidates. However, APRI offers distinct practical advantages due to fewer required variables. Additionally, our study validates the WHO guidelines, demonstrating that its simplified APRI-based strategy is acceptably reliable for expanding CHB care in resource-limited settings.

4023 | THE ASSOCIATION BETWEEN THE COMPOSITION RATIO OF HBSAG (SUBVIRAL PARTICLES/VIRAL PARTICLES) AND HCC DEVELOPMENT IN HBEAG-NEGATIVE CHB

Tetsuya Hosaka[1] Fumitaka Suzuki[1] Yasue Takeuchi[1] Hitomi Sezaki[1] Satoshi Saitoh[1] Shunya Goto[1] Shigeki Yamamoto[1] Yasuka Eriksson[1] Yoshiyuki Suzuki[1] Norio Akuta[1] Hiromitsu Kumada[1], [1]Toranomon Hospital

Background: HBsAg is translated not only from cccDNA but also from integrated HBV and released into the bloodstream. Furthermore, HBsAg in the blood includes both viral particle (VP)-derived forms and subviral particles (SVP), with SVP constituting the majority. In this study, we evaluated the association between VP and SVP equivalents in HBsAg levels and HCC development. **Methods:** We enrolled 1,741 HBeAg-negative and non-cirrhotic patients without antiviral therapy who were followed for at least one year. For VP and SVP equivalents in HBsAg, values derived from VP were converted to HBV DNA in copies/mL. SVP values were converted using the formula 1 IU of HBsAg = 8×10^8 SVP (Luckenbaugh K, et al. JVH 2014). We evaluated HCC development based on baseline HBsAg composition ratio (log SVP/VP). **Results:** (1) The median log SVP/VP was 8.1. By disease stage, it was 8.8 in the inactive phase, 7.6 in the indeterminate, and 6.0 in the active phase, showing a tendency for Log SVP/VP to decrease with progression of disease stage (P-trend < 0.001). Furthermore, patients with genotype B had significantly lower Log SVP/VP compared to other genotypes (7.1 vs 8.5, P < 0.001).(2) When the Log SVP/VP cutoff was set at 7.0, annual HCC incidence rates were 6.6 per 1,000 P-Y in the low Log SVP/VP group and 1.4 per 1,000 P-Y in the high group, showing a significantly higher incidence in the low group (P < 0.001). Multivariable Cox regression showed the low log SVP/VP was associated with HCC development, adjusted for age, sex, ALT, platelet counts, genotype, HBcrAg, and HBV DNA. Conversely, raw HBsAg level itself was not associated with HCC. Furthermore, we stratified the cohort into four groups by log SVP/VP and HBcrAg status as shown in Figure. Patients with low log SVP/VP and HBcrAg levels ≥ 4 log U/mL had the highest incidence rate of HCC (Figure). **Conclusion:** The composition ratio of HBsAg levels between SVP and VP was associated with HCC development in HBeAg-negative and non-cirrhotic patients without antiviral therapy. This suggests that, together with HBcrAg, it may reflect the transcriptional activity of cccDNA in the liver.

4024 | A PROCOLLAGEN TYPE III N-TERMINAL PROPEPTIDE BASED NONINVASIVE MODEL FOR ASSESSING HEPATIC INFLAMMATION IN CHRONIC HEPATITIS B

Xinyu Hu[1] Qianqian Chen[2] Fajuan Rui[3] Jie Li[1], [1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, [2]The Affiliated Huai'an Hospital of Xuzhou Medical University and Huai'an Second People's Hospital, [3]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing

Background: Accurate identification of significant liver inflammation is essential for risk stratification and treatment decision-making in patients with chronic hepatitis B (CHB). Serum PRO-C3, a marker of type III collagen formation and active fibrogenesis, may reflect ongoing hepatic injury. This study aimed to evaluate the diagnostic value of PRO-C3 for identifying significant liver inflammation in patients with CHB. **Methods:** A total of 324 patients with CHB who underwent liver biopsy between October 2017 and December 2021 were retrospectively enrolled. Liver inflammation was graded using the Scheuer scoring system, with significant inflammation defined as grade ≥ 3. Baseline clinical, virological, biochemical, and noninvasive fibrosis-related parameters were compared between groups. Independent predictors were identified by multivariable logistic regression. Diagnostic performance was assessed using receiver operating characteristic, calibration, decision curve, and subgroup analyses. **Results:** Among 324 patients with CHB, 70 (21.6%) had significant liver inflammation (G3–4). Compared with patients with G0–2 inflammation, those with G3–4 inflammation had significantly higher levels of ALT, AST, GGT, HBV DNA, PRO-C3, APRI, FIB-4, and liver stiffness, but lower platelet counts. Median PRO-C3 was markedly higher in the G3–4 group than in the G0–2 group (51.84 vs. 20.86 ng/mL, $P < 0.001$). In multivariable analysis, PRO-C3 remained independently associated with significant inflammation (adjusted OR 1.114, 95% CI 1.036–1.241, $P = 0.014$), along with AST and total bilirubin. PRO-C3 alone showed good diagnostic performance, with an AUC of 0.806 (95% CI 0.748–0.865). At the optimal cutoff of 42.72 ng/mL, PRO-C3 achieved 70.0% sensitivity, 81.5% specificity, and 90.8% negative predictive value. Combining PRO-C3 with AST improved discrimination, yielding an AUC of 0.873 (95% CI 0.829–0.917), with 84.3% sensitivity, 77.2% specificity, and 94.7% negative predictive value. Decision curve and calibration analyses further supported its clinical utility, showing the highest net benefit and lowest Brier score (0.105). Subgroup analyses confirmed stable diagnostic performance across age, sex, BMI, HBeAg status, HBV DNA, and ALT strata. **Conclusion:** Serum PRO-C3 is an independent and clinically useful noninvasive biomarker for identifying significant liver inflammation in patients with chronic hepatitis B. A simple model combining PRO-C3 with AST provides superior diagnostic accuracy, improved calibration, and greater clinical net benefit compared with conventional biochemical markers. These findings support the potential role of PRO-C3-based assessment as a practical tool for noninvasive inflammatory risk stratification in CHB, including patients with normal ALT levels.

4025 | NON-INVASIVE PREDICTION MODEL CONSTRUCTION AND FOLLOW-UP OF SIGNIFICANT HEPATIC INFLAMMATION AND FIBROSIS IN CHRONIC HEPATITIS B PATIENTS WITH NORMAL ALT

Xiong Pei[1] Dongbo Wu[2] Hong Tang[3], [1]Sichuan University West China Hospital, [2]West China hospital, Sichuan University, [3]West China hospital, Sichuan University

Background: Many chronic hepatitis B (CHB) patients with persistently normal alanine transaminase (ALT) have hidden liver inflammation and fibrosis, but they are often neglected in clinical practice. Reliable non-invasive tools for risk stratification are lacking. This study aimed to investigate the clinical and liver pathological characteristics of treatment-naive CHB patients with normal ALT; to establish and validate non-invasive models for significant hepatic inflammation and fibrosis, and to explore long-term outcomes after antiviral therapy. **Methods:** A retrospective study enrolled 235 patients who underwent liver biopsy between May 2018 and July 2023 at West China Hospital. Demographic, laboratory, liver stiffness measurement (LSM), and pathological data ($G \geq 2$ for significant inflammation, $S \geq 2$ for significant fibrosis) were collected. Patients were randomly divided into training and validation sets at a 7:3 ratio. Logistic regression and machine learning models were constructed. Independent predictors were screened, and model performance was evaluated by AUC, calibration, and DCA. Long-term follow-up was performed in 168 patients who received antiviral therapy, with liver-related adverse events recorded. **Results:** Among 235 patients, significant inflammation was found in 56 (23.83%) and significant fibrosis ($S \geq 2$) in 44 (18.72%). Age > 40 years, BMI ≥ 24 kg/m², HBeAg negativity, and moderate HBV DNA (10^4–10^7 IU/mL) were associated with higher histological risks. For significant inflammation, we established the BLA (BMI-Liver stiffness-Albumin) model. The AUC were 0.81 (95%CI: 0.73–0.90) and 0.80 (95%CI: 0.67–0.93) for the training and validation set, seperately. SHAP analysis revealed albumin contributed most to model prediction. We further compared the performance of seven machine learning models, and the naive Bayes model achieved the highest AUC (0.8015) .For significant liver fibrosis, we constructed the H-BA2LF (History-BMI-Age/ALP-LSM-Fibrinogen) model. The training set AUC reached 0.88 (95%CI: 0.81–0.95), and the validation set AUC was 0.82 (95%CI: 0.70–0.94). SHAP analysis demonstrated fibrinogen was the most important predictor. Among all machine learning models, logistic regression showed the highest AUC (0.8185) .During up to 7 year follow-up of 168 treated patients, 32 developed liver nodules , 20 developed cirrhosis, and 2 developed HCC. Multivariate analysis confirmed that baseline ALT and LSM were independent risk factors for adverse outcomes. Moreover, HBsAg decreased continuously from 6 months onward, and LSM improved early and remained stable. **Conclusion:** ALT-normal CHB patients carry substantial risks of hidden significant inflammation and fibrosis. Our BLA and H-BA2LF show good predictive performance. Albumin and fibrinogen are the most important features in each model. Long-term antiviral therapy improves liver status, but close monitoring remains necessary.

4026 | PERFORMANCE OF PAGE-B AND MODIFIED PAGE-B SCORES FOR HEPATOCELLULAR CARCINOMA IN A MULTI-NATIONAL LATIN AMERICAN HEPATITIS B COHORT

Erin Mann[1] Enrique Carrera Estupiñan[2] Javier Diaz Ferrer[3] Jhon Prieto Ortiz[4] Domingo Balderramo[5] Marco Arrese[6] Andre Boonstra[7] Angelo Mattos[8] Jose Debes[1], [1]University of Minnesota, [2]Universidad San Francisco de Quito, [3]Universidad de San Martin de Pores, [4]CEHYD (Centro de Enfermedades Hepáticas y Digestivas), [5]Instituto Universitario de Ciencias Biomédicas de Córdoba, [6]Pontificia Universidad Católica de Chile, [7]Erasmus University Medical Center, [8]Federal University of Health Sciences of Porto Alegre

Background: The PAGE-B score predicts hepatocellular carcinoma (HCC) risk in patients with chronic hepatitis B virus (HBV) infection and is used to guide surveillance decisions. Performance of PAGE-B in Latin American populations has not been well characterized, with the available data coming only from Brazil. We evaluated PAGE-B and modified PAGE-B (mPAGE-B) in a multi-national Latin American HBV cohort. **Methods:** We analyzed HBV patients from cross-sectional and prospective cohorts at sites in Argentina, Brazil, Chile, Colombia, Ecuador, and Peru. The analytic cohort was restricted to patients with complete data for the PAGE-B components (age, gender, platelets). PAGE-B was calculated for all patients; mPAGE-B, which adds serum albumin, was calculated for the subset with albumin data and compared with PAGE-B in the same patients. Analyses were performed in the full cohort and in the subgroup of patients with documented HBV treatment. In the prospective cohort, incident HCC over 12 months from first visit was identified. Negative predictive value (NPV) and positive predictive value (PPV) were calculated for each score at its low-risk cutoff. NPV and PPV were compared between scores using a paired test for predictive values. **Results:** The cross-sectional cohort included 258 patients (mean age 57.5 years, SD 13.8; 58.1% male), of whom 91 (35.3%) had HCC. Patients were from Argentina (n = 14), Brazil (n = 92), Chile (n = 3), Colombia (n = 4), Ecuador (n = 48), and Peru (n = 97). In the full cohort, PAGE-B had an NPV of 73.3% and PPV of 37.9%. Among patients with available albumin (n = 201), of whom 49 had HCC (24.4%), mPAGE-B performed slightly better than PAGE-B (NPV 94.4% vs. 93.2%, p = 0.61; PPV 28.5% vs. 29.3%, p = 0.40), though differences were not statistically significant. In the treated subgroup (n = 103), PAGE-B had an NPV of 88.5% and PPV of 13.0%; among treated patients with albumin values (n = 93), of whom 11 had HCC (11.8%), mPAGE-B again outperformed PAGE-B (NPV 90.5% vs. 87.5%, p = 0.49; PPV 12.5% vs. 11.6%, p = 0.51), though differences were not statistically significant. Only one patient developed incident HCC in the prospective cohort, limiting evaluation of the scores' prognostic performance. **Conclusion:** In this first multi-country Latin American evaluation, both PAGE-B and mPAGE-B demonstrated high NPV for HCC, with mPAGE-B performing slightly better. These findings support the utility of PAGE-B and mPAGE-B in guiding HCC surveillance decisions in Latin American patients with HBV.

4027 | EARLY QHBSAG NON-DECLINE IS NOT TREATMENT FAILURE: WEEK-24 REASSESSMENT IDENTIFIES DELAYED RESPONDERS TO PEG-IFNα

Haishi Wu[1] Zhiliang Gao[2] Na Gao[1], [1]Sun Yat-sen University Third Affiliated Hospital., [2]Sun Yat-sen University Third Affiliated Hospital

Background: During 48-week Peg-IFNα therapy for chronic hepatitis B (CHB), week-12 qHBsAg non-decline can create uncertainty but may not indicate uniform non-response. We tested whether week-12 and week-24 qHBsAg reassessment stratifies seroclearance probability and whether aminotransferase activation marks favorable dynamics. **Methods:** From the Everest Project, a real-world multicenter study in China, we analyzed 15,897 NA-suppressed, HBeAg-negative CHB patients with low HBsAg treated with 48-week Peg-IFNα. HBsAg seroclearance was defined as the first documented HBsAg < 0.05 IU/mL within 0-370 days. Week-12 non-decline was defined as no seroclearance by week 12 and a < 0.5-log10 qHBsAg decline from baseline. A favorable week-24 trajectory was defined as seroclearance by week 24 or an additional ≥ 0.5-log10 qHBsAg decline between weeks 12 and 24. Wilson CIs and logistic regression adjusted for baseline/week-12 qHBsAg were used. **Results:** Overall, 3,972/15,897 patients (25.0%; 95% CI 24.3%-25.7%) achieved HBsAg seroclearance. Among week-12 evaluable patients, a favorable week-12 trajectory

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(seroclearance by week 12 or a ≥0.5-log10 qHBsAg decline) identified higher seroclearance probability (2,506/4,658; 53.8%), whereas week-12 non-decliners had lower probability (581/6,356; 9.1%; 95% CI 8.5%-9.9%). Among week-24 evaluable non-decliners, 1,352/4,105 (32.9%) showed a favorable week-24 trajectory. This trajectory was associated with substantially higher seroclearance probability than persistent plateau, weak decline, or rise (408/1,352 [30.2%; 95% CI 27.8%-32.7%] vs 43/2,753 [1.6%; 95% CI 1.2%-2.1%]; adjusted OR 30.8, 95% CI 21.7-43.8; P < 0.001). Week-24 reassessment thus separated this subgroup into ~30% versus near-zero seroclearance probabilities. ALT elevation ≥2-fold baseline was associated with delayed qHBsAg decline among week-12 non-decliners after adjustment for baseline/week-12 qHBsAg (OR 1.42, 95% CI 1.24-1.63; P < 0.001). **Conclusion:** Week-12 qHBsAg non-decline should not be interpreted as treatment failure during Peg-IFNα therapy. Week-24 reassessment identifies non-decliners who remain likely to achieve HBsAg seroclearance, while ALT elevation ≥2-fold baseline may signal delayed qHBsAg decline despite an unfavorable week-12 trajectory. These findings support patient counseling and post-treatment planning during a 48-week course.

4028 | ENHANCED HBCAG IMMUNOASSAY ENABLES DETECTION OF CLINICALLY RELEVANT LOW-LEVEL HBV VIREMIA FOR TREATMENT ELIGIBILITY

Rene Geissler[1] Megha Patel[1] Anika Koehler[1] Joerg Herzogenrath[1] Eddie Almaraz[1] Justin Blumenthal[1] Amit Kumar[1] Todd Solbrig[1] Cyrille Kouligueul Diedhiou[2] Moustapha Mbow[2] Noel Manga[3] Souleymane Mboup[2] Ambroise Ahouidi[2] Michael Berg[1] Gavin Cloherty[1], [1]Abbott, [2]IRESSEF, [3]Hôpital Universitaire de la Paix

Background: Accurate staging of chronic hepatitis B is essential for guiding treatment decisions and predicting clinical outcomes. Current treatment guidelines rely on HBV DNA quantification, with therapeutic thresholds set at ≥2,000 IU/mL or ≥20,000 IU/mL depending on liver enzyme levels, HBeAg status, and evidence of fibrosis or cirrhosis. Despite these guidelines, access to molecular diagnostics for HBV DNA measurement remains limited in many low- and middle-income countries (LMICs) where most infections (~80%) occur, creating barriers to timely and effective care. Importantly, non-phosphorylated HBcAg, located in HBV DNA-containing particles, has emerged as surrogate biomarker for HBV DNA. However, more sensitive HBcAg immunoassays could offer additional clinical utility by enabling HBV detection at clinically relevant thresholds. **Methods:** We modified a first-generation (v1) HBcAg-specific assay by incorporating a new formulation and monoclonal antibodies. Additionally, this updated assay format was implemented on a digital platform (v2), improving clinical sensitivity on average 225-fold. **Results:** The enhanced version (v2) achieved a limit of quantification of 30 fg/mL, corresponding to approximately 1,000 HBV DNA IU/mL. Comparative analysis of v1 and modified v2 assays demonstrated a reduction in the detection threshold from $4.9x10^5$ to 1,000 HBV DNA IU/mL, which aligns with treatment eligibility criteria. Longitudinal blood draws from acute HBV patients and single timepoint specimens from treatment-naïve blood donors showed significantly improved detection and quantification using the v2 HBcAg assay. **Conclusion:** The HBcAg v2 assay enables increased detection of low viral titers consistent with treatment guidelines and corresponds directly to HBV DNA levels. Its ability to specifically detect low-abundance HBcAg enhances disease staging and may support therapeutic management, particularly in resource limiting settings, where affordable and deployable diagnostic tools are urgently needed.

4029 | HBCRAG AS A BIOMARKER FOR PREDICTING RELAPSE FOLLOWING NUCLEOS(T)IDE ANALOGUE DISCONTINUATION IN CHRONIC HEPATITIS B: A PROSPECTIVE PILOT STUDY

Premashis Kar[1] Pravinkumar Rejliwal[2] Pabitra Sahu[3], [1]Maulana Azad Medical College, [2]Max Superspeciality HOPSITAL, [3]Max Superspeciality Hospital

Background: Discontinuation of nucleos(t)ide analogue (NA) therapy in selected patients with chronic hepatitis B (CHB) may achieve functional cure but

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

carries a risk of virological and biochemical relapse. Hepatitis B core-related antigen (HBcrAg), a surrogate marker of intrahepatic covalently closed circular DNA (cccDNA) activity, may help identify patients suitable for treatment cessation. We evaluated the utility of HBcrAg in combination with HBV DNA for predicting relapse after NA discontinuation. **Methods:** In this prospective pilot study, 59 consecutive non-cirrhotic, HBeAg-positive CHB patients aged 18–80 years who had received ≥ 12 months of NA therapy and achieved undetectable HBV DNA and HBcrAg were enrolled. Antiviral therapy was discontinued, and patients were followed for 6 months with serial HBV DNA and HBcrAg measurements. Relapse was defined as HBV DNA > 2000 IU/mL and/or alanine aminotransferase (ALT) > 2× the upper limit of normal. **Results:** During the 6-month follow-up period, a proportion of patients experienced virological and/or biochemical relapse despite undetectable HBV DNA at treatment cessation. Patients who maintained HBcrAg negativity after discontinuation were more likely to remain in sustained remission. Persistent HBcrAg negativity demonstrated potential utility as an adjunctive marker for identifying patients at lower risk of relapse following NA withdrawal. **Conclusion:** HBcrAg may complement HBV DNA in monitoring treatment response and predicting relapse after NA discontinuation in CHB. Sustained HBcrAg negativity was associated with a lower likelihood of relapse and may aid in selecting candidates for treatment cessation. Larger studies with longer follow-up are needed to validate the role of HBcrAg in guiding NA discontinuation strategies.

4030 | MACHINE LEARNING–BASED MODEL FOR PREDICTING SIGNIFICANT FIBROSIS IN CHRONIC HEPATITIS B PATIENTS IN THE INDETERMINATE PHASE

Shaoqiu Zhang[1] Li Zhu[2] Haiqin Pu[3] Jian Wang[1] Tao Fan[4] Ye Xiong[4] Chao Jiang[5] Juan Xia[1] Yuanwang Qiu[6] Xingxiang Liu[3] Chuanwu Zhu[2] Rui Huang[1] Qun Zhang[7] Chao Wu[1], [1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, [2]The Affiliated Infectious Diseases Hospital of Soochow University, [3]Huai'an No. 4 People's Hospital, [4]Nanjing Drum Tower Hospital Clinical College of Nanjing University of Chinese Medicine, [5]Nanjing Drum Tower Hospital Clinical College of Jiangsu University, [6]The Fifth People's Hospital of Wuxi, [7]Zhongda Hospital, School of Medicine, Southeast University

Background: Although the shared decision-making approach is recommended for the management of chronic hepatitis B (CHB) patients with indeterminate phase according to the AASLD 2025 hepatitis B guidelines, the presence of significant fibrosis is an important factor informing antiviral treatment decisions. Using machine learning approaches, we developed and validated a noninvasive model to accurately predict significant fibrosis in CHB patients in the indeterminate phase. **Methods:** A total of 751 patients with CHB who fulfilled the 2025 AASLD criteria for the indeterminate phase and underwent liver biopsy were retrospectively included from 5 medical centers in China. Significant fibrosis was defined as liver fibrosis of stage ≥ S2 according to Scheuer's classification. Patients were randomly divided into a training cohort and a validation cohort at a ratio of 7:3. Candidate variables were selected by LASSO logistic regression and Boruta algorithm in the training cohort. Clinically relevant feature sets were compared using gradient boosting machine (GBM) with 10-fold cross-validation, and multiple machine learning algorithms were trained using the final feature set, including logistic regression, random forest, extreme gradient boosting (XGBoost), GBM, support vector machine (SVM), and decision tree. The final model was compared with aspartate aminotransferase (AST) to platelet ratio index (APRI) and fibrosis index based on 4 factors (FIB-4) in the validation cohort by the area under the receiver operating characteristic curve (AUROC), calibration, and decision curve analysis. **Results:** The training and validation cohorts included 522 and 229 patients, respectively, with significant fibrosis observed in 301 (57.7%) and 132 (57.6%) patients. The final model was constructed using GBM and incorporated five variables (HBV DNA, platelet count, prothrombin time, albumin, and AST). In the validation cohort, the GBM model achieved an AUROC of 0.755 (95% confidence interval [CI]: 0.693-0.816), which was significantly higher than APRI (AUROC: 0.681, 95% CI: 0.611-0.750, P = 0.015) and FIB-4 (AUROC: 0.669, 95% CI: 0.599-0.738, P = 0.012). It also showed reliable calibration function (Brier score of 0.199 and Hosmer-Lemeshow test of P > 0.05) and had higher net benefit in decision curve analysis. **Conclusion:** This novel machine learning model, which includes five routinely available variables, outperformed APRI and FIB-4 and provided reliable risk prediction for significant liver fibrosis in CHB patients with indeterminate phase. This model may serve as a practical tool for treatment decision-making in such population.

4031 | CLINICAL AND LIPID-RELATED METABOLIC BIOMARKERS ASSOCIATED WITH LIVER FIBROSIS IN PATIENTS WITH CHRONIC HEPATITIS B AND MASLD: A SYSTEMATIC REVIEW AND META-ANALYSIS

Zhenghaoyu Huang[1] Jinyang Gong[1] Han Lin[1] Mengmeng Liu[2] Xu Li[2] Yonghong Guo[2], [1]University of Shanghai for Science and Technology, [2]Gongli Hospital of Shanghai Pudong New Area

Background: Chronic hepatitis B (CHB) and metabolic dysfunction-associated steatotic liver disease (MASLD) frequently coexist and may jointly contribute to liver fibrosis progression. Metabolic dysregulation, including lipid-related abnormalities and liver injury markers, may reflect fibrogenic activity in this dual-etiology population. We aimed to systematically evaluate clinical and lipid-related metabolic biomarkers associated with significant liver fibrosis in patients with CHB and MASLD. **Methods:** We systematically searched PubMed, Embase, Cochrane Library, Web of Science, CBM, CNKI, Wanfang, and VIP from inception to May 6, 2026, following PRISMA 2020 guidance. Eligible studies included adults with CHB and concomitant MASLD who reported serum metabolic or clinical biomarkers according to liver fibrosis status. Significant fibrosis was defined as fibrosis stage $\geq$F2, assessed by liver biopsy or validated non-invasive methods including liver stiffness measurement, FIB-4, or NFS. Pooled mean differences (MDs) with 95% confidence intervals (CIs) were calculated using fixed- or random-effects models according to heterogeneity. Study quality was assessed using the Newcastle–Ottawa Scale. **Results:** A total of 11 studies involving 3,431 patients with CHB and MASLD were included, of whom 1,143 had significant fibrosis and 2,288 had non-significant fibrosis. Compared with patients without significant fibrosis, those with significant fibrosis had higher levels of gamma-glutamyl transferase (GGT; MD = 14.51, 95% CI 9.68–19.34; I^2 = 72%; P < 0.001) and alanine aminotransferase (ALT; MD = 8.59, 95% CI 6.14–11.04; I^2 = 0%; P < 0.001). Platelet count was significantly lower in patients with significant fibrosis (MD = -33.81, 95% CI -51.38 to -16.23; I^2 = 85%; P < 0.001). HDL-C was also lower in the significant fibrosis group (MD = -0.05, 95% CI -0.08 to -0.02; I^2 = 80%; P = 0.001). No significant differences were observed for total cholesterol (MD = 0.01, 95% CI -0.10 to 0.12; I^2 = 14%; P = 0.86), triglycerides (MD = -0.04, 95% CI -0.17 to 0.09; I^2 = 62%; P = 0.53), or LDL-C (MD = 0.21, 95% CI -0.11 to 0.54; I^2 = 82%; P = 0.20). **Conclusion:** In patients with CHB and concomitant MASLD, significant liver fibrosis was associated with higher GGT and ALT levels and lower platelet count and HDL-C levels. In contrast, total cholesterol, triglycerides, and LDL-C were not significantly associated with fibrosis status. These findings highlight the close relationship between liver biochemical abnormalities and fibrosis in this dual-etiology population, supporting closer monitoring and optimized management to improve liver biochemical profiles. These readily available biomarkers may help support non-invasive liver fibrosis risk stratification in patients with coexisting CHB and MASLD.

4032 | INTEGRATION OF MICROBIAL SIGNATURES INTO MACHINE LEARNING MODELS SIGNIFICANTLY IMPROVES PREDICTION OF ADVERSE OUTCOMES IN PATIENTS WITH HEPATITIS B-RELATED CIRRHOTIC ASCITES

Jiaran Sun[1] Ruifeng Yang[1], [1]Department of Clinical Laboratory, Peking University Shougan

Background: Traditional clinical assessment methods have limitations in early identification of poor prognosis in hepatitis B-related cirrhotic ascites. This study aimed to evaluate the value of a novel machine learning model that integrates microbial signatures with conventional clinical features for predicting 90-day end-stage liver disease (ESLD) events in patients with hepatitis B-related cirrhotic ascites. **Methods:** A total of 306 patients with cirrhotic ascites who underwent ascitic fluid culture between 2019 and 2024 were retrospectively enrolled. Among them, 206 patients from 2019–2022 were assigned as the training set, and 100 patients from 2022–2024 served as an independent test set. The primary outcome was ESLD events occurring within 90 days after ascitic fluid sampling, including liver failure-related death, liver transplantation, hepatorenal syndrome, or grade III–IV hepatic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

encephalopathy. Clinical and microbial features were analyzed. Three models were constructed: a baseline MELD-Na model, a logistic regression model, and an eXtreme Gradient Boosting (XGBoost) model integrating all features. Model performance was evaluated on the independent test set. For the XGBoost model, SHapley Additive exPlanations (SHAP) values were used to rank feature importance. **Results:** The overall 90-day endpoint event rate was 35%. Compared to the non-ESLD group, patients with ESLD exhibited significantly worse microbial profiles (higher rates of positive ascitic fluid culture, polymicrobial infection, carbapenem resistance, and availability of fewer than two effective antibiotics) and clinical parameters (MELD-Na score, ascitic fluid polymorphonuclear leukocyte count, procalcitonin, and serum creatinine). The XGBoost model demonstrated significantly superior predictive performance, with an AUC of 0.85 on the test set, outperforming both the MELD-Na model (AUC = 0.72) and the logistic regression model (AUC = 0.78) ($P < 0.05$). SHAP analysis further confirmed that carbapenem resistance was the most influential microbial predictor, while MELD-Na score, procalcitonin, and availability of fewer than two effective antibiotics were also important features. **Conclusion:** Integrating microbial signatures, with a focus on antimicrobial resistance, substantially improves the prediction of short-term adverse outcomes in patients with cirrhotic ascites. This model may facilitate early identification of high-risk patients and guide precise clinical intervention.

4033 | CLINICAL APPLICATION OF SERUM ALBUMIN BINDING FUNCTION DETECTION METHOD BASED ON ELECTRON PARAMAGNETIC RESONANCE

Wen Xie[1] Ge Yidi[1], [1]Beijing Ditan Hospital

Background: As an important protein that reflects the synthetic function of the liver, the structural integrity and binding function of albumin are often damaged during the progression of liver disease, and the traditional total albumin concentration detection is difficult to accurately reflect the true functional state of albumin. This research aims to establish and verify a serum albumin binding function detection method based on Electron paramagnetic resonance (EPR) technology, and verify its application in different evolutionary stages of hepatitis B-related liver disease. **Methods:** This study uses EPR technology as the detection method, and uses 16-bit nitrogen oxide free radical labeling stearic acid as a spin probe. Based on the principles of age, gender and underlying disease matching, the study included a total of 180 cases in six groups, including chronic hepatitis B, hepatitis B cirrhosis, hepatocellular carcinoma and healthy control groups. Analyze the EPR spectrum through the spectrum fitting methods. The experimental spectrum of the complex formed after the combination of HSA and 16-DSA is mainly composed of three different components, namely the strong-binding component, the weak-binding component and the free component. Among them, the strong binding component corresponds to the probe part that binds to the albumin molecule with high intensity; the weak binding component reflects the medium-strength binding state between the probe and the albumin; the free component represents the free probe molecule that is not bound to albumin. Under the condition that the molar ratio of the probe and albumin remains constant, the higher the proportion of free components in the total spectrum, indicating that the comprehensive binding ability of albumin to foreign molecules is weaker, that is, the binding performance is poor.This research was approved by the Ethics Committee of Ditan Hospital. (AF/SS-21/05.2) **Results:** Based on the system optimization of EPR detection conditions, this study has established a set of serum albumin binding function detection methods with high accuracy and excellent detection efficiency. On the basis of this study, this study further carried out testing and verification. This study results showed that the albumin binding function gradually decreased with the severity of liver disease. **Conclusion:** Based on EPR technology to detect serum albumin binding function technology, this study further optimizes the detection conditions to establish a more efficient detection process. Through verification in different stages of liver disease, it was found that albumin binding function gradually decreased with the aggravation of the severity of hepatitis B-related liver disease.

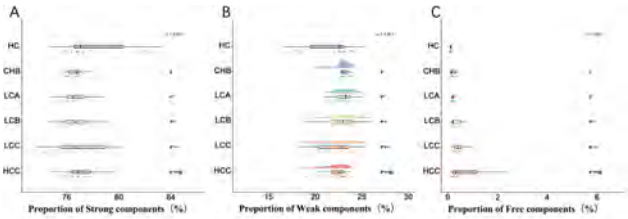

Figure. Comparison of the proportion of different components after spectrum fitting in the healthy control and hepatitis B-related liver disease group
A. Comparison of the proportion of free components; B. Comparison of the proportion of strong binding components; C. Comparison of the proportion of weakly combined components.The p value in the figure represents the overall comparison result between the four groups. Each group made a two-by-two comparison, # indicating that compared with the healthy control group. The difference is statistically significant ($p< 0.05$), * indicates that the difference with the chronic hepatitis B group is statistically significant ($p< 0.05$). + indicates that the difference with hepatitis B cirrhosis Child-pugh A-level group is statistically significant ($p< 0.05$), ÷ indicates that the difference with hepatitis B cirrhosis Child-pugh A-level group is statistically significant ($p< 0.05$), ※ indicates that it is compared with hepatitis B cirrhosis Child-pugh B-level group The difference is statistically significant ($p< 0.05$). If it is not marked, the difference is not statistically significant.
CHB: Chronic hepatitis B; HCC: Hepatocellular carcinoma; HC: Healthy control; LCA: Child-Pugh class A liver cirrhosis; LCB: Child-Pugh class B liver cirrhosis; LCC: Child-Pugh class C liver cirrhosis; LC: Liver cirrhosis.

4034 | ◆ FORTY YEARS AFTER UNIVERSAL HEPATITIS B VACCINATION IN TAIWAN: CURRENT SEROEPIDEMIOLOGY AND REMAINING GAPS TOWARD ELIMINATION

Kai-Chi Chang[1] Mei-Hwei Chang[1] Huey-Ling Chen[1] Yen-Hsuan Ni[1], [1]National Taiwan University Hospital

Background: Universal infant hepatitis B virus (HBV) vaccination programs have substantially reduced the prevalence of HBV infection worldwide. We aimed to evaluate the long-term efficacy of universal HBV vaccination after 40 years of implementation in Taiwan and to identify the remaining barriers toward HBV elimination. **Methods:** A total of 2,378 individuals aged 0–60 years were recruited in 2025 from four administrative regions in Taiwan according to population distribution. Serum levels of hepatitis B surface antigen (HBsAg), hepatitis B surface antibody (anti-HBs), and hepatitis B core antibody (anti-HBc) were assessed. **Results:** After 40 years of universal vaccination, the overall seropositivity rates for HBsAg and anti-HBc in Taiwan were 3.36% and 18.8%, respectively. Compared with the pre-vaccination cohort, the post-vaccination cohort demonstrated markedly lower seropositivity rates for both HBsAg (0.82% vs. 7.5%, $p < 0.001$) and anti-HBc (2.85% vs. 44.7%, $p < 0.0001$). Among breakthrough HBsAg-positive cases in the vaccinated cohort, mother-to-child transmission remained the predominant route of HBV infection.Among participants without evidence of HBV infection (HBsAg-negative/anti-HBc-negative), detectable protective anti-HBs levels (> 10 mIU/mL) were observed in 49.5% (708/1429) of the vaccinated cohort. Anti-HBs seropositivity varied across age groups within the vaccinated cohort, reaching the lowest level in adolescents aged 10–19 years (35.7%), compared with 63.3% in children aged < 10 years, 56.5% in individuals aged 20–29 years, and 60.2% in those aged 30–39 years. **Conclusion:** A profound reduction in HBV infection has been achieved after 40 years of universal HBV vaccination in Taiwan. However, despite the persistently low prevalence of HBsAg positivity, complete eradication of HBV infection has not yet been achieved. Vaccine-induced anti-HBs antibodies waned over time while still maintaining effective protection against chronic HBV infection. Mother-to-child transmission remains a critical barrier to HBV elimination, highlighting the importance of optimizing perinatal screening and antiviral intervention strategies.

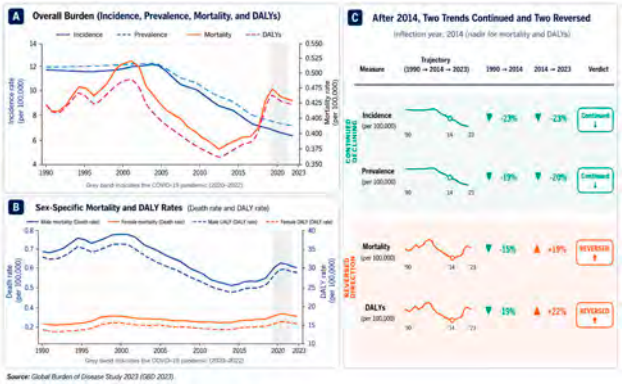
4035 | ◆ THE HIDDEN BURDEN OF CHRONIC HEPATITIS B: MORTALITY AND DISABILITY PERSIST DESPITE DECLINING INCIDENCE: A GLOBAL BURDEN OF DISEASE ANALYSIS, 1990–2023



Mohamed Eldesouki[1] Mohammed Youssef[2] Ahmed Ibrahim[3] Omar Alkasabrah[4] Mohammad Nabil Rayad[5] Abdelfattah Taha[6] Theodore Dacosta[5] Yatinder Bains[1], [1]New York Medical College at Saint Michael Medical Center, [2]Hunt Regional Medical Center, [3]San Joquin General Hospital, [4]Landmark Medical Center, [5]New York Medical College at Saint Michael's Medical Center, [6]LSCFT Trust

Background: Chronic hepatitis B (HBV) is a leading driver of liver-related morbidity and mortality in the United States. However, contemporary U.S. trends among young and middle-aged individuals are incompletely characterized. We examined three decades of chronic HBV incidence, prevalence, mortality, and disability-adjusted life year (DALY) trends to characterize the contemporary burden in this middle-aged population. **Methods:** We analyzed Global Burden of Disease Study 2023 estimates from the IHME for chronic hepatitis B among U.S. adults aged 15–49 years from 1990–2023. Annual age-standardized rates per 100,000 were extracted for incidence, prevalence, mortality, and DALYs, overall and by sex. Temporal trends were characterized by cumulative percent change from 1990 to 2023. We also compared two analytic epochs (1990→2014 and 2014→2023) and identified inflection points. Sex disparities were assessed using annual male-to-female rate ratios. Estimates are reported with 95% uncertainty intervals. **Results:** Among U.S. adults aged 15–49 years, chronic HBV incidence declined by 40.6% from 1990 to 2023, decreasing from 11.66 to 6.92 per 100,000, while prevalence declined by 35.0%, from 475.3 to 309.0, reflecting vaccination and screening gains. In contrast, mortality increased by 0.6% from 0.452 to 0.455, while DALYs decreased by only 0.9%, from 22.66 to 22.45 per 100,000 (Figure 1A).Sex-based disparities were pronounced in 2023: men had approximately 2-fold higher mortality than women (0.60 vs 0.30 per 100,000) and 2-fold higher DALY rates (29.77 vs 14.92 per 100,000). The male-to-female gap was smaller for prevalence (350.96 vs 265.92 per 100,000) and incidence (8.16 vs 5.65 per 100,000), corresponding to ratios of 1.32–1.44 (Figure 1B).Period-specific analysis showed a clear divergence after 2014. From

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

1990 to 2014, all four measures declined, including incidence (−23%), prevalence (−19%), mortality (−15%), and DALYs (−19%). From 2014 to 2023, incidence and prevalence continued to decline by 23% and 20%, respectively. In contrast, mortality and DALYs shifted from prior decline to large increases, rising by 19% and 22%, respectively. Mortality and DALYs reached their lowest levels around 2014–2015, followed by a sustained increase through 2023, with both measures peaking in 2021 during the COVID-19 pandemic period. (Figure 1C) **Conclusion:** Despite substantial declines in chronic HBV incidence and prevalence among U.S. young adults, mortality and DALYs rates did not decline over three decades and increased sharply after 2014, with further increases during the COVID-19 pandemic period. This divergence reflects the ongoing burden of established chronic HBV infection and gaps in diagnosis, linkage to care, and antiviral treatment. Intensified HBV screening, treatment initiation, and longitudinal liver disease prevention are needed to convert gains in HBV prevention into reductions in mortality and disability.

4036 | ◆ BASELINE HEPATITIS B SURFACE ANTIGEN LEVEL PREDICTS IMMUNE-ACTIVE PHASE TRANSITION IN INACTIVE CHRONIC HEPATITIS B

Tai-Chung Tseng[1] Shang-Chin Huang[2] Pei-Yu Yang[1] Tung-Hung Su[1] Hung-Chih Yang[2] Chen-Hua Liu[1] Jia-Horng Kao[1], [1]National Taiwan University Hospital, [2]National Taiwan University

Background: Chronic hepatitis B (CHB) remains a major global health concern, primarily because of the development of hepatocellular carcinoma (HCC). Previous studies have shown that inactive CHB patients with hepatitis B surface antigen (HBsAg) levels < 100 IU/mL have a negligible risk of HCC. Since transition to the immune-active (IA) phase is a key driver of HCC development and a major indication for antiviral treatment initiation, this study aimed to explore whether a baseline HBsAg level < 100 IU/mL is associated with a lower risk of IA phase transition in inactive CHB patients. **Methods:** A total of 291 inactive CHB patients (non-cirrhotic, HBeAg-negative, normal ALT levels, and HBV DNA < 2,000 IU/mL) were retrospectively enrolled from National Taiwan University Hospital between 2000 and 2010. Patients underwent regular follow-up at least twice yearly. The primary endpoint was IA phase transition, defined as ALT > 2× the AASLD-defined upper limit of normal together with HBV DNA > 2,000 IU/mL. HBV DNA and HBsAg levels were measured using stored serum samples. **Results:** Over a median follow-up of 12.4 years, 15 inactive CHB patients developed IA phase transition, corresponding to an annual incidence of 0.35%. Among the cohort, 124 (42.0%) patients had HBsAg levels < 100 IU/mL. Patients with HBsAg < 100 IU/mL (vs. ≥ 100 IU/mL) had lower risk of IA phase transition, with a crude hazard ratio (HR) of 0.11 (95% CI: 0.01-0.89). This association remained significant after adjustment for age and sex. Notably, only one inacitve CHB patients with HBsAg < 100 IU/mL developed IA phase transition during the follow-up. **Conclusion:** Serum HBsAg levels < 100 IU/mL effectively identify inactive CHB patients with a minimal risk of IA phase transition. Since an HBsAg level < 100 IU/mL has been shown to identify inactive CHB patients with an HCC risk below the HCC surveillance threshold, our data suggest that excluding these patients from regular follow-up carries a minimal risk of missing the opportunity for antiviral treatment initiation, which is a key component in defining partial HBV cure.

4037 | ◆ AN OPEN-SOURCE PHENOTYPING ALGORITHM TO SUPPORT HEPATITIS B CASE-FINDING AND LINKAGE TO CARE

Nathaniel Ash[1] Brandon Mui[2] Brooke Wyatt[3] Anna Mageras[1] Jihae Jeon[1] Alyson Harty[3] Lauren Alpert[1] Mark Miller[1] Tatyana Kushner[4] Douglas Dieterich[1] Andrea Branch[3], [1]Icahn School of Medicine at Mount Sinai, [2]Renaissance School of Medicine at Stony Brook University, [3]Icahn School of Medicine at Mount Sinai (ISMMS), [4]Weill-Cornell Medical College

Background: Chronic hepatitis B virus (HBV) infection affects 296 million people globally and remains a major public health threat. Antiviral therapy remains underutilized even among treatment-eligible patients. Proactive case-finding tools have previously been shown to close care gaps in other chronic liver diseases and are needed to improve the HBV care pipeline. We aimed to develop an open-source phenotyping algorithm to facilitate HBV case-finding and linkage to care. **Methods:** An HBV case-finding algorithm was developed using structured query language coding to collect and analyze data from EPIC electronic medical records, incorporating 145 laboratory test values, five antiviral medications, patient age, and last date of data entry or death. Algorithm performance was validated against manual review of 200 randomly selected patient charts. The validated algorithm was then applied to records of 4,095,070 individuals in the Mount Sinai Data Warehouse (2003–2024). Treatment eligibility was assessed per EASL guidelines using HBsAg, HBV DNA, ALT, and FIB-4 scores. Patients eligible for treatment without a recorded prescription were flagged for outreach. **Results:** The algorithm achieved 99.0% accuracy, with 90.9% sensitivity, 99.5% specificity, 90.9% PPV, and 99.5% NPV. Among 4,095,070 individuals, 149,037 had HBsAg and/or HBV DNA testing and 17,001 had HBV DNA data available for treatment eligibility assessment. Significant treatment gaps were identified across all eligibility categories. Notably, 54.6% of patients with HBV DNA > 20,000 IU/mL and ALT > 2x ULN lacked a prescription; 52.9% of those with HBV DNA > 2,000 IU/mL, ALT > ULN, and/or FIB-4 > 2.67 lacked a prescription; and 58.2% of patients with FIB-4 > 3.25, indicating likely cirrhosis, had no recorded HBV prescription. Additionally, 2,205 HBsAg-positive patients lacked HBV DNA testing, including 83 with ALT > 2x ULN, precluding treatment eligibility assessment. **Conclusion:** We developed a high-performance, portable HBV case-finding algorithm. It revealed substantial treatment gaps across a large, diverse health system. Over half of treatment-eligible patients with advanced fibrosis or cirrhosis lacked antiviral prescriptions, highlighting a critical need for proactive outreach and longitudinal care management. The algorithm is freely available on GitHub with a user manual and is adaptable to both EPIC and non-EPIC systems, enabling scalable implementation to improve HBV care delivery.

4038 | ◆ LONG-TERM RISK OF LIVER-RELATED EVENTS IN PATIENTS WITH RESOLVED HDV INFECTION COMPARED WITH HBV MONOINFECTION: A PROPENSITY SCORE-MATCHED ANALYSIS

Habiba Kamal Khodir[1] Karin Lindahl[2] Katarina Århem[2] Caroline Gahrton[2] Heiner Wedemeyer[3] Soo Aleman[2], [1]Karolinska Institutet, [2]1Dept of Infectious Diseases, Karolinska University Hospital/ Karolinska Institutet, Stockholm, Swede, [3]3D-SOLVE: EU-funded Network on individualized management of hepatitis D, 4Department of Gastroentero

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Patients with resolved HDV replication have a more favorable prognosis compared to those with persistent HDV replication. However, the long-term risk of liver-related events compared with HBV-monoinfection remains unclear. We aimed to compare liver disease progression between patients with resolved HDV infection and HBV monoinfection. **Methods:** We conducted a retrospective cohort study including all adults with resolved HDV infection, defined as anti-HDV positivity with at least two negative HDV RNA tests, and patients with chronic HBV monoinfection attending the Department of Infectious Diseases at Karolinska University Hospital, Stockholm, Sweden between 1990-2024. Data were retrieved from InfCare Hepatitis registry. Patients with resolved HDV infection were propensity score-matched up to 1:5 with HBV-monoinfected controls by birth, sex, date of initial visit, HBeAg status, and region of origin. Patients with prior liver transplantation, HCC at baseline, or < one year follow-up were excluded. The incidence rates and cumulative risks of liver-related events (decompensation, HCC, liver-related death, or liver transplantation) were assessed using Kaplan-Meier analysis and compared with Cox regression. **Results:** In total, 110 patients with resolved HDV infection were matched to 522 patients with HBV monoinfection. Median age at diagnosis was 34.5 years in both groups. The resolved HDV group included more males (79.1% vs. 56.3%, $p < 0.001$), Caucasians (31.1% vs 18.8%), anti-HCV positive patients (56.4% vs 0.4%), and patients with alcohol overconsumption (52.7% vs. 5.9%). Baseline ALT, AST, bilirubin, albumin, INR, and liver stiffness values were comparable, but cirrhosis was more frequent in the resolved HDV group (21.8% vs 9.6%). During a median follow-up of 9.5 (IQR 5.1-16.8) years, liver-related events occurred in 20 (18.2%) of resolved group versus 30 (5.2%) of HBV-monoinfection group. This corresponds to annual incidence rates of 1.7%, and 0.5%, respectively, and 10-, 15- and 20-year cumulative risks of 15.8%, 19.9% and 23.3% in the resolved group vs, 4.8%, 7.5% and 8.3% in the HBV monoinfection group (all $p < 0.05$). Independent predictors of liver events were older age (aHR = 1.1), diabetes (aHR = 2.30), alcohol overconsumption (aHR = 2.3), anti-HDV+ (aHR = 2.44) and baseline cirrhosis (aHR = 2.67). **Conclusion:** Patients with resolved HDV infection showed a higher long-term risk of liver events than those with HBV-monoinfection. This excess risk was driven by previous HDV infection as well as comorbid factors and baseline liver cirrhosis. Closer monitoring and multidisciplinary management should be considered in this population.

4039 | ◆ THE MISSING CASES: A NATIONWIDE SURVEY OF HEPATITIS B KNOWLEDGE AND PRACTICE AMONG 1,107 TURKISH PRIMARY CARE PHYSICIANS

Imran Hasanoglu[1] Rahmet Guner[1], [1]Ankara Yildirim Beyazit University Bilkent City Hospital

Background: Primary care physicians (PCPs) are the frontline workforce for hepatitis B virus (HBV) screening, vaccination, and long-term monitoring; their performance

directly shapes a country's capacity to reach the WHO 2030 elimination targets. Despite national elimination targets, real-world knowledge and practice patterns among PCPs remain poorly characterized. **Methods:** A cross-sectional, face-to-face survey was conducted across all 81 provinces of Türkiye between December 2024 and November 2025. With the logistical support and dedication of the Humanis team, a 105-member field team surveyed 1,107 PCPs at 634 primary care centers. The 11-question survey assessed HBV prevalence, risk-group recognition, screening test selection, natural history, management of HBsAg-positive mothers and patients, treatment principles, and doctors' perception of HBV caseload on their own patient lists. **Results:** A total of 1,107 PCPs completed the survey. Correct-answer rates ranged from 33% to 89% across the eleven questions. Recognition of routine preventive concepts was high: 89% correctly interpreted isolated anti-HBs positivity as prior vaccination and 86% the combined approach to HBsAg-positive mothers and newborns. In contrast, only 33% correctly identified Türkiye's HBsAg prevalence as ~4%, and only 40% recognized that perinatally acquired HBV becomes chronic in ~90% of cases. Half (50%) misclassified HBcAb as a routine screening test, and 58% answered the chronic HBV treatment question incorrectly. Risk-group recognition was uneven: dialysis patients (96%) and injection drug users (95%) were widely recognized, whereas household contacts (74%) and travelers to endemic regions (75%) were least recognized. When asked whether the HBV cases on their patient list matched the caseload expected under Türkiye's ~4% prevalence, 65% (725/1,107) answered "no"; of these, 76% (671/888) also reported patients of unknown HBV serology. **Conclusion:** This nationwide study, the largest HBV knowledge assessment ever conducted among PCPs in Türkiye, demonstrates substantial gaps in fundamental HBV management. These deficiencies may delay diagnosis, contribute to missed chronic infections, and undermine elimination strategies. Targeted educational interventions and simplified primary-care algorithms may strengthen the role of PCPs in HBV elimination.

[32]Foundation IRCCS CaGranda Ospedale Maggiore Policlinico, Milan, Italy, [33]National Yang Ming Chiao Tung University, Taipei, Taiwan, [34]Makerere University College of Health Science, Kampala, Uganda, [35]Faculdade Medicina da Universidade de Sao Paulo, Sao Paulo, Brazil, [36]Padua University Hospital, Padua Italy, [37]School of Medicine, Recep Tayyip Erdoğan University, Rize, Türkiye, [38]The Global NASH/MASH Council, Washington DC, USA, [39]Center for Outcomes Research in Liver Diseases, Washington DC, USA, [40]College of Medicine, University of the Philippines, Manila, Philippines

Background: Despite declining HBV-related HCC incidence due to vaccination and antiviral therapy, HBV remains a leading etiology of HCC in many regions. Appropriate HCC surveillance enables earlier diagnosis and improves curative treatment outcomes. We assessed global HCC surveillance practice patterns among clinicians managing chronic HBV patients and factors affecting these patterns. **Methods:** An international group of experts from the Global Liver Council developed and conducted a global online survey on HBV/HDV clinical practice patterns from June-September 2025. Based on HCC screening responses, participants were classified as screening: a) all HBsAg-positive patients (universal), b) only those with cirrhosis or HCC risk factors (risk-based), or c) none. Multivariable analysis identified factors independently associated with screening practices ($P < 0.05$). Variables evaluated included: provider demographics (sex, age, medical degree, years in practice), specialty, practice setting, HBV patient caseload, HBV knowledge, comfort treating HBV, patient encounter and treatment frequencies, guidelines followed, and geographic region. **Results:** There were 611 survey responses [hepatologists/gastroenterologists (68%), infectious disease (11.5%), and other specialties (20.5%)] from 7 global regions [Southeast (SE) Asia 25%, Europe 24%, Middle East & North Africa (MENA) 21%, South Asia 11%, USA 9%, Latin America 8%, Africa 3%]. EASL guidelines were most frequently followed (46%), then AASLD (21%), WHO (12.6%), APASL (10.1%) or other guidelines (10%). Of 561 participants responding to HCC screening practices, 4 (0.7%) reported no screening for HBsAg-positive patients and were excluded. Among the remaining 557 participants, 48.8% screened all HBsAg-positive patients (universal), while 51.2% screened only those with cirrhosis or HCC risk factors (risk-based). Associated factors by screening pattern are shown in Table. Universal screening was independently associated with practicing outside USA or Europe: Middle East/North Africa [OR = 1.91 (95% CI: 1.18–3.10), $P = 0.008$], Southeast Asia [OR = 1.97 (1.30–2.97), $P = 0.001$], and Africa [OR = 2.87 (1.03–8.02), $P = 0.044$]; and with infectious disease specialty [OR = 1.98 (1.08–3.62), $P = 0.028$]. **Conclusion:** HCC surveillance practice patterns in chronic HBV patients are independently affected by geographic region and medical specialty. Risk-based screening, recommended by most guidelines, is more frequently adopted in USA/Europe and by hepatologists/gastroenterologists, while universal screening of all HBsAg-positive patients is more common in Asia/Africa and among infectious disease specialists. Standardized, evidence-based HCC screening approaches are needed globally to improve outcomes in HBsAg-positive patients.

Table. Factors affecting current practice patterns of HCC surveillance in chronic HBV patients (patients)

		All HBsAg+ N=272	Risk based N=285	P value
Sex	Male	161 (59.6%)	163 (57.6%)	0.63

4041 | ◆ ACCELERATED HEPATITIS B VACCINATION YIELDS HIGH SEROPROTECTION INDEPENDENT OF IFNL3 POLYMORPHISMS IN HAITIAN MIGRANTS

Javier Perez-Valenzuela[1] Patricio Astudillo[1] Javier Uribe[1] José Ignacio Vargas[1] Carlos Benitez[1] Marcelo López-Lastra[1] Ruth Nuñez[1] Valentina Ross[1] Jacinta Soza[1] Karla Pino[1] Francisco Fuster[2] Alejandro Soza Ried[1], [1]Pontificia Universidad Católica de Chile, [2]Hospital Gustavo Fricke

Background: Hepatitis B virus (HBV) infects over 240 million people worldwide, increasing the risk of cirrhosis and hepatocellular carcinoma. While Chile has a low chronic HBV prevalence (0.15%), recent migration trends may alter this figure. Previous research demonstrated a significantly higher prevalence of HBV infection among Haitian migrants in Chile versus the local population. Achieving World Health Organization's (WHO) 2030 elimination goals requires innovative strategies targeting high-risk populations. Vaccination is the most effective preventive strategy, and an accelerated schedule could improve adherence. Genetic polymorphisms are associated with vaccine responses; in particular, favorable IFNL3 polymorphisms may be linked to an enhanced immune response. We evaluated the immune response to an accelerated HBV schedule in Haitian migrants in Chile and identified clinical, demographic, and genetic factors. **Methods:** This open-label prospective study enrolled adult Haitian migrants given an accelerated HBV vaccination schedule (0, 1, and 2 months). Immune response (anti-HBs $\geq$10 mIU/mL) was assessed 4-8 weeks post-vaccination. Additionally, IFNL3 SNPs rs12979860 and rs8099917 were genotyped; their distribution was tested for Hardy-Weinberg equilibrium (HWE). Clinical, demographic, and genetic associations were analyzed using Fisher's exact test and the Mann-Whitney U test ($p<0.05$ considered significant). **Results:** Eighty-two participants completed the full vaccination schedule (median age 37 years, 54.9% female). Seroprotection rate was 91.5% (95% CI: 85.3-97.6%); anti-HBs geometric mean titer (GMT) among responders was 529.7 mIU/mL (95% CI 362.4-774.2), with 88% (66/75) achieving high response ($\geq$100 mIU/mL). No immediate adverse effects occurred. Genotype analysis was performed in a subset. For rs12979860 (n = 67), distribution was TT: 64.2% (n = 43), CT: 28.4% (n = 19), and CC: 7.5% (n = 5). For rs8099917 (n = 70), distribution was TT: 88.6% (n = 62) and TG: 11.4% (n = 8). Both SNPs were in HWE. No significant

differences were found between responders and non-responders regarding age, sex, body mass index, obesity, diabetes, hypertension, smoking status, or IFNL3 genotype distribution. **Conclusion:** The accelerated HBV vaccination schedule elicited a high immune response comparable to standard approaches and was independent of IFNL3 genetic polymorphisms. High GMT and proportion of responders suggest robust and potentially durable protection. This is epidemiologically vital for key migrant populations, as high seroprotection reduces HBV susceptibility, limits transmission, and reinforces national control strategies. The data suggest that accelerated HBV vaccination could be a cornerstone of public health policy for migrants, offering an effective solution to adherence challenges and helping achieve WHO HBV elimination targets in high-prevalence groups.

Characteristic	Vaccinated (n=82)	Non-responders (n=7)	Responders (n=75)	p-value
Female sex, n (%)	45/82 (54.9)	4/7 (57.1)	41/75 (54.7)	> 0.9
Age, years (median, IQR)	37 (12)	39 (15)	36 (13)	0.6
Body Mass Index, kg/m² (median, IQR)	26.9 (6.9)	28.7 (7.6)	26.7 (6.0)	0.11

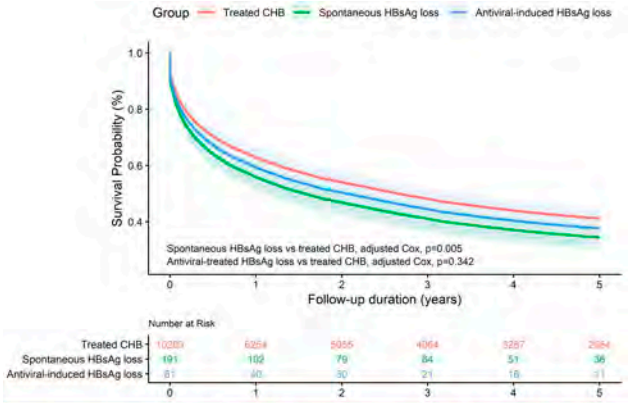
★ 4042 | ◆ POORER HEPATOCELLULAR CARCINOMA (HCC) SURVIVAL FOLLOWING SPONTANEOUS BUT NOT NUCLEOS(T)IDE ANALOGUE (NA)-INDUCED HEPATITIS B SURFACE ANTIGEN (HBSAG) LOSS IN CHRONIC HEPATITIS B (CHB)

Terry Cheuk-Fung Yip[1] Jimmy Che-To Lai[1] Mandy Lai[1] Vincent Wong[1] Henry Lik-Yuen Chan[2] Grace Wong[1],



[1]The Chinese University of Hong Kong, Hong Kong, [2]Union Hospital, Hong Kong

Background: Current European and American guidelines provide limited guidance on HCC surveillance after HBsAg loss, and surveillance may be less standardized, particularly after spontaneous HBsAg loss. We compared survival in patients with HCC diagnosed after spontaneous HBsAg loss, after NA-induced HBsAg loss, and during NA therapy in patients with CHB. **Methods:** We identified two territory-wide retrospective cohorts from Hong Kong: adults with CHB who developed HCC after HBsAg loss between 2005 and 2024, and adults with CHB who developed HCC during entecavir/tenofovir therapy in the same period. Patients with HBsAg loss after liver transplantation (LT), or patients with CHB who had LT before entecavir/tenofovir therapy, were excluded. Patients were followed from HCC diagnosis until death, Dec 31, 2024, or 5 years from HCC diagnosis, whichever came first. Mortality risk was compared using multivariable Cox regression and propensity score weighting (PSW), adjusting for age, sex, cirrhosis, calendar year of HCC diagnosis, and HCC treatment. **Results:** We included 10,203 patients with HCC during NA therapy, 191 with HCC after spontaneous HBsAg loss, and 81 with HCC after NA-induced HBsAg loss. Patients with HCC after spontaneous HBsAg loss, HCC after NA-induced HBsAg loss, and HCC during NA therapy had mean ages of 69 ± 10, 68 ± 11, and 65 ± 11 years, respectively. The proportions of men were 80%, 78%, and 82%, and the prevalence of cirrhosis was 46%, 65%, and 56%, respectively. Compared with HCC during NA therapy, HCC treatment distribution differed modestly for HCC after spontaneous HBsAg loss (p = 0.027), with curative therapy in 33.0% vs 35.7%, locoregional therapy in 25.1% vs 22.4%, and best supportive care in 41.4% vs 37.3%, respectively. Treatment distribution was similar for HCC after NA-induced HBsAg loss compared with HCC during NA therapy (p = 0.796). At a median follow-up of 1.9 (0.3-5.0) years, death occurred in 5,576 (54.7%) patients with HCC during NA therapy, 110 (57.6%) with HCC after spontaneous HBsAg loss, and 47 (58.0%) with HCC after NA-induced HBsAg loss. Compared with HCC occurring during NA therapy, HCC after spontaneous HBsAg loss was associated with higher mortality (adjusted hazard ratio [aHR] 1.31, 95% CI 1.09-1.58, p = 0.005), while HCC after NA-induced HBsAg loss was not associated with increased mortality (aHR 1.15, 95% CI 0.86-1.53; p = 0.342) (Figure). Similar findings were observed after PSW: weighted aHR 1.35 (95% CI 1.10-1.66), p = 0.004 for spontaneous HBsAg loss, and weighted aHR 1.17 (95% CI 0.88-1.57), p = 0.286 for NA-induced HBsAg loss. **Conclusion:** HCC diagnosed after spontaneous HBsAg loss was associated with poorer survival than HCC diagnosed during NA

therapy, whereas survival after NA-induced HBsAg loss was comparable. These findings suggest a potential surveillance gap after spontaneous HBsAg loss and support risk-based continuation of HCC surveillance post HBsAg loss.

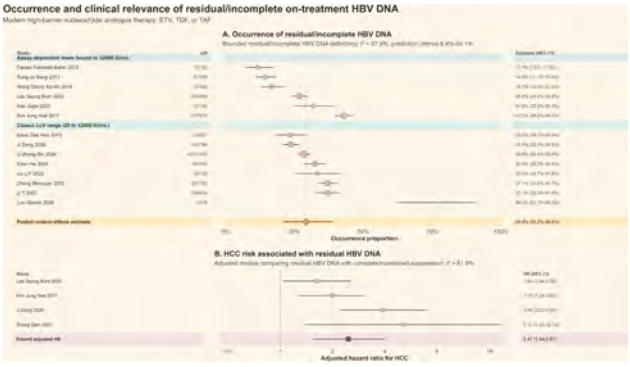
4043 | ◆ RESIDUAL HBV DNA DURING NUCLEOS(T)IDE ANALOGUE THERAPY FOR CHRONIC HEPATITIS B: PREVALENCE AND ASSOCIATION WITH HCC RISK



Ali Hemade[1] Ashwin Balagopal[1] Bryan Lau[1] Chloe Thio[1] David Thomas[1], [1]Johns Hopkins University

Background: HBV DNA that is detectable during nucleos(t)ide therapy is often referred to as low-level viremia, incomplete suppression, or residual viremia. Its frequency and clinical relevance as compared to complete viral response remain uncertain due to heterogeneity in construct definition and assay differences. **Methods:** We conducted a systematic review and meta-analysis of papers on residual viremia in chronic hepatitis B patients treated with first-line nucleos(t)ide analogue therapy. We only included papers that defined residual HBV DNA as quantitatively bounded to avoid construct drift. Data were extracted on complete viral response HBV DNA threshold, assay limits, timing/persistence, regimen context, denominators, outcomes, model adjustment domains, and risk of bias. We used random-effects to pool the estimated prevalence of residual HBV DNA and adjusted hepatocellular carcinoma (HCC) hazard ratios (HR) where appropriate. **Results:** Across PubMed, Embase, Scopus, citation chasing, and other sources, 7,653 potentially relevant records were identified. After deduplication, 4,076 were screened. After dual independent title/abstract screening, 94 full texts were assessed, 34 studies were included, and 21 contributed to quantitative analysis. In 14 studies with 7,338 patients, residual HBV DNA was characterized during treatment as 20–≤2,000 IU/mL or from an assay-dependent lower bound to ≤2,000 IU/mL. Pooled estimate of HBV DNA prevalence was 29.3% (95% CI, 21.2% - 38.9%; prediction interval, 8.4% - 65.1%). Between-study heterogeneity was high (I^2 = 97.8%) due to differences in assay lower limits of detection/quantification, upper thresholds, and persistence definitions. We included 4 suitable adjusted models comparing low level residual HBV DNA to complete viral response/suppression for HCC risk. Residual HBV DNA was associated with higher HCC risk (pooled adjusted HR, 2.47; 95% CI, 1.54–3.97; I^2 = 61.9%). Non-HCC outcomes were too heterogeneous to pool meaningfully, but residual HBV DNA was also associated consistently with measures of liver fibrosis progression. **Conclusion:** Residual HBV DNA during first-line NA therapy is common and associated with higher adjusted HCC risk as compared

to complete suppression, findings that strongly support development of more potent antiviral regimens. However, since pretreatment HBV DNA is associated with both residual HBV DNA and HCC risk, confounding may have biased or pooled HR away from the null.

4044 | ◆ INTEGRATED EMERGENCY DEPARTMENT-BASED SCREENING FOR HEPATITIS B AND HEPATOCELLULAR CARCINOMA IN TANZANIA: A PROSPECTIVE MULTICENTER STUDY

James Ford[1] Erin Mann[2] James Ford[3] Muhanuzi Biita[4] Jenny Wagner[5] Francis Sakita[3] Johnstone Kayandabila[4] Juma Mfinanga[4] Seraphine Mrosso[4] Kalipa Gedion[6] Akash Desai[1] Julian Hertz[6] Hendry Sawe[3] Jose Debes[2], [1]University of California, San Diego, [2]University of Minnesota, [3]Kilimanjaro Christian Medical Center, [4]Muhimbili National Hospital, [5]California State University, [6]Duke University School of Medicine

Background: Hepatitis B (HBV) is a leading cause of hepatocellular carcinoma (HCC) worldwide and early detection is critical for improving survival. We evaluated implementation and clinical outcomes of a combined HBV and HCC screening program integrated into emergency departments (ED) workflows in Tanzania. **Methods:** We conducted a multicenter, prospective, implementation study between July 2023 and March 2025 at two tertiary referral centers in Dar es Salaam and Moshi, Tanzania, respectively. Prior to launch, we engaged key stakeholders including emergency physicians, hepatologists, oncologists, hospital administrators, and laboratory personnel to adapt screening workflows, define referral pathways, and ensure operational feasibility. Patients and accompanying visitors presenting to the ED were recruited and provided informed consent. Patients were screened for HBV using rapid, point-of-care hepatitis B surface antigen test kits. Those who tested positive underwent additional laboratory testing, HCC screening via point-of-care ultrasound (POCUS) and were referred to hepatology clinic. Data were analyzed using descriptive statistics and between group comparisons were made using tests of proportions. **Results:** Among 6,246 total enrolled patients, 54% (n = 3,337) were female with a median age was 39 years (IQR 27-54). Overall HBV prevalence was 6.6% (408/6,246). Prevalence was significantly higher in Dar es Salaam (7.8%, 253/3,256) compared with Moshi (5.2%, 159/2,990), with an absolute difference of 2.6% (95% CI 1.3% to 3.8%). Among HBV-positive patients, linkage to follow-up care occurred in 72% (292/408) and 57% (53/93) of treatment-eligible patients initiated started on antiviral therapy. Nearly all HBV-positive participants (97%, 395/408) underwent same-visit HCC screening via POCUS, of whom 5% (19/395) had concerning lesions. Confirmatory, triple-phase contrasted topography of the liver was successfully completed in 78% (15/19) of individuals with concerning POCUS lesions. HCC was diagnosed in 93% of these cases (14/15), and oncological treatment was initiated in 67% (10/15) of cases. **Conclusion:** ED–based HBV screening paired with integrated ultrasound evaluation for HCC is feasible and yields high rates of linkage-to-care and treatment initiation in a resource-limited setting. Emergency departments represent a promising and underutilized setting for combined infectious disease and cancer screening in regions with high HBV burden.

Wu[7] Huifeng Yang[8] Dickens Theodore[9] Yuanyuan Kong[10], [1]GSK, Epidemiology, London, UK, [2]Liver Disease Center, Beijing Friendship Hospital, Capital Medical University, Beijing, China, [3]EVYD Technology, RWE Global, Short Hills, NJ, USA, [4]Tianjin Happy Life Technology Co. Ltd, Innovative Healthcare Solution, RWE Global, Shanghai, China, [5]GSK, Value Evidence and Outcomes, Shanghai, China, [6]GSK, Clinical Development, London, UK, [7]GSK, Medical Affairs, Shanghai, China, [8]The Second Hospital of Tianjin Medical University, Tianjin, China, [9]GSK, Durham, NC, USA, [10]Beijing Friendship Hospital, Capital Medical University, Beijing, China

Background: Chronic hepatitis B virus (HBV) infection remains a major global public health challenge contributing to cirrhosis and liver cancer worldwide (~1.1 million deaths per year). In China, ~75 million people are chronically infected with HBV (~5.9% hepatitis B surface antigen [HBsAg] prevalence). Although HBsAg levels can predict treatment response and favorable virological outcomes, quantitative HBsAg (qHBsAg) testing is scarcely performed, limiting real-world evidence. This study assessed the associations between low HBsAg levels, subsequent HBsAg loss, and long-term adverse clinical outcomes such as compensated cirrhosis, decompensated liver disease, and hepatocellular carcinoma (HCC) during follow-up, in mainland China. **Methods:** We conducted a retrospective cohort study using regional electronic health records from Tianjin, China, including 82 hospitals (2016–2023). Adult patients (pts) with chronic HBV infection and a detectable qHBsAg test were included; the index date was the first recorded detectable qHBsAg test. Multivariable Cox regression analyses were performed among pts with HBsAg $\leq$3000 IU/mL and $\leq$1000 IU/mL, with no severe liver disease (i.e. cirrhosis, hepatic decompensation, or liver transplantation) at baseline (BL). **Results:** Among 33,826 pts with chronic HBV infection and detectable qHBsAg (mean [SD] age: 43.3 [13.4] years; 57.8% male), 15,529 had HBsAg $\leq$3000 IU/mL and no clinical evidence of severe liver disease at BL; 3238 (20.9%) of this subgroup received anti-HBV therapy at BL. HBsAg loss (N = 454; median time from index: 1589 days) was associated with substantially lower risks of clinical progression: 66% lower risk of compensated cirrhosis (adjusted hazard ratio [aHR]: 0.34, 95% CI: 0.24, 0.50), 95% lower risk of decompensated liver disease (aHR: 0.05, 95% CI: 0.02, 0.13), and 88% lower risk of HCC (aHR: 0.12, 95% CI: 0.04, 0.31) compared with no loss. HBsAg $\leq$100 IU/mL (N = 3932) was associated with 36%, 21%, and 16% reduced risks of compensated cirrhosis (aHR: 0.64, 95% CI: 0.57, 0.71), decompensated liver disease (aHR: 0.79, 95% CI: 0.71, 0.89), and HCC (aHR: 0.84, 95% CI: 0.72, 0.98), respectively. HBsAg $\leq$10 IU/mL (N = 1531) reduced the risk of compensated cirrhosis by 39% (aHR: 0.61, 95% CI: 0.51, 0.71) and decompensated liver disease by 20% (aHR: 0.80, 95% CI: 0.67, 0.95); the reduction in HCC risk did not reach statistical significance. Similar results were observed for the subgroup with HBsAg $\leq$1000 IU/mL (N = 9837) (**Figure**). **Conclusion:** Among a mixed treated and untreated cohort of chronic HBV pts with HBsAg levels $\leq$3000 IU/mL and $\leq$1000 IU/mL, both low HBsAg level and HBsAg loss were strongly associated with reduced risk of clinical progression. These findings support the clinical value of qHBsAg measurement for risk stratification and highlight low HBsAg levels and HBsAg loss as meaningful markers of favorable long-term outcomes in a real-world setting. **Funding** : GSK (219254)

Background: Tamoxifen (TAM), a gold standard for breast cancer treatment, frequently induces tamoxifen-induced steatohepatitis (TASH) as a side effect. Severe cases often require treatment discontinuation, potentially worsening oncological outcomes. Despite its clinical significance, effective preventive or therapeutic strategies for TASH remain unestablished. This study aimed to identify candidate agents that suppress TASH using the WHO global database of individual case safety reports (VigiBase) and to validate their efficacy through cellular experiments. **Methods:** We analyzed 9,778 cases involving TAM from VigiBase. Hepatic adverse events were identified using 54 MedDRA/J ver.28.0 terms related to fatty liver and hepatitis. Disproportionality analysis was performed by calculating the Reporting Odds Ratio (ROR) to screen for concomitant medications associated with a significantly lower frequency of hepatic adverse events. For in vitro validation, HepG2 cells were exposed to TAM to induce intracellular triglyceride (TG) accumulation. The effects of 1α,25-dihydroxyvitamin D3 (VD3) on TG accumulation and the expression of lipid metabolism-related genes were evaluated using Oil Red O staining and RT-qPCR. **Results:** The disproportionality analysis revealed a significantly lower reporting frequency of TAM-induced hepatic injury in patients receiving concomitant Vitamin D3 compared to those without it. In HepG2 cells, TAM exposure markedly increased intracellular TG accumulation, which was suppressed by VD3 in a concentration-dependent manner. Gene expression analysis demonstrated that VD3 significantly attenuated the TAM-induced upregulation of *SREBP-1c* and *PPARγ*, both of which are master regulators of lipogenesis. **Conclusion:** By integrating large-scale real-world data with mechanistic experiments, we demonstrated that VD3 potentially prevents TASH. Since VD3 is an established drug with a well-known safety profile, it holds promise as a novel supportive therapy to ensure the continuity of breast cancer treatment. Further validation using multicenter clinical data is warranted to confirm these real-world benefits.

4047 | HEPATITIS B/HEPATITIS D SCREENING AND LINKAGE-TO-CARE IN HIGHLY MARGINALIZED URBAN POPULATIONS IN SPAIN: THE DESCRIBE STUDY

Pablo Ryan[1] Antonio Madejon[2] Sabela Lens[3] Mario delHoyo[4] Marina Camblor Murube[5] Jorge Valencia[4] Xavier Forns[3] Francisco Javier Garcia-Samaniego[6], [1]Infectious Diseases Unit. Hospital Universitario Infanta Leonor/Universidad Complutense/CIBER.Madrid, [2]Liver Unit. Hospital Universitario La Paz. Madrid, [3]Liver Unit. Hospital Clinic/CIBER/IDIBAPS/Universitat de Barcelona. Barcelona, [4]Infectious Diseases Unit. Hospital Universitario Infanta Leonor. Madrid, [5]Faculty of Medine. Universidad Autónoma de Madrid (UAM). Madrid, [6]Liver Unit. Hospital Universitario La Paz/ IdiPAZ/Universidad Autónoma de Madrid (UAM). Madrid

Background: Socially marginalized urban (MU) populations remain disproportionately affected by viral hepatitis and frequently limited experience access to linkage-to-care services. Data on HBV and HDV infections in highly vulnerable populations reached through outreach and harm-reduction programs remain limited. **Methods:** Cross-sectional study of MU recruited through mobile outreach and harm-reduction programs in the two biggest Spanish cities (Madrid and Barcelona). Sociodemographic characteristics, healthcare access, substance use, and HIV/HBV-HDV/HCV screening data were collected. Participants underwent positive hepatitis rapid testing and liver disease staging, and were referred to specialized care if positive. **Results:** A total of 2,138 participants were included. Median age 40 years (IQR 28–51), and 67.2% male. Most participants were Caucasian (65%), Hispanic (20%), or African (7%). Housing and healthcare vulnerability were substantial, with 71% reporting unstable housing (shelters; 32.7%, refugee centers: 2.6%, and street homelessness: 7.2%), 38.7% lacking stable social support and 58.3% reporting barriers to healthcare access. Sexual risk behaviors were frequent, including inconsistent condom use (69.5%) and multiple condomless partners (33.8%). Drug use was reported by 51% of participants; among them, 89% reported use in the previous year, mainly cocaine (42.8%) and heroin (30.1%). Injection drug use was also frequent, with 49.7% reporting lifetime injection and of them, 74.6% active injection during the previous year; 33.8% received opioid substitution therapy. A high burden of viral hepatitis was observed, particularly HCV infection, while HBV and HDV were less frequent but clinically relevant (Table 1). Among the 687 participants with positive hepatitis rapid testing (HCV and/or HBV), 55.5% were linked to specialized care. Liver disease assessment was available in 355: F3 in 10.1% and F4 (liver cirrhosis) in 7.9%. Most participants with available Child-Pugh staging had compensated liver disease. **Conclusion:** Community-based hepatitis screening and harm-reduction programs identified highly MU populations with a high burden of viral hepatitis and significant liver disease. These outreach-based HBV/HDV screening strategies may improve access to specialized care and support hepatitis elimination

4048 | IMPACT OF UNIVERSAL GUIDELINE CHANGES ON NATIONAL HEPATITIS B VIRUS SCREENING AND VACCINATION RATES

Allen Luo[1] Rene Nichols[1] Christopher Wong[1] Kali Zhou[1], [1]Keck School of Medicine of USC

Background: Recent guideline changes have shifted Hepatitis B virus (HBV) screening and vaccination from risk-based to a universal approach. The ACIP recommended universal HBV vaccination for adults aged 19-59 in 2022, followed by 2023 CDC guidelines for universal one-time adult screening with a triple panel test. We evaluated temporal trends in HBV screening and vaccination in the United States (US) before and after guideline release. **Methods:** We utilized TriNetX, a multicenter research network of 66 US healthcare organizations, representing over 90 million patients across academic and non-academic centers. Two cohorts were identified for multiple-group interrupted time series analyses: (1) Cohort A: adults $\geq$18 years with no prior HBV screening and (2) Cohort B: adults aged 19-59 years with no prior HBV vaccination. Those with pre-existing HBV were excluded for both. In Cohort A, we compared incident HBV screening rates per 1000 person-years for HBsAg, anti-HBs, and anti-HBc in 6-month intervals before (March 2015-Feburary 2023) and after (September 2023-August 2025) the CDC guideline release. In Cohort B, we similarly compared rates of initiation of HBV vaccine before (March 2015-February 2022) and after (September 2022-August 2025) the ACIP guideline release. A 6-month washout period was included for both. Parallel trends were assessed with F-tests and autocorrelation with Newey-West standard errors. Incident HIV screening served as a negative control. **Results:** All HBV screening tests and vaccination rates showed significant immediate increases following guideline implementation (see Figure). HbsAg testing rates increased from 24.5 to 30.3 screenings per 1000 person-years ($\beta = 5.30$, 95% CI 3.19-7.41; $p < 0.001$). Anti-HBs testing rates increased from 13.9 to 18.3 per 1000 person-years ($\beta = 4.95$, 95% CI 4.01-5.88; $p < 0.001$), while anti-HBc testing rates increased from 10.6 to 13.9 per 1,000 person-years ($\beta = 3.63$, 95% CI 2.70-4.56; $p < 0.001$. HBV vaccination also increased from 2.6 to 4.0 per 1000 person-years ($\beta = 1.195$, 95% CI 0.118–2.273; $p = 0.03$). Sustained post-intervention increases were seen for anti-HBs ($\beta = 0.511$, 95% CI 0.249-0.773; $p < 0.001$), anti-HBc ($\beta = 0.292$, 95% CI 0.062-0.522; $p = 0.013$), and HBV vaccination ($\beta = 0.438$, 95% CI 0.293-0.583; $p < 0.001$). The HIV negative control showed a significant increase following intervention ($\beta = 4.43$, 95% CI 1.53-7.32; $p = 0.003$), but no significant post-intervention trend increase. **Conclusion:** Implementation of universal HBV screening and vaccination guidelines was associated with significant and immediate increases in testing and immunization rates in the US. However, anti-HBs/HBc testing rates lagged behind HBsAg despite triple panel recommendation. Longer follow-up is needed to determine if these increases are sustained and lead to meaningful improvement in HBV transmission and clinical outcomes at the population-level.

4049 | LOW PAGE-B AND MODIFIED PAGE-B (MPAGE-B) SCORES MAY UNDERESTIMATE LIFETIME HEPATOCELLULAR CARCINOMA (HCC) RISK IN OLDER PATIENTS WITH NON-CIRRHOTIC CHRONIC HEPATITIS B (CHB): IMPLICATIONS FOR HCC SURVEILLANCE

Iris Tsz-Yau Chow[1] Cheuk Fung Yip[1] Wai Sun Vincent Wong[1] Mandy Lai[1] Jimmy Che-To Lai[1] Vicki Wing-Ki Hui[1] Lilian Yan Liang[1] Yee-Kit Tse[1] Henry Lik-Yuen Chan[1] Grace Wong[1], [1]the Chinese University of Hong Kong

Background: International guidelines recommend HCC surveillance starting at age 40 in men and 50 in women among patients with non-cirrhotic CHB, as well as in patients with PAGE-B ≥ 10 or mPAGE-B ≥ 9. However, some patients classified as low risk by PAGE-B or mPAGE-B scores are older than the recommended surveillance thresholds. We evaluated the predictive performance of PAGE-B and mPAGE-B scores and the annual HCC incidence in patients classified as low risk. **Methods:** This retrospective cohort study included adult patients with CHB who received treatment with entecavir (ETV), tenofovir disoproxil fumarate (TDF), or tenofovir alafenamide (TAF) between 2005 and 2022 in Hong Kong. Lifetime HCC risk and annual HCC incidence were estimated using age as the time scale (Figure). Patients were followed from their age at ETV/TDF/TAF treatment initiation and were censored at cirrhosis development. Inverse probability of censoring weighting was applied to account for informative censoring. Non-HCC death was treated as a competing risk. PAGE-B and mPAGE-B scores were analyzed as time-updating covariates, and their predictive performance was evaluated using integrated time-dependent areas under the receiver operating characteristic curves (itAUROCs). **Results:** Of 64,952 patients with non-cirrhotic CHB receiving ETV/TDF/TAF treatment, 36,364 (56.0%) were male, with a mean age at treatment initiation of 55.9 ± 13.6 years. During a median follow-up of 5.6 (IQR 3.2-9.0) years, 2,639 (4.1%) developed HCC. The itAUROC of the PAGE-B score reduced from 0.71 (95% CI 0.67-0.76) at age 50 to 0.68 (0.65-0.71) at age 60 and 0.64 (0.61-0.68) at age 70. Similarly, the itAUROC of the mPAGE-B score reduced from 0.70 (95% CI 0.65-0.76) at age 50 to 0.67 (0.64-0.71) at age 60 and 0.65 (0.62-0.69) at age 70. Among women aged 50-60 years, annual HCC incidence was 0.06% in those with low PAGE-B and 0.05% in those with low mPAGE-B; the corresponding incidence among women aged 60-70 years using PAGE-B score was 0.21%. Among women without cirrhosis who had intermediate-to-high PAGE-B scores, the annual HCC incidence exceeded 0.2%, except for those aged 50-60 years classified as intermediate risk by mPAGE-B. Among men without cirrhosis, the annual HCC incidence was 0.1% in those aged 40-50 years with a low mPAGE-B; below the recommended threshold for HCC surveillance. The annual HCC incidence exceeded 0.2% among men without cirrhosis who had intermediate-to-high PAGE-B or mPAGE-B scores, except for those aged 30-40 years classified as intermediate risk by PAGE-B. **Conclusion:** PAGE-B score may underestimate HCC risk in women older than 60 years, as their annual HCC risk is above 0.2% even when the score classifies them as low risk; hence, HCC surveillance remains necessary. On the other hand, women aged 50-60 years with a low PAGE-B or mPAGE-B score, and men aged 40-50 years with a low mPAGE-B score, have an annual HCC risk of $< 0.2\%$; therefore, routine HCC surveillance may not be required.

4050 | GAPS IN THE CHRONIC HEPATITIS B CASCADE OF CARE AND ANTIVIRAL TREATMENT LEADS TO SIGNIFICANTLY GREATER RISK OF LIVER-RELATED COMPLICATIONS

Robert Wong[1] Zeyuan Yang[2] Ramsey Cheung[3], [1]Stanford/VA Palo Alto Healthcare System, [2]VA Palo Alto Health Care System, [3]Stanford University Medical Center

Background: Gaps in the chronic hepatitis B (CHB) cascade of care contribute to delays in linkage to care, assessment for treatment eligibility, and initiation of antiviral therapy. These delays contribute to continued disease progression in patients with CHB. We aim to evaluate the clinical impact of gaps and delays in the CHB cascade of care among a national cohort of U.S. Veterans. **Methods:** Longitudinal national Veterans Affairs data were queried to identify adults with laboratory confirmed CHB from 1/1/2010-12/31/2025. Cascade of care assessed included GI/liver clinic (≥1 visit annually), laboratory monitoring (ALT and HBV DNA), assessment of treatment eligibility (AASLD criteria), receipt of antiviral therapy, and incidence of liver-related event (LRE) (ie. decompensated cirrhosis, hepatocellular carcinoma, death). Adjusted multivariable Cox proportional hazards models evaluated the impact of lack of treatment (among treatment-eligible) on risk of LRE. **Results:** Among 25,845 adults with CHB (mean age 57.2y, 92% men, 83% non-Asian ethnicity, 6.3% cirrhosis), 50.2% had annual GI/liver clinic follow up and 47.8% had ALT and HBV DNA testing within 12 months of diagnosis. At baseline, 17.9% were treatment eligible, among whom only 32.8% were treated. During a median follow up of 7.7 years (IQR 4.6-11.8), 28.6% of patients who were initially ineligible became eligible. Among all treatment-eligible patients, only 37.8% received antiviral therapy, which was higher in men vs. women (38% vs. 33%, OR 1.68, 95% CI 1.29-2.19), higher in Asians vs. non-Hisapnic whites (67% vs. 38%, OR 2.32, 95% CI 1.83-2.93). Higher treatment was observed in patients who had annual GI/Liver follow up (OR 4.71, 95% CI 4.28-5.21) or close laboratory monitoring (OR 1.82, 95% CI 1.65-2.02). Receiving antiviral therapy was associated with significantly lower incidence of LRE (11.5 vs. 16.6 per 100 person-years, HR 0.80, $p < 0.01$), which was seen across sex, age, race/ethnicity (Figure). Presence of diabetes mellitus (HR 1.40, $p < 0.01$) or cirrhosis (HR 6.90, $p < 0.01$) were also associated with greater risk or LRE. **Conclusion:** Among a predominantly non-Asian cohort of Veterans with CHB, major gaps in the CHB cascade of care were observed, including inconsistent GI/Liver clinic and laboratory monitoring, which led to only 37.8% of treatment eligible patients receiving antiviral therapy. These findings are alarming, given that timely receipt of treatment was associated with a 20% reduction in LRE.

4052 | EFFECTIVENESS OF NUCLEOS(T)IDE ANALOGUES IN LIVER FAILURE WITH CHRONIC HEPATITIS B VIRUS INFECTION: A MULTICENTER, RETROSPECTIVE STUDY BASED ON A LARGE-SCALE REAL-WORLD DATABASE

Jingbo Wang[1] Zhizhen Hu[2] Yan Huo[2] Fanru Nie[2], [1]the Sixth People's Hospital of Shenyang, [2]Jiangsu Hansoh Pharmaceutical Group Co., Ltd.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: In clinical practice, chronic hepatitis B (CHB) virus infection patients exhibit marked heterogeneity in treatment response among different populations, particularly those with comorbidities. Large-scale real-world data on nucleos(t)ide analogues (NAs) anti-hepatitis B virus (HBV) therapy remain limited, especially for newer agents like tenofovir amibufenamide (TMF) . **Methods:** This study used data from the Chronic Hepatitis B Specialty Cohort Database ("CHUANSHUO Project") of the National Center for Infectious Diseases. Patients with chronic HBV infection treated with TMF or other oral NAs between January 2023 and December 2024 were included. Effectiveness and safety were analyzed in the overall population and different cohorts. Main inclusion criteria were a diagnosis of CHB, chronic HBV infection, hepatitis B surface antigen (HBsAg) carrier, HBV carrier, or persistent HBsAg (+) $\geq$6 months. We evaluated the effectiveness of NAs in the liver failure cohort (defined by medical history) via assessment of changes in virological, biochemical, and coagulation parameters at 4 weeks. **Results:** A total of 366 liver failure patients were included (mean age 49.98 ± 12.17 years, 77.60% male), of whom 45 received TMF. For virological responses, median HBV DNA change from baseline to week 4 was -2.55 (IQR: -3.51, -1.39) $\log_{10}$ IU/mL. HBsAg also showed a median change of -0.23 (-0.66, 0.13) $\log_{10}$ IU/mL (P = 0.0002). The median change in alanine transaminase (ALT) was -176.20 (-582.80, -28.00) U/L (P < 0.0001), the ALT normalization rate was 44.41% (135/304) by local laboratory criteria and 28.00% (91/325) by AASLD criteria. The median change in aspartate transaminase (AST) was -126.10 (-421.50, -24.00) U/L (P < 0.0001). Total bilirubin (TBIL) showed a median change of -31.55 (-120.90, 5.10) μmol/L (P < 0.0001). For coagulation function, the median changes were 9.00% (-1.92%, 19.80%) for prothrombin activity (PTA) and -0.16 (-0.39, 0.06) for international normalized ratio (INR) (both P < 0.0001). Only four deaths were recorded in patients received NAs. In the TMF subgroup, rapid viral load declined within 4 weeks: HBV DNA decreased by -2.98 (-4.32, -1.99) $\log_{10}$ IU/mL (baseline: 6.37 [5.40, 7.76] $\log_{10}$ IU/mL vs. 4-week: 3.32 [2.75, 3.64] $\log_{10}$ IU/mL, P < 0.0001), and ALT dropped sharply by -297.50 (-732.40, -52.30) U/L. **Conclusion:** In this multicenter, retrospective real-world study, NAs therapy significantly improved virological, biochemical and coagulation parameters from baseline to week 4 in liver failure patient with chronic HBV infection. TMF also achieved rapid viral load reduction. These findings provide real-world evidence for short-term effectiveness of NAs in this critical population.

Table 1 Four-Week Virological, Biochemical and Coagulation Responses to NAs in Liver Failure Patients with Chronic Hepatitis B Virus Infection (N=366).

Variables	Baseline	Four week	Change from baseline	P
HBV DNA, log10IU/mL, median (IQR)	6.14 (4.53, 7.10)	3.23 (2.68, 3.83)	-2.55 (-3.51, -1.39)	<.0001
HBsAg, log10IU/mL, median (IQR)	3.23 (2.60, 3.81)	2.95 (2.40, 3.40)	-0.23 (-0.66, 0.13)	0.0002
ALT, U/L, median (IQR)	237.00 (69.00, 653.00)	46.60 (27.80, 77.00)	-176.20 (-582.80, -28.00)	<.0001
AST, U/L, median (IQR)	212.55 (90.70, 505.20)	61.00 (42.00, 103.50)	-126.10 (-421.50, -24.00)	<.0001
TBIL, μmol/L, median (IQR)	144.15 (60.70, 268.75)	74.95 (42.60, 160.00)	-31.55 (-120.90, 5.10)	<.0001
PTA, %, median (IQR)	46.50 (30.00, 62.20)	57.00 (42.62, 75.80)	9.00 (-1.92, 19.80)	<.0001
INR, median (IQR)	1.65 (1.38, 1.95)	1.44 (1.19, 1.76)	-0.16 (-0.39, 0.06)	<.0001

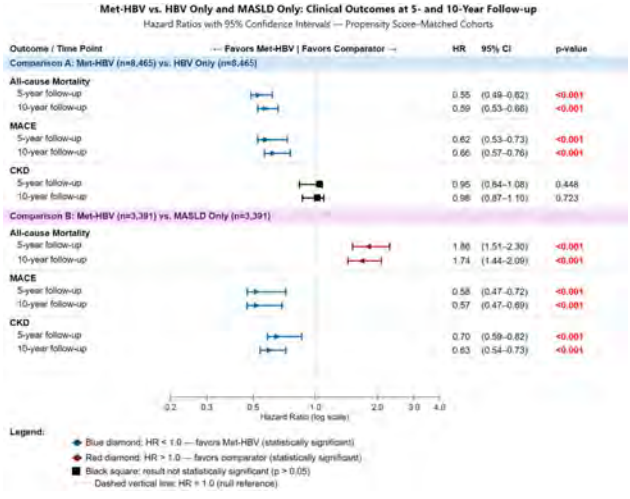
4053 | CARDIOVASCULAR, RENAL, AND MORTALITY OUTCOMES IN PATIENTS WITH MET-HBV COMPARED TO PATIENTS WITH HBV AND MASLD ALONE: A REAL-WORLD PROPENSITY-MATCHED ANALYSIS



Guy Loic Nguefang[1] Sarpong Boateng[2] Yussif Issaka[2] Ridwan Lawal[3] Bright Nwatamole[4] Chimezirim Ezeano[5] Edgard Luna Landa[1] Yazan A. Al-Ajlouni[6] Basile Njei[7], [1]Texas Tech University Health Sciences Center, [2]Yale New Haven Health, Bridgeport Hospital, [3]University of Texas Rio Grande Valley, [4]Zucker School of Medicine at Hofstra, [5]Advocate Aurora Healthcare, [6]Montefiore Medical Center/Albert Einstein College of Medicine, [7]Yale University

Background: Met-HBV represents an emerging entity characterized by the coexistence of MASLD and HBV. Evidence suggests that patients with Met-HBV experience accelerated fibrosis progression, even with effective viral suppression. However, the extent to which metabolic and viral factors interact and influence long-term mortality, cardiovascular and renal outcomes remains unclear. We aimed to compare clinical outcomes in patients with Met-HBV versus those with HBV and those with MASLD alone. **Methods:** We conducted a retrospective cohort study using the TriNetX database. We included patients >18 years old. We identified three mutually exclusive cohorts: (1) Patients with a diagnosis of MASLD and HBV and at least one metabolic risk factor were classified as Met-HBV. (2) patients with MASLD and metabolic risk factor without HBV (3) patients with HBV without metabolic risk factors and MASLD. We excluded individuals with prior organ transplants, HCV, pregnancy, and malignancy. We then conducted two propensity score–matched (PSM) comparisons: Met-HBV vs. HBV and Met-HBV vs. MASLD. Outcomes included all-cause mortality, Major Adverse Cardiovascular Events

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(MACE), and chronic kidney disease (CKD), assessed at 5 and 10 years. Kaplan–Meier survival analysis and Cox proportional hazards regression were used for time-to-event analyses. A statistically significant result was defined as $p < 0.05$. **Results:** After PSM, we included 8,465 patients per group in the Met-HBV vs. HBV comparison and 3,391 patients per group in the Met-HBV vs. MASLD comparison. Compared to patients with HBV only, Met-HBV was paradoxically associated with significantly lower mortality at 5 years (HR 0.55, 95% CI 0.49–0.62) and 10 years (HR 0.59, 95% CI 0.53–0.66) and lower MACE at 5 years (HR 0.62, 95% CI 0.53–0.73) and 10 years (HR 0.66, 95% CI 0.57–0.76), all $p < 0.001$. No significant difference in CKD risk was observed at either time point. Compared to patients with MASLD only, Met-HBV was associated with significantly higher mortality at 5 years (HR 1.86, 95% CI 1.51–2.30) and 10 years (HR 1.74, 95% CI 1.44–2.09), both $p < 0.001$. However, Met-HBV was associated with lower MACE at 5 years (HR 0.58, 95% CI 0.47–0.72) and 10 years (HR 0.57, 95% CI 0.47–0.69) and lower CKD at 5 years (HR 0.70, 95% CI 0.59–0.82) and 10 years (HR 0.63, 95% CI 0.54–0.73; all $p < 0.001$). **Conclusion:** Met-HBV is a unique entity with divergent outcome patterns. The lower mortality and MACE in Met-HBV versus HBV may reflect surveillance bias. Compared to MASLD, Met-HBV carries significantly higher mortality, likely driven by the additive burden of chronic viral hepatitis on liver-related outcomes. Overall, these findings underscore that Met-HBV is a clinically distinct entity whose outcomes cannot be predicted by simply summing the risks of its individual components, and they highlight the need for tailored risk stratification and management strategies.

4054 | PREVALENCE OF HDV INFECTION AND LIVER DISEASE SEVERITY IN A LARGE COHORT OF PATIENTS IN TWO BIG URBAN ÁREAS IN SPAIN. FINAL RESULTS OF HDV-DESCRIBE STUDY

Pablo Ryan[1] Antonio Madejon[2] Sabela Lens[3] Mario del Hoyo[4] Marina Camblor Murube[5] Jorge Valencia[4] Xavier Forns[3] Francisco Javier Garcia-Samaniego[6], [1]Infectious Diseases Unit. Hospital Universitario Infanta Leonor/Universidad Complutense/CIBER.Madrid, [2]Liver Unit. Hospital Universitario La Paz. Madrid, [3]Liver Unit. Hospital Clinic/CIBER/IDIBAPS/Universitat de Barcelona. Barcelona, [4]Infectious Diseases Unit. Hospital Universitario Infanta Leonor. Madrid, [5]Faculty of Medine. Universidad Autónoma de Madrid (UAM). Madrid, [6]Liver Unit. Hospital Universitario La Paz/ IdiPAZ/Universidad Autónoma de Madrid (UAM). Madrid

Background: The prevalence of hepatitis delta virus (HDV) infection among patients with chronic hepatitis B virus (HBV) infection varies across studies. This study aimed to assess the prevalence of HDV infection and evaluate the impact of HDV viremia on liver disease severity. **Methods:** A retrospective multicenter study was conducted in three hospitals in Madrid and Barcelona, Spain. Sociodemographic and clinical data from HBsAg-positive patients were collected through medical records review using REDCap. HDV prevalence was calculated and HDV-positive patients were descriptively analyzed. **Results:** A total of 2,667 HBsAg-positive patients were included. Overall, 1,620/2,667 (60%) underwent HDV testing. Screening rates were higher in Liver Units than others in-hospital Units. The serologic prevalence of HDV coinfection was 5.2% (138/2,667), and 39.9% of HDV-positive individuals had detectable HDV-RNA, with a mean viral load of 1.5 × 10^5 copies/mL (overall prevalence of viremic HDV infection: 2%). The median age of HDV-positive patients was 52.8 years; 58% were male and 35% were non-native individuals.Based on transient elastography or liver biopsy, cirrhosis (F4) was identified in 7.6% of the overall cohort compared with 46.8% of HDV-positive patients. Liver-related clinical events were more frequent in patients with HDV infection than in those without evidence of HDV infection (45% *vs*. 1.4%). Among HDV-positive patients, 18% were on the waiting list for liver transplantation and 10% had hepatocellular carcinoma.Ten patients (7.2%) had previously received pegylated interferon therapy,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

although 7 of them remained HDV-RNA positive. In multivariate analysis, detectable HDV-RNA was independently associated with cirrhosis (OR 8.1; 95% CI 2.9–22.7; p < 0.001). **Conclusion:** In this large urban Spanish cohort of HBsAg-positive patients, HDV serologic prevalence was 5.2%. Cirrhosis and liver-related events were highly prevalent, particularly among patients with detectable HDV-RNA. Exposure to interferon-based therapies was uncommon. In addition, the HDV cascade of care was suboptimal in patients managed off liver units. **Funding Sources:** Proyect HDV-DESCRIBE funded by Gilead Sciences and Project PI22/00849, funded by Instituto de Salud Carlos III (ISCIII) and co-funded by the European Union.

Background: Variation in HBV treatment practice may hinder viral hepatitis elimination, particularly for immunotolerant patients (HBeAg-positive with HBV DNA >20,000 IU/mL and normal ALT). We assessed clinician management patterns for immunotolerant patients and factors affecting treatment decisions. **Methods:** An international expert panel from the Global Liver Council developed and distributed a 37-item anonymous online survey from June-September 2025 to evaluate providers' knowledge and clinical practice patterns in HBV/HDV management. Immunotolerant patients were defined as HBeAg-positive cases with HBV DNA > 20,000 IU/mL and normal ALT. Multivariable logistic regression analysis was performed using $P < 0.05$ significance threshold. Potential predictive factors included: sex, age, medical degree, years in practice, specialty, practice setting, percentage of HBV patients in practice, HBV knowledge, comfort treating HBV, monthly and total HBV patient encounters and treatment frequencies, guidelines followed, and geographic region. **Results:** The survey was completed by 611 clinicians (hepatologists/gastroenterologists: 68%; infectious disease: 11.5%; other specialties: 20.5%) from seven global regions. EASL guidelines were most frequently followed (46%), followed by AASLD (21%), WHO (12.6%), APASL (10.1%), and other guidelines (10%). Of 540 responders regarding immunotolerant patient treatment, 25.9% treated routinely, 47.8% treated occasionally (patients with certain characteristics), and 26.2% treated based on patient preference (18.1%) or not at all (8.1%). Factors associated with each management pattern are shown in Table.In multivariate analysis, factor independently associated with "treat routinely" was having treated ≤50 HBsAg-positive patients (25.4% of sample) [OR (95% CI): 2.15 (1.40–3.29), $P = 0.0005$]. Factors associated with "treat occasionally" (versus patient preference or no treatment) included hepatology [OR: 3.00 (1.67–5.38), $P < 0.001$], gastroenterology [OR: 1.94 (1.10–3.42), $P = 0.023$], European practice location [OR: 2.22 (1.24–3.99), $P = 0.007$], urban setting [OR: 2.00 (1.00–3.99), $P = 0.049$], and female sex [OR: 1.92 (1.20–3.12), $P = 0.006$].Among 258 participants reporting occasional therapy, treatment criteria included: age ≥30 years (17.2%) or >40 years (52%); liver stiffness ≥8 kPa (50%) or >12 kPa (72.7%); Asian or African origin (15–16%); and family history of HBV cirrhosis/hepatocellular carcinoma (87.5%). **Conclusion:** Management of immunotolerant patients varies widely globally. Approximately 50% of physicians treat selectively based on patient characteristics, 25% treat routinely, and 25% treat based on patient preference or withhold therapy. Provider experience, specialty, geographic location, and demographics significantly affect treatment decisions in this clinically uncertain patient group.

Table. Factors affecting clinician management patterns for immunotolerant chronic HBV patients.

		Treat routinely N=140	Treat occasionally N=258	Treat none N=142	P value
Sex	Male	74 (53.2%)	146 (56.8%)	94 (66.7%)	0.06
	Female	65 (46.8%)	111 (43.2%)	47 (33.3%)	
Age	18-34 years	35 (25.0%)	53 (20.5%)	30 (21.1%)	0.57

4056 | HEPATITIS B TESTING PATTERNS IN INDIVIDUALS RECEIVING HIV PRE-EXPOSURE PROPHYLAXIS (PREP) AND PREP USE AMONG INDIVIDUALS WITH HBV INFECTION

Chia-Yu Chiu[1] Steven Mudroch[1] Samantha Kaplan[1] Sara Scherrer[1] Hillary Dunlevy[1] Michael Kriss[1] Lisa Forman[1] James Burton[1] Katherine Frasca[1], [1]University of Colorado

Background: Pre-exposure prophylaxis (PrEP) can be classified as tenofovir-based or tenofovir-sparing. Discontinuation of tenofovir-based PrEP or transition to a tenofovir-sparing PrEP may increase the risk of HBV reactivation. In addition, HBV screening among individuals receiving PrEP has not been systematically reported. **Methods:** We conducted a retrospective review of patients prescribed PrEP within UCHealth between 2016 and 2025. HBV serologic screening included hepatitis B surface antigen (HBsAg), hepatitis B core antibody (anti-HBc), and hepatitis B surface antibody (anti-HBs). Based on the 2018 AASLD guideline, HBV infection included past (HBsAg –/Anti-HBc+) and chronic HBV infection (HBsAg+/Anti-HBc+). HBV reactivation is defined according to 2018 AASLD criteria. We reported the rate of HBV screening in the PrEP population and HBV reactivation among the PrEP population with HBV infection. **Results:** During the study period, 1,854 patients were prescribed PrEP, of whom 3% (n = 50) had HBV infection (41 past HBV, 9 chronic HBV). PrEP was prescribed by infectious disease (ID) (52%), primary care physicians (PCP) (45%), and hepatologists (HEP) (3%). Testing rates differed significantly among PrEP prescribers. HBsAg testing was performed in 79%, 58%, and 90% of individuals by ID, PCP, and HEP ($p < 0.01$). Anti-HBc testing was performed in 41%, 40%, and 65% of individuals, respectively ($p < 0.01$). Anti-HBs testing was performed in 82%, 50%, and 89% of individuals, respectively ($p < 0.01$). Among the 50 patients with HBV infection, 56% were diagnosed at the time of PrEP initiation. Although no standardized HBV monitoring protocol was implemented, none developed HBV reactivation, including three patients who transitioned to tenofovir-sparing PrEP (Figure). **Conclusion:** There is a significant gap in HBV screening among individuals receiving PrEP. Although absence of HBV testing should not be a barrier to PrEP initiation or continuation, clinicians should recognize that discontinuation of tenofovir-based PrEP or transition to tenofovir-sparing regimens poses the risk of HBV reactivation and de novo HBV infection. PrEP programs also provide an important opportunity to identify and prevent HBV infection through tenofovir-based PrEP, and HBV vaccination.

4057 | HIGH HBV SEROPREVALENCE AND HOST GENETIC LANDSCAPES (IFNL3) IN HAITIAN MIGRANTS: A CROSS-SECTIONAL STUDY IN CHILE

Javier Perez-Valenzuela[1] Patricio Astudillo[1] Javier Uribe[1] José Ignacio Vargas[1] Carlos Benitez[1] Marcelo López-Lastra[1] Ruth Nuñez[1] Valentina Ross[1] Jacinta Soza[1] Karla Pino[1] Francisco Fuster[2] Alejandro Soza Ried[1], [1]Pontificia Universidad Católica de Chile, [2]Hospital Gustavo Fricke

Background: Hepatitis B virus (HBV) affects 240 million people, increasing the risk of cirrhosis and hepatocellular carcinoma. Recent migration has expanded the Haitian population in Chile. Haiti has high HBV endemicity, but health assessments in this vulnerable group are scarce. Genetic polymorphisms, specifically IFNL3 variants, are linked to infection susceptibility and treatment response. Prior studies focused on Asian and non-African cohorts, leaving African ancestry populations underrepresented. We aimed to estimate the seroprevalence of HBV exposure, chronic HBV infection, HCV, and HIV in Haitian migrants in Chile and evaluated demographic, clinical, and genetic factors associated with the risk of the chronic infection among HBV-exposed participants. **Methods:** In this cross-sectional study of adult Haitian migrants in Santiago, clinical and demographic data were collected and serological assays performed for HBsAg, anti-HBs, anti-HBc, anti-HCV, and HIV. Among HBV-exposed participants (anti-HBc positive), subjects were categorized as chronic vs. resolved infection based on HBsAg status. Host IFNL3 single nucleotide polymorphisms (SNPs) rs12979860 and rs8099917 were genotyped by real-time PCR. Genotype distributions were evaluated for Hardy-Weinberg equilibrium (HWE). Associations in exposed subjects were analyzed using Fisher's exact and Mann-Whitney U tests. **Results:** Of 381 enrolled participants (median age 37, 52% female), seroprevalence was: anti-HBc 31% (116/371), anti-HBs 29% (107/370), HBsAg 2.4% (9/368), anti-HCV 0.5% (2/369), and HIV 0.8% (3/366). Among 116 HBV-exposed, 9 (7.8%) had chronic and 107 (92.2%) resolved infection. In the genotyped population (n = 102), the favorable rs12979860 CC genotype was absent in HBsAg-positive patients and present in 14.9% of resolved participants (0/8 vs 14/94; p = 0.59), without HWE deviation (p = 0.82). For rs8099917, distribution was TT 97.1% (99/102), TG 1.9% (2/102), and GG 1.0% (1/102), showing a HWE deviation (p = 0.03) due to low minor allele frequency. No significant differences were found between chronic and resolved patients regarding age, sex, body mass index, obesity, diabetes, hypertension, or smoking status or *IFNL3* genotype distribution. **Conclusion:** Haitian migrants in Chile show high HBV exposure (31%) and chronic infection (2.4%), vastly exceeding local figures (0.15%). Most exposed individuals (92.2%) resolved infection. The host IFNL3 polymorphisms did not reach statistical significance regarding chronic infection vs clearance, potentially limited by small number of cases, though the favorable rs12979860 CC genotype was exclusively observed in individuals who resolved the infection. These findings underscore the need for targeted public health policies, such as screening and vaccination programs, to mitigate HBV burden and support healthcare integration for this vulnerable community.

Characteristic	Exposed (n=116)	Chronic Infection (n=9)	Resolved (n=107)	p-value
Female sex, n (%)	45/116 (38.8)	4/9 (44.4)	41/107 (38.3)	0.73
Age, years (median, Q1-Q3)	40 (34-46)	36 (33-44)	40 (34-46)	0.60
Body Mass Index, kg/m² (median, Q1-Q3)	26.4 (23.4-30.1)	29.1 (22.3-31.7)	26.2 (23.6-30.0)	0.32
Obesity, n (%)	26/96 (27.1)	3/6 (50.0)	23/90 (25.6)	0.34
Hypertension, n (%)	39/103 (37.9)	4/7 (57.1)	35/96 (36.5)	0.42
Diabetes Mellitus, n (%)	5/111 (4.5)	0/9 (0)	5/102 (4.9)	> 0.9
Smoking, n (%)	1/114 (0.9)	0/9 (0)	1/105 (1.0)	> 0.9
SNP *rs12979860*, n (%)				0.59
CC	14/102 (13.7)	0/8 (0)	14/94 (14.9)	
CT/TT	88/102 (86.3)	8/8 (100)	80/94 (85.1)	
SNP *rs8099917*, n (%)				> 0.9

Manolakopoulou[2] Pinelopi Antonakaki[2] Maria Tampaki[2] Maria Melanie Deutsch[2] Spilios Manolakopoulos[2], [1]Hepatogastroenterology Unit, [2]Hepatogastroenterology Unit, Hippocration General Hospital of Athens

Background: Chronic HBV infection remains a significant public health problem globally known to lead to cirrhosis,and hepatocellular carcinoma. In recent years there has also been a continuous increase in cases of metabolic syndrome (MetS) in the general population, with or without metabolic-associated steatotic liver disease (MASLD), which may aggravate pre-existing liver disease. The impact of the coexistence of MetS with chronic hepatitis B (CHB),(MET-HBV) has not been sufficiently investigated. The aim of this study is to describe the characteristics of patients with MET-HBV followed up at our tertiary centre. **Methods:** All HBsAg-positive patients with available data followed up between 2015 and 2025 at our Unit were identified. These patients either presented with a recent diagnosis for specialized management or were initially diagnosed at our centre. Clinical, laboratory, and demographic data was retrieved from medical records. Cirrhosis was diagnosed based on clinical and laboratory findings and/or liver stiffness values >12 kPa on elastography. A history of arterial hypertension was defined as use of antihypertensive medication at first visit. Type 2 diabetes mellitus was defined as fasting glucose >126 mg/dl at the first visit and/or use of antidiabetic treatment. Dyslipidemia was defined as use of lipid lowering therapy at first visit. Patients consuming >30 g of alcohol daily were excluded. **Results:** We present data from 747 patients; median age was 49.9 years (range 17–83), 55.7% (n = 416) were male. 50.9% were of Greek origin, 49.1% came from other countries. At presentation 42.6% had normal BMI, 36.7% were overweight (25–30 kg/m²) and 20.7% were obese (>30 kg/m²). Men had higher BMI than women (26.83 vs 26.12 kg/m²,p = 0.046). Type 2 diabetes was found in 9.5%, hypertension in 22.6% and dyslipidemia in 21.8% of patients. A total of 388 patients (52%) underwent elastography and 54 (7.2%) had liver biopsy performed at diagnosis/first visit. Among them 68.6% had no or mild fibrosis, 13.1% had moderate fibrosis and 8.8% had advanced fibrosis. Multivariate analysis showed that diabetes mellitus (p = 0.028), BMI >30 kg/m² (p = 0.077) and history of antiviral treatment (p = 0.001) were associated with advanced fibrosis/cirrhosis (defined as liver stiffness values >9 kPa). When analysis was restricted in treated patients high BMI (>30 kg/m²) remained associated with advanced fibrosis. On the other hand, in untreated patients (inactive carriers): diabetes (p = 0.008), high BMI (p = 0.016), and dyslipidemia (p = 0.017) were significantly associated with advanced fibrosis. 2.7% of patients developed HCC and 7.3% of patients passed away during follow-up. **Conclusion:** A significant proportion of patients with CHB in Greece are overweight or present with features of metabolic syndrome. BMI >30 kg/m² appears to worsen liver injury and contribute to devlopment of advanced liver fibrosis, regardless of of HBV infection .

4059 | ASSESSING CHRONIC HEPATITIS B LIVER FIBROSIS STAGING AND ANTIVIRAL TREATMENT PATTERNS AT A COMMUNITY HEALTH CENTER IN NORTHERN CALIFORNIA

Zinnia Dong[1] Morgan Manter[1] Amy Tang[1], [1]North East Medical Services

Background: Liver elastography is recommended for people with chronic hepatitis B virus (HBV) infection, with chronic HBV guidelines using a fibrosis stage of F2 or greater as a treatment indicator. Community health centers (CHCs) care for over 50,000 people with HBV in the United States and are high-impact settings for HBV management. North East Medical Services (NEMS) is a large, federally funded CHC in the San Francisco Bay Area with an HBV registry-based care management program of over 3,500 active patients that began offering on-site vibration controlled transient elastography (VCTE) in 2021. We aimed to summarize findings and characteristics of NEMS patients with HBV who completed VCTE. **Methods:** We retrospectively analyzed electronic health record data of NEMS patients with chronic HBV and VCTE results between 1/1/21 to 4/30/26. If multiple VCTE assessments were completed, results from the first assessment were analyzed. Chart review was performed for patients with F4 stage without HBV antiviral treatment prescribed. **Results:** We identified 1,685 patients with HBV who completed VCTE with a median age of 58 years and fibrosis stage distribution of 1453 (86%) F0-1, 136 (8%) F2, 57 (3%) F3, and 39 (2%) F4. F2 staging or greater was significantly associated with male compared to female sex ($\chi^2 = 22.8$, $p < 0.01$; OR = 2.0, 95% CI [1.5,2.7]). HBV antiviral treatment prescription rate was 38% (639/1685) overall and 69% (161/232) among patients with ≥F2 staging. For the 5 patients with F4

stage without HBV treatment prescribed, most were referred to hepatology for further evaluation and treatment (80%, 4/5). **Conclusion:** At a large CHC, on-site VCTE identified clinically significant fibrosis in 14% of patients with chronic HBV, including 6% with advanced fibrosis or cirrhosis. HBV antiviral treatment prescription was higher among patients with F2 or greater fibrosis with increased treatment prescription rates as fibrosis scores increased. These findings support VCTE integration at a CHC and its potential impact in timely HBV antiviral treatment and primary care-based HBV management.

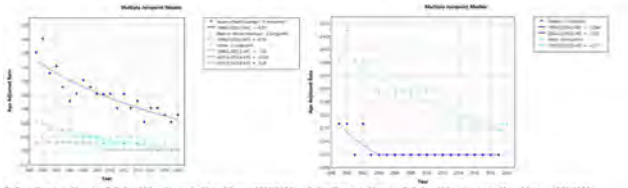
4060 | TEMPORAL TRENDS IN HEPATITIS B-RELATED MORTALITY IN THE UNITED STATES, 1999–2020

Albert Gyato[1] Mahader Wossene[2] Estherla Twene[3] Tsegaye Gebreamlak[2] Priyanka Dudani[2] Aditi Puri[2], [1]Loyola Medicine- MacNeal Hospital, [2]Loyola Medicine-MacNeal Hospital, [3]Bursky Public Health, Washington University in St. Louis



Background: Hepatitis B virus (HBV) infection is a leading cause of severe acute and chronic liver disease worldwide. In the United States, there has been a general decline in HBV incidence and prevalence. While universal childhood vaccination has contributed to a significant reduction in HBV incidence among younger populations, chronic HBV infection remains prevalent in adults, contributing to severe complications such as liver cirrhosis and hepatocellular carcinoma. In the era of prevention through screening, antiviral therapy and expanded vaccination, we aim to understand the current trends in HBV-related mortality and identify remaining gaps. **Methods:** This study used a retrospective, serial cross-sectional analysis of the national death certificate data from the CDC WONDER datasets from 1999 to 2020. Adults 18 years and older with Hepatitis B listed as the underlying cause of death were included. The primary outcome was the age-adjusted hepatitis B mortality rate (AAMR) calculated per 100,000 population. Mortality was stratified by sex, race (White, Black or African American, and Asian or Pacific Islander), and census region (large central metropolitan, smaller metropolitan, and rural). Temporal trends were assessed with Joinpoint regression expressed as average annual percent change (AAPC) and 95% confidence intervals (CI). Statistical significance was defined as $p < 0.05$. **Results:** From 1999 to 2020, 13,549 hepatitis B-related deaths occurred among U.S. adults, with an overall AAMR of 0.2 per 100,000 (95% CI: 0.2-0.2). Males accounted for 69% of deaths versus 31% among females. White individuals accounted for 63.0% of mortality, followed by Asian or Pacific Islanders (20.2%) and Black or African Americans (16.1%). HBV-related mortality declined significantly across all populations. AAMR was higher in males than females (0.4 to 0.2 vs 0.2 to 0.1; AAPC -4.2% vs -3.4%). Asian or Pacific Islanders had the highest mortality burden (AAMR 1.5 to 0.6; AAPC -4.4%), while Black or African Americans showed the steepest decline (AAMR 0.5 to 0.1; AAPC -6.7%). Large central metropolitan areas had the highest AAMR (0.5) and greatest decline (AAPC -5.0%). Smaller metropolitan areas declined from 0.3 to 0.1 (AAPC -4.7%, $p < 0.05$), while rural areas declined from 0.2 to 0.1 (AAPC -3.5%, $p < 0.05$). **Conclusion:** These findings revealed a sustained decline in HBV-related mortality from 1999 to 2020, likely due to advances made in HBV vaccinations and medical treatment. Despite this, there remained racial and sex disparities. Asian or Pacific Islanders had disproportionately higher mortality, possibly due to the higher prevalence of chronic HBV and a high proportion of individuals born in endemic countries or regions. Sex disparities are suspected to be due to increased opportunities for women to be identified and vaccinated during pregnancy. There is a need for continued targeted interventions to eliminate persistent racial and sex disparities.

4061 | FACTORS ASSOCIATED WITH INCOMPLETE HBV DNA SUPPRESSION AMONG ADULTS IN NORTH AMERICA WITH HBV-HIV CO-INFECTION TREATED WITH TENOFOVIR

Jenny Oh[1] Marc Ghany[2] Wendy King[3] Mark Anderson[4] Raymond Chung[5] Gavin Cloherty[6] Richard Sterling[7], [1]NIH, [2]NIH/NIDDK, [3]Cleveland Clinic, [4]Abbott Laboratories, [5]Massachusetts General Hospital, [6]Abbott, [7]Virginia Commonwealth University

Background: Human immunodeficiency virus (HIV) commonly co-exists with hepatitis B virus (HBV). Both HBV and HIV are susceptible to nucleos(t)ide analogue therapy, allowing dual treatment with a single regimen. However, ~15% of HBV–HIV co-infected individuals fail to achieve complete HBV suppression despite effective HIV control. The reason is unclear. We aimed to identify factors associated with HBV incomplete viral suppression (IVS; HBV DNA ≥1,000 IU/mL) during tenofovir disoproxil fumarate (TDF) therapy and to interrogate the HBV genome for novel mutations associated with TDF resistance. **Methods:** Data and serum samples from HBV–HIV co-infected adults on TDF participating in the HBV–HIV Co-infection Ancillary Study of the Hepatitis B Research Network were evaluated. Among those with suppressed HIV RNA (<400 copies/mL), logistic regression was used to identify demographic, clinical, and virologic factors associated with HBV IVS. Whole HBV genome sequencing was performed by next-generation sequencing (NGS) among participants with IVS, with and without HIV RNA suppression. Phylogenetic analysis was conducted using GenBank reference sequences. Mutational analysis was focused on the reverse transcriptase (RT) domain of the HBV polymerase. **Results:** 91/114 participants had suppressed HIV RNA (<400 copies/mL). Among the 91, median duration of HBV-HIV infection was 20 years; 7.2% had CD4 <200 cells/mm³ and 13 (14%) had HBV IVS. In univariable analyses, higher BMI, higher ALT, low CD4 count (<200 cells/mm^3), higher qHBeAg, higher HBsAg, higher HBV RNA and higher HBcrAg were associated with HBV IVS (Table 1). In multivariable analysis, only HBV RNA was significant. Whole HBV genome sequencing was performed on 26 participants with IVS, 13 participants with and 13 without HIV RNA suppression. Multiple polymorphisms were identified in the RT domain but no mutational hotspots or known TDF resistance mutations (rtA194T, rtR192P, or MLVV) were identified. **Conclusion:** These findings indicate incomplete HBV DNA suppression among co-infected adults with HIV control on TDF is not due to TDF resistance, but rather a result of high covalently closed circular DNA transcriptional activity (reflected by elevated HBV RNA), suggesting this population may require more potent antiviral therapy to achieve HBV suppression.

4062 | ARE TWO DOSES OF HEPB-CPG SUFFICIENT TO PROVIDE IMMUNITY IN PEOPLE WITH HIV AND PRIOR HEPATITIS B VACCINE NONRESPONSE? A SYSTEMATIC REVIEW AND META-ANALYSIS

Mexan Mapouka[1], [1]University of Maryland Capital Region Health

Background: People with HIV (PWH) are less likely to develop protective serologic responses to conventional hepatitis B vaccines. Recent recommendations suggest that nonresponders to the initial vaccination series should be reimmunized with two or three doses of HepB-CpG (Heplisav-B). However, large pooled data assessing the efficacy of two-doses of HepB-CpG compared with three doses of HepB-Alum vaccines (Engerix-B or Recombivax HB) among PWH remain limited. While two prior studies independently demonstrated the superiority of two-dose HepB-CpG compared to three-dose HepB-alum in separate study populations, they were limited by modest sample sizes and incomplete follow-up in both treatment arms. By pooling data across these trials,this meta-analysis aimed to provide more evidence regarding the comparative effectiveness of the two-dose HepB-CpG versus three-dose HepB-alum vaccination strategy. **Methods:** A systematic review and meta-analysis following PRISMA guidelines was conducted. PubMed, Embase, Web of Science, and CENTRAL were searched through 01/24/2026. The random-effects model was used to estimate the pooled risk ratios and seroconversion rates with 95% confidence intervals using the Comprehensive Meta-Analysis software (version 4.0; BIOSTAT, Englewood, NJ, USA). Heterogeneity was assessed using the I^2 statistic. **Results:** A total of 493 participants were included (248 HepB-CpG, 245 HepB-Alum). Mean age was 45 years; most were male. The cohort included White (46%), Black (37%), Asian (12%), and Hispanic (29%) participants. Individual studies showed higher seroconversion with HepB-CpG. Reilly-Evans et al. reported RR 1.62 (93.4% vs 57.6%), and Marks et al. reported RR 1.16 (93.1% vs 80.6%). However, pooled analysis showed no statistically significant difference, and did not confirm clear superiority of the two-dose HepB-CpG regimen (RR 1.35; 95% CI 0.97, 1.87; $p = 0.079$), with high heterogeneity ($I^2 = 86.5\%$). Subgroup analysis showed reduced seroprotection in diabetes (70.2%) and smokers (84%), both below the 90% optimal threshold. **Conclusion:** Although individual studies suggested higher seroconversion with HepB-CpG, pooled data did not show statistically significant superiority, and do not confirm that two-dose HepB-CpG alone is sufficient over HepB-Alum in prior nonresponders. Evidence suggests outcomes are influenced by heterogeneity and host factors. Current findings support consideration of additional third booster dose of HeB-CPG to achieve desirable seroconversion compared with three doses of HepB-Alum in PWH who had previously failed hepatitis B vaccination . Additional measures remain optimizing CD4+ levels to enhance immune response in diabetics and smokers.

Table 1. Baseline Characteristics of Participants by Vaccine Type and Pooled Sample

Variable	Reilly-Evans et al., 2023	Marks et al., 2025	Pooled

Background: In a previously reported long-term cohort treated with tenofovir amibufenamide (TMF), 94.5% of patients achieved HBV DNA < 20 IU/mL after 5 years. In this high-response setting, the small subset of patients with low level viremia or virological fluctuation remains clinically important. It is unclear whether these events occur randomly or cluster within identifiable subgroups. **Methods:** This study used a combined phase III–IV clinical cohort of TMF with prospective follow-up. A total of 589 patients from the evaluable population were included based on predefined criteria. An endpoint event was defined as either failure to achieve HBV DNA < 20 IU/mL or any case of virological rebound (> 1 $\log_{10}$ IU/mL increase from nadir). Baseline factors associated with endpoint were assessed using logistic regression analysis. The analysis was designed to identify patterns of risk enrichment and a constrained classification and regression tree (CART) was established to enable clinically interpretable risk stratification. For continuous predictors, optimal cut-offs were determined by maximizing node purity (information gain) across all candidate thresholds. **Results:** Among 589 patients, 31 (5.3%) reached endpoint during 5 years of follow-up, indicating a low overall event rate. Events were not randomly distributed but showed concentration within specific baseline subgroups. In a univariable analysis, younger age and higher baseline HBV DNA level were associated with increased risk of endpoint events (Figure 1). In a multivariable analysis, age remained the only independent predictor (adjusted OR 0.95 per year, 95% CI 0.91–1.00, P = 0.030). In the CART analysis, age was consistently selected as the primary splitting variable, with 35 years as the optimal cut-off. Patients aged > 35 years had a low event rate (2.9%), while those ≤ 35 years had a higher rate (8.0%). Among patients aged ≤ 35-year, baseline HBV DNA > 7.7 $\log_{10}$ IU/mL further enriched risk, with an event rate of 12.2%, compared with 3.1% in the

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

remaining patients. Other factors (e.g., cirrhosis and HBeAg positivity) provided limited additional stratification. **Conclusion:** In this high response TMF cohort, low level viremia or virological fluctuation was infrequent and non-randomly distributed, with higher risk in younger patients and those with high baseline HBV DNA. Age is a key predictor of sustained virological response during long-term TMF therapy.

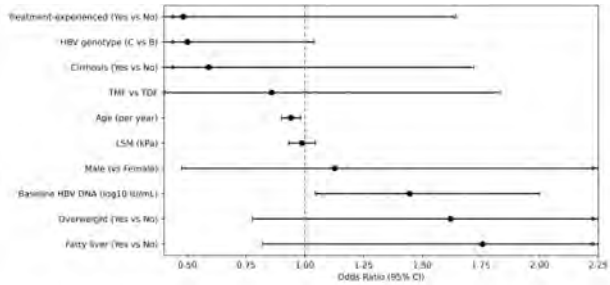

Figure 1. Baseline factors associated with endpoint events

Forest plot of univariable logistic regression analyses showing baseline factors associated with endpoint events. Odds ratios (ORs) and 95% confidence intervals (CIs) are displayed. Variables with unstable estimates due to sparse events (e.g., HBeAg status and abnormal ALT) were excluded from the plot.

4064 | DIFFERENTIAL EFFECT OF ANTIVIRAL THERAPY ON HEPATOCELLULAR CARCINOMA RISK ACCORDING TO HBV DNA TRAJECTORIES IN HBEAG-NEGATIVE CHRONIC HEPATITIS B: A MULTINATIONAL STUDY

Ho Soo Chun[1] Minjong Lee[1] Hye Ah Lee[2] Tae Hun Kim[1] Terry Cheuk-Fung Yip[3] Lilian Yan Liang[3] Shang-Chin Huang[4] Tai-Chung Tseng[5] Grace Wong[3] Seung Up Kim[6], [1]Ewha Womans University College of Medicine, [2]Ewha Womans University Seoul Hospital, [3]The Chinese University of Hong Kong, [4]National Taiwan University, [5]National Taiwan University Hospital, [6]Yonsei University College of Medicine

Background: Prognostic significance of HBV DNA trajectories in HBeAg-negative chronic hepatitis B (CHB) remains unclear. We assessed whether the effect of antiviral therapy (AVT) on hepatocellular carcinoma (HCC) risk differs according to the duration of moderate-to-high viremia and its association with fibrosis progression. **Methods:** This multinational study recruited 9,336 treatment-naïve, non-cirrhotic HBeAg-negative CHB patients from South Korea, Hong Kong, and Taiwan (2007–2022). HBV DNA levels during the initial 3-year follow-up defined four groups: Group 1, persistent $<10{,}000$ IU/mL; Groups 2 and 3, moderate-to-high viremia ($\geq 10{,}000$ IU/mL) for <18 and ≥ 18 months, respectively; Group 4, AVT initiation within 3 years. **Results:** During a median follow-up of 10.0 (interquartile range, 7.0–12.2) years, 111 patients developed HCC (0.13/100 person-years). The annual HCC incidence was 0.08%, 0.20%, 0.36%, and 0.13% in Groups 1–4, respectively. Compared with Group 1, HCC risk increased with longer moderate-to-high viremia duration (Group 2: adjusted sub-distribution hazard ratio [aSHR] = 2.23; Group 3: aSHR = 4.02; all $P < 0.05$), whereas Group 4 showed a comparable risk. In propensity score analyses, the cumulative HCC incidence remained significantly higher in Group 3 than in Group 4 (all $P < 0.05$), but not in Group 2, even in patients with significant fibrosis or elevated alanine aminotransferase. Fibrosis progression also increased with longer moderate-to-high viremia duration, with the highest risk in Group 3 (P for trend < 0.001). **Conclusion:** Prolonged moderate-to-high viremia increased HCC and fibrosis progression risks in non-cirrhotic HBeAg-negative CHB, and the benefit of AVT appeared to differ by viremia duration, with benefit mainly in prolonged exposure.

4065 | HBV DNA-BASED TREATMENT THRESHOLDS FAIL TO REFLECT FIBROSIS BURDEN AND LONG-TERM OUTCOMES IN INDETERMINATE-PHASE CHRONIC HEPATITIS B

Seung Up Kim[1] Hanah Lee[2] Tae Hyung Kim[3] Yeon Seok Seo[3] Dae Won Jun[4] Soo Young Park[5] Hyun Woong Lee[1] Sang Gyune Kim[6], [1]Yonsei University College of Medicine, [2]Chung-Ang University Hospital, [3]Korea University College of Medicine, [4]Hanyang University College of Medicine, [5]Kyungpook National University College of Medicine, [6]Mayo Clinic Rochester

Background: Management of patients with indeterminate-phase chronic hepatitis B (CHB) remains challenging because current decisions are largely based on serum HBV DNA thresholds, which may not adequately reflect underlying liver fibrosis burden or long-term prognosis. We investigated the clinical limitations of HBV DNA-based treatment stratification and evaluated whether fibrosis burden better predicts liver-related outcomes in patients with indeterminate-phase CHB. **Methods:** We retrospectively analyzed 497 patients with indeterminate-phase CHB who underwent liver biopsy. Histologic fibrosis stage, inflammation grade, and steatosis were assessed at baseline, and patients were categorized according to HBV DNA levels and treatment eligibility based on current guideline thresholds. Long-term outcomes included hepatocellular carcinoma (HCC), cirrhosis progression, hepatic decompensation, and composite liver-related events. **Results:** During a median follow-up of 148.0 months (total 5,740.7 person-years), 50 patients developed HCC, 68 showed cirrhosis progression, 26 experienced hepatic decompensation, [KSG1] and 109 developed composite liver-related events. In multivariable Cox analysis, fibrosis stage independently predicted liver-related outcomes (hazard ratio [HR] per 1-stage increase, 1.41; 95% confidence interval [CI], 1.15–1.72; $P = 0.0009$), whereas HBV DNA level was not independently associated with outcomes (HR, 0.90; 95% CI, 0.82–1.00; $P = 0.051$). Substantial discordance was observed between HBV DNA category and histologic fibrosis burden. Among patients with low-to-moderate HBV DNA levels (< 7 log IU/mL), 72.1% had significant fibrosis ($\geq$F2), while 35.5% of patients with high HBV DNA levels (> 7 log IU/mL) had minimal fibrosis (F0–1). Among patients with significant fibrosis ($\geq$F2), 80.3% had low-to-moderate HBV DNA levels, while among patients with HBV DNA levels within conventional treatment thresholds (4-8 log IU/mL), 20% showed no histologic indication for treatment. Noninvasive fibrosis markers showed good diagnostic performance for predicting significant fibrosis. Fibroscan demonstrated the highest accuracy for $\geq$F2 fibrosis (AUROC 0.818), $\geq$F3 fibrosis (AUROC 0.877), and cirrhosis (AUROC 0.870), outperforming FIB-4 and APRI. **Conclusion:** Current HBV DNA-based thresholds may misclassify a substantial proportion of patients with indeterminate-phase CHB, leading to both undertreatment of high-risk patients and overtreatment of low-risk patients. Risk stratification incorporating fibrosis burden, supported by noninvasive fibrosis markers, may improve individualized treatment decisions beyond HBV DNA-based approaches alone.

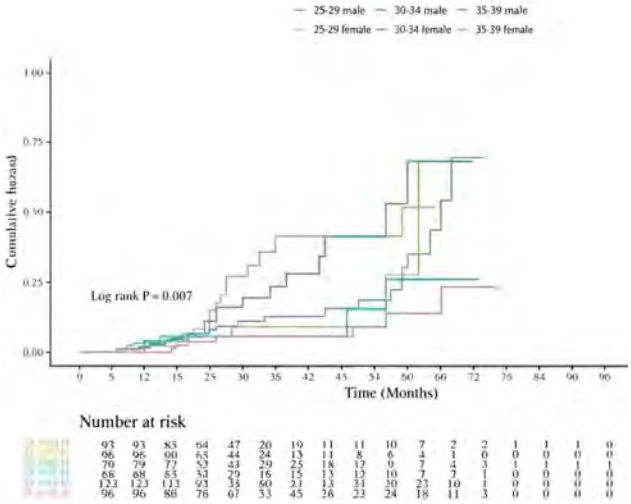
4066 | PREVALENCE OF HEPATITIS A TO E VIRUSES AMONG THE UNITED STATES POPULATION, 2011-2023

Zhiwei Chen[1] Jing Tang[2] Yan Han[3] Zhao Li[4], [1]The second affiliated hospital of CQMU, [2]Second Affiliated Hospital, Chongqing Medical University, [3]The Second Affiliated Hospital of Chongqing Medical University, [4]The Seventh People's Hospital of Chongqing

Background: With the 2030 WHO target for the elimination of viral hepatitis threat approaching, updated epidemiological data on hepatitis A–E in the United States is essential to optimize public health policies and facilitate progress toward this goal. **Methods:** This cross-sectional study included data of nationally representative participants aged ≥6 years in the National Health and Nutrition Examination Survey from 2011 to 2023. National trends in prevalence of hepatitis A to E were analyzed, and stratified by sex, age, and ethnicity and race. **Results:** A total of 39,753, 39,874, 39,644 and 39,879 eligible participants were included for analyses of hepatitis A, B, C and E, respectively. For HBV, the prevalence of current HBV infection (HBsAg and anti-HBc positivity) was 0.3% (95% CI: 0.2%–0.4%), remaining stable from 2011 to 2023. The prevalence of HBV susceptibility (HBsAg, anti-HBc and anti-HBs negativity) was 71.4% (95% CI: 70.4%–72.2%), with no obvious fluctuation across the study period. HBV vaccination coverage with at least one dose decreased from 50.4% (95% CI: 47.8%–53.1%) in 2011 to 48.4% (95% CI: 46.2%–50.7%) in 2020. A prominent declining trend was observed among individuals born after 1991, with coverage dropping from 90.0% (95% CI: 86.9%–92.4%) to 83.6% (95% CI: 81.3%–85.7%) (P for trend = 0.001). Notably, 57.0% (95% CI: 55.6%–58.4%) of HBV-vaccinated participants still remained susceptible to HBV. Among patients with current HBV infection, the seroprevalence of anti-HDV, retested using an updated laboratory assay, was 1.3% (95% CI: 0.3%–6.1%). For HCV, the seroprevalence of anti-HCV was 1.6% (95% CI: 1.4%–1.8%), and the prevalence of current HCV infection confirmed by positive HCV-RNA was 0.7% (95% CI: 0.6%–0.9%). Although anti-HCV seropositivity stayed stable over time, current HCV infection decreased from 0.8% (95% CI: 0.4%–1.4%) in 2011 to 0.4% (95% CI: 0.3%–0.7%) in 2023, with the most remarkable reduction seen in the population aged ≥50 years. The proportion of active infection among anti-HCV-positive individuals also declined significantly from 65.5% (95% CI: 46.4%–80.6%) to 31.3% (95% CI: 23.3%–40.7%) (P for trend = 0.005). For HAV, anti-HAV seroprevalence rose steadily from 41.6% (95% CI: 38.7%–44.6%) to 48.0% (95% CI: 44.7%–51.4%) (P for trend < 0.001), whereas HAV vaccination coverage maintained a relatively steady level throughout the years. For HEV, the prevalence of anti-HEV IgM positivity remained stable from 1.6% (95% CI: 1.2%–2.2%) in 2011 to 1.7% (95% CI: 1.2%–2.3%) in 2023. **Conclusion:** The sustained decline of current HCV infection reflects encouraging progress in hepatitis C prevention and treatment. However, the falling HBV vaccination coverage and rising anti-HAV seroprevalence might become emerging public health challenges. Targeted and strengthened interventions are urgently required to address these issues and advance the global agenda of viral hepatitis elimination. **Disclosures:** Zhiwei Chen:Nothing to Disclose, Jing Tang:Nothing to Disclose, Yan Han:Nothing to Disclose, Zhao Li:Nothing to Disclose.

4067 | SEX DIFFERENCES IN DISEASE PROGRESSION AMONG PATIENTS WITH CHRONIC HBV INFECTION



Dachuan Cai[1] Yiting Dai[1], [1]The Second Affiliated Hospital of Chongqing Medical University

Background: Chronic hepatitis B virus (HBV) infection shows sex disparities in progression, with males carrying higher risks for cirrhosis and hepatocellular carcinoma (HCC). However, current antiviral guidelines do not incorporate sex-related factors. We aim to investigate sex differences in chronic HBV progression and evaluate whether sex should guide antiviral therapy initiation for risk stratification. **Methods:** This retrospective cohort enrolled 555 treatment-naïve chronic hepatitis B patients (Jan 2016–Dec 2025). Patients were stratified by sex and age and followed longitudinally. The primary endpoint was overall liver disease progression (OLDP: hepatitis exacerbation, cirrhosis, or HCC). Kaplan–Meier, log-rank tests, and Cox models identified progression risk factors. Subgroup analyses targeted untreated patients. Propensity score matching (PSM) balanced baselines to evaluate antiviral impacts, while linear mixed-effects models assessed sex-specific virological responses. **Results:** A total of 555 patients were included, comprising 295 males and 260 females, with a cumulative follow-up of 16,722 person-months. During follow-up, 74 patients developed OLDP, corresponding to an incidence density of 5.31 per 100 person-years. The incidence density was significantly higher in males than in females (7.27 vs. 2.98 per 100 person-years, P < 0.001).The overall 5-year cumulative incidence of OLDP was 11.90%, which was significantly higher in males (P = 0.001). After age stratification, significant differences in cumulative incidence were observed across subgroups (P = 0.007). Multivariable Cox regression identified female sex as an independent protective factor for disease progression (HR = 0.47, 95% CI 0.27–0.80). This protective effect was more pronounced in untreated patients (HR

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

= 0.33, 95% CI 0.14–0.75).After PSM, antiviral therapy was not significantly associated with reduced progression risk (HR = 0.94, P > 0.05), whereas female sex remained independently protective (HR = 0.32, 95% CI 0.10–0.96). Antiviral therapy significantly reduced HBV DNA levels (P < 0.001), although differences in the rate of virological response were observed among sex–age subgroups (P < 0.001). **Conclusion:** Significant sex differences exist in disease progression among patients with chronic hepatitis B, with females exhibiting a substantially lower risk than males. This protective effect is more evident in untreated populations, suggesting that the disparity mainly reflects differences in the natural history of the disease. A potential interaction between sex and age was observed. Incorporating sex and age into risk stratification models may help optimize individualized decisions regarding the initiation of antiviral therapy and facilitate more precise clinical management.

4068 | ALCOHOL CONSUMPTION INCREASES RISK OF HEPATOCELLULAR CARCINOMA IN CHRONIC HEPATITIS B PATIENTS

Yukai Chen[1] Fajuan Rui[2] Jie Li[2] Yuemin Nan[1], [1]The Third Hospital of Hebei Medical University, [2]Nanjing Drum Tower Hospital

Background: Both chronic hepatitis B (CHB) and alcohol consumption are risk factors for hepatocellular carcinoma (HCC). However, their synergistic effect on HCC development is not fully elucidated. Therefore, we evaluated the association between alcohol consumption and HCC development in CHB patients. **Methods:** Patients with CHB were enrolled between March 1, 2005 and December 30, 2025 at two medical centers in China. COX proportional hazards regression model and Kaplan-Meier curves were used to evaluate the association between alcohol consumption and HCC risk in CHB patients. **Results:** A total of 1,010 CHB patients were included, among whom 129 (12.77%) developed HCC during 3,684 person-years of follow-up. Compared to those without HCC, CHB patients with HCC had higher alcohol intake levels (2.00 vs. 0.00×100 g/week, $P<0.001$). Multivariable Cox regression showed that each 100 g/week increase in alcohol intake was associated with a higher risk of HCC (adjusted hazard ratio [aHR] 1.29, $P<0.001$) in CHB patients. Compared with low (<140/210 g/week) and low-to-moderate (≤350/420 g/week) alcohol intake, high alcohol intake (>350/420 g/week) was associated with an increased risk of HCC (aHR 3.30 and 3.22, respectively; both $P<0.001$). In stratified analyses, similar associations were observed in both cirrhotic (aHR 1.29, 3.45, and 2.88) and non-cirrhotic CHB patients (aHR 1.31, 3.15, and 3.88). **Conclusion:** Alcohol consumption independently increases HCC risk among CHB patients, regardless of cirrhosis status. These findings highlight the importance of systematic assessment and control of alcohol intake to reduce HCC risk in CHB patients.

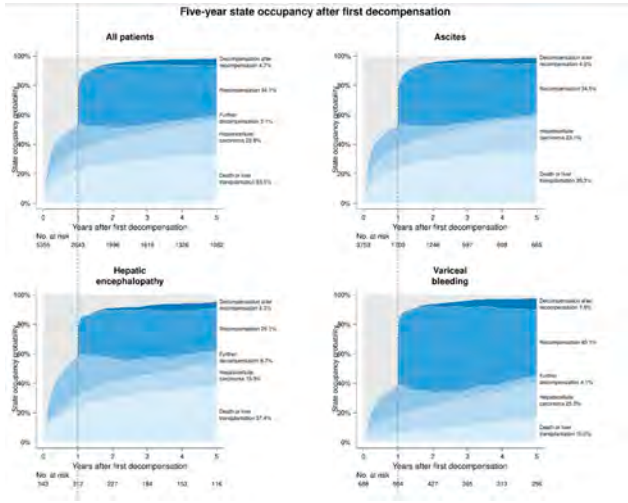
4069 | MULTISTATE TRAJECTORIES PREDICT RECOMPENSATION AFTER FIRST HEPATITIS B VIRUS (HBV)-RELATED DECOMPENSATED CIRRHOSIS



Vicki Wing-Ki Hui[1] Grace Wong[1] Wai Sun Vincent Wong[1] Jimmy Che-To Lai[1] Cheuk Fung Yip[1], [1]The Chinese University of Hong Kong

Background: Chronic HBV infection-related hepatic decompensation may improve after antiviral therapy, but the chance of recompensation varies across patients. We characterized multistate trajectories after first decompensation and assessed whether the presenting event identifies different probabilities of

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

recompensation, further decompensation, hepatocellular carcinoma (HCC), and death or liver transplantation (LT). **Methods:** We conducted a territory-wide retrospective cohort study of adults with HBV-related decompensated cirrhosis receiving first-line antiviral therapy in Hong Kong between 2000 and 2023. First decompensation was classified according to Baveno VII criteria as ascites, hepatic encephalopathy (HE), variceal bleeding, or multiple complications, and patients were followed across subsequent states of further decompensation, recompensation, decompensation after recompensation, HCC, and death/LT. Disease trajectories were evaluated using transition probabilities and state occupancy at 1, 3, and 5 years. **Results:** Among 5,355 patients, first decompensation was ascites (n = 3,753), HE (n = 543), variceal bleeding (n = 688), or a combination of these events (n = 371). Baseline severity differed by the presenting event. Patients with variceal bleeding were younger and had less severe liver dysfunction (age 57.4 ± 11.1 years; Child-Pugh 9 [9–10]; MELD 10.7 ± 3.0), while patients with HE were older and had more advanced liver disease (age 61.0 ± 14.0 years; Child-Pugh 10 [10–12]; MELD 16.3 ± 8.1). Patients with ascites were aged 62.4 ± 12.4 years, had Child-Pugh 10 [9–11] and MELD 13.2 ± 5.5. From first decompensation, the most common next transition was recompensation (39%), followed by further decompensation (33%), death/LT (16%), and HCC (12%). Patient outcomes changed markedly over time: at 1 year, 27.3% remained in first decompensation, 19.7% achieved recompensation, 17.6% progressed to further decompensation, 13.0% developed HCC, and 22.4% died/received LT. By 5 years, only 1.8% remained in first decompensation, while 34.1% achieved recompensation, 33.5% died/underwent LT, and 22.9% developed HCC. Patients presenting with HE had lower 5-year recompensation occupancy (26.0%) and higher death/LT occupancy (42.6%), whereas variceal bleeding had higher recompensation occupancy (39.4%) and lower death/LT occupancy (20.4%). Ascites showed an intermediate pattern, with 34.5% occupying recompensation and 35.3% death/LT at 5 years. **Conclusion:** The chances of recompensation differ according to the presenting event. Variceal bleeding is followed by a greater potential for recompensation, whereas HE marks limited reversibility and higher risk of death/LT. Early reassessment may guide monitoring and timely transplant referral and assessment.

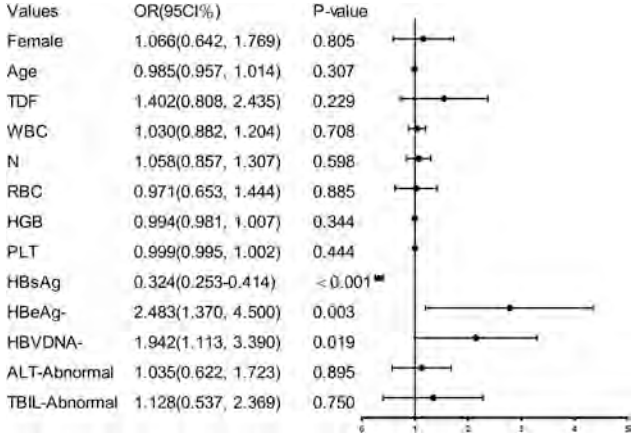
4070 | EFFECT OF BASELINE HBSAG LEVEL AND HBEAG STATUS ON HBSAG SEROCLEARANCE AND TIME TO CLEARANCE FOLLOWING PEG-IFNα THERAPY



Wen Deng[1] Minghui Li[2] Yao Xie[2], [1]Beijing Ditan Hospital, Capital medical university, [2]Department of Hepatology Division 2, Beijing Ditan Hospital, Capital Medical University

Background: To analyze the factors influencing the achievement of HBsAg seroconversion in chronic hepatitis B virus (HBV) infection patients undergoing pegylated interferon α (Peg-IFNα) therapy and compare the differences in seroconversion time between different subgroups. **Methods:** A retrospective study was conducted including 411 chronic HBV infected patients who received Peg-IFNα therapy (≥ 6 months or < 6 months but achieved HBsAg seroconversion) at Beijing Ditan Hospital, Capital Medical University from September 2019 to January 2024. Demographic, treatment, clinical biochemical, blood routine, and HBV serological/virological baseline and follow-up data were collected. Binary logistic regression was used to analyze the factors influencing HBsAg seroconversion, and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

the Log-rank test and Cox regression were employed to compare the seroconversion times between subgroups. **Results:** The median follow-up time was 18.00 months. A total of 74 patients (18.00%) achieved HBsAg seroconversion. The baseline HBeAg-negative rate (78.38% vs. 59.35%) and HBV DNA-negative rate (72.97% vs. 58.16%) in the seroconversion group were significantly higher than in the non-seroconversion group. The baseline HBsAg (median: 1.09 vs. 3.33 log10 IU/ml) and HBV DNA (median: 1.00 vs. 1.00 log10 IU/ml) levels were significantly lower in the seroconversion group ($P < 0.05$). Univariate analysis indicated that lower baseline HBsAg, HBV DNA levels, and negative HBeAg and HBV DNA status were associated with HBsAg seroconversion ($P < 0.05$). Multivariate analysis showed that only lower baseline HBsAg level was an independent predictor of HBsAg seroconversion (OR = 0.306, 95% CI: 0.233–0.402, $P < 0.001$). Among seroconverted patients, those with baseline HBeAg-negative status were more likely to achieve early seroconversion within 48 weeks of treatment compared to those with positive HBeAg status [HR = 2.685 (1.143, 6.307), $P = 0.023$]. **Conclusion:** In chronic HBV patients undergoing Peg-IFNα therapy, lower baseline HBsAg levels are an independent predictor of HBsAg seroconversion, and baseline HBeAg-negative status may suggest an earlier occurrence of HBsAg seroconversion.

4071 | COMMUNITY-BASED SCREENING FOR HBV, HCV AND HDV AMONG THE MONGOLIAN POPULATION LIVING IN FRANCE: PRELIMINARY RESULTS OF THE MONDELTA STUDY

Francois Bailly[1] Francois Villeret[1] Fabien Zoulim[1] Enkhtuul Batbold[2] Birke Bartosch[3] Armand Abergel[4] Paule Letertre-Gibert[5] Frédéric Heluwaert[6] Caroline Jezequel[7] Antonio Saviano[8] Marjorie Viallon[1], [1]Lyon Hepatology Institute, IHU EVEREST; Croix Rousse Hospital; Hospices Civils de Lyon, [2]Lyon Hepatology Institute, IHU EVEREST, [3]Lyon Hepatology Institute, IHU EVEREST, [4]CHU Clermont Ferrand, [5]Service d'hépatogastro-entérologie, CH Alpes-Leman, Contamine-sur-Arve, France, [6]Service d'hépatogastro-entérologie, CH Annecy-Genevois; Epagny; France, [7]Service des Maladies du foie CHU de Rennes, Hôpital Pontchaillou, CHU de Rennes, Rennes; France, [8]Service d'hépatogastro-entérologie, CHU de Strasbourg; Strasbourg; France

Background: In Mongolia, the prevalence of hepatitis B virus (HBV) and hepatitis D virus (HDV) is the highest in the world. In 2018, a study of the Mongolian community living in California found an HBV prevalence of 9.7% with 42% testing positive for HDV. The Mongolian community living in France is estimated to number between 5,000 and 6,000 people. **Methods:** The MonDelta study (NCT: 07038863) is a French national multicenter study focusing on Mongolian population living in France who are 15 years of age or older; it began in September 2025. Community screening days are organized in several cities, featuring Rapid Diagnostic Orientation Test (RDOT) for HBV and HCV. In the event of a positive RDOT, additional serological testing and elastography are performed. For any positive HBV RDOT, a HDV serology is performed. During these screening days, sessions are performed to raise awareness of viral hepatitis and promote the prevention of liver disease. **Results:** 126 patients were screened at four French centers over the course of six screening days. Median age at screening was 47 years (IQR: 37–54), with majority of female (59.5%). Three HBV RDOT were positive (prevalence of 2.4%), all confirmed by a positive HBsAg and quantifiable serum HBV DNA. One HDV serology result was positive with undetectable serum HDV RNA. Among these 3 HBsAg-positive patients, only one was a new case of chronic HBV infection. One patient resumed treatment with Tenofovir (which had been discontinued due to loss to follow-up) and one patient started treatment with Entecavir. Eight HCV RDOT were positive (representing a prevalence of 6.3%): only one patient had quantifiable HCV RNA and antiviral treatment was initiated. Median elasticity was 6.55 kPa (IQR: 4.6–7.6); one case of cirrhosis secondary to HCV was diagnosed. **Conclusion:** These preliminary data confirm a higher prevalence of HBV and HCV in Mongolian population than in the general French population, but lower than the prevalence rates reported in other studies of the Mongolian population. The study is continuing, with several centers set to open in the coming weeks.

4072 | FAMILY-LEVEL CLUSTERING OF HEPATITIS B VIRUS INFECTION AMONG US-BOUND REFUGEES, 2018–2023

Erin Mann[1] Kelly Searle[1] Jose Debes[1], [1]University of Minnesota

Background: Hepatitis B virus (HBV) clusters within households in endemic regions, with infection in children thought to be shaped by maternal or paternal status. Most prior evidence comes from clinic-based studies in unvaccinated populations; family-level HBV epidemiology among US-bound refugees has not been examined. **Methods:** We analyzed HBsAg screening data from refugees undergoing overseas health assessments through the United States Refugee Admissions Program, October 2018–September 2023. Family clusters were defined as fully screened nuclear families (mother, father, and ≥1 child) with ≥2 HBV-positive members. Among children <12 years, generalized estimating equations (GEE) logistic regression estimated adjusted odds ratios (aOR) for child HBV infection by family member HBV status, adjusted for region, sex, age, year, family size, and pre-resettlement vaccine doses. **Results:** Among 19,469 fully screened nuclear families (102,509 individuals), 1,341 (6.9%) had ≥1 HBV-positive member. Of these, 116 (8.7%) had ≥2 HBV-positive members (family clusters). The most common HBV+ cluster types were mother-offspring (41.4%), both parents only (20.7%), and siblings only (18.1%). Clustering was more common in families with an HBV-positive mother (18.0% vs. 4.1%), with the largest contrasts in Asia (24.7% vs. 3.0%) and the Eastern Mediterranean (12.2% vs. 1.5%). Among 34,919 children <12 years in 13,714 nuclear families, 59 children across 40 families tested HBV-positive. Having an HBV-positive mother (aOR 29.55, 95% CI 14.79–59.06) and HBV-positive sibling (aOR 42.37, 95% CI 19.23–93.36) were each strongly and independently associated with child HBV infection; paternal infection was weaker and not significant (aOR 2.29, 95% CI 0.96–5.51). Predicted probability of child infection rose from 0.03% (95% CI 0.01–0.05) when no family member was infected to 22.94% (95% CI 12.64–33.24) with mother and sibling infected and 37.73% (95% CI 17.89–57.58) with mother, father, and sibling all infected. **Conclusion:** HBV clustering in refugee families is driven primarily by maternal infection, with risk to children rising sharply when multiple family members are infected. The strong sibling effect and regional gradient may reflect underlying maternal HBeAg status, a key driver of perinatal transmissibility. These findings can help understand HBV family dynamics for targeted testing and care.

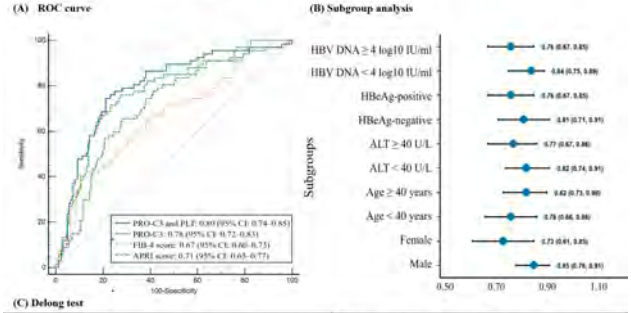
4073 | DEVELOPMENT AND VALIDATION OF A MODEL OF INCORPORATING SERUM N-TERMINAL PROPEPTIDE OF TYPE III COLLAGEN AND PLATELET COUNT TO PREDICT ADVANCED FIBROSIS IN CHRONIC HEPATITIS B

Xue Bai[1] Qianqian Chen[1] Jie Li[1], [1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University



Background: Accurate non-invasive identification of advanced fibrosis (≥S3) is crucial for improving outcomes in chronic hepatitis B (CHB) patients. Serum PRO-C3, a marker of collagen synthesis, has shown promise. This study aimed to develop and validate a novel serum-based model incorporating PRO-C3 and routine clinical parameters for diagnosing CHB-related advanced fibrosis and cirrhosis (≥S3). **Methods:** This retrospective study enrolled 324 treatment-naïve CHB patients who underwent liver biopsy from two centers. Patients from center 1 (n = 227) formed the training cohort, and those from center 2 (n = 97) formed the validation cohort. Baseline clinical characteristics, serum Pro-C3 (ELISA), liver stiffness measurement (LSM), APRI, and FIB-4 were collected. Histological fibrosis staging used the Scheuer system (S0-S4), with ≥S3 defined as advanced fibrosis. Univariate and multivariate logistic regression were performed to identify independent predictors and construct a predictive model. The model's diagnostic performance was evaluated using the area under the receiver operating characteristic curve (AUC), sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), decision curve analysis (DCA), and calibration curves. Its robustness was tested across various patient subgroups. **Results:** In the overall cohort

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(n = 324), 83 patients (25.6%) had ≥ S3 fibrosis. In multivariate analysis, PRO-C3 (OR: 1.04, 95% CI: 1.02-1.05, P < 0.01) and platelet count (PLT) (OR: 0.99, 95% CI: 0.98-1.00, *P* = 0.04) were independent predictors. The derived model was: Logit(P) = −1.190 + 0.038 × (PRO-C3) − 0.007 × (PLT). In the training cohort, this Pro-C3 and PLT model achieved an AUC of 0.80 (95% CI: 0.74-0.85) for diagnosing ≥ S3 fibrosis, with a PPV of 59.5% and NPV of 88.1%. Its performance was superior to FIB-4 (AUC: 0.67, *P* < 0.01) and APRI (AUC: 0.71, P = 0.02), and comparable to Pro-C3 alone (AUC: 0.78, *P* = 0.17). The model was validated in the external cohort with an AUC of 0.84 (95% CI: 0.75-0.91). DCA indicated greater net clinical benefit, and calibration curves showed good agreement between predicted and observed probabilities. The model maintained diagnostic efficacy (AUCs > 0.70) across all tested subgroups, including different genders, ages, ALT levels, HBeAg statuses, and HBV DNA levels. **Conclusion:** The novel serum model combining Pro-C3 and platelet count demonstrates good and robust diagnostic performance for identifying CHB-related advanced fibrosis and cirrhosis (≥ S3), offering a convenient and accurate non-invasive tool for clinical decision-making.

Figure. Diagnostic performance of the combined PRO-C3 and PLT model for advanced liver fibrosis in patients with chronic hepatitis B.

(C) Delong test

Model	Cut-off	Sensitivity	Accuracy	Delong test (*P*)*	Model	Cut-off	Sensitivity	Accuracy	Delong test (*P*)*

4074 | PATIENT AND PHYSICIAN PERSPECTIVES ON UNMET NEEDS IN CHRONIC HEPATITIS B VIRUS (HBV) MANAGEMENT IN CHINA

Lu Zhang[1] Jingyu Tong[2] Xin He[2] Menchi Wu[2] Sune Hao[2] Afisi Ismaila[3] Minghui Li[1], [1]Beijing Ditan Hospital, Capital Medical University, Beijing, China, [2]GSK, Shanghai, China, [3]GSK, Collegeville, PA, USA

Background: Clinical guidelines recommend functional cure (FC), defined as ≥ 24 weeks of sustained HBV DNA < lower limit of quantification and hepatitis B surface antigen (HBsAg) loss after finite therapy, as the optimal treatment (tx) endpoint for chronic hepatitis B virus (HBV) infection. Yet, FC is rarely achieved with current therapies, nucleos(t)ide analogs (NAs) and pegylated interferon (Peg-IFN). This study assessed physicians' and patients' (pts) tx goals, perceptions of FC, unmet clinical needs relating to NAs and Peg-IFN, and expectations for new therapies across China. **Methods:** Pts with chronic HBV infection receiving stable tx and physicians who are experienced in HBV management were enrolled. Eligible physicians were associate chief physicians or above in tertiary hospitals located in Tier 1 or 2 cities. Eligible pts had a self-reported diagnosis of chronic HBV infection for ≥ 1 year and received stable NA therapy for ≥ 1 year. At least half of pts had to have had prior Peg-IFN therapy. A 60-minute, one-to-one interview was conducted with eligible physicians and pts. **Results:** In total, 25 physicians and 20 pts were enrolled. Pt and physician characteristics are shown in the table. All physicians and pts expressed an acceptance of or desire to achieve FC. NAs were reported as the main tx with 17/20 (85%) pts starting on them within 3 months of diagnosis. The median proportion of pts with chronic HBV receiving Peg-IFN treatment, as reported by physicians, was 12.5%. Physicians (n = 25) reported that, among pts using Peg-IFN, the majority (median: 90%) received it in combination with NAs. Physicians cited limited FC (23/25 [92%]), long-term use (22/25 [88%]), and high relapse rates (18/25 [72%]) as the top three unmet needs of NA therapy. Most pts (19/20 [95%]) hoped to discontinue NAs; the most cited reasons included long treatment duration (14/19 [74%]) and side effect concerns (10/19 [53%]). The two most common unmet needs of Peg-IFN identified by physicians were pronounced adverse events (22/24 [92%]) and limited eligible population (21/24 [88%]). For pts achieving HBsAg clearance, most (24/25 [96%]) physicians reported the need for Peg-IFN consolidation therapy. 19/25 (76%) physicians reported that all pts would continue NA therapy after Peg-IFN discontinuation. For future therapies, physicians and pts expressed their expectation regarding treatment with higher HBsAg clearance rate/better efficacy (physicians: 22/22 [100%]; pts: 20/20 [100%]), improved safety/fewer side effects (physicians: 18/22 [82%]; pts: 16/20 [80%]), and shorter tx duration (physicians: 14/22 [64%]; pts: 14/20 [70%]) being the highest priorities. **Conclusion:** FC is recognized as the tx goal for chronic HBV infection in China. Substantial unmet needs remain associated with current chronic HBV tx, NAs and Peg-IFN, and there is a strong demand for innovative FC therapy with higher HBsAg clearance,

4075 | DEVELOPMENT OF A HEPATITIS B SHARED-DECISION MAKING TOOL (BSMART) FOR TREATMENT INITIATION TO SUPPORT NEW AASLD/IDSA HEPATITIS B PRACTICE GUIDELINE

Su Wang[1] Laziza Khodjaeva[2] Ruth Brogden[1] Jaymie Yango[1] Xu-Wuih Chai[3] Maggie Wang[3] Alexandrina Itile[3] Patrick Hilden[1] Mindy Houng[3] Elaine Zhai[3], [1]Cooperman Barnabas Medical Center, [2]Rutgers University, [3]Barnabas Health Medical Group

Background: The AASLD/IDSA Hepatitis B Practice Guidelines, updated November 2025, expands treatment eligibility utilizing a shared decision making (SDM) framework for hepatitis B (HBV) patients in 3 groups–the indeterminate and immune tolerant stages and for prevention of horizontal transmission. In December 2025, the HBV Primary Care Guidance was released, and simplify treatment guideline and include patient preference as one of 4 indicators to treat. Tools are needed to support clinicians to assess patient reported outcome (PRO), and to guide the shared decision making process. **Methods:** We developed the Hepatitis B Shared Management and Action Resource Tool (BSMART) to ascertain the HBV impact on patients, concerns and priorities in their HBV care, and to guide patients and physicians through a shared decision making process. Two surveys were piloted, the B-SMART for patients not on antiviral therapy, and the Hepatitis B On-Treatment Adherence Survey for those on therapy. Descriptive analysis were done examining treated and untreated patients and AASLD HBV phase categories. **Results:** From November 2025 to May 2026, 90 patients were enrolled from an internal medicine clinic in New Jersey, of whom 42 (52.5%) were male and the mean age was 55.2 years (range 27–83). Of the 89 who completed surveys, 37 (41%) were not on antiviral therapy (BSMART group) and 52 (58%) were on treatment. Of the BSMART patients phased per 2025 AASLD/IDSA guidelines, 41% (14) were in the indeterminate phase and 59% (20) were in the inactive phase. There were 1 immune tolerant and 2 active phase patients not included due to small numbers. The vast majority of patients reported little to no impact on their daily life from HBV (95% BSMART vs. 85% on treatment, $p = 0.471$). "Liver cancer/cirrhosis" was the top concern across all groups ($p = 0.776$). "Transmission to family" was the 2nd most reported concern across all groups with those untreasted higher at 73% vs. 52% on-treatment ($p = 0.051$)."Tired or low energy" was reported by 16% BSMART, 15% on-treatment ($p = 1.000$), and "stigma or being treated differently" was reported by 11% BSMART, 13% on-treatment ($p = 0.757$), both equally distributed between groups. Only 4–15% of all groups reported being "not very concerned." **Conclusion:** Despite the vast majority of all patients reporting "feeling fine with no symptoms," fatigue and worry were common for all patients, and most patients had a number of concerns. Concern over transmission was reported more in people not treated than in those treated. This is especially relevant because "prevention of high risk horizontal transmission" is a new treatment indication in the AASLD/IDSA guidelines. The B-SMART survey tool elicited patient reported outcomes and patient preferences and values, and such tools are important to assist in the HBV shared decision making process.

4076 | TRENDS IN DIETARY AND LIFESTYLE PATTERNS IN HEPATITIS B VIRUS AND LIVER-RELATED OUTCOMES: LIMITATIONS OF NHANES 1999–2018

Kimberly Ho[1] Christina Raker[1] Hanna Abuhay[2] Man-Fung Yuen[3] Lung Yi Mak[3] Paige McLean Diaz[4], [1]Brown University, [2]Weill Cornell Medicine, [3]The University of Hong Kong, [4]Brown Medicine/Brown University Health

Background: Chronic hepatitis B virus (CHB) infection affects an estimated 880,000 persons in the United States, with significant variation in demographic representation. This study examined HBV seroprevalence trends, dietary and lifestyle characteristics, and liver-related outcomes using the National Health and Nutrition Examination Survey (NHANES). **Methods:** We analyzed data from 52,028 adults aged ≥18 years with HBV serology using NHANES in two survey periods (1999-2008 and 2009-2018). CHB was defined as HBsAg-positive and recovered HBV as HBsAg-negative. Data were analyzed by logistic or linear regression for complex survey data. **Results:** CHB prevalence was highest among non-US-born adults (1.00% and 1.34%), non-Hispanic Black adults (0.92% and 0.73%), and non-Hispanic Asians (2.56% and 2.20%). Between 1999 and 2018, CHB prevalence did not significantly change, and demographic representation remained stable. Regarding dietary data, CHB carriers consumed significantly less total fat (63 vs 83 g, p = 0.003) and saturated fat (18 vs 28 g, p < 0.001) in 1999-2008 compared to the general population. In 2009-2018, total and saturated fat intake along with total dietary energy, carbohydrates, and protein in CHB carriers all approached levels seen in the general population. Inverse trends for oils and added sugars were observed in CHB carriers in both survey periods. No significant associations were found between alcohol consumption or late-night snacking and CHB in either period. CHB was associated with markedly elevated odds of self-reported current liver conditions compared to no infection in both periods (adjusted OR 19.5 in 1999-2008; OR 7.8 in 2009-2018; interaction p = 0.04). **Conclusion:** Dietary and lifestyle differences observed in CHB in the US more likely reflect the immigrant and ethnic composition of the affected population (predominantly Asian and sub-Saharan African origin) rather than causal dietary effects or HBV-driven behavioral changes. Furthermore, the small sample of CHB in NHANES limited the extent to which robust comparative analyses can be performed to determine how lifestyle factors influence liver-related outcomes in CHB. Thus, while there were decreased odds of current liver conditions in CHB seen over time (adjusted OR 19.5 [1999-2008] vs 7.8 [2009-2018]), this may be secondary to improved disease management, shifts in population composition, or survival bias.

Figure 1. Demographic representation among CHB adults in NHANES (1999-2018).

4077 | CHARACTERISTICS OF PERSONS ON TREATMENT FOR HEPATITIS B WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN THE UNITED STATES, 2014–2025

Ademola Osinubi[1] Yuna Zhong[1] Julian Grass[1] Hasan Symum[1] Eyasu Teshale[1], [1]CDC

Background: Despite advances in hepatitis B virus (HBV) and human immunodeficiency virus (HIV) treatment, coinfection with HBV and HIV remain associated with substantial morbidity and mortality. We described persons on treatment for hepatitis B coinfected with HIV and compared characteristics by HIV infection status using national pharmacy claims data from the United States. **Methods:** Using IQVIA's longitudinal prescription claims data, we identified persons receiving HBV antivirals with a hepatitis B ICD-10-CM diagnosis code during 2014–2025. Among this hepatitis B treated cohort, we defined HIV coinfection as the presence of ≥1 HIV ICD-10-CM diagnosis codes. We calculated chi-square tests to compare the demographic, payer, and prescriber characteristics of persons on HBV treatment with and without HIV coinfection. Statistical significance was defined as $p < .05$. **Results:** Of the 283,834 persons receiving HBV treatment, 9,836 (3.5%) were coinfected with HIV. Among those on HBV treatment with HIV coinfection, the majority were male (79.6%) and aged ≥ 60 years (55.3%); most hepatitis B treatment claims were paid by Medicare (47.2%) and commercial insurers (31.3%). Approximately half of prescribers were specialists; the proportion of persons treated by specialists decreased from 2014 (53.9%) to 2025 (47.1%). During the same period, the proportion of prescriptions written by nurse practitioners increased from 11.5% in 2014 to 20.0% in 2025. The largest proportion (41.9%) of coinfected persons resided in the Southern U.S Census region. Compared to persons on HBV treatment without HIV, persons on HBV treatment with HIV coinfection were more likely to be male (79.6% vs 58.6%), ≥60 years (55.3% vs 49.2%), have hepatitis B treatment paid by Medicare (47.2% vs 31.0%), and reside in the Southern region (41.9% vs 28.5%) ($p < .001$). **Conclusion:** Using a longitudinal prescription claims dataset with national-level coverage we found 3.5% of persons receiving HBV treatment were living with HIV infection. These findings highlight the ongoing health care needs of persons with HBV/HIV coinfection and the importance of targeted public health interventions.

4078 | NATURAL HISTORY OF UNTREATED HBV-RELATED ADVANCED FIBROSIS: REASSESSING HCC RISK IN THE CONTEXT OF THE 2025 EASL GUIDELINES

Seung Up Kim[1] Beom Kyung Kim[1] Cheuk Fung Yip[2] Sang Hoon Ahn[3] Vincent Wong[4], [1]Yonsei University, [2]State Key Laboratory of Digestive Disease, The Chinese University of Hong Kong, Hong Kong, [3]Yonsei University College of Medicine, [4]The Chinese University of Hong Kong

Background: The 2025 EASL HBV guidelines recommend antiviral therapy (AVT) for advanced fibrosis (AdvF) with detectable HBV-DNA, which is regarded to be a routine AVT criterion for liver cirrhosis (LC). This study assessed HCC risk among patients with untreated viremic AdvF to determine whether the observed risk supported earlier initiation of AVT. **Methods:** South Korean patients with untreated viremic AdvF, who did not fulfill conventional AVT criteria (n = 302), and those with AVT-treated Child–Pugh A LC (n = 1694), were enrolled. LC was defined by imaging or liver stiffness (LS) on vibration-controlled transient elastography >11 kPa. AdvF was defined as LS of 8–11 kPa without LC on imaging. Multivariate Cox regression and propensity score matching (PSM; 2:1) were used to compare HCC risk. **Results:** Multivariable analyses revealed that patients with untreated viremic AdvF [A1] exhibited HCC risk comparable with that of

[E2] AVT-treated LC (adjusted hazard ratio [aHR] 0.667 [95% confidence interval (CI) 0.432–1.602]; $p = 0.089$). Male sex and higher Fibrosis-4 index score were independently associated with HCC risk (all $p < 0.05$). In an external validation Hong Kong cohort (n = 302), patients with untreated viremic AdvF exhibited an HCC risk comparable with that of AVT-treated LC (aHR 0.926 [95% CI 0.512–1.678]; $p = 0.797$). Male sex and higher albumin–bilirubin (i.e., "ALBI") score were independently associated with HCC risk (all $p < 0.05$). PSM in both cohorts also confirmed comparable risk for HCC between the groups (all $p > 0.05$). **Conclusion:** Across 2 independent East Asian cohorts, the risk for HCC in those with untreated viremic AdvF was not negligible and at a level that may warrant the reconsideration of conventional AVT thresholds, supporting the rationale of the 2025 EASL HBV guidelines. **Disclosures:** Seung Up Kim:Nothing to Disclose, Beom Kyung Kim:Nothing to Disclose, Cheuk Fung Yip:Nothing to Disclose, Sang Hoon Ahn:Nothing to Disclose, Vincent Wong:Abbott: Speaking and Teaching, AbbVie: Advisor, AbbVie: Speaking and Teaching, Boehringer Ingelheim: Advisor, Echosens: Advisor, Echosens: Speaking and Teaching, Gilead Sciences: Advisor, Gilead Sciences: Speaking and Teaching, Gilead Sciences: Grant/Research Support, Novo Nordisk: Advisor, Pfizer: Advisor, TARGET PharmaSolutions: Advisor, Illuminatio Medical Technology: Stock – privately held company, Eli Lilly: Consultant, Merck: Consultant, Altimmune: Consultant, AstraZeneca: Consultant, Roche Diagnostics: Consultant, Furui: Consultant.

4079 | VIRAL HEPATITIS PREVALENCE AMONG MIGRANTS LIVING IN CATALONIA, SPAIN: RESULTS FROM COMMUNITY-BASED SCREENING ACTIONS

Adriana Palom[1] Jordi Gomez i Prat[2] Ariadna Rando-Segura[3] Helena Ortin i Berga[2] Tahir Rafi[4] Sumaira Malik[4] Alícia Garcia-Circuns[4] Hakima Ouaarab[2] Chia Ning Chung Huang[4] Juan Arenas Ruiz-Tapiador[5] Javier Garcia-Samaniego[6] Maria Buti[1], [1]Liver Unit, Hospital Universitari Vall d'Hebron, CIBERehd, Barcelona, Spain, [2]Department of Infectious Diseases, Hospital Universitari Vall d'Hebron, Barcelona, Spain, [3]Microbiology Department, Hospital Universitari Vall d'Hebron, Barcelona, Spain, [4]Vall d'Hebron Research Institute (VHIR), Public Health and Community Team (eSPiC), Barcelona, Spain, [5]Policlínica Gipuzkoa-Quiron Salud, CIBERehd, San Sebastian, Spain, [6]Liver Unit, Hospital Universitario La Paz, IdiPAZ, Madrid, Spain

Background: WHO hepatitis screening strategies prioritize migrants from highly endemic countries, assuming that prevalences in migrant communities are the same of their countries of origin. We aimed to compare the prevalence of hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis D virus (HDV) among migrants living in Catalonia with published estimates from their countries of origin. **Methods:** We analyzed data from 4 community-based screening programs that were conducted among migrants from Pakistan, Mongolia, Romania and China in Catalonia. Screening activities were performed in community settings to facilitate population access and better approximate the real prevalence in migrant communities. Point-of-care HBV and HCV screening was performed, with confirmatory serological and virological testing when required. Observed prevalences were compared with Polaris Observatory epidemiological estimates from the respective countries of origin. **Results:** A total of 1,813 individuals were screened between April 2022 and April 2026. Among 1,003 participants from Pakistan, the prevalence of HBsAg was 0.8% and anti-HCV was 1.8%, both lower than the estimated prevalences in the country of origin (1.6% and 7.5%, respectively). In the cohort from Mongolia (n = 222), HBsAg prevalence was 3.6%, anti-HCV prevalence was 5.8% (with detectable HCV-RNA in 0.5%), and HDV was present in 0.9%. These values were lower than reported national prevalences, where HBV and HCV exceed 8-11% and HDV remains highly endemic (approximately 60% among HBsAg+). Among 330 participants from Romania, anti-HCV prevalence was 1.5% (with detectable HCV-RNA in 0.3%) and HBsAg prevalence was 1.5%, in comparison with national prevalences of approximately 3-4% for HCV and 3% for HBV. No subjects with HDV were identified. In the cohort from China (n = 258), HBsAg prevalence was 5.8%, anti-HCV prevalence was 0.4%, and no HDV infections were identified. These findings were similar to expected estimates for China (HBsAg 5.6%, anti-HCV 0.91%, anti-HDV 1%). **Conclusion:** Migrants from highly endemic countries living in Catalonia had substantially lower prevalences of HBV, HCV, and HDV than those reported in their countries of origin. Since these estimates come from community-based screening actions, they likely better reflect the true epidemiological burden in migrants living in Catalonia. These findings suggest that migratory flows are not directly comparable to the epidemiological reality of countries of origin, as each migration process is shaped by specific contextual factors that influence health outcomes.

4080 | HEPATITIS DELTA TESTING RATES REMAIN LOW AMONG INDIVIDUALS WITH CHRONIC HEPATITIS B: A US ADMINISTRATIVE CLAIMS ANALYSIS

Alice Stead[1] Amanda Singer[2] Sundaresan Murugesan[1] Laura Telep[1] Kyle Hammond[2] Celine Der-Torossian[1] Craig Meyer[1] David Wyles[1] Robert Gish[3], [1]Gilead Sciences, [2]Gilead Sciences, Inc., [3]Robert G Gish Consultants LLC

Background: Hepatitis delta virus (HDV) infection remains underdiagnosed in the United States (US) due to previously limited diagnostic assays, low clinician awareness, inconsistent guidelines and lack of approved therapies. Prior studies, limited to select populations, show low testing rates in the chronic Hepatitis B virus (CHB) population. This study evaluated HDV testing trends and predictors among individuals with CHB in US administrative claims data. **Methods:** This retrospective study used Optum's de-identified ClinFormatics® Data Mart (2015-2025). CHB was identified by ≥ 1 inpatient or ≥ 2 outpatient international classification of disease (ICD) codes, laboratory evidence (positive hepatitis B DNA or hepatitis B surface antigen [HBsAg]), or CHB treatment with supporting ICD and/or laboratory codes. Individuals were required to have ≥ 365 days of continuous enrollment before the CHB index date and no prior HDV infection. Subgroups included HBsAg-positive individuals and those with HDV risk factors (HIV or hepatitis C co-infection, or history of injection drug use). HDV testing was identified by procedure codes on or after index. The proportion of individuals tested and annual testing rates were estimated; temporal trends were evaluated using a Mann-Kendall (MK) test. Cox proportional hazards models identified predictors of testing, reported as hazard ratios (HRs) and 95% confidence intervals (CIs). **Results:** Among 39,245 individuals with CHB, 1,386 (3.5%) received an HDV test during follow-up. Testing remained low, with 1.0% of individuals with CHB tested in 2025 (rate 1.13 per 100 person-years), compared to 0.6-1.1% annually from 2015 to 2024. The overall proportion tested was modestly higher among those with HBsAg positivity (508/10711, 4.7%) and those with HBsAg positivity plus HDV risk factors (43/732, 5.9%). The proportion tested in these subgroups increased slightly from 2020-2025. The MK test indicated an upward trend in testing among the HBsAg-positive with risk factors group but remained low overall (3.4% tested in 2025). In the full CHB cohort, individuals more likely to be tested were older (age group > 34 years), male sex, Asian, Black, or Other race, located in the Southern or Eastern US, HBsAg positive, treated for CHB, or had hepatic decompensation. Contrary to clinical guidelines, those with hepatitis C infection were less likely to be tested for HDV (aHR: 0.52, 95% CI: 0.39-0.70), and HIV infection and injection drug use were not associated with increased likelihood of testing. **Conclusion:** In this US claims-based study, HDV testing among those with CHB was persistently low over the last decade, even in those with recognized risk factors. These data highlight a large gap between guideline recommendations and clinical practice. The approval of bulevirtide in the US provides a treatment option for individuals with HDV infection, but efforts are needed to address the unmet need of routine testing and linkage to care.

4081 | ALCOHOL USE IMPAIRS VIROLOGICAL AND BIOCHEMICAL RESPONSES IN CHRONIC HEPATITIS B

Yukai Chen[1] Yuemin Nan[2] Jie Li[3] Fajuan Rui[3] Shaoya Li[2] Jiawei Cui[2] Zhandong Lin[2] Yaoyao Mao[2], [1]The Third Hospital of Hebei Medical University, [2]Hebei Medical University Third Hospital, [3]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School

Background: Background:Both chronic hepatitis B (CHB) and alcohol consumption are established risk factors for adverse hepatic outcomes. However, the impact of alcohol use on treatment responses during long-term antiviral therapy in CHB remains unclear. We therefore examined the association between alcohol consumption and virological and biochemical responses in a longitudinal cohort. **Methods:** Methods:In this longitudinal cohort study, patients with CHB were consecutively enrolled from two tertiary centers in China between March 1, 2005 and December 30, 2025. Patients were stratified according to alcohol consumption status (Drink vs. Non-Drink). Endpoints included biochemical response (ALT < 35/25 U/L), HBeAg seroclearance, complete viral suppression (HBV DNA < 20 IU/mL), and a composite endpoint of biochemical and virological response. Cumulative incidences were estimated using the Kaplan–Meier method and compared using the log-rank test. **Results:** Results:During a follow-up of up to 60 months, non-drinkers consistently exhibited higher cumulative incidences of virological and biochemical responses compared with drinkers. For biochemical response (ALT < 35/25 U/L), cumulative rates at 12, 36, and 60 months were 38.65%, 70.01%, and 91.25% in non-drinkers, compared with 29.31%, 62.23%, and 86.27% in drinkers (P = 0.026). Similarly, HBeAg seroclearance rates were 27.65%, 41.70%, and 59.09% in non-drinkers versus 15.96%, 24.05%, and 44.00% in drinkers (P < 0.001). For complete viral suppression (HBV DNA < 20 IU/mL), corresponding rates were 50.09%, 88.76%, and 98.60% in non-drinkers, compared with 33.49%, 69.89%, and 87.84% in drinkers (P < 0.001). Consistently, the composite endpoint of biochemical and virological response was achieved in 8.11%, 21.93%, and 46.98% of non-drinkers, as compared with 3.17%, 8.12%, and 25.24% of drinkers (P < 0.001). Overall, response rates increased over time in both groups, with persistently lower probabilities observed among drinkers throughout follow-up. **Conclusion:** Conclusions:Alcohol consumption is significantly associated with poorer virological and biochemical responses in patients with chronic hepatitis B receiving long-term antiviral therapy. These findings indicate that alcohol use is a clinically relevant and potentially modifiable factor that influences treatment efficacy, underscoring the importance of its systematic assessment and management in the clinical care of CHB patients.

4082 | TEMPORAL CHANGES IN HBSAG LOSS RATES BEFORE AND AFTER COVID-19 VACCINATION: AN INTERRUPTED TIME SERIES ANALYSIS

Jonggi Choi[1] Allion Carroll[2] Vy Nguyen[3] Megan Michta[2] Young Suk Lim[4] Raymond Chung[2], [1]University of Ulsan, Asan Medical Center, [2]Massachusetts General Hospital, [3]Harvard Medical School, [4]Asan Medical Center

Background: Hepatitis B surface antigen (HBsAg) loss, a functional cure in chronic hepatitis (CHB), is rare. We evaluated temporal changes in HBsAg loss rates in relation to the COVID-19 vaccination rollout. **Methods:** We performed an interrupted time series (ITS) analysis using electronic health records from 59,946 adults with CHB at a tertiary referral center in South Korea (2002–2025). Monthly HBsAg loss incidence rates were estimated using a competing risk framework. National COVID-19 vaccination coverage was used as a surrogate measure of population-level exposure. A three-phase segmental regression model was assessed changes in HBsAg loss rates before vaccination, during a predefined vaccination effect period (18 months following ≥80% of two-dose coverage), and after this period. Hepatocellular carcinoma (HCC) incidence was analyzed as a negative control outcome. **Results:** Over 382,509 person-years of follow-up, 2,291 HBsAg loss events occurred. Pre-vaccination HBsAg loss rates were stable. At the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

vaccination rollout (November 2021), HBsAg loss rates increased significantly (incidence rate ratio 1.56; 95% confidence interval 1.26–1.93; p < 0.001), followed by a plateau. A significant decline in slope was observed in the post-vaccination period (p = 0.003), suggesting attenuation over time. Results were consistent across multiple sensitivity analyses and subgroups. In contrast, HCC incidence showed no significant changes across phases. **Conclusion:** The COVID-19 vaccination rollout was temporally associated with a transient increase in HBsAg loss rates in CHB, followed by gradual attenuation. These findings suggest a potential population-level immunomodulatory effect of vaccination on HBV dynamics, warranting further investigation using individual-level data.

4083 | CLINICAL OUTCOMES OF GRAY-ZONE CHRONIC HEPATITIS B COMPARED WITH INACTIVE CHRONIC HEPATITIS B

Yiwei Hang[1] Siqi Zhang[2] David Kaplan[3], [1]Hospital of the University of Pennsylvania, [2]Center for Clinical Epidemiology and Biostatistics, University of Pennsylvania, [3]University of Pennsylvania

Background: Current guidelines recommend treatment of chronic hepatitis B virus (CHB) based on abnormal serum aminotransferase or significant liver fibrosis. However, the decision to initiate antiviral treatment remains less clear in "gray zone" (GZ) patients. The objective of this study was to describe the natural history of GZ patients not receiving antiviral treatment, to determine the rates of clinical flares, subsequent treatment initiation and major adverse liver outcomes (MALO), and to compare their trajectory to that of inactive carriers. **Methods:** This is a single-center retrospective study of mono-infected adults with CHB, defined as having two positive HBsAg six months apart between July 1, 2005 and June 30, 2025, who were not receiving antiviral therapy. Eligible patients were identified through the Center for Data, Outcomes and Team Science (CDOTS) registry (Serper M, et al.). The upper limit of normal (ULN) of ALT was defined as < 35 U/L for men and < 25 U/L for women per AASLD. GZ CHB was defined by ALT ≤ 1x ULN with HBV DNA between 2,000 and 20,000 IU/mL, or ALT 1-2x ULN with HBV DNA < 2,000 IU/mL. Inactive CHB was defined as ALT ≤ 1x ULN and HBV DNA < 2000 IU/mL. The index date was the first date when both HBV DNA and ALT values were available. Outcomes included HBV flare (ALT ≥ 3 times baseline ALT and > 100 U/L), antiviral initiation, cirrhosis, hepatocellular carcinoma (HCC), and death. **Results:** A total of 33 patients were included, of whom 14 met the definition of GZ. Patients in the GZ tended to be younger than inactive carriers. Over a median follow-up of 12.1 years, two GZ patients developed HBV flare and one developed HCC. The GZ patient who ultimately developed HCC manifested ALT flare and elevated HBV DNA six months after the index date prompting treatment initiation, but was then lost to follow-up for 2 years before presenting with multifocal HCC at age 57. Three other GZ patients were started on antivirals for increased HBV DNA, during pregnancy, and for a clinical trial, respectively. The remaining 10 GZ patients required no therapy and developed no clinical events. Overall, the rates of flare, cirrhosis, HCC, and death were similar between GZ and inactive carriers. Kaplan-Meier analysis showed no significant difference in time to antiviral initiation (log-rank p = 0.64). **Conclusion:** Treatment initiation for CHB remains complex, especially for patients who do not fit into the classic disease stages. GZ patients exhibit relatively low rates of progression to HBV flare or clinical outcomes. Most did clinically well in the absence of antiviral therapy during 12.1 years of follow-up or received antiviral therapy when appropriate indications involved. Under standard clinical observation, a conservative approach to treatment initiation among young patients with GZ features may be reasonable.

Table 1: Comparison of clinical characteristics and outcomes between gray zone and inactive chronic hepatitis B

		Inactive CHB	Gray-zone CHB	p-value
N		19	14	
Age (median, [IQR])		45 [31, 57]	33 [29, 47]	0.19
Sex (N, %)				
	Men	8 (42)	4 (28)	
	Women	11 (58)	10 (72)	
Race (N, %)

4084 | ◆ STOPPING NUCLEOSIDE ANALOUGUES IN HBEAG NEGATIVE CHRONIC HEPATITIS B WITH HBSAG < 100 IU/ML LEADS TO HIGH RATES OF HBSAG LOSS BUT RISK OF ALT FLARES: HALT NUC RANDOMISED CONTROL TRIAL

Seng Gee Lim[1] Wei Lyn yang[2] Rajneesh Kumar[3] Jessica Tan[4] Yin Mei Lee[1] Guan Huei Lee[1] Yock Young Dan[1] Daniel Huang[5] How Cheng Low[6] Gladys Tan[6] Htet Htet Toe Wai Khine[1] Amy Tay[1] Tiffany Fortney[7] Mark Anderson[7] Gavin Cloherty[8] Liang Shen[9], [1]National University Health System, [2]Tan Tock Seng Hospital, [3]Singapore General Hospital, [4]Changi General Hosptial, [5]National University Hospital, Singapore, [6]National University Hospital, [7]Abbott Laboratories, [8]Abbott, [9]Singapore Clinical Research Institute

Background: Despite multiple studies and clinical trials there is still controversy with regards to stopping nucleos(t)ide analogue (NA) therapy in HBeAg negative Chronic Hepatitis B(CHB) reflected in differences in guideline recommendations. A meta-analysis with metaregression identified the level of HBsAg, namely HBsAg < 100 IU/ml as an optimal threshold to stop NA therapy but this has not been tested in clinical trials. **Methods:** We conducted an investigator initiated randomised control trial of HBeAg negative CHB patients on NA > 12months with HBsAg < 100 IU/ml randomised to 2:1 stop NA or continue NA stratified by HBsAg < 10 or ≥ 10 IU/ml with the primary endpoint of HBsAg loss 144 weeks after randomisation in a multicentre randomised clinical trial of four tertiary hospitals in Singapore (clinicaltrials.gov NCT0410217). Safety of special interest were ALT flares ≥ 2x upper limit of normal (ULN), 5xULN and 10xULN. Analysis was by intention-to-treat and SPSS was used to analyse the results. **Results:** A total of 120 (HALT 81, continue 39) patients were randomized. The mITT population included 117 (HALT 78, continue 39) patients. One patient withdrew at baseline and two patients whose HBsAg were negative at baseline visit. The primary mITT endpoint of HBsAg loss at 144 weeks was achieved in 24/78 (30.4%) HALT and 3/39 (7.7%) continue (p = 0.005). HBsAg seroconversion was seen in 15/24 (62.5%) and 2/3 (66.6%) patients with HBsAg loss in HALT and continue arms respectively (p = 0.052). Apriori subgroup analysis of HBsAg < 10 IU/ml showed HBsAg loss at 144 weeks in 13/21 (61.9%) HALT versus 3/12 (25%) continue arm (p = 0.071). ALT ≥ 10xULN was seen in 8.7% versus 8.2% of HALT and continue for patients with HBsAg < 10 IU/ml. NA treatment > 10years and prior interferon was associated with higher rates of HBsAg loss (p < 0.05). ALT flares of ≥ 2x ULN, 5xULN and 10xULN were seen in 36.2% vs 7.7%, 22.5% vs 2.6% and 15% vs 2.6% of HALT and continue patients respectively (p < 0.001, p = 0.006, and p = 0.058 respectively). Bilirubin ≥ 1.5xULN occurred in 6.2% of HALT and 2.6% of continue arms (p = 0.662). HBeAg seroreversion occurred in 11.2% of HALT and 2.6% of continue patients (p = 0.163). Hospitalisations due to severe ALT flare occurred in 4.17% of HALT and none in continue patients. One patient in continue arm stopped NA as he ran out of study medication during COVID. HBV RNA at baseline was predictive of ALT flares (AUROC = 0.683, 95% CI 0.516 – 0.851, p = 0.032). At the cut-off value of ≥ 1.70254, the sensitivity, specificity, PPV and NPV of predicting severe ALT flare (ALT > 10xULN) are 100%, 51.1%, 15.4% and 100% respectively. **Conclusion:** While stopping NA in HBeAg negative CHB patients with HBsAg < 100 IU/ml comes with high rates of HBsAg loss, they carry a significant risk of severe ALT flares, HBeAg seroreversion, and hospitalisation.

4085 | EFFICACY AND SAFETY OF SMALL INTERFERING RNA AGENTS FOR CHRONIC HEPATITIS B: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS

Rahul Falodia[1] Ubaid Ahmed[2], [1]All India Institute of Medical Sciences Jodhpur, [2]Dow University of Health Sciences

Background: BackgroundSmall interfering RNA (siRNA) agents represent a promising therapeutic class for chronic hepatitis B virus (HBV) infection designed to silence viral transcripts and achieve a functional cure. However, a comprehensive evaluation of the comparative efficacy and safety of advanced siRNA pipelines remains lacking. **Methods:** MethodsMEDLINE, Embase, Cochrane CENTRAL, and ClinicalTrials.gov were searched through January 2026 for Phase I–III clinical trials evaluating siRNA agents (monotherapy or combination regimens) on background nucleos(t)ide analogue (NA) therapy. Frequentist random-effects network meta-analysis (NMA) and pairwise pooling were applied. The primary endpoint was the proportion of patients achieving hepatitis B surface antigen (HBsAg) levels < 100 IU/mL at the end of treatment (EOT). **Results:** ResultsEight clinical trials enrolling a total of 1,012 participants evaluating three distinct siRNA agents JNJ-73763989 (JNJ-3989), xalnesiran, or elebsiran were identified. In the NA-controlled NMA (5 studies, 7 nodes, I^2 = 0%), all active siRNA combinations demonstrated significant superiority over NA alone for achieving HBsAg < 100 IU/mL except elebsiran monotherapy (OR 2.39, p = 0.399). The highest odds of response were seen with JNJ-3989+NA (OR 140.68, 95% CI 31.53–627.67, p < 0.0001, NNT = 2) and JNJ-3989+capsid assembly modulator (CAM) +NA (OR 62.17, 95% CI 14.63–264.28, p < 0.0001, NNT = 2), followed by xalnesiran+pegylated interferon (pegIFN)+NA (OR 15.25, 95% CI 4.76-48.82) and xalnesiran+TLR7+NA (OR 14.83, 95% CI 4.83–45.54).For continuous continuous HBsAg change, siRNA regimens led to a significantly greater reduction vs. controls (weighted mean difference [WMD] −1.78 $\log_{10}$ IU/mL, 95% CI −1.89 to −1.66, I^2 = 24%). Single-arm synthesis of all 13 active arms yielded an overall response rate of 70.43% (95% CI 62.88–77.01%), peaking with pegIFN co-administration at 82.44%. Risks for Grade 3/4 adverse events (RR 1.30, 95% CI 0.49–3.44) and serious adverse events (RR 0.84, 95% CI 0.31–2.31) were comparable to controls, while ALT elevations were numerically higher (RR 3.11, 95% CI 0.62–15.56), heavily driven by pegIFN co-administration. **Conclusion:** Conclusion-siRNA agents induce profound, clinically meaningful reductions in surface antigen titers. Regimens incorporating JNJ-3989 demonstrate the highest relative probability of short-term response. Co-administration with pegIFN maximizes absolute surface antigen suppression but warrants close monitoring for immunomodulatory ALT flares.

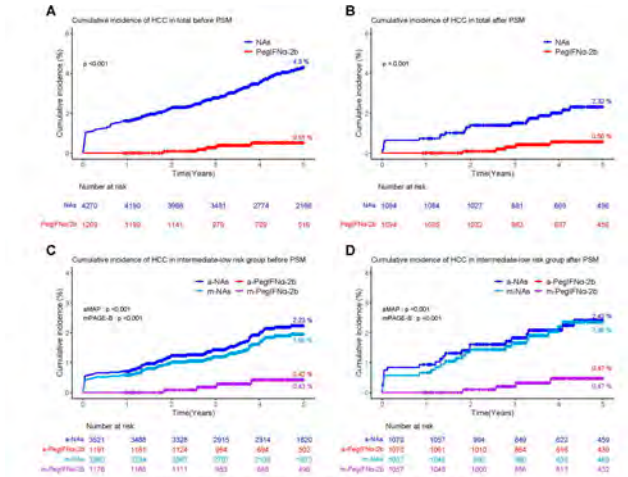
4086 | HEPATOCELLULAR CARCINOMA RISK AND ITS PREDICTORS IN CHRONIC HEPATITIS B PATIENTS RECEIVING DIFFERENT ANTIVIRAL STRATEGIES: EVIDENCE FROM MULTIPLE LARGE-SCALE REAL-WORLD DATABASES



Xiulan Xue[1] Zheming Zhu[2] Yahua Lin[3] Anni Guo[3] Jiaxin Hong[3] Yalin Yin[3] Ruoyi He[3] Jianyong Zeng[1], [1]The Graduate School of Fujian Medical University, Fuzhou, 350122, China, [2]Xiamen Health and Medical

Big Data Center, Xiamen, 361008, China, [3]Xiamen Amoytop Biotech Co. Ltd, Xiamen, 361028, China

Background: Hepatitis B virus (HBV) infection constitutes a leading etiology of hepatocellular carcinoma (HCC), contributing to over 50% of incident cases worldwide and up to 70% in China. While antiviral treatment substantially lowers HCC risk in chronic hepatitis B (CHB) patients, prior research indicates that peginterferon alpha (PegIFNα)-based therapy yields an additional 80%-90% risk reduction over nucleos(t)ide analogues (NAs) monotherapy. This study aimed to evaluate the real-world HCC risk and predictors in CHB patients receiving different antiviral strategies, leveraging a large-scale real-world database. **Methods:** This study utilized data from the databases of Xiamen Health and Medical Big Data Center (2016-2025) and People's Insurance Company of China (PICC; 2020-2025). The cohort enrolled 1,209 CHB patients completing ≥48 weeks of PegIFNα-2b (Pegbing®) therapy and 4,270 treated with NAs monotherapy. Median follow-up durations were 236 weeks and 269 weeks, respectively. Propensity score matching (PSM) was applied to minimize baseline differences, and multivariate Logistic regression analysis was used to identify the risk factors for HCC. **Results:** 165 patients developed HCC during follow-up. The cumulative HCC incidence at 5 years was significantly lower in the PegIFNα-2b group than NAs group (0.51% vs. 4.3%, HR = 0.11, P < 0.001; fig. A). Similar results were obtained in the PSM cohort (0.56% vs. 2.32%, HR = 0.23, P = 0.001; fig. B).Patients were stratified by HCC risk utilizing the aMAP and mPAGE-B scores. Subgroup analysis demonstrated that PegIFNα-2b significantly reduced the incidence of HCC, even among patients at intermediate to low risk. Before PSM, the cumulative HCC incidence at 5 years was significantly lower in PegIFNα-2b group defined by aMAP (0.42% vs. 2.23%, HR = 0.18, P < 0.001) and mPAGE-B (0.43% vs. 1.95%, HR = 0.21, P < 0.001; fig. C). These findings were replicated in the PSM cohort (aMAP: 0.47% vs. 2.42%, HR = 0.17, P < 0.001; mPAGE-B: 0.47% vs. 2.36%, HR = 0.18, P < 0.001; fig. D).Multivariate analysis showed that NAs therapy (vs. PegIFNα-2b therapy, HR = 7.33, P < 0.001), male gender (HR = 2.18, P < 0.001), age ≥ 50 years (HR = 2.53, P < 0.001), HBV DNA positive (HR = 2.10, P = 0.014), high HBsAg levels (HR = 1.47, P < 0.001), high ALT levels (HR = 1.00, P = 0.010), FIB-4 ≥ 3.25 (HR = 1.02, P = 0.031), high albumin levels (HR = 1.04, P = 0.002), cirrhosis (HR = 1.73, P = 0.004), and family history of HCC (HR = 2.33, P < 0.001) were independently associated with an increased risk of HCC. **Conclusion:** This analysis from Large-scale real-world databases demonstrate that PegIFNα-based therapy is associated with an approximate 80% reduction in HCC development compared to NAs monotherapy, even among patients at intermediate to low risk. In addition, sex, age, HBV DNA status, HBsAg, ALT, albumin levels, FIB-4 scores, cirrhosis, and family history of HCC were also associated with HCC development.

The cumulative HCC incidence between the PegIFNα and NAs group
(A, B) The Kaplan-Meier (KM) curves for the entire cohort before (A) and after (B) PSM.
(C, D) The KM curves for intermediate to low HCC risk patients stratified by aMAP/mPAGE-B scores before (C) and after (D) PSM.

4087 | CLINICAL IMPACT OF ANTIVIRAL THERAPY ON REDUCING HCC AND CIRRHOSIS RISKS IN THE INDETERMINATE PHASE OF CHRONIC HEPATITIS B

Hanah Lee[1] Sang Gyune Kim[2] Soo Young Park[3] Young Youn Cho[1] Hyung Joon Kim[1] Yeon Seok Seo[4] Sung Hwan Yoo[5] Seung Up Kim[6] Dae Won Jun[7], [1]Chung-Ang University College of Medicine, Seoul, Korea, [2]Soonchunhyang University Bucheon Hospital, Seoul, Korea, [3]Kyungpook National University Hospital, School of Medicine, Kyungpook National University, [4]Korea University, College of Medicine, Seoul, Korea, [5]Gangnam Severance Hospital, Yonsei University College of Medicine, Seoul, [6]Yonsei University College of Medicine, Seoul, Korea, [7]Hanyang University College of Medicine, Seoul, Korea

Background: Many patients in the indeterminate phase chronic hepatitis B (CHB) remain untreated due to rigid criteria. We aimed to evaluate whether untreated indeterminate patients have higher risks of hepatocellular carcinoma (HCC) and liver cirrhosis (LC) compared to treated active phase patients, and to evaluate the clinical benefits of antiviral therapy (AVT) in indeterminate phase

subgroups. **Methods:** A total of 15,684 patients with HBV were analyzed from the VLINK HBV cohort, a multi-center database including data from seven tertiary-level hospitals. Patients with indeterminate phase was sub-stratified: Low-ALT (ALT U/L), moderate-level viremia (ALT 40–80 IU/L, DNA 2,000–8log), and low-level viremia (DNA2,000, ALT > 40 IU/L) groups. We calculated incidence rates (IR) per 100 person-years (PY) and adjusted hazard ratios (aHR) using Cox proportional hazards models. **Results:** In the HBeAg-positive group, untreated indeterminate patients showed a higher HCC IR (**0.938**) and LC IR (**1.84**) compared to treated active patients, who had an IR of **0** for both outcomes (**aHR = 1.85**, 95% CI 1.24–2.76 for HCC; **aHR = 2.12**, 95% CI 1.45–3.10 for LC). Similarly, untreated HBeAg-negative indeterminate patients had a higher HCC IR (**0.532**) than treated active patients (IR = **0.218**), representing a significantly elevated risk (**aHR = 1.42**, 95% CI 1.08–1.87). Within the indeterminate phase, AVT significantly reduced the LC IR from **2.888** to **1.521** (**aHR = 0.52**, 95% CI 0.38–0.71) and the HCC IR from **1.114** to **0.899** (**aHR = 0.68**, 95% CI 0.45–0.92) in moderate-level viremia group. Furthermore, in the low-level viremia **group,** the AVT-treated group showed a significantly lower HCC IR (**0.656**) compared to the untreated group (**0.947**; **aHR = 0.58**, 95% CI 0.35–0.96). **Conclusion:** Untreated indeterminate phase patients have higher risk of HCC and LC development than patients receiving AVT in the active phase. A more proactive antiviral strategy for indeterminate phase patients is essential to overcome the current treatment gap.

4088 | RETREATMENT WITH SHORT-COURSE PEGINTERFERON ALPHA-2B LEADS TO HIGH HBSAG LOSS IN INTERFERON-EXPERIENCED CHRONIC HEPATITIS B PATIENTS WITH FAVORABLE INITIAL RESPONSE

Haiguang Xin[1] Xiaoyu Hu[2] Hong Tang[3] Chengrun Xu[4] Hongliang He[5] Li Zhu[6] Chuanwu Zhu[7] Feng Liu[8] Yufeng Gao[9] Jia Shang[10] Qingfa Ruan[11] Liang Chen[12] Xuehua Sun[13] Jing Feng[14] Liguan Liu[15] Haidong Zhao[16] Xiangyong Li[17] Lei Wang[18] Yumin Xu[1] Shaowen Jiang[1] Qing Guo[19] Qing Xie[1], [1]Ruijin Hospital, Shanghai Jiaotong University School of Medicine, [2]Disease at Hospital of Chengdu University of TCM, [3]West China Hospital of Sichuan University, [4]The 909th Hospital of the PLA Joint Logistic Support Force, [5]The First Affiliated Hospital of USTC (Anhui Provincial Hospital), [6]Public Hearth Clinical Center of Chengdu, [7]The Affiliated Infectious Diseases Hospital of Soochow University, [8]Tianjin Second People's Hospital, [9]The First Affiliated Hospital of Anhui Medical University, [10]Henan Provincial People's Hospital, [11]Xiamen Hospital of T.C,M., [12]Shanghai Public Health Clinical Center, [13]Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, [14]Weifang People's Hospital, [15]The 910th Hospital of the People's Liberation Army Joint Logistics Support Force, [16]Xiamen Chang Gung Hospital, [17]The Third Affiliated Hospital of Sun Yat-sen University, [18]The Second Qilu Hospital of Shandong University, [19]Ruijin Hospital,Shanghai Jiaotong University School of Medicine

Background: Data on retreatment for chronic hepatitis B (CHB) are limited. We aimed to evaluate the efficacy of peginterferon alpha-2b (PegIFNα-2b) retreatment in interferon-experienced CHB patients with favorable initial response. **Methods:** This prospective, real-world study (NCT06323681) recruited participants who had previously received interferon therapy (discontinued ≥ 3 months) and demonstrated a post-treatment HBsAg decline of ≥ 80%, had HBsAg ≤ 500 IU/mL at the current screening and experienced an HBsAg rebound of ≤ 50% of the initial treatment baseline. Patients were assigned to receive either PegIFNα-2b (Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) with or without nucleos(t)ide analogues (NAs) (Group A), or NAs alone (Group B). Following a 48-week treatment course, the primary endpoint was HBsAg loss rate at week 48. The efficacy of the subgroup of patients who experienced relapses after achieving HBsAg loss with initial interferon therapy was also analyzed. **Results:** A total of 1,000 and 325 patients were included in groups A and B, respectively. Prior to the initial interferon therapy, the mean HBsAg levels were 2600.6 IU/mL in Group A and 1304.2 IU/mL in Group B. By the end of the first round of treatment, these levels had declined to 69.3 and 128.6 IU/mL, representing average reductions of 95.0% and 91.3%, respectively. At the start of the current study, the mean HBsAg levels were 64.3 IU/mL in Group A and 110.1 IU/mL in Group B. Among population with available data, the HBsAg loss rate in Group A increased from 30.5% at week 24 to 42.0% at week 48, whereas that in Group B changed from 3.9% to 5.8%, with Group A being significantly higher (all p values < 0.001). Similarly, among the total population reaching each timepoint, Group A maintained significantly higher HBsAg loss rates than Group B, at 27.4% vs. 1.5% at week 24 ($p < 0.001$) and 38.2% vs. 2.4% at week 48 ($p < 0.001$) (Fig. 1). Within Group A, 79 patients experienced HBsAg relapse after achieving HBsAg loss with initial interferon therapy. Of these, 96.2% had an HBsAg level < 100 IU/mL at the start of current treatment, with a median level of 0.36

(0.16–1.78) IU/mL. Following 48 weeks of PegIFNα-2b retreatment, the HBsAg loss rates in this relapsed subgroup were 73.5% in the data-available population and 68.5% in the total population reaching the treatment point. Among the 334 patients in Group A who obtained HBsAg loss, the mean duration of PegIFNα-2b retreatment to achieve HBsAg loss was 21.13 ± 9.77 weeks. **Conclusion:** Interferon-experienced CHB patients with good initial HBsAg responses achieved high HBsAg loss rates after PegIFNα-2b retreatment. For patients who relapsed after achieving HBsAg loss with initial treatment, the HBsAg loss rate reached approximately 70%. The PegIFNα-2b retreatment course to achieve HBsAg loss was short. Consequently, these patients are suggested with PegIFNα-2b retreatment to achieve functional cure as early as possible.

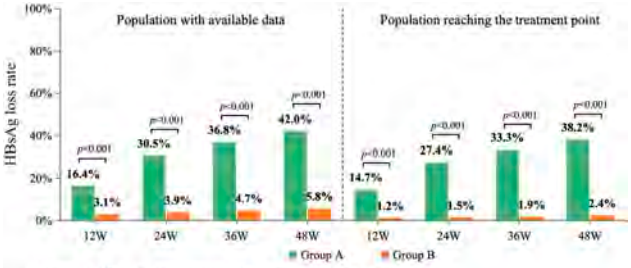

Figure 1. HBsAg loss rates of different groups among all patients.

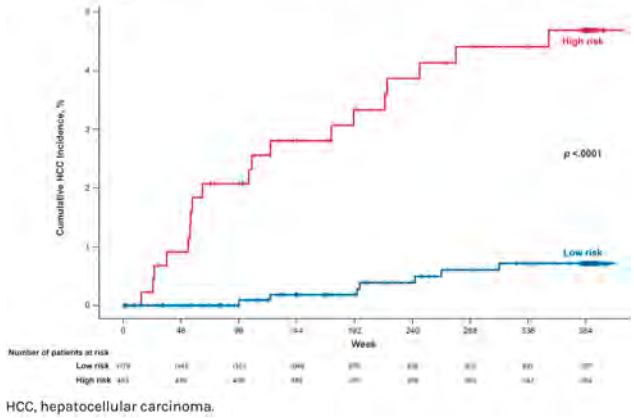
4089 | COMBINING PAGE-B SCORE WITH FIBROTEST IMPROVES HCC RISK STRATIFICATION IN PATIENTS TREATED WITH TENOFOVIR-BASED TREATMENT

Milan Sonneveld[1] Grace Wong[2] Wai-Kay Seto[3] Kosh Agarwal[4] Jinlin Hou[5] Ming-Lung Yu[6] Hiroshi Yatsuhashi[7] Frida Abramov[8] Hongyuan Wang[8] Leland Yee[8] Maria Buti[9] Young Suk Lim[10] Harry Janssen[11], [1]Erasmus University Medical Center, Rotterdam, the Netherlands, [2]The Chinese University of Hong Kong, Shatin, Hong Kong, [3]The University of Hong Kong, Pok Fu Lam, Hong Kong, [4]King's College Hospital NHS Foundation Trust, London, UK, [5]Nanfang Hospital, Southern Medical University, Guangzhou, China, [6]Kaohsiung Medical University Hospital; Kaohsiung Medical University, Kaohsiung, Taiwan, [7]National Hospital Organization Nagasaki Medical Center, Nagasaki, Japan, [8]Gilead Sciences, Inc., Foster City, CA, USA, [9]Hospital Universitario Vall d'Hebron, Barcelona; CIBEREHD del Instituto Carlos III, Madrid, Spain, [10]Asan Medical Centre, University of Ulsan College of Medicine, Seoul, South Korea, [11]Erasmus University Medical Center, Rotterdam, the Netherlands; University Health Network, ON, Canada



Background: Nucleos(t)ide analogue (NA) therapy reduces but does not eliminate the risk of hepatocellular carcinoma (HCC) in patients with chronic hepatitis B (CHB). The PAGE-B score is widely used to stratify HCC risk, but it identifies only a limited proportion of patients at low risk of developing HCC during long-term NA therapy. We aimed to evaluate whether FibroTest values can be used to optimize HCC risk stratification. **Methods:** In 2 similarly designed studies (GS-US-320-0108 and -0110), hepatitis B e antigen (HBeAg)-negative and -positive patients with CHB with hepatitis B virus DNA ≥20,000 IU/mL and alanine aminotransferase >60 U/L (males) or >38 U/L (females) were randomized (2:1) to tenofovir alafenamide (TAF) 25 mg or tenofovir disoproxil fumarate 300 mg given once daily in a double-blind phase for up to 3 years, followed by open-label TAF through year 8 (Y8). The PAGE-B score was calculated for all patients with available data; patients were assigned to low (≤9), intermediate (10–17 points), and high (≥18 points) risk groups based on previously reported cutoffs. Patients also underwent FibroTest (BioPredictive, Paris, France) assessment and were classified as having no to mild fibrosis (≤0.48), moderate to severe fibrosis (0.49–0.74), or cirrhosis (≥0.75) based on previously reported cutoffs. The Kaplan–Meier method was used to estimate cumulative HCC incidence at Y8. **Results:** Of the 1632 patients included, 1354 (83%) were Asian, 1063 (65%) were male, and 1039 (64%) were HBeAg positive, with a median (Q1, Q3) baseline age of 39 (31, 49) years. Through up to 8 years of treatment, 26 (1.6%) patients developed HCC. At baseline, PAGE-B scores (assessed in 1631 patients) were low, intermediate, and high in 642 (39%), 830 (51%), and 159 (10%) patients, respectively. Among patients with a low PAGE-B score, 4 (0.6%) developed HCC through Y8 (negative predictive value [NPV] for HCC at Y8 = 99.4%).At baseline, FibroTest values (available for 1594 patients) were ≤0.48, 0.49–0.74, and ≥0.75 in 1103 (69%), 336 (21%), and 155 (10%) patients, respectively. Among patients with FibroTest values ≤0.48, 6 (0.5%) developed HCC (NPV for HCC at Y8 = 99.5%). A combined strategy defining low risk as

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

either a PAGE-B score ≤9 and/or a FibroTest value ≤0.48 expanded the low-risk population to 72% while maintaining a very high NPV for HCC at Y8 (NPV = 99.4%). The cumulative incidence of HCC development differed between low- and high-risk groups for the combined strategy (0.7% vs 4.7% at Y8; 0.87 vs 6.23 per 1000 person-years; $p < .0001$; **Figure**). **Conclusion:** A FibroTest value ≤0.48 is associated with a low risk of HCC in patients treated with tenofovir-based therapy. Combining PAGE-B with FibroTest better identified a low-risk population, as reflected by the increased proportion of patients classified as low risk (72%) vs with PAGE-B alone (39%), while maintaining a high NPV for HCC risk. These findings support refined HCC risk stratification in treated CHB populations.

Figure. Cumulative Incidence of HCC Development Over 8 Years (Combined PAGE-B and FibroTest Strategy)

HCC, hepatocellular carcinoma.

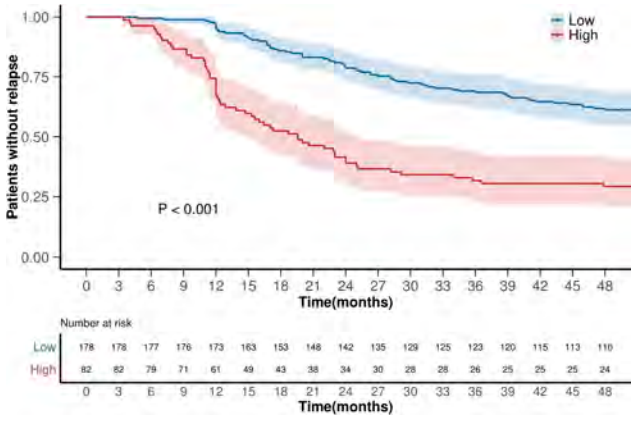
4090 | 48-WEEK HBSAG SEROCLEARANCE AND PREDICTORS IN CHB PATIENTS WITH HBSAG <100 IU/ML RECEIVING PEGIFNα THERAPY



Yiwen Zhang[1] Qin Du[2] Jingzhe Zhang[1] Jiayin Wang[3] Jun Li[1] Yuchen Bao[4] Qing Ye[3] Huiling Xiang[3], [1]The Third Central Clinical College of Tianjin Medical University, [2]Nankai University Affinity the Third Central Hospital, [3]Central Hospital, Tianjin University /Tianjin Third Central Hospital, [4]Tianjin University,Tianjin University Central Hospital (Tianjin Third Central Hospital)

Background: HBsAg seroclearance is the optimal endpoint for functional cure in chronic hepatitis B (CHB). Although patients with HBsAg <100 IU/mL are considered favorable candidates for cure, spontaneous clearance remains rare and risks of hepatitis flare, cirrhosis, and hepatocellular carcinoma persist. Pegylated interferon alpha (PegIFNα) can improve functional cure rates, but data regarding its efficacy and predictive markers in this population remain limited. This study aimed to evaluate the efficacy of PegIFNα therapy and the predictive value of the ALT/HBsAg ratio

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

for 48-week HBsAg seroclearance in CHB patients with HBsAg < 100 IU/mL. **Methods:** This retrospective study enrolled 277 CHB patients with baseline HBsAg < 100 IU/mL who received pegylated interferon alpha-2b (PEG-IFN α-2b), alone or combined with nucleos(t)ide analogues (NAs), at Tianjin Third Central Hospital between October 2018 and January 2026. The primary endpoint was HBsAg seroclearance within 48 weeks. Cox proportional hazards regression was used to evaluate the association between log10(ALT/HBsAg) and HBsAg seroclearance. Multivariable models adjusted for potential confounders. Subgroup analyses assessed result robustness. Receiver operating characteristic analysis identified the optimal cutoff value, and Kaplan–Meier analysis compared cumulative HBsAg seroclearance rates between groups. **Results:** The cumulative 48-week HBsAg seroclearance and seroconversion rates were 49.8% and 36.1%, respectively. Compared with the non-seroclearance group, patients achieving HBsAg seroclearance were younger, had lower baseline HBsAg levels,lower prevalence of family history of hepatitis B, milder fibrosis, and higher log10(ALT/HBsAg) levels.In univariable Cox analysis, each one-unit increase in log10(ALT/HBsAg) was associated with a 77% higher likelihood of HBsAg seroclearance (HR = 1.77, 95% CI:1.48~2.13 , P < 0.001). After multivariable adjustment, log10(ALT/HBsAg) remained an independent predictor of HBsAg seroclearance (HR = 1.51, 95% CI: 1.19~1.92, P < 0.001). Kaplan–Meier analysis showed significantly different cumulative HBsAg seroclearance rates among log10(ALT/HBsAg) subgroups (log-rank P < 0.001). **Conclusion:** CHB patients with HBsAg < 100 IU/mL achieved favorable 48-week HBsAg seroclearance and seroconversion rates following PegIFNα therapy, supporting the benefit of active antiviral intervention in this population. The ALT/HBsAg ratio was independently associated with HBsAg seroclearance and may help identify patients most likely to achieve functional cure with PegIFNα therapy.

4091 | FIVE-YEAR DURABILITY OF FUNCTIONAL CURE FOLLOWING PEGINTERFERON ALPHA-2B THERAPY IN CHRONIC HEPATITIS B: A SINGLE-CENTER ANALYSIS FROM REAL-WORLD STUDIES

Shiji Xu[1] Weiqiang Gan[1] Na Gao[1] Zhishuo Mo[1] BingLiang Lin[1] Zhiliang Gao[1], [1]The Third Affiliated Hospital of Sun Yat-sen University

Background: Functional cure of chronic hepatitis B (CHB) is the optimal endpoint for significantly reducing hepatocellular carcinoma (HCC) risk. Our real-world Everest Project demonstrated substantial success in achieving functional cure using peginterferon alpha (PegIFNα). However, data on long-term off-treatment durability in large cohorts remain scarce. Furthermore, while emerging novel therapeutics (e.g., ASO) exhibit potent on-treatment viral suppression, their off-treatment durability remains largely suboptimal. Thus, we evaluated the up to 5-year durability, relapse patterns, and clinical outcomes in a large cohort of PegIFNα-treated patients who achieved functional cure. **Methods:** This single-center observational study included CHB patients who achieved functional cure following PegIFNα-2b (Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) therapy. The cohort comprised patients from the Third Affiliated Hospital of Sun Yat-sen University, originally enrolled in multicenter projects (Everest [NCT04035837], E-cure [NCT05182463], STARHB [ChiCTR2200061541]). Patients were monitored for functional cure sustainability and HCC incidence. HBV markers (HBsAg, HBV DNA) were dynamically recorded upon relapse. **Results:** A total of 829 patients achieving functional cure were included. During the study, 509, 365, 235, 154, and 74 patients completed 1-, 2-, 3-, 4-, and 5-year follow-ups, respectively. Maintenance rates remained highly stable: 97.1% (494/509), 93.7% (342/365), 92.8% (218/235), 92.2% (142/154), and 93.2% (69/74) at years 1 through 5 (Figure 1). During the follow-up, 32 patients experienced relapse, comprising isolated HBsAg relapse in 17 (53.1%), isolated HBV DNA relapse in 2 (6.3%), and concurrent relapse in 13 (40.6%) patients. Viral levels at relapse were extremely low: median HBsAg was 0.34 (0.09–6.25) IU/mL, and HBV DNA was 38.0 (30.0–62.5) IU/mL. Only one patient developed HCC during the up to 5-year follow-up. **Conclusion:** The 5-year maintenance rate of PegIFNα-2b-induced functional cure in CHB patients exceeds 90%, demonstrating robust off-treatment durability that offers a distinct

advantage over the high relapse rates of current emerging therapies. Relapses are rare and characterized by marginal virological rebounds. The low HCC incidence in this large cohort substantiates the long-term clinical benefits of PegIFNα-driven functional cure.

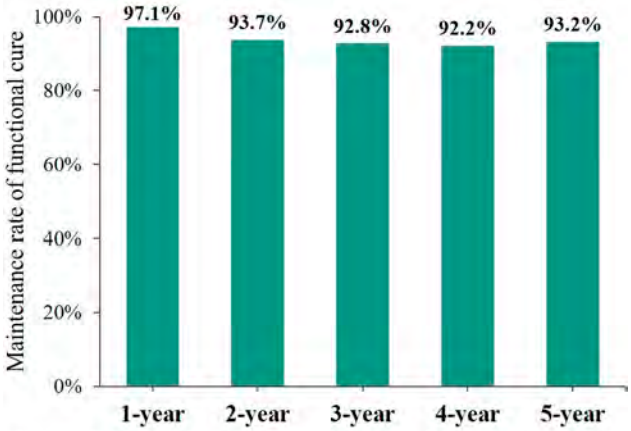

Figure 1. Up to 5 years maintenance rate of functional cure.

4093 | MODELING HDV RNA, HBSAG AND ALT KINETICS IN PATIENTS TREATED WITH BULEVIRTIDE AND PEGYLATED INTERFERON-ALPHA FOR 96 WEEKS IN THE SEE-D TRIAL

Adquate Mhlanga[1] Emmanuel Zavalis[2] Scott Cotler[1] Karin Lindahl[2] Susanne Cederberg[2] Annika Olsson[2] Niklas Bjorkstrom[2] Pietro Lampertico[3] Heiner Wedemeyer[4] Harel Dahari[1] Soo Aleman[2], [1]Loyola University Chicago, [2]Karolinska University Hospital, [3]University of Milan, [4]Hannover Medical School

Background: Bulevirtide (BLV) was recently approved by the FDA. In the MYR 204 trial, 48 week combination therapy with BLV and pegylated Interferon-alpha (peg-IFN) showed higher rates of on-treatment undetectable HDV RNA compared to either drug as monotherapy. SEE-D investigates the effect of 96 weeks combination therapy. We aim to explain HDV-host dynamics during BLV and peg-IFN therapy using mathematical modeling. **Methods:** 31 patients with chronic hepatitis D were enrolled at Karolinska University Hospital, Sweden (EU no. 2023-504414-29-00). They received 96-weeks of combination treatment with BLV (2 mg/day) and peg-IFN. One early dropout and one participant without quantifiable HDV RNA values were excluded. We used our recent mathematical model (http://dx.doi.org/10.2139/ssrn.6809660) accounting for both blocking of viral production (peg-IFN efficacy, ε) and blocking of infection (BLV efficacy; η), with total efficacy of ε_{tot}. Due to parameter identifiability issues, BLV efficacy was fixed at 80% as recently estimated under BLV monotherapy (http://dx.doi.org/10.2139/ssrn.6809660). The critical drug efficacy (CDE) was estimated, such that for ε_{tot} > CDE, HDV is ultimately cleared (i.e., cure), while ε_{tot} < CDE results in a new lower viral plateau or viral breakthrough. **Results:** The 29 participants initially showed a rapid first-phase HDV RNA decline (-0.91 $\log_{10}$ IU/mL/month), followed by undetectability (n = 26; Fig.1A), or a plateau close to LLoQ (n = 3; Fig. 1B) followed by viral breakthrough (VB, Fig.1C). The model reproduced the observed HDV kinetics and estimated ε_{tot} of 96% (95% CI 95 – 98), which exceeded CDE in 90% of the participants (Fig. 1A) but was below the CDE in the three participants who reached a lower plateau (Fig 1B), and a VB (Fig. 1C). Modeling explained VB by an increase of HDV-free hepatocytes. ALT normalization (Fig. 1) was explained by a decline in HDV-infected cells. HBsAg kinetics were explained by a constant number of HBsAg-producing hepatocytes during treatment (Fig. 1), except for in 3 participants who exhibited a >1 log HBsAg decline from baseline, which may reflect loss of HBsAg-producing cells and/or interferon-mediated inhibition of HBsAg production. **Conclusion:** The high rates of undetectable HDV RNA, with the finding that most patients who achieved TND had total efficacy exceeding the critical drug efficacy threshold, suggest that prolonged combination therapy substantially improves antiviral activity and increases the likelihood of sustained viral suppression.

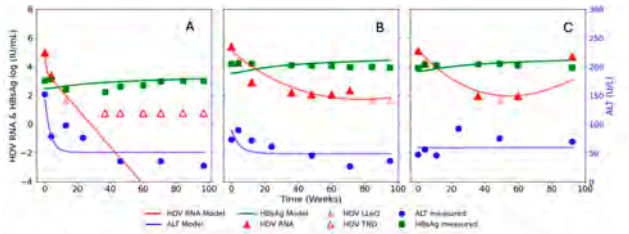

Figure 1. Measured kinetics (symbols) and modeling best curve fits (lines) in representative responder patients with a rapid sustained HDV RNA clearance (**A**), decline that becomes flat-partial at LLoQ (**B**), viral breakthrough (**C**). Estimated peg-IFN efficacy in blocking production in A, B and C was ε= 96%,ε= 57%, and ε = 5%, with BLV efficacy in blocking infection fixed at η=80% for all patients, corresponding to total ε_{tot} of 99%, 91%, and 81%, respectively. HDV RNA was measured using Robogene 2.0 (lower limit of detection, LLD = 6 IU/mL).

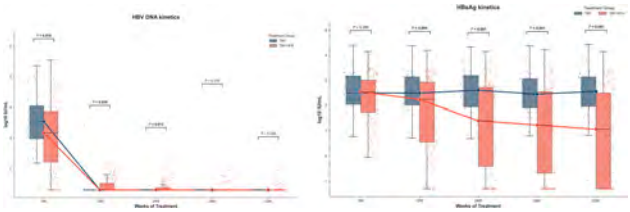
4094 | PEGYLATED INTERFERON α PLUS TENOFOVIR ALAFENAMIDE ACHIEVED A HIGHER HBSAG SEROCLEARANCE RATE THAN TENOFOVIR ALAFENAMIDE MONOTHERAPY IN TREATMENT-NAÏVE INDETERMINATE-PHASE CHRONIC HEPATITIS B PATIENTS WITH NEGATIVE HBEAG (FORESIGHT PROJECT)



Mengya Liu[1] Huan Liu[1] Jiayi Wang[1] Juan Liao[1] Min He[1] Libo Yan[1] Lingyao Du[1] Lang Bai[1] Dongbo Wu[1] Juan Wang[2] Xia Zhu[2] Dong-Mei Zhang[2] Xing Cheng[2] Hong Li[2] Hong Tang[2], [1]Center of Infectious Diseases, West China Hospital of Sichuan University, Chengdu 610041, China;, [2]Center of Infectious Diseases, West China Hospital of Sichuan University, Chengdu 610041, China

Background: The indeterminate phase comprises chronic HBV-infected patients who do not fit into the four phases defined by current guidelines based on ALT, HBeAg, and HBV DNA levels. HBeAg-negative patients account for 70%–85% of this population. Although previous guidelines did not recommend antiviral therapy for these patients, they remain at risk of cirrhosis and hepatocellular carcinoma, warranting early antiviral treatment. However, the efficacy of different therapies in this population remains unclear. This study compared the clinical efficacy of nucleos(t)ide analogues (NAs) monotherapy versus NAs plus pegylated interferon alpha (Peg-IFNα) in treatment-naïve, HBeAg-negative, indeterminate-phase CHB patients with normal ALT. **Methods:** This prospective cohort enrolled treatment-naïve CHB patients with normal ALT ($\leq$40 U/L), negative HBeAg, and detectable HBV DNA ($\geq$20 IU/mL). Patients received TAF monotherapy or TAF plus Peg-IFN-α for 52 weeks according to patient preference. HBV DNA, HBV seromarkers, liver biochemistry, and blood cell counts were assessed every 12 weeks. The primary endpoint was undetectable HBV DNA (HBV DNA $<$20 IU/mL) at Week 52. The secondary endpoint was HBsAg seroclearance (HBsAg $<$0.05 IU/mL) at Week 52 (ChiCTR2200063868). **Results:** Among 183 enrolled patients, 42 received TAF monotherapy and 141 received TAF plus Peg-IFNα. Overall, the median age was 37.0 years (IQR: 34.0–44.0), and 49.2% were male. HBV DNA levels declined significantly at all follow-up time points ($p < 0.05$). At Week 52, 88.0% (161/183) achieved undetectable HBV DNA. In the TAF monotherapy group, median HBV DNA decline was 2.2 $\log_{10}$ IU/mL, and 92.9% (39/42) achieved undetectable HBV DNA. In the combination group, median HBV DNA decline was 1.9 $\log_{10}$ IU/mL, and 86.5% (122/141) achieved undetectable HBV DNA. The rate of undetectable HBV DNA was comparable between the two groups ($p = 0.402$). Overall, 20.8% (38/183) patients achieved HBsAg seroclearance at Week 52. Median HBsAg titer remained unchanged in the monotherapy group [2.5 (2.0-3.2) vs. 2.6 (2.0-3.1) log10 IU/mL, $p = 0.07$], and no patient achieved HBsAg seroclearance. Notably, median HBsAg titer in the combination group decreased from 2.5 to 1.1 $\log_{10}$ IU/mL at Week 52 ($p < 0.05$), with 27.0% (38/141) achieved HBsAg seroclearance, significantly higher than that in the monotherapy group ($p < 0.05$). Among patients achieved HBsAg seroclearance, 78.9% (30/38) further achieved HBsAg seroconversion, with a median anti-HBs titer of 132.5 mIU/mL (IQR: 76.4–208.5) at

Week 52. **Conclusion:** Both TAF monotherapy and TAF plus Peg-IFNα effectively reduced HBV DNA levels, whereas combination therapy yielded superior HBsAg seroclearance in treatment-naïve, HBeAg-negative, indeterminate-phase CHB patients. These findings support active intervention with TAF plus Peg-IFNα to achieve HBsAg loss in this historically untreated population.

4095 | IDENTIFYING CHRONIC HEPATITIS B PATIENTS WHO BENEFIT FROM CONTINUING PEG-IFNα BEYOND WEEK 24: A MACHINE LEARNING AND CLINICAL MODEL APPROAC

Jiayi Wang[1] Chen Zhou[1] Mengya Liu[1] Ning Han[1] Huan Liu[1] Hong Li[1] Lang Bai[1] Lingyao Du[1] Yilan Zeng[2] Hong Zhang[3] Juan Liao[1] Min He[1] Xuebing Chen[4] Jiahong Yang[5] Xing Cheng[1] Libo Yan[1] Hong Tang[1], [1]West China Hospital, [2]ublic Health Clinical Center of Chengdu, [3]Public Health Clinical Center of Chengdu, [4]epartment of Infectious Diseases, People's Hospital of Deyang City, [5]Department of Infectious Diseases, People's Hospital of Deyang City

Background: Chronic hepatitis B (CHB) remains a major global health burden and a leading cause of cirrhosis and hepatocellular carcinoma. Sustained HBsAg decline, particularly HBsAg loss, is critical in improving long-term clinical outcomes. Compared with nucleos(t)ide analogs (NAs), pegylated interferon-alpha (Peg-IFNα) more effectively promotes HBsAg reduction through combined antiviral and immunomodulatory effects. However, administration of Peg-IFNα beyond Week 24 provides limited benefit for many patients while increasing treatment burden. Therefore, a tool to identify patients likely to benefit from continued therapy is needed. We aimed to develop a simple model to guide individualized treatment decisions beyond Week 24. **Methods:** We analyzed a multicenter, prospective cohort of 832 NAs-experienced, HBeAg-negative CHB patients receiving Peg-IFNα add-on therapy for ≥ 48 weeks (NCT04035837). Among patients without HBsAg clearance at Week 24, treatment benefit from continued therapy was defined as HBsAg clearance at Week 48 or a >1 log10 IU/mL HBsAg decline from Weeks 24-48. Variables with a Pearson correlation coefficient >0.8 or variance inflation factor >5 were excluded to minimize multicollinearity. Predictors were selected using LASSO regression, the Boruta algorithm, and 1,000 bootstrap resamples. Nine machine learning (ML) models and a logistic regression (LR) model were developed and validated. **Results:** Overall, 615 (73.9%) patients remained HBsAg-positive at Week 24, among whom 159 (25.9%) achieved treatment benefit by Week 48. Age and Week 24 HBsAg level were identified as the most robust predictors. Among all ML models, the multilayer perceptron (MLP) demonstrated the best balance of discrimination and stability (AUC 0.721, 95% CI: 0.640–0.794). Stratification according to MLP-probabilities yielded distinct benefit rates in the test cohort (6.5% vs. 27.2% vs. 42.6% for low-, intermediate-, and high-probability groups, respectively; $p < 0.001$). The LR model showed comparable performance (AUC 0.716, 95% CI: 0.634-0.791, $p = 0.185$ *vs.* MLP) while offering greater clinical interpretability. Optimal cut-offs were 40 years for age and 0.772 log10 IU/mL (5.92 IU/mL) for Week 24 HBsAg. Based on these thresholds, patients were classified into a high-probability group (age <40 years and HBsAg <6.0 IU/mL), a low-probability group (age ≥40 years and HBsAg ≥6.0 IU/mL), and an intermediate-probability group (all remaining patients). Corresponding benefit rates were 50.0%, 9.4%, and 32.2%, respectively ($p < 0.001$). **Conclusion:** The MLP-based model identified patients unlikely to benefit from continued Peg-IFNα therapy, whereas patients aged <40 years with HBsAg <6.0 IU/mL at Week 24 are more likely to benefit from treatment continuation beyond Week 24.

4096 | PREGNANCY-INITIATED ANTIVIRAL THERAPY REDUCES THE RISK OF POSTPARTUM HEPATIC FLARES IN HIGHLY VIREMIC HBV-INFECTED WOMEN

Wan-Hsin Wen[1] Jin-Chung Shih[2] Chun Jen Liu[3] Yu Chun Chen[4] Mei-Hwei Chang[5] Huey-Ling Chen[5], [1]Cardinal Tien Hospital, [2]Department of Obstetrics and Gynecology, National Taiwan University College of Medicine and Hospital, [3]Department of Internal Medicine, National Taiwan University College of Medicine and Hospital, [4]Department of Pediatrics, National Taiwan University Hospital, [5]National Taiwan University

Background: Short-term antiviral therapy during late pregnancy is a standard strategy to prevent mother-to-child transmission (MTCT) among highly viremic HBV-infected women. However, the impact of maternal antiviral treatment on postpartum alanine aminotransferase (ALT) flares remains unclear. Previous studies have often defined hepatic flares using single-point measurements, which may fail to capture the dynamic nature of peripartum ALT fluctuation. This study aimed to identify independent predictors of postpartum hepatic flares by leveraging a trajectory-based approach. **Methods:** A prospective cohort of 333 highly viremic (HBV DNA > 200,000 IU/mL) mothers was followed from late pregnancy through 6 months postpartum, with protocol-driven ALT monitoring at baseline, 1 month post-baseline, delivery, and 1, 2, 4, 6 months postpartum. Pregnancy-treated women (n = 232) received tenofovir disoproxil fumarate or tenofovir alafenamide from the third trimester until 2–4 weeks postpartum. Based on a previously validated group-based trajectory model, four distinct peripartum ALT trajectories were identified: Pattern 1 (stable ALT throughout; 86.8%), Pattern 2 (moderate postpartum ALT elevation; 8.1%), Pattern 3 (marked postpartum ALT flares; 2.7%), and Pattern 4 (elevated ALT before delivery; 2.4%). Women with moderate and marked postpartum ALT elevations (Patterns 2 and 3) were combined into a composite postpartum flare group (n = 36), while those with stable ALT trajectories (Pattern 1) served as the reference group (n = 289). Multivariate logistic regression was performed to identify independent predictors of the postpartum flare trajectory. **Results:** In multivariate binary logistic regression adjusting for age, HBV genotype, and baseline viral load, antiviral therapy during pregnancy was identified as a powerful independent protective factor against postpartum ALT flares (adjusted odds ratio [aOR] = 0.35, 95% confidence interval [CI]: 0.15–0.80, p = 0.013). Conversely, higher baseline ALT was independently associated with an increased risk of subsequent postpartum flares (aOR = 1.08 per 1 U/L increase, 95% CI: 1.05–1.11, p < 0.001). Age (aOR = 1.10, p = 0.088), HBV genotype C (aOR = 1.51, p = 0.321), and baseline log10 viral load (aOR = 1.83, p = 0.131) were not significantly associated with the development of postpartum ALT flares. **Conclusion:** Among highly viremic HBV-infected women, approximately 10% exhibit peripartum ALT trajectories characterized by postpartum elevations or flares. Late-pregnancy antiviral therapy confers a protective effect against these flares, whereas higher baseline ALT increases the risk of subsequent flares. These findings underscore the benefit of maternal antiviral intervention in safeguarding postpartum hepatic stability. Additionally, our results highlight the need for vigilant monitoring, particularly in those with elevated baseline ALT.

4097 | TENOFOVIR ALAFENAMIDE FOR HBV PROPHYLAXIS AFTER LIVER TRANSPLANTATION: A 36-MONTH LONGITUDINAL REAL WORLD STUDY

Yuanmei Che[1] Jiaqi Zhang[2] Biao Wang[1] Xinyu Yang[2] Qinglin Ma[2], [1]Jiangxi Provincial People's Hospital, The First Affiliated Hospital of Nanchang Medical College, [2]Nanchang University

Background: HBV prophylaxis after liver transplantation requires durable viral suppression with favorable hepatic and renal safety. Data on long-term outcomes of tenofovir alafenamide (TAF) in this setting remain limited. **Methods:** This retrospective single-center cohort study included liver transplant recipients with HBV infection who received TAF 25 mg daily with tacrolimus-based immunosuppression. Clinical,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

virological, biochemical, and renal parameters were assessed at baseline and 6, 12, 24, and 36 months. HBV reactivation was defined as recurrent detectable HBV DNA after prior suppression **Results:** A total of 51 recipients were included. At baseline, median age was 49 (27-65) years, 47/51 (92.2%) were male, median BMI was 23.6 (17.6-32.1) kg/m², median HBsAg was 2.30 (0.00-3.95) log10 IU/mL, median ALT was 38 (8-2601) U/L, and median creatinine was 66 (38-111) µmol/L; baseline HBV DNA suppression was observed in 13/22 (59.1%) tested patients. HBsAg loss occurred in 32/39 (82.1%) at 6 months, 32/42 (76.2%) at 12 months, 31/35 (88.6%) at 24 months, and 16/17 (94.1%) at 36 months. HBV reactivation occurred in 1/45 (2.2%) patients at 12 months, with no new reactivation thereafter. Median ALT declined from 38 (8-2601) U/L at baseline to 24 (6-575) at 6 months, 20 (7-238) at 12 months, 16 (5-64) at 24 months, and 18 (6-98) U/L at 36 months; ALT normalization rates were 40/51 (78.4%), 43/51 (84.3%), 37/44 (84.1%), and 17/19 (89.5%) across follow-up, respectively. Median creatinine changed from 66 (38-111) µmol/L at baseline to 72 (38-208), 78 (45-197), 78 (35-176), and 65 (38-137) µmol/L, suggesting overall renal stability during long-term treatment. **Conclusion:** In liver transplant recipients with HBV infection, TAF provided durable prophylactic efficacy with a low HBV reactivation rate, progressive HBsAg clearance, improved ALT profiles, and stable renal function over 36 months, supporting both its antiviral effectiveness and long-term safety in this population.

Table 1. Baseline Characteristics of Liver Transplant Recipients (N=51)

Variable	Overall (N=51)
Demographics	
Age, years	49 (27-65)
Male, n (%)	47 (92.2)
BMI, kg/m²	23.6 (17.6-32.1)

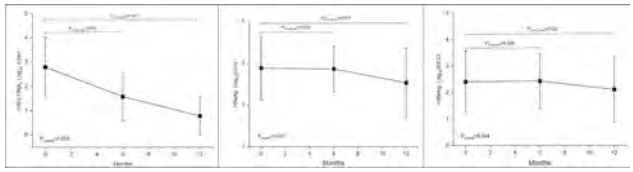
4098 | VIROLOGICAL AND BIOCHEMICAL RESPONSES OF PROLONGED COMBINATION THERAPY WITH BULEVIRTIDE AND PEGYLATED INTERFERON FOR 120 WEEKS IN CHRONIC HEPATITIS D PATIENTS WITH ADVANCED FIBROSIS/CIRRHOSIS: INTERIM RESULTS FROM SEE-D TRIAL AT 120 WEEKS

Soo Aleman[1] Habiba Kamal Khodir Habiba Kamal[1] Katarina Århem[1] Emmanuel Zavalis[1] Annika Olsson[1] Niklas Björkström[2] Karin Lindahl[3], [1]1Dept of Infectious Diseases, Karolinska University Hospital/Karolinska Institutet, Stockholm, Swede, [2]4Dept of Clinical Microbiology, Karolinska University Hospital/Karolinska Institutet, Stockholm, Swe, [3]1Dept of Infectious Diseases, Karolinska University Hospital/Karolinska Institutet, Stockholm

Background: In MYR301 with BLV monotherapy, 90% of patients who achieved continuously undetectable HDV RNA for at least 72 weeks at w144 maintained undetectable HDV RNA off-therapy, this supports continuously undetectable HDV RNA duration as a surrogate for durable virological response. However, clinical trial data on extended combination therapy beyond 96 weeks remain limited. The SEE-D study evaluates the efficacy of a 96-week combination regimen of BLV and pegIFN followed by BLV monotherapy, here we present interim results at w120. **Methods:** Thirty-one patients with chronic hepatitis D and advanced fibrosis or cirrhosis were treated in the SEE-D clinical trial at Karolinska University Hospital, Sweden. Therapy consisted of BLV 2 mg and pegIFN alfa-2a 180 µg for the first 48 weeks followed by 135 µg for the subsequent 48 weeks, together with nucleos(t)ide analogues. HDV RNA was quantified using the RoboGene HDV RNA Quantification Kit 2.0 (lower limit of detection 6 IU/mL). HBsAg responses were classified as: responder ($\geq$2 log decrease or $<$200 IU/mL), partial responder ($\geq$1 to $<$2 log decrease), and non-responder ($<$1 log decrease). **Results:** Baseline characteristics were mean age 44.6 ($\pm$8.6) years, 58.1% men, 87.1% Asian, 70.9% IFN-experienced; median liver stiffness 12.8 kPa (IQR 4.4), median HDV RNA 5.1 log_{10} IU/mL (IQR 1.4), and median HBsAg 3.9 log_{10} IU/mL (IQR 0.4). In the intention-to-treat (ITT) analysis, undetectable HDV RNA was achieved in 76.0% (19/25) at w84, 75.9% (22/29) at w96 and 85.7% (12/14) at w120. In the per-protocol (PP) analysis (excluding two patients who were lost to follow-up), undetectable HDV RNA was achieved in 82.6% (19/23) at w84, in 81.5% (22/27) at w96 and in 100% (12/12) at w120. By w96, the median duration of sustained undetectable HDV RNA was 60 weeks (IQR 51–72),

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient



© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

with 72.4% (21/29) maintaining undetectable levels for ≥48 weeks. In PP analysis, abnormal ALT decreased from 77.4% (24/31) at baseline to 21.4% (6/28) at w72, 28.6% (8/28) at w96 and 7.7% (1/13) at w120. In PP analysis of HBsAg, 14.8% (4/27) were responders and 3.7% (1/27) were partial responders at w96; corresponding figures at w120 were 15.4% (2/13) and none (0/13), respectively. The median HBsAg decline was 0.2 $\log_{10}$ (IQR 0.5) IU/mL at w96 with three (11.1%) achieving HBsAg level <20 IU/mL at this time point, and one patient achieved HBsAg loss. **Conclusion:** In the SEE-D trial, BLV plus prolonged pegIFN combination therapy resulted in high rates of continuously undetectable HDV RNA for ≥60 weeks by w120. These findings support the use of extended pegIFN in combination with BLV when aiming for finite therapy.

4099 | REDUCTION OF SERUM HBV DNA BY TENOFOVIR ALAFENAMIDE IN PAEDIATRIC CHRONIC HEPATITIS B PATIENTS SWITCHED FROM ENTECAVIR: AN EXPLORATORY STUDY

Jie Zheng[1] Jia Wang[2] Yage Zhu[3] Lei Shi[3] Tianyan Chen[3], [1]First Affiliated Hospital of Xi'an Jiaotong University, [2]The Eighth Hospital of Xi'an, [3]The First Affiliated Hospital of Xi'an Jiaotong University

Background: Globally, an estimated 46.5 million children and adolescents suffered from chronic hepatitis B (CHB) as of 2019. Current clinical guidelines recommend potent antiviral agents with high genetic barrier to resistance for pediatric CHB, including entecavir (ETV), tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide fumarate (TAF). Previous research showed that the 12-month HBV DNA undetectable rate was about 78% with ETV monotherapy, indicating that around 20% of these patients still had detectable serum HBV DNA after treatment. Studies in adult CHB patients have demonstrated that switching from ETV to TAF remained effective in terms of HBV suppression. Limited data were reported for switching from ETV to TAF in children and adolescents. The study was to explore whether TAF could significantly reduce serum HBV DNA in pediatric CHB patients switched from ETV. **Methods:** This is a retrospective cohort study. Twelve CHB children switched from ETV to TAF monotherapy were enrolled between 2019 and 2025. All of the children were between 12 and 18 years old at the baseline (time of switching to TAF) and had been on ETV for at least 12 months. Serum HBV DNA, HBsAg and HBeAg were log transformed prior to the analysis. Means+/-standard deviations were reported for the continuous variables and the count numbers (percentages) were reported for the categorical variables. The change in serum HBV DNA, HBsAg, HBeAg and ALT were tested by using Repeated Measures Analysis of Variance (ANOVA). **Results:** Twelve CHB children switched from ETV to TAF monotherapy were analyzed with the average age at TAF treatment 13.1+/-1.4 years old. Five (41.7%) out of the 12 CHB children were female. Ten of the 12 patients switched from ETV to TAF due to inadequate therapeutic response to ETV, and their serum HBV DNA were all positive at baseline (the time of TAF treatment). The median time on ETV was 27.2 (Interquartile range [IQR]: 18.0, 39.3) months. The median time patients received TAF treatment was 16.8 (IQR: 8.0, 28.8) months. Baseline virological biomarkers were 2.79+/-1.23 Log10 IU/ml for serum HBV DNA, 3.88+/-0.76 Log10 IU/ml for HBsAg and 2.41 +/-1.16 Log10 S/CO for HBeAg. Baseline ALT was 34.6 +/-33.8 U/L, two children had ALT greater than 40 U/L at baseline. After switching to TAF, serum HBV DNA decreased significantly over time (baseline: 2.79 +/-1.23, 6 months:1.58+/-0.99, 12 months: 0.78+/-0.78 Log10 IU/ml, overall P value = 0.003). HBsAg (baseline: 3.88+/-0.76, 6 months:3.86+/-0.55, 12 months: 3.53 +/-0.83 Log10 IU/ml,overall P value = 0.023) and HBeAg (baseline:2.41+/-1.16, 6 months: 2.44+/-1.03, 12 months: 2.12+/-1.24 Log10 S/CO,overall P value = 0.004) decreased significantly as well. ALT was not found significantly changed over time. **Conclusion:** Switching from ETV to TAF monotherapy could reduce serum HBV DNA significantly among children with CHB. TAF could be a promising alternative particularly for those with inadequate response to ETV.

4100 | RESMETIROM IN PATIENTS WITH MASH AND CHRONIC HEPATITIS B VIRUS INFECTION: REAL-WORLD SAFETY AND HEPATIC BIOMARKER RESPONSE

Mohammad Alabbas[1] Kenan Abou Chaer[2] Omar Sims[1] Walaa Mahmoud[3] Naim Alkhouri[4], [1]Cleveland Clinic Foundation, [2]Department of Internal Medicine, Detroit Medical Center/Wayne State University, Detroit, MI, USA, [3]Cleveland Clinic, [4]Summit Clinical Research

Background: Data on resmetirom use in patients with concomitant metabolic dysfunction-associated steatohepatitis (MASH) and chronic hepatitis B virus infection (CHB) are limited because chronic viral hepatitis was excluded from phase 3 resmetirom trials. We evaluated hepatic biomarker trajectories and safety after resmetirom initiation in MASH patients with EHR-defined CHB versus HBV-negative controls. **Methods:** Adults with MASH initiating resmetirom were identified in the TriNetX Research Network of 109 healthcare organizations. CHB was defined by chronic HBV diagnosis and/or HBV serologic evidence, including HBsAg positivity; HBV-negative controls required HBsAg negativity and no HBV diagnosis. Exclusions included acute HBV, hepatitis C, autoimmune, cholestatic, alcohol-related liver disease, baseline cirrhosis or hepatic decompensation, hepatocellular carcinoma, and liver transplant. Index was first resmetirom exposure. Laboratory values were assessed at baseline (-183 to -1 days) and days 1-90, 91-180, and 181-365. Outcomes through 365 days were compared before and after 1:1 propensity-score matching on demographics, comorbidities, medications, and laboratory values. TriNetX-generated p values were used for comparisons. **Results:** The unmatched cohort included 36 CHB+ and 592 HBV-negative patients; 31 per group remained after matching. Before matching, CHB+ patients had slightly higher mean age but the same median age versus HBV-negative patients (60.4 ± 9.8 vs 57.4 ± 14.1 years; median 59 vs 59) and were more often male (63.9% vs 40.4%). Baseline ALT (69.6 ± 67.3 vs 66.9 ± 68.6 U/L) and AST (51.0 ± 49.8 vs 51.0 ± 53.3 U/L) were similar. In CHB+, ALT/AST were 68.2 ± 68.0/46.8 ± 41.7 at days 1-90, 69.5 ± 56.5/54.3 ± 37.3 at days 91-180, and 38.1 ± 22.8/32.1 ± 13.0 U/L at days 181-365; albumin and platelets remained stable. Across days 1-365, ALT and AST did not differ between CHB+ and HBV-negative patients (ALT 47.0 ± 30.8 vs 50.8 ± 42.3, $p = 0.637$; AST 36.5 ± 16.3 vs 40.6 ± 30.6, $p = 0.480$). ALT normalization (≤ 30 U/L) occurred in 30.6% versus 26.0% ($p = 0.548$), and ALT ≤ 46 U/L occurred in 55.6% versus 46.6% ($p = 0.297$). After matching, ALT normalization was 35.5% in both groups, and ALT ≤ 46 U/L was 58.1% versus 64.5% ($p = 0.602$). In CHB+, no coded drug-induced liver injury/toxic liver disease, pancreatitis, acute kidney injury, atrial fibrillation/flutter, hepatic decompensation, or death occurred through 365 days. **Conclusion:** In this small real-world cohort, resmetirom-treated MASH patients with EHR-defined CHB had late aminotransferase improvement, stable hepatic synthetic markers, and outcomes comparable to HBV− controls. Missing HBV virologic, serologic, and treatment data limit interpretation and support prospective validation in confirmed CHB populations.

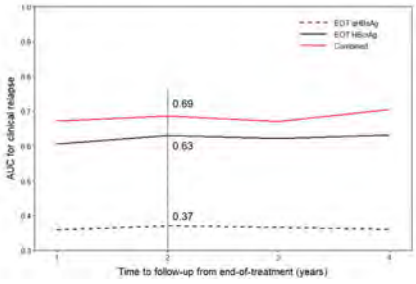
4101 | END-OF-TREATMENT HBCRAG OUTPERFORMS QHBSAG IN PREDICTING CLINICAL RELAPSE AFTER NUCLEOS(T)IDE ANALOGUE CESSATION IN HBEAG-POSITIVE CHRONIC HEPATITIS B

Yen-Chun Liu[1] Chien-Wei Peng[1] Rachel Wen-Juei Jeng[1] Rong-Nan Chien[1] Yun-Fan Liaw[1], [1]Chang Gung Memorial Hospital, Linkou medical center



Background: Most studies of HBV viral biomarkers for predicting outcomes after nucleos(t)ide analogue cessation have included mixed pretreatment HBeAg-positive and HBeAg-negative populations. Data remain limited for patients with pretreatment HBeAg-positive chronic hepatitis B. We therefore evaluated the relative

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

predictive value of end-of-treatment quantitative HBsAg and hepatitis B core-related antigen for off-therapy clinical relapse after Nuc cessation in this population. **Methods:** HBeAg-positive patients who stopped Nuc therapy per APASL criteria (HBV DNA undetectable ≥1 year; HBeAg loss for ≥1 year) with available EOT qHBsAg and HBcrAg data were analyzed. were analyzed. Clinical relapse (CR) was defined as ALT ≥2 times upper limit of normal and HBV DNA ≥2000 IU/mL. Time-dependent AUCs, cumulative incidence functions, Fine-Gray regression, and smoothed hazard functions evaluated predictive performance and biomarker-outcome associations; retreatment was treated as a competing risk. **Results:** Among 159 HBeAg-positive CHB patients who discontinued Nuc therapy, the mean age was 45 years, 74% were male, 22% had cirrhosis, and the median follow-up was 5.4 years. Median EOT qHBsAg and HBcrAg levels were 2.9 $\log_{10}$ IU/mL and 4.6 $\log_{10}$ U/mL, respectively. EOT HBcrAg outperformed qHBsAg for 2-year CR prediction, with AUCs of 0.63 versus 0.37, respectively; $p<0.001$. Adding qHBsAg to HBcrAg did not significantly improve discrimination beyond HBcrAg alone. In multivariable Fine-Gray analysis, EOT HBcrAg ≥4.5 $\log_{10}$ U/mL independently predicted CR, with an adjusted SHR of 2.71; 95% CI, 1.59–4.63; $p<0.001$, whereas EOT qHBsAg ≥3 $\log_{10}$ IU/mL did not. Patients with EOT HBcrAg ≥4.5 $\log_{10}$ U/mL had higher 2-year cumulative CR incidence than those with HBcrAg <4.5 $\log_{10}$ U/mL: 73% versus 48%; Gray's $p=0.004$. Smoothed hazard curves showed sustained late CR hazard beyond 6 months in patients with HBcrAg ≥4.5 $\log_{10}$ U/mL, and HBeAg seroreversion further identified the highest-risk subgroup. **Conclusion:** In HBeAg-positive CHB patients stopping Nuc therapy, EOT HBcrAg outperformed qHBsAg in predicting off-therapy clinical relapse and identified sustained late relapse risk beyond 6 months. Patients with EOT HBcrAg ≥4.5 $\log_{10}$ U/mL may warrant intensified off-therapy surveillance, particularly if HBeAg seroreversion occurs during follow-up.

4102 | CONTINUOUS OR CYCLICAL PEGINTERFERON ALFA-2B TREATMENT INDUCES COMPARABLE HBSAG LOSS IN INACTIVE HEPATITIS B VIRUS CARRIERS

Huibin Ning[1] Jia Shang[1] Huiming Jin[1] Kuan Li[1] Zhen Peng[1], [1]Henan Provincial People's Hospital, Zhengzhou, China

Background: Inactive hepatitis B virus (HBV) carriers (IHCs) exist a higher risk of hepatocellular carcinoma and liver-related mortality compared to individuals without chronic HBV infection. Peginterferon alfa (PegIFNα) therapy enables a significant proportion of IHCs to clear HBsAg, thereby reducing the risk of long-term adverse events. This study aimed to compare the efficacy of continuous versus cyclical PegIFNα-2b regimens in IHCs. **Methods:** In this randomized controlled trial, IHCs (defined as chronic HBV-infected individuals with HBV DNA < 2000 IU/mL, HBeAg negativity, HBsAg < 1000 IU/mL, and normal alanine aminotransferase levels) aged 18 to 65 years were randomly assigned to receive either continuous or cyclical PegIFNα-2b (Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) therapy. The continuous group received PegIFNα-2b 180 μg weekly throughout the study, whereas the cyclical group received PegIFNα-2b 180 μg weekly for 8 weeks, followed by a 4-week pause, repeated in 12-week cycles. The treatment period for both groups did not exceed 96 weeks. **Results:** A total of 77 IHCs were included, comprising 37 in the PegIFNα-2b continuous group and 40 in the PegIFNα-2b cyclical group. At baseline, there were no significant differences between the two groups in median age (39 [36, 46] vs. 42 [37, 50] years, $p=0.211$), proportion of males (54.1% vs. 62.5%, $p=0.603$), HBsAg levels (1.85 [1.06, 2.37] vs. 1.94 [1.21, 2.53] $\log_{10}$ IU/mL, $p=0.456$), proportion of patients with HBsAg ≤ 100 IU/mL (56.8% vs. 55.0%, $p=1.000$), HBV DNA negativity rate (54.1% vs. 40%, $p=0.314$), and ALT levels (23.4 [16.5, 33.3] vs. 22.4 [17.9, 30.7] U/L, $p=0.456$). Sixty-two IHCs completed 24 weeks of treatment. By week 24, the continuous and cyclical groups showed comparable HBsAg loss rates (32.1% [9/28] vs. 20.6% [7/34], $p=0.457$), HBsAg seroconversion rates (18.2% [4/22] vs. 13.8% [4/29], $p=0.970$), and HBV DNA undetectable rates (80% [12/15] vs. 100% [21/21], $p=0.126$), although the median HBsAg decline was higher in the continuous group (1.39 [1.04, 2.25] vs. 0.58 [0.15, 1.39] $\log_{10}$ IU/mL,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

$p = 0.005$). Stratified analysis by baseline HBsAg levels revealed that the continuous group had numerically higher, but not statistically significant, HBsAg loss rates than the cyclical group (baseline HBsAg ≤100 IU/mL: 43.8% vs. 33.3%, $p = 0.787$; >100 IU/mL: 16.7% vs. 6.2%, $p = 0.791$). At week 24, the median ALT and AST levels in the cyclical group were 33.9 (22.4, 47.0) and 29.3 (23.2, 40.2) U/L, respectively, which were significantly lower than those in the continuous group (58.6 [42.5, 94.9] and 43 [39.6, 74.7] U/L, respectively, all $p < 0.001$). **Conclusion:** In IHCs, cyclical administration of PegIFNα-2b produced comparable efficacy and fewer hepatic biochemical abnormalities than continuous administration, supporting its potential as a valuable strategy for wider clinical implementation.

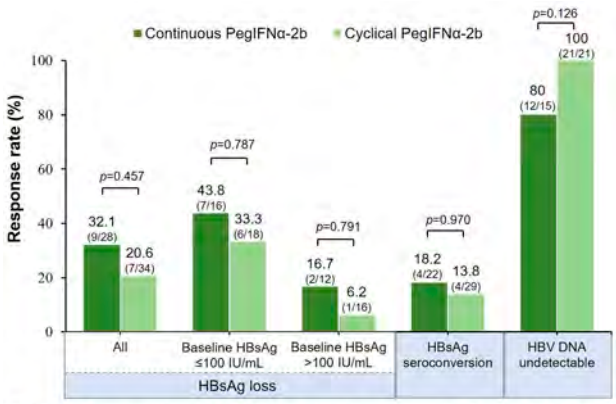

Figure 1. Response rate at week 24 following continuous or cyclical PegIFNα-2b treatment.

4103 | TENOFOVIR ALAFENAMIDE IMPROVES ALT AND HCC RISK STRATIFICATION IN CHRONIC HEPATITIS B WITH NORMAL OR MILDLY ELEVATED ALT

Jaehong Jeong[1] Dong Yun Kim[1] Jae Seung Lee[1] Mi Na Kim[1] Hye Won Lee[1] Beom Kyung Kim[1] Jun Yong Park[1] Do Young Kim[1] Sang Hoon Ahn[1] Seung Up Kim[1],
[1]Yonsei University College of Medicine, Seoul, Korea

Background: Guidelines for antiviral treatment initiation in non-cirrhotic chronic hepatitis B (CHB) patients with HBV DNA level > 2,000 IU/mL, but with normal or mildly elevated alanine aminotransferase (ALT) remain controversial. We evaluated whether tenofovir alafenamide (TAF) improves ALT normalization and attenuates hepatocellular carcinoma (HCC) risk scores in this population. **Methods:** This interim analysis of an ongoing prospective single-center cohort study included non-cirrhotic CHB patients with HBV DNA level > 2,000 IU/mL, but with normal or mildly elevated ALT. Patients were classified into those who initiated TAF (antiviral treatment [AVT] group, n = 106) and those under untreated observation (control group, n = 32). At 1-year of follow-up, we assessed longitudinal ALT changes, ALT normalization rates by AASLD, EASL and KASL criteria, and HCC risk score transitions using HCC risk models including REACH-B and CU-HCC. **Results:** Over 1 year, the AVT group achieved a significant ALT reduction (median 24.5→21.0 U/L), while controls remained unchanged (26.0→26.5 U/L; interaction $p = 0.003$). AVT significantly improved ALT normalization rates by AASLD (64.2%→80.2%, $p = 0.002$) and KASL (71.7%→85.8%, $p = 0.003$), exhibiting divergent trends compared to the unchanged controls (Group×Time $p = 0.007$ and $p = 0.001$). For HCC risk stratification, category improvements were more frequent in AVT versus controls by REACH-B (14.2% vs. 3.1%) and CU-HCC (14.2% vs. 6.2%). Furthermore, continuous risk scores declined significantly faster in AVT for both models (interaction $p = 0.004$ and $p = 0.022$), whereas PAGE-B and aMAP showed no between-group differences ($p > 0.05$). **Conclusion:** TAF initiation in grey-zone non-cirrhotic CHB patients significantly improved ALT levels and achieved greater attenuation in HCC risk stratification compared to untreated controls, supporting the beneficial efficacy of early initiation of AVT in this population.

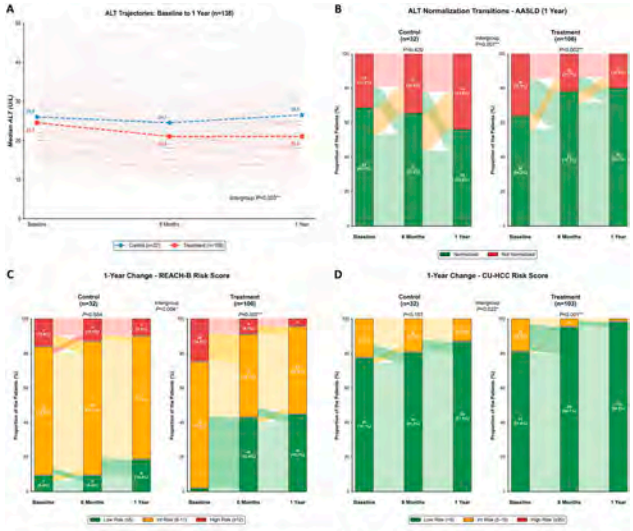

Figure 1. Longitudinal changes in ALT levels and HCC risk scores over 1 year in CHB patients with normal or mildly elevated ALT. (A) Individual patient ALT trajectories from baseline to 1 year in the antiviral treatment (AVT) and untreated control groups. (B) Transitions in ALT normalization status evaluated according to the AASLD criteria. Changes in HCC risk stratification categories (Improved, Stable, or Worsened) over 1 year assessed by the (C) REACH-B and (D) CU-HCC models. The AVT group exhibited significantly higher rates of ALT normalization and HCC risk category improvement compared to the control group.

4104 | EFFECT OF NUCLEOS(T)IDE ANALOGUES WITH OR WITHOUT PEGINTERFERON ALFA-2B ON 48-WEEK OUTCOMES IN CHRONIC HEPATITIS B PATIENTS WITH HIGH HBSAG LEVEL: PRELIMINARY RESULTS FROM A MULTICENTER, PROSPECTIVE STUDY IN CHINA

Yuemin Nan[1] Suxian Zhao[2] Qing Ye[3] Jia Li[4] Aihua Gao[5] Haifang Cao[6] Lijun Chang[7] Musong Li[8] Qingge Zhang[9] Haiyan Kang[10] Ying Guo[11] Fenxiang Li[12] Suling Chen[13], [1]Hebei Medical University Third Hospital, [2]Hebei Medical University Third Hospital, [3]Tianjin Third Central Hospital, [4]Tianjin Second People's Hospital, [5]The Third Hospital Of Cangzhou, [6]Qinghai Provincial Fourth People's Hospital, [7]Yuncheng Central Hospital, [8]People's Hospital of Baoding City, [9]People's Hospital of Xingtai City, [10]The Fifth Hospital of Shijiazhuang, [11]Taiyuan Third People's Hospital, [12]Linfen third people's hospital, [13]Changzhi Med Coll, Heping Hosp, Changzhi, Peoples R China

Background: Achieving hepatitis B surface antigen (HBsAg) loss and functional cure in patients with chronic hepatitis B (CHB) remains a significant challenge, particularly in those with high baseline HBsAg > 1500 IU/mL. This study provides evidence on the clinical benefit of a phased strategy by evaluating different antiviral therapies in patients with baseline HBsAg < 5000 IU/mL, particularly those > 1500 IU/mL. **Methods:** This multicenter, prospective, real-world study (the Glocure Project) enrolled CHB patients aged 18–65 years who were nucleos(t)ide analogues (NAs)-experienced or treatment-naïve, with HBsAg ≤ 5000 IU/mL from 12 medical centers in China. Patients were assigned to the NAs monotherapy group or the peginterferon α-2b (PegIFNα-2b) plus NAs group. This preliminary analysis evaluated the dynamic changes in HBsAg levels in both groups after 48 weeks of treatment, focusing on baseline HBsAg 1500 ~ 5000 IU/mL. **Results:** A total of 1230 patients in the PegIFNα-2b +NAs group and 597 patients in the NAs monotherapy group who had completed 48 weeks of treatment. At baseline, the combination group had higher proportion of males (69.9% vs. 64.0%, p = 0.0108), while the mean age (42.4 vs. 45.3 years, p < 0.05), HBsAg levels (3.12 vs. 3.20 $\log_{10}$ IU/mL, p < 0.05), and HBeAg positivity rate (25.45% vs. 32.83%, p = 0.005) were all lower, the HBV DNA levels were comparable (6.18 vs. 6.03 $\log_{10}$ IU/mL, p > 0.05). The proportions of patients with baseline HBsAg < 100, 100~ < 1500, and 1500~5000 IU/mL were 21.5% vs. 13.0%, 44.8% vs. 44.3%, and 33.7% vs. 42.7% respectively. After treatment, the PegIFNα-2b+NAs group showed significantly greater HBsAg reductions from baseline at both week 24 (-0.755 vs. -0.101 $\log_{10}$ IU/mL, p < 0.05) and week 48 (-0.938 vs. -0.167 $\log_{10}$ IU/mL, p < 0.05). In addition, the proportion of patients with HBsAg < 100 IU/mL was significantly higher in the combination group at week 24 (38.3% vs. 14.5%, p < 0.05) and week 48(43.1% vs. 15.3%, p < 0.05). Notably, subgroup analysis with baseline HBsAg 1500 ~ 5000 IU/mL. The baseline HBsAg levels were comparable (3.46 vs. 3.47 $\log_{10}$ IU/mL, p = 0.196). After treatment, the combination group showed greater HBsAg reductions from baseline at week 24 (-0.480 vs. -0.127 $\log_{10}$ IU/mL, p < 0.05) and week 48 (-0.715 vs. -0.196 $\log_{10}$ IU/mL, p < 0.05). At week 48, the combination group had a higher proportion achieving HBsAg < 1500 IU/mL (60.0% vs. 22.4%, p < 0.0001). **Conclusion:** In CHB patients with baseline HBsAg < 5000 IU/mL, PegIFNα-2b+NAs therapy induced greater and faster HBsAg reductions than NAs monotherapy, and more patients reached HBsAg < 1500 IU/mL and HBsAg < 100 IU/mL. These findings support PegIFNα-2b+NAs as a more effective treatment strategy for patients with high HBsAg levels, and may serve as a promising strategy for chronic hepatitis B patients with high HBsAg levels into advantageous populations eligible for clinical cure.

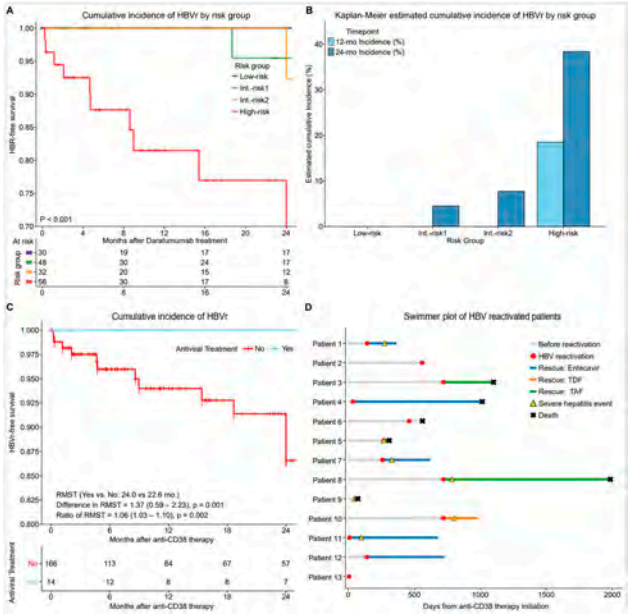
4105 | INCIDENCE AND RISK STRATIFICATION OF HEPATITIS B REACTIVATION IN PATIENTS RECEIVING ANTI-CD38 MONOCLONAL ANTIBODY THERAPY



Pil Soo Sung[1], [1]Seoul St Mary's Hospital

Background: The human anti-CD38 monoclonal antibody daratumumab, used for multiple myeloma,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

induces substantial immunosuppression and may increase susceptibility to hepatitis B virus reactivation (HBVr). While reactivation has been documented in anti-HBc–positive individuals, real-world data evaluating the efficacy of prophylactic antiviral therapy and risk-stratification models are limited. **Methods:** We retrospectively analyzed a cohort of 180 anti-HBc–positive, HBsAg-negative patients among 709 multiple myeloma patients treated with daratumumab between 2015 and 2025. Clinical outcomes were compared between patients receiving prophylactic nucleos(t)ide analogue (NA) therapy (n = 14) and those who did not (n = 166). Independent predictors of HBVr were identified using multivariate Cox regression analysis to develop a risk-stratification model. **Results:** The overall incidence of HBVr in the untreated cohort was 7.8% (13/166), categorizing daratumumab as a moderate-risk agent (1–10%) according to the EASL framework. Baseline anti-HBs titers < 100 IU/L and the use of daratumumab as later-line (relapsed/refractory) therapy were identified as independent risk factors. In the high-risk subgroup (possessing both factors), the crude incidence of HBVr was 19.6% (11/56), while the estimated 24-month cumulative incidence approached 40%. No reactivation events were observed in the prophylactic NA group. Severe hepatitis (n = 7) and liver-related mortality (n = 3) occurred exclusively in the untreated group, predominantly among high-risk patients. **Conclusion:** Anti-CD38 therapy is associated with a significant and preventable risk of HBVr, particularly in a high-risk phenotype characterized by low baseline anti-HBs and later-line treatment. Routine NA prophylaxis should be prioritized for this high-risk group to prevent life-threatening liver complications, while intensified monitoring may be considered for intermediate-risk patients.

Disclosures: Pil Soo Sung:Nothing to Disclose.

4106 | RETREATMENT EFFICACY AND OVERALL OUTCOMES IN PATIENTS WITH CHRONIC HEPATITIS B WHO RELAPSED AFTER CLINICAL CURE

Huiling Xiang[1] Jun Li[2] Fei Yan[2] Jing Liang[1] Qing Ye[1], [1]Tianjin University Central Hospital (Tianjin Third Central Hospital), [2]The Third Central Clinical College of Tianjin Medical University

Background: To investigate the clinical efficacy of retreatment in patients with chronic hepatitis B (CHB) who have relapsed after achieving clinical cure; to compare the hepatitis B surface antigen (HBsAg) re-clearance rates among different retreatment regimens; and to analyze the natural course of the disease in patients with multiple relapses and those who have not received treatment. **Methods:** This single-center retrospective cohort study included CHB patients who achieved clinical cure (defined as HBsAg < 0.05 IU/mL, HBV DNA < 20 IU/mL, and normal liver function for ≥ 12 weeks after stopping therapy) and subsequently experienced confirmed relapse (HBsAg and/or HBV DNA re-positivity, with follow-up tests remaining positive 4–12 weeks later) at Tianjin University Central Hospital between January 2017 and June 2025. The relapse rate, relapse patterns, and HBsAg re-clearance after retreatment were analyzed. Retreatment regimens included pegylated interferon alpha-2b (Peg-IFNα-2b) monotherapy or combined with nucleos(t)ide analogs (NAs), and NAs monotherapy. HBsAg re-clearance rates were compared among regimens. Outcomes of patients with multiple relapses or no retreatment were also described. **Results:** A total of 322 clinically cured patients were enrolled; 41 experienced relapse, resulting in a relapse rate of 12.73%, with a median time to relapse of 30.86 weeks after discontinuation of treatment. The predominant type of relapse was HBsAg-positive and HBV DNA-negative (38 cases, accounting for 92.68%). Among the 41 patients who relapsed, 37 received retreatment, while 4 did not. The overall HBsAg re-clearance rate following retreatment was 48.65% (18/37). Among these, the HBsAg re-clearance rate in the Peg-IFNα-2b-based treatment group (27 patients) was 55.56% (15/27), which was significantly higher than the 30.00% (3/10) observed in the NAs monotherapy group (10 patients). Among the 18 patients who achieved HBsAg re-clearance, 83.3% (15/18) were from the Peg-IFNα-2b-based treatment group. Among these 18 patients, 4 subsequently experienced a third relapse, and only 1 achieved re-

clearance after another round of retreatment. Among the 4 untreated patients, with a median follow-up of 177 weeks, none achieved HBsAg re-clearance, and all maintained low levels of HBsAg and HBV DNA. **Conclusion:** After clinical cure of CHB, the relapse rate was 12.73%. Re-treatment after relapse can still achieve a high rate of HBsAg re-clearance. Regimens based on Peg-IFNα-2b demonstrated a significantly higher rate of HBsAg re-clearance compared to NAs monotherapy, and 83.3% of re-clearance achievers received this regimen. Untreated patients failed to clear HBsAg over a median 3.4-year follow-up, suggesting that clinical cure is unlikely without antiviral therapy. Thus, Peg-IFNα-2b-based retreatment is recommended.

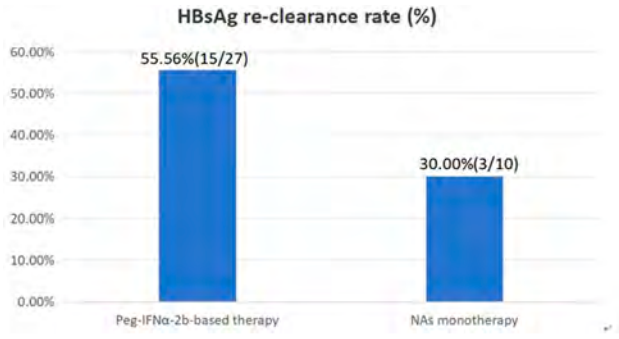

Figure 1. HBsAg Re-clearance Rates in Relapsed CHB Patients by Retreatment Regimen.

4107 | IMPACT OF CHRONIC HEPATITIS B COMORBID WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE ON HBSAG RESPONSE AND DISEASE PROGNOSIS

Guiqun Huang[1] Guanghui Ren[1] Shi Yin[1] Ying Zhu[1], [1]The First Affiliated Hospital of Dalian Medical University, Dalian, 116011, China

Background: To investigate the virological and fibrotic characteristics of chronic hepatitis B (CHB) patients with concurrent metabolic dysfunction-associated steatotic liver disease (MASLD), and to analyze the impact of metabolic dysfunction-associated steatohepatitis (MASH) risk stratification on virological and fibrotic indicators, as well as HBsAg response. **Methods:** A total of 1356 CHB patients were retrospectively enrolled, including 889 in the CHB-only group and 467 in the CHB+MASLD group. The CHB+MASLD group was further stratified into no-MASH, suspected-MASH, and high-risk MASH subgroups based on the FibroScan-AST (FAST) scores. Among all patients, 626 (383 in the CHB-only group and 243 in the CHB +MASLD group) had follow-up data and were included in the HBsAg response analysis. Antiviral therapies during follow-up included nucleos(t)ide analogues (NAs) monotherapy, peginterferon alpha-2b (PegIFNα-2b, Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) monotherapy, PegIFNα-2b plus NAs therapy, and no therapy. Data on virology, liver function, complete blood count, transient elastography, and noninvasive fibrosis markers were collected. Inverse probability of treatment weighting (IPTW) was applied to balance baseline differences between groups, and a Spearman correlation analysis was performed to assess correlations. A Cox proportional hazards regression model was used to analyze the predictors of HBsAg response. **Results:** After adjustment by IPTW, patients in the CHB+MASLD group exhibited a higher BMI (25.83 vs. 24.73 kg/m², P = 0.026) and lower HBsAg (3.27 vs. 3.42 $\log_{10}$ IU/mL, P = 0.009), HBeAg (-0.94 vs. -0.80 $\log_{10}$ S/CO, P < 0.001), and pgRNA (1.94 vs. 2.60 $\log_{10}$ copies/mL, P = 0.009) levels compared to the CHB-only group. Regarding fibrotic characteristics, patients in the CHB+MASLD group had higher liver stiffness measurement (LSM), fibrosis-4 (FIB-4), and AST-to-platelet ratio index (APRI) values than those in the CHB-only group (all P < 0.05). In the CHB+MASLD group, an increased MASH risk was associated with elevated liver injury and fibrosis markers, as well as lower HBsAg levels (P < 0.001). The FAST score showed a weak negative correlation with HBsAg levels (r = –0.176, P < 0.001). Follow-up analysis revealed that HBsAg response rates at all time points were higher in the high-risk MASH subgroup than in the CHB-only group and the no-MASH subgroup (P < 0.001). Multivariate Cox regression analysis identified lower baseline HBsAg levels (HR = 0.697, P < 0.001) and higher MASH risk stratification (HR = 3.930, P < 0.001) as independent predictors of higher HBsAg response rates (Table 1). **Conclusion:** Patients with CHB combined with MASLD exhibit lower virological markers but a heavier fibrotic burden. An increased risk of MASH is associated with liver injury and fibrosis progression. Baseline HBsAg level and MASH risk stratification are independent predictors of HBsAg response.

4108 | CHARACTERISTICS OF CIRCULATING IMMUNE CELLS AND CYTOKINE PROFILES IN PEDIATRIC PATIENTS WITH CHRONIC HEPATITIS B UNDERGOING ANTIVIRAL THERAPY

Haifang Cao[1] Hong Zhang[2] Qinghua Lu[1] Ling Xu[3] Yang Zhao[3] Feng Ren[3] Hongfei Zhang[3], [1]The 4th People's Hospital of Qinghai Province, Xining, China, [2]Chengdu Public Health Clinical Center, Chengdu, China, [3]Beijing Youan Hospital, Capital Medical University, Beijing, China

Background: Hepatitis B surface antigen (HBsAg) loss, or functional cure (FC), is the optimal therapeutic goal for chronic hepatitis B (CHB). However, the immunological landscape associated with FC in pediatric patients remain poorly defined. This study aimed to comprehensively characterize the circulating immune cell states, serum cytokine profiles, and viral markers in pediatric CHB patients to elucidate the mechanisms underlying FC. **Methods:** We performed high-dimensional mass cytometry (CyTOF) on PBMCs from 89 pediatric CHB patients (aged 3–18 years), categorized into: treatment-naïve (n = 36), NAs-treated (n = 25), and FC patients (n = 28, treated with NAs + peginterferon alpha-2b [PegIFNα-2b, Pegbing®, Xiamen Amoytop Biotech Co., Ltd.]). Serum cytokines/chemokines were measured via multiplex assays. Viral activity was assessed by quantifying HBVcrAg and HBVpgRNA levels using ELISA and qPCR, respectively. **Results:** Unsupervised analysis revealed a reconfigured circulating immune landscape in pediatric CHB patients who achieved FC, distinct from both treatment-naïve and NAs-treated patients without achieving FC. Viral marker analysis confirmed that FC patients achieved superior viral suppression compared to the other groups: HBcrAg levels were significantly lower in the FC group (123.6 ± 79.03 U/L) compared to NAs-treated (1341 ± 375.2 U/L) and treatment-naïve patients (3450 ± 263.1 U/L). Similarly, HBV pgRNA levels were significantly lower in FC patients (1.846 ± 0.3573 copies/μL) compared to those in the NAs-treated (198.3 ± 98.91 copies/μL) and treatment-naïve groups (1874 ± 468.9 copies/μL). Immunologically, FC patients exhibited a unique signature characterized by the expansion of NKT and TCRγδ+ T cells and a distinct chemokine receptor profile. Furthermore, systemic cytokine analysis showed that FC patients displayed a coordinated regulatory network, with significantly modulated pro-inflammatory cytokines and upregulated anti-inflammatory/regulatory factors (IL-10, IL-1Ra, IL-7, IL-12p70) compared to the untreated or NAs-treated groups. **Conclusion:** Pediatric CHB patients achieving FC exhibit profound viral suppression alongside a unique circulating immune profile, defined by T-cell functional reconstitution and a balanced regulatory cytokine network. These findings suggest that the synergistic effect of PegIFNα-2b and NAs facilitates both deep viral clearance and immune restoration, providing a strong rationale for immunotherapeutic strategies in pediatric CHB.

4109 | SAFETY AND EFFICACY OF TENOFOVIR DISOPROXIL FUMARATE REGIMEN FROM PRECONCEPTION ON PREGNANT WOMEN WITH CHRONIC HEPATITIS B: A PROSPECTIVE COHORT STUDY

Liyang Zhou[1] Xueting Ou[1] Panpan Zhai[1] Yinxing Lin[1] Bing Situ[1] Jun Huang[2] Xing-Fei Pan[1], [1]The Third Affiliated Hospital, Guangzhou Medical University, [2]Sino-French Hoffmann Institute, Guangzhou Medical University

Background: Antiviral prophylaxis in late pregnancy reduces hepatitis B virus (HBV) mother-to-child transmission (MTCT), but data on preconception-initiated tenofovir disoproxil fumarate (TDF) throughout pregnancy for chronic hepatitis B (CHB) relatively remain limited. This study evaluated the safety and efficacy of this strategy in well-matched cohorts. **Methods:** This prospective cohort study enrolled 153 pregnant women with chronic hepatitis B infection (2017–2020). Eight-six received TDF from preconception because of CHB and throughout pregnancy (the treatment group). Sixty-seven untreated controls had normal alanine transaminase (ALT) and HBV DNA $< 2\times10^5$ IU/mL during

pregnancy (the control group). Groups were baseline-balanced in age and ALT. All infants received standard immunoprophylaxis and were followed ≥7 months postpartum. Primary outcomes included maternal virologic/biochemical control, pregnancy complications, and infant safety and HBV infection status. **Results:** Maternal age and ALT levels were comparable at baseline between groups. Antiviral treatment was well-tolerated in all mothers of the treatment group. Maternal HBV DNA levels were significantly lower in the treatment group both at delivery and 3 months postpartum ($P = 0.001$), compared with that of the control group. Maternal ALT was slightly higher in the treatment group at delivery ($P = 0.010$) but comparable between groups at 3 months postpartum ($P = 0.185$). There was no a statistically significant difference in pregnancy complications, gestational age, or delivery mode between the two groups, respectively ($P > 0.05$). Birth weight, birth length, and congenital anomaly rates were similar between the two groups ($P > 0.05$), respectively. None of infants in the two groups was positive for HBsAg at 7 months of age. **Conclusion:** It was safe and effective for pregnant women with CHB and their infants to take TDF from pre-conception to the entire pregnancy.

4110 | OUTCOME OF CHRONIC HEPATITIS B PATIENTS WITH HIGH HBSAG LEVEL AT 52 WEEKS AFTER PEGINTERFERON ALPHA-2B AND NUCLEOS(T)IDE ANALOGS COMBINATION THERAPY

Wenhua Zhang[1] Haitao Tang[1] Qinghua Lu[2] Haifang Cao[2] Tingxia Chao[1] Fengmei Wang[1] Wenling Jia[1] Chunhui Liang[1] Feng Ren[3] Hongfei Zhang[3], [1]Gansu Wuwei Tumour Hospital, Wuwei, China, [2]The 4th People's Hospital of Qinghai Province, Xining, China, [3]Beijing Youan Hospital, Capital Medical University, Beijing, China

Background: Chronic hepatitis B (CHB) patients with HBV DNA < LLOQ, HBeAg negative and HBsAg < 1500 IU/mL after prior nucleos(t)ide analogs (NAs) treatment were the preferred population for clinical cure (PPCC). Nucleotides with add-on interferon treatment (NUC-IFN) provide significantly higher rates of HBsAg loss in CHB patients. The purpose of this study aims to observe the efficacy of NAs combined with PegIFNα-2b in treating CHB patients with HBsAg > 1500 IU/mL (Non-preferred population for clinical cure, NPPCC). **Methods:** The CREATED EXCELLENT study (ChiCTR2400081073) is a multi-center, prospective, non-randomized, open-label, positive-controlled study. CHB patients with NAs treated for ≥3 months and HBsAg > 1500 IU/mL were enrolled and divided into two groups. The NAs monotherapy group continued to receive their original NAs (ETV/TDF/TAF/TMF) treatment, while the PegIFNα-2b+NAs group received PegIFNα-2b (180 μg/week, Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) subcutaneously in addition to NAs. The total treatment period was 52 weeks, and all participants were followed up for 24 weeks after the end of treatment (EOT). Primary efficacy outcome 1) the proportion of patients with HBsAg < 1500 IU/mL; 2) the reduction in HBsAg levels from baseline. **Results:** 682 patients were screened, 308 patients failed to meet enrollment criteria, and 373 were enrolled. Among the enrolled patients, 187 patients received NAs monotherapy;186 patients received PegIFNα-2b+NAs therapy. In PegIFNα-2b+NAs treated group, there are 9 patients reached HBsAg loss at EOT, 4 patents HBsAg seroconversion; In NAs monotherapy group, there are 2 patients reached HBsAg loss, 1 patients HBsAg seroconversion at EOT. The baseline average HBsAg level was 18767.23 ± 5623.33 IU/mL in NAs group and was 17346.91IU/mL ($P > 0.05$) in PegIFNα-2b+NAs group. At EOT, there are 6963.92 ± 1127.89 IU/mL in NAs group and 3589.40 ± 1223.47 IU/mL in PegIFNα-2b+NAs group ($P < 0.001$); the stratification ratio of patients with HBsAg < 1500, 1500 < HBsAg < 3000, 3000 < HBsAg < 9000, and more than 9000 IU/mL were 50.51%, 14.11%, 31.06%, and 9.32%, respectively, in the PegIFNα-2b+NAs group; the rates were 16.00%, 27.15%, 30.63%, and 26.22 % in the NAs group, respectively. **Conclusion:** Compared with NAs monotherapy, PegIFNα-2b combined with NAs therapy for the treatment of NPPCC (HBsAg > 1500 IU/mL) rapidly reduced HBsAg levels, and increased the number of PPCC (HBsAg < 1500 IU/mL), thereby providing a new

4111 | SUSTAINED FUNCTIONAL CURE AND ITS PREDICTORS WITH PEGINTERFERON ALPHA-2B COMBINATION THERAPY AT 156 WEEKS EXTENDED FOLLOW-UP AFTER A PHASE 3 TRIAL

Fengqin Hou[1] Jia Shang[2] Qing Xie[3] Chunliang Lei[4] Jianmei Lin[5] Guoxin Hu[6] Zhiliang Gao[7] Yilan Zeng[8] Jiabin Li[9] Qianguo Mao[10] Liying Zhu[11] Jun Chen[12] Xiaozhong Wang[13] Zuxiong Huang[14] Jiming Zhang[15] Ping An[16] Xiulan Xue[17] Yan Huang[18] Tianyan Chen[19] Jianqi Lian[20] Yueyong Zhu[21] Huiling Xiang[22] Xinyue Chen[23] Hui Guo[24] Ruoyi He[25] Yalin Yin[25] Li Sun[25] Guiqiang Wang[26], [1]Peking University First Hospital, Beijing, 100034, China, [2]Henan Provincial People's Hospital, Zhengzhou, 450000, China, [3]Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, 200000, China, [4]Guangzhou Eighth People's Hospital, Guangzhou Medical University, Guangzhou, 510000, China, [5]Sichuan Provincial People's Hospital·Sichuan Academy of Medical Sciences, Chengdu, 610000, China, [6]Peking University Shenzhen Hospital, Shenzhen, 518000, China, [7]The Third Affiliated Hospital, Sum Yat-Sen University, Guangzhou, 510000, China, [8]Public Health Clinical Center of Chengdu, Chengdu, 610000, China, [9]The First Affiliated Hospital of Anhui Medical University, Hefei, 230000, China, [10]Xiamen Hospital of Traditional Chinese Medicine, Xiamen, 361000, China, [11]The Fourth Affiliated Hospital of Harbin Medical University, Harbin, 150001, China, [12]Shenzhen Third People's Hospital, Shenzhen, 518000, China, [13]Xinjiang Uygur Autonomous Region Hospital of Traditional Chinese Medicine, Urumqi, 830000, China, [14]Mengchao Hepatobiliary Hospital of Fujian Medical University, Fuzhou, 350000, China, [15]Huashan Hospital, Fudan University, Shanghai, 200040, China, [16]The Sixth People's Hospital of Shenyang, Shenyang, 110000, China, [17]The First Affiliated Hospital of Xiamen University, Xiamen, 361000, China, [18]Xiangya Hospital Central South University, Changsha, 410000, China, [19]The First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, 710061, China, [20]The Second Affiliated Hospital of the Air Force Military Medical University of CPLA, Xi'an, 710038, China, [21]The First Affiliated Hospital of Fujian Medical University, Fuzhou, 350000, China, [22]Tianjin Third Central Hospital, Tianjin, 300170, China, [23]Beijing Youan Hospital, Capital Medical University, Beijing, 100000, China, [24]First Teaching Hospital of Tianjin University of Traditional Chinese Medicine, Tianjin, 300170, China, [25]Xiamen Amoytop Biotech Co. Ltd, Xiamen, 361028, China, [26]Peking University First Hospital, Beijing, 100034, China; Peking University International Hospital, Beijing, 102206, China

Background: Functional cure, the ideal therapeutic goal in chronic hepatitis B (CHB), can be achieved through peginterferon alpha (PegIFNα) treatment. This study aimed to evaluate the long-term durability of PegIFNα-2b-induced functional cure and its predictors. **Methods:** Patients who achieved functional cure (maintain HBsAg loss and HBV DNA undetectable for 24 weeks follow-up after all drugs discontinuation) at the end of a phase 3 trial (NCT04846491) were enrolled in cohort 1 of this long-term follow-up study (NCT06707922) and observed for 5 years. In the preliminary phase 3 trial, nucleos(t)ide analogue (NA)-experienced patients were randomized to receive tenofovir disoproxil fumarate (TDF) monotherapy (group 1), TDF combined with PegIFNα-2b 180 μg/week (group 2) or 90 μg/week (group 3); after 48 weeks of TDF treatment, patients in group 1 either continue TDF monotherapy (group 1a) or add PegIFNα-2b 180 μg/week (group 1b). Treatment-naïve patients were also included to receive TDF combined with PegIFNα-2b 180 μg/week (group 4). The treatment period was 144 weeks and the follow-up was 24 weeks. PegIFNα-2b (Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) were given intermittently in cycles. **Results:** A total of 88 patients who achieved functional cure were enrolled in cohort 1 of this follow-up study, comprising 32, 23, 29 and 4 patients from groups 2, 1b, 3 and 4 of the preliminary phase 3 trial, respectively, with no patients from group 1a. Among NA-experienced patients (groups 2, 1b, and 3), the mean age ranged from 36.1 to 41.5 years, with 58.6%–82.6% being male and 86.2%–91.3% being HBsAb positive. For treatment-naïve patients (group 4), the mean age was 30.5 years,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

25% were male, and 100% were HBsAb positive. By 156 weeks of follow-up, 87.5% (28/32), 82.6% (19/23), 86.2% (25/29), and 100% (4/4) of patients maintained functional cure in groups 2, 1b, 3 and 4, respectively. Among the 12 patients who experienced relapse, 10 had only HBsAg relapse, with a mean HBsAg level of 0.129 ± 0.106 IU/mL at the time of relapse, while 2 had only HBV DNA relapse (≥20 IU/mL). Multivariate analysis revealed that the HBsAb level at the time of functional cure (OR 1.032, 95%CI 1.007-1.077, $p = 0.034$) served as an independent predictor of the durability of functional cure. **Conclusion:** PegIFNα-2b combination therapy induced durable functional cure, with maintenance rates exceeding 80% in NA-experienced patients and being 100% in treatment-naïve patients at 156 weeks of extended follow-up. Patients who relapsed after functional cure had extremely low HBsAg levels at the time of relapse, and higher HBsAb levels were associated with better durability of functional cure. These findings strongly support the proactive use of PegIFNα-based regimens to achieve sustained functional cure and safe treatment discontinuation in patients with CHB.

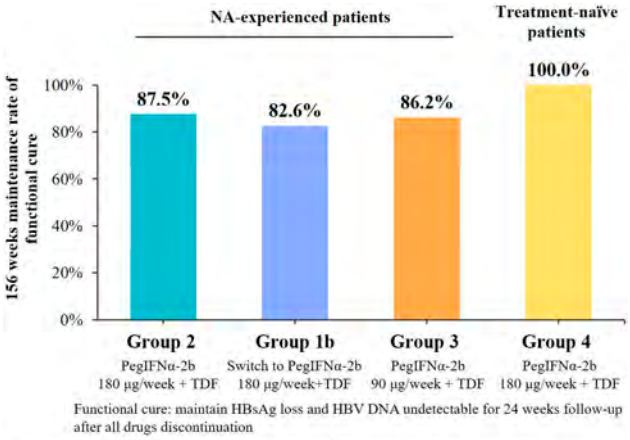

Figure 1. 156 weeks maintenance rate of functional cure in each group.

4112 | FUNCTIONAL CURE OF PEGINTERFERON ALFA-2B RETREATMENT IN CHRONIC HEPATITIS B PATIENTS WITH LOW HBSAG LEVELS AFTER INITIAL THERAPY IN A PHASE 3 STUDY

Fengqin Hou[1] Jia Shang[2] Qing Xie[3] Chunliang Lei[4] Jianmei Lin[5] Guoxin Hu[6] Zhiliang Gao[7] Yilan Zeng[8] Jiabin Li[9] Qianguo Mao[10] Liying Zhu[11] Jun Chen[12] Xiaozhong Wang[13] Zuxiong Huang[14] Jiming Zhang[15] Ping An[16] Xiulan Xue[17] Yan Huang[18] Tianyan Chen[19] Jianqi Lian[20] Yueyong Zhu[21] Huiling Xiang[22] Xinyue Chen[23] Hui Guo[24] Ruoyi He[25] Yalin Yin[25] Li Sun[25] Guiqiang Wang[26], [1]Peking University First Hospital, Beijing, 100034, China, [2]Henan Provincial People's Hospital, Zhengzhou, 450000, China, [3]Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, 200000, China, [4]Guangzhou Eighth People's Hospital, Guangzhou Medical University, Guangzhou, 510000, China, [5]Sichuan Provincial People's Hospital·Sichuan Academy of Medical Sciences, Chengdu, 610000, China, [6]Peking University Shenzhen Hospital, Shenzhen, 518000, China, [7]The Third Affiliated Hospital, Sum Yat-Sen University, Guangzhou, 510000, China, [8]Public Health Clinical Center of Chengdu, Chengdu, 610000, China, [9]The First Affiliated Hospital of Anhui Medical University, Hefei, 230000, China, [10]Xiamen Hospital of Traditional Chinese Medicine, Xiamen, 361000, China, [11]The Fourth Affiliated Hospital of Harbin Medical University, Harbin, 150001, China, [12]Shenzhen Third People's Hospital, Shenzhen, 518000, China, [13]Xinjiang Uygur Autonomous Region Hospital of Traditional Chinese Medicine, Urumqi, 830000, China, [14]Mengchao Hepatobiliary Hospital of Fujian Medical University, Fuzhou, 350000, China, [15]Huashan Hospital, Fudan University, Shanghai, 200040, China, [16]The Sixth People's Hospital of Shenyang, Shenyang, 110000, China, [17]The First Affiliated Hospital of Xiamen University, Xiamen, 361000, China, [18]Xiangya Hospital Central South University, Changsha, 410000, China, [19]The First Affiliated Hospital of Xi'an Jiaotong University, Xi'an, 710061, China, [20]The Second Affiliated Hospital of the Air Force Military Medical University of CPLA, Xi'an, 710038, China, [21]The First Affiliated Hospital of Fujian Medical University, Fuzhou, 350000, China, [22]Tianjin Third Central Hospital, Tianjin, 300170, China, [23]Beijing Youan Hospital, Capital Medical University, Beijing, 100000, China, [24]First Teaching Hospital of Tianjin University of Traditional Chinese Medicine, Tianjin, 300170, China, [25]Xiamen Amoytop Biotech Co. Background: Peginterferon alpha (PegIFNα) treatment induces functional cure in a considerable proportion of chronic hepatitis B (CHB) patients. However, still many patients fail to achieve this endpoint after initial therapy, and data on the efficacy of PegIFNα retreatment remain limited. This study investigated the efficacy of PegIFNα retreatment for patients who initially responded well but did not attain functional cure in a phase 3 study. **Methods:** This is a long-term follow-up study (NCT06707922) of a randomized controlled phase 3 trial (NCT04846491). At the end of the phase 3 trial, nucleos(t)ide analogue (NA)-experienced patients with HBsAg decline $\geq$ 1 $\log_{10}$ IU/mL and HBsAg level < 100 IU/mL, as well as treatment-naïve patients with HBsAg decline $\geq$ 1.5 $\log_{10}$ IU/mL and HBsAg level < 1500 IU/mL were enrolled in cohort 2. All patients initially received treatment with PegIFNα-2b (Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) 180 μg/week combined with tenofovir alafenamide fumarate (TAF) for 72 weeks, after which the drugs were discontinued and patients were followed up to 5 years. PegIFNα-2b was given intermittently in cycles (8 weeks of treatment + 4 weeks of interval, repeating every 12 weeks). The 24-week post-treatment follow-up was completed, and the data were analyzed here. **Results:** A total of 47 NA-experienced patients and 15 treatment-naïve patients were enrolled in cohort 2. The mean ages of the two populations were 42.5 ± 7.2 and 34.5 ± 7.9 years, and 85.1% and 66.7% were male. Among NA-experienced patients, the mean baseline HBsAg level was 13.0 ± 17.8 IU/mL, and all patients were negative for HBeAg and HBV DNA. Among treatment-naïve patients, the mean baseline HBsAg level was 272.8 ± 328.5 IU/mL, 73.3% were HBeAg negative and 100% were HBV DNA undetectable. During treatment, HBsAg levels in both NA-experienced and treatment-naïve patients gradually decreased with the extension of treatment duration. Among NA-experienced patients, the proportions achieving HBsAg loss with undetectable HBV DNA were 42.6% at week 48 and 46.8% at week 72. Furthermore, 36.2% of patients achieved functional cure at 24 weeks follow-up after discontinuation both TAF and PegIFNα-2b. The proportions of treatment-naïve patients who attained HBsAg loss with undetectable HBV DNA at weeks 48 and 72 were 26.7% and 40%, respectively, and the functional cure rate was 33.3%. **Conclusion:** The functional cure rate of PegIFNα-2b retreatment in both NA-experienced and treatment-naïve patients exceeded 30%. Patients who respond well initially to PegIFNα should be considered for PegIFNα retreatment to better pursue functional cure.

4113 | PROGNOSIS OF ENTECAVIR VERSUS TENOFOVIR IN HBV-RELATED HEPATOCELLULAR CARCINOMA: EVIDENCE FROM A NATIONWIDE COHORT

Chang Wook Park[1] Jin-Wook Kim[1] Sook-Hyang Jung[1] Min Kyung Park[2] Gwang Hyeon Choi[1] Eun Sun Jang[1], [1]Seoul National University Bundang Hospital, [2]Seoul National University Hospital

Background: While some reports suggest differential prognostic impacts of antiviral agents in hepatitis B virus (HBV)-related hepatocellular carcinoma (HCC), these findings often lack generalizability due to their single-center nature. We investigated the association between antiviral agent type and overall survival in patients with HBV-related HCC using a nationwide real-world cohort. **Methods:** Using the Korean Liver Cancer Registry database from 2014 to 2021, we identified patients with HBV-related HCC who received entecavir or tenofovir disoproxil fumarate as initial antiviral therapy. Overall survival was compared between groups using multivariable Cox regression analyses. To minimize potential confounding and selection bias, propensity score matching was additionally performed. **Results:** The ETV and TDF groups comprised 1,796 and 2,409 patients, respectively. The mean age was significantly lower in the TDF group than in the ETV group (57.1 vs. 58.8 years, $p < 0.001$). The proportion of male patients (80.6% vs. 76.7%, $p = 0.002$), those with Child–Pugh class B or C (22.8% vs. 21.4%, $p = 0.002$), and those with distant metastasis (13.3% vs. 10.7%) was significantly higher in the TDF group than in the ETV group. The proportion of patients who received curative treatment was 42.2% in the ETV group and 39.0% in the TDF group.During a mean follow-up of 50 months in the overall cohort, 2,175 deaths were observed. In multivariable Cox regression analysis of the overall cohort, TDF was independently associated with improved overall survival compared with ETV (HR

0.89, 95% CI 0.81–0.98; p = 0.023). This association remained significant in multivariable Cox regression analysis after propensity score matching (HR 0.88, 95% CI 0.79–0.98; p = 0.017). However, in stabilized inverse probability of treatment weighting analyses, TDF did not showed demonstrated a consistent favorable trend for overall survival compared with ETV (HR 0.90, 95% CI 0.79–1.03; p = 0.115). **Conclusion:** In this nationwide cohort of patients with HBV-related HCC, TDF was independently associated with modest improvement of overall survival compared with ETV after multivariable and propensity score-based adjustments.

4114 | HIGH TREATMENT ADHERENCE IS ASSOCIATED WITH LOWER HCC RISK IN CIRRHOSIS, AND TENOFOVIR ALAFENAMIDE IS ASSOCIATED WITH FAVORABLE OUTCOMES

Young Seok Kim[1], [1]Soon Chun Hyang University

Background: Adherence to antiviral therapy is essential for viral suppression in chronic hepatitis B (CHB), yet its effect on hepatocellular carcinoma (HCC) remains uncertain. We examined the association between nucleos(t)ide analogue (NA) adherence and HCC risk, focusing on tenofovir alafenamide (TAF) versus entecavir (ETV). **Methods:** Treatment-naïve adults with CHB initiating TAF or ETV were identified from the Korean National Health Insurance Service database. Adherence was measured using the medication possession ratio, with high adherence defined as ≥ 90%. The primary outcome was HCC incidence. **Results:** A total of 28,448 patients were included, of whom 19,001 (66.8%) showed high adherence and 9,447 (33.2%) low adherence. In the overall cohort, HCC incidence was comparable between high- and low-adherence groups (14.89 vs. 13.76 per 1,000 person-years; IRR 1.08, 95% CI 0.95–1.24). Among cirrhotic patients, however, high adherence was associated with substantially lower HCC incidence (32.92 vs. 49.59 per 1,000 person-years; IRR 0.66, 95% CI 0.57–0.78). Multivariable analysis confirmed high adherence as an independent protective factor (HR 0.77, 95% CI 0.66–0.90). Notably, within the high-adherence group, TAF was linked to a significantly lower HCC risk than ETV (HR 0.54 vs. 0.89; log-rank p < 0.001), whereas low adherence to either agent conferred no protection. Logistic regression further identified ETV use as a strong predictor of poor adherence (OR 2.80, 95% CI 2.65–2.96). **Conclusion:** High adherence to antiviral therapy reduces HCC risk in cirrhotic CHB patients. TAF was associated with higher adherence and lower HCC incidence than ETV, although causal inference beyond adherence is limited in this observational study.

4115 | IMPACT OF FAMILY HISTORY OF HEPATOCELLULAR CARCINOMA ON THE EFFICACY OF COMBINED PEG-IFN α-2B ANTIVIRAL THERAPY IN PATIENTS WITH CHRONIC HEPATITIS B

Huimin Liu[1] Lijian Ran[1] Siwei Miao[1] Li Jiang[1] Yan Zhu[1] Guohong Deng[1], [1]The First Affiliated Hospital of Army Medical University

Background: Although family history (FH)-positive hepatocellular carcinoma (HCC) is a recognized risk factor for disease progress in chronic hepatitis B (CHB), its effect on hepatitis B surface antigen (HBsAg) seroclearance during pegylated interferon α-2b (PEG-IFN α-2b) plus nucleos(t)ide analogues (NAs) therapy is unknown. This study aimed to explore the correlation between FH of HCC and HBsAg seroclearance in CHB patients treated with PEG-IFN α-2b plus NAs, and to identify independent risk factors associated with HBsAg seroclearance. **Methods:** Clinical data were retrospectively collected from 2108 CHB patients who received > 24 weeks of PEG-IFN α-2b plus NAs therapy at Southwest Hospital from May 2019 to February 2026. Patients were aged 5–67 years with baseline HBsAg ≤ 124925 IU/mL. All patients were divided into the FH group (n = 313) and non-FH group (n = 1795) based on whether they had FH of HCC. A 1:2 propensity score matching (PSM) was performed to balance baseline confounders, including demographic, hematological, biochemical, immunological, virological and adverse reaction-related indicators. The endpoint was HBsAg seroclearance (≤ 0.05 IU/mL). Logistic regression was used to find independent factors, and a nomogram was constructed. Receiver operating characteristic (ROC) curves, calibration curves, and decision curve analysis (DCA) were used to evaluate the discrimination, calibration and clinical utility of the model. **Results:** After PSM, 918 patients were enrolled, including 308 in the FH group and 610 in the non-FH group, with balanced baseline characteristics between the two groups (all P > 0.05) **(Tab.1)** . At the end of treatment, the FH group exhibited a significantly lower HBsAg seroclearance rate than the non-FH group (20.1% vs 26.1%, $\chi^2 = 3.95$, P = 0.047) **(Tab.2)** . Univariate logistic regression identified FH-positive HCC as a significant factor for HBsAg seroclearance, while multivariate regression further demonstrated that baseline HBsAg

(log10 level) (OR = 1.68, 95%CI: 1.55–1.83, P < 0.001) and treatment duration (OR = 0.96, 95%CI: 0.95–0.97, P < 0.001) were independent predictors **(Tab.3)** . A nomogram was established **(Fig.1A)** and showed superior discriminative performance compared with single baseline HBsAg or HCC FH alone(Fig.2). The model presented good agreement and clinical applicability, as verified by calibration curves **(Fig.1B)** and DCA **(Fig.1C)** . **Conclusion:** FH of HCC is not an independent risk factor for reduced HBsAg seroclearance in CHB patients treated with PEG-IFN α-2b plus NAs. Elevated baseline HBsAg level and shorter treatment duration are key factors contributing to lower HBsAg seroclearance rates.Therefore, clinical attention should be paid to baseline HBsAg levels in CHB patients with an FH-positive HCC. Sufficient courses of PEG-IFN α-2b plus NAs antiviral therapy are recommended for patients with high baseline HBsAg to improve the probability of HBsAg seroclearance.

4116 | COMPARATIVE RISK OF HEPATOCELLULAR CARCINOMA IN CHRONIC HEPATITIS B PATIENTS TREATED WITH TENOFOVIR ALAFENAMIDE VERSUS TENOFOVIR DISOPROXIL FUMARATE: A SYSTEMATIC REVIEW AND META-ANALYSIS

Xue Bai[1] Nan Geng[1] Jie Li[1], [1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University

Background: Tenofovir alafenamide (TAF) and tenofovir disoproxil fumarate (TDF) are widely used antiviral therapies for chronic hepatitis B (CHB). However, their relative efficacy in reducing hepatocellular carcinoma (HCC) remains uncertain. This meta-analysis aimed to compare HCC incidence rate ratios (IRRs) between CHB patients treated with TAF and TDF. **Methods:** PubMed, Embase, Web of Science, and the Cochrane Library were searched from inception to May 2025 for studies reporting HCC outcomes in TAF- vs. TDF-treated CHB patients. IRRs and cumulative incidence proportions (%) across different follow-up years were pooled using inverse-variance weighted meta-analysis and logit-transformed proportions, respectively, under common- and random-effects models. Heterogeneity was assessed by the I^2 statistic. This study was registered with PROSPERO (CRD42024618942). **Results:** Of 2,596 records screened, 11 studies comprising 63,409 CHB patients (TAF: 28,694; TDF: 34,715) were included. Over a median follow-up of 4,619 PYs, the TAF group showed a lower 5-year cumulative incidence (3.37% vs. 5.07%) of HCC compared to the TDF group. The pooled IRR was 0.74 (95% CI, 0.68, 0.81; P < 0.01), with no significant heterogeneity (I^2 = 0%; P = 0.76). The results of subgroup analyses by cohort type (whole vs. treatment-naive), follow-up years (≥5 vs. <5), continent (non-Asia vs. Asia), person year (accurate vs. estimated), sample size (≥1000 vs. <1000), and mean or median age (≥50 vs. <50) all favoured TAF. **Conclusion:** TAF is associated with a significantly lower incidence of HCC compared to TDF, which may provide insights for the clinical medication of CHB.

4117 | CLINICAL IMPACT OF COEXISTING MASLD ON LONG-TERM OUTCOMES AFTER SWITCHING TO TENOFOVIR ALAFENAMIDE IN PATIENTS WITH CHRONIC HEPATITIS B: A MULTICENTER COHORT STUDY

Eiichi Ogawa[1] Motoyuki Kohjima[2] Toshimasa Koyanagi[3] Kazufumi Dohmen[4] Aritsune Ooho[5] Akira Kawano[6] Norihiro Furusyo[7] Eiji Kajiwara[8] Takeaki Satoh[9] Kazuhiro Takahashi[10] Koichi Azuma[11] Rie Sugimoto[12] Yasunori Ichiki[13] Hiromasa Amagase[14] Masatake Tanaka[15] Hideyuki Nomura[16] Jun Hayashi[17], [1]Kyushu University Hospital, [2]NHO Kyushu Medical Center, [3]Fukuoka City Hospital, [4]Chihaya Hospital, [5]Steel Memorial Yawata Hospital, [6]Kitakyushu Municipal Medical Center, [7]Taihaku Avenue Clinic, [8]Kajiwara Clinic, [9]NHO Kokura Medical Center, [10]Hamanomachi Hospital, [11]Kyushu Central Hospital, [12]NHO Kyushu Cancer Center, [13]JCHO Kyushu Hospital, [14]Amagase Clinic, [15]Graduate School of Medical Sciences, Kyushu University, [16]Haradoi Hospital, [17]Kyushu University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly recognized in patients with chronic hepatitis B (CHB) and may contribute to fibrosis progression and liver-related complications. However, long-term data on the clinical impact of MASLD in CHB patients receiving tenofovir alafenamide (TAF) remain limited. We aimed to evaluate the long-term virological, biochemical, and renal outcomes of CHB patients switched from prior nucleos(t)ide analogues to TAF according to the presence or absence of coexisting MASLD. **Methods:** This multicenter study used a TAF treatment database and included 419 adult CHB patients without a history of hepatocellular carcinoma who were followed for 5 years after switching to TAF. Patients were stratified by MASLD status at baseline, defined at the time of TAF switch. Virological outcomes included the rate of HBV DNA suppression (< 10 IU/mL) and decline in hepatitis B surface antigen (HBsAg) level. Biochemical response was assessed by alanine aminotransferase (ALT) normalization. Renal safety was evaluated by changes in estimated glomerular filtration rate (eGFR). **Results:** At baseline, the mean age was 57.5 ± 12.6 years, 254 patients (61.4%) were male, 301 (72.7%) had normal ALT, 54 (13.0%) had cirrhosis, and 154 (36.8%) had MASLD. Prior antiviral therapy consisted of entecavir in 177 patients, tenofovir disoproxil fumarate in 122, and combination therapy in 115. At 5 years after switching to TAF, the rate of HBV DNA suppression increased significantly in both groups, from 88.3% to 100% in the MASLD group and from 87.2% to 99.6% in the non-MASLD group (both $P < 0.01$). Over 5 years of TAF therapy, the decline in HBsAg was comparable between the groups: 0.39 ± 0.43 logIU/mL in the MASLD group (annual decline, 0.078 logIU/mL) versus 0.35 ± 0.42 logIU/mL in the non-MASLD group (annual decline, 0.070 logIU/mL). ALT normalization improved in both groups, from 54.5% to 71.4% in the MASLD group and from 89.8% to 94.7% in the non-MASLD group; however, the ALT normalization rate remained significantly lower in patients with MASLD ($P < 0.01$). Change in eGFR over 5 years was similar between the groups (-4.53 ± 8.35 vs. -4.09 ± 10.9, respectively). **Conclusion:** Coexisting MASLD did not compromise long-term antiviral efficacy or renal safety after switching to TAF. However, patients with MASLD showed persistently lower biochemical response, suggesting that residual liver injury may be driven in part by metabolic dysfunction rather than insufficient viral control. Integrated metabolic management should therefore be considered alongside antiviral therapy in CHB patients with MASLD.

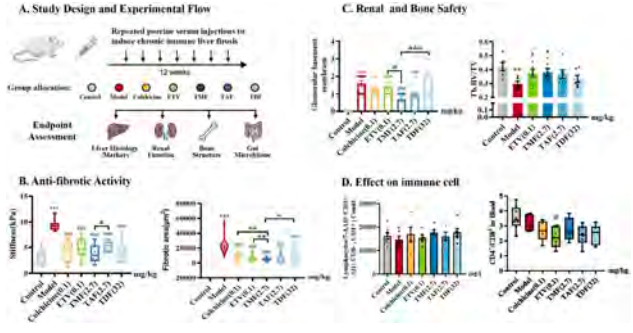
4118 | TENOFOVIR AMIBUFENAMIDE (TMF) IMPROVES LIVER FIBROSIS, RENAL FUNCTION, AND SKELETAL HEALTH IN A RAT MODEL OF CHRONIC IMMUNE-MEDIATED LIVER FIBROSIS



Zhizhen Hu[1] Yan Huo[1] Fanru Nie[1], [1]Jiangsu Hansoh Pharmaceutical Group Co., Ltd.

Background: Long-term anti-HBV therapy may adversely affect bone and renal function. Tenofovir amibufenamide (TMF) is a novel second-generation tenofovir prodrug with antiviral efficacy comparable to tenofovir disoproxil fumarate (TDF) and a more favourable safety profile in phase III trials. The underlying mechanisms remain incompletely understood. This study compared antifibrotic, renal, skeletal, and immunological effects of TMF with other nucleos(t)ide analogues in a rat model of chronic immune-mediated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

liver fibrosis. **Methods:** Rats were randomized by body weight into 7 groups (n = 16 per group): control, model, colchicine, entecavir (ETV), TMF, tenofovir alafenamide (TAF), and TDF. Chronic immune-mediated liver fibrosis was induced by repeated porcine serum injections. Control and model groups received 0.5% CMC-Na solution; others received corresponding medications at clinically equivalent doses once daily, 6 days weekly for 12 weeks. Liver fibrosis was evaluated by ultrasound elastography, histopathology, serum fibrosis markers, and hepatic hydroxyproline content. Renal function was assessed using renal injury biomarkers and renal histopathological analysis. Skeletal parameters were determined by dual-energy X-ray absorptiometry and micro-computed tomography. Hematologic parameters and immune cell profiles were analyzed by automated hematology analysis and flow cytometry (Figure 1A). **Results:** TMF significantly reduced liver stiffness compared with the model group (3.82 ± 1.82 vs 9.35 ± 1.07 kPa; $P < 0.001$) and showed greater reduction than TAF ($P < 0.05$). TMF improved hepatocellular necrosis and portal inflammation, reduced lesion area (0.01 ± 0.00 vs 0.18 ± 0.05 μm²; $P < 0.001$) and decreased fibrotic area (5015.91 vs 23257.86 μm²; $P < 0.001$) versus model, ETV($P < 0.01$) and TDF ($P < 0.05$) (Figure 1B). Despite similar routine renal parameters, TMF lowered cystatin C and improved renal protection versus model (3.10 ± 1.37 vs 8.50 ± 2.42; $P < 0.001$), ETV ($P < 0.05$) and TDF ($P < 0.001$) (Figure 1C). TMF preserved bone mineral density (BMD) and significantly increased bone volume fraction (BV/TV: 0.381 ± 0.064 vs 0.297 ± 0.045; $P < 0.05$) versus model, whereas TDF showed lower BMD and weaker skeletal benefits than TMF. TMF also numerically elevated immune cells versus the model group with no statistical significance (Figure 1D). **Conclusion:** In a rat model of chronic immune-mediated liver fibrosis, TMF provides superior antifibrotic, renal and skeletal protection with potential immunomodulatory benefits. These findings support further investigation of TMF as an anti-HBV therapy with benefits beyond viral suppression.

4119 | EARLY HBSAG DECLINE WITH PRADEFOVIR MESYLATE-BASED STRATEGIES IN CHRONIC HEPATITIS B: A REAL-WORLD EXPLORATORY STUDY

Yingying Zhang[1] Jinghan Zhu[1] Yiling Chen[2] Heqing Huang[1] Hong Lu[1] Zutao Chen[1], [1]The Fourth Affiliated Hospital of Soochow University, [2]Medical College of Soochow University

Background: HBsAg clearance remains difficult to achieve with long-term nucleos(t)ide analogue therapy in chronic hepatitis B. Pradefovir mesylate (PDF) is a novel anti-HBV agent, but its early serological effect in patients with different treatment backgrounds remains insufficiently characterized. We evaluated HBsAg kinetics and safety during PDF-based therapy in patients with chronic hepatitis B. **Methods:** This exploratory real-world study included 113 patients with chronic hepatitis B receiving PDF-based treatment. Patients were categorized into four groups: switch from nucleos(t)ide analogues to PDF without recent pegylated interferon-α (PegIFN-α) exposure; PDF monotherapy after prior nucleos(t)ide analogue plus PegIFN-α therapy; treatment-naïve PDF monotherapy; and treatment-naïve PDF plus PegIFN-α. HBsAg changes at weeks 12 and 24 were assessed, together with the proportions of patients achieving HBsAg reductions > 0.5 and > 1 log10 IU/mL. Safety was evaluated using liver and renal function, platelet count, uric acid, and lipid parameters. **Results:** Baseline characteristics differed across groups, reflecting distinct treatment backgrounds. At week 12, early HBsAg decline was already observed in selected patients, particularly among treatment-naïve patients receiving PDF plus PegIFN-α, although the magnitude of decline became more evident by week 24. At week 24, the greatest HBsAg decline was observed in this group, with a median reduction of 0.50 log10 IU/mL from baseline (P = 0.049). In this group, 50.0% and 33.3% of patients achieved HBsAg reductions > 0.5 and > 1 log10 IU/mL, respectively. Patients receiving PDF monotherapy after prior nucleos(t)ide analogue plus PegIFN-α therapy also showed notable serological responses, with 39.3% and 28.6% achieving HBsAg reductions > 0.5 and > 1 log10 IU/mL at week 24, respectively. No clear signal of renal impairment or lipid deterioration was observed. Isolated fluctuations in liver function and platelet-related parameters did not show a consistent pattern attributable to PDF treatment. **Conclusion:** PDF-based therapy was associated with early HBsAg decline in selected patients with chronic hepatitis B, particularly when combined with PegIFN-α in treatment-naïve

patients or used after prior PegIFN-α-based therapy. These findings suggest that PDF may be a promising component of treatment strategies aimed at enhancing HBsAg reduction. Larger prospective studies are warranted to confirm the optimal patient population and therapeutic strategy.

4120 | KINETIC CHARACTERIZATION OF HBV DNA, HBSAG AND ALT AFTER DISCONTINUATION OF NA TREATMENT IN PATIENTS WITH CHRONIC HEPATITIS B

Leeor Hershkovich[1] Gustaf Rydell[2] Johan Ringlander[2] Scott Cotler[1] Harel Dahari[1] Magnus Lindh[2], [1]Loyola University Chicago, [2]University of Gothenburg

Background: Detailed HBV kinetic characterization after nucleos(t)ide analog (NA) discontinuation is lacking. We aim to characterize the kinetics of HBV DNA, HBsAg, and ALT during the first ~1 year post NA treatment cessation. **Methods:** 26 patients with chronic HBV who were receiving NA and were candidates for discontinuation of NA therapy were prospectively enrolled at 3 medical centers in Sweden. After NA stopped, blood samples were collected frequently (Fig.1). NA treatment was resumed in 8 patients in the first year (6 due to severe flare, 2 due to unsatisfactory outcome) were excluded in this analysis. **Results:** For the 18 participants who did not restart NA, median baseline HBsAg was 3.1 log IU/mL (IQR 2.2-3.4) and median baseline ALT was 22.4 U/L (IQR 18.4-38.1). While baseline HBV DNA was at or below LLoQ for 16/18 participants, 2 patients had baseline viral load of 2.8 and 3.0 log IU/mL. 6 participants experienced a decline (>0.59 log) in HBsAg (Fig.1A, B), while the remaining 12 had stable HBsAg (Fig.1C, D) after NA was stopped. Among the 6 participants with a HBsAg decline, the median reduction from baseline was 1.4 log (IQR 0.8-2.6) by the end of 60 weeks, including one who achieved undetectable HBsAg (Fig.1A). The HBsAg decline group had significantly lower (p = 0.001) median baseline HBsAg (2.1 log IU/mL, IQR 2.0-2.2) compared to the stable HBsAg group (3.3 log IU/mL, IQR 3.1-3.5).All patients (except for one, with baseline viral load at 2.8 log IU/mL) had a rise in virus after NA was stopped, which peaked at median week 8.1 (IQR 8.0-8.9) with median magnitude 4.3 log IU/mL (IQR 3.9-5.0). The increase in viral load was similar between the HBsAg stable and decline groups. Interestingly, 2 participants in the HBsAg stable group had a very slow rise in viral load (Fig.1D), which peaked at median week 22, followed by a plateau. Following a peak, all those with HBsAg decline (n = 6/6) also experienced an immediate decline in viral load to <2 log IU/mL by week 20 (Fig.1A, B). Only 2/12 (17%) participants with stable HBsAg experienced a similar viral decline; the rest (n = 10/12) had a viral decline after the peak which did not fall below 2 log IU/mL and then plateaued (Fig.1C, D).Three participants had transient ALT increases with peaks above 5x upper the limit of normal (ULN), of whom one was in the stable HBsAg group (>7x ULN), and two were in the HBsAg decline group, with peak values 9x ULN (Fig.1A) and 23x ULN. **Conclusion:** The combination of baseline HBsAg below 2.5 log IU/mL, and a viral pattern characterized by a rise in viral load followed by a return to <2 log IU/mL by week 20 post treatment cessation were predictive of HBsAg decline (>0.5 log) within the first year, with 100% PPV and 92% NPV for HBsAg decline.

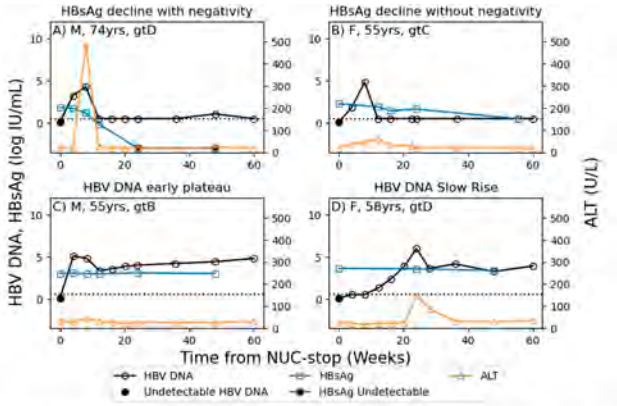

Figure 1: Representative kinetics in the first 60 weeks after stopping NA therapy, including ALT, HBV DNA (Cobas 6800, Roche; LLoQ 10 IU/mL), and HBsAg (Alinity, Abbott; LLoQ 0.05 IU/mL). **(A)** Shows the one participant with HBsAg decline that reaches TND, and **(B)** shows an example of HBsAg decline (>0.5 log) without reaching negativity. **(C)** Shows an example of stable HBsAg with an early HBV DNA plateau, while **(D)** shows an example of stable HBsAg with a slow HBV DNA rise. Dotted horizontal line shows HBV DNA LLoQ, filled markers represent undetectable HBV DNA or HBsAg. Each figure includes the sex (M or F), age, and HBV genotype of the displayed participant. Normal ALT was defined as 45 U/L for male and 30 U/L for female participants.

MIng Chiao Tung University, Taiwan, [5]I-Shou University

Background: Antiviral therapy for chronic hepatitis B (CHB) reduces the risk of hepatocellular carcinoma (HCC), but its real-world uptake before HCC development remains poorly characterized at the population level. There is a paucity of nationwide data to clarify the magnitude of this care gap and to characterize patients who missed the opportunities of using antiviral therapy to prevent HCC. We aimed to quantify, at the national level, the proportion of patients with CHB who developed HCC without prior antiviral therapy, and to compare clinical and healthcare-utilization profiles between treated and untreated patients. **Methods:** We conducted a nationwide retrospective cohort study using the National Health Insurance Laboratory Databases (NHILD) in Taiwan. All adults with CHB who developed incident HCC between January 1, 2016, and December 31, 2023, were included. Antiviral exposure prior to HCC was ascertained from prescription records. Laboratory values within ±90 days of HCC diagnosis were extracted, with the most recent measurement per patient retained. We compared characteristics of patients with and without antiviral treatment prior to HCC diagnosis. **Results:** We identified a total of 34,550 patients with HBV-related HCC (median age 63.44 years; 78.81% male; 29.46% with cirrhosis, at the diagnosis of HCC), and 68.74% (23,751/34,550) had not received antiviral therapy before HCC diagnosis. Compared with treated patients, untreated patients had higher serum ALT (median 43 vs 30 U/L, $p < .0001$), AST (56 vs 34 U/L, $p < .0001$), and HBV DNA (4.51 vs 0 $\log_{10}$ IU/mL, $p < .0001$). Notably, the platelet counts were significantly higher in untreated patients (188 vs 148 $\times 10^9$/L, $p < .0001$), indicating less pronounced liver fibrosis. Prior to HCC development, untreated patients had significantly fewer ALT measurements (1.01 vs 2.59 per year, $p < .0001$), HBV DNA tests (0 vs 0.28 per year, $p < .0001$), and abdominal ultrasounds (0.30 vs 1.22 per year, $p < .0001$). Pre-HCC antiviral coverage rose from 24.28% in 2016 to 39.40% in year 2023. **Conclusion:** Approximately 68.74% of patients who developed HBV-related HCC in Taiwan had not received antiviral therapy before HCC diagnosis. Our findings indicate persistent gaps in the CHB care cascade in Taiwan despite universal health insurance coverage, highlighting the need to strengthen linkage to care and expand treatment eligibility.

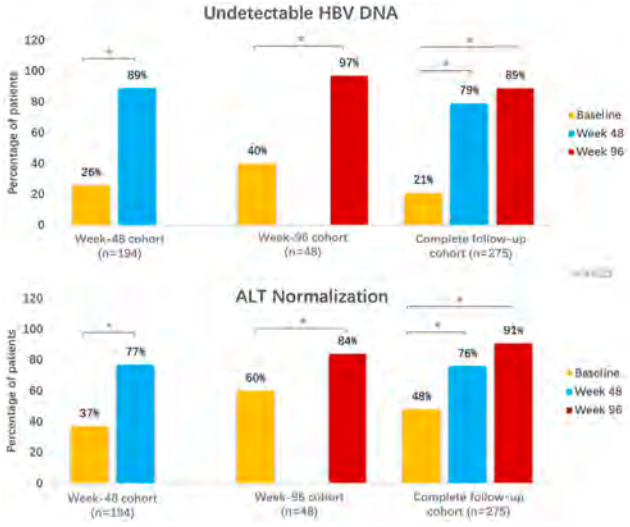
4122 | TENOFOVIR ALAFENAMIDE IN DECOMPENSATED HEPATITIS B CIRRHOSIS: MULTICENTER REAL-WORLD OUTCOMES THROUGH 48-96 WEEKS



Hu Li[1] Li Liu[2] Huagang Xiong[3] Xiaozhong Wang[4] Songsong Xie[5] Li Shi[6] Wenjuan Shi[7] Guicheng Wu[8] Shujun Zhang[9] Quan Zhang[10] Basa Zhuoga[11] Guangying Shi[12] Yongping Zhang[13] Huiyan Zhang[14] Zhengjie Chen[1] Lu Zhang[1] Dachuan Cai[1] Peng Hu[1] Hong Ren[1], [1]The Second Affiliated Hospital of Chongqing Medical University, Chongqing, China, [2]Kunming Third People's Hospital, Yunnan, China, [3]Guiyang Public Health Clinical Center, Guizhou, China, [4]Traditional Chinese Medical Hospital Affiliated to Xinjiang Medical University, Xinjiang, China, [5]The First Affiliated Hospital of Shihezi University, Xinjiang, China, [6]People's Hospital of Tibet Autonomous Region, Tibet, China, [7]The No.2 People's Hospital of Lanzhou, Gansu, China, [8]Chongqing University Three Gorges Hospital, Chongqing, China, [9]The First Affiliated Hospital of Chongqing Medical University, Chongqing, China, [10]The Affiliated Hospital of Guizhou Medical University, Guizhou, China, [11]The Third People's Hospital of Tibet Autonomous Region, Tibet, China, [12]Hospital of Xinjiang Production and Construction Corps, Xinjiang, China, [13]People's Hospital of Xinjiang Uyghur Autonomous Region, Xinjiang, China, [14]The Third Affiliated Hospital of Chongqing Medical University, Chongqing, China

Background: Evidence for tenofovir alafenamide (TAF) in decompensated hepatitis B (HBV) cirrhosis is limited. We assessed real-world antiviral effectiveness and safety of TAF in this population. **Methods:** We performed a multicenter retrospective study across 14 hospitals (April 2017–March 2026). Adults with decompensated HBV cirrhosis treated with TAF were followed for 48 or 96 weeks. The primary efficacy indicator was hepatitis B virus (HBV) DNA seronegative conversion rate at 48 and 96-weeks, and the secondary efficacy indicator was alanine aminotransferase (ALT) normalization rate at 48 and 96-weeks. Safety assessments included renal function, lipid parameters, and adverse drug reactions. **Results:** A total of 517 cases from 14 hospitals were included. Of these, 340 were males, with a median age of 52 years (range 21–81). Follow-up comprised three non-overlapping cohorts: 194 patients

had data through week 48, 48 through week 96 (without week 48), and 275 had complete assessments at baseline, week 48, and week 96. In the week-48 cohort (n = 194), the proportion with undetectable HBV DNA increased from 26.09% (49/184) at baseline to 88.55% (147/166) at week 48 ($p < 0.05$), and ALT normalization increased from 39.69% (77/194) to 77.32% (150/194) ($p < 0.05$). In the week-96 cohort(n = 48), undetectable HBV DNA improved from 39.53% (17/43) to 86.05% (37/43) at week 96 ($p < 0.05$), and ALT normalization rose from 59.57% (28/47) to 84.44% (38/45) ($p < 0.05$). In the complete follow-up cohort(n = 275), undetectable HBV DNA increased from 21.05% (56/266) at baseline to 79.10% (212/268) at week 48 and 88.85% (239/269) at week 96 (both $p < 0.05$); ALT normalization increased from 47.64% (131/275) to 75.75% (203/268) at week 48 and 91.39% (244/267) at week 96 (both $p < 0.05$). For safety profile, renal function and lipid parameters remained stable after 48 or 96 weeks versus baseline (all $p > 0.05$), with no new safety signals. **Conclusion:** In this large multicenter real-world cohort of decompensated HBV cirrhosis, TAF was associated with robust viral suppression and improved ALT normalization through 96 weeks, with stable renal and lipid safety profiles.

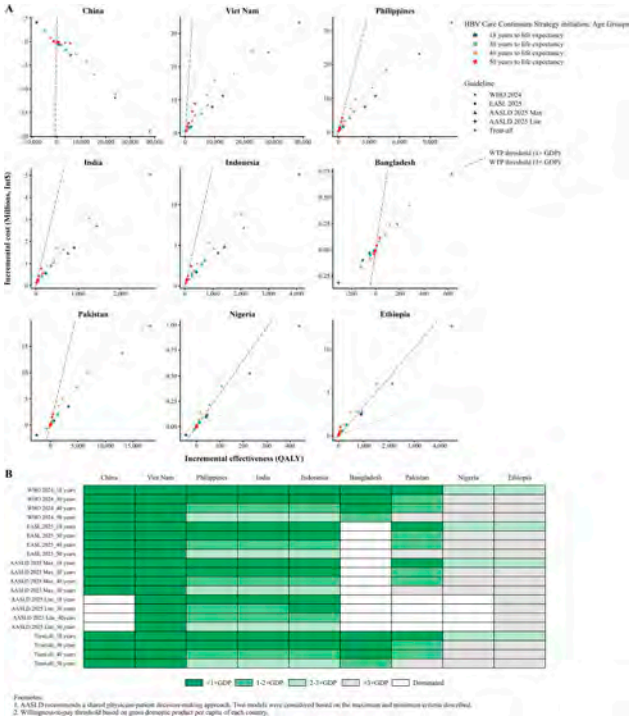
4123 | COST-EFFECTIVENESS ANALYSIS OF CHRONIC HEPATITIS B TREATMENT EXPANSION GUIDELINE RECOMMENDATIONS IN THE TOP NINE COUNTRIES WITH MAJOR GLOBAL BURDEN



Hanting Li[1] Jiandong Zhou[2] Dijing You[2] Polin Chan[3] Hong You[4] Jie Li[5] Ajeet Bhadoria[6] Amit Goel[7] Cosmas Rinaldi Lesmana[8] Andri Sanityoso Sulaiman[8] Solomon Obekpa[9] Danjuma Adda[10] Hailemichael Desalegn[11] Shahinul Alam[12] Vo Thong[13] Minh Khuê Pham[14] Pham Chi Tran[15] Janus Ong[16] Ian Homer Cua[17] Saeed Hamid[18] Lung Yi Mak[2] Man-Fung Yuen[2] Mindie Nguyen[19] Lei Zhang[20] William Cw Wong[2] Wai-Kay Seto[2], [1]School of Public Health, Sun Yat-sen University, Guangzhou, China, [2]The University of Hong Kong, [3]World Health Organization South-east Asia Regional Office, [4]Capital Medical University, Beijing, China, [5]Nanjing Drum Tower Hospital, Nanjing University, Nanjing, China, [6]All India Institute of Medical Sciences (AIIMS), Uttarakhand, India, [7]Sanjay Gandhi Postgraduate Institute of Medical Sciences, India, [8]Dr. Cipto Mangunkusumo National General Hospital, Medical Faculty Universitas Indonesia, [9]National Postgraduate Medical College of Nigeria, Lagos, Nigeria, [10]Centre For Initiative and Development, Taraba, Nigeria, [11]St Paul's Hospital, Millennium Medical College, Addis Ababa, Ethiopia, [12]Bangabandhu Sheikh Mujib Medical University, Dhaka, Bangladesh, [13]University of Medicine and Pharmacy, [14]Faculty of Public Health , Haiphong University of Medicine and Pharmacy, Vietnam, [15]Hue Central Hospital, Vietnam, [16]University of the Philippines, Manila, Philippines, [17]St. Luke's Medical Center, [18]Aga Khan University, Karachi, Pakistan, [19]Stanford University Medical Center, [20]Monash University, Melbourne, Australia

Background: Recent international chronic hepatitis B (CHB) guidelines, including updated recommendations from the World Health Organization (WHO), European Association for the Study of the Liver (EASL), & American Association for the Study of Liver Diseases (AASLD), have substantially expanded and simplified eligibility criteria for antiviral treatment. The cost-effectiveness of implementing these strategies across endemic countries remains uncertain. We evaluated the cost-effectiveness of major international CHB treatment expansion recommendations in nine countries: China, India, Indonesia, Nigeria, Ethiopia, Bangladesh, Vietnam, Philippines & Pakistan, which together account for more than two-thirds of the global hepatitis B virus infected population. **Methods:** A state-transition Markov model was developed to simulate the natural history and management of CHB in the nine countries. Treatment expansion recommendations based on WHO 2024, EASL 2025, two models of AASLD 2025 ("Max" & "Lite" based on shared decision-making), & "Treat-all" were compared. Analyses were conducted across multiple CHB care continuum strategies (diagnosis to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

disease monitoring to treatment) initiation ages, from 18, 30, 40, & 50 years, over a lifetime horizon from a healthcare payer perspective. Quality-adjusted life years (QALYs) & incremental cost-effectiveness ratios (ICERs) were assessed against country-specific willingness-to-pay (WTP) thresholds based on gross domestic product per capita. **Results:** When comparing WHO, EASL and AASLD guidelines (Figure 1), China demonstrated cost-saving outcomes across nearly all strategies initiation ages, with negative ICERs (USD $-497 to $-46/QALY) observed. The expanded strategy strategies were cost-effective in Vietnam, Philippines, India & Indonesia with WHO_18 being the most cost-effective (ICERs $864/QALY, $2919/QALY, $1881/QALY & $3369/QALY respectively). EASL & AASLD remained cost-effective but at greater costs with fewer QALYs averted. ICERs increased incrementally with older age of strategy initiation; Pakistan ($1052/QALY for WHO_18) loses cost-effectiveness for all strategies with initiation at 50 years. Only WHO was cost-effective in Bangladesh ($1357/QALY at 18 yrs), while cost-effectiveness in Nigeria and Ethiopia was limited to initiation at 18 years ($2313/QALY & $2853/QALY for WHO_18). Treat-all approaches generally produced the lowest ICERs across initiation ages. **Conclusion:** Expanded antiviral treatment eligibility strategies for CHB were generally cost-effective in countries with the highest global HBV burden, particularly when strategy was initiated at an earlier age. WHO 2024 and Treat-all consistently produced the lowest ICERs, supporting the potential economic value of broader treatment expansion. Cost-effectiveness varied substantially across settings & was more limited in lower-income countries with lower WTP thresholds.

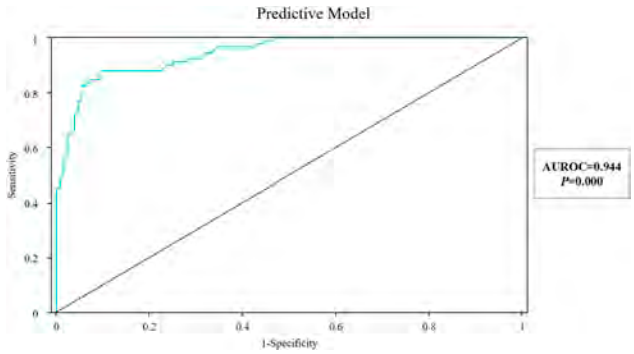
4124 | EFFICACY AND SAFETY OF TENOFOVIR ALAFENAMIDE FOR CHRONIC HEPATITIS B PATIENTS WITH ADVANCED FIBROSIS AND PARTIAL VIROLOGIC RESPONSES TO ORAL NUCLEOS(T)IDE ANALOGUES

Ming-Lun Yeh[1], [1]Kaohsiung Medical University Hospital

Background: On-treatment low-level viremia (LLV) is associated with an increased risk of hepatocellular carcinoma (HCC) compared to maintained virological response. However, management strategies for chronic hepatitis B (CHB) patients with a partial response to nucleot(s)ide analogues (NUCs) remain poorly defined. This study evaluated the efficacy and safety of switching to tenofovir alafenamide (TAF) in CHB patients with advanced fibrosis and a partial response to prior NUC therapy. **Methods:** This prospective study enrolled CHB patients with advanced fibrosis who had received non-TAF NUC therapy for >52 weeks but remained DNA-detectable. All participants were switched to TAF 25 mg/day for 96 weeks. Efficacy was measured by virological response (HBV DNA <20 IU/mL), biochemical response (ALT normalization per AASLD criteria), and changes in liver stiffness and HBsAg titers. **Results:** Sixty-eight patients were enrolled (median age 56 years; 51.5% male; 47.1% HBeAg-positive); 60 patients completed 96 weeks of treatment. Prior therapies included entecavir (75.0%) and TDF (19.7%). The virological response rate increased significantly over time, reaching 75.0% (45/60) at week 96. Combined virological and biochemical response was achieved by 53.3% of patients at week 96. Among HBeAg-positive patients, HBeAg loss and seroconversion occurred in 13.3% and 10.0%, respectively. Median HBsAg titers significantly declined from 1803 IU/mL at baseline to 1135 IU/mL at week 96 ($P < 0.05$). Furthermore, median liver stiffness improved from 7.7 kPa to 6.0 kPa, with the proportion of patients achieving liver stiffness <9.5 kPa increasing from 57.4% to 80.0%. Renal function (eGFR/creatinine) and body weight remained stable. Eight patients discontinued early, including two unrelated deaths. Four cases of new-onset HCC were identified during study period. **Conclusion:** In CHB patients with advanced fibrosis and a partial response to prior NUCs, switching to TAF effectively suppresses viral replication, promotes HBsAg decline, and leads to a significant reduction in liver stiffness.

Disclosures: Ming-Lun Yeh:Nothing to Disclose.



4125 | IDENTIFICATION OF NEW EARLY PREDICTIVE MARKERS FOR HBSAG LOSS IN PATIENTS WITH CHRONIC HEPATITIS B UNDERGOING 24-WEEK PEGYLATED INTERFERON α-2B TREATMENT

Min Qiu[1] Jiaqi Pan[1] Ka Zhang[1], [1]the Third Affiliated Hospital of Sun Yat-Sen University

Background: The loss of hepatitis B surface antigen (HBsAg) is considered an optimal outcome in the treatment of chronic hepatitis B (CHB) with pegylated interferon α-2b (Peg-IFN α-2b). However, the availability of reliable early predictive markers remains limited. **Methods:** CHB patients who underwent 24 weeks of Peg-IFN α-2b therapy were categorized into two cohorts: HBsAg loss and non-loss groups. Analyses were conducted to find predictors of HBsAg loss and evaluate the early predictive value of on-treatment HBsAg levels and CBC-derived inflammatory indices for HBsAg loss at week 24. **Results:** HBsAg loss was observed in 91 of the 242 participants (37.6%) following a 24-week regimen of Peg-IFN α-2b therapy. Participants with HBsAg loss had much lower initial HBsAg levels (15.1IU/mL) than those without loss (313IU/mL, $P = 0.01$). Independent predictors of HBsAg loss at week 24 included age (OR = 0.912, $P = 0.003$), sex (OR = 0.103, $P = 0.005$), HBsAg level at week 12 (OR = 0.075, $P < 0.001$), neutrophil to lymphocyte ratio (NMLR) at week12 (OR = 0.222, $P = 0.005$), systemic immune inflammation response index (SIRI) at week 12 (OR = 11.48, $P = 0.001$), and hemoglobin (HGB) decline at week 12 (OR = 0, $P = 0.019$). A predictive model using these variables showed high accuracy for forecasting HBsAg loss at week 24, with an ROC AUC of 0.944 (95% CI: 0.916-0.972), indicating early predictive value in clinical practice. **Conclusion:** At week 12, on-treatment HBsAg levels and CBC-derived inflammatory indices (NMLR, SIRI, and HGB decline) are useful early indicators for predicting HBsAg loss in CHB patients undergoing 24 weeks of Peg-IFN α-2b therapy. Baseline age and sex also independently predict outcomes.

4126 | PREDICTORS OF HBEAG LOSS AND NOMOGRAM DEVELOPMENT IN PATIENTS WITH CHRONIC HEPATITIS B TREATED WITH PEGINTERFERON α-2B

Shiyu Wang[1] Wen Deng[1] Weihua Cao[1] Yaqin Zhang[1] Xin Wei[1] Zixuan Gao[1] Linmei Yao[1] Shuojie Wang[1] Yao Xie[1] Minghui Li[1], [1]Department of Hepatology Division 2, Beijing Ditan Hospital, Capital Medical University, Beijing

Background: To develop a predictive model using LASSO regression based on serological and clinical indicators for achieving hepatitis B e antigen (HBeAg) seroconversion at week 48 of pegylated interferon alpha-2b therapy in patients with chronic hepatitis B, and to evaluate its predictive performance. **Methods:** A total of 192 patients with chronic hepatitis B who received PEG-IFNα-2b therapy and completed 48 weeks of follow-up were enrolled. Clinical and laboratory data were collected at baseline and week 12. Patients were classified into HBeAg seroconversion and non-seroconversion groups according to week-48 HBeAg status. Between-group comparisons were performed using t-test, Wilcoxon rank-sum test, or chi-square test, as appropriate. Candidate predictors were screened by univariate analysis and LASSO regression, followed by multivariate logistic regression to establish a predictive model. A nomogram was constructed, and model performance was assessed using ROC analysis, bootstrap validation, calibration curves, decision curve analysis, and clinical impact curves. **Results:** Among 192 patients with chronic hepatitis B, 25 achieved HBeAg seroconversion at week 48 of treatment. Eleven variables—age, sex, NA_type, HBsAg_0log, HBeAg_0log, HBVDNA_0log, HBsAg_drop12, HBeAg_drop12, HBVDNA_drop, ALT_change12, and PLT_drop12—were included in the LASSO regression. After LASSO regression selection, HBsAg_0log, HBeAg_0log, and HBeAg_drop12 were incorporated into multivariate logistic regression analysis. Multivariate analysis showed that HBsAg_0log (OR = 0.67, 95% CI: 0.42–0.69), HBeAg_0log (OR = 0.45, 95% CI: 0.24–0.83), and HBeAg_drop12 (OR = 7.22, 95% CI: 2.90–17.90) were independent predictors of HBeAg seroconversion at week 48. A nomogram prediction model was constructed based on these variables, yielding an area under the ROC curve (AUC) of 0.791. After 1,000 bootstrap internal validations, the model demonstrated good discriminative ability and stability. The calibration curve showed good agreement between predicted probabilities and actual observations, and decision curve analysis indicated favorable clinical net benefit across a wide range of threshold probabilities. **Conclusion:** A nomogram based on HBsAg_0log, HBeAg_0log, and HBeAg_drop12 was developed using LASSO regression incorporating patient baseline characteristics and serological indicators. This model can predict the probability of HBeAg seroconversion in CHB patients treated with PEG-IFNα-2b, and may serve as a valuable reference for clinical decision-making.

Stomatological Hospital of Nanjing Medical University, [4]The Affiliated Infectious Diseases Hospital of Soochow University, [5]Xi'an Eighth Hospital, School of Medicine (SOM), Xi'an Jiaotong University, [6]Nanjing Second Hospital, Nanjing University of Chinese Medicine, [7]Huai'an No. 4 People's Hospital, [8]Zhongda Hospital, School of Medicine, Southeast University

Background: Low serum hepatitis B surface antigen (HBsAg) levels (< 100 IU/mL) was associated with a reduced risk of adverse outcomes in patients with chronic hepatitis B (CHB). The long-term benefit of antiviral therapy in CHB patients with low HBsAg levels is not clear. This study compared the clinical outcomes between untreated and treated HBeAg-negative CHB patients with low HBsAg. **Methods:** A total of 949 HBeAg-negative CHB patients with HBsAg < 100 IU/mL, detectable HBV DNA, ALT < 2 times of upper limit of normal (40 U/L) and without liver cirrhosis were enrolled from six medical centers in China. Inverse probability of treatment weighting (IPTW) and propensity score matching (PSM) were performed to balance the baseline characteristics between groups. The clinical outcomes of this study were liver-related events (LREs, including hepatocellular carcinoma and cirrhosis) and HBsAg seroclearance. **Results:** During a median follow-up of 2.9 years, 26 patients developed LREs and 51 achieved HBsAg seroclearance. 41.3% of patients received nucleos(t)ide analogues (NAs) treatment. After IPTW, untreated group had a significantly higher 6-year cumulative incidence of LREs than NA-treated group (10.5% vs. 2.4%, P = 0.004). In the multivariable Cox regression, NA treatment was associated with low risk of LREs (adjusted hazard ratio [aHR]: 0.26, 95% confidence interval [CI]: 0.09-0.77, *P* = 0.015), while family history of of HCC or cirrhosis (aHR: 5.43, 95% CI: 1.68-17.51, *P* = 0.005) and mildly elevated ALT (1-2×ULN) (aHR: 2.85, 95% CI: 1.22-6.68, *P* = 0.016) were associated with higher risk of LREs. Results remained consistent after excluding patients with significant liver fibrosis at baseline. However, NA treatment was not significantly associated with HBsAg seroclearance. Similar findings were observed in the PSM cohort. **Conclusion:** HBeAg-negative CHB patients with low HBsAg levels, detectable HBV DNA, and mildly elevated ALT may still benefit from NA treatment, with a reduced risk of LREs.

4128 | PREDICTIVE VALUE OF FAMILY HISTORY OF HEPATITIS B FOR HBSAG CLEARANCE AFTER PEGYLATED INTERFERON ALPHA-2B TREATMENT AND SUBGROUP ANALYSIS

Jun Li[1] Yiwen Zhang[1] Qin Du[2] Yanchao Fu[3] Jiayin Wang[3] Chao Yang[3] Jing Liang[3] Qing Ye[3] Huiling Xiang[3], [1]The Third Central Clinical College of Tianjin Medical University, [2]Nankai University Affiliated Third Central Hospital, [3]Tianjin University Central Hospital (Tianjin Third Central Hospital)

Background: To investigate whether a family history of hepatitis B virus (HBV) infection independently predicts hepatitis B surface antigen (HBsAg) clearance in patients with chronic hepatitis B (CHB) receiving pegylated interferon alpha-2b (Peg-IFNα-2b) and to identify the patient subgroups in which this association is most pronounced. **Methods:** This single-center, retrospective cohort study consecutively enrolled 1384 CHB patients who received Peg-IFNα-2b for ≥ 12 weeks between December 2021 and September 2025 at Tianjin University Central Hospital. Patients were categorized according to the presence or absence of a family history of HBV infection. Multivariable logistic regression was used to adjust for baseline confounders and evaluate the independent effect of family history on HBsAg clearance. Pre-specified subgroup analyses were performed stratified by sex, age, HBV DNA level, HBsAg level, hepatitis B e antigen (HBeAg) status, cirrhosis, and metabolic dysfunction-associated steatotic liver disease (MASLD) to explore potential heterogeneity. **Results:** Of the 1384 patients, 713 (51.52%) had a family history of HBV infection. The HBsAg clearance rate was significantly lower in the family history-positive group than in the family history-negative group (10.80% vs. 16.24%, P = 0.003). At baseline, the family history-positive group exhibited a higher virologic burden: the proportions of patients with HBV DNA > 2000 IU/mL (16.71% vs. 12.27%, P = 0.021), HBsAg > 1500 IU/mL (46.62% vs. 38.37%, P = 0.002), and positive HBeAg (23.26% vs. 16.27%, P = 0.005) were all significantly greater than those in the family history-negative group. After adjusting for baseline confounders, a family history of HBV infection remained an independent risk factor for lower HBsAg clearance [odds ratio (OR) = 0.631, 95% confidence interval (CI): 0.417-0.955, P = 0.029]. In subgroup analyses, the inverse association between family history and HBsAg clearance persisted in women (OR = 0.397, P = 0.002), younger patients (OR = 0.483, P = 0.013), those with lower HBV DNA levels (OR = 0.682, P = 0.022), lower HBsAg levels (OR = 0.701, P = 0.050), HBeAg-negative patients (OR = 0.646, P = 0.019), patients without cirrhosis (OR = 0.611, P = 0.005), and those with MASLD (OR = 0.404, P = 0.002). **Conclusion:** A family history of HBV infection is an independent risk factor for failure to achieve HBsAg clearance during Peg-IFNα-2b therapy in CHB patients. This

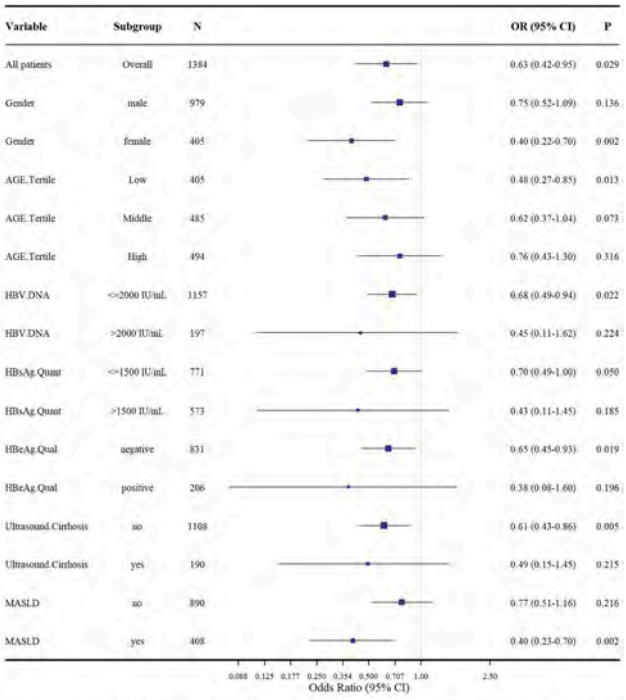
association remains significant among women, younger patients, HBeAg-negative patients, those without cirrhosis, those with MASLD, and patients with lower levels of HBV DNA and HBsAg. These findings suggest that CHB patients with a positive family history may require more potent or prolonged antiviral strategies to improve HBsAg clearance rates.



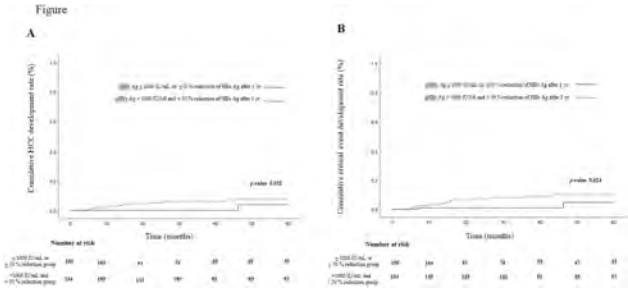


Figure 1. Forest plot of subgroup analyses for the association between family history of hepatitis B and HBsAg clearance.

4129 | QUANTITATIVE HEPATITIS B SURFACE ANTIGEN (QHBSAG) DYNAMICS IN PATIENTS WITH CHRONIC HEPATITIS B UNDERGOING ANTIVIRAL THERAPY: ASSOCIATION WITH THE RISK OF HCC

Jung Hwan Yu[1] Jin-Woo Lee[2] Yunmi Ko[2], [1]Inha university, [2]Inha university hospital

Background: This study evaluated the clinical implications of hepatitis B surface antigen quantification (qHBsAg) in patients with chronic hepatitis B (CHB) treated with entecavir (ETV), tenofovir disoproxil fumarate (TDF), or tenofovir alafenamide (TAF). We specifically aimed to identify the association between qHBsAg levels and the risk of developing hepatocellular carcinoma (HCC). **Methods:** Between January 2009 and December 2023, clinical data and qHBsAg levels were analyzed for 279 patients (ETV: n = 65, TDF: n = 164, TAF: n = 50) who initiated antiviral therapy.The method of measuring the HBs Ag quantitative value in all patients was the Architect HBsAg QT (Abbott Diagnostic, Wiesbaden, Germany). All of them had been HBs Ag-positive for longer than six months and had undergone antiviral therapy for a CHB infection according to the guidelines published by the American Association for the Study of Liver Diseases (AASLD). **Results:** During a mean follow-up period of 43.2 months, 105 patients (44.8%) achieved either a > 50% reduction in qHBsAg or a qHBsAg level < 1,000 IU/mL after one year of treatment. Patients meeting these criteria showed a significantly lower incidence of HCC ($p < 0.032$) and decompensated cirrhosis ($p < 0.023$) compared to those who did not. There were no significant differences in HCC development ($p = 0.290$) or qHBsAg reduction rates ($p = 0.204$) among the ETV, TDF, and TAF groups. Multivariate analysis identified the present of cirrhosis ($p = 0.043$) as an independent predictor of critical event development. **Conclusion:** A significant reduction in qHBsAg (> 50% decrease or level < 1,000 IU/mL) at one year of antiviral therapy is associated with a lower risk of HCC and decompensated cirrhosis. Monitoring qHBsAg levels can serve as a valuable predictive marker for long-term clinical outcomes in CHB patients treated with ETV, TDF, or TAF.

Background: This study aimed to compare the clinical outcomes of different pegylated interferon alfa-2b (Peg-IFNα-2b)-based treatment strategies in nucleos(t)ide analogue (NA) -experienced patients with chronic hepatitis B (CHB), and to develop internally validated models for predicting hepatitis B surface antigen (HBsAg) loss at week 48. **Methods:** In this single-center retrospective real-world cohort, 865 NA-experienced patients with CHB were initially screened, and 765 eligible patients were included in the final analysis. According to the treatment regimen, patients were classified into four groups: Peg-IFNα-2b monotherapy, Peg-IFNα-2b plus entecavir (ETV), Peg-IFNα-2b plus tenofovir disoproxil fumarate (TDF), and Peg-IFNα-2b plus tenofovir alafenamide (TAF). Longitudinal changes in four binary outcomes, including HBsAg loss, hepatitis B e antigen (HBeAg) loss, undetectable hepatitis B virus DNA (HBV DNA), and alanine aminotransferase (ALT) normalization, were examined using generalized estimating equation (GEE) logistic models, with particular attention to treatment-by-time interactions. Adjusted multivariable logistic regression was then used to compare week-48 outcomes across treatment groups. Missing data were handled through complete-case analysis, multiple imputation, and inverse probability weighting as sensitivity analyses. Baseline and simplified week-12 dynamic models were constructed to predict HBsAg loss at week 48. Model performance was assessed using the area under the receiver operating characteristic curve (AUC), Brier score, bootstrap correction, and 10-fold cross-validation. **Results:** Across follow-up, all four groups showed overall improvements in HBsAg loss, HBeAg loss, HBV DNA suppression, and ALT normalization. After adjustment for baseline covariates, the Peg-IFNα-2b plus TAF group showed the highest estimated probability of HBsAg loss at week 48 (46.6%), compared with Peg-IFNα-2b monotherapy (25.7%), Peg-IFNα-2b plus TDF (33.3%), and Peg-IFNα-2b plus ETV (28.9%). For HBeAg loss, HBV DNA negativity, and ALT normalization, no consistent or robust between-group differences were observed at week 48. The baseline prediction model achieved an apparent AUC of 0.853 and a bootstrap-corrected AUC of 0.842. The simplified week-12 dynamic model yielded an apparent AUC of 0.842 and a bootstrap-corrected AUC of 0.841. Among patients with available week-12 HBsAg data, the simplified week-12 model reached an AUC of 0.850, which was comparable to the predictive value of week-12 HBsAg alone. **Conclusion:** Different Peg-IFNα-2b treatment strategies were associated with virological and biochemical improvements, and the TAF combination regimen was associated with a higher probability of HBsAg loss. Lower baseline HBsAg level, younger age, and TAF combination therapy were associated with 48-week HBsAg loss.

Ltd, Xiamen, 361028, China

Background: In a randomized controlled phase 3 trial, treatment with peginterferon alfa-2b (PegIFNα-2b, Pegbing®, Xiamen Amoytop Biotech Co., Ltd.) at 180 μg/week resulted in HBsAg loss and HBV DNA undetectable at 24 weeks after discontinuation of all drugs—that is functional cure—in 31.4% of nucleos(t)ide analogue (NA)-experienced chronic hepatitis B patients. Here, we analyzed the impact of baseline characteristics on the achievement of functional cure. **Methods:** NA-experienced patients with HBsAg < 1,500 IU/mL, HBeAg < 10 COI, and HBV DNA < 100 IU/mL were enrolled in a phase 3 trial (NCT04846491) and randomly assigned to receive tenofovir disoproxil fumarate (TDF) monotherapy (group 1), TDF plus PegIFNα-2b 180 μg/week (group 2) or 90 μg/week (group 3). The treatment period was 144 weeks and the follow-up was 24 weeks. PegIFNα-2b was administered intermittently in cycles. This post-hoc analysis evaluated the impact of baseline HBsAg levels, HBeAg and HBV DNA statuses on functional cure in the PegIFNα-2b 180 μg/week group (group 2). **Results:** Among NA-experienced patients receiving PegIFNα-2b 180 μg/week combination therapy (group 2), the overall functional cure rate was 31.4%. In the HBeAg-negative subgroup, the functional cure rates for patients with baseline HBsAg ≤ 100 and >100 −≤1000 IU/mL were 66.7% (18/27) and 30.4% (17/56), respectively (Figure 1). Among HBeAg-negative patients with undetectable HBV DNA, the functional cure rates were 65.4% (17/26) for patients with baseline HBsAg ≤ 100 IU/mL and 27.8% (15/54) for patients with >100 −≤1000 IU/mL, respectively. **Conclusion:** A finite regimen of PegIFNα-2b resulted in functional cure in over 30% of NA-experienced patients. Lower baseline HBsAg levels were associated with higher functional cure rates. Notably, even in the subgroup with baseline HBsAg levels >100−≤1000 IU/mL and HBeAg-negative, a robust functional cure rate of 30% was observed.

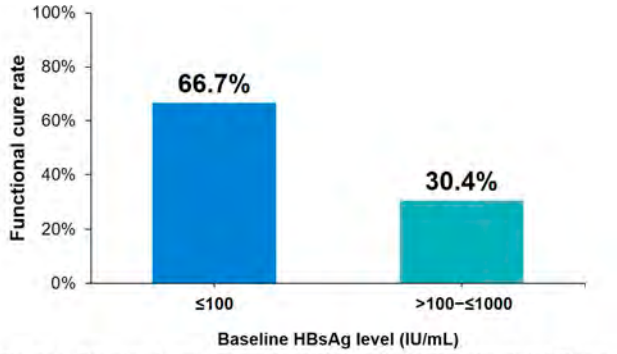

Figure 1. Functional cure rates stratified by baseline HBsAg levels in HBeAg-negative patients in the PegIFNα-2b 180 μg/week combination group.

4132 | IMPACT OF TENOFOVIR AMIBUFENAMIDE ON LIVER STIFFNESS MEASUREMENT IN CHRONIC HEPATITIS B PATIENTS WITH CONCOMITANT MASLD: A REAL-WORLD STUDY

Wen Xie[1] Jingjing Wang[1] Wenya Chen[1] Qi Wang[1] Hong Zhao[1] Liugai Liu[1], [1]Beijing Ditan Hospital, Capital Medical University

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Tenofovir amibufenamide (TMF) is a Chinese original first-line antiviral agent for the treatment of chronic hepatitis B (CHB). Metabolic dysfunction-associated steatotic liver disease (MASLD) is a common comorbidity in CHB patients and may influence the improvement of liver stiffness measurementf (LSM) following antiviral therapy. However, more evidence is needed regarding the efficacy of TMF in CHB patients with concomitant MASLD. **Methods:** This retrospective real-world study enrolled 192 CHB patients who received TMF monotherapy for at least 48 weeks, including 74 (38.5%) with baseline MASLD. All patients underwent transient elastography (FibroScan) at baseline and week 48 to record LSM and controlled attenuation parameter (CAP). According to the device operating instructions, the upper limit of normal LSM was 7.0 kPa, and the upper limit of normal CAP was 238 dB/m. The primary endpoint was the proportion of patients with a $\geq$30% decline in LSM from baseline. Changes in LSM decline, virologic suppression (HBV DNA < 20 IU/mL), ALT normalization ($\leq$40 U/L), and lipid profiles were compared between the two groups. **Results:** At baseline, median LSM was within the normal range in both groups (6.6 kPa for both). After 48 weeks of treatment, the proportion of patients with a $\geq$30% decline in LSM was 18.9% in the MASLD group and 26.3% in the non-MASLD group, with no statistically significant difference between the two groups (P = 0.242). Virologic suppression rates (77.0% vs. 82.2%, P = 0.381) and ALT normalization rates (85.5% vs. 87.0%, P = 0.772) were also similar between the two groups. Within the MASLD group, patients with a $\geq$30 dB/m decline in CAP (n = 28, 43.8%) had a higher proportion of $\geq$30% LSM decline compared to those without CAP improvement (28.6% vs. 8.3%, P = 0.047). Lipid profile analysis showed a decrease in triglyceride levels in the MASLD group (1.38 vs. 1.09 mmol/L, P = 0.031), while total cholesterol, HDL, and LDL remained stable (all P > 0.05). **Conclusion:** This study yields three main findings. First, in CHB patients with baseline LSM within the normal range, the presence of MASLD did not affect the efficacy of TMF in achieving LSM decline, virologic suppression, or ALT normalization after 48 weeks of treatment. Second, improvement in hepatic steatosis was associated with a higher proportion of LSM decline, suggesting that metabolic control may enhance anti-fibrotic efficacy. Third, lipid profiles remained stable during TMF treatment, with a trend toward decreased triglycerides and no adverse metabolic effects. In summary, TMF, as a Chinese original first-line antiviral agent, offers both consistent antiviral efficacy and favorable metabolic safety in CHB patients with concomitant MASLD.

4133 | ANALYSIS OF THE EFFICACY AND SAFETY OF PRADEFOVIR MESYLATE TABLETS IN THE TREATMENT OF CHRONIC HEPATITIS B: A REAL-WORLD STUDY OF 81 PATIENTS

Yuemin Nan[1] Yukai Chen[2] Yaoyao Mao[2] Rongqi Wang[2] Suxian Zhao[2] Na Fu[2], [1]Third hosptial of Hebei medical university, [2]Hebei Medical University Third Hospital

Background: Chronic Hepatitis B (CHB) is caused by persistent infection with the Hepatitis B virus (HBV). Globally, there are approximately 254 million chronic carriers, with 1,100,000 annual deaths. In China, the HBsAg prevalence rate is 5%-6%, equating to about 75 million patients, representing a significant disease burden. Pradefovir Mesylate Tablets (PDF), a liver-targeting prodrug launched in 2024, was confirmed in Phase III clinical trials to effectively suppress HBV DNA replication and rapidly and potently reduce Hepatitis B surface antigen (HBsAg) levels, laying the foundation for clinical cure of CHB. However, due to its recent market entry, there is an urgent need for real-world clinical treatment data to provide strategies for individualized treatment optimization. **Methods:** This retrospective study analyzed the complete medical records of 81 NAs-experienced CHB patients nationwide who received PDF treatment. Data collected and analyzed included baseline levels and levels at 12 and 24 weeks post-treatment for HBV DNA, HBsAg, HBeAg, serum

ALT, as well as the occurrence of adverse events during treatment, to evaluate the efficacy and safety of Pradefovir Mesylate Tablets. **Results:** After PDF treatment, the 81 CHB patients showed significant improvements in virological and serological markers. Specifically: The HBV DNA undetectable rate reached 63.04% (29/46) at week 12 and 73.91% (34/46) at week 24; Among patients with baseline HBV DNA levels between the lower limit of detection and 2000 IU/mL (n = 19), 12 patients (63.0%) achieved HBV DNA undetectability at week 12, and 14 patients (73.68%) at week 24; Among 6 patients with high viral load (HBV DNA $\geq 10^7$ IU/mL), the HBV DNA undetectable rates were 33.33% (n = 2) at week 24; The HBsAg loss rate was 3.75% (n = 3) at week 12 and 5% (n = 4) at week 24; The proportion of patients with HBsAg $\leq$ 1000 IU/mL increased from 30.86% (n = 25) at baseline to 35.80% (n = 29) at week 12 and 40.74% (n = 33) at week 24; The HBeAg seroconversion rate was 3.85% (n = 1) at week 12 and 11.54% (n = 3) at week 24; The ALT normalization rate was 72.73% (n = 16) at week 12; No significant changes were observed in liver function, kidney function, or blood lipid levels before and after treatment, and no significant adverse events were identified. **Conclusion:** In real-world clinical practice, PDF effectively suppresses HBV DNA replication and rapidly promotes HBsAg clearance, demonstrating good clinical efficacy and safety. Its clinical application value warrants further exploration in the future.

4134 | MACHINE LEARNING-BASED MODEL FOR PREDICTING HBSAG SEROCLEARANCE IN CHRONIC HEPATITIS B PATIENTS RECEIVING PEG-IFN COMBINED WITH TAF/TDF

Tianyu Ma[1] Minghui Li[1], [1]Beijing Ditan Hospital, Capital Medical University

Background: Functional cure is the ideal treatment goal for chronic hepatitis B (CHB). Pegylated interferon (Peg-IFN) combined with tenofovir alafenamide (TAF) or tenofovir disoproxil fumarate (TDF) is a commonly used regimen. However, early and accurate prediction of which patients will achieve HBsAg loss remains challenging. This study aimed to develop and validate a machine learning model for early prediction of functional cure in CHB patients receiving Peg-IFN combined with TAF/TDF. **Methods:** We retrospectively included 302 CHB patients from a single center as the training cohort, and 142 patients from a subsequent time period as the internal temporal validation cohort. Functional cure was defined as achieving HBsAg < 0.05 IU/mL within 18 months or less after treatment initiation. A total of 68 clinical and laboratory variables at baseline and at 3 months were collected. Feature selection was performed using the Boruta algorithm and least absolute shrinkage and selection operator (LASSO) regression, and collinear variables were removed from the pooled set of selected variables. Eleven machine learning algorithms were constructed, including Random Forest (RF), Support Vector Machine (SVM), Logistic Regression (LR), K-Nearest Neighbors (KNN), Partial Least Squares (PLS), Gradient Boosting Machine (GBM), Neural Network (NN), Naïve Bayes (NB), Linear Discriminant Analysis (LDA), LASSO (glmnet), and Adaptive Boosting (AdaBoost). Model performance was evaluated using the area under the receiver operating characteristic curve (AUC), accuracy, sensitivity, specificity, F1 score, and decision curve analysis (DCA). The optimal model was interpreted using SHapley Additive exPlanations (SHAP). **Results:** Functional cure was achieved in 46 of 302 patients (15.2%) in the training cohort and in 33 of 142 patients (23.2%) in the validation cohort. Six variables were ultimately selected: baseline HBsAg (log10), 3-month HBsAg decline (log10), 3-month red blood cell count (RBC_3), age, 3-month change in ALT (log10), and 3-month HBeAg (log10). Among all models, the GBM model exhibited good discriminative ability, with an AUC of 0.839 (95% CI: 0.766–0.913) in the validation set, and showed the highest net benefit in decision curve analysis within the clinically relevant threshold range (0.1–0.4), suggesting superior clinical utility. SHAP analysis revealed that 3-month HBsAg decline and baseline HBsAg were the most important predictors. **Conclusion:** The GBM-based prediction model accurately identifies CHB patients likely to achieve functional cure following treatment with Peg-IFN combined with TAF/TDF. This model offers favorable clinical net benefit and can assist clinicians in individualized treatment decisions, although external validation in multicenter cohorts remains necessary.

4135 | DYNAMIC CHANGES AND VIROLOGICAL CORRELATIONS OF HBV RNA DURING PEGIFN ADD-ON THERAPY IN NUCLEOS(T)IDE ANALOGUE-EXPERIENCED PATIENTS WITH CHRONIC HEPATITIS B

Ziyu Zhang[1] Minghui Li[2], [1]Beijing Ditan Hospital affiliated Capital Medical University, [2]Capital Medical University affiliated Beijing Ditan Hospital

Background: HBV RNA is considered to originate from intrahepatic covalently closed circular DNA (cccDNA) transcriptional products and may reflect HBV transcriptional activity. In chronic hepatitis B (CHB) patients receiving long-term nucleos(t)ide analogue (NA) therapy, HBV DNA is often effectively suppressed, whereas the dynamic changes and clinical significance of HBV RNA remain unclear. This study aimed to characterize HBV RNA dynamics during PegIFN-α add-on therapy in NA-experienced patients with CHB and to evaluate its correlations with virological and clinical parameters. **Methods:** A total of 295 patients with CHB who had received NA therapy for more than 24 weeks and subsequently received PegIFN-α 180 μg add-on therapy were enrolled. HBV RNA, HBV DNA, HBsAg, HBeAg, and liver function parameters were collected at baseline and at weeks 12, 24, and 48. Spearman correlation analysis was performed to assess correlations between HBV RNA and other clinical parameters. Baseline characteristics were also compared between HBV RNA-positive and HBV RNA-negative patients. **Results:** At baseline, 36.61% (108/295) of patients were HBV RNA-positive. Compared with HBV RNA-negative patients, HBV RNA-positive patients had significantly higher levels of HBsAg, HBV DNA, and HBeAg (all $P < 0.001$), as well as higher ALT and AST levels (both $P < 0.001$).Among HBV RNA-positive patients, HBV RNA levels showed a strong positive correlation with HBeAg ($r = 0.792$, $P < 0.001$) and moderate positive correlations with HBsAg ($r = 0.597$, $P < 0.001$) and HBV DNA ($r = 0.590$, $P < 0.001$). No significant correlations were observed between HBV RNA and liver function parameters, including ALT, AST, TBIL, and ALB (all $P > 0.05$).During PegIFN-α add-on therapy, HBV RNA levels gradually declined over time. Median HBV RNA levels decreased from 1.40 (1.40, 3.07) log10 copies/mL at baseline to 1.40 (1.40, 2.12) log10 copies/mL at week 48 ($P < 0.001$). Meanwhile, HBsAg levels continuously declined, whereas HBV DNA remained suppressed from the early treatment phase onward. **Conclusion:** In NA-experienced patients with CHB, HBV RNA was well correlated with HBsAg, HBV DNA, and HBeAg, suggesting that it may reflect HBV transcriptional activity. HBV RNA showed an overall declining trend during PegIFN-α add-on therapy but demonstrated limited correlation with liver function parameters, indicating that HBV RNA mainly reflects virological activity rather than host immune-mediated liver injury.

4136 | SHORT-TERM EFFICACY AND SAFETY ANALYSIS OF PDF MONOTHERAPY VERSUS PDF COMBINED WITH INTERFERON FOR CHRONIC HEPATITIS B

Wenwen Ren[1] Ying Wang[1] Xiaolan Shi[1] Chi Lv[1] Juan Li[1], [1]the First Affiliated Hospital of Zhengzhou University

Background: Pradefovir mesylate (PDF), a novel liver-targeting adefovir prodrug developed using the HepDirect™ prodrug technology, has become an important treatment option for adult patients with chronic hepatitis B (CHB). However, real-world clinical evidence regarding its short-term efficacy and safety remains insufficient. Therefore, this study aimed to evaluate the short-term efficacy of PDF monotherapy versus PDF combined with interferon in a real-world setting, and to observe their impact on liver and kidney function. **Methods:** This study retrospectively analyzed the efficacy and safety of 12-week short-term treatment with PDF monotherapy (PDF, $n = 78$) or PDF combined with interferon (PDF+IFN, $n = 29$) in 107 CHB patients. The primary efficacy endpoints included the HBV DNA negative conversion rate and reduction magnitude, changes in HBsAg levels and HBsAg negative conversion rate, and the ALT normalization rate. Safety indicators covered liver function, kidney function, lipids, and others. **Results:** At the end of 12 weeks of treatment, the HBV DNA negative conversion rate in the PDF group was 52.50%, which was significantly higher than that in the PDF+IFN group (18.75%, $P = 0.021$). In the PDF group, the quantitative HBV DNA level decreased from a baseline of 2.50 ± 1.97 $\log_{10}$ IU/mL to 1.97 ± 1.15 $\log_{10}$ IU/mL at week 12, with a mean decline of -0.53 ± 1.42 $\log_{10}$ IU/mL ($P = 0.044$). In the PDF+IFN group, the HBV DNA level decreased from

2.88 ± 2.20 log_{10} IU/mL at baseline to 2.07 ± 0.94 log_{10} IU/mL at week 12, with a mean decline of –0.81 ± 1.52 log_{10} IU/mL (P = 0.075). No HBsAg seroclearance occurred in either group; however, the PDF+IFN group showed a significantly greater reduction in HBsAg level than the PDF group (–0.35 ± 0.42 vs. –0.08 ± 0.20, P = 0.0023). During the treatment period, no statistically significant difference was observed in ALT levels between the two groups (P > 0.05), and no other serious adverse events occurred. **Conclusion:** PDF monotherapy for 12 weeks effectively suppresses HBV DNA with a favorable safety profile; the addition of interferon further reduces HBsAg, offering added value in strategies aiming for HBsAg decline.

4137 | LIVER FUNCTION ABNORMALITIES AND ANTIVIRAL TREATMENT PATTERNS IN HBV-INFECTED PREGNANT WOMEN FOLLOWING IVF-ET: A SINGLE-CENTER RETROSPECTIVE STUDY

Xueting Ou[1] Liyang Zhou[1] Panpan Zhai[1] Sichen Li[1] Shiyun Wu[1] Xing-Fei Pan[1], [1]The Third Affiliated Hospital, Guangzhou Medical University

Background: It remains unclear that whether hepatitis flare during pregnancy could affect the maternal and neonatal outcomes of HBV-infected patients who had undergone in vitro fertilization-embryo transfer (IVF-ET). In the present study, we compared the clinical characteristics, pregnancy complications, and antiviral treatment strategies between HBV-infected patients with and without abnormal liver function after IVF-ET, in order to provide evidence for the management of liver disease during the pregnancy period. **Methods:** A retrospective study was conducted on HBV-infected patients who underwent IVF-ET at the Third Affiliated Hospital of Guangzhou Medical University between 2022 and 2023. Patients were divided into two groups based on liver function during pregnancy: abnormal liver function group (n = 23) and normal liver function group (n = 78). Demographic characteristics, virological parameters, medical history, pregnancy complications, features of liver dysfunction, and treatment regimens were collected, respectively. Non-parametric tests and chi-square tests were used for intergroup comparisons. **Results:** There were no statistically significant differences in age, HBeAg positivity rate, underlying diseases, or pregnancy complications between the two groups, respectively (P > 0.05). The abnormal liver function group showed a trend toward higher HBV DNA levels compared to the normal liver function group (median 6.09 vs. 3.37 log IU/mL, P = 0.054).The first onset of liver dysfunction was often at gestational week 6, with median ALT and AST levels of 69.80 U/L and 48.60 U/L, respectively. The rate of taking antiviral drug was similar between the two groups (69.57% vs. 73.08%, P = 0.741). However, the proportion of patients initiating antiviral therapy before pregnancy was significantly higher in the abnormal liver function group (26.09% vs. 7.69%, P = 0.017), and the median gestational week of initiating antiviral therapy was earlier (22.00 vs. 28.00 weeks, P = 0.012) compared to the normal liver function group. There was no a statistically significant difference in the choice of TDF or TAF regimen between the two groups. Liver-protecting therapy was administered to 69.57% of patients with abnormal liver function. **Conclusion:** In HBV-infected pregnant women who had undergone IVF-ET, abnormal liver function during pregnancy may be associated with higher HBV DNA levels and need initiating antiviral therapy in the early-to-mid pregnancy. Hepatitis flare often occurs in the first trimester in patients with high viral loads, highlighting the importance of monitoring liver function during early pregnancy. Due to the retrospective nature and limited sample size of this study, further prospective studies with larger cohorts need doing to validate these findings.

Table 1. Baseline characteristics, obstetric complications, and treatment strategies of HBV-infected patients with or without abnormal liver function after IVF-ET

Characteristic	Abnormal LF group (n=23)	Normal LF group (n=78)	*P* value
Demographics and virology			
Age (years)	33.00 (30.00, 36.50)	31.00 (34.00, 37.00)	0.274

4138 | ◆ LIPID-BASED CRISPR/CAS3 NANODRUG VIA MICROFLUIDIC TECHNOLOGY FOR HBV GENOME EDITING AND TREATMENT

Li Li[1] Xiangru Shan[1] Xinyue Guo[1] Yibei Xiao[2] Chuanlong Zhu[1], [1]The First Affiliated Hospital of Nanjing Medical University, [2]China Pharmaceutical University

Background: Hepatitis B virus (HBV) infection is a major etiological driver of chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma. Although current antiviral therapies effectively suppress HBV replication, they fail to eradicate intracellular HBV DNA, leaving patients vulnerable to viral rebound and disease recurrence after treatment discontinuation. The CRISPR/Cas3 system, characterized by sequencespecific target recognition and processive degradation of DNA, offers a promising therapeutic strategy for the precise targeting and clearance of HBV DNA. **Methods:** Based on conserved functional regions of the HBV genome, a crRNA targeting genes within the C region was rationally screened and designed. mRNAs encoding the Cascade–Cas3 system were generated by in vitro transcription, and a stable, uniform liposome-based nanodrug was constructed using microfluidic technology. The HBV DNA editing efficiency and potential off-target effects of the Cascade–Cas3 system were assessed by targeted capture sequencing. Furthermore, the antiviral efficacy of this system was systematically evaluated both in vitro and in vivo using multiple complementary approaches, including qPCR, ELISA, and WB. **Results:** The targeted capture sequencing verified the sequence-specific targeting of the HBV genome by the designed crRNA. The characterization experiments by DLS and TEM confirmed that nanodrug is an electrically neutral sphere with a particle size of approximately 80 nm and uniform distribution. Moreover, the encapsulation rate of LNP is 90%, demonstrating excellent stability and biocompatibility. Functionally, qPCR analysis showed that the lipid-based therapeutic formulation reduced HBV cccDNA and total HBV DNA by approximately 70% in HepG2.2.15 cells. In parallel, the expression of HBsAg and HBeAg was significantly suppressed, with reductions of 54.64% and 64.14% in HepG2.2.15 cells. The important point is that in the modelmice infected with hepatitis B virus, systemic administration reduced the HBV DNA in the liver by approximately 90%. The WB and immunohistochemical staining of liver tissue further corroborated the potent inhibitory effect of this nanodrug on HBsAg production in vivo. **Conclusion:** This study established a lipid-based CRISPR/Cas3 nanodrug and systematically evaluated it across multiple dimensions, including crRNA design, nanodrug fabrication, and both in vitro and in vivo efficacy assessments. The nanodrug demonstrated potent anti-HBV activity while maintaining favorable biocompatibility, providing compelling experimental evidence for the application of CRISPR/Cas3 in HBV-targeted nucleic acid therapy.

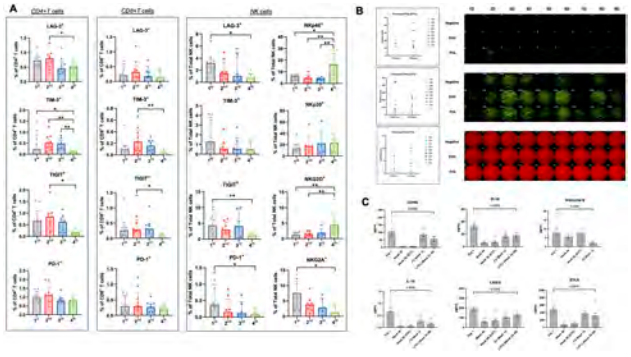
4139 | ◆ IMMUNE-MODULATORY EFFECTS OF PEVIFOSCORVIR SODIUM IN HBEAG-POSITIVE PATIENTS WITH CHRONIC HEPATITIS B INFECTION



Lung Yi Mak[1] Andreas Jekle[2] Liqiong Yang[1] Sushmita Chanda[2] Lilian Adame[2] Heleen Roose[3] Lawrence Blatt[4] Min Wu[2] Kha Le[2] Tse-I Lin[5] Man-Fung Yuen[1], [1]The University of Hong Kong, [2]Aligos Therapeutics, Inc., San Francisco, United States, [3]Aligos Belgium BV, [4]Aligos Therapeutics, Inc., [5]Aligos Belgium, Leuven, Belgium

Background: Pevifoscorvir sodium (pevy, ALG-000184) is a novel Type E Capsid Assembly Modulator which demonstrated potent on-treatment viral antigen suppression in the Phase 1 study ALG-000184-201 (NCT04536337) in participants with chronic hepatitis B infection who received oral, once daily 300 mg pevy for 96 weeks. After the end of the pevy treatment (EOT), these antiviral effects were sustained up to 48 weeks of follow-up (FU) while on entecavir (ETV) alone (Mak LY et al. EASL 2026 #Wed-588). Here, we report the immunomodulatory effects during and after PEVY treatment. **Methods:** 9 of 10 HBeAg-positive participants form study ALG-000184-201 were recruited for $\geq$ 24 weeks (wk) of ETV-only FU. Peripheral blood was

collected at baseline, wks 48 and 96 of PEVY, and FU 24-48 wks after EOT. Plasma cytokine levels were determined by ProcartaPlex™ multiplex kits. PBMCs were evaluated ex vivo by multicolor flow cytometry for CD4+, CD8+, regulatory T cells (Tregs), NK cells, and coinhibitory markers. HBV-specific T cell function was assessed by Fluorospot assay for IFN-g, TNF-a, and IL-2 after co-culturing synthetic HBV peptide (envelope [env] and polymerase [pol]) using the ImmunoSpot® Software. **Results:** Expression of co-inhibitory markers ($\geq$ 2 among LAG-3, TIM-3, TIGIT, PD-1) on CD4+T, CD8+T and NK cells, and proportion of Treg were significantly reduced at 24-48 wks after EOT compared to earlier timepoints. Expression of activating NK receptors (NKG2D, NKp46) increased over time, while expression of inhibitory NK receptor (NKG2A) was reduced on NK cells (Fig.A). There was no apparent correlation of baseline qHBsAg levels with the PBMC phenotypes, but baseline TIGIT expression on CD4+T was positively correlated with wk 96 HBsAg level and HBsAg change at wk 48, wk 96, and at FU. Baseline TIGIT expression on CD8+T cells was positively correlated with wk 96 HBsAg level. Fluorospot analysis showed presence of HBV-specific T cells [env or pol] producing IFN-g, TNF-a, and IL-2 (Fig.B). The frequency of IL-2 producing HBV-specific T cells (pol) were negatively correlated with TIM-3 on CD4+T and TIGIT on CD8+T at FU. IFN-g-producing HBV-specific T cells [pol] were also negatively correlated with LAG-3 on CD4+T cells at FU. Interestingly, IFN-g-producing T cells were positively correlated with LAG-3 and TIGIT on NK cells, suggestive of involvement of NK cells in modulating HBV-specific T cell function. Plasma cytokine analysis revealed significant reduction of both pro-inflammatory cytokines (CD40L, IP-10, granzyme B) and inhibitory cytokines (IL-10, LAG-3, BTLA) with time plateauing during PEVY treatment (Fig.C), suggestive of complex immunomodulatory effect associated with PEVY which persisted partially after EOT. **Conclusion:** Potent suppression of HBsAg during and after PEVY treatment was associated with robust immunomodulatory changes in the peripheral compartment, favoring enhancement of immune control of HBV infection.

Memorial Hospital, Linkou, Taiwan; Chang Gung University, Linkou, [7]University of Milan, Milan, Italy, [8]National University Health System, Singapore, [9]Sichuan Provincial People's Hospital, Chengdu, China, [10]SIDS Hospital and Research Center, Surat, India, [11]Carol Davila Medicine and Pharmacy University Bucharest, Bucharest, Romania, [12]Ruijin Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China, [13]Korea University Ansan Hospital, Ansan, Republic of Korea, [14]The University of Hong Kong, Hong Kong, China, [15]GSK, London, UK, [16]GSK, Stevenage, UK, [17]GSK, Dubai, United Arab Emirates, [18]GSK, Collegeville, PA, USA, [19]GSK, Durham, NC, USA

Background: Functional cure (FC) is defined as ≥24 weeks of sustained hepatitis B surface antigen (HBsAg) not detected (<0.05 IU/mL) and hepatitis B virus (HBV) DNA < lower limit of quantification (LLOQ [20 IU/mL]) off all HBV treatment with or without hepatitis B surface antibody. FC is the optimal treatment endpoint for chronic HBV infection but is rarely achieved with currently available antiviral therapies. Bepirovirsen, an unconjugated antisense oligonucleotide, is an investigational medicine in development for the treatment of chronic HBV infection. In the Phase 3 B-Well 1 & 2 studies (NCT05630807, NCT05630820), a subset of participants achieved FC 24 weeks post nucleos(t)ide analog (NA) and bepirovirsen cessation (B-Well Week 72). Eligible participants who reached the end of B-Well 1 & 2 (Week 96) were enrolled into the long-term durability of efficacy study, B-Sure (NCT04954859; ongoing), to further assess the durability of FC. Here we present data from the first interim analysis of B-Well NA-cessated participants enrolled into B-Sure. **Methods:** Participants who discontinued NAs and achieved FC or had HBsAg <1 IU/mL and HBV DNA <LLOQ at B-Well Week 96 were eligible for enrollment into B-Sure. Participants were enrolled into B-Sure up to 3 months after the end of B-Well. As both studies were ongoing at the data cut-off date (DCO), not all participants had reached the end of B-Well 1 & 2 studies. Maintenance of FC was defined as sustained HBsAg not detected and HBV DNA <LLOQ off all HBV treatment without the use of rescue medication. Loss of FC was defined as the first occurrence of either confirmed HBsAg reversion or HBV DNA reversion, or use of any rescue medication. Durability of FC is reported for participants who achieved FC in B-Well. **Results:** In total, 95 participants who achieved FC in B-Well 1 & 2 were enrolled into the ongoing B-Sure study at the DCO. Of these, 5/95 (5%) participants had lost FC in B-Well and 90/95 (95%) were maintaining FC at enrollment to B-Sure. Among these 90 participants, 37/37 (100%) participants who had reached the B-Sure Month 3 visit at the DCO maintained FC; and 4/4 (100%) who had reached Month 9 visit were maintaining FC, demonstrating at least 15 months durability of FC (i.e. 6 months of FC durability in B-Well 1 & 2, up to 3 months before enrollment into B-Sure, and 9 months in B-Sure) (**Figure**). **Conclusion:** Once achieved, FC remains durable in participants who achieved and maintained FC to B-Well Week 96, up to their latest available data in B-Sure, which is at least 15 months for some participants. Ongoing follow-up of B-Well participants enrolled into B-Sure will be important to confirm the durability of FC in a larger subset of patients. **Funding:** GSK (206882).

4141 | SAFETY, PHARMACOKINETICS AND PHARMACODYNAMICS OF THE DUAL-TARGET HBV/PD-L1 SIRNA SA1211: PHASE 1 INTERIM RESULTS DEMONSTRATING ROBUST HBSAG SUPPRESSION AND IMMUNE RESTORATION IN CHB PARTICIPANTS

Yanhua Ding[1] Yue Hu[1] Junqi Niu[1] Nan Liu[2] Hui Chen[2] Wenbo Zheng[1] Hong Zhang[1] Xiaojiao Li[1] Feifei Zhao[2] Hongli Zhang[2] Zhiwei Yang[2], [1]The First Hospital of Jilin University, [2]Suzhou Siran Biotechnology Co.,Ltd.

Background: SA1211 is a dual-target siRNA designed to silence HBV and PD-L1 mRNA, aiming to reduce HBsAg and relieve PD-L1-mediated immune suppression. This Phase 1 study evaluated the safety, pharmacokinetics (PK), pharmacodynamics (PD) and immunomodulatory effects in healthy volunteers and CHB participants. Interim blinded data are reported. **Methods:** This study consists of single-ascending dose (SAD) in healthy volunteers and multiple-ascending dose (MAD) in CHB participants. SAD planned doses ranged from 50 mg to 600 mg with follow-up to Day 85; interim safety and PK were analyzed for 50–450 mg. MAD enroll CHB participants with baseline HBsAg $\leq$1000 IU/mL, who will receive subcutaneous SA1211 at 150 mg, 300 mg and 450 mg on Day 1/15/29. Interim data were available for 150 mg up to Day 57 and 300 mg up to Day 15. Evaluations covered safety, plasma/urinary PK, HBsAg level, HBV-specific T cell phenotypes and peripheral PD-L1 expression. **Results: Safety**: SA1211 was well tolerated across 50–450 mg. The most common adverse events were Grade 1 injection-site pain/erythema and transient abnormalities in laboratory tests (e.g., elevated C-reactive protein (CRP), elevated liver enzymes etc.) and all resolved spontaneously. No SAE or treatment discontinuation occurred. **PK**: Plasma exposure increased more than dose-proportionally from 50–450 mg (nonlinear). Mean 0-24h urinary excretion < 11%, indicating renal elimination is minor. Similar PK profiles were observed for both siRNA strands and across healthy volunteers and CHB participants. **PD-HBsAg**: In the 150 mg cohort (n = 10), mean $\log_{10}$ HBsAg declined by 0.73 at Week 8. One participant achieved sustained clearance (< 0.05 IU/mL) from Week 4, and one participant achieved HBsAg decline from 136.1 to 2.75 IU/mL. In the 300 mg cohort (n = 9, Week 2 only), mean $\log_{10}$ HBsAg dropped by 0.38; one participant showed a > 1.9 $\log_{10}$ decline (75.77→0.945 IU/mL) approaching clearance. These blinded interim PD data demonstrate potent, rapid and durable HBsAg suppression, supporting the dual-target siRNA strategy for functional cure. **Immunomodulation**: On Day 29 in the 150 mg dose group, HBV-specific effector $CD8^+$ T cells increased ~76% from baseline; exhausted $PD\text{-}1^+$, $TIM3^+$ and $LAG3^+$ $CD8^+$ subsets decreased by 37%, 70% and 55%, respectively. Peripheral PD-L1 expression was downregulated by 15%, confirming dual-target engagement and reversal of T cell exhaustion. **Conclusion:** Interim blinded data show that SA1211 has favorable safety, nonlinear PK, robust HBsAg reduction and immune restoration in CHB participants. These results support further clinical development for functional cure. **Disclosures:** Yanhua Ding:Nothing to Disclose, Yue Hu:Nothing to Disclose, Junqi Niu:Nothing to Disclose, Nan Liu:Nothing to Disclose, Hui Chen:Nothing to Disclose, Wenbo Zheng:Nothing to Disclose, Hong Zhang:Nothing to Disclose, Xiaojiao Li:Nothing to Disclose, Feifei Zhao:Nothing to Disclose, Hongli Zhang:Nothing to Disclose, Zhiwei Yang:Nothing to Disclose.

4142 | PEVIFOSCOVIR SODIUM REDUCES HBSAG LEVELS TO < 3000 IU/ML IN HBEAG POSITIVE SUBJECTS WITH CHRONIC HBV INFECTION FOLLOWING LONG-TERM ON-STUDY TREATMENT

Man-Fung Yuen[1] Edward Gane[2] Kosh Agarwal[3] Junqi Niu[4] Hong Ren[5] Yanhua Ding[6] Alina Juzov[7] Xier Liang[8] Lung Yi Mak[1] Min Wu[9] Kha Le[9] Andreas Jekle[9] Lawrence Blatt[9] Sushmita Chanda[9] Tse-I Lin[10] Jinlin

Background: Pevifoscorvir sodium (PEVY, ALG-000184) is a novel Type E Capsid Assembly Modulator (CAM-E). In the Phase 1 study ALG-000184-201 (NCT04536337), 96 weeks of 300 mg PEVY ± the nucleoside analog entecavir (ETV) have demonstrated potent on-treatment suppression of HBV DNA, RNA, and viral antigens in participants with chronic HBV infection. Here, we describe in detail the HBsAg reductions observed in HBeAg+ participants during 96 weeks of PEVY ± ETV treatment (ALG-000184-201) as well as during post-PEVY long-term follow-up (LTFU) treatment with ETV in an investigator-initiated study (REG26-1185). **Methods:** A total of 20 HBeAg+ participants with baseline HBsAg > 3000 (3.5 $\log_{10}$) IU/mL were evaluated for HBsAg during 96 weeks of 300 mg PEVY monotherapy (n = 10, P4CB) or PEVY + ETV (n = 10, P4C2) combination therapy and during up to 8 weeks of ETV-only Follow-Up (FU). Additionally, a subset of 9 HBeAg+ participants with PEVY monotherapy completed ETV LTFU of 24-48 weeks in an investigator-initiated study. **Results:** The mean HBsAg levels at baseline, Week 48 and 96 were 4.4, 3.5 and 3.5 $\log_{10}$ IU/mL, respectively. Substantially greater reductions were observed in participants with high baseline HBsAg (> 10000 IU/mL, n = 15) compared to those with low baseline HBsAg (3000-10000 IU/mL, n = 5). At Week 48 and 96, 60% (9 of 15) and 50% (6 of 12) of participants with high baseline HBsAg level achieved HBsAg < 3000 IU/mL. The mean baseline HBsAg level of the subset of 9 participants, that completed 24-48 weeks of ETV LTFU were 4.26 $\log_{10}$ IU/mL. Of these, 57% (4/7) of participants with high baseline HBsAg achieved HBsAg < 3000 IU/mL at both Week 48 and 96, further increased to 83% (5/6) at the last LTFU visit as of data cutoff date. In contrast, of the 3 participants with baseline HBsAg levels < 10000 IU/mL, none reached HBsAg levels < 3000 IU/mL at weeks 48 and 96, and only one at LTFU. **Conclusion:** The extent in HBsAg reduction during PEVY mono and combination therapy was dependent on baseline HBsAg levels with substantially higher reductions in participants with baseline HBsAg levels > 10000 IU/mL. Of these participants, 9/15 (60 %) achieved HBsAg < 3000 IU/mL at Week 48, suggesting potential eligibility for a functional cure combination regimen, that might include an antisense oligonucleotide agent (Table 1).

Table 1: HBeAg+ participants achieving HBsAg < 3000 IU/mL after 96 weeks of PEVY ± ETV and up to 24-48 weeks of ETV LTFU

Baseline HBsAg Level	N	Participants with HBsAg <3000 IU/mL (%)		
		At 48 weeks of PEVY ± ETV	At 96 weeks of PEVY ± ETV	At 24-48 weeks of ETV LTFU after 96 weeks of PEVY
3000-10000 IU/mL	5	0/5 (0%)	0/5 (0%)	1/3 (33%)
> 10000 IU/mL	15	9/15 (60%)	6/12 (50%)	5/6 (83%)
All	20	9/20 (45%)	6/17 (35%)	6/9 (67%)

4143 | A SINGLE SUBCUTANEOUS DOSE OF THE LONG-ACTING CAPSID ASSEMBLY MODULATOR SR-1891 PRODUCES DURABLE, SUPERIOR SUPPRESSION OF SERUM HBV DNA AND RNA COMPARED WITH DAILY ENTECAVIR FOR ≥7 WEEKS IN HUMANIZED AND TRANSGENIC MOUSE MODELS OF CHB

Romano Di Fabio[1] Marco Manenti[1] Alessandro Grillo[1] Pietro Di Lucia[1] Elisa Bono[2] Leonardo Giustini[2] Lorena Donnici[3] Marika Longo Minnolo[3] Katherine Squires[4] Gaston Picchio[2] Raffaele De Francesco[5] Matteo Iannacone[6] Micol Rava'[1] Luca Guidotti[6], [1]Vita-Salute San Raffaele University, [2]IRCCS San Raffaele Scientific Institute, [3]INGM, National Institute of Molecular Genetics, [4]Former Antios Therapeutics, [5]INGM, National Institute of Molecular Genetics & Università degli Studi di Milano, [6]Vita-Salute San Raffaele University & IRCCS San Raffaele Scientific Institute

Background: Chronic HBV infection remains a major global health burden, underscoring the need for novel suppressive therapies with improved antiviral potency and adherence versus current nucleos(t)ide analogues. We report the discovery and preclinical characterization of SR-1891, an ultrapotent (sub-nM) capsid assembly modulator (CAM) that provides long-acting antiviral activity after a single subcutaneous (s.c.) administration. **Methods:** SR-1891 was evaluated for in vitro anti-HBV activity, ADME and PK properties. Antiviral efficacy was assessed following a single s.c. dose of SR-1891 (4 mg/mouse) in HBV-infected immunodeficient liver-humanized mice (HBV Hu; baseline viremia 4×10^8–2×10^9 copies/mL) monitored longitudinally for human serum albumin (HSA), or in immunocompetent HBV-transgenic mice (HBV Tg; 10^7–10^8 copies/mL). This dose is comparable to that used during preclinical development of lenacapavir, a long-acting CAM approved for HIV treatment. At abstract submission, both cohorts remained alive and under follow-up through week 7. Control animals received continuous oral entecavir (ETV; 0.1 mg/kg/day in drinking water). Serum HBV DNA, RNA, HBeAg, HBsAg, and ALT were measured longitudinally. In selected HBV Tg, liver histopathology and hepatocellular capsid distribution were evaluated at week 4. **Results:** A single s.c. administration of SR-1891 demonstrated ADME and PK characteristics consistent with long-acting potential, including low intrinsic clearance and high metabolic stability across species, and liver exposure 34-fold above the 10× protein-adjusted EC90 at the last measurement (day 28). Daily ETV treatment produced progressive multi-$\log_{10}$ reductions in serum HBV DNA through week 7 (reaching −3.3 $\log_{10}$ in HBV Hu and the limit of detection [LOD; ~−4.0 $\log_{10}$] in HBV Tg), without affecting serum HBV RNA or viral antigens. In contrast, a single SR-1891 injection induced faster, deeper and more durable DNA reductions , reaching ≥4 $\log_{10}$ declines by week 5 onward in HBV Hu and by week 2 onward in HBV Tg. Unlike ETV, SR-1891 also reduced serum HBV RNA, with declines ≥-2.5 $\log_{10}$ by week 2 in HBV Hu and to the LOD (≥-2.5 $\log_{10}$) from week 1 in HBV Tg. SR-1891 also produced ~50% reductions in HBeAg and HBsAg beginning at week 5 in cccDNA-bearing HBV Hu, whereas no antigen reductions were observed in cccDNA-deficient HBV Tg. Both ETV and SR-1891 were well tolerated, with stable HSA levels, no ALT elevations, and no histologic evidence of liver injury or aberrant empty capsid accumulation. **Conclusion:** A single dose of SR-1891 produced potent, durable antiviral activity exceeding continuous daily ETV, with efficacy maintained for at least 7 weeks after dosing. Selective reductions in viral antigens in HBV Hu further suggest a potential effect on cccDNA, biogenesis, maintenance and/or function. Ongoing studies evaluating the antiviral activity beyond week 7 and effects on hepatic cccDNA will be presented at the meeting.

4144 | NEW CLINICAL CARE PATHWAY IN ERA OF HBV FUNCTIONAL CURE: A US MULTIDISCIPLINARY EXPERT CONSENSUS

Joseph Ahn[1] Andrea Caracostis[2] Chloe Choi[3] Dawn Drazek[4] Jane Giang[5] Robert Gish[6] Loc Le[7] Mindie Nguyen[8] Amanda Noska[9] Nancy Reau[10] Jimyeong Son[11] Mark Sulkowski[12] Yee Hui Yeo[13] Julie Yoshimachi[14] Chari Cohen[15] Calvin Pan[16] Norah Terrault[17], [1]Endeavor Health, Chicago, IL, USA, [2]HOPE Clinic, Houston, TX, USA, [3]Getwell Medicare PC, Woodside, NY, USA, [4]Carolinas Medical Center, Atrium Health, Charlotte, NC, USA, [5]UNC Health Department of Pharmacy, Chapel Hill, NC, USA, [6]Hepatitis B Foundation, Doylestown, PA, USA, [7]Johns Hopkins/Woodholme Gastroenterology Associates, Pikesville, MD, USA, [8]Stanford University School of Medicine, Palo Alto, CA, USA, [9]University of Minnesota Medical School, Minneapolis, MN, USA, [10]Rush University Medical Center, Chicago, IL, USA, [11]North Shore University Hospital, Manhasset, NY, USA, [12]Johns Hopkins, Baltimore, MD, USA, [13]Cedars-Sinai Medical Center, Los Angeles, CA, USA, [14]Charles B. Wang Community Health Center, New York, NY, USA, [15]Hepatitis B Foundation, Baruch S. Blumberg Institute, Doylestown, PA, USA, [16]NYU Langone Health, NYU Grossman School of Medicine, New York, NY, USA, [17]Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Background: Current care pathways for chronic hepatitis B (CHB) relying on long-term viral suppression deliver minimal functional cure (FC) rates. As therapies achieving higher FC rates emerge, care pathways need to be updated. In 2025, a group of global hepatology experts proposed a 9-step FC care pathway with limited consensus due to heterogeneity in health care systems across countries.[1] We aimed to develop an updated US-focused CHB care pathway for the implementation of FC therapies. **Methods:** A nominal group technique was used to achieve consensus on a US pathway. US stakeholders from multiple disciplines reviewed evidence and guidance relevant to FC care pathways from a targeted literature review and completed a silent brainstorm on the global pathway[1] considering US-specific adaptations. Two consensus meetings were held in 2026. In the first meeting, 8 stakeholders, mainly nonspecialists, discussed changes to the global pathway and voted on an updated pathway. In the second meeting, 11 stakeholders, mainly specialists, discussed the global pathway as well as the amended US pathway and voted on a revised pathway. In each meeting, revisions continued until consensus was achieved for every step. **Results:** In the first meeting, a new US pathway with 6 steps was developed with 100% consensus. Key modifications focused on patient characterization and education, establishment of treatment eligibility, treatment initiation, and care plan development. In the second meeting, the pathway was expanded into 8 steps with 100% consensus (Figure), separating shared decision making processes at the start/end of treatment and adding nuances to monitoring steps. Across both meetings, stakeholders identified several key implementation areas, including quantitative hepatitis B surface antigen testing, access to FC treatment, tools and systems for supporting patient engagement/adherence, provider resources/education, and specific FC treatment algorithms. The role of care coordinators, as well as the need for community engagement and awareness building, were emphasized for successful adoption of FC therapies. **Conclusion:** The new 8-step US FC pathway and implementation priorities may help guide the paradigm shift in CHB management from chronic viral suppression to finite FC therapy.

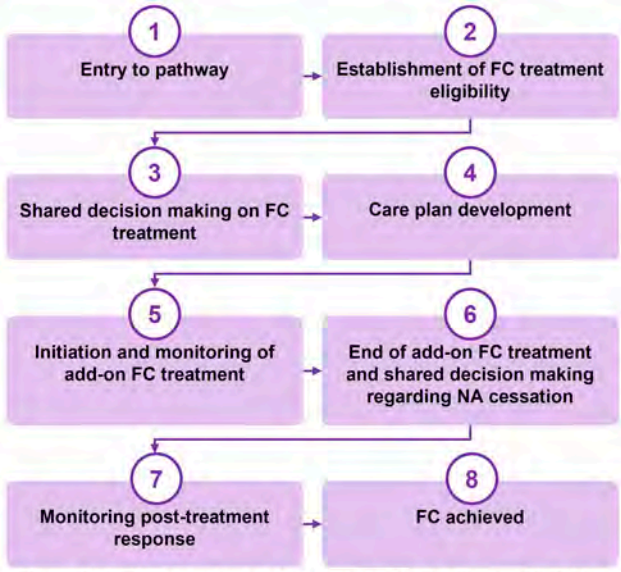

Figure: New FC care pathway in CHB developed by the diverse stakeholders representing different specialties (eg, primary care, advanced practice providers, public health and advocacy representatives, pharmacists, hepatologists, gastroenterologists, infectious disease specialists) and healthcare delivery models in the US (eg, academia and community health centers). The FC care pathway included 8 steps: (1) Entry to pathway: Characterization of patient with CHB (including assessment of qHBsAg, fibrosis stage, HCC risk); patient education (discussion of disease and treatment options); HCC surveillance. (2) Establishment of FC treatment eligibility: Evaluation of patient eligibility (including initiation of NA therapy). (3) Shared decision making on FC treatment: Consideration of risks, benefits, and logistics. (4) Care plan development: Determination of insurance coverage and laboratory costs; arrangement of transportation; coordination with care team members (eg, family, pharmacist, care coordinator). (5) Initiation and monitoring of add-on FC treatment: Adherence to medication and laboratory testing; side effect management; response-guided therapy. (6) End of add-on FC treatment and shared decision making regarding NA cessation. (7) Monitoring post-treatment response: Adherence to clinical and laboratory monitoring; NA retreatment (if needed). (8) FC achieved: Long-term monitoring (reactivation, risk-based HCC surveillance). CHB, chronic hepatitis B; FC, functional cure; HBV, hepatitis B virus; HCC, hepatocellular carcinoma; NA, nucleos(t)ide analog; qHBsAg, quantitative hepatitis B surface antigen.

4145 | TREATMENTS REDUCING HBX SHAPE THE HEPATITIS B VIRUS RESERVOIR TOWARDS A MORE REPRESSIVE CHROMATIN STATE IN VIVO

Maura Dandri[1] Johannes Bächer[1] Moritz Calaminus[1] Andrea Pirosu[1] Tassilo Volz[2] Katja Giersch[1] Marc Lütgehetmann[1] Lena Allweiss[1], [1]University Medical Center Hamburg-Eppendorf, [2]University Medical Centre Hamburg-Eppendorf

Background: Therapeutic interventions that suppress the activity of the HBV reservoir, the cccDNA minichromosome, are urgently needed, as cccDNA silencing may promote functional HBV cure. The structural maintenance of chromosomes 5/6 complex (SMC5/6) is a host restriction factor degraded by HBx. We previously showed that siRNA targeting all HBV transcripts or interferon alpha (pegIFNα) reduced HBV transcripts and proteins, including HBx, in HBV-infected humanized mice, enabling reappearance of SMC5/6 in approximately 40% of human hepatocytes and its association with the cccDNA (Allweiss, Gut 2022). Moreover, SMC5/6-mediated cccDNA silencing persisted after treatment withdrawal when the entry inhibitor bulevirtide was administered to protect hepatocytes from new infections. Herein, we aimed to investigate the epigenetic landscape of SMC5/6-associated cccDNA molecules in mice that received either siRNA, pegIFNα or pegIFNβ, which acts on the same cellular receptor. **Methods:** Post-translational modifications (PTMs) of cccDNA-bound histones, total H3 levels, and SMC5/6 occupancy (via its subunit NSE4) were analyzed by chromatin immunoprecipitation-qPCR (ChIP-qPCR) in livers of HBV-infected humanized mice treated either with siRNA (4 weeks), pegIFNα, or pegIFNβ (25ng/gr, twice/week for 6 weeks). To improve sensitivity, we established sequential ChIP protocols (Re-ChIP) to assess epigenetic marks specifically on NSE4-bound cccDNA molecules. HBV markers were measured by qPCR, WB, and IF. Correlation analyses evaluated associations between intrahepatic viral parameters and cccDNA epigenetic marks. **Results:** pegIFNβ had a stronger antiviral effect than pegIFNα in reducing viremia (-2.6Log vs -1.2Log) and intrahepatic HBV RNA (-1.6Log vs -0.6Log). Both IFN treatments reduced HBx (determined by WB) and promoted the association of SMC5/6 to the cccDNA. However, pegIFNβ significantly increased the levels of

the heterochromatin mark H3K9me3 and total H3 levels on cccDNA, while the ratio of active marks (H3K27ac, H3K4me3) to H3 decreased. Re-ChIP enabled assessment of SMC5/6-bound cccDNA molecules in mice receiving siRNA or peg-IFNα. In NSE4-occupied cccDNA, H3K9me3 levels exceeded those of active histone PTMs H3K27ac and H3K4me3, thus confirming the repressive pattern observed by peg-IFNβ. Moreover, the levels of repressive mark H3K9me3, NSE4 and H3 negatively correlated with HBV DNA and transcription levels across mice and antiviral treatment regimens. **Conclusion:** Treatment with pegIFNβ exerted the strongest antiviral effect in immunodeficient humanized mice, resulting in potent SMC5/6-mediated cccDNA silencing. Our data suggest that cccDNA silencing following HBx reduction shifts the epigenetic landscape of the minichromosome toward a more repressed state, highlighting the potential of HBx-targeting therapies to induce sustained silencing of the HBV reservoir.

4146 | INTRAHEPATIC HBSAG REDUCTION BY IMDUSIRAN IS ASSOCIATED WITH REMODELING OF EXHAUSTED T-CELL PHENOTYPES IN CHRONIC HEPATITIS B

Lydia Tang[1] Emily Thi[2] Tetiana Pozniak[3] Alip Ghosh[3], [1]Institute of Human Virology, University of Maryland School of Medicine, [2]Arbutus Biopharma, [3]Institute of Human Virology School of Medicine University of Maryland, Baltimore

Background: Chronic hepatitis B (CHB) accounts for a substantial proportion of primary hepatocellular carcinoma worldwide and remains a major cause of liver-related mortality. Functional cure, defined by sustained hepatitis B surface antigen (HBsAg) loss with or without anti-HBs seroconversion off all therapy, occurs in approximately 1% of individuals receiving current antiviral therapy. While nucleos(t)ide analogues (NUC) effectively suppress hepatitis B virus (HBV) replication, they rarely lead to HBsAg clearance. Loss of HBsAg is associated with recovery of HBV-specific immunity, suggesting that therapeutic reduction of HBsAg may facilitate immune restoration. Small interfering RNAs (siRNAs) that target HBV transcripts and reduce HBsAg expression are under development; however, their effects on intrahepatic immune cell phenotypes remain poorly defined. This study evaluated the impact of the *N*-acetylgalactosamine–conjugated, pangenotypic siRNA imdusiran (AB-729) on intrahepatic T-cell phenotypes in CHB. **Methods:** Starting July 2024, adults with CHB virally suppressed on NUC without liver fibrosis were enrolled at the Institute of Human Virology, University of Maryland School of Medicine. Participants received imdusiran 60 mg subcutaneously every 8 weeks for 4 doses. Paired liver biopsies were obtained within 24 hours after the first dose and 8 weeks after the final dose. Fresh liver samples were analyzed by flow cytometry to assess intrahepatic immune phenotypes. Viral markers and clinical laboratory parameters, including alanine aminotransferase (ALT), direct bilirubin, and complete blood counts, were monitored. **Results:** Five participants were enrolled. Transient ALT elevations ($\leq$5× the upper limit of normal, without concurrent increases in direct bilirubin) were observed in 4 participants, while the fifth exhibited no ALT changes. HBsAg levels decreased in all participants; in 3 participants with available data, HBsAg change from baseline at week 24 ranged from -1.2 to -2.8 $\log_{10}$ IU/mL. Paired liver biopsy data is available for 4 participants. Markers of T-cell exhaustion were reduced: PD-1 decreased in $CD4^+$ but not $CD8^+$ T cells (mean reduction from 64% to 52%). 2B4 and TIGIT declined in both $CD4^+$ (2B4: 15% to 3%; TIGIT: 32% to 24%) and $CD8^+$ T cells (2B4: 62% to 39%; TIGIT: 44% to 40%). $CCR7^-$ effector memory T cells decreased within the $CD4^+$ population (mean reduction from 95.5% to 79.7%) but not in $CD8^+$. CD38 and HLA-DR expression were markedly reduced on both $CD4^+$ and $CD8^+$ T cells. **Conclusion:** Reduction of intrahepatic HBsAg via siRNA therapy was associated with remodeling of dysfunctional intrahepatic T-cell phenotypes, characterized by decreased expression of exhaustion markers and contraction of effector memory populations. These findings support intrahepatic antigen reduction as a strategy for restoring liver immune dysfunction in CHB.

4147 | ANTIVIRAL AND IMMUNE PROFILING OF HECN2401213, A POTENTIAL BEST-IN-CLASS HBV ANTISENSE OLIGONUCLEOTIDE

Pu Wang[1] Yong Xie[1] Chujun Liu[1] Yuzhuang Li[2] YingLin Zuo[1] Baohua Gu[1] Jing Li[1] Yunfu Chen[1], [1]Sunshine Lake Pharma Co., Ltd., [2]Dongguan HEC Biopharmaceuticals R&D Co., Ltd.

Background: Functional cure in chronic hepatitis B (CHB) remains a significant challenge. While most novel anti-HBV agents fail to achieve meaningful HBsAg loss, HBV antisense oligonucleotides (ASOs) such as bepirovirsen (GSK-836) and AHB-137 have demonstrated unique activity as monotherapy, owing to their dual mechanism of RNase H-mediated viral RNA degradation and immunomodulatory effects. Here we characterize HECN2401213, a next-generation HBV ASO engineered for superior antiviral potency, and evaluate its immunomodulatory profiles across multiple pre-clinical models. **Methods:** Antiviral activities were assessed in HepG2.2.15 cells, HBV-infected primary human hepatocytes (PHH), adeno-associated virus (AAV)-HBV and HBV-transgenic mouse models. Immunomodulatory activities were evaluated in human peripheral blood mononuclear cells (PBMCs), a toll-like receptor 8 (TLR8) reporter cell line and hTLR8 knock-in mice. Further hepatic immune profiling was done via flow cytometry and single-cell RNA sequencing (scRNA-seq) in wild-type C57BL/6 mice. **Results:** In the PHH-HBV model, HECN2401213 demonstrated approximately 4-fold higher antiviral potency than GSK-836, with EC_{50} values ranging from 1.1 to 2.3 nM across various viral markers. In AAV-HBV mice, HECN2401213 produced a 2.68 $\log_{10}$ IU/mL reduction in plasma HBsAg versus 1.38 $\log_{10}$ IU/mL for GSK-836 at an identical dose/regimen ($p < 0.001$, n = 5/group). *In vitro*, HECN2401213 and GSK-836 induced comparable level of cytokines (e.g. IL-6) in human PBMC and exhibited similar TLR8 agonism in reporter cell lines. In hTLR8 knock-in mice, both ASOs triggered significant IL-12 elevation in serum and liver. In C57BL/6 mice, both agents markedly expanded intrahepatic immune cell populations, consistent with robust hepatic innate immune activation. Notably, HECN2401213 significantly upregulated MHC class II-related gene (e.g., H2-Ab1, H2-Eb1, Cd74, and Cd86) and increased glycolysis towards antiviral states in Kupffer cells, which are pivotal for effective intrahepatic T-cell priming during chronic HBV infection. **Conclusion:** HECN2401213 exhibits best-in-class potential, characterized by significantly superior antiviral efficacy and balanced, finely-tuned immunomodulatory activities. These data strongly support its advancement into clinical development, either as monotherapy or in combination regimens, to accelerate functional cure rates in CHB. IND-enabling studies are ongoing.

[13]Department of infectious diseases, The Second Xiangya Hospital of Central South University, [14]Jiangsu Hansoh Pharmaceutical Group Co., Ltd.

Background: The PROMOTE study has demonstrated significant efficacy of tenofovir amibufenamide (TMF) at weeks 48 and 96 in chronic HBV-infected patients with normal alanine aminotransferase (ALT) levels, with favorable bone, renal and lipid safety profiles. Here, we reported the 144-week long-term results of the PROMOTE study. **Methods:** In this multicenter, randomized, open-label, blank-controlled trial conducted in China, eligible patients aged 18-65 years with chronic HBV-infection (serum HBV DNA >20 IU/mL) and normal ALT levels ($\leq$1×ULN [40 IU/L]) were enrolled. Patients were randomly assigned (1:1) to receive once-daily TMF for 240 weeks or blank control group. The efficacy endpoints included the proportion of patients achieving HBV DNA <20 IU/mL, the changes in HBsAg and ALT levels. **Results:** A total of 193 patients were included in the full analysis set (93 in the TMF group and 100 in the blank control group). Baseline characteristics were well-balanced between groups. The proportion of patients achieving HBV DNA <20 IU/mL in the TMF group increased steadily, from 74.2% at week 48 to 77.4% at week 96 and 81.7% at week 144, with significant differences versus the blank control group (all $p<0.001$). Patients with baseline HBV DNA $\geq$8 $\log_{10}$ IU/mL showed a steady increase in virologic response rate, reaching 4.8% at week 48, 38.1% at week 96 and 52.4% at week 144. Similar trends were observed in other difficult-to-treat subgroups, including patients aged $\leq$30 years, baseline HBV DNA $\geq$7 $\log_{10}$ IU/mL, or HBeAg-positive. Moreover, among patients with baseline HBV DNA $\geq$8 $\log_{10}$ IU/mL who did not achieve virologic response, HBV DNA levels decreased significantly by 6.23 $\log_{10}$ IU/mL from baseline as early as week 48. In the TMF group, the proportion of patients achieving ALT <0.5×ULN increased significantly by week 48 and remained stable, whereas it showed little change in the blank control group. One patient in the TMF group achieved HBsAg loss with seroconversion at week 48, sustained through week 144. In the blank control group, 9 patients who experienced disease progression met the treatment criteria per current Chinese guidelines and subsequently initiated TMF treatment during the 144-week follow-up period. No antiviral resistance was observed in the TMF group through 144 weeks, including two patients who experienced virologic breakthrough. In the blank control group, one patient experienced an ALT flare (ALT >5×ULN). Changes from baseline in estimated glomerular filtration rate, creatinine clearance, serum creatinine, calcium, phosphorus, and lipid parameters (including triglyceride, high-density lipoprotein cholesterol and TC/HDL) during the 144 weeks were similar between groups (all $p>0.05$). **Conclusion:** Long-term treatment with TMF provided sustained virologic benefits in patients with CHB and normal ALT, with a favorable renal, bone, and lipid safety profile at week 144.

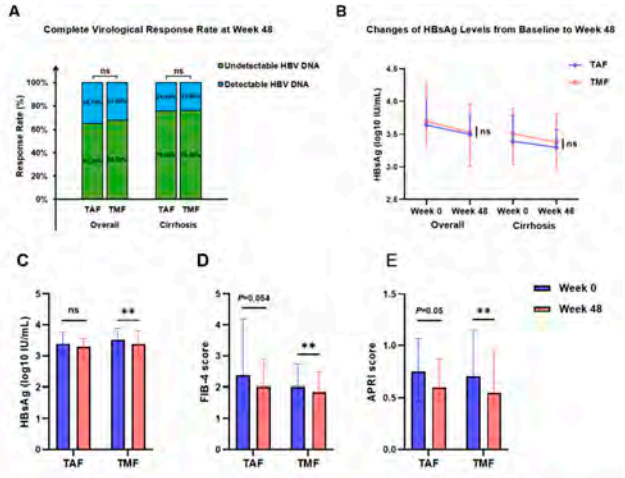
4149 | EFFICACY AND SAFETY OF TENOFOVIR ALAFENAMIDE VERSUS TENOFOVIR AMIBUFENAMIDE IN CHRONIC HEPATITIS B PATIENTS WITH LOW-LEVEL VIREMIA



Wenting Peng[1] Lei Fu[2] Chuan Jiang[2], [1]Xiangya Hospital Central South University, [2]Xiangya Hospital CSU

Background: Low-level viremia (LLV) during nucleos(t)ide analogue (NA) therapy remains a challenging issue in chronic hepatitis B (CHB), as LLV is associated with fibrosis progression, hepatocellular carcinoma (HCC), and virological breakthrough. Tenofovir alafenamide (TAF) and tenofovir amibufenamide (TMF) are both potent first-line agents with favorable safety profiles; however, real-world data in NA-treated LLV patients are limited, especially in those with cirrhosis. This study compares the efficacy and safety of TAF and TMF in this population, with a focused analysis on the compensated cirrhosis subgroup. **Methods:** This retrospective study enrolled NA-treated CHB patients with LLV (HBV DNA: 10-2000 IU/mL) who switched to TAF or TMF between November 2018 and December 2024. The primary endpoint was the rate of complete virological response (CVR; defined as undetectable HBV DNA) at week 48. Secondary endpoints included HBsAg decline, HBeAg loss, ALT normalization, lipid profile changes, and non-invasive fibrosis indices (FIB-4, APRI). For the cirrhosis subgroup, changes in

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

portal vein diameter and spleen thickness were additionally evaluated. **Results: Overall Cohort (N = 359):** The week-48 CVR was 65.3% (130/199) in the TAF group and 68.1% (109/160) in the TMF group ($P > 0.05$). HBeAg-negative patients showed significantly higher CVR rates than HBeAg-positive patients ($P < 0.05$). Inter-group comparisons revealed no significant differences in HBsAg decline or lipid profile alterations at week 48 ($P > 0.05$). **Cirrhosis Subgroup (N = 101):** Week-48 CVR rates were comparable between the TAF (75.6%, 44/59) and TMF (76.2%, 32/42) groups ($P > 0.05$), with higher CVR again observed in HBeAg-negative patients ($P < 0.05$). No significant differences were found between the two groups in HBsAg decline, FIB-4, or APRI scores ($P > 0.05$). Within-group analysis showed that in the TMF group, HBsAg decline, FIB-4, and APRI scores decreased significantly from baseline ($P < 0.05$), whereas the TAF group did not show statistically significant decreases in these parameters. No cirrhosis progression or HCC was observed during the 48-week follow-up in either group. **Conclusion:** In NA-treated CHB patients with LLV, TMF, and TAF demonstrated comparable virological suppression and lipid stability at week 48. In the cirrhosis subgroup, both agents also showed comparable CVR rates and similar effects on non-invasive fibrosis indices. Although within-group analyses revealed significant improvements in HBsAg levels and non-invasive fibrosis indices with TMF in cirrhotic patients, its potential superiority over TAF warrants further investigation.

(A) Complete virological response (CVR) rates at week 48: Comparison of CVR (defined as undetectable HBV DNA) at week 48 between the TAF and TMF groups in the overall cohort and the cirrhosis subgroup.

(B) Changes in HBsAg levels from baseline to week 48: Trends of HBsAg level changes from baseline (Week 0) to week 48 in the TAF and TMF groups within the overall cohort and the cirrhosis subgroup.

(C-E) Within-group changes of clinical indices in the cirrhosis subgroup: Within-group analysis showing the changes in (C) HBsAg levels, (D) FIB-4 scores, and (E) APRI scores from baseline (0W) to week 48 (48W) in the cirrhosis subgroup.

Background: Bepirovirsen (BPV), an antisense oligonucleotide, is the first anti-hepatitis B virus (HBV) therapy in global Phase 3 trials with functional cure (FC) as the primary outcome. Baseline predictors of response analyses may be helpful in assessing whether there is heterogeneity in the treatment effect. This exploratory analysis investigated the baseline predictors of FC following BPV treatment in the B-Well 1 and 2 trials. **Methods:** B-Well 1 and 2 are global double-blind Phase 3 trials, including non-cirrhotic adults with nucleos(t)ide analog (NA)-suppressed chronic HBV infection (HBV DNA < 90 IU/mL) and hepatitis B surface antigen (HBsAg) > 100– ≤ 3000 IU/mL. Participants (pts) were randomized 2:1 to BPV 300 mg or placebo (PBO) weekly for 24 weeks (wks), and discontinued NAs at Wk48, if eligible. FC is defined as HBV DNA < lower limit of quantification and HBsAg loss 24 wks after cessation of all HBV treatment. Baseline variables examined in this analysis included age, alanine aminotransferase, aspartate aminotransferase to platelet ratio index, baseline NA type, body mass index, estimated glomerular filtration rate, hepatitis B core-related antigen (log10), hepatitis B e-antigen (HBeAg) status, platelet, quantitative HBsAg (log10), quantitative HBV DNA (log10), race, sex, study, time on current NA, treatment, and HBV genotype, which was assessed using a multimethod approach since pts were virally suppressed on NA. Logistic regression analysis using backward elimination based on Akaike information criterion (AIC) was used to identify baseline predictors of FC, and a multivariable model was constructed which included study, treatment, and HBsAg strata irrespective of their impact on AIC. **Results:** In this multivariable analysis, 944 pts from B-Well 1 and 832 pts from B-Well 2 were included. Among BPV-treated pts, 19% (227/1182) achieved FC whereas no PBO pts achieved FC (0/594). Lower baseline HBsAg (log10) was strongly associated with higher FC rates (odds ratio [OR]: 0.12, 95% CI: 0.067, 0.218; p < 0.0001). Younger age (OR: 0.95, 95% CI: 0.931, 0.962; p < 0.0001), female sex (OR: 1.63, 95% CI: 1.144, 2.314; p = 0.0067), and HBeAg negative status (OR: 0.42, 95% CI: 0.193, 0.930; p = 0.0323) were also significantly associated with FC. HBV genotype was significantly associated with FC (p = 0.0013), with the highest FC rates observed in genotype A, followed by B, D, and C (**Table**). **Conclusion:** A lower baseline HBsAg (log10) was a strong predictor of FC after 24 wks of BPV treatment. As the B-Well studies collected samples for novel biomarkers, future analyses may incorporate novel biomarkers as potential baseline predictors of response to develop a more comprehensive multivariable model that could serve as a reference to evaluate simpler models meant for clinical use. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820)[For the B-Well Study Group]

Table. Statistical analysis of baseline variables significantly associated with FC success

Background: Bepirovirsen (BPV) is an antisense oligonucleotide and is the first anti-hepatitis B virus (HBV) therapy in global Phase 3 trials with functional cure (FC) as the primary outcome. The aim of this post-hoc analysis is to describe the hepatitis B surface antigen (HBsAg) dynamics in participants (pts) who did not achieve FC. **Methods:** B-Well 1 and 2 are global double-blind Phase 3 trials. Non-cirrhotic adults with nucleos(t)ide analog (NA)-suppressed chronic HBV infection (HBV DNA <90 IU/mL) and HBsAg $>100–\leq3000$ IU/mL were randomized 2:1 to BPV 300 mg or placebo (PBO) weekly for 24 weeks (wks).

Pts discontinued NAs at Wk48, if eligible. HBsAg and HBV DNA levels were monitored throughout the study. FC was defined as ≥24 wks of sustained HBV DNA < lower limit of quantification (LLOQ) and HBsAg loss (<0.05 IU/mL) after finite therapy (i.e. off all HBV therapy including NAs), with or without hepatitis B surface antibody. DNA suppression was defined as ≥24 wks of sustained HBV DNA **Results:** Among pooled B-Well 1 and 2 BPV pts, 24% (295/1220) pts stopped NAs at Wk48. At Wk72, 19.1% (233/1220) achieved FC and an additional 4.1% (50/1220) achieved DNA suppression without FC (**Figure**), of which 49 pts maintained HBsAg <10 IU/mL (one pt had missing quantitative HBsAg); no PBO pts stopped NAs or achieved FC. Of 12 pts who stopped NAs and failed to achieve either FC or DNA suppression at Wk72, 5 had confirmed HBV DNA elevation (HBV DNA >20 IU/mL but <2000 IU/mL) and the remaining 7 pts could not be evaluated (e.g. due to withdrawal from study, missing data, or reinitiation of NAs not for the purpose of DNA control). Of the pts who did not achieve FC or DNA suppression at Wk72, 44.6% (418/937) BPV pts versus 1.3% (8/614) PBO pts had a >0.5 log decrease in HBsAg from baseline and 27.4% (257/937) BPV pts versus 0.5% (3/614) PBO pts also had a >1 log decrease in HBsAg from baseline. This included 23 BPV pts and one PBO pt who continued NAs at Wk48 and consequently were not assessed for FC but had HBsAg loss at Wk72. **Conclusion:** At Wk72, approximately 1 year after the end of BPV treatment, 19.1% of BPV pts had FC, and an additional 4.1% of BPV pts had DNA suppression with low, but detectable HBsAg. Of remaining pts, 27.4% of BPV pts had a >1 log decrease in HBsAg from baseline. By comparison, no PBO pts achieved FC and 0.5% of PBO pts experienced the same level of HBsAg reduction relative to baseline at Wk72. Long-term follow-up will determine the clinical significance of observed reductions in HBsAg from baseline in the absence of FC. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820) [For the B-Well Study Group]

Collegeville, PA, USA, [4]GSK, Stevenage, Hertfordshire, UK (at time of study conduct), [5]GSK, Upper Providence, NJ, USA, [6]GSK, Durham, NC, USA

Background: Bepirovirsen (BPV) is an antisense oligonucleotide that targets a conserved 20-nucleotide sequence within hepatitis B virus (HBV) pregenomic RNA and mRNAs. B-Well 1 and 2 are global, randomized, double-blind, Phase 3 trials assessing the efficacy and safety of weekly BPV 300 mg or placebo (PBO) for 24 weeks in participants (pts) with nucleos(t)ide analog (NA)-suppressed chronic HBV infection, with functional cure (FC) as the primary outcome. This analysis assessed the association of BPV binding site single nucleotide polymorphisms (SNPs) detected at baseline with FC rate (Week 72) and end of treatment (EOT; Week 24) hepatitis B surface antigen (HBsAg) serum level reduction. **Methods:** Next-generation sequencing was used to sequence HBV DNA/RNA at baseline for all pts. A SNP was reported in any nucleotide polymorphism (substitution, deletion or insertion) with allelic frequency $\geq$5%. FC was defined as $\geq$24 weeks of sustained HBV DNA **Results:** In a pooled analysis of B-Well 1 and 2, baseline sequence information was only available for 19% (n = 227/1223) of BPV pts and 20% (n = 120/611) of PBO pts as pts were on NAs. BPV binding site SNPs presented with low prevalence in both BPV (n = 14/227; 6%) and PBO (n = 15/120; 13%) treatment groups; 20 unique binding site SNPs were identified at baseline. BPV binding site SNP C1589A was most commonly observed and was present in 1 PBO- and 4 BPV-treated pts. FC was achieved for 14% (n = 2/14) of pts on BPV with baseline binding site SNPs versus 10% (n = 22/211) of pts on BPV without baseline binding site SNPs. Baseline binding site SNPs G1588T and C1589A were identified in pts who achieved FC. In pts treated with BPV, numerically lower reductions in change from baseline EOT HBsAg levels were observed in pts with baseline BPV binding site SNPs versus those with wild-type binding sites; this was consistent in both studies (mean change from baseline: −2.21 vs −2.94 $\log_{10}$ IU/mL [n = 7 vs n = 108; B-Well 1]; −2.78 vs −2.99 $\log_{10}$ IU/mL [n = 5 vs n = 90; B-Well 2]). **Conclusion:** Baseline SNPs within the BPV binding site were infrequent, with low prevalence across studies and treatment groups; C1589A was the most frequently observed SNP at baseline. Pts with baseline BPV binding site SNPs had reductions in HBsAg levels at EOT, albeit numerically lower when compared with those with wild-type BPV binding site sequences. The clinical impact of BPV binding site baseline SNPs on BPV treatment cannot be determined at this stage and will be subject to further evaluation. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820)[for the B-Well Study Group]

4153 | SERUM BIOMARKERS ASSOCIATED WITH AND MEDIATING THERAPEUTIC ALANINE AMINOTRANSFERASE (ALT) INCREASES DURING BEPIROVIRSEN TREATMENT IN B-WELL 1 AND B-WELL 2

Jenn Singh[1] Johannes Freudenberg[1] Sorcha O'Byrne[2] Jared Delahaye[1] Kai Fu[1] Puneet Dhawan[1] Luca Pagliaroli[1] Sohil Joshi[1] Kristen Consalvo[1] Corey Poveda-Rogers[1] Rob Elston[2] Melanie Paff[1] Dickens Theodore[3] Jill Walker[4], [1]GSK, Collegeville, PA, USA, [2]GSK, Stevenage, UK, [3]GSK, Durham, NC, USA, [4]GSK, San Francisco, CA, USA

Background: Bepirovirsen (BPV) is an antisense oligonucleotide that targets a conserved 20-nucleotide sequence within hepatitis B virus (HBV) pregenomic RNA and mRNAs. B-Well 1 and 2 are global, randomized, double-blind, Phase 3 trials assessing the efficacy and safety of weekly BPV 300 mg or placebo (PBO) for 24 weeks (wks) in participants (pts) with nucleos(t)ide analog (NA)-suppressed chronic HBV infection, with functional cure (FC) as the primary outcome. Approximately 25% of pts treated with BPV in B-Well experienced transient ALT increases ($\geq$3x upper limit of normal). Here, we investigated serum biomarkers and their association with ALT increase in pts on BPV in the B-Well studies. **Methods:** The Olink Explore 1536 platform was used to perform proteomic analysis on serum samples longitudinally. Pt serum was used to measure roughly 1400 individual proteins. A multipronged post hoc analysis was performed. First, a targeted assessment of ALT dynamics and longitudinal profiles of 83 prespecified cytokines, chemokines, and other proteins (associated with ALT in the B-Together study,[1] HBV, and/or liver heath) were compared across increasing ALT changes from

baseline (CFB). This was followed by a mediation analysis in all proteins to computationally model the cause of ALT increase and quantify the effect of BPV on ALT. FC was defined as ≥ 24 wks of sustained HBV DNA < lower limit of quantification and hepatitis B surface antigen (HBsAg) loss after finite therapy. **Results:** In pts on BPV, ALT increase was associated with greater and earlier HBsAg reduction; most, but not all, FC responders had an ALT increase (≥ 3-fold CFB). The targeted analysis revealed six protein expression profiles; some protein levels increased before and during ALT increase (e.g. TNF and IL-10) and others solely corresponded with ALT temporal dynamics (e.g. KRT18 and AIFM1). Mediation analysis identified a subset of proteins where higher expression at Wk4 subsequently led to higher ALT increases later in the treatment phase. Proteins associated with T cells (PD-1, 4-1BB, LAG3) and B cells (FCER2, FCRL2, CD22) had significant mediating effects on ALT increases during BPV treatment. Proteins associated with other cell types such as macrophages and dendritic cells (TIMD4, MARCO) also had significant mediating effects of BPV on ALT. **Conclusion:** In the B-Well trials, ALT increase was associated with greater and earlier HBsAg decline, and most, but not all, FC responders on BPV had ALT increase (≥ 3-fold CFB). ALT increase accentuates some protein induction associated with BPV treatment while others corresponded with ALT temporal dynamics. Mediation analysis highlighted that B- and T-cell activation are key immune processes leading to ALT increase. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820)[for the B-Well Study Group]1. 4154 | ALT FLARE AND HBSAG DYNAMICS IN FUNCTIONAL CURE OF HBEAG-NEGATIVE CHRONIC HEPATITIS B

Yaqin Zhang[1] Minghui Li[1], [1]Beijing Ditan Hospital, Capital Medical University

Background: ALT flare during pegylated interferon-based therapy may reflect immune activation in chronic hepatitis B. This study evaluated the association between ALT flare, HBsAg dynamics, and 24-month functional cure in HBeAg-negative patients receiving pegylated interferon plus nucleos(t)ide analogues. **Methods:** This retrospective study included 149 HBeAg-negative chronic hepatitis B patients treated with pegylated interferon plus nucleos(t)ide analogues. Patients were classified as no flare, moderate flare, or marked flare. Moderate flare was defined as ALT ≥ 1.5× the upper limit of normal and ≥ 2× baseline ALT, but < 3× the upper limit of normal; marked flare was defined as ALT ≥ 3× the upper limit of normal. Functional cure at 24 months was defined as HBsAg ≤ 0.05 IU/mL. HBsAg dynamics and functional cure rates were compared among groups. Logistic regression was used to identify factors associated with functional cure. **Results:** Among 149 patients, 122 had no flare, 19 had moderate flare, and 8 had marked flare. Overall, 28 patients achieved 24-month functional cure, with a cure rate of 18.8%. Functional cure rates were 15.6%, 36.8%, and 25.0% in the no-flare, moderate-flare, and marked-flare groups, respectively (P = 0.079). Moderate flare showed a higher cure rate than no flare in exploratory pairwise comparison (36.8% vs. 15.6%, P = 0.050), but this was not significant after multiple-comparison adjustment. Patients with functional cure had lower baseline HBsAg levels and greater 6-month HBsAg decline. Moderate/marked ALT flare was associated with functional cure in univariate analysis (OR = 2.71, 95%CI: 1.06–6.92, P = 0.037), but this association was attenuated after adjustment. Six-month HBsAg decline remained the strongest predictor of functional cure (OR = 4.76, 95% CI: 2.28–9.96, P < 0.001). The combined model of baseline HBsAg category and 6-month HBsAg decline showed good predictive performance, with an AUC of 0.898. **Conclusion:** In HBeAg-negative chronic hepatitis B, moderate ALT flare was associated with a higher trend of functional cure, but was not an independent predictor after accounting for HBsAg-related factors. Baseline HBsAg category and 6-month HBsAg decline may better predict functional cure.

4155 | ORAL DELIVERY OF EGCG VIA A DUAL-SHELL FERRITIN NANOPLATFORM RESTORES LYSOSOMAL FUNCTION AND SUPPRESSES HBV REPLICATION

Yixin Dong[1], [1]The First Affiliated Hospital with Nanjing Medical University

Background: Hepatitis B virus (HBV) disrupts lysosomal maturation and acidification, resulting in incomplete autophagy that supports viral persistence. Restoration of lysosomal function has emerged as a promising host-directed therapeutic strategy against HBV. Epigallocatechin gallate (EGCG) has been reported to enhance lysosomal acidification and suppress HBV replication; however, its application is limited by poor stability and low intestinal permeability. We developed a dual-shell chitosan/ferritin nanoplatform (CHE) to improve oral delivery and antiviral efficacy of EGCG. **Methods:** EGCG was encapsulated within recombinant human H-chain ferritin nanocages using a pH-triggered disassembly/reassembly strategy, followed by chitosan coating to generate CHE nanoparticles. Nanoparticle stability and gastrointestinal release behavior were evaluated in simulated digestive conditions. Intestinal transport was assessed using differentiated Caco-2 monolayers and Transwell co-culture systems containing Caco-2 and HepG2.2.15 or HepAD38. Lysosomal acidification, cathepsin B maturation, and autophagic flux were analyzed by acridine orange staining and Western blotting. Antiviral activity was determined by measuring intracellular HBV DNA, pgRNA, HBsAg, and HBeAg levels. **Results:** CHE markedly improved EGCG stability and delayed gastrointestinal release compared with free EGCG and ferritin-loaded EGCG (HE). In differentiated Caco-2 monolayers, CHE significantly enhanced transepithelial transport while maintaining epithelial barrier integrity. In HepG2.2.15 and HepAD38 cells, CHE restored lysosomal acidification and increased mature-cathepsin B expression, indicating recovery of lysosomal function. CHE further promoted autophagic flux, as evidenced by enhanced degradation of p62 and increased LC3 turnover. These effects translated into significantly greater inhibition of HBV DNA and pgRNA synthesis, accompanied by reduced HBsAg and HBeAg secretion. Importantly, CHE retained superior antiviral activity following transport across intestinal epithelial monolayers in co-culture models. **Conclusion:** A dual-shell ferritin-based oral nanoplatform effectively overcomes the stability and intestinal delivery limitations of EGCG and significantly enhances its anti-HBV activity. Restoration of lysosomal acidification and autophagic flux represents a key mechanism underlying viral suppression. These findings support lysosomal restoration as a novel host-directed therapeutic approach for chronic HBV infection and establish CHE as a promising oral nano-therapy for antiviral intervention.

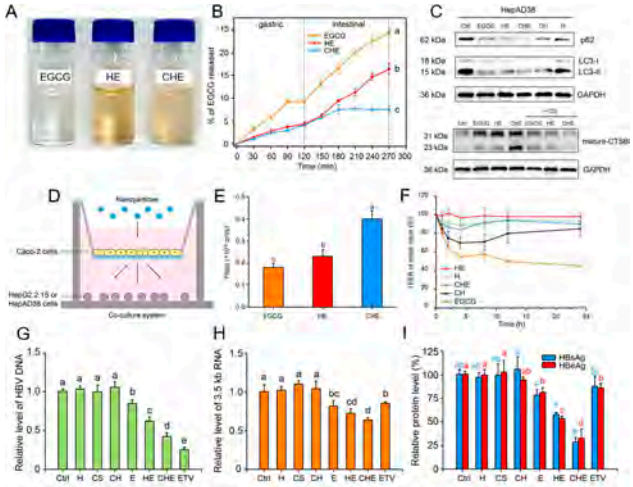

Figure. (A) Representative images of different samples, including EGCG, HE, and CHE. (B) In vitro simulated gastrointestinal digestion analysis. (C) Western blot analysis of p62, LC3, and mature-cathepsin B (mature-CTSB) expression. (D) Schematic illustration of the Transwell model with a differentiated Caco-2 monolayer established over 21 days. (E) P_{app} of free EGCG and EGCG encapsulated within HE and CHE nanoparticles after 24 h of incubation with Caco-2 monolayers in Transwell inserts. (F) Effects of different formulations on TEER values of Caco-2 monolayers over a 24 h exposure period. Inhibitory effects on HBV DNA (G), pgRNA (3.5 kb RNA) (H), HBsAg and HBeAg (I) secretion in HepAD38 cells. Different letters indicate statistically significant differences ($p < 0.05$), as determined by Duncan's multiple range test.

4156 | THE POTENTIALLY BEST-IN-CLASS HBV ASO ALG-170675 DEMONSTRATES A FAVOURABLE PRECLINICAL PROFILE: EFFICACY IN AN AAV-HBV MOUSE MODEL, PHARMACOKINETICS AND SAFETY IN MOUSE AND MONKEY

Jin Hong[1] Dinah Misner[1] Kusum Gupta[1] Vivek Rajwanshi[1] Jimmy Lu[2] Sandra Chang[1] Hyunsoon Kang[1] Min Luo[1] Antitsa Stoycheva[1] Dana Cho[1] John Cortez[1] Kellan Passow[1] Jacquelyn Sousa[1] Shane Daguison[1] Jieun Song[1] Lillian Adame[1] Cheng Liu[1] Sarah Stevens[1] Aneerban Bhattacharya[1] Lawrence Blatt[3] Leonid Beigelman[4] David Smith[1] Sushmita Chanda[1] Li Sun[2] Julian Symons[1], [1]Aligos Therapeutics, [2]Amoytop Biotech., [3]Aligos Therapeutics, Inc., [4]Former employee of Aligos Therapeutics

Background: ALG-170675 is a next generation HBV ASO with dual RNase H and human TLR8 agonist activities and is currently in late-stage preclinical development. ALG-170675 demonstrated better efficacy and liver PK than GSK-836 when dosed at 40 mg/kg x 6 in AAV-HBV mice. No liver toxicity was observed when ALG-170675 was dosed at 50 mg/kg x 7 in either uninfected or HBV-infected PXB mice with humanized livers (Publication 1155, AASLD 2025). Here, ALG-170675 was dosed in an AAV-HBV mouse model in

combination with a close analog of ALG-000184 (HBV CAM-E). ALG-170675 combinations with the nucleos(t)ide analog entecavir (ETV), HBV siRNA ALG-125903 (parent drug of ALG-125755) and ALG-001075 (parent drug of ALG-000184) were also studied in vitro. Pharmacodynamics (PD), pharmaco-/toxicokinetics (PK/TK) and toxicology of ALG-170675 were evaluated in mouse and monkey. **Methods:** HBV cell models, such as HepG2.2.15 and HepG2.117, were used for combination studies in vitro to assess reduction in HBsAg and HBV DNA, respectively. In vivo ALG-170675 dose response and combination studies were performed in the AAV-HBV mouse model. PK, PD and toxicity/TK evaluations in mouse and monkey were conducted at Wuxi AppTec. **Results:** When dosed at 10, 20 and 40 mg/kg x 6 in AAV-HBV mice, ALG-170675 showed dose response related reductions in HBsAg levels with up to a 0.66 $\log_{10}$ IU/mL additional maximum HBsAg reduction compared to GSK-836. Elevated liver exposures compared to GSK-836 were observed. When close analogs of ALG-170675 and ALG-000184 were combined in AAV-HBV mice, both plasma HBsAg and HBV DNA showed additive to synergistic effects. Further, in vitro combination studies showed additive effects when ALG-170675 was combined with ETV, or CAM-E ALG-001075, or HBV siRNA ALG-125903. ALG-170675 was absorbed and distributed rapidly following a single subcutaneous (SC) dose in CD-1 mice. ALG-170675 was stable in plasma as the intact ASO was the major circulating entity (>99%). Liver concentrations were measurable through 28 days, with a half-life of ~7 days. Following repeat SC administrations over 28 days, the exposures increased proportionally from 10 to 100 mg/kg/dose in mice and monkeys. No sex difference or accumulation of systemic exposures was observed in monkeys. Monkey PD markers IL-1RA, MCP-1, and CRP were elevated. ALG-170675 was well tolerated in 1-month repeat-dose range-finding toxicity studies in mice and monkeys and NOAELs were determined to be 30 mg/kg/dose in both species. Adverse effects at the higher dose of 100 mg/kg/dose included hepatocellular necrosis in mice accompanied by increases in liver enzymes and thymic lymphocytic hypocellularity in monkeys. **Conclusion:** ALG-170675 showed potential to be a best-in-class HBV ASO based on preclinical studies conducted to date. Preclinical development is underway, with ALG-170675 expected to enter the clinic in late 2026.

4157 | ALT TRAJECTORY PATTERNS ARE ASSOCIATED WITH VIROLOGICAL RESPONSE STABILITY IN CHB PATIENTS RECEIVING PEG-IFN COMBINATION THERAPY

Dianya Qiu[1] Minghui Li[1], [1]Capital Medical University Affiliated Beijing Ditan Hospital

Background: Alanine aminotransferase (ALT) dynamics may reflect hepatic inflammation and immune activity during antiviral therapy for chronic hepatitis B (CHB). However, the relationship between longitudinal ALT trajectory patterns and the stability of virologic response (VR) during pegylated interferon (PEG-IFN)-based combination therapy remains unclear. **Methods:** A total of 255 CHB patients receiving PEG-IFN combined with tenofovir alafenamide (TAF) or tenofovir disoproxil fumarate (TDF) with 24-month follow-up were enrolled. ALT normalization was defined as ALT $\leq$40 U/L, and VR as HBV DNA $\leq$20 IU/mL. Sustained virologic response (SVR) was defined as VR maintained at months 12, 18, and 24. Group-based trajectory modeling (GBTM) was used to identify dynamic ALT patterns, and associations between ALT trajectories and virologic outcomes were evaluated. **Results:** ALT normalization increased from 62.4% at baseline to 74.9% at month 24, while the VR rate increased from 63.9% to 91.0%. Three ALT trajectories were identified: low-stable ALT (86.3%), persistent abnormal/fluctuating elevated ALT (5.5%), and high ALT with rapid decline (8.2%). The persistent abnormal/fluctuating elevated ALT group showed the lowest SVR rate (50.0%) compared with the low-stable ALT group (79.5%) and the high ALT with rapid decline group (81.0%) ($P = 0.033$). At month 24, VR rates were 95.2%, 91.4%, and 78.6%, respectively, with no significant difference among groups ($P > 0.05$). Among patients without VR at baseline, time to VR did not differ significantly across ALT trajectory groups (log-rank $P = 0.15$). Agreement between ALT flare and HBV DNA flare was low (Kappa = 0.068). **Conclusion:** CHB patients receiving PEG-IFN combination therapy exhibit distinct dynamic ALT trajectories. Persistent abnormal or fluctuating ALT elevation is associated with reduced

SVR stability, suggesting that longitudinal ALT trajectory analysis may help identify patients at risk for unstable virologic suppression during treatment. Given the small sample sizes in some trajectory subgroups, these findings should be considered exploratory, and the independent predictive value of ALT trajectories requires validation in larger cohorts.

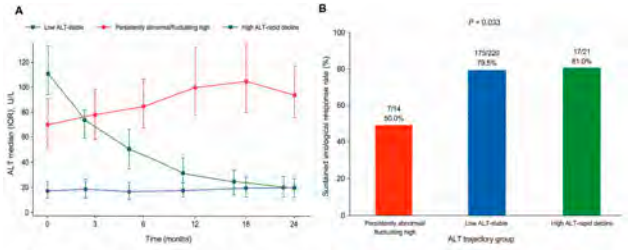

Figure 1. Association between ALT trajectory patterns and sustained virological response stability during PEG-IFN combination therapy. (A)Distinct ALT trajectory groups during treatment follow-up. (B)Sustained virological response by ALT trajectory group.

Disclosures: Dianya Qiu:Nothing to Disclose, Minghui Li:Nothing to Disclose.

4158 | PEVIFOSCORVIR SODIUM (CAM-E) IS SUPERIOR TO NUCLEOS(T)IDE ANALOGS IN SUPPRESSING HEPATITIS B VIRUS DOUBLE-STRANDED LINEAR DNA IN VITRO

Yannick Debing[1] Antonios Kountouratzis[1] Hannah Vanrusselt[1] Jordi Verheyen[1] Julian Symons[2] Lawrence Blatt[3] Tse-I Lin[1] Andreas Jekle[3], [1]Aligos Belgium BV, [2]Aligos Therapeutics, [3]Aligos Therapeutics, Inc.

Background: Circulating hepatitis B virus (HBV) DNA consists mostly of relaxed circular DNA (rcDNA) and double-stranded linear DNA (dslDNA). dslDNA is the precursor form for HBV DNA integration into the host genome, which contributes to disease progression and development of hepatocellular carcinoma. It remains unclear to what extent nucleos(t)ide analogs (NAs), such as tenofovir disoproxil fumarate (TDF) and entecavir (ETV), affect rcDNA vs. dslDNA production. Additionally, the HBV capsid assembly process has emerged as a key target for the treatment of chronic HBV infection. The capsid assembly modulator (CAM) pevifoscorvir sodium (pevy) has demonstrated best-in-class reductions of HBV DNA, RNA, HBsAg, HBeAg and HBcrAg in participants with chronic HBV infection. Here, we investigated the effects of NAs and CAMs on production and secretion of HBV rcDNA and dslDNA in vitro. **Methods:** HBV rcDNA and dslDNA were quantified by a specifically developed multiplex digital PCR (dPCR) procedure that allows to distinguish and quantify each form in a way that is not possible with conventional quantitative PCR. The effects of NAs TDF and ETV and CAM ALG-001075 (pevy active parent) on intracellular and secreted HBV rcDNA and dslDNA were assessed in HepG2.117, HepAD38, HBV-infected HepG2-NTCP cells and primary human hepatocytes. **Results:** The specificity of the dPCR protocol was confirmed with selective nuclease digestions of either rcDNA or dslDNA before analysis. In all tested cellular systems, NAs and CAM ALG-001075 inhibited the production of both rcDNA and dslDNA in a dose-dependent fashion. Interestingly, NAs TDF and ETV showed a clear difference in inhibiting rcDNA vs. dslDNA, with consistently lower EC_{50} values for rcDNA than for dslDNA, again in all tested cellular systems. Conversely, CAM ALG-001075 showed similar EC_{50} values for both forms, in line with its mechanism of action, blocking pgRNA encapsidation, which precedes the reverse transcription to rcDNA and dslDNA. Intriguingly, relative ratios of rcDNA vs. dslDNA differed between cellular systems and between intracellular and secreted fractions of HBV DNA. Quantification of dslDNA and rcDNA in patient samples will be presented at the conference as well. **Conclusion:** CAM ALG-001075 demonstrated pronounced and equipotent inhibition of HBV rcDNA and dslDNA production in vitro, whereas NAs were less effective at inhibiting dslDNA than rcDNA production. These results suggest that CAMs could be superior to NAs in preventing HBV DNA integration, not only through deeper suppression of HBV DNA levels, but also by more effective suppression of dslDNA, the precursor to integration.

4159 | THERAPEUTIC VACCINATION WITH TLR9-ADJUVANTED HBSAG IN CHRONIC HEPATITIS B: A PHASE 1 PROOF-OF-CONCEPT STUDY

Gaayathri Krishnan[1] Tetiana Pozniak[2] Alip Ghosh[2] Salma Sharaf[2] Shyamasundaram Kottilil[2] Lydia Tang[2], [1]University of Maryland, [2]Institute of Human Virology

Background: Chronic hepatitis B (CHB) infection results from inadequate host immune control of the hepatitis B virus (HBV). Although nucleos(t)ide analogs (NUCs) effectively suppress viral replication, they rarely achieve a functional cure, defined as sustained loss of hepatitis B surface antigen (HBsAg) and undetectable

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

HBV DNA following treatment discontinuation. We investigated if achieving HBsAb production lead to sustained HBsAg loss in CHBToll-like receptor 9 (TLR9) is central to activating innate immunity and is a promising immunomodulatory target in CHB. Expressed on dendritic cells and B cells, TLR9 recognizes HBV DNA and promotes downstream antiviral and humoral immune responses. In CHB, TLR9 expression is reduced and signaling is impaired. Preclinical studies demonstrate that TLR9 agonists, particularly in combination with NUCs, increase antiviral cytokine production and reduce surface antigen levels, supporting their therapeutic potential. The BOOST-9 study evaluated HEPLISAV-B (Dynavax Technologies Corporation), an FDA-approved prophylactic HBV vaccine containing HBsAg adjuvanted with a TLR-9 agonist, as a therapeutic vaccination strategy to assess safety, tolerability, and immunological and virological efficacy in patients with CHB. **Methods:** BOOST-9 was a single-site, pilot phase 1 proof-of-concept study evaluating safety and humoral and virologic responses to toll-like receptor 9 adjuvanted HBV vaccination. Ten adults with CHB on NUCs, without liver fibrosis, received two 0.5 mL intramuscular injections of HEPLISAV-B (day 0 and week 4), with follow-up at weeks 8 and 24, and at 12 months. Clinical (HBV DNA, renal and liver function tests, complete blood count, and quantitative HBsAb) and research labs (B cell ELISpots, flow cytometry, and pregenomic RNA [pgRNA]) were collected throughout. **Results:** All 10 subjects (ages 31-71) completed vaccination and 8 weeks of follow-up. No grade 3 or above adverse events (AE) occurred. The most common AE was injection site reactions (50%). At week 8, HBsAg levels remained stable or declined, with 8 participants demonstrating modest reductions ranging from 0.1 to 0.5 log10. HBsAb titers increased in two participants, including one with a significant rise to 452 IU/mL. pgRNA levels were below the lower limit of quantification (25 copies/mL) throughout the study. **Conclusion:** HEPLISAV vaccination was safe and well-tolerated in patients with CHB. Induction of HBV-specific humoral response was observed in a subset of participants. There was a trend toward reduced HBsAg levels, suggesting a potential early immunologic effect. These fundings support further investigation of TLR9-mediated therapeutic vaccination as a strategy to restore HBV-specific immunity particularly in combination with antiviral agents and advance toward a functional cure. **Disclosures:** Gaayathri Krishnan:Nothing to Disclose, Tetiana Pozniak:Nothing to Disclose, Alip Ghosh: Nothing to Disclose, Salma Sharaf:Nothing to Disclose, Shyamasundaram Kottilil:Nothing to Disclose, Lydia Tang:Arbutus: Grant/Research Support, Gilead Sciences: Grant/Research Support, Moderna: Grant/Research Support, Ausperbio: Grant/Research Support.

4160 | ANALYSIS OF HEPATITIS B VIRUS (HBV) GENOTYPE ASSOCIATION TO BEPIROVIRSEN TREATMENT RESPONSE IN PATIENTS WITH CHRONIC HBV INFECTION: PHASE 3 B-WELL 1 AND 2 STUDIES

Jerome Bouquet[1] Christopher Sampson[2] Maria Agostini[1] William Jordan[3] Scott Speer[1] Sonia Maciejewski[3] Michael Maguire[2] Phillip Yates[2] Yu Tao[3] Sai Vinusha Kosaraju[3] Ritesh Dhimmar[3] Michael Willis[2] Geoffrey Quinn[2] Jennifer Cremer[4] Amir Youssef[3] Ahmed Nader[3] Tamara Lukic[5] Lin-Ming Shen[6] Dickens Theodore[4] Melanie Paff[3] Rob Elston[2] Jill Walker[1], [1]GSK, South San Francisco, CA, USA, [2]GSK, Stevenage, UK, [3]GSK, Collegeville, PA, USA, [4]GSK, Durham, NC, USA, [5]GSK, Dubai, United Arab Emirates, [6]GSK, Waltham, MA, USA

Background: Bepirovirsen (BPV) is an antisense oligonucleotide that targets a conserved 20 nucleotide sequence within HBV pregenomic RNA and mRNAs. B-Well 1 and 2 are global randomized, double-blind, Phase 3 trials assessing the efficacy and safety of weekly 300 mg BPV or placebo (PBO) for 24 weeks (wks) in participants (pts) with nucleos(t)ide analog-suppressed chronic HBV infection. Functional cure (FC) was the primary outcome. Comprehensive HBV genotype (GT) information is useful to better understand heterogeneity in clinical trials for HBV but difficult to obtain in virally suppressed pts. Here, we present pooled GT distribution and hepatitis B surface antigen (HBsAg) reduction at Wk24 and FC rate at Wk72 by viral GT from the B-Well studies. **Methods:** GT was assigned in this order based on availability: (1) medical history, (2) baseline next generation sequencing of HBV RNA, and (3) baseline serology assay targeting HBsAg GT-specific epitopes (IMMUNIS HBV Genotype EIA). FC (primary outcome) was defined as $\geq$24 wks of sustained HBV DNA < lower limit of quantification and HBsAg loss after finite therapy, with or without hepatitis B surface antibody. **Results:** HBV genotype information was available for 975/978 (99.7%) B-Well 1 and 843/856 (98.5%) B-Well 2 pts. In pts treated with BPV across both B-Well studies (B-Well 1 [N = 650] and 2 [N = 570]), all 10 GTs (A–J) were observed. GT distribution across pooled studies was comparable between BPV and PBO treatment groups; most pts treated with BPV were GTs C (31%; n = 376), D (26%; n = 318), B (25%; n = 308), and A (10%; n = 126). A significant reduction in HBsAg levels from baseline to Wk24 was observed in all GTs with more than 1 pt. The mean maximal log decline in HBsAg levels from baseline to Wk24 was similar across GTs A–D (−2.90 log10 IU/mL to −3.59 log10 IU/mL). FC response rates at Wk72 were similar across GTs, with GT A exhibiting

the highest FC rate in the HBsAg ≤3000 IU/mL and ≤1000 IU/mL populations (HBsAg ≤3000 IU/mL: 28%; ≤1000 IU/mL: 39%), followed by GTs B (21%; 27%), D (20%; 27%), and C (15%; 23%). **Conclusion:** The multi-tiered approach allowed for determination of HBV GTs in ≥99% of pts enrolled in the B-Well studies that were virally suppressed. The strengths of the B-Well studies were size and global reach reflected in the broad range of HBV GTs. Though subgroups with low representation (GTs F–J) were not fully evaluable, the treatment effect of BPV on FC rate was favorable across HBV GTs and greatest among GT A. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820) [for the B-Well Study Group]

4161 | INTEGRATING BASELINE HBSAG CATEGORY AND MONTH-6 HBSAG DECLINE TO PREDICT FUNCTIONAL CURE IN CHRONIC HEPATITIS B

Yaqin Zhang[1] Shiyu Wang[2] Zixuan Gao[2] Minghui Li[2],
[1]Beijing Ditan Hospital, Capital Medical University,
[2]Department of Hepatology Division 2, Beijing Ditan Hospital, Capital Medical University

Background: Early on-treatment decline in hepatitis B surface antigen (HBsAg) may help identify patients with chronic hepatitis B who are more likely to benefit from pegylated interferon (Peg-IFN)-based therapy. This study aimed to develop a month-6 HBsAg response-based framework for predicting 24-month outcomes across HBeAg status. **Methods:** This retrospective real-world study included 273 patients with chronic hepatitis B receiving Peg-IFN plus nucleos(t)ide analogues. According to HBsAg decline at month 6, patients were categorized as strong responders (≥1 log), partial responders (0.5–1 log), weak responders (0–0.5 log), and non-responders/rebounders (≤0 log). The primary endpoint was functional cure at month 24, defined as HBsAg ≤0.05 IU/mL. The secondary endpoint was HBsAg decline ≥1 log at month 24. Logistic regression was used to evaluate factors associated with functional cure. **Results:** Among 273 patients, 38 achieved functional cure at month 24, with an overall rate of 13.9%. HBsAg decline ≥1 log at month 24 was observed in 86 patients (31.5%). The month-6 strong, partial, weak, and non-response/rebound groups included 46, 36, 135, and 56 patients, respectively. Functional cure rates differed significantly across month-6 response categories, reaching 45.7% in strong responders, compared with 11.1%, 6.7%, and 7.1% in partial, weak, and non-response/rebound groups, respectively (P < 0.001). In multivariable analysis, month-6 HBsAg decline remained independently associated with 24-month functional cure (OR = 4.01, 95%CI: 2.22–7.24, P < 0.001). The combined model integrating baseline HBsAg category and month-6 HBsAg decline showed the best predictive performance, with an AUC of 0.903, compared with baseline HBsAg category alone and month-6 HBsAg decline alone. **Conclusion:** Month-6 HBsAg decline provides clinically meaningful stratification for 24-month functional cure in patients receiving Peg-IFN-based combination therapy. A response-adapted framework integrating baseline HBsAg category and early HBsAg kinetics may help identify patients with a higher probability of sustained antigenic benefit and guide individualized continuation of Peg-IFN-based treatment.

4162 | QUALITY OF LIFE IMPROVEMENTS OBSERVED IN B-CLEAR COMPLETE RESPONDERS FOLLOWING BEPIROVIRSEN TREATMENT: OFF-TREATMENT FOLLOW-UP IN THE B-SURE STUDY

Shannon Keith[1] Afisi Ismaila[2] Lauren Maynard[3] Geoffrey Quinn[3] Alexandra Walker[4] Jane Dong[5] Isabelle Santhiapillai[3] Yi Cui[3] Melanie Paff[2] Dickens Theodore[6] Rob Elston[3] Marjan Hezareh[4], [1]GSK, Wilmington, DE, USA, [2]GSK, Collegeville, PA, USA, [3]GSK, Stevenage, UK, [4]GSK, London, UK, [5]GSK, Shanghai, China, [6]GSK, Durham, NC, USA

Background: Patients (pts) with chronic hepatitis B virus (HBV) infection can experience stigma, anxiety and other impacts on their health-related quality of life (HRQoL). Bepirovirsen is an unconjugated antisense oligonucleotide in Phase 3 clinical trials for the treatment of chronic HBV infection. Complete (CR) or partial (PR) responders at the end of the Phase 2b B-Clear study (NCT04449029) were eligible for the long-term durability B-Sure study (NCT04954859). Here we present Hepatitis B Quality of Life (HBQoL) scores of B-Clear pts on nucleos(t)ide analogue (NA) therapy (On-NA) who were CR at the end of B-Clear and entered B-Sure. **Methods:** CR was defined as hepatitis B surface antigen (HBsAg) < 0.05IU/mL and HBV DNA < lower limit of quantification (LLOQ). If eligible, pts discontinued NA treatment 3 months (mo) into B-Sure (≥ 9 mo from their last bepirovirsen dose) and were followed further to determine achievement of functional cure (FC) and durability of response off all HBV therapy. Participants completed the HBQoL v1.0 questionnaire at B-Clear baseline (BL) and throughout the B-Sure study (mo 0, 3, 9, 21 and 33). Mean scores for each of the six subdomains and overall HBQoL scores at B-Clear BL and B-Sure mo 33 (i.e. 24 mo post-FC achievement) are reported. Data are descriptive; a higher HBQoL score indicates worse HRQoL. **Results:** In total, 14 CRs were enrolled into B-Sure; 10/14 CRs discontinued NAs 3 mo into B-Sure. 8/10 pts maintained CR at Month 9 and achieved FC; 8/8 had maintained FC for 24 mo and 7/7 for 30 mo (follow-up ongoing). At B-Clear BL, psychological well-being, anticipation anxiety, vitality, stigma, vulnerability and transmissibility subdomain scores were 38.0, 41.7, 22.3, 23.7, 35.3 and 44.9, respectively. Corresponding subdomain scores were 18.4, 27.3, 15.6, 15.3, 22.2 and 25.0, at B-Sure mo 33, for CRs who discontinued NAs at 3 mo, respectively. For CRs who did not discontinue NAs, subdomain scores were 45.4, 33.4, 40.0, 33.3, 33.4 and 20.9 at B-Sure mo 33, respectively. At B-Clear BL, the overall HBQoL score was 33.8 for CR participants (n = 13). At mo 33 of B-Sure, overall HBQoL score was 20.1 for CRs who discontinued NAs at 3 mo (n = 9), and 36.3 for CRs who did not discontinue NAs at 3 mo (n = 2). **Conclusion:** Following discontinuation of NA treatment in B-Sure, improvements in all HBQoL domains and overall HBQoL scores were observed in On-NA CRs enrolled in B-Sure. Improvements were also seen for some HBQoL subdomains in CRs who did not discontinue NA treatment. **Funding:** GSK (206882; NCT04954859).

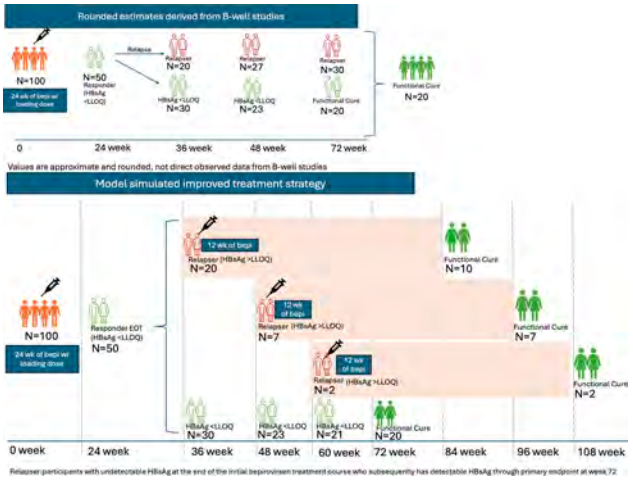
4163 | PREDICTING THE EFFECTS OF BEPIROVIRSEN DOSING IN PATIENTS WHO RELAPSE AFTER AN INITIAL COURSE OF TREATMENT



Qianwen Wang[1] Melanie Paff[2] Andrew Skingsley[3] Dickens Theodore[4] Attila Mihalyi[5] Ahmed Nader[6], [1]Clinical Pharmacology and Quantitative Medicine, GSK, UK, [2]Specialty Product Development, GSK, US, [3]Vx Clinical Sc. Flu/Covid/Pandemic/Exploratory, GSK, UK, [4]Hepatology Clinical Development, GSK, US, [5]Global Medical Affairs - Specialty Care, GSK, Belgium, [6]Clinical Pharmacology and Quantitative Medicine, GSK, US

Background: Achieving functional cure (FC) in chronic hepatitis B (CHB) remains a major unmet need, with a substantial proportion of patients failing to sustain response after finite therapy. Clinical experience with peginterferon suggests retreatment may benefit selected patients, but there is limited evidence to guide similar strategies for novel agents. Bepirovirsen, an antisense oligonucleotide targeting HBV, has demonstrated clinical benefit in recent Phase 3 studies; with approximately 44% treated patients achieving undetectable HBsAg and HBV DNA. **Methods:** A previously developed mechanistic PKPD model describing bepirovirsen treatment effect and HBsAg dynamics was extended to conduct an *in-silico* evaluation of retreatment scenarios. Virtual populations were generated using resampling techniques and stratified into clinically relevant subgroups based on Phase 3 studies (Figure 1), assuming that response parameters following the initial course of treatment were unchanged for the second course.

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Simulations evaluated HBsAg trajectories and FC outcomes under different treatment regimens and in different patient subgroups. **Results:** Simulations suggest that a second course of 12-week treatment of bepirovirsen may result in FC in a majority of relapsers. In contrast, no benefit was predicted for null responders (< 0.5 log drop of HBsAg with detectable HBsAg at end of the first course of bepirovirsen). Limited benefit was predicted in partial responders (> 0.5 log HBsAg reduction but still detectable HBsAg at the end of the first course), mainly driven by a subgroup with HBsAg levels between 0.05 and 1 IU/mL at the end of first course. Earlier treatment in relapsers was associated with higher predicted FC compared with delayed treatment. Based on simulated treatment strategies, initiation of second course of treatment for relapsers within the week 36–72 window is proposed for evaluation in future studies (Figure 1). Limited benefit was predicted for alternative dosing strategies such as regimen of 24 weeks or the inclusion of a loading dose. **Conclusion:** Model simulated results demonstrated a substantial increment in FC for initial responders who relapse when treated with 12 additional weeks of weekly bepirovirsen. This quantitative framework can be used to inform additional treatment strategies and offers key insights to guide a more efficient clinical development program. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820)Figure 1: Patient journey: B-well studies (rounded estimates from data using quantitative HBsAg assay, upper panel), simulated treatment in relapsers after initial course of bepirovirsen (lower panel).

4164 | A SECOND-GENERATION HBV SIRNA EXHIBITS BEST-IN-CLASS POTENTIAL IN TREATING CHRONIC HEPATITIS B AND D IN PRECLINICAL STUDIES

Jin Hong[1] Vivek Rajwanshi[1] Kellan Passow[1] Hyunsoon Kang[1] Min Luo[1] Shane Daguison[1] Jacquelyn Sousa[1] Kusum Gupta[1] Cheng Liu[1] Antitsa Stoycheva[1] Aneerban Bhattacharya[1] Jieun Song[1] Lillian Adame[1] Alexander Leung[1] Dana Cho[1] John Cortez[1] Dinah Misner[1] Lawrence Blatt[2] Leonid Beigelman[3] David Smith[1] Julian Symons[1], [1]Aligos Therapeutics, [2]Aligos Therapeutics, Inc., [3]Former Employee of Aligos Therapeutics

Background: HBV siRNAs such as AB-729, VIR-2218, RG6346 and JNJ-3989 can effectively reduce HBsAg in chronic hepatitis B (CHB) subjects. However, to achieve functional cure, siRNAs need to be combined with immunomodulatory agents such as interferon. HBV siRNA is also being evaluated as a lead-in therapy to improve the functional cure rate of HBV ASO. In HBV/HDV coinfected patients, HBV siRNA appears to significantly improve the time to HDV RNA undetectability when combined with an anti-HBsAg monoclonal antibody. The potential first/best in class CAM-E, pevifoscorvir sodium (pevy, ALG-000184) and potential best in class HBV ASO ALG-170675 could potentially benefit from the addition of an HBV siRNA in treating CHB and CHD. A Phase 1 study of the HBV siRNA, ALG-125755 found that it was well tolerated with a favorable PK profile and HBsAg lowering at all dose levels evaluated. In this new preclinical study, a multi-pronged approach was taken to further improve the potency, stability, hepatocyte-specific delivery and safety of ALG-125755 with the aim of developing a best-in-class HBV siRNA. **Methods:** In vitro inhibition of HBsAg release by siRNA was performed in the HepG2.2.15 cell line after transfection. The stability of HBV siRNAs was determined in mouse liver homogenates. Off target activity was evaluated by RNAseq in HepG2.2.15. The binding of different GalNAc moieties to the asialoglycoprotein receptor (ASGR) was measured in human and mouse liver microsomes. In the AAV-HBV mouse model, HBV siRNAs conjugated with GalNAc were administered subcutaneously with serial blood collections for HBsAg and ALT assessment. **Results:** ALG-127563 emerged as one of the lead 2nd generation HBV siRNAs. It showed an EC_{50} of 4.5 pM in inhibiting HBsAg release while ALG-125755 and 3 Phase 2/3 competitor siRNAs exhibited double-digit pM EC_{50} values. After a 96 hour incubation in mouse liver homogenate, 92% of the antisense strand (AS) of ALG-127563 remained intact, exhibiting superior stability relative to the AS of ALG-125755 or Phase 2/3 siRNAs with intact AS remaining at 60 to 70%. The GalNAc

moiety used in ALG-125755 was also optimized, resulting in a 4X improvement in binding to human liver microsome ASGR. In an HBV-infected 3-D human liver chip study with no transfection, siRNA with a 2nd gen GalNAc demonstrated improvement with up to an 84% additional HBsAg knock down. ALG-127563 RNASeq and human PBMC assays demonstrated a clean in vitro safety profile. In a 35-day AAV-HBV mouse study, a single dose of 5 mg/kg ALG-127563 showed a maximum HBsAg knock down of 2.43 $\log_{10}$ IU/mL while dosing of clinical stage compounds showed a 1.8-1.9 $\log_{10}$ IU/mL maximum reduction. The durability of HBsAg reduction by ALG-127563 was also enhanced compared to that of clinical benchmarks. **Conclusion:** ALG-127563 demonstrated improved in vitro and in vivo potency when compared with ALG-125755 and Ph2/3 siRNAs. Further studies are ongoing.

4165 | SG12, A NOVEL HBV-TARGETING ANTISENSE OLIGONUCLEOTIDE (ASO) WITH DUAL MECHANISMS, DEMONSTRATES SUPERIOR EFFICACY AND FAVORABLE PK/SAFETY IN PRECLINICAL STUDIES

Yue Huang[1] Xiaohua Yu[1] Yuhang Wang[1] Haisheng Wang[1], [1]SicaGene BioScience Co., Ltd.

Background: Achieving functional cure for chronic hepatitis B (CHB) remains a high medical need with promising potential pursued by innovative therapeutics. SG12 is a novel HBV-targeting ASO with a unique dual antiviral mechanism. This study evaluated its preclinical efficacy, pharmacokinetics, safety, and mechanism of action. **Methods:** Anti-HBV activity was assessed in HepG2.2.15 cells, HBV transgenic mice, and rAAV8-1.3HBV mice, with bepirovirsen as control. Mechanistic studies examined SG12 colocalization with Kupffer cells. PK and safety were evaluated in CD-1 mice and cynomolgus monkeys following single or repeated doses. **Results:** SG12 significantly inhibited HBV activity in vitro and in vivo, showing superior efficacy versus bepirovirsen with approximately greater than 1-log improvement in HBsAg reduction at the same dose level. SG12 efficiently colocalized with Kupffer cells, confirming a dual mechanism of gene silencing and innate immune activation. PK results showed rapid absorption, slow elimination (notably in monkeys), high liver enrichment, high protein binding, and good metabolic stability. In a 28-day repeat-dose toxicity study, the maximum tolerated dose (MTD) in cynomolgus monkeys was 20 mg/kg. In 29-day dosing with 28-day recovery studies, the non-observed adverse effect level (NOAEL) was 20 mg/kg in CD-1 mice and 15 mg/kg in cynomolgus monkeys. No genotoxicity, hemolysis, or systemic allergic reactions were observed, and immunogenicity was low. **Conclusion:** SG12 exhibits superior anti-HBV efficacy, favorable liver-targeting PK, and a reliable safety profile in preclinical studies. Its dual mechanism supports further clinical development for CHB functional cure. It is currently being evaluated in Phase 1 clinical study.

4166 | PERSPECTIVES AND PREFERENCES ON POTENTIAL LONG-ACTING ANTIVIRAL TREATMENT MODALITIES AMONG PEOPLE LIVING WITH HEPATITIS B: A GLOBAL QUALITATIVE STUDY

Yasmin Ibrahim[1] David Thomas[2] Karine Dubé[3] Chari Cohen[1], [1]Hepatitis B Foundation, [2]Johns Hopkins School of Medicine, [3]Perelman School of Medicine, University of Pennsylvania

Background: Long-acting antiviral (LAA) therapies are emerging as potential promising future alternatives to daily oral treatment for chronic hepatitis B. However, patient perspectives on different LAA modalities remain poorly understood. This study aimed to explore perceptions, preferences, and acceptability of potential LAA treatment modalities among people living with hepatitis B (PLWHB) globally. **Methods:** This IRB-approved qualitative focus group study was conducted as part of a larger mixed-methods investigation among PLWHB. An initial focus group was conducted with six participants representing Africa, Asia, North America, and Europe. Discussions explored experiences with current hepatitis B treatment and perspectives on hypothetical LAA modalities, including injectables, microneedle patches, and implants. The focus group guide was aligned with survey questions to support

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

thematic triangulation across qualitative and quantitative data. Data were analyzed thematically. **Results:** Participants described several challenges associated with current daily oral treatment, including the burden of medication access and approval processes, and fear of committing to a daily pill for life. Overall, participants expressed openness toward the concept of LAA therapies; however, acceptability differed across proposed modalities (injection vs microneedle patch vs implant). Although a long-acting pill was not among the proposed modalities, some participants identified oral treatment as their preferred option as it allowed them to maintain a sense of control over their treatment journey. Preferences were shaped by multiple considerations beyond modality alone, including perceived effectiveness, safety, convenience (ease of use, needing cold chain, non-invasive), duration, reversibility, and accessibility. Through discussions, participants highlighted the importance of clear communication and adequate information regarding potential benefits and risks to support treatment acceptability and informed decision-making. **Conclusion:** PLWHB expressed interest in LAA therapies as alternatives to daily oral treatment, although preferences varied across modalities. These initial findings underscore the importance of incorporating patient perspectives early in the development of future LAAs and highlight the need for transparent communication regarding treatment risks, benefits, and practical considerations.

4167 | EARLY ON-TREATMENT HBSAG DECLINE PREDICTS FUNCTIONAL CURE IN CHB PATIENTS RECEIVING PEG-IFN-BASED THERAPY

Zixuan Gao[1] Minghui Li[1], [1]Capital Medical University Affiliated Beijing Ditan Hospital

Background: Functional cure remains an important therapeutic goal in chronic hepatitis B (CHB). Early on-treatment biomarkers predicting hepatitis B surface antigen (HBsAg) loss during pegylated interferon (PEG-IFN)-based therapy remain incompletely defined. **Methods:** We retrospectively analyzed 328 CHB patients receiving PEG-IFN-based therapy in a real-world cohort. Functional cure was defined as sustained HBsAg loss confirmed on two separate occasions at least 6 months apart. Baseline and on-treatment HBsAg levels were collected at weeks 12, 24, and 48. Early HBsAg decline was calculated as the reduction in log10 HBsAg relative to baseline. Cox regression, ROC analysis, and Kaplan–Meier analyses were performed to evaluate predictors of functional cure. **Results:** Forty-one patients (12.5%) achieved functional cure. Patients achieving functional cure had significantly lower baseline HBsAg levels compared with non-responders (0.87 vs. 2.98 log10 IU/mL, $P < 0.001$). Multivariable Cox analysis demonstrated that lower baseline HBsAg (HR 0.217, 95% CI 0.147–0.321, $P < 0.001$), greater week 24 HBsAg decline (HR 1.481, 95% CI 1.046–2.098, $P = 0.027$), and greater week 48 HBsAg decline (HR 2.917, 95% CI 1.941–4.385, $P < 0.001$) were independently associated with functional cure. ROC analysis showed that week 24 HBsAg decline predicted functional cure with an AUC of 0.780 and an optimal cutoff value of 0.65 log10 IU/mL. Week 48 HBsAg decline demonstrated an AUC of 0.817 with an optimal cutoff value of 0.33 log10 IU/mL. Kaplan–Meier analysis demonstrated significantly lower functional cure-free probability among patients with rapid early HBsAg decline (log-rank $P < 0.001$). **Conclusion:** Early on-treatment HBsAg decline is strongly associated with long-term functional cure in CHB patients receiving PEG-IFN-based therapy. Dynamic monitoring of HBsAg kinetics may help identify patients most likely to achieve functional cure.

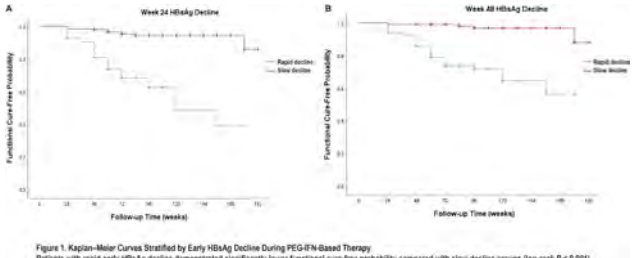

Figure 1. Kaplan–Meier Curves Stratified by Early HBsAg Decline During PEG-IFN-Based Therapy
Patients with rapid early HBsAg decline demonstrated significantly lower functional cure-free probability compared with slow decline groups (log-rank $P < 0.001$).

4168 | IN VITRO AND IN VIVO POTENCY, PHARMACOKINETIC PROFILE IN MICE AND MONKEYS, AND COMPREHENSIVE GLP SAFETY EVALUATION OF ACT201 (ALG-170675), A NOVEL ASO FOR CHRONIC HEPATITIS B

Yuejin Yu[1] Jingyi Xu[1] Jimmy Lu[1] Jinjia Zhang[1] Zhiyu Luo[1] Yatin Zhuo[1] Xiaorong Chen[1] Yanlan Lin[1] Guangqiang Pei[1] Yuejun Li[1] Yuanyuan Chen[1] Dinah Misner[2] Kusum Gupta[2] Vivek K. Rajwanshi[2] Hyunsoon Kang[2] Jin Hong[2] Li Huang[1] Li Sun[1] Yalin Yin[1] Huihuang Lin[1] Xuejing Li[1], [1]Amoytop Biotech Co., No. 330 Wengjiao Road, Haicang, Xiamen, Fujian, P.R. China, [2]Aligos Therapeutics, Inc., 1 Corporate Drive, South San Francisco, CA 94080, USA

Background: HBsAg loss is central to the functional cure of chronic hepatitis B (CHB). Antisense oligonucleotides (ASOs) represent a highly promising class of investigational therapies for CHB, with the potential to advance the achievement of functional cure. Based on sequence design and screening, ACT201 (ALG-170675) is a next-generation hepatitis B virus (HBV) ASO in late stage pre-clinical development. We have validated the drug's antiviral activity and fully characterized its pharmacokinetic and comprehensive GLP safety profile in mice and monkeys. **Methods:** Analysis of in vitro antiviral activity in HepG2.2.15 was conducted by Aligos Therapeutics. Antiviral potency assay in HepG2 cells transfected with HBV genotype A-J plasmids was conducted by WuXi AppTec. PK, tissue distribution and toxicity/TK evaluations in mice and monkeys were conducted at WuXi AppTec and Joinn Laboratories. **Results:** In HepG2.2.15 cells, ACT201 strongly inhibited HBsAg release with a mean EC_{50} of 10.33 nM. ACT201 also demonstrated significant release of HBsAg inhibition without cytotoxicity in HepG2 cells transfected with HBV A-J plasmids.In the AAV-HBV mouse model, ACT201 showed a better therapeutic index than GSK-836 (bepirovirsen). ACT201 showed higher levels of HBsAg and HBeAg reduction than GSK-836 at corresponding 40, 20, and 10 mg/kg dose levels, with as high as 0.66 $\log_{10}$ IU/mL additional mean HBsAg reduction on Day 28. Furthermore, ACT201 did not show a positive ALT signal during the treatment period, while the GSK-836 40 mg/kg group showed a positive ALT signal on Day 21 and 28, indicating a superior safety profile for ACT201. Following a single subcutaneous injection in mice (10, 20, 40 mg/kg) and monkeys (2, 4, 8 mg/kg), the plasma exposure increased in a dose-dependent manner. In monkeys, the systemic exposure levels in the liver increased with increasing dose, with the rate of increase closely matching the theoretical dose ratio, and liver exposure levels were significantly higher than those in plasma.In a 4-week study administering ACT201 via subcutaneous injection to mice and monkeys at a maximum dose of 50 mg/kg, all animals tolerated the treatment well, and NOAELs were determined to be 50 mg/kg in both species. The primary effects observed were typical ASO-related effects, such as macrophage vacuolization and/or basophilic granules; following an 8-week recovery period, these histopathologic changes were either completely resolved or showed a trend toward resolution. ACT201 exhibited no abnormal effects in safety pharmacology, genotoxicity, hemolysis and sensitization tests, and irritation was reversible, demonstrating its favorable safety profile. **Conclusion:** ACT201 has potent antiviral activity, favorable liver-targeted PK and a robust safety profile. Its balanced efficacy and safety profile in vivo suggests a potential best-in-class potential for CHB therapy. Clinical development is anticipated to begin in late 2026.

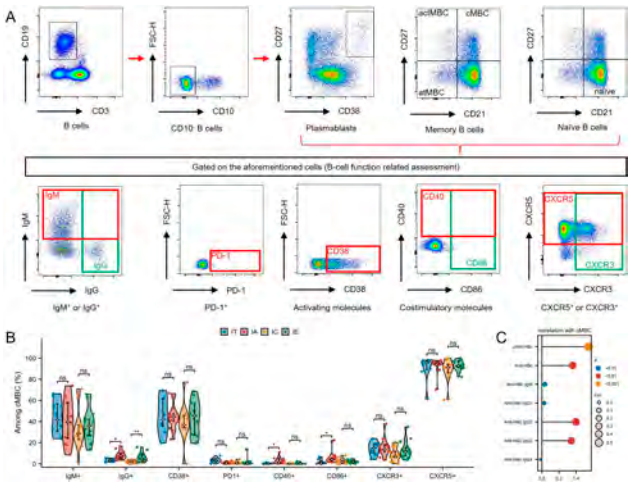
4169 | ◆ EXPANSION OF IGG$^+$ CLASSICAL MEMORY B CELLS CONSTITUTES THE CELLULAR BASIS FOR ANTI-HBC MAINTENANCE IN PATIENTS WITH CHRONIC HEPATITIS B



Yanjie Lin[1] Chi Zhang[1] Hong Zhao[1] Juan Du[2] Yao Xie[2] Minghui Li[2] Guiqiang Wang[1], [1]Peking University First Hospital, [2]Beijing Ditan Hospital, Capital Medical University

Background: Chronic hepatitis B virus (HBV) infection affects more than 254 million people worldwide, and accurate assessment of hepatic inflammatory activity is critical for disease management. Quantitative hepatitis B core antibody (qAnti-HBc) has been shown to correlate closely with histological liver inflammation and may serve as a potential non-invasive inflammatory biomarker. However, the cellular immunological basis underlying its dynamic changes remains unclear, particularly the identity of the B cell subset responsible

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

for anti-HBc production and maintenance. **Methods:** 48 patients with untreated chronic HBV infection stratified by natural history phase and 10 healthy controls were prospectively enrolled. Peripheral blood mononuclear cells (PBMCs) were isolated, and multiparameter flow cytometry was used to systematically analyze B cell subset across disease phases. qAnti-HBc levels were quantified and correlated with immunological findings. **Results:** In patients at the immune clearance and immune reactivation phase, the proportion of circulating IgG^+ classical memory B cells (cMBCs) was significantly higher than that in the immune-tolerant and immune control phases, accompanied by upregulation of CD40 and CD86 and downregulation of PD-1. Among all B cell subsets examined, IgG^+ cMBCs showed the strongest positive correlation with qAnti-HBc ($r = 0.548$, $P < 0.001$). **Conclusion:** The expansion of IgG^+ cMBCs closely parallels hepatic inflammatory activity and qAnti-HBc levels, suggesting that IgG^+ cMBC expansion represents the core cellular basis for Anti-HBc production and long-term maintenance in CHB patients, providing direct cellular immunological support for the clinical utility of qAnti-HBc.

4170 | ◆ THE COEXISTENCE OF HBSAG AND ANTI-HBS FACILITATES FUNCTIONAL CURE OF CHRONIC HEPATITIS B WITH INTERFERON TREATMENT

Huiying Yu[1] Zhiliang Gao[1], [1]The Third Affiliated Hospital of Sun Yat-sen University

Background: The coexistence of HBsAg and anti-HBs (HBsAg+/Anti-HBs+) represents a unique serological profile associated with distinct immune states, hepatic inflammation, and fibrosis. This study aimed to investigate the impact of serum HBsAg+/anti-HBs+ profile on functional cure outcomes in chronic hepatitis B (CHB) patients treated with pegylated interferon alpha (pegIFN-alpha). **Methods:** We retrospectively analyzed clinical data from 945 CHB patients enrolled in the “Everest Project”, a clincial project for functional cure of CHB patients. These patients whose HBsAg < 1500 IU/mL, HBV DNA < 100 IU/mL, HBeAg were negative at baseline, were treated with pegIFN-alpha with or without nucleos(t)ide analogues for at least 48 weeks.The prevalence of baseline HBsAg+/anti-HBs+ status, clinical cure rates following pegIFN-alpha therapy, and post-cure HBsAg reversion rates were evaluated. **Results:** Among 945 patients, 52 (5.5%) exhibited baseline HBsAg+/anti-HBs+ , and 112 developed this double positive pattern during pegIFN-alpha therapy. Double positive patients showed a significantly higher functional cure rate than single positive (HBsAg+/anti-HBs-) patients (51.83% vs 36.88%, OR: 1.842, 95% CI: 1.305–2.567, p = 0.0004), but also a higher risk of HBsAg reversion after cure (29.41% vs 14.93%, OR: 2.374, 95% CI: 1.334–4.207, p = 0.0038). Multivariate logistic regression identified HBsAg+/anti-HBs+ status, lower baseline HBsAg levels, and younger age as independent predictors of functional cure. What’s more, Double positive status and lower peak anti-HBs titers after HBsAg loss independently predicted HBsAg reversion. Notably, cured single positive patients more frequently achieved anti-HBs titers > 100 U/L, and especially > 1000 U/L, compared to double positive patients. In both groups, cured patients exhibited greater aminotransferase elevations at week 12 of therapy than uncured patients. In the cured group, the elevation of aminotransferase in the double positive subgroup showed a trend of being greater than that in the single positive subgroup. Survival curve analysis showed, single positive cured patients achieved functional cure fastest and had the lowest reversion risk, whereas the median time to cure was longest in the group double positive after interferon therapy and the risk of HBsAg reversion was highest in the group double positive before interferon therapy. **Conclusion:** HBsAg +/anti-HBs+ CHB patients exhibit higher functional cure rates but also greater HBsAg reversion risks following pegIFN-alpha therapy, with double positive status serving as an independent predictor for both outcomes.

4171 | ◆ PD-1 EXPRESSION STRATIFIES TERMINAL/ EXHAUSTION-ASSOCIATED AND INFLAMMATORY ATYPICAL MEMORY B-CELL STATES IN CHRONIC HEPATITIS B

Thi Kim Duyen Nguyen[1] Yen-Chun Liu[2] Hsiang-Wei Huang[3] Chia-Wei Lin[3] Jian He Fan[3] Wei-Ting Ku[3] Rachel Wen-Juei Jeng[3] Chun-Yen Lin[3], [1]Chang Gung University, [2]Chang Gung Memorial Hospital, Linkou main branch, [3]Chang Gung Memorial Hospital, Linkou Medical Center

Background: Atypical memory B cells (atMBCs) are expanded in chronic hepatitis B (CHB) and are generally regarded as a dysfunctional or exhausted B-cell population. However, whether atMBCs represent a homogeneous dysfunctional population or contain divergent immunopathological states remains unclear. We examined whether PD-1 expression stratifies atMBC subsets linked to hepatic inflammation, bystander CD8 T-cell activation, and immunoregulatory crosstalk. **Methods:** scRNA-seq/CITE-seq was performed on peripheral B cells from 17 HBeAg-negative CHB patients. Unsupervised clustering, pseudotime trajectory analysis, and pathway enrichment characterized atMBC states. Flow cytometry quantified PD-1 $^{+}$/PD-1 $^{-}$ atMBCs, PD-1^{+} Tregs, and CD38^{+}HLA-DR^{+} CD8 T cells (bystander-activated, hepatotoxic-like) in validation cohorts. Intracellular cytokine staining evaluated IL-6, TNF-α, and IL-10 production by PD-1-defined atMBC subsets. Correlations were assessed using Spearman rank analysis, with $p < 0.05$ considered significant. **Results:** Unsupervised analysis resolved two transcriptionally distinct atMBC subsets. One occupied a terminal differentiation state with high PD-1 at RNA and protein levels, elevated FCRL5 and T-bet (TBX21), and suppressed BCR signaling (NES = -1.89, $p = 0.001$), consistent with an exhaustion-associated phenotype. Flow cytometry showed that PD-1^{+} atMBC frequency correlated positively with ALT ($r = 0.509$, $p = 0.003$) and CD38^{+}HLA-DR^{+} CD8 T-cell expansion ($r = 0.605$, $p = 0.003$; $n = 22$), while the frequency of PD-1^{-} atMBCs among B cells showed no correlation with ALT levels. Total atMBC frequency showed no ALT association, revealing clinically relevant heterogeneity not captured by total atMBC abundance. Functionally, PD-1^{+} atMBCs produced significantly less IL-6 and TNF-α than PD-1^{-} atMBCs ($n = 19$, $p < 0.001$), while IL-10 production remained comparable across PD-1^{+} atMBCs, PD-1^{-} atMBCs, and cMBCs. Notably, IL-10^{+}/PD-1^{+} atMBCs correlated with PD-1^{+} Tregs ($r = 0.575$, $p = 0.025$), whereas IL-6^{+} and TNF-α^{+}/PD-1^{-} atMBCs correlated with CD38^{+}HLA-DR^{+} CD8 T cells ($r = 0.702$, $p = 0.0035$ and $r = 0.529$, $p = 0.0428$ respectively) and showed a trend toward correlation with ALT levels ($r = 0.524$, $p = 0.054$ and $r = 0.538$, $p = 0.047$ respectively), identifying the PD-1^{-} compartment as the active source of B-cell-derived inflammatory cytokines associated with hepatic inflammation. **Conclusion:** PD-1 stratifies atMBCs into two functionally opposing states in CHB: PD-1^{-} atMBCs harbor cytokine-producing effectors linked to hepatic inflammation, while PD-1^{+} atMBCs represent a terminal/exhaustion-associated state that possibly reflects a shared cytokine niche, co-expanding with PD-1^{+} Tregs and bystander-activated CD8^{+} T cells. PD-1 thus acts not as a simple exhaustion marker but as a stratifying axis distinguishing active B-cell inflammatory effectors from passive niche-coupled exhaustion in CHB.

4172 | ◆ HBV CORE-RELATED ANTIGEN LEVELS CORRELATE WITH QUANTITATIVE HBSAG LEVELS REGARDLESS OF HBEAG STATUS AND ANTIVIRAL THERAPY

Hee Sun Cho[1] Soon Kyu Lee[1] Soon Woo Nam[1] Jung Hyun Kwon[1], [1]The Catholic University of Korea

Background: Hepatitis B core-related antigen (HBcrAg), which reflects the combined levels of HBcAg, HBeAg, and the p22 core-related protein, has been shown to correlate strongly with serum HBV DNA and intrahepatic covalently closed circular DNA (cccDNA) levels. In this study, we aimed to evaluate HBcrAg levels according to several clinical factors and to assess the correlation between HBcrAg and quantitative HBsAg levels. **Methods:** We prospectively enrolled 876 consecutive patients with chronic HBV infection who underwent HBcrAg testing between March 2025 and February 2026. HBcrAg levels were compared according to age, HBeAg status, and antiviral therapy. In addition, correlation analyses were performed to evaluate the relationship between HBcrAg and quantitative HBsAg levels across HBeAg status and antiviral therapy. **Results:** The median age of the study population was 57.9 years, and 56.7% (n = 497) were male. Approximately half of the patients (n = 433, 49.4%) were receiving antiviral therapy. The mean HBcrAg level was 2.9 LogU/mL and was significantly higher in younger patients (< 45 years) than in older patients (4.1 vs. 2.7 LogU/mL; p < 0.0001; Figure A) and in HBeAg-positive patients compared with HBeAg-negative patients (5.9 vs. 2.4 LogU/mL; p < 0.0001). Among HBeAg-positive patients, HBcrAg levels were significantly higher in those not receiving antiviral therapy (p < 0.0001; Figure B). In contrast, among HBeAg-negative patients, HBcrAg levels were significantly lower in those receiving antiviral therapy (p < 0.0001; Figure C). HBcrAg levels showed a significant positive correlation with quantitative HBsAg levels (R = 0.44, p < 0.0001; Figure D). This correlation was consistently observed across HBeAg status and antiviral therapy, with the strongest correlation found in HBeAg-positive patients not receiving antiviral therapy (R = 0.53, p = 0.0053; Figure E). HBcrAg levels were also positively correlated with HBV DNA levels in both HBeAg-positive and HBeAg-negative patients (p < 0.05). Notably, among 67 patients who achieved HBsAg loss, approximately 25% (17/67) still had detectable HBcrAg levels. **Conclusion:** Our findings suggest that HBcrAg levels were lower in older patients and in those with negative HBeAg status. HBcrAg levels were significantly correlated with quantitative HBsAg levels regardless of HBeAg status or antiviral therapy, suggesting that HBcrAg may serve as a useful surrogate marker of viral activity across different clinical settings.

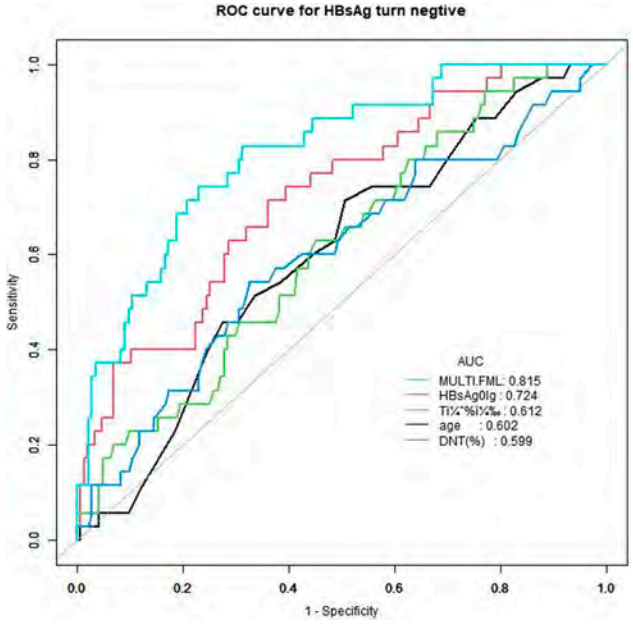
4173 | INTEGRATED MODEL WITH BASELINE T-CELL AND DNT CELL PROPORTIONS ACCURATELY IDENTIFIES CANDIDATES FOR PEG-IFNα-2B-INDUCED HBSAG SEROCLEARANCE



Jing Chen[1] Qin Du[1] Peng Wang[1] Jianyin Wang[1] Yanchao Fu[1] Huiling Xiang[1], [1]Central Hospital, Tianjin University; Tianjin Institute of Hepatobiliary Disease, Tianjin, China

Background: Clinical cure of chronic hepatitis B (CHB) is defined as hepatitis B surface antigen (HBsAg) seroclearance. Interferon (IFN) efficacy is highly dependent on host immune status. However, most existing prediction models rely on conventional virological parameters and lack direct, quantifiable baseline immunological markers, limiting accurate identification of patients most likely to benefit from IFN therapy. This study aimed to evaluate the predictive value of baseline T-cell proportion and double-negative T (DNT) cell proportion for pegylated interferon-α-2b (peg-IFNα-2b)-induced HBsAg seroclearance and to develop an optimized predictive model integrating clinical and immunological parameters. **Methods:** A total of 182 patients with CHB or compensated cirrhosis receiving initial peg-IFNα-2b therapy were retrospectively enrolled. Least Absolute Shrinkage and Selection Operator (LASSO) regression was used for variable selection, and Cox regression was applied to identify independent predictors, with a focus on baseline T-cell and DNT cell proportions. A predictive model was constructed and internally validated via bootstrap resampling. Model performance was assessed using receiver operating

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

characteristic (ROC) curves, calibration curves, and decision curve analysis. A risk-stratification system was established based on model scores, and HBsAg seroclearance rates were compared across strata. **Results:** The overall HBsAg seroclearance rate was 19.23% (35/182). Multivariate Cox regression identified baseline T-cell proportion (HR = 1.087, P = 0.00724) and DNT cell proportion (HR = 1.060, P = 0.03519) as independent protective factors for HBsAg seroclearance, while age and baseline HBsAg level were independent risk factors. The integrated model demonstrated good calibration and stability, with an AUC of 0.838 in the training set and 0.760 in the validation set, significantly outperforming models based solely on conventional clinical or virological parameters. Three-tier risk stratification revealed that the immune-favorable group (high T-cell and DNT cell proportions) achieved a 48-week HBsAg seroclearance rate of 46.34%, substantially higher than the intermediate (19.67%) and poor-prognosis (5.20%) groups (P < 0.0001). **Conclusion:** Baseline T-cell and DNT cell proportions are key, independent immunological markers for predicting peg-IFNα-2b-induced HBsAg seroclearance, significantly improving the predictive performance of conventional clinical/virological indicators. This integrated model accurately identifies optimal candidates for IFN therapy and provides a critical basis for individualized immunotherapy in CHB.

4174 | SINGLE-CELL TRANSCRIPTOMIC ANALYSIS REVEALS DYNAMIC HBV EXPRESSION STATES IN HBV-ASSOCIATED HEPATOCELLULAR CARCINOM

Zhi Chen Yan[1] PeiChing Chang[1] Chun-Ying Wu[2], [1]National Yang Ming Chiao Tung University, [2]National Yang MIng Chiao Tung University, Taiwan

Background: Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death, with 55%-80% of cases arising in the context of chronic hepatitis B virus (HBV) infection. Although HBV vaccination programs have reduced new infections, chronic HBV remains affecting approximately 350 million people worldwide. Single-cell analysis has been widely applied to investigate the TME of HCC, with primary focus on elucidating the immune landscape. Interaction analyses have also primarily highlighted immune-immune crosstalk; however, the single-cell characteristics of HBV-infected HCC cell interactions have yet to be elucidated. **Methods:** Using single-cell RNA sequencing, we identified HBV-infected HCC cells at single-cell resolution and stratified tumor cell populations according to HBV transcript abundance. Trajectory analysis combined with inferCNV revealed a progressive evolutionary pattern originating from tumor cells with intermediate HBV transcript levels (HCC-c4), advancing toward high HBV transcript expression (HCC-c1 and HCC-c2), followed by bifurcation into distinct branches that either maintained intermediate viral transcript levels (HCC-c3 and HCC-c5) or potentially underwent viral transcript silencing (HCC-c6). **Results:** Gene ontology analysis identified eight major functional categories enriched among HCC subpopulations. Notably, HCC-c4, defined as the trajectory origin population, exhibited activation of proliferation, survival, cellular movement, and cancer-associated pathways. As HBV transcript levels increased, HCC-c2 became predominantly associated with cellular movement-related pathways, whereas HCC-c1 demonstrated enrichment of apoptosis-related pathways and cellular responses to therapeutics. These findings suggest that progressive HBV activation may initially enhance tumor aggressiveness and migratory potential, followed by induction of stress-response and apoptotic programs. Then, the trajectory diverges into two distinct branches. One branch, enriched for intermediate HBV transcript levels, included HCC-c3 and HCC-c5, which displayed functional profiles similar to HCC-c1. The second branch contained HCC-c6, a rare subpopulation with minimal HBV transcript expression. **Conclusion:** Collectively, these findings indicate the emergence of heterogeneous tumor evolutionary states originating from intermediate and progressing toward peak HBV

transcription, followed by bifurcation into distinct cellular fates. One branch maintained HBV transcription, whereas the other exhibited loss of HBV transcription. **Disclosures:** ZHI CHEN YAN:Nothing to Disclose, PeiChing Chang:Nothing to Disclose, Chun-Ying Wu: Nothing to Disclose.

4175 | HBX EXPLOITS GLUCOSE TO PROMOTE HEPATOCELLULAR CARCINOMA DEVELOPMENT VIA ITS PHOSPHORYLATION AND ENHANCEMENT OF THE TCA CYCLE

Xiaoyun Huang[1] Ying Lin[1] Fenglin Chen[1], [1]Fujian Medical University Union Hospital

Background: Type 2 diabetes and chronic hepatitis B virus (HBV) infection are both established drivers of hepatocellular carcinoma (HCC), yet the interplay between hyperglycemia and HBV oncogenic activity remains poorly defined. The HBV X protein (HBx) is a classic oncoprotein capable of simultaneously reprogramming multiple signaling pathways and elevates blood glucose as well, but whether—and how—hyperglycemia modulates HBx function is largely unknown. We aimed to investigate how glucose availability influences HBx function. **Methods:** As HBx is low in patient tissue, human hepatoma lines stably expressing low or high HBx (plus vector controls) were generated by lentiviral infection to exclude overexpression artifacts. $^{13}C_6$-glucose was used to trace flux through TCA cycle intermediates (measured by GC-MS) in cells cultured in high glucose (30 mM). Proteomic profiling was performed on hepatoma cells expressing no, low, or high HBx under high-glucose conditions. Murine hepatoma cells stably expressing luciferase with no, low, or high HBx were injected via tail vein into db/db mice, and tumor dissemination was tracked by in vivo bioluminescence imaging. Single-cell transcriptomics was performed on three regions of one diabetic-HBV HCC tumor. Finally, HBx phosphorylation was assessed by immunoprecipitation in cells cultured in 5.5 mM versus 30 mM glucose. **Results:** Under high glucose, HBx significantly increased labeled TCA cycle intermediates (citrate, α-ketoglutarate, succinate, fumarate, malate) at both low and high expression levels ($P < 0.05$). Proteomic analysis showed differentially expressed proteins enriched in carbohydrate, oxoacid, and nucleobase-containing small-molecule metabolism; KEGG analysis implicated metabolic pathways (purine metabolism, pentose phosphate pathway, cysteine/methionine metabolism) and tumor-associated pathways (HIF-1, TNF, cell adhesion/cytoskeletal regulation). In db/db mice, HBx-expressing hepatoma cells produced more tumor foci and higher bioluminescence than vector controls ($n = 5$, $P < 0.05$). Single-cell profiling of the diabetic-HBV HCC tumor (~29,700 cells) resolved malignant hepatocytes into region-biased subpopulations co-expressing a pro-invasive program (SPP1, FN1, CD24, AKR1B10), consistent with the proteomic pathways and the metastatic phenotype in vivo. HBx phosphorylation was ~35% higher in 30 mM than 5.5 mM glucose. **Conclusion:** Concurrent diabetes and HBx enhance hepatoma cell metastasis. HBx exploits excess glucose to fuel the TCA cycle and reprogram metabolic and migration-associated pathways. Elevated HBx phosphorylation may underlie this glucose-adaptive behavior. These findings reveal how HBx leverages glucose to potentiate HCC metastatic potential, offering new insight into glucose-regulated oncoprotein biology.

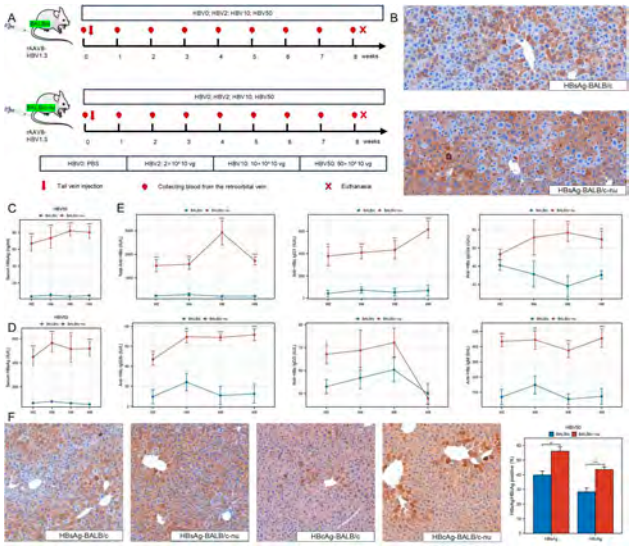
4176 | T CELL DEFICIENCY ENHANCES HUMORAL IMMUNITY BUT FAILS TO CONTROL HBV: EVIDENCE FOR DUAL PATHWAYS OF ANTI-HBC PRODUCTION



Yanjie Lin[1] Chi Zhang[1] Hong Zhao[1] Juan Du[2] Yao Xie[2] Guiqiang Wang[1] Minghui Li[2], [1]Peking University First Hospital, [2]Beijing Ditan Hospital, Capital Medical University

Background: Chronic hepatitis B virus (HBV) infection affects approximately 250 million people worldwide and is a major cause of cirrhosis and hepatocellular carcinoma. Accurate assessment of hepatic inflammatory activity is essential for disease staging and antiviral treatment decisions. Quantitative hepatitis B core antibody (qAnti-HBc) has been shown to correlate closely with liver inflammation and host immune activation, supporting its potential as a non-invasive biomarker. However, the cellular immunological mechanisms underlying anti-HBc production and maintenance remain unclear, particularly whether it depends on T cell involvement. **Methods:** AAV8-HBV1.3 infection model was established in wild-type BALB/c mice and T cell-deficient BALB/c-nu mice to induce persistent HBV antigen expression. Serum HBsAg, HBeAg, total anti-HBc, and its isotypes were dynamically measured. Hepatic HBsAg and HBcAg expression was assessed by immunohistochemistry, and liver transcriptomic sequencing was performed to analyze immune-related pathways. **Results:** Sustained HBV antigen expression was successfully established in both groups. HBV-BALB/c-nu mice exhibited significantly higher levels of HBsAg and HBeAg than HBV-BALB/c mice. Anti-HBc was detectable in both groups. However, HBV-BALB/c-nu mice showed delayed peak timing and markedly

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

elevated levels, suggesting that anti-HBc production involves both T cell-dependent and T cell-independent pathways. Enhanced humoral immunity was observed in HBV-BALB/c-nu mice, characterized by increased IgM and multiple IgG subclasses. Transcriptomic analysis revealed upregulation of B cell-related genes (Cd19, Ms4a1, Cd79a/b) and enrichment of pathways related to humoral immunity, immunoglobulin-mediated responses, and complement activation, along with activation of macrophage and natural killer cell pathways. Despite this compensatory response, viral control remained ineffective, as hepatic HBsAg and HBcAg levels were significantly higher in HBV-BALB/c-nu mice. **Conclusion:** Anti-HBc can be generated through both T cell-dependent and T cell-independent pathways. T cell deficiency induces compensatory enhancement of humoral immunity centered on B cells but fails to achieve effective viral clearance, highlighting the critical role of T cells in HBV-specific immune regulation.

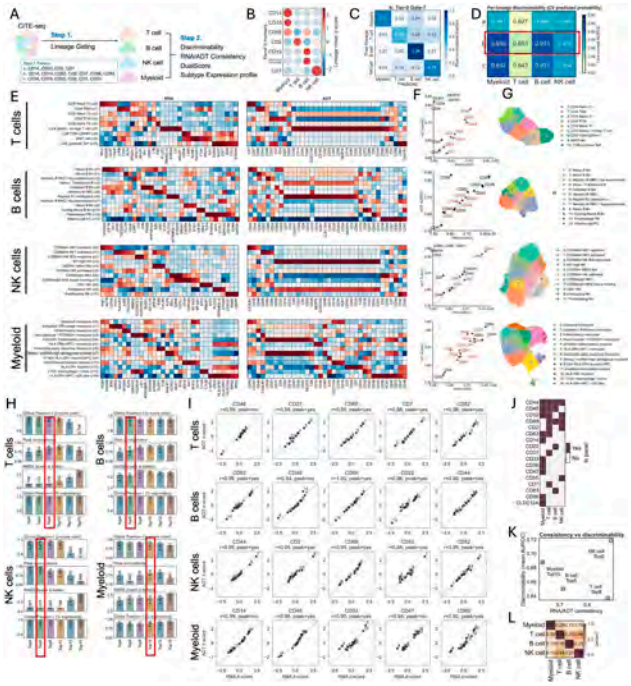
4177 | DUAL MODALITY MARKERS FOR PERIPHERAL BLOOD MONONUCLEAR CELL SUBTYPING IN CHRONIC HEPATITIS B VIRUS INFECTION



Fengge Zhu[1] Man-Fung Yuen[1] Lung Yi Mak[1], [1]The University of Hong Kong

Background: We aim to identify a set of markers for peripheral blood mononuclear cell (PBMC) subtyping that are applicable for both scRNA-seq and flow cytometry, based on a CITE-seq dataset of human PBMCs. **Methods:** We analyzed a CITE-seq dataset (GSE291286) containing 153 PBMC samples from 24 patients with chronic hepatitis B infection. A Weighted Nearest Neighbour (WNN) proxy method was applied by concatenating RNA and antibody derived tags (ADT) principal components and Leiden clustering on the joint kNN graph. Modality-specific discrimination for markers was quantified by the area under the receiver operating characteristic curve (AUROC) with *sklearn.metrics.roc_auc_score*. A custom dual-modality score (DualScore) was defined to rank markers according to their cross-modality performance. **Results:** Three lineage panels (Panel a, b and c, Figure 1A, B) were tested to assign cells to the 4 major compartments (myeloid, T, B, and NK) using stratified five-fold cross-validation of standardized multinomial logistic regression. Panel b (CD14, CD19, CD22, CD2, CD7, CD55, CD33) provided the strongest cross-validated lineage discrimination (one-vs-rest AUROC 0.853-0.935), with excellent recovery of B cells (row-normalized recall 0.95) and myeloid cells (0.81) (Figure 1C, D).For each purified lineage (Myeloid, T, B, NK) (Figure 1E, G), lineage-specific Top-N ADT panels were selected from DualScore-ranked, ADT-mapped shared RNA/ADT markers by evaluating candidate sizes (N = 4, 5, 8, 10, 12, 15) on within-lineage WNN clusters and choosing the list with the highest balanced score (Global Pearson r, Peak concordance, normalized RMSE (Root mean square error)) among candidates with Pearson r $\geq$ 0.75, yielding T cell Top8 (*CD48, CD27, CD69, CD7, CD52, CD2, CD63, CD44*), B cell Top5 (*CD83, CD48, CD69, CD22, CD44*), NK cell Top5 (*CD44, CD2, CD69, CD55, CD52*), and Myeloid Top10 (*CD14, CD48, CD33, CD47, CD86, CD36, CD44, CD63, CD52, CLEC12A*) (Figure 1F, H).We plotted cluster-level z-scored mean expression (RNA versus ADT) of the candidate markers for each lineage (Figure 1H, Top 5 highlighted in red). Most markers showed strong cross-modality alignment ($r > 0.90$), including CD48 ($r = 0.99$) and CD27 ($r = 0.98$) in T cells, CD83 ($r = 0.99$) and CD48 ($r = 0.94$) in B cells, CD44 ($r = 0.99$) and CD2 ($r = 0.99$) in NK cells, CD36 ($r = 1.00$) and CD14 ($r = 0.99$) in myeloid cells, supporting their use as a dual-modality marker set (Figure 1I).Across the 4 major lineages, Top-N marker panels share only CD44 universally, while most markers are lineage-restricted (Figure 1J). Top-N marker panel for NK cells showed the strongest combined performance (Figure 1K), lineage-specific marker composition and limited cross-lineage overlap (Jaccard < 0.44, Figure 1L). **Conclusion:** We curated a set of marker panels for PBMC subtyping suitable

4178 | HEPATIC STEATOSIS ALONE IS INSUFFICIENT TO DRIVE HBSAG LOSS IN EXPERIMENTAL MODELS OF CHRONIC HEPATITIS B WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE

Xupeng Hong[1] Yichen Zhou[2] Kaicheng U[1] Alireza Ramandi[2] Leon Seifert[1] Chenhui Zou[1] Corrine Quirk[1] Luis Chiriboga[3] Charles Rice[1] Ype De Jong[2],
[1]Laboratory of Virology and Infectious Disease, The Rockefeller University, New York, NY, USA., [2]Division of Gastroenterology and Hepatology, Weill Cornell Medicine, New York, NY, USA., [3]Department of Pathology, NYU Langone New York University Langone Medical Center, New York, NY, USA

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) and its progressive inflammatory form, metabolic dysfunction-associated steatohepatitis, are increasingly common chronic liver diseases. Clinical studies suggest that concurrent MASLD in patients with chronic hepatitis B virus (HBV) infection is associated with higher rates of HBsAg seroclearance, but the underlying mechanism remains unclear. Here, we used multiple experimental models of chronic HBV infection to investigate the bidirectional interactions between hepatic steatosis and HBV infection, assessing both the effects of steatosis on HBV antigen expression and viral replication and the impact of HBV infection on steatosis development. **Methods:** We performed a meta-analysis of patient studies to assess the relationship between chronic HBV infection and liver steatosis, as well as the association between hepatic steatosis and spontaneous HBsAg clearance. We then examined the effects of oleic acid and palmitic acid treatment, which induces lipid accumulation, in HBV-infected primary human hepatocytes in vitro. To model MASLD in vivo, we fed HBV-transgenic mice a western diet and fed HBV-infected human liver chimeric mice 10% high-fructose corn syrup. Finally, we used an adeno-associated virus (AAV)-HBV mouse model to further assess the effects of hepatic steatosis on HBV antigen expression. **Results:** Meta-analysis showed that HBV infection was negatively associated with liver steatosis (OR, 0.71; 95% CI, 0.67-0.75; I^2 = 0%), whereas hepatic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

steatosis was associated with spontaneous HBsAg clearance (OR, 1.40; 95% CI, 1.17-1.67; I^2 = 0%). In HBV-infected primary human hepatocytes, oleic acid and palmitic acid treatment induced lipid accumulation but did not reduce secreted HBV antigens, and decreased HBV antigen was observed only after the onset of cell death. In HBV-transgenic mice, western diet feeding induced hepatic steatosis, but serum HBsAg and HBeAg levels remained unchanged. Notably, HBV-transgenic mice gained body weight more slowly and developed less severe steatosis than wild-type littermates, suggesting that HBV may attenuate MASLD progression. Similarly, HBV-infected human liver chimeric mice fed 10% high-fructose corn syrup developed less hepatic steatosis than non-infected controls, while HBsAg and HBV DNA levels were not reduced compared with HBV-infected human liver chimeric mice on a normal diet. Finally, in the AAV-HBV mouse model, induction of hepatic steatosis alone did not alter serum HBsAg levels. **Conclusion:** Across complementary in vitro and in vivo models, our results suggest that hepatic steatosis does not directly reduce HBV antigen levels or viral replication. Instead, adaptive immune responses and hepatocyte injury may be required for HBsAg loss in the setting of MASLD/steatotic liver disease.

4179 | DOCK11 PROMOTES HBV CCCDNA FORMATION BY REGULATING PARP1 RECRUITMENT TO RCDNA

Hideo Takayama[1] Kouki Nio[1] Taro Yamashita[1],
[1]Kanazawa University

Background: Chronic hepatitis B virus (HBV) infection is a major cause of liver fibrosis and hepatocarcinogenesis. Current antiviral therapies cannot eliminate covalently closed circular DNA (cccDNA), a stable nuclear viral reservoir. We previously identified Dedicator of Cytokinesis 11 (DOCK11) as a host factor required for HBV replication. Poly (ADP-ribose) polymerase 1 (PARP1) has been reported to bind relaxed circular DNA (rcDNA) and facilitate cccDNA formation. However, the mechanisms governing PARP1 recruitment to rcDNA remain unclear. Here, we investigated the role of DOCK11 in cccDNA formation and its underlying mechanism. **Methods:** To assess the role of DOCK11 in cccDNA maintenance, we measured luciferase activity over time in hepatoma cell lines transfected with minicircle HBV cccDNA with a Gaussia Luciferase reporter (mcHBV-GLuc cccDNA). To evaluate its role in cccDNA formation, we established an in vitro assay in which rcDNA isolated from culture supernatants was incubated with nuclear extracts. DOCK11-associated HBV DNA-interacting proteins were identified by immunoprecipitation followed by LC-MS/MS. Protein interactions and localization were analyzed by immunoprecipitation and super-resolution microscopy. **Results:** DOCK11 depletion in Huh7 and HepG2 cells led to a marked, time-dependent reduction in luciferase activity after mcHBV-GLuc cccDNA transfection, indicating impaired cccDNA maintenance, with a potential contribution to cccDNA stability. In the in vitro assay, DOCK11 overexpression significantly enhanced cccDNA formation, whereas DOCK11 knockout markedly suppressed it. LC-MS/MS revealed PARP1 as a central component of the DOCK11–HBV DNA complex. DOCK11 and PARP1 co-localized in hepatoma cells and human liver tissue. Notably, DOCK11 did not affect PARP1 protein expression or enzymatic activity, but was essential for its recruitment to DNA damage sites and HBV DNA. This was demonstrated by UV-induced damage assays and PARP1 immunoprecipitation. Collectively, these findings indicate that DOCK11 facilitates cccDNA formation by promoting PARP1 recruitment to rcDNA. **Conclusion:** DOCK11 controls PARP1 recruitment to rcDNA without altering its expression or activity, thereby promoting HBV cccDNA formation and persistence. Targeting the DOCK11–PARP1 axis may represent a novel therapeutic strategy for eliminating HBV cccDNA.

Background: Chronic hepatitis B virus (HBV) infection is a major risk factor for hepatocellular carcinoma (HCC), but its precise mechanisms remain incompletely understood. Yes-associated protein (YAP), a transcriptional coactivator of the Hippo pathway, plays important roles in liver regeneration and HCC. Therefore, we investigated whether HBV contributed to YAP-related hepatocarcinogenesis. **Methods:** HBV-mediated YAP activation was examined in HBV-infected HepG2-NTCP, Huh-7-NTCP cells, and primary hepatocytes from human chimeric mice by quantitative RT-PCR, Western blots, immunofluorescence staining, and a luciferase reporter system in which the YAP promoter region was inserted upstream of the luciferase gene. SK-HEP-1 cells, which express tumor necrosis factor (TNF) receptor-2, were treated with recombinant human TNF-alpha, and YAP activation was evaluated. Human CD14-positive monocyte-derived macrophages were exposed to purified HBV particles, and cytokine production was examined at the mRNA and protein levels. SK-HEP-1 cells were treated with the culture supernatants from HBV-exposed macrophages, and YAP reporter activity was measured with or without neutralizing antibodies against several cytokines. **Results:** In contrast to previous reports suggesting a direct link between HBV and YAP activation, HBV infection did not induce apparent YAP activation in HepG2-NTCP cells or primary human hepatocytes. Meanwhile, we found that recombinant TNF-alpha induced YAP dephosphorylation, nuclear translocation, and upregulation of YAP target genes in SK-HEP-1 cells and primary human hepatocytes. High copy numbers of HBV induced human macrophages to produce TNF-alpha in a time- and HBV dose-dependent manner. Furthermore, the culture supernatants from HBV-exposed macrophages activated YAP in SK-HEP-1 cells. HBV induced several other inflammatory cytokines, such as interleukin (IL)-1beta, IL-6, and IL-12, from macrophages, but only neutralization of TNF-alpha abolished YAP activation, whereas neutralization of other cytokines had no effect. Cell proliferation, cell cycle-related proteins, and proliferation-related signaling in SKHEP-1 cells were inhibited by YAP knockdown and enhanced by recombinant TNF-alpha. **Conclusion:** HBV does not directly activate YAP in hepatocytes, but indirectly activates YAP through macrophage-derived TNF-alpha, which subsequently promotes tumor-associated signaling in HCC cells. These findings identify a macrophage–TNF-alpha–YAP axis as a novel indirect mechanism of HBV-related hepatocarcinogenesis, which partially explains why HBV-related HCC occurs even in a non-cirrhotic liver.

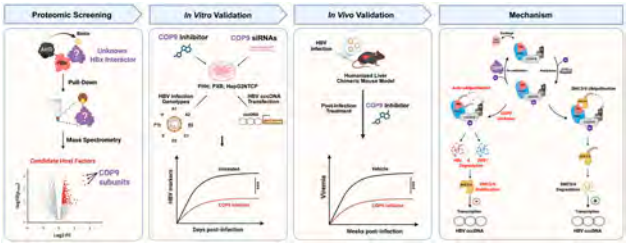
4181 | PROTEOMIC IDENTIFICATION OF THE COP9 SIGNALOSOME AS A DRUGGABLE REGULATOR OF HBV CCCDNA TRANSCRIPTION THROUGH HBX DEGRADATION



Karim Mouzannar[1] Anne Schauer[1] Susannah Stephenson-Tsoris[1] Zhensheng Zhang[1] Min Zhang[1] Seung Bum Park[1] D. Eric Anderson[1] T. Jake Liang[1], [1]Liver Diseases Branch, NIDDK, NIH, Bethesda, Maryland, USA

Background: Hepatitis B virus X protein (HBx) is essential for viral replication by activating cccDNA transcription and antagonizing host restriction factors. Its most well-established mechanism is the degradation of the SMC5/6 complex via the DDB1–Cullin 4 (CRL4) E3 ubiquitin ligase. However, additional HBx-host interactions likely exist and remain poorly defined, limiting our understanding of cccDNA regulation and development of HBx-targeted antiviral strategies. **Methods:** We performed AirID-based proximity labeling coupled with mass spectrometry to identify novel HBx-interacting proteins in live cells. AirID enables high-specificity detection of transient and weak protein interactions, outperforming co-immunoprecipitation and conventional biotinylation approaches. COP9 function was disrupted using (i) siRNA knockdown of multiple subunits and (ii) pharmacological inhibition of CSN5 (COP9i), the catalytic deneddylase subunit regulating CRL activity and an emerging therapeutic target in oncology. **Results:** Our proteomic screen identified multiple COP9 signalosome subunits as HBx interactors, with CSN5 as the top hit. Knockdown of COP9 subunits (CSN5, CSN6, CSN7A, CSN8) significantly reduced HBV markers in HBV-infected primary human hepatocytes (PHH) and HepG2-NTCP cells.Pharmacological inhibition with COP9i showed potent antiviral activity with a favorable therapeutic window (EC_{50}: 50–100 nM; EC_{90}: 150–300 nM; CC_{50} > 10 μM) and a broad pan-genotypic efficacy (A1, A2, B2, C1, D3, E, F1b, H). *In vivo*, post-infection oral administration of COP9i in HBV-infected FRG humanized mice significantly reduced serum HBV DNA levels.Mechanistically, COP9 inhibition selectively suppressed cccDNA transcription as demonstrated using a cccDNA reporter system (mcHBV-Luc). COP9i induced robust HBx degradation. Inhibition of COP9 locks CRL4 in a hyper-neddylated state,

promoting auto-ubiquitination and degradation of HBx and DDB1, leading to stabilization of SMC5/6 and sustained repression of cccDNA transcription. **Conclusion:** The COP9 signalosome is a previously unrecognized and druggable regulator of HBV cccDNA transcription. Targeting COP9 induces HBx degradation and restores SMC5/6-mediated restriction, providing a mechanistically defined and translational antiviral strategy.

4182 | PRE-ENCODED PLASMA PROTEOMIC SIGNATURE PREDICTS IMMUNE-ACTIVE TRANSITION IN INDETERMINATE-PHASE CHRONIC HEPATITIS B

Won-Mook Choi[1] Heeju Ryu[2] Young Suk Lim[3], [1]Department of Gastroenterology, Asan Medical Center, University of Ulsan College of Medcine, Korea, [2]Department of Immunology, School of Medicine, Sungkyunkwan University, Korea, [3]Department of Gastroenterology, Asan Medical Center, University of Ulsan College of Medicine, Korea

Background: Patients with indeterminate-phase chronic hepatitis B (CHB), particularly those with high viremia (HBV DNA >2,000 IU/mL) and persistently normal or mildly elevated alanine aminotransferase (ALT), remain poorly characterized regarding their immunological profiles and heterogeneous clinical trajectories. We investigated whether plasma proteomic signatures could predict immune trajectory in CHB and whether transition to the immune-active phase occurs as an acute switch-like event rather than gradual immunological drift. **Methods:** Longitudinal plasma proteomic profiling using the Olink Target 96 Inflammation panel was performed in 32 CHB patients from the observational arm of the ATTENTION study (NCT03753074), a multicenter randomized trial in non-cirrhotic patients with high viremia and normal or mildly elevated ALT. Patients were classified into persistently indeterminate CHB (G1, n = 11), transition to immune-active CHB (G2, n = 12), and spontaneous transition to inactive CHB (G3, n = 9). Differential abundance, longitudinal mixed-effects, and changepoint analyses centered on clinical event timing (T_0) were performed. A baseline multi-protein biomarker model predicting immune-active transition was subsequently developed. **Results:** Baseline global plasma proteomes overlapped substantially across groups. However, longitudinal analyses demonstrated that G2 represented the only proteomically distinct trajectory, whereas G3 remained indistinguishable from G1 despite viral suppression. G2 acutely diverged from both G1 and G3 at the time of clinical event, with 83–89% of proteomic transitions clustering within $T_0 \pm 1$ timepoint. The G2 program was characterized by IFN-γ/CD8/NK-cell activation signatures, including CXCL9, CXCL10, CXCL11, CDCP1, IL-18, and TNFRSF9. IL-10 showed a context-dependent dual role, with baseline elevation preceding immune-active transition and transient surge at T_0 correlating with IFN-γ and ALT recovery. A baseline inflammatory panel comprising IL-10, CDCP1, and CXCL9 accurately predicted future G2 patients (AUC = 0.98). **Conclusion:** In indeterminate-phase CHB, immune trajectory appears pre-encoded within the baseline plasma proteome and diverges through an acute switch-like event. Baseline plasma biomarkers may enable prospective identification of patients at risk for immune-active transition.

4183 | SYNERGISTIC EFFECTS OF GUIZHI JIA HUANGQI DECOCTION COMBINED WITH NUCLEOS(T)IDE ANALOGUES AND PEGYLATED INTERFERON ON FUNCTIONAL CURE OF CHRONIC HEPATITIS B: A 48-WEEK IMMUNOVIROLOGICAL ANALYSIS

Xiaoyu Hu[1], [1]Hospital of Chengdu University of Traditional Chinese Medici

Background: The clearance rate of hepatitis B surface antigen (HBsAg) remains limited in patients with chronic hepatitis B (CHB) receiving nucleos(t)ide analogue (NA) combined with pegylated interferon (Peg-IFN) therapy. Traditional Chinese medicine (TCM) possesses immunomodulatory properties; however, its efficacy and underlying mechanisms when combined with NAs and Peg-IFN remain unclear. **Methods:** A total of 111 patients with CHB were enrolled and assigned to either a dual-therapy group (NA + Peg-IFN, n = 55) or a triple-therapy group (TCM + NA + Peg-IFN, n = 56) for 48 weeks. Virological, hematological, biochemical, and immunological parameters were evaluated. Immunological indices were analyzed at baseline and week 24 using flow cytometry. **Results:** The triple therapy group (TCM + NA + Peg-IFN) exhibited significantly higher HBsAg clearance rates (44.6% vs. 20.0%, P = 0.006) and seroconversion rates (33.9% vs. 16.4%, P = 0.033) compared with the dual therapy group. Immunologically, treatment in the triple therapy group led to a marked reduction in PD-1 expression on B cells (11.1% → 4.7%, P = 0.002) and $CD8^+$ T cells (23.5% → 16.9%, P = 0.02), accompanied by a significant increase in $CD8^+$ T cell counts (P = 0.04). Additionally, serum IL-8 levels were significantly elevated (P = 0.041). Regarding safety, white blood cell (WBC) and neutrophil (NEUT) counts at weeks 4, 8, and 12 were significantly better in the triple therapy group compared with the dual therapy group (P < 0.05). During the 24-week follow-up, no serious adverse events were observed in either group, and patients who achieved HBsAg clearance did not experience HBsAg recurrence. **Conclusion:** The triple therapy regimen combining TCM, NA, and Peg-IFN enhances the functional cure rate in chronic hepatitis B (CHB) and mitigates Peg-IFN-induced reductions in WBC and NEUT counts. Mechanistically, these effects are likely mediated through reversal of B cell and $CD8^+$ T cell exhaustion, promotion of $CD8^+$ T cell expansion, and induction of controlled IL-8–mediated immune activation.

Synergistic Effects of Guizhi Jia Huangqi Decoction Combined with Nucleos(t)ide Analogues and Pegylated Interferon on Functional Cure of Chronic Hepatitis B: A 48-Week Immunovirological Analysis

Xiaoyu Hu

Department of Infectious Diseases, Hospital of Chengdu University of Traditional Chinese Medicine, Chengdu, People's Republic of China

Abstract

Background: The clearance rate of hepatitis B surface antigen (HBsAg) remains limited in patients with chronic hepatitis B (CHB) receiving nucleos(t)ide analogue (NA) combined with pegylated interferon (Peg-IFN) therapy. Traditional Chinese medicine (TCM) possesses immunomodulatory properties; however, its efficacy and underlying mechanisms when combined with NAs and Peg-IFN remain unclear.

Methods: A total of 111 patients with CHB were enrolled and assigned to either a dual-therapy group (NA + Peg-IFN, n = 55) or a triple-therapy group (TCM + NA + Peg-IFN, n = 56) for 48 weeks. Virological, hematological, biochemical, and immunological parameters were evaluated. Immunological indices were analyzed at baseline and week 24 using flow cytometry.

Results: The triple therapy group (TCM + NA + Peg-IFN) exhibited significantly higher HBsAg clearance rates (44.6% vs. 20.0%, P = 0.006) and seroconversion rates (33.9% vs. 16.4%, P = 0.033) compared with the dual therapy group. Immunologically, treatment in the triple therapy group led to a marked reduction in PD-1 expression on B cells (11.1% → 4.7%, P = 0.002) and $CD8^+$ T cells (23.5% → 16.9%, P = 0.02), accompanied by a significant increase in $CD8^+$ T cell counts (P = 0.04). Additionally, serum IL-8 levels were significantly elevated (P = 0.041). Regarding safety, white blood cell (WBC) and neutrophil (NEUT) counts at weeks 4, 8, and 12 were significantly better in the triple therapy group compared with the dual therapy group (P < 0.05). During the 24-week follow-up, no serious adverse events were observed in either group, and patients who achieved HBsAg clearance did not experience HBsAg recurrence.

Conclusions: The triple therapy regimen combining TCM, NA, and Peg-IFN enhances the functional cure rate in chronic hepatitis B (CHB) and mitigates Peg-IFN-induced reductions in WBC and NEUT counts. Mechanistically, these effects are likely mediated through reversal of B cell and $CD8^+$ T cell exhaustion, promotion of $CD8^+$ T cell expansion, and induction of controlled IL-8–mediated immune activation.

1.Background

Currently, nucleos(t)ide analogue (NA) combined with pegylated interferon (Peg-IFN) therapy represents a major strategy for achieving functional cure in chronic hepatitis B (CHB); however, the rate of hepatitis B surface antigen (HBsAg) clearance remains suboptimal (1). Traditional Chinese medicine (TCM) has been reported to possess immunomodulatory and anti-inflammatory properties (2), yet its efficacy and underlying mechanisms when combined with NAs and Peg-IFN remain unclear. Therefore, this study aimed to evaluate the 48-week clinical cure rate of a TCM + NA + Peg-IFN triple regimen and to systematically characterize treatment-related changes in virological responses, peripheral immune cell profiles—including T cells, B cells, natural killer (NK) cells, and their PD-1 expression—and selected serum inflammatory cytokines.

2. Materials and Methods

2.1 Study Design

This was a prospective, single-center, exploratory cohort study that enrolled 111 patients with CHB between January 2024 and December 2025. Eligibility criteria included baseline HBsAg levels < 1500 IU/mL and hepatitis B virus (HBV) DNA levels below the lower limit of detection (< 100 IU/mL). Patients were assigned to either the dual-therapy group (Dual), which received NA + Peg-IFN treatment (n = 55), or the triple-therapy group (Combination), which received TCM + NA + Peg-IFN treatment (n = 56).

2.2 Interventions

Patients in the dual-therapy group received NA combined with pegylated interferon α-2b (Peg-IFNα-2b, 180 μg/week) for 48 weeks. Patients in the triple-therapy group received the same regimen supplemented with Guizhi Jia Huangqi Decoction granules (one dose daily, administered three times per day) for 48 weeks.

2.3 Study Endpoints

The primary endpoint was the HBsAg clearance rate at week 48. Secondary endpoints included HBsAg seroconversion rate, HBeAg seroconversion rate (in patients who were HBeAg-positive at baseline), incidence of alanine aminotransferase (ALT) flare, and safety outcomes. ALT flare was defined as ALT > 2 × the upper limit of normal (ULN) with a peak value > 80 U/L during the 48-week treatment period. Functional cure was defined as HBsAg clearance at week 48 that remained negative 24 weeks after treatment discontinuation. Seroconversion was defined as HBsAg clearance accompanied by HBsAb positivity (≥ 10 mIU/mL).

2.4 Definition of Response Status

According to HBsAg clearance status at week 48, patients were categorized into a responder group (patients achieving HBsAg clearance) and a non-responder group (patients without HBsAg clearance) for subsequent analysis of ALT flare incidence.

2.5 Laboratory Assessments

Peripheral venous blood samples were collected at weeks 0, 2, 4, 8, 12, 24, 36, and 48 during treatment. The following parameters were assessed: Virological parameters: Serum HBsAg, HBeAg, and HBV DNA levels were measured at baseline, weeks 4, 8, 12, 24, 36, and 48, as well as at the 24-week post-treatment follow-up. Hematological and biochemical parameters: White blood cell count (WBC), neutrophil count (NEUT), platelet count (PLT), thyroid function panel (six parameters), alanine aminotransferase (ALT), and aspartate aminotransferase (AST) were assessed at baseline, weeks 4, 8, 12, 24, 36, 48, and at the 24-week post-treatment follow-up. Immunological parameters: Peripheral blood collected at baseline and week 24 was analyzed by flow cytometry for PD-1 expression on CD8+ T cells, B-cell counts, PD-1 expression on B cells, NK cell counts, and CD4/CD8 ratio. Inflammatory mediators: Serum IL-8 levels were measured using enzyme-linked immunosorbent assay (ELISA).

2.6 Statistical Analysis

Within-group comparisons were performed using the paired t-test or Wilcoxon signed-rank test, as appropriate. Between-group comparisons were conducted using the independent-samples t-test, Mann–Whitney U test, or chi-square test. A two-sided P value < 0.05 was considered statistically significant.

2.7 Ethical Approval

This study was approved by the Ethics Committee of the Hospital of Chengdu University of Traditional Chinese Medicine. Written informed consent was obtained from all participants prior to enrollment.

3. Results

3.1 Baseline Demographic and Clinical Characteristics

A total of 111 patients with CHB were enrolled in this study, including 55 patients in the dual-therapy group (NA + Peg-IFNα-2b) and 56 patients in the triple-therapy group (TCM + NA + Peg-IFNα-2b). As shown in Table 1, no significant differences were observed between the two groups with respect to age, sex distribution, HBeAg positivity rate, baseline HBsAg levels, or baseline ALT levels (all $P > 0.05$), indicating comparable baseline characteristics. All enrolled patients had HBV DNA levels below the lower limit of detection (< 100 IU/mL) at baseline, and thyroid function parameters were within the normal range.

Table 1. Baseline Demographic and Clinical Characteristics

Variable	Dual-Therapy Group (n = 55)	Dual-Therapy Group(n = 56)	*P* value
Age (years)	47±9	44.5±9	0.145
Sex (male/female)	39/16	45/11	0.246
HBeAg positivity, *n* (%)	4（7.3%）	5（8.9%）	0.749
Baseline HBsAg	62.45（13.22，130.53）	106.36（26.58，150）	0.105
(IU/mL)			
Baseline ALT (U/L)	23（17，37）	26（18.75，38.25）	0.637

3.2 Virological Response and ALT Flare

At week 24, the HBsAg clearance rates were 26.8% in the triple-therapy group and 14.5% in the dual-therapy group ($P = 0.112$), while HBsAg seroconversion rates were 19.6% and 10.9% ($P = 0.201$), respectively. By week 48, the triple-therapy group achieved significantly higher HBsAg clearance (44.6% vs. 20.0%, $P = 0.006$) (Figure 1A) and HBsAg seroconversion rates (33.9% vs. 16.4%, $P = 0.033$) (Figure 1B) compared with the dual-therapy group. Regarding ALT flare, patients who achieved HBsAg clearance (responders) had a significantly higher incidence than non-responders (50.0% vs. 30.7%, $P = 0.048$) (Figure 1C).

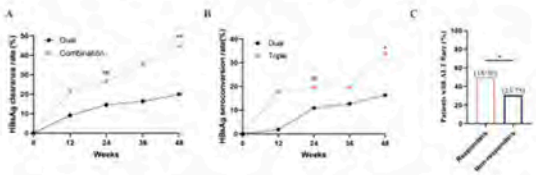

Figure 1. Week 48 efficacy endpoints and incidence of ALT flare. (A) HBsAg clearance rate. (B) HBsAg seroconversion rate. (C) Incidence of ALT flare. ALT flare was defined as ALT > 2 × the upper limit of normal (ULN) with a peak value > 80 U/L during the 48-week treatment period. Responders were defined as patients who achieved HBsAg clearance at week 48. Data are presented as percentages. Between-group comparisons were performed using the chi-square test. *$P < 0.05$, **$P < 0.01$.

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

3.3 Immune and Inflammatory Responses

3.3.1 Dynamic Changes in T Cells

At 24 weeks of treatment, PD-1 expression on $CD8^+$ T cells was significantly reduced from baseline in both groups: from 21.8% to 16.0% in the dual therapy group ($P = 0.013$) and from 23.5% to 16.9% in the triple therapy group ($P = 0.02$) (Figure 2A). $CD8^+$ T cell counts exhibited divergent trends: they increased significantly in the triple therapy group ($P = 0.04$) but decreased significantly in the dual therapy group ($P < 0.01$) (Figure 2B). In contrast, the CD4/CD8 ratios showed no notable changes from baseline in either group (Figure 2C).

3.3.2 Dynamic Changes in NK Cells

At 24 weeks of treatment, total NK cell counts decreased significantly from baseline in both groups: from 231.9×10^6/L to 174.3×10^6/L in the dual therapy group ($P = 0.027$) and from 227.2×10^6/L to 180.0×10^6/L in the triple therapy group ($P = 0.029$) (Figure 2D). The CD4/CD8 ratio remained largely unchanged in both groups (Figure 2C). Additionally, no significant differences were observed in NK cell PD-1 expression before and after treatment in either group (Figure 2E).

3.3.3 B-Cell Responses

With respect to total B-cell counts, a significant reduction was observed in the dual-therapy group at week 24 compared with baseline ($P = 0.007$) (Figure 2E). Although a similar decreasing trend was observed in the triple-therapy group, the difference did not reach statistical significance (Figure 2F).

Notably, the proportion of PD-1–expressing B cells was significantly reduced in the triple-therapy group at week 24 compared with baseline ($P = 0.002$), whereas only a non-significant downward trend was observed in the dual-therapy group.

3.3.4 Inflammatory Mediators

IL-8 is a pro-inflammatory and pro-fibrotic cytokine, and persistently elevated IL-8 levels may indicate uncontrolled hepatic inflammation and progression toward fibrosis or hepatocellular carcinoma. Compared with the dual-therapy group, the triple-therapy group exhibited significantly higher serum IL-8 levels at week 24 ($P = 0.041$), suggesting that the addition of TCM to interferon-based therapy may induce a stronger immune activation state (Figure 2G). This finding is consistent with the higher HBsAg clearance rate observed in the triple-therapy group and supports enhanced immune activation as an important driver of functional cure. Importantly, the increase in IL-8 was not accompanied by severe adverse events, indicating that this immune response was well tolerated.

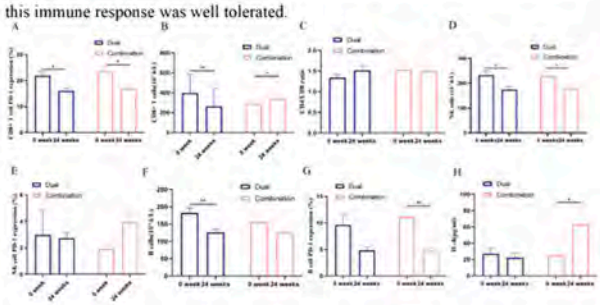

Figure 2 Changes in immunological and inflammatory response indicators (week 0 vs. week 24). (A) CD8+ T cell PD-1 expression rate; (B) CD8+ T cell count; (C) CD4/CD8 ratio; (D) Total NK cell count; (E) NK cell PD-1 expression rate; (F) B cell count; (G) B cell PD-1 expression rate; (H) Serum IL-8 level. Data are presented as mean ± standard deviation. Paired t-tests were used for within-group comparisons. $^*P < 0.05$, $^{**}P < 0.01$.

4. Safety Evaluation

During the treatment period, WBC, NEUT, and PLT levels in both groups exhibited a declining trend between weeks 4 and 12. WBC and NEUT reached their lowest values at week 4, whereas PLT levels were lowest at week 8. At weeks 4 and 8, the triple therapy group had significantly higher WBC and NEUT levels compared with the dual therapy group ($P < 0.05$), while PLT levels did not differ significantly between groups at any time point (Figures 3A–C). After week 12, WBC, NEUT, and PLT levels gradually recovered toward normal ranges in both groups. No patients experienced grade 3/4 neutropenia or clinically significant thrombocytopenia requiring intervention.

Regarding hepatic safety, no significant difference was observed in the incidence of ALT flare—defined as ALT > 2 × the ULN with a peak value > 80 U/L during the 48-week treatment period—between the dual-therapy and triple-therapy groups (29.1% vs. 32.1%, respectively) (Figure 3D).
In addition, no clinically meaningful abnormalities in thyroid function were detected in either group throughout treatment. During the subsequent 24-week follow-up period, no serious adverse events were observed in either group, and no HBsAg reversion occurred among patients who had achieved HBsAg clearance.

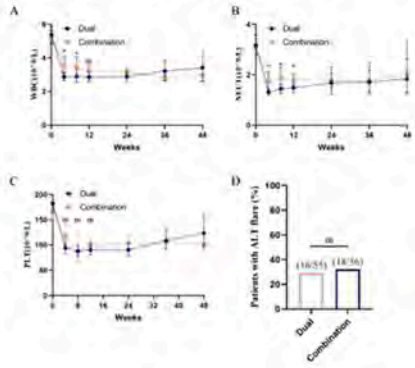

Figure 3 Hematological and hepatic safety parameters during treatment. (A) White blood cell (WBC) count; (B) Neutrophil (NEUT) count; (C) Platelet (PLT) count; (D) Incidence of ALT flare. ALT flare was defined as ALT > 2×ULN with a peak value > 80 U/L within the 48-week treatment period. Data are presented as mean ± standard deviation. Paired t-tests were used for within-group comparisons of continuous variables, and chi-square tests were used for between-group comparisons of categorical variables. $^*P < 0.05$, $^{**}P < 0.01$.

4.Discussion

The present study found that the triple therapy (TCM + NA + Peg-IFN) significantly improved HBsAg clearance rate (44.6% vs. 20.0%) and seroconversion rate (33.9% vs. 16.4%) compared to the dual therapy. Furthermore, in the triple group, B-cell PD-1 expression significantly decreased from baseline (11.1% to 4.7%, $P = 0.002$), CD8+ T-cell PD-1 expression also significantly decreased (23.5% to 16.9%, $P = 0.02$), and CD8+ T-cell count significantly increased ($P = 0.04$). These findings suggest that the Chinese herbal medicine may enhance both humoral and cellular immune functions by simultaneously reversing B-cell and CD8+ T-cell exhaustion and promoting CD8+ T-cell expansion, thereby facilitating HBsAg clearance and seroconversion.

Notably, our previous studies demonstrated that Guizhi Jia Huangqi Decoction can inhibit HBV entry into hepatocytes through blockade of the NTCP receptor, thereby preventing new infection events. In addition, this formula can directly suppress cccDNA transcription, reducing HBsAg production at its source (3). This direct antiviral activity may create a more favorable environment for immune-mediated viral clearance. On the one hand, by reducing newly infected hepatocytes, the persistent production and release of viral antigens—including HBsAg—are diminished, thereby alleviating immune exhaustion caused by chronic high antigen exposure. On the other hand, stabilization and gradual reduction of the infected hepatocyte pool may establish a more permissive microenvironment for subsequent interferon-mediated immune clearance.

From an immunomodulatory perspective, serum IL-8 levels were significantly elevated in the triple-therapy group without an accompanying increase in severe adverse events. Although IL-8 is generally considered a pro-inflammatory and pro-fibrotic cytokine, and persistently elevated IL-8 levels are often associated with uncontrolled hepatic inflammation, the increase observed in this study was consistent with the higher HBsAg clearance rate. Mechanistic studies have shown that interferon can induce IL-8 expression, while upregulated IL-8 may directly suppress HBsAg production and release in hepatocytes by enhancing the expression of bone marrow stromal antigen 2 (BST2) (4). These findings support the concept that an early and moderate increase in inflammatory cytokines during interferon therapy may reflect effective immune reactivation (5).

Taken together, we propose a "dual-mode synergistic" model through which TCM combined with interferon promotes functional cure in CHB. Specifically, TCM exerts direct antiviral effects through NTCP blockade, thereby interrupting new infection events at the upstream level and reducing the immunological burden on the host. Simultaneously, the combination of TCM and interferon may reverse PD-1–mediated B-cell exhaustion and induce controlled IL-8–associated immune activation at the downstream level, thereby enhancing immune-mediated viral clearance. This synergistic strategy of "source blockade" and "terminal clearance" may represent the central mechanism underlying the superior HBsAg clearance achieved by the triple regimen and provides a theoretical basis for optimizing integrative therapeutic strategies for CHB. It should be noted that during the study period, 9 and 7 patients in the dual and triple groups, respectively, discontinued treatment prematurely, while 23 and 9 patients did not reach the treatment endpoint. Although the dropout rates were generally manageable in both groups and may introduce some bias into the efficacy assessment, the overall completion rate remained acceptable. Future studies with larger sample sizes and optimized follow-up management are needed to further validate the findings of this study.

4184 | THE LANDSCAPE OF HBV INTEGRATION BURDEN ACROSS CHRONIC HEPATITIS B, CIRRHOSIS, AND HEPATOCELLULAR CARCINOMA

Xingyue Yi[1] Na Wu[2] Fang Wei[3] Zhiwei Chen[2] Hong Ren[2], [1]Chongqing Medical University, [2]the Second Affiliated Hospital of Chongqing Medical University, [3]Chongqing University Three Gorges Hospital

Background: Chronic hepatitis B (CHB) remains a major global public health burden, which can progress into liver cirrhosis (LC) and eventually hepatocellular carcinoma (HCC). Accumulating evidence has established that HBV integration into the host genome is a critical oncogenic event in HCC pathogenesis, driving genomic instability, aberrant gene expression, and malignant transformation. However, the distinct characteristics of HBV integration across the three progressive disease stages—CHB, LC, and HCC—remain poorly understood. **Methods:** We collected liver tissues from patients with CHB, HBV-related LC, and HBV-related HCC at the Second Affiliated Hospital of Chongqing Medical University. Viral capture sequencing precisely detected genome-wide HBV integration breakpoints to analyze integration patterns, distribution, and clonal expansion of HBV-integrated hepatocytes across stages. RNA sequencing profiled host gene expression, with integrative bioinformatics exploring the relationship between clonal expansion of HBV-integrated hepatocytes and immune infiltration. **Results:** This cross-sectional study enrolled 103 patients: 45 with CHB, 22 with LC, 35 with HCC. The number of unique integration types was significantly higher in CHB than in LC/HCC (123 vs 42.5, 123 vs 71, both $P < 0.01$), reflecting early heterogeneous integration and reduced integration diversity. Clonal expansion of HBV-integrated hepatocytes was markedly elevated in HCC (18.70 vs 5.02, 18.70 vs 4.73, both $P < 0.001$), indicating monoclonal dominance during malignancy. Integration diversity correlated positively with HBsAg and ALT; clonal expansion of HBV-integrated hepatocytes correlated positively with AFP and age. The peak of HBV genomic breakpoints was located in the X gene, gradually shifting toward the DR2 region from CHB to HCC. A total of 44 shared genes were identified. Among these, integration frequencies of LOC100507412 and TERT progressively increased, while those of PCDH15 and CTNNA2 gradually decreased. These integration patterns may facilitate

disease progression from CHB to LC and ultimately to HCC. Genes positively associated with clonal expansion of HBV-integrated hepatocytes were enriched in cell cycle and proliferation pathways, while negatively associated genes in immune-metabolic pathways. Clonal expansion of HBV-integrated hepatocytes positively correlated with intrahepatic M2 macrophages, suggesting immunosuppression. **Conclusion:** This study systematically delineates the HBV integration features across CHB-LC-HCC, showing decreasing diversity and increasing clonality from early infection to HCC, providing new insights into disease progression.

4185 | SARCOPENIA DELAYS EARLY VIROLOGICAL RESPONSE BUT DOES NOT AFFECT LONG-TERM PROGNOSIS IN PATIENTS WITH CHRONIC HEPATITIS B AND LIVER CIRRHOSIS

Yeonwoo Cha[1] In Hee Kim[1] Chang Hun Lee[1] Byung Chul Jin[1] Yun Chae Lee[1] Seung Young Seo[1] Seong Hun Kim[1] Seung Ok Lee[1], [1]Jeonbuk National University Hospital

Background: This study aimed to investigate the clinical significance of sarcopenia in virological response (VR) and long-term prognosis among treatment-naïve chronic hepatitis B (CHB) patients with liver cirrhosis (LC). **Methods:** We retrospectively reviewed the data of treatment-naïve CHB patients who initiated antiviral therapy between 2007 and 2018 at Jeonbuk National University Hospital. Eligible patients were those diagnosed with LC who had maintained antiviral therapy for more than a year. L3 skeletal muscle index (L3SMI) was calculated using computed tomography, and sarcopenia was defined using the gender quartile method (cut-off: <46.0 cm^2 /m^2 for males and <35.37 cm^2 /m^2 for females). **Results:** A total of 283 patients (71 in the sarcopenic group and 212 in the non-sarcopenic group) were enrolled. The sarcopenic group was significantly older and had a higher frequency of alcohol consumption history compared to the non-sarcopenic group. Mean baseline HBV DNA levels and MELD scores did not differ significantly between the groups. The cumulative VR rates were significantly lower in the sarcopenic group at 1 and 2 years, indicating a delay in viral suppression. However, VR rates became comparable after 3 years of continuous therapy. There were no significant differences in serial MELD scores, cumulative HCC incidence, or overall survival rates between the two groups. Consistent trends were observed in subgroup analyses of patients with sarcopenic obesity and those aged ≥ 60 years. In multivariate analysis for 5-year overall survival, baseline log HBV DNA, VR at 1 year, MELD score, and HCC development were independent prognostic factors, whereas sarcopenia was not. **Conclusion:** Sarcopenia in patients with CHB-related LC tends to delay the achievement of an early virological response, but it does not affect serial MELD scores, HCC incidence, or long-term survival. Consequently, preserving liver function and achieving early viral suppression are more critical for prognosis than maintaining muscle mass in this population.

4186 | UPREGULATING B CELL POPULATION AND MATURATION WITH INCREASING CD4 TO CD8 RATIO IN HEPATITIS B E ANTIGEN-NEGATIVE HEPATITIS B VIRUS CARRIERS WITH CRYOGLOBULINEMIA

Ming-Ling Chang[1], [1]Department of Gastroenterology and Hepatology

Background: The immunological basis for lower hepatitis B surface antigen (HBsAg) levels in hepatitis B e antigen (HBeAg)-negative hepatitis B virus (HBV) carriers with than those without cryoglobulinemia remains elusive. We aim to elucidate it. **Methods:** A prospective cohort of 75 HBeAg-negative HBV carriers with normal alanine aminotransferase levels without any anti-HBV therapy who had been surveyed for cryoglobulinemia was conducted. The serum and peripheral blood mononuclear cells (PBMCs) were assessed for biochemistry and flowcytometry, respectively. **Results:** Of 75 patients (mean age: 56.7 years), 40 (53.3%) were males. More frequently female (57.8%, $p = 0.018$), higher proportions of peripheral total B cell (4.54+/-2.91 vs. 2.67+/-1.47%, $p = 0.015$), mature B cell (CD19+CD10-/CD19) 97.3+/-1.12 vs. 95.4+/-1.69%, $p = 0.013$) and helper T cells (Th) (59.0 +/-10.9 vs. 50.9+/-11.8%, $p = 0.028$), but lower proportions of cytotoxic T cells (Tc) (28.8 +/-10.2 vs. 37.3 +/-11.4%, $p = 0.017$) (namely, higher Th/Tc ratio, 2.42 +/-1.16 vs. 1.50 +/-0.7 3, $p = 0.019$) and immature B cell (CD19+CD10+/CD19)(2.42+/-1.05 vs. 4.26+/-1.64%, $p = 0.014$) were noted in patients with than those without cryoglobulinemia. All the proportions of other investigated T and B cell subpopulations including HBsAg-specific B cells, early (7-AAD-Annexin V+ CD19) or late apoptotic B cells (7-AAD+Annexin V+ CD19) and serum human B cell activation factor (BAFF) levels (1139.4 +/-294 vs. 1165.3+/-361 pg/mL, $p = 0.796$) were comparable between patients with and without mixed cryoglobulinemia. Among the PBMCs, low titer HBV DNA (32-69 IU/ml) were mainly found in B cells, regardless of mixed cryoglobulinemia, and in CD8 cells (47 IU/ml) of patients with cryoglobulinemia. **Conclusion:** Through infecting PBMCs, cryoglobulinemia is associated with upregulating total B cell and Th cell populations, accelerating B cell maturation, but downregulating Tc cell populations in HBeAg-negative HBV carriers.

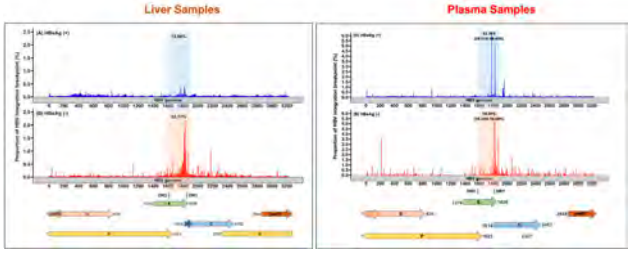
4187 | COMPARISONS OF INTEGRATED HBV DNA (IDNA) PROFILES BETWEEN MATCHED LIVER AND PLASMA SAMPLES FROM PATIENTS WITH HBEAG (+) AND HBEAG(-) CHRONIC HEPATITIS B

Daryl Lau[1] Hsin-Ni Liu[2] Zhili Wang[3] Zach Heimer[3] Selena Lin[3] Fwu-Shan Shieh[3] Haitao Guo[4] Ying-Hsiu Su[5], [1]Beth Israel Deaconess Medical Center, Harvard Medical School, [2]The Baruch S. Blumberg Institute, [3]JBS Science Inc. Lansdale, PA, [4]University of Pittsburgh, [5]Baruch S. Blumberg Institute



Background: HBsAg can be derived from intrahepatic cccDNA and integrated HBV DNA (iDNA). We previously analyzed the iDNA patterns from liver tissues of 24 HBeAg(+) and 32 HBeAg(-) treatment-naive CHB patients and correlated them with other virological biomarkers. Since liquid biopsies are more conveniently accessible than liver biopsies, we compared the hepatic and plasma iDNA profiles of these patients to evaluate if they can yield similar results. **Methods:** For iDNA detection, total DNA from liver and plasma samples was subjected to HBV hybridization-targeted next generation sequencing (HBV-NGS) assay for identification of the HBV-host junction sequences (HBV-JS). The ChimericSeq bioinformatics pipeline determined % HBV-JS of all HBV reads and their breakpoint coordinates. **Results:** Intrahepatic cccDNA, serum HBV DNA, HBV RNA, HBcrAg and qHBsAg were higher in HBeAg(+) CHB. The quantity of HBV DNA templates detected in both liver and plasma showed a significant correlation with serum viral load (Liver: Spearman's rho = 0.72, Plasma: rho = 0.74; $p < 0.001$ for both). HBeAg(+) participants generally had lower % iDNA in total HBV DNA from both liver and plasma compared to the HBeAg(-) ones. Only 4 HBeAg(+) subject had > 60% iDNA in liver and none in plasma. In contrast, 22(69%) and 7(22%) of HBeAg(-) participants had > 60% iDNA in the liver and plasma, respectively. For HBeAg(+) CHB, the iDNA integration sites were more random with 15.9% and 33.8% from liver and plasma localized to the DR2-DR1 region, respectively. [Figure] For HBeAg(-) CHB, > 50% of the iDNA integrations in both liver and plasma were clustered at the DR2-DR1 'HCC hot spot' region. [Figure] **Conclusion:** Plasma HBV DNA represents apoptotic DNA fragments released from the entire liver, with preferential survival of nucleosome-protected or transcription factor–associated regions following nuclease degradation. In contrast, liver biopsy tissue reflects the total HBV DNA content present within a very small sampled tissue. In both liver and plasma, HBeAg(-) CHB was associated with higher iDNA concentrations and frequency of DR2-DR1 iDNA distributions. The

striking enrichment peaks in plasma iDNA at DR2-DR1 for both HBeAg(+) and (-) patients likely represented the dense histone and/or transcription factor association around the nt 1800 region. Liquid biopsy has the potential to detect changes in iDNA profiles during therapy and to monitor functional cure. In addition, iDNA distribution likely can serve as a HCC biomarker.

4188 | THE RELATIONSHIP BETWEEN HBV DELETION MUTATIONS AND DISEASE PROGRESSION BASED ON WHOLE-GENOME ANALYSIS

Takashi Honda[1] Yoji Ishizu[1] Norihiro Imai[1] Takanori Ito[1] Kena Yamamoto[1] Shinya Yokoyama[1] ITO Kimihito[2] Yoshiki Murakami[3] Hiroki Kawashima[1], [1]Nagoya University Graduate School of Medicine, [2]Division of Bioinformatics, Hokkaido University, [3]Department of Molecular Pathology, Tokyo Medical University

Background: Deletions and mutations in HBV-DNA are associated with the progression of hepatitis. In particular, hepatitis B virus (HBV) is prone to genetic mutations during replication, and the emergence of viruses with deletions or mutations in specific regions is known to significantly alter the disease state. This study analyzed the association between deletions in various ORF regions of HBV and clinical features using whole-genome analysis with long-read sequencing. **Methods:** 78 patients with chronic hepatitis B who visited the outpatient clinic of Nagoya University Hospital were included in the analysis. HBV DNA was extracted from serum, and the HBV DNA sequence was analyzed using long-read sequencing. A consensus sequence was determined based on the HBV genome database (https://hbvdb.lyon.inserm.fr/HBVdb/HBVdbIndex), and the amino acid sequence was determined for each ORF. Clinical data (liver injury markers, HBV virus markers, tumor markers) were grouped according to the presence or absence of deletions in each HBV ORF, and differences were examined using the Wilcox test. Furthermore, for HBeAg seroconversion, HBV DNA negativity, functional remission, liver cancer development during disease progression, and HBsAg seroconversion, each HBV protein was grouped based on the presence or absence of deletion, and differences were examined using Fisher's test. **Results:** Of the 78 cases analyzed, deletions were found in 8 cases in the preS1 region, 7 in the preS2 region, 0 in the S region, 2 in the X region, 2 in the precore region, 5 in the core region, and 17 in the polymerase (pol) region. Significant differences were observed in total bilirubin (T.Bil), prothrombin time (PT), albumin (Alb), and platelet count (Plt) depending on the presence or absence of deletion in the preS1 region. In the precore region, differences were observed in Plt and ALT. Furthermore, significant differences were observed between the two groups in AST, ALT, GGTP, AFP, HBVDNA, HBeAg, platelet count, and total bilirubin in the core region, and in Alb in the pol region. On the other hand, no differences were observed between the presence or absence of deletions in sAg and eAg seroconversion, HBV DNA negativity, functional cure, or hepatocellular carcinoma development. Whole-genome analysis of HBV using long-read sequencing enabled comprehensive analysis of HBV genome deletions that were difficult to detect with conventional methods. The appearance of deletions in the core region was suggested to be associated with hepatitis activity and disease progression, while deletions in preS1 and the core region were associated with the progression of liver fibrosis. **Conclusion:** These findings suggest that differences in the deletion site in the HBV genome may have different effects on pathological conditions such as inflammation and fibrosis progression.

4189 | PLSCR1 ASSOCIATES WITH INTERFERON RESPONSE IN CHB PATIENTS ACHIEVING HBSAG SEROCLEARANCE

Huiling Xiang[1] Qin Du[2] Jingzhe Zhang[3] Jun Li[3] Jiayin Wang[4] Qing Ye[5], [1]Tianjin University Central Hospital (Tianjin Third Central Ho, [2]Nankai University Affiliated Third Central Hospital, Tianjin University Central Hospital (Tianjin Third, [3]The Third Central Clinical College of Tianjin Medical University, Tianjin University Central Hospita, [4]Department of Gastroenterology and Hepatology, Tianjin University Central Hospital (Tianjin Third Cen, [5]Tianjin University Central Hospital (Tianjin Third Central Hospital)

Background: Pegylated interferon-alpha (peg-IFNα) induces HBsAg seroclearance in a subset of chronic hepatitis B (CHB) patients, but the key molecular drivers remain unclear. This study aimed to identify proteins linked to IFN response, immune landscape, and metabolic profiles associated with HBsAg loss. **Methods:** Forty-five CHB patients treated with 48-week peg-IFNα were enrolled: 29 with persistent HBsAg positive (D1) and 16 with HBsAg seroclearance (D2). Proteomics, immune infiltration (CIBERSORT/TIMER2.0), KEGG enrichment, PPI network, K-means clustering, and proteome-metabolome correlation were performed. PLSCR1 expression was validated in HPA database. **Results:** A total of 220 differentially expressed proteins were identified in D2 vs D1, with PLSCR1 as the most significantly upregulated. PLSCR1 correlated positively with B cells, T cells, monocytes, and macrophage infiltration. It clustered with antiviral ISGs (MX1, IFIT3, IFITM3, ISG20) and was central in PPI networks linking interferon signaling and metabolic pathways. Proteome-metabolome analysis showed PLSCR1 correlated with purine and glycolytic metabolites, supporting energy metabolism rewiring. HPA confirmed predominant PLSCR1 expression in macrophages. **Conclusion:** PLSCR1 is strongly associated with peg-IFNα-induced HBsAg seroclearance, correlating with enhanced interferon response, immune cell infiltration, and macrophage metabolic reprogramming. PLSCR1 may serve as a potential biomarker for IFN response in CHB.

4190 | SAFETY AND REAL WORLD OUTCOMES OF HBV NAT POSITIVE, RECIPIENT NEGATIVE KIDNEY TRANSPLANTATION

Sara Gaines[1] Benyam Addissie[2] Sandeep Khurana[1] Alberto Unzueta[1] Clifford Akateh[1] Anil Kotru[1] Michael Marvin[1], [1]Geisinger Medical Center, [2]University of Rochester

Background: The use of hepatitis B virus (HBV) nucleic acid test (NAT) positive donor organs has emerged as a strategy to expand the donor pool. Data describing real world outcomes in HBV NAT positive, recipient negative kidney transplantation remain limited. We evaluated HBV serologic outcomes, antiviral prophylaxis requirements, and the impact of perioperative hepatitis B immune globulin (HBIG) and pre transplant immunity in this population. **Methods:** This retrospective cohort study included adult recipients of HBV NAT positive kidney transplants between October 2023 through November 2025. Patients were monitored for HBV serologies pre and post transplant. Antiviral prophylaxis with entecavir was initiated perioperatively per institutional protocol. Outcomes included development and persistence of hepatitis B core antibody (HBcAb) positivity, durability of immunity, and need for lifelong antiviral therapy. **Results:** Eighteen HBV NAT positive kidney transplants were performed. One patient had baseline HBcAb positivity and will remain on lifelong antiviral prophylaxis. Ten patients reached ≥12 months of follow up. Seven maintained immunity and remained HBcAb negative at 12 months, allowing

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

discontinuation of antiviral therapy. Three patients developed persistent HBcAb positivity and remain on lifelong prophylaxis; two received intraoperative HBIG, and two lacked documented pre transplant immunity, defined as hepatitis B surface antibody < 100 mIU/mL. Five of ten patients at ≥ 12 months received intraoperative HBIG; three developed HBcAb positivity, including one transient case which resolved by month 9. Eight patients had < 12 months of follow up; four developed or maintained HBcAb positivity at 3 months, three of whom received HBIG, and 1 lacked immunity pre transplant. Overall, nine patients received HBIG; six demonstrated HBcAb positivity at 3 months, one of which spontaneously resolved. Two patients with immunity who did not receive HBIG developed HBcAb positivity at 3 months; one of which remained at 12 months while the other continues to demonstrate positivity at 6 months of follow-up. Three patients received an HBV/HCV co infected organ and had pre existing immunity; one developed persistent HBcAb positivity. No patient developed hepatitis B surface antigen positivity or HBV viremia. **Conclusion:** HBV NAT positive kidney transplantation appears safe with appropriate antiviral prophylaxis. Development of HBcAb positivity occurred but acute infection did not. Lack of pre transplant immunity and administration of HBIG were associated with HBcAb seroconversion. These findings support consideration of expanding the use of HBV NAT positive donor organs.

4191 | FACTORS ASSOCIATED WITH HEPATITIS B SURFACE ANTIGEN SERO-CLEARANCE IN HEMODIALYSIS PATIENTS

Raja Khan[1] Nasir Hasan Luck[2] Abbas Ali Tasneem[2] Kiran Bajaj[2], [1]Bahrain Specialist hospital, [2]Sindh Institute of Urology and Transplantation

Background: The data regarding the factors predicting hepatitis B surface antigen (HBsAg) sero-clearance in hemodialysis patients with chronic hepatitis B is scarce. Therefore, our aim was to determine the HBsAg sero-clearance rates in the hemodialysis population and to identify the factors predictive of HBsAg sero-clearance in this population. **Methods:** It was prospective observational study including all the patients with HBsAg reactive chronic hepatitis B undergoing hemodialysis from January 2019 to December 2020. While, those patients with HBV and hepatitis D co-infection or those with HBV and hepatitis C co-infection or HBV and HIV co-infection were excluded from the study. Patients were then followed for two years for HBsAg loss which was repeated yearly for the clearance. Significant factors on univariate analysis underwent multivariate logistic regression analysis to ascertain the independent predictors of HBsAg loss in hemodialysis population. **Results:** A total of 213 patients with chronic HBV undergoing hemodialysis patients were enrolled in this study. After two years of hemodialysis, HBsAg loss was observed in 26(12%) patients. On univariate analysis, HBsAg levels < 1000IU/ml, HBV DNA levels < 5000IU/ml, HBeAg negative disease and multiple sessions of hemodialysis was associated with increased HBsAg loss while on multivariate analysis, HBV DNA levels < 5000 IU/ml at baseline and multiple sessions of hemodialysis were the independent predictors of loss of HBsAg in hemodialysis patients. **Conclusion:** The rate of HBsAg clearance is high in hemodialysis population especially those with decreased HBV DNA levels at baseline and undergoing multiple sessions of hemodialysis per week.

understood. Based on our previous findings that HIV/HBV co-infection results in stronger fibrogenic signaling than HBV mono-infection through increased TGF-β1 levels, and that HBV infection drives fibrogenesis through increased pyruvate production and reduced PPARα expression, we investigate whether HIV-induced dysregulation of the TGF-β1–PKM2–PPARα axis contributes to fibrogenesis in hepatocytes and hepatic stellate cells. **Methods:** Hepatocytes (NTCP-HepG2, HepAD38) and hepatic stellate cells (LX2) were exposed to supernatants from HepAD38 cells (HBVsup) and/or HIV-infected U937 macrophages or CEMT4 T-cell lines (HIVsup). Fibrotic and metabolic gene expression were assessed by qPCR, and extracellular pyruvate levels were quantified using a colorimetric assay. Combination treatments with pyruvate, TGF-β1, and HIV gp120 protein were performed to evaluate synergistic effects on metabolic and fibrotic responses in NTCP-HepG2 and LX2 cells. TGF-β1 inhibition experiments were performed to evaluate its role in HIV-associated metabolic reprogramming. **Results:** Exposure to HIV-derived supernatants, HIV gp120, or pyruvate each induced expression of glycolytic (GLUT1, PKM2, and LDHA) and profibrotic genes (TGFB1, TIMP1, and COL1A1) and suppressed PPARα expression in NTCP-HepG2 and LX2 cells. HBV/HIV co-infection induced higher expression of these genes than HBV or HIV infection or exposure alone. Combination treatments involving pyruvate, TGF-β1, and HIV gp120 synergistically amplified metabolic and fibrotic responses compared to dual-combination or single-factor treatments. Extracellular pyruvate accumulation increased in cell supernatants under HIV-associated conditions and was further amplified during HBV/HIV co-infection and combination treatments. Treatment with a PPARα agonist reduced glycolytic and profibrotic responses induced by HIV-associated factors, implicating TGF-β1 as a mediator of HIV-associated metabolic reprogramming. **Conclusion:** HIV co-infection exacerbates HBV-induced liver fibrogenesis through TGF-β1-mediated metabolic reprogramming characterized by glycolytic activation, extracellular pyruvate accumulation, and suppression of PPARα signaling. Synergistic interactions between extracellular pyruvate and HIV-associated factors further amplified metabolic and profibrotic responses in NTCP-HepG2 and LX2 cells. These findings suggest that HIV infection enhances HBV-induced metabolic reprogramming and fibrogenesis through a TGF-β1-PKM2-PPARα axis, identifying this pathway as a promising therapeutic target of HBV/HIV-associated liver fibrosis.

4193 | MATHEMATICAL MODELING SUGGESTS HEPLISAV-B INDUCES BLOCKAGE OF INTRACELLULAR HBSAG SYNTHESIS ALONGSIDE REDUCTION OF AAV-HBV

Aarim Khan[1] Louis Shekhtman[2] Adquate Mhlanga[1] Ashish Goyal[1] Jiapeng Wu[3] Lishan Su[3] Harel Dahari[1] James Ahodantin[4], [1]Loyola University Chicago, [2]Loyola University Chicago & Bar Ilan University, [3]Institute of Human Virology, University of Maryland School of Medicine, [4]University of Nebraska Medical Center

Background: Heplisav-B is a newly FDA approved prophylactic 2-dose hepatitis B vaccine with a CpG adjuvant. We recently demonstrated the therapeutic benefits of Heplisav-B in an AAV-HBV mouse model and aim herein to understand the kinetics of serum HBV DNA, HBsAg, HBeAg, and anti-HBs IgG (IgG) using mathematical modeling. **Methods:** Ten AAV-HBV infected mice were included. Heplisav-B was administered to 6 mice at weeks 4 and 8. Blood samples were collected every 2-4 weeks until the end

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

of the experiment (EOE) at week 25 as described in (PMID: 41889877). The modes of action (MOA) of Heplisav-B were modelled by a reduction in virus template AAV-HBV levels (MOA 1), an increase in IgG synthesis (MOA 2), and a reduction in intracellular HBsAg synthesis (MOA 3). **Results:** In the unvaccinated agglomerate mouse, the model recapitulated the observed increase and plateau in serum HBV-DNA, HBeAg, and HBsAg as well as the observation that IgG remained undetectable (Fig.1A). In the vaccinated agglomerate mouse, observed kinetics were similar to the unvaccinated agglomerate mouse up until vaccination, after which there was a 2.4 log(ge/ml) decrease in serum HBV-DNA by week 8 followed by a subsequent 2.5 log(ge/ml) increase until EOE, a 2.6 log(ng/ml) decline in serum HBsAg by week 8 to below detection that remained until EOE, a 0.3 log(PEIU/ml) decline in serum HBeAg by EOE, and a gradual 3.0 log (U/ml) increase and plateau in IgG until EOE (Fig.1B). Additionally, intracellular HBV-RNA, HBV-DNA, and AAV-HBV were approximately 0.6 log, 1.0 log, and 0.6 log lower, respectively, than in unvaccinated mice at EOE. Modeling predicted that an 80% reduction in AAV-HBV levels (MOA 1) and a 2.5-fold increase in IgG production (MOA 2) were sufficient to capture the kinetics of HBeAg and IgG, as well as the relative decline in intracellular AAV-HBV, HBV-RNA and HBV-DNA, but were insufficient to explain serum HBV DNA and/or HBsAg kinetics without including an initial 99.9% blocking of HBsAg synthesis which gradually decays to 98.5% by EOE (MOA 3). **Conclusion:** Modeling suggests that reduction of AAV-HBV and enhanced anti-HBs IgG production are insufficient to explain the therapeutic effects of Heplisav-B in AAV-HBV–infected mice without assuming potent suppression of intracellular HBsAg synthesis. These findings support a mechanism in which Heplisav-B exerts both antiviral and immunomodulatory effects, leading to sustained HBsAg suppression and partial control of viral replication.

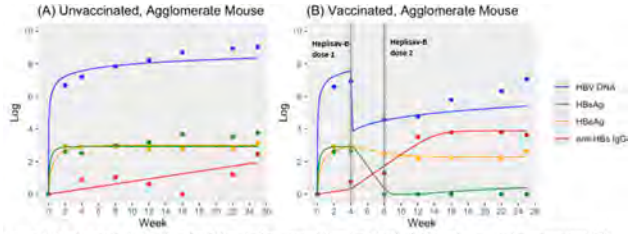

Figure 1. Mathematical modeling (solid lines) of measured kinetics (dots) of the agglomerated unvaccinated **(A)** and vaccinated **(B)** mice. Gray vertical lines indicate 1st and 2nd dose of Heplisav-B vaccine. *HBsAg detection limit is represented by horizontal dotted line.* We assumed in the model that the number of HBV-infected hepatocytes is fixed from infection to EOE. In each infected hepatocyte, three products are produced from AAV-HBV: intracellular HBV RNA, HBsAg, and HBeAg. Within the cell, HBV RNA is converted to HBV DNA, and HBsAg is either converted to HBsAg subviral particles or incorporated into virus-like particles containing HBV RNA or HBV DNA during secretion. Anti-HBs IgG follows a logistic growth model and is cleared when it forms a complex with serum HBsAg, HBV RNA, or HBV DNA. The late rebound in serum HBV DNA despite persistent HBsAg suppression may reflect increased production of naked HBV DNA or defective viral particles, warranting further investigation.

4194 | ◆ NEOADJUVANT TRIPLE IMMUNE CHECKPOINT BLOCKADE PREVENTS POST-RESECTION RECURRENCE IN MURINE HEPATOCELLULAR CARCINOMA

Lea Lemaitre[1] Siya Agrawal[2] Venika Kakarla[2] Dawiyat Massoudi[2] Ankit Srivastava[2] Renumathy Dhanasekaran[2], [1]Stanford University, [2]Stanford

Background: Recurrence following surgical resection remains the dominant driver of HCC mortality, yet adjuvant immunotherapy benefits only a minority of patients. We hypothesized that residual tumor cells exploit multiple co-occurring immune evasion pathways beyond CTLA4/PD-L1, and that targeting these mechanisms at the right time relative to surgery could prevent recurrence. **Methods:** We established a syngeneic orthotopic immunocompetent mouse model of HCC by implanting Hep53.4 cells directly into the liver, followed by surgical resection of the tumor-bearing lobe to recapitulate post-hepatectomy recurrence. This model enabled head-to-head evaluation of neoadjuvant (pre-resection) and adjuvant (post-resection) ICI delivery in the context of an intact immune system. Xenium spatial transcriptomics profiled 1.4 million liver cells from treated tissues (n = 12; 1.4 million cells). CODEX multiplexed spatial proteomics (54 markers) was applied to HCC patients with post-surgical recurrence (n = 124, n = 1,065,284 cells). Findings were validated in patient-derived organoid co-cultures with autologous $CD8^+$ T cells and monocyte-derived macrophages. **Results:** Standard dual ICI (aPD-L1 + aCTLA-4) failed to reduce post-resection murine HCC recurrence adjuvantly (56% vs. 100%, p = 0.10) or neoadjuvantly (50% vs. 100%, p = 0.18). Xenium analysis revealed that $Havcr2^+$ cells comprised 15.4% of exhausted $CD8^+$ T cells, with 56–77% maintaining Tim-3^+ exhausted $CD8^+$ neighbors expressing Lgals9 within 30µm, in both control and dual-therapy treated groups, identifying Tim-3/Galectin-9 signaling as a persistent resistance mechanism. CODEX confirmed high Tim-3 expression on $CD8^+$ T cells and Tregs in patients with post-surgical recurrence (both pAdj < 0.05). We therefore targeted Tim-3 directly: adjuvant tri-therapy (aPD-L1 + aCTLA-4 + aTim-3) failed to reduce recurrence (89% vs. 100%), whereas neoadjuvant tri-therapy dramatically reduced liver recurrence (38% vs. 100%, p = 0.007), liver metastasis count (mean 1.1 vs. 5.0, p = 0.001), lung metastasis incidence (23% vs. 100%, p = 0.001), and lung

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

metastasis count (mean 0.5 vs. 8.6, $p < 0.001$). while preserving functional intratumoral $CD8^+$ T cells. In PDO co-cultures, robust tumor killing required both $CD8^+$ T cells and macrophages, confirming that T cell reinvigoration and macrophage reprogramming cooperate to drive the therapeutic effect. **Conclusion:** We demonstrate that Tim-3/Galectin-9-mediated crosstalk between exhausted $CD8^+$ T cells and pro-tumoral macrophages establishes a critical immunosuppressive niche that standard checkpoint blockade fails to dismantle. By targeting this axis neoadjuvantly, triple checkpoint blockade reshapes the tumor immune microenvironment prior to resection and dramatically reduces recurrence establishing Tim-3 inclusion and treatment timing as co-equal determinants of immunotherapy efficacy in resectable HCC.

4195 | ◆ THERAPEUTIC ATTRITION CREATES APPARENT SURVIVAL ADVANTAGES IN DELAYED SYSTEMIC THERAPY FOR HEPATOCELLULAR CARCINOMA

Francisco Vargas-Navarro[1] Wagner Ramirez[1] María Fernanda Lynch Mejía[1] Daniel Pérez-Muñoz[2] Fiorella Ajún-Ulate[2] Andrés Solera-Vega[2] Silvia Alfaro Cartín[3] Karen Melissa Rodríguez Masís[3] Dennis Brenes Redondo[4] Pablo Coste[5], [1]Liver Unit, Hospital R.A. Calderón Guardia / LiverLab CR, [2]Liver Unit, Hospital R.A. Calderón Guardia, [3]Department of Oncology, Hospital Dr. Rafael Ángel Calderón Guardia, [4]Department of Oncology, Hospital Dr. Max Peralta Jiménez, [5]Liver Unit, Hospital Dr. Rafael Ángel Calderón Guardia / LiverLab CR

Background: Delayed transition from locoregional to systemic therapy is common in hepatocellular carcinoma (HCC), yet its clinical implications remain controversial due to survivor and time-zero biases. We evaluated therapeutic attrition, timing of systemic therapy initiation, and survival outcomes in a real-world HCC cohort from Central America. **Methods:** We conducted a multicenter real-world longitudinal cohort study including consecutive adults with confirmed HCC managed across two tertiary referral centers between 2018 and 2024. Therapeutic trajectories were reconstructed longitudinally. Transition to systemic therapy (sorafenib or atezolizumab-bevacizumab) was classified as early (first or second treatment) or delayed (≥ 2 prior treatments). Overall survival (OS) was analyzed both from HCC diagnosis and from systemic therapy initiation using Kaplan-Meier and Cox proportional hazards models adjusted for ALBI grade, ECOG performance status, and BCLC stage. **Results:** Among 260 patients with HCC, 184 (70.8%) received active treatment, 111 (42.7%) underwent multiple therapeutic interventions, but only 50 (19.2%) ultimately reached systemic therapy, demonstrating substantial therapeutic attrition. Thirty-five patients (70%) transitioned early and 15 (30%) underwent delayed transition. When OS was measured from systemic therapy initiation, survival did not differ between groups (log-rank $p = 0.77$). However, when OS was measured from HCC diagnosis, delayed transition was associated with longer survival (log-rank $p = 0.003$; adjusted HR 0.40, $p = 0.019$), consistent with survival time-zero and survivor selection biases. **Conclusion:** Therapeutic attrition substantially limits access to systemic therapy in real-world HCC care. Apparent survival advantages associated with delayed transition primarily reflect survival time-zero and survivor biases, cautioning against naïve interpretation of survival analyses in treatment sequencing studies.

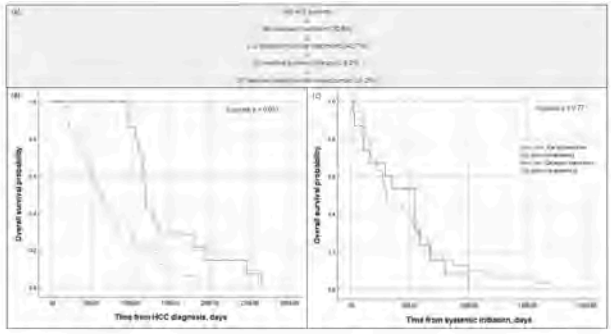

Figure 1. Therapeutic attrition and survival time-zero definition bias in real-world hepatocellular carcinoma. (A) Therapeutic attrition cascade across the HCC care pathway. Among 260 patients with HCC, 184 (70.8%) received active treatment, 111 (42.7%) underwent multiple therapeutic interventions, 50 (19.2%) ultimately reached systemic therapy, and 37 (14.2%) received atezolizumab-bevacizumab. (B) Kaplan-Meier estimates of overall survival from HCC diagnosis according to timing of transition to systemic therapy. Patients undergoing delayed transition (≥2 prior treatments) appeared to have longer survival than those initiating systemic therapy early (≤1 prior treatment) (log-rank p = 0.003). (C) Kaplan-Meier estimates of overall survival from systemic therapy initiation according to timing of transition. No significant survival differences were observed between early and delayed transition groups (log-rank p = 0.77). Together, these findings illustrate the impact of therapeutic attrition and survival time-zero bias in real-world HCC analyses

4196 | ◆ SPATIAL INTERACTION BETWEEN PD-L1(+) TUMOR-ASSOCIATED MACROPHAGES AND CD8(+) T CELLS INFLUENCES RESPONSE TO ATEZOLIZUMAB PLUS BEVACIZUMAB IN HEPATOCELLULAR CARCINOMA

Takuto Nosaka[1] Tatsushi Naito[2] Junki Yamashita[1] Yosuke Murata[1] Yu Akazawa[1] Tomoko Tanaka[1] Kazuto Takahashi[1] Yasunari Nakamoto[1], [1]University of Fukui, [2]University of Fuku

Background: Intercellular interactions among immune cells play an important role in combination immunotherapy for hepatocellular carcinoma (HCC). We previously reported that PD-L1(+) tumor-associated macrophages (TAMs) regulate antitumor immune responses (Neoplasm 2025). In this study, we analyzed the spatial proximity between PD-L1(+) TAMs and CD8(+) T cells in pretreatment liver tumor biopsy specimens from patients with HCC and examined its association with the therapeutic efficacy of systemic treatments, including atezolizumab plus bevacizumab (Atezo+Bev) and lenvatinib. In addition, we evaluated the underlying molecular and cellular pathology using next-generation sequencing (NGS) analysis. **Methods:** Multiplex immunohistochemistry was performed on biopsies from patients treated with Atezo+Bev (n = 23) or lenvatinib (n = 20). An interaction variable was defined via nearest-neighbor analysis as CD8(+) T cells within 25 μm of PD-L1(+) TAMs, normalized to cell counts. Associations with tumor shrinkage and progression-free survival (PFS) were examined. CD8(+) T cell phenotypes were evaluated via GZMB and TIM3. Transcriptomic profiling of resected HCCs was conducted using next-generation sequencing and gene set enrichment analysis (GSEA). Predictive performance was assessed using ROC analysis. Internal validation of the predictive model was performed using bootstrap resampling to estimate optimism-corrected discriminatory performance. **Results:** In Atezo+Bev-treated patients, multivariate analysis identified the PD-L1(+) TAM–CD8(+) T cell interaction variable as an independent factor associated with PFS (HR = 0.8373; 95% CI, 0.6870–0.9773; $p < 0.05$), together with vascular invasion (HR = 4.252). The median nearest-neighbor distance from PD-L1(+) TAMs to CD8(+) T cells was shorter in tumors with shrinkage than in those with progression (14 μm vs. 24 μm). ROC analysis for discriminating PFS > 1 year showed an apparent AUC of 0.881 for the interaction variable. This association was absent in the lenvatinib cohort. High-interaction tumors showed increased proportions of GZMB(+) and TIM3(+) CD8(+) T cells. Transcriptomic analysis revealed upregulation of inflammatory, cytotoxic, chemotactic, and immunoregulatory genes (TIGIT and LAG3), with enrichment of chemokine (CXCL9), IFN-gamma, and IL-10 signaling pathways. **Conclusion:** Spatial proximity between PD-L1(+) TAMs and CD8(+) T cells defines an immune niche characterized by coexisting immune activation and regulatory programs and is strongly associated with Atezo+Bev responsiveness in HCC. These findings suggest that this spatial proximity reflects the immune pathobiology of HCC and may serve as a promising tissue biomarker for predicting responses to combination immunotherapy. **Disclosures:** Takuto Nosaka:Nothing to Disclose, Tatsushi Naito:Nothing to Disclose, Junki Yamashita:Nothing to Disclose, Yosuke Murata:Nothing to Disclose, Yu Akazawa:Nothing to Disclose, Tomoko Tanaka:Nothing to Disclose, Kazuto Takahashi:Nothing to Disclose, Yasunari Nakamoto:Nothing to Disclose.

4197 | ◆ PRE-TREATMENT PERIPHERAL BLOOD MONONUCLEAR CELL ANGIOGENESIS-RELATED SIGNATURE IS ASSOCIATED WITH SPP1-POSITIVE MACROPHAGES IN HEPATOCELLULAR CARCINOMA

Satoshi Narahara[1] Hiromitsu Ohbo[1] Takahiro Mizuta[1] Toshinori Toyota[1] Daiki Maeda[1] Kentaro Tanaka[1] Hiroki Inada[1] Sotaro Kurano[1] Yoko Yoshimaru[1] Takehisa Watanabe[1] Katsuya Nagaoka[1] Hiroko Setoyama[1] Haruki Uojima[1] Yasuhito Tanaka[1], [1]Department of Gastroenterology and Hepatology, Faculty of Life Sciences, Kumamoto University

Background: Atezolizumab plus bevacizumab (Atezo+Bev) is widely used for advanced hepatocellular carcinoma (HCC); however, reliable biomarkers predicting treatment response before therapy initiation remain unclear. We investigated pre-treatment peripheral blood mononuclear cells (PBMCs), paired liver tumor biopsy samples, and surgical specimens to identify biomarkers associated with response to Atezo+Bev. **Methods:** Among 119 patients with advanced HCC who received Atezo+Bev as first-line therapy between November 2018 and December 2025, 30 patients with available pre-treatment PBMC samples and adequate follow-up were enrolled. Initial therapeutic response was assessed by mRECIST and patients were classified into responders (complete response [CR]/partial response [PR]) and non-responders (stable disease [SD]/progressive disease [PD]). RNA sequencing of pre-treatment PBMCs was performed. To evaluate intratumoral localization of gene expression, spatial transcriptomic analysis using the Visium platform was additionally conducted on liver tumor specimens. **Results:** Gene set enrichment analysis of pre-treatment PBMCs demonstrated significant enrichment

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

of angiogenesis-related gene sets in non-responders compared with responders (NES = 1.63, FDR q < 0.05). Leading-edge analysis further identified a coordinated gene program associated with angiogenesis, extracellular matrix remodeling, and myeloid cell biology, with SPP1 emerging as a central component of this resistance-associated signature. Spatial transcriptomic analysis of HCC tissues revealed heterogeneous intratumoral distribution of angiogenesis-related signatures, with prominent enrichment at the tumor margin. Importantly, regions with high angiogenesis-related signatures showed spatial overlap with macrophage-enriched areas. SPP1 expression was spatially co-localized with CD68-positive macrophage-rich regions, indicating the accumulation of SPP1-positive TAM-like myeloid populations within pro-angiogenic tumor niches. These findings suggest that the angiogenesis-related PBMC signature observed in non-responders reflects, at least in part, a systemic myeloid program linked to pro-angiogenic and immunosuppressive tumor microenvironments. **Conclusion:** Pre-treatment PBMCs from non-responders exhibited an SPP1-centered angiogenesis-associated myeloid program that was spatially linked to intratumoral accumulation of SPP1-positive TAM-like cells at the tumor margin. These findings identify a previously unrecognized blood–tumor axis associated with resistance to atezolizumab plus bevacizumab in HCC.

4198 | ◆ COMPOSITE SCORE FROM A MULTI-TARGET HCC BLOOD TEST REFLECTS TUMOR SIZE AND STAGE IN THE ALTUS STUDY

Binu John[1] Mark Camardo[2] Amit Singal[3] Neehar Parikh[4] Ju Dong Yang[5] Lewis Roberts[6] Natasha Kureshi[2] Paul Elias[2] Elle Kielar-Grevstad[2] Paul Limburg[2], [1]University of Miami and Miami VA, [2]Abbott, Madison, WI, [3]Department of Internal Medicine, University of Texas Southwestern Medical Center, Dallas, [4]University of Michigan Medical Center, [5]Cedars-Sinai Medical Center, [6]Mayo Clinic Rochester

Background: A multi-target hepatocellular carcinoma (HCC) blood test (mt-HBT) generates a continuous composite score from methylated DNA, AFP, and patient sex to aid in HCC detection in adults with cirrhosis or chronic HBV, with a score ranging from 0 to 1 and a 0.2255 positivity cutoff. While mt-HBT binary performance has been reported, associations between composite score and tumor burden, LI-RADS category, and liver disease etiology and severity have not been characterized. **Methods:** ALTUS was a prospective, multicenter U.S. study in which 2,463 adults underwent HCC surveillance and concurrent mt-HBT testing. Participants were classified by central CT/MRI review as HCC (LR-5, LR-TIV), indeterminate (LR-3, LR-4, LR-M), or non-HCC (LR-neg, LR-1, LR-2). Associations between composite score and tumor size, number, and stage (Milan, BCLC) were assessed for HCCs via Spearman correlation, tertile analysis, and interaction regression. Composite score was modeled against LI-RADS category for the full cohort (40 HCC, 157 indeterminate, 2,266 non-HCC) and against disease severity (ALBI) and etiology among non-HCCs. **Results:** Composite score was strongly correlated with tumor size ($\rho = 0.63$) but not tumor number. Scores in the largest tumor size tertile (median 4.25 cm) were significantly higher ($p = 0.002$, Fig 1a) than those in the lowest tertile (median 1.54 cm). Scores were significantly higher for HCCs outside Milan versus within Milan ($p = 0.003$, Fig 1b), while the effect of BCLC stage was not significant ($p = 0.06$). Milan status modified the tumor size effect, with each 1-cm increase within Milan associated with a score increase of 0.24 (95% CI, 0.12–0.37), compared to 0.02 (-0.07–0.11) per cm outside Milan. Scores increased stepwise with LI-RADS category (Fig 1c, $p < 0.001$), with LR-3s and LR-4s having higher mean scores than non-HCCs and lower mean scores than LR-Ms, LR-5s, and LR-TIVs. ALBI score correlated weakly ($\rho = 0.11$) with composite score among non-HCCs (Fig 1d). Scores were marginally higher in non-viral etiology versus viral etiology (0.02 difference; 95% CI, 0.0005–0.03; $p = 0.04$). **Conclusion:** mt-HBT composite score correlated with tumor size, Milan status, and LI-RADS category, while disease etiology and severity had little impact on score variability. Indeterminate observations had scores between non-HCCs and LR-5s, likely reflecting some prevalent HCCs. These data support interpretation of the composite score as a quantitative measure of tumor-related factors rather than background liver disease.

4199 | ◆ LONGITUDINAL ELEVATION OF IL-10 FOLLOWING ATEZOLIZUMAB PLUS BEVACIZUMAB IS ASSOCIATED WITH FAVORABLE RESPONSE AND SURVIVAL IN ADVANCED HEPATOCELLULAR CARCINOM

Hee Sun Cho[1] Soon Kyu Lee[1] Soon Woo Nam[1] Jung Hyun Kwon[1], [1]The Catholic University of Korea

Background: We previously reported that early increases in interleukin-10 (IL-10) and tumor necrosis factor-α (TNF-α) levels following atezolizumab plus bevacizumab (Ate/Bev) therapy predict survival in patients with advanced hepatocellular carcinoma (HCC). In this study, we aimed to longitudinally assess serial cytokine changes and evaluate their association with outcome in advanced HCC patients receiving Ate/Bev. **Methods:** We prospectively enrolled 154 consecutive patients with advanced HCC who were treated with Ate/Bev between July 2022 and June 2025. Of these, 54 patients who provided blood samples at three time points—before initiation of Ate/Bev, prior to the second cycle, and prior to the fourth cycle—were included in the cytokine analysis. Serum levels of IL-2, IL-6, IL-10, IL-12, IL-17, interferon-γ (IFN-γ), and TNF-α were measured at each time point, and temporal changes in cytokine levels were examined. The primary endpoint was overall survival, while secondary endpoints included treatment response. **Results:** During a mean follow-up of 11.4 months, 42 patients (77.7%) died. The median age was 66.0 years, with most patients being male (92.6%), and the predominant etiology was viral-related HCC (85.2%). Serial changes in IL-2, IL-6, IL-12, IL-17, IFN-γ, and TNF-α levels were not significantly associated with overall survival. In contrast, IL-10 levels significantly increased following

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Ate/Bev treatment (p = 0.01), particularly among patients who achieved disease control (p = 0.022) (Figure A, B). Changes in IL-10 levels were positively correlated with changes in the CRP levels (r = 0.38, p = 0.004) (Figure C). Notably, patients exhibiting an increase in IL-10 levels demonstrated significantly better survival compared with those showing a decrease (p = 0.042) (Figure D). In multivariable analysis, an increase in IL-10 levels and CRP levels remained an independent predictor of overall survival in advanced HCC patients treated with Ate/Bev. **Conclusion:** Our findings suggest that serial changes in cytokine levels—particularly IL-10—following Ate/Bev therapy may serve as a useful biomarker for monitoring treatment response and predicting clinical outcomes in patients with advanced HCC.

4200 | ◆ MACHINE LEARNING BASED HEPATIC SAFETY SCORE PREDICTS DECOMPENSATION IN HEPATOCELLULAR CARCINOMA SYSTEMIC THERAPY

Ji Won Han[1] Jaejun Lee[2] Keungmo Yang[2] Kwon Yong Tak[2] Hyun Yang[2] Si Hyun Bae[2] Hee Sun Cho[2] Heechul Nam[2] Chang Wook Kim[3] Haelim Lee[2] Hee Yeon Kim[2] Sung Won Lee[2] Ahlim Lee[2] Do Seon Song[2] Seok-Hwan Kim[2] Myeong Jun Song[2] Soon Woo Nam[2] Soon Kyu Lee[2] Soon Kyu Lee[2] Jung Hyun Kwon[2] Pil Soo Sung[2] Jeong Won Jang[2], [1]The Catholic University of Korea, Seoul St. Mary's Hospital, [2]The Catholic University of Korea, [3]Uijeongbu St. Mary's Hospital

Background: Hepatocellular carcinoma (HCC) frequently coexists with portal hypertension, significantly increasing the risk of hepatic decompensation (HD) and variceal bleeding during systemic therapy. **Methods:** We developed a machine learning based hepatic safety score (MHSS) using data from 2,026 patients with unresectable HCC to predict clinically significant portal hypertension (CSPH) and prognosis. A random forest model was trained in a derivation cohort (n = 1,262) and validated in an independent cohort (n = 764). **Results:** The MHSS demonstrated robust performance (AUROC 0.840) in CSPH and predicting HD. Stratification revealed that high MHSS patients faced significantly elevated risks of HD (HR 3.25), variceal bleeding (VB, HR 4.90), and mortality (HR 2.21). Crucially, while atezolizumab-bevacizumab offered a survival advantage in low MHSS patients, it was associated with high bleeding risk and no survival benefit in the high MHSS group compared to other regimens. A simulation of MHSS guided treatment selection demonstrated a 24% reduction in HD, a 40% reduction in VB, and a 26% reduction in mortality. **Conclusion:** In conclusion, the MHSS effectively predicts CSPH, decompensation, and survival in patients with HCC prior to systemic therapy. By enabling individualized risk stratification, the MHSS may guide personalized treatment selection between bevacizumab-containing and alternative regimens, ultimately improving patient outcomes.

★ 4201 | ◆ WNT/β-CATENIN–MUTATED HCC: PATHWAY-LEVEL PROFILE AND GENE-LEVEL HETEROGENEITY DEFINING DISTINCT SUBTYPES

Pegah Farrokhi[1] David Stenehjem[1], [1]University of Minnesota

Background: WNT/β-catenin pathway mutations occur in 25–40% of hepatocellular carcinoma (HCC) and are associated with an immune-excluded phenotype and variable response to immune checkpoint inhibitors (ICI), though the magnitude and consistency of this association across patient subgroups remain debated. Clinical characteristics, co-mutation architecture, and biological heterogeneity within the WNT pathway lack comprehensive characterization at a multi-cohort level. **Methods:** We performed integrated clinicogenomic analysis of 1,785 advanced or metastatic HCC patients from the AACR Project GENIE registry across 8 institutional cohorts. WNT alterations were defined as somatic mutations in *CTNNB1, AXIN1, APC, CREBBP, or GSK3B*. TMB-high was defined as ≥10 mut/Mb. Fractional genome alteration (FGA) and somatic mutation count distinguished mutation-load vs. copy-number-driven TMB differences. **Results:** WNT mutations occurred in 40.8% of patients (*CTNNB1* 27.9%, *AXIN1* 8.4%, *APC* 4.7%). *CREBBP* and *GSK3B* sample sizes were too small to analyze. At the pathway level, WNT-mutated patients were significantly older (median 63 vs. 59 years), predominantly male (85.6% vs. 74.8%), with lower serum AFP ($p = 0.04$); viral etiology and cirrhosis were similar. Tumors were microsatellite stable.WNT-mutated HCC showed significant negative co-occurrence with *TP53* (OR = 0.63) and positive with *TERT* (OR = 1.57), *ARID1A* (OR = 1.80), and *CDKN2A* (OR = 2.38). They had significantly higher mutation counts (median 82 vs.62) and higher TMB-high rates (5.8% vs.1.5%) without an FGA increase (0.21 vs. 0.22), reflecting increased somatic mutation load over chromosomal instability.Gene-level analysis revealed pronounced heterogeneity within the pathway. *CTNNB1* and *AXIN1* rarely co-mutated (OR = 0.29; FDR < 0.01).*CTNNB1* mutation was the main driver of the pathway-level phenotype: low AFP, better differentiation (71.1% vs. 44.2%, $p < 0.01$), *TP53* negative co-occurrence (OR = 0.48, $p < 0.01$), *TERT* and *CDKN2A* co-occurrence, and TMB-high enrichment (6.0% vs. 2.2%, $p < 0.01$).*AXIN1*-mutated HCC had significantly higher AFP (≥400 ng/mL: 37.5% vs. 19.6%), elevated PIVKA-II, higher FGA (0.3 vs. 0.2) indicating instability, *ARID1A* co-occurrence, and no TMB elevation ($p = 0.20$).*APC*-mutated tumors had the highest mutation burden (median 108 vs. 70; $p < 0.01$), highest TMB-high rate (10.8% vs. 2.9%; $p < 0.01$), and *PTEN* co-occurrence. **Conclusion:** WNT/β-catenin–mutated HCC is a distinct subset; older age, male predominance, low AFP, *TP53* mutual exclusivity, and mutation-load–driven TMB elevation without chromosomal instability. Whether this elevated TMB translates to clinical immunogenicity warrants prospective evaluation given conflicting ICI response data. Importantly, the pathway is internally heterogeneous: *CTNNB1* drives the TMB-elevated, well-differentiated phenotype, while *AXIN1* defines a chromosomal-instability–driven, high-AFP subtype.

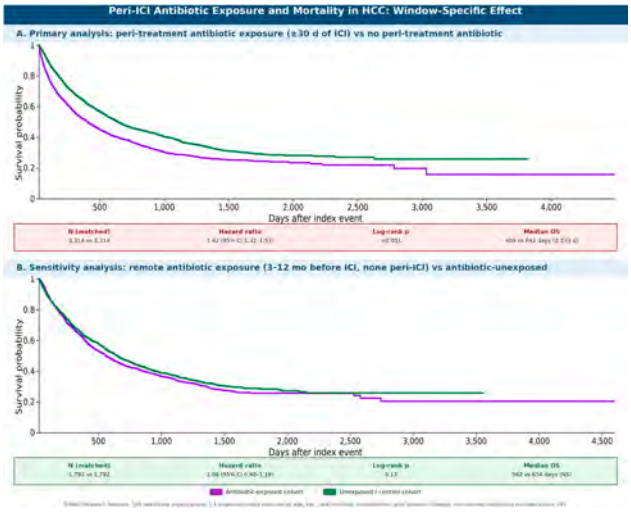
4202 | ◆ PERI-TREATMENT ANTIBIOTIC EXPOSURE AND SURVIVAL IN HEPATOCELLULAR CARCINOMA PATIENTS RECEIVING IMMUNE CHECKPOINT INHIBITORS: A LARGE REAL-WORLD PROPENSITY-MATCHED COHORT STUDY



Mazen Elsheikh[1] Hamza Salim[2] Osamah Salim[3] Sherry Fares[1] Karim Adhem[1] Mohamad Ali Ibrahim[1] Chandni Bhagtaney[1] Angela Aguilar[1] Ximena Ramirez Morales[1] Prasun Jalal[1], [1]Baylor College of Medicine, [2]Department of Gastroenterology and Hepatology, University of Texas Medical Branch, Galveston, TX, [3]Sam Houston State University College of Osteopathic Medicine

Background: Immune checkpoint inhibitors (ICIs) are standard of care for advanced hepatocellular carcinoma (HCC), yet only a minority of patients derive durable benefit. Antibiotics disrupt the gut microbiome and have been linked to reduced ICI efficacy across malignancies, but prior HCC studies produced conflicting results and were underpowered. We examined whether antibiotic exposure within ±30 days of ICI initiation is associated with mortality in HCC patients. To test the gut-microbiome hypothesis, we also assessed whether remote antibiotic exposure, long before ICI, carried the same risk. **Methods:** We conducted a propensity-score-matched retrospective cohort study using the TriNetX Research Network (109 healthcare organizations). Adults with HCC (ICD-10 C22.0) who received any ICI (nivolumab, pembrolizumab, ipilimumab, atezolizumab, durvalumab, tremelimumab, tislelizumab, or toripalimab) on or after HCC diagnosis were included, with first ICI as the index event. Exposed patients received at least one systemic antibiotic (10 drug classes) within ±30 days of index; unexposed patients received none. Groups were matched 1:1 on demographics,

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

cirrhosis, comorbidities (diabetes, COPD, alcohol-related disorders), prior systemic therapy (sorafenib, lenvatinib, regorafenib, cabozantinib), microbiome-modulating co-medications (rifaximin, proton pump inhibitors), and alpha-fetoprotein ≥400 ng/mL. Outcomes were counted from 30 days after index to avoid immortal-time bias. To confirm any harm was specific to the peri-treatment window, a pre-specified sensitivity analysis compared patients who received antibiotics 3 to 12 months before ICI, but none within ±30 days, against patients with no recent antibiotics. The primary outcome was all-cause mortality (Kaplan-Meier, Cox proportional hazards). **Results:** After matching, 3,314 exposed patients were compared with 3,314 unexposed controls (all standardized differences <0.05). Peri-treatment antibiotic exposure was associated with significantly increased mortality (HR 1.42, 95% CI 1.32–1.53; log-rank p<0.001); median overall survival was 409 versus 642 days (Δ 233 days). In the sensitivity analysis (1,792 vs 1,792 matched), remote antibiotic exposure showed no significant survival difference versus antibiotic-unexposed controls (HR 1.08, 95% CI 0.98–1.19; log-rank p=0.13). The 95% CIs of the two analyses did not overlap. **Conclusion:** In the largest real-world HCC ICI cohort to date (6,628 matched), antibiotic exposure at ICI initiation was associated with a 42% increased hazard of death, whereas exposure 3 to 12 months earlier was not. This window-specific harm argues against confounding by patient frailty and supports a microbiome-mediated interaction with ICI efficacy, favoring antibiotic stewardship at ICI initiation in HCC.

★ 4203 | ◆ SERIAL MONITORING OF CIRCULATING TUMOR CELLS REFLECTS TREATMENT RESPONSE ACROSS SYSTEMIC THERAPIES IN UNRESECTABLE HEPATOCELLULAR CARCINOMA

Yosuke Murata[1] Takuto Nosaka[1] Yu Akazawa[1] Tomoko Tanaka[1] Tatsushi Naito[1] Kazuto Takahashi[1] Yasunari Nakamoto[1], [1]University of FUKUI

Background: The strategy of systemic therapy for hepatocellular carcinoma (HCC) has changed with the introduction of immune checkpoint inhibitors. However, clinically useful biomarkers for treatment response remain limited and mechanisms of disease progression have not been fully elucidated. Circulating tumor cells (CTCs) are a form of liquid biopsy that offers a noninvasive approach and is expected to serve as a biomarker for treatment response and to reveal mechanisms of disease progression. We serially collected CTCs from patients with HCC undergoing Atezolizumab plus Bevacizumab (AB), Durvalumab plus Tremelimumab (DT) and Lenvatinib (LEN). Changes in molecular profiles of CTCs were analyzed to assess clinical utility of CTCs for treatment response and investigate mechanisms of disease progression. **Methods:** We obtained 5 mL of peripheral blood from 63 patients with HCC treated by systemic therapy. CTCs were isolated with RosetteSep Human CD45 Depletion Cocktail and enriched cells were stained with monoclonal antibodies targeting Pan-CK and CD45. CD45(-) and Pan-CK(+) cells were defined as CTCs by flow cytometry with FACSAria II. CTC-derived RNA of patients (AB/DT/LEN:16/7/10) was analyzed by 373-gene targeted RNA sequencing with next-generation sequencing (NGS). Gene set enrichment analysis was also performed. **Results:** Baseline CTC counts were higher in patients with advanced-stage disease, including elevated DCP, multiple tumors, vascular invasion, and distant metastasis. At response evaluation, CTC counts decreased in responders in each treatment group (p<0.05). ROC analysis showed that CTC count changes had a higher predictive value for treatment response (AUC=0.837) than AFP and DCP. In 373-gene NGS analysis, baseline CTCs of patients with aggressive tumor features, including vascular invasion or high CTC counts, showed increased expression of cancer progression-related genes, CDKN2B and BCL2L1 (p<0.05). Unsupervised hierarchical clustering classified patients into responders and non-responders in each treatment group, and responders showed longer PFS (p<0.05). Pathway analysis revealed that TGF-β signaling was upregulated in non-responders to AB and LEN during the clinical course, whereas interferon signaling was

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

upregulated in non-responders to DT ($p < 0.05$). Furthermore, baseline expression of TGF-β signaling-related genes, CRABP2 and PDGFRB was higher in non-responders to AB treatment ($p < 0.05$). **Conclusion:** In systemic therapy for HCC, CTC counts more accurately and sensitively reflect changes in tumor burden than existing biomarkers. Gene expression analysis suggested that different pathways, such as TGF-β and interferon signaling, are associated with treatment resistance depending on the therapy. Molecular profiling of CTCs may serve as a useful biomarker for monitoring treatment response and elucidating the underlying mechanisms of disease progression in systemic therapy for HCC.

4204 | ◆ NECROSIS-BIOLOGY DISCORDANCE IN HEPATOCELLULAR CARCINOMA LOCOREGIONAL THERAPY PRIOR TO LIVER TRANSPLANTATION

Keri Zhou[1] Devi Veeramgari[1] Yonatan Kaplan[1] Madeline Chiang[1] Aashrith Madagiri[1] Sami Ali[1] Daisuke Imai[2] Yuzuru Sambommatsu[2] Vinay Kumaran[2] Muhammad Saeed[2] Aamir Khan[2] Amit Sharma[2] Adrian Cotterell[2] Hannah Lee[3] David Bruno[2] Seung Lee[2], [1]Virginia Commonwealth University School of Medicine, [2]Virginia Commonwealth University Hume-Lee Transplant Center, [3]Virginia Commonwealth University

Background: Pathologic tumor necrosis after locoregional therapy (LRT) is commonly used to estimate prognosis in hepatocellular carcinoma (HCC) prior to liver transplantation. High necrosis is traditionally interpreted as a favorable prognostic sign, reassuring clinicians and guiding post-transplant surveillance. However, whether favorable necrosis can be overridden by adverse tumor biology remains poorly understood. **Methods:** This retrospective cohort study included 243 patients with HCC who underwent LRT prior to liver transplantation. Patients were stratified into four groups based on concordance between pathologic tumor necrosis on explant and tumor biology: Group 1 (Concordant Low Risk; high necrosis/good biology), Group 2 (Hidden High Risk; high necrosis/adverse biology), Group 3 (Biology-Reassured; low necrosis/good biology), and Group 4 (Concordant High Risk; low necrosis/adverse biology). High necrosis was defined as $>= 90\%$ on explant pathology. Adverse biology was defined by the presence of any of the following: AFP non-response after LRT, post-LRT AFP > 20 ng/mL, MVI on explant pathology, or poor tumor grade (Grade 3 or 4). The primary outcome was recurrence-free survival (RFS), defined as time to recurrence or death. Secondary outcomes included early RFS failure ($<= 24$ months) and extrahepatic involvement at first recurrence. Between-group differences were assessed using chi-square tests. Multivariable Cox proportional hazards and binary logistic regression modeled outcomes, adjusting for tumor diameter, MVI, and AFP response. An additive biology score (0-4) tested dose-response relationships. Kaplan-Meier curves were compared by log-rank test. **Results:** RFS event rates differed significantly across discordance groups ($\chi^2 = 13.48$, $p = 0.004$). Group 2 demonstrated a 31.7% event rate versus 17.6% in Group 1. This held after adjusting for other risk factors including tumor size and MVI. Early failure within 24 months occurred in 15.0% of Group 2 patients versus 8.2% in Group 1 (OR 2.41, 95% CI 1.09–5.32, $p = 0.030$). Group 2 had higher odds of extrahepatic spread at first recurrence compared to Group 1 (OR 3.55, 95% CI 1.02–12.3, $p = 0.046$). Survival curves separated significantly ($p = 0.012$): median RFS was not reached in Group 1, 68.4 months for Group 2, and 18.2 months for Group 4. **Conclusion:** Adverse tumor biology significantly mitigates the protective signal of necrosis. Patients with discordant high necrosis but poor biology are misclassified as low-risk under necrosis-based criteria alone and experience recurrence at twice the expected rate. These findings support integrating biological markers alongside necrosis assessment to improve post-transplant surveillance stratification in HCC.

Table: Comparison of Post-Transplant Outcomes by Necrosis-Biology Discordance Group

Outcome Measure	Group 1: Concordant Low Risk (High Necrosis/Good Biology)	Group 2: Hidden High Risk (High Necrosis/Adverse Biology)	Statistical Comparison (Group 2 vs. Group 1)
RFS Event Rate (Recurrence/Death)	17.6%	31.7%	chi-sq = 13.48; p = 0.004
Early RFS Failure (<=24 mo)	8.2%	15.0%	OR 2.41 (1.09–5.32); p = 0.030
Extrahepatic Spread at Recurrence	Reference	3.4x higher odds	OR 3.55 (1.02–12.3); p = 0.046
Median RFS (Months)	Not Reached	68.4	Log-rank p = 0.012
Biology Dose-Response	–	–	Biology Score (0-4) significant

4205 | ◆ SUSTAINED ENRICHMENT OF BUTYRATE- AND ACETATE-PRODUCING MICROBES IS ASSOCIATED WITH BETTER OUTCOMES TO ATEZOLIZUMAB PLUS BEVACIZUMAB IN ADVANCED HEPATOCELLULAR CARCINOMA

Soon Kyu Lee[1] Juhyeong Ko[2] Joo Yeon Jhun[1] Jung Hyun Kwon[3] Soon Woo Nam[1] Mi-La Cho[1] Yunju Jeong[2] Hye Won Lee[4], [1]College of Medicine, The Catholic University of Korea, [2]Kyung Hee University, [3]The Catholic University of Korea, [4]Yonsei University College of Medicine

Background: We conducted a prospective, multicenter study to identify functional microbial signatures and metabolite profiles associated with treatment response and to evaluate their potential as predictive biomarkers of clinical outcomes following atezolizumab plus bevacizumab (Ate/Bev) therapy in advanced hepatocellular carcinoma (HCC). **Methods:** We prospectively enrolled 71 patients (discovery cohort) with advanced HCC who received Ate/Bev as first-line systemic therapy between 2022 and 2024 at two tertiary university hospitals. Baseline (pre-treatment) fecal microbiome samples and follow-up samples obtained at the time of the first radiologic response assessment were serially collected to evaluate treatment response–associated changes in the gut microbiome and metabolite profiles. Age-matched healthy controls (HC; n = 10) were included for comparison of baseline fecal microbiome composition. For validation, fecal microbiome samples were obtained from patients with long-term response (LRes; n = 12) treated with Ate/Bev at an independent hospital. LRes was defined as a sustained treatment response for more than 12 cycles of therapy. In vitro experiments using PBMCs from patients with HCC were performed to assess the effects of microbial metabolites on exhausted $CD8^+$ T cells. **Results:** At baseline, patients with advanced HCC exhibited significantly reduced gut microbial diversity compared with healthy controls (HC) (Fig. A). Only subtle differences were observed between responders (Res) and non-responders (NRes) at baseline. However, post-treatment microbiome analysis revealed that the Res group demonstrated a significant increase in gut microbial diversity along with distinct compositional changes. Notably, responders were enriched in bacterial taxa with short-chain fatty acid (SCFA)–producing potential (Fig. B). The increased microbial diversity with enrichment of key acetate- and butyrate-producing genera were further enhanced in the LRes group (Fig. C). *In vitro* experiments demonstrated that treatment with acetate or butyrate significantly reduced the expression of $TIGIT^+$ and $PD\text{-}1^+$ $CD8^+$ T cells. Venn diagram analysis across NRes, Res, and LRes groups identified a consensus set of 22 bacterial taxa associated with favorable response, including enrichment of 20 SCFA-producing taxa and depletion of *[Ruminococcus]_gnavus_group* (Fig. D). Microbial signature–based stratification using the top 40% most prevalent taxa derived from these 22 taxa consistently discriminated overall survival outcomes (Fig. E), which were consistently significant in the multivariable Cox analysis. **Conclusion:** Our findings indicate that a responder-specific microbial signature, marked by enrichment of SCFA-producing taxa and depletion of dysbiosis-associated markers, is associated with improved treatment response and may represent a potential predictive biomarker for survival in advanced HCC.

4206 | ◆ USING HISTOTRIPSY TO TREAT LIVER TUMORS IN THE OUTPATIENT SETTING

Roukaya Hassanein[1] Deanna Oliver[2] Anna Hefner[2] Mikaela Banuelos[1] Fatma Barakat[3] Tarek Hassanein[2], [1]Southern California Abdominal Cancer Group, [2]Southern California Liver Centers, [3]SCTI Research Foundation

Background: Liver tumors continue to pose a major health and economic burden. Despite advancements in therapeutic options liver transplantation remains the only curative option, which poses eligibility and

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

availability challenges. Histotripsy is a novel, non-invasive, focused ultrasound pulses designed to mechanically liquify tumors. It is a sonic beam therapy platform that can destroy targeted liver tumors at a subcellular level. It received FDA approval in 2023 and has been mainly used in hospital-based/academic settings. We report on our outpatient center's experience **Methods:** Between November 2024 and May 2026, 34 patients (pts) diagnosed with liver tumors were treated with Histotripsy. Each Histotripsy consisted of at least 1 session. Each session treated a unique liver lesion. Actual number of treatments per session and duration of each treatment was tailored to each pt's disease burden and need. Histotripsy eligibility work-up was done. Histotripsy was performed mainly by a Hepatologist or Surgeon. **Results:** 50% male. 35.3% Hispanic, 94.1% white. Mean age was 66.4 ± 13.9 years. All were Child-Pugh A or B. 50% had Hepatocellular Carcinoma, 14.8% Cholangiocarcinoma, 17.6% Colorectal, and 17.6% metastasis. Prior to Histotripsy: 64.8% had 1 lesion, 17.6% had 2 lesions, 17.6 had 3 or more lesions. 14.7% of pts received at least one cycle of Immune Checkpoint Inhibitors (ICI), 26.5% had chemotherapy, and 5.9% had both ICI and Chemotherapy. Histotripsy: 50% had 1 treatment/session, 38.2% 2-3 treatments/session, and 11.8% 4-6 treatments. Each treatment treated a different lesion. Longest session duration was 142 minutes. Median duration of a single treatment was 25 minutes (3-90 minutes). Safety and Outcomes: No significant complications during Histotripsy were observed. 73.5% of pts are alive. No changes in liver enzymes, inflammation markers, coagulation, and MELD score post Histotripsy. 28% experienced mild adverse reactions such as skin erythema on treatment site. 2 pts had acute renal injury that resolved within a week of supportive care/hydration. **Conclusion:** Histotripsy is a novel form of focused ultrasound that uses high amplitude, very short pulses to create a "bubble cloud" designed to mechanically destroy and liquefy targeted liver tumors. As the first outpatient, community-based Hepatology medical practice to implement Histotripsy, it proved to be doable to implement in a non-hospital setting. Patients were able to have multiple treatments in a single session. No pts needed overnight observation. Histotripsy is tolerable and a highly effective non-invasive therapy for treating different kinds of liver tumors in the outpatient setting. Analysis of combining Histotripsy with ICI and/or LRT is underway. Histotripsy protocol continues to be implemented as standard of care with the goal of prolonging disease-free survival in patients with liver tumors, especially Hepatocellular Carcinoma.

4207 | ◆ MULTICENTER PROPENSITY-WEIGHTED COMPARISON OF HEPATIC ARTERIAL INFUSION CHEMOTHERAPY AND TYROSINE KINASE INHIBITORS IN PATIENTS WITH ADVANCED HEPATOCELLULAR CARCINOMA PREVIOUSLY TREATED WITH ATEZOLIZUMAB–BEVACIZUMAB

Kwon Yong Tak[1] Pil Soo Sung[2], [1]Seoul St. Mary's Hospital, [2]Seoul St Mary's Hospital

Background: Following the failure of first-line atezolizumab–bevacizumab (AB), the optimal second-line strategy for advanced hepatocellular carcinoma (HCC) remains undefined. The 2025 BCLC recommendations emphasize individualized decision-making under the CUSE framework. This study aimed to compare the clinical outcomes of hepatic arterial infusion chemotherapy (HAIC) and tyrosine kinase inhibitors (TKIs) in this setting. **Methods:** This multicenter retrospective study included 90 patients (HAIC, n = 51; TKIs, n = 39) from four tertiary centers who experienced disease progression after AB. Baseline characteristics, including higher tumor burden and portal vein tumor thrombosis (PVTT) in the HAIC group, were adjusted using inverse probability of treatment weighting (IPTW). Tumor response was assessed via mRECIST by blinded radiologists. Primary endpoints were progression-free survival (PFS) and overall survival (OS). **Results:** HAIC yielded significantly higher objective response rates (35.3% vs. 5.1%, $P = .002$) and disease control rates (66.7% vs. 25.6%, $P < .001$) compared to TKIs. In the IPTW-weighted analysis, HAIC was associated with significantly longer PFS (7.1 vs. 3.4 months; $P < .001$), although OS did not differ significantly between the groups (10.5 vs. 6.3 months; $P = .31$). Notably, the TKI group had a substantially higher rate of treatment discontinuation due to toxicity compared to the HAIC group (53.8% vs. 15.7%). **Conclusion:** As a second-line treatment after AB failure, HAIC provides superior radiologic response and longer PFS compared to TKIs. While no definitive OS benefit was observed, these findings support HAIC as an effective investigational salvage option, particularly for patients with liver-dominant disease requiring robust intrahepatic control.

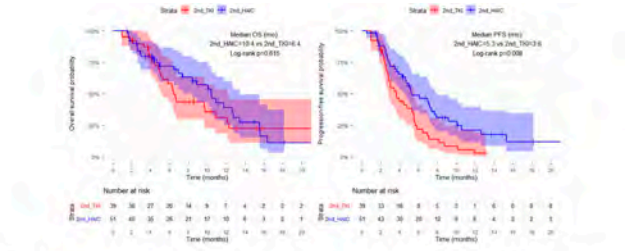

Fig 3. Overall survival comparison and B. Progression free survival between patients treated with second-line HAIC and second-line TKIs using the Kaplan-Meier curve. HAIC, hepatic arterial infusion chemotherapy; TKI, tyrosine kinase inhibitor; OS, overall survival, PFS, progression-free survivial.

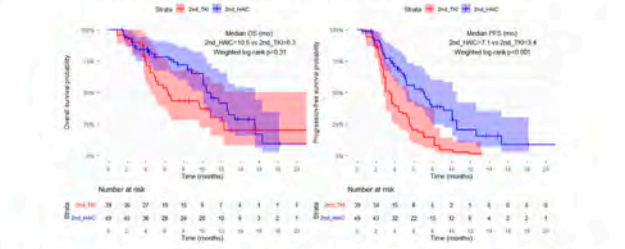

Fig 4. IPTW-weighted Kaplan–Meier curves for OS and PFS in patients treated with HAIC versus TKIs following AB therapy failure. Weighted Cox proportional hazards regression was applied with IPTW to adjust for baseline differences. OS and PFS were compared between treatment groups using weighted log-rank tests. OS, overall survival; PFS, progression-free survival; IPTW, inverse probability of treatment weighting; HAIC, hepatic arterial infusion chemotherapy; TKI, tyrosine kinase inhibitor; AB, atezolizumab–bevacizumab.

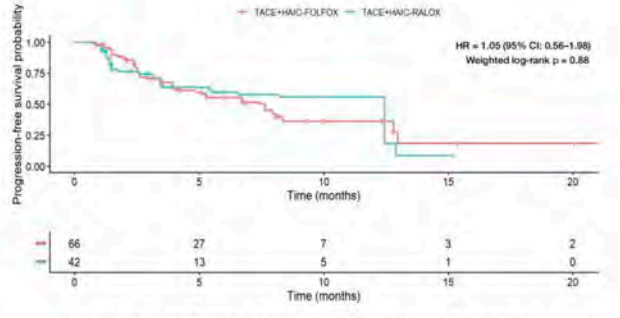
4208 | ◆ TRANSARTERIAL CHEMOEMBOLIZATION COMBINED WITH RALOX-HAIC VERSUS FOLFOX-HAIC FOR UNRESECTABLE HEPATOCELLULAR CARCINOMA: A RETROSPECTIVE IPTW-ADJUSTED STUDY

Yusi Ding[1] Yuanyi Chen[1] Wenjun Wang[1] Yaping Li[1] Guoying Pan[1] Xiaoli Jia[1], [1]The Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China

Background: Transarterial chemoembolization (TACE) and hepatic arterial infusion chemotherapy (HAIC) are widely used for unresectable hepatocellular carcinoma (uHCC), especially in China. FOLFOX (oxaliplatin, fluorouracil, leucovorin) is the most common HAIC regimen, but its prolonged 46-hour infusion limits convenience. Raltitrexed, a thymidylate synthase inhibitor with a longer half-life, allows shorter infusion and may be a more convenient alternative. This study compared the efficacy and safety of TACE combined with RALOX-HAIC (oxaliplatin plus raltitrexed) versus TACE combined with FOLFOX-HAIC in uHCC patients. **Methods:** This retrospective study included 108 patients with uHCC treated between January 2023 and December 2025. Among them, 66 patients received TACE plus FOLFOX-HAIC and 42 received TACE plus RALOX-HAIC. Treatment efficacy was assessed using objective response rate (ORR), disease control rate (DCR), and progression-free survival (PFS). Treatment-related adverse



Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

events were also compared between groups. Inverse probability of treatment weighting (IPTW) was applied to balance baseline demographic and clinical characteristics. Multivariable Cox regression analysis was performed to identify factors associated with PFS. **Results:** After IPTW adjustment, tumor response was comparable between the TACE–RALOX-HAIC and TACE–FOLFOX-HAIC groups. ORR was identical in both groups (48.2% vs. 60.8%, *P* = 0.270, while DCR did not differ significantly between groups (69.5% vs. 78.1%, *P* = 0.336). Median PFS was 12.43 months in the TACE–RALOX-HAIC group and 7.30 months in the TACE–FOLFOX-HAIC group, with no statistically significant difference observed between treatments (hazard ratio, 1.05; 95% confidence interval, 0.56-1.98; *P* = 0.880). In multivariable analysis, extrahepatic metastasis and poor performance status were independently associated with shorter PFS. The overall incidence of grade 3/4 treatment-related adverse events was similar between groups. Fever occurred more frequently in the TACE–RALOX-HAIC group than in the TACE–FOLFOX-HAIC group (40.5% vs. 19.7%, *P* = 0.027). **Conclusion:** In this IPTW-adjusted retrospective study, TACE combined with RALOX-HAIC demonstrated comparable efficacy and safety to TACE combined with FOLFOX-HAIC in patients with uHCC. Given its shorter infusion duration, RALOX-HAIC may provide a more convenient alternative to FOLFOX-HAIC without compromising antitumor activity. Prospective studies are warranted to validate these findings.

Table. Tumor Response by mRECIST after IPTW.

Treatment / Response	TACE+HAIC-FOLFOX n=66	TACE+HAIC-RALOX n=42	*P* value
CR	3 (4.2%)	4 (8.9%)	0.481
PR	37 (56.6%)	16 (39.3%)	
SD	11 (17.3%)	9 (20.4%)	
PD	14 (21.9%)	13 (31.3%)	
ORR	40 (60.8%)	20 (48.2%)	0.270
DCR	51 (78.1%)	29 (69.5%)	0.336

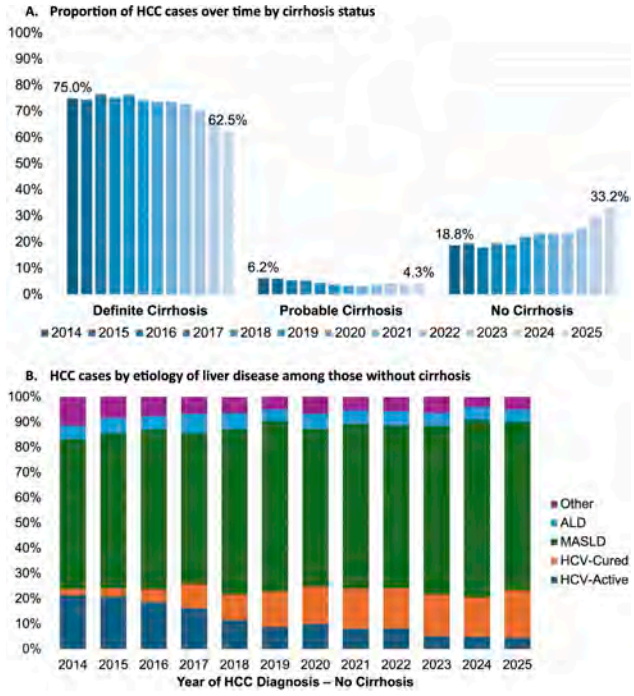
4210 | THE RISING BURDEN OF MASLD-ASSOCIATED NON-CIRRHOTIC HEPATOCELLULAR CARCINOMA: A NATIONAL STUDY OF U.S. VETERANS



Nicole Kim[1] Philip Vutien[1] Bret Mecham[2] Vyshnika Sriskantharajah[2] Elliott Lowy[2] Kristin Berry[2] George Ioannou[2], [1]University of Washington, [2]Veterans Affairs Puget Sound Health Care System

Background: Hepatocellular carcinoma (HCC) can occur in patients without liver cirrhosis. We aimed to examine the trends in HCC diagnoses by cirrhosis status and etiology of liver disease among U.S. Veterans over time. **Methods:** We identified U.S. Veterans diagnosed with incident HCC between 1/1/2014 and 10/26/2025. Cirrhosis status was categorized as "definite" based on ICD-codes for cirrhosis and/or related complications within 1 year of the HCC diagnosis date, "probable" based on not meeting criteria for definite cirrhosis but having a FIB-4 score >3.25 or a transient elastography liver stiffness measurement >12.5 kPa within 2 years before or 6 months after the HCC diagnosis date, and "no cirrhosis" based on not meeting criteria for definite and probable cirrhosis. Descriptive statistics were performed to stratify HCC diagnoses by cirrhosis status, etiology of liver disease, and diagnosis year. **Results:** There were 33,628 U.S. Veterans diagnosed with new HCC during 2014-2025, with 73%, 4.6%, and 22.4% of cases occurring in the setting of definite, probable, and no cirrhosis respectively. The mean age at HCC diagnosis was 68 years (SD 8.2) and majority were male (98.5%), White (70.2%), with leading liver disease etiologies of hepatitis C (HCV; 47.4%), metabolic dysfunction-associated steatotic liver disease (MASLD; 33.9%) and alcohol-related liver disease (ALD; 13.3%). From 2014 to 2025, the proportion of HCC cases with definite and probable cirrhosis decreased by 12.5% and 1.9% respectively, while HCC cases without cirrhosis increased by 14.4% (18.8% to 33.2%, Figure A). While most patients with HCV- and ALD-related HCC had definite cirrhosis (>85%), 43% of patients with MASLD-related HCC did not have cirrhosis. In 2025, 66.8% of non-cirrhotic HCC cases were due to MASLD (Figure B). Patients with non-cirrhotic HCC were also more likely to be female (2.4% vs. 1.3%; p<0.001), older (median age 71 vs. 67 years; p<0.001), and have MASLD (64.7% vs. 23.4%; p<0.001) than those with definite cirrhosis. **Conclusion:** In the last decade, the proportion of HCC cases without liver cirrhosis increased from 18.8% to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

33.2%, with the majority (66.8% in 2025) due to MASLD. These findings emphasize the need to develop rational strategies and recommendations for surveillance and early detection of MASLD-associated non-cirrhotic HCC.

4211 | DISSECTING FEMALE SURVIVAL ADVANTAGE AND TREATMENT ALLOCATION IMBALANCE IN HEPATOCELLULAR CARCINOMA: A KOREAN NATIONWIDE REGISTRY STUDY

Ji Won Han[1] Do Seon Song[2], [1]The Catholic University of Korea, Seoul St. Mary's Hospital, [2]The Catholic University of Korea

Background: Female patients with hepatocellular carcinoma (HCC) often present with more favorable tumor characteristics and better survival than male patients. However, whether this apparent advantage reflects a residual within-stage survival benefit or favorable stage distribution remains unclear. We aimed to decompose sex-based survival differences and evaluate treatment non-receipt after accounting for tumor case mix. **Methods:** We analyzed 19,695 patients with newly diagnosed HCC from the Korean Primary Liver Cancer Registry between 2008 and 2020. Stage-stratified Kaplan–Meier analysis and stepwise Cox regression were used to assess the female survival advantage. Multivariable logistic regression evaluated the association between female sex and treatment non-receipt after adjustment for age, stage, liver function, performance status, tumor size, and macrovascular invasion. Subgroup analyses were performed by age and etiology. **Results:** Among 19,695 patients, 4,135 (21.0%) were female. Women were older but had smaller tumors, less macrovascular invasion, and more early-stage disease than men (mUICC Stage I–II: 61.7% vs 50.2%, p < 0.001). Despite this favorable stage distribution, overall treatment non-receipt was similar between women and men (18.1% vs 18.4%, p = 0.508). Stage-stratified survival curves overlapped across all mUICC stages. In stepwise Cox regression, the unadjusted female survival advantage (HR 0.829) attenuated after adjustment for stage and liver function and remained modest after full adjustment (HR 0.910), suggesting a predominantly stage-distribution–mediated advantage. In logistic regression, female sex was not associated with treatment non-receipt in crude analysis (OR 1.056, p = 0.403), but became independently associated after full adjustment (OR 1.237, p = 0.006). This imbalance was most apparent in the Other/MASLD subgroup (OR 1.624, p = 0.001) and patients aged >65 years (OR 1.321, p = 0.006). **Conclusion:** The apparent female survival advantage in HCC was largely explained by favorable stage distribution. Case-mix adjustment revealed treatment allocation imbalance, particularly among elderly women and patients with non-viral, non-alcohol-related etiologies.

4212 | TACE IN THE SETTING OF PORTAL VEIN THROMBOSIS: EVALUATING RISKS AND OUTCOMES IN HCC AND CIRRHOSIS

Het Patel[1] Erik Dehkes[1] Barbara Halicki[1] Hammad Liaquat[1], [1]St. Luke's University Healthcare Network

Background: Transarterial chemoembolization (TACE) is a standard locoregional therapy for hepatocellular carcinoma (HCC) in patients with cirrhosis. The presence of portal vein thrombosis (PVT) is common in advanced disease and may impact hepatic perfusion, procedural safety, and clinical outcomes following TACE. This study evaluates differences in patient characteristics and inpatient outcomes among patients with cirrhosis and HCC undergoing TACE with and without PVT. **Methods:** We conducted a retrospective cohort study using the National Inpatient Sample (NIS) database to identify adults with cirrhosis and HCC who underwent TACE between 2019 and 2022. Patients were stratified based on the presence or absence of PVT. Demographics, comorbidities, hospital characteristics, and inpatient complications were compared between groups. Statistical analyses were performed using STATA software, with significance defined as $p < 0.05$. **Results:** Of the 3,660 patients who met inclusion criteria, 76.6% were male and mean age was similar between groups (64.9 versus 65.8 years, $p \geq 0.05$). Demographics, including gender and race, were otherwise comparable between groups ($p \geq 0.05$). Charlson Comorbidity Index (CCI) was similar between groups (≥ 0.05), except for CCI score 6, which was higher in the PVT group ($p < 0.05$). Although patients with PVT had lower rates of alcohol use ($p < 0.05$), there were no significant differences in COPD, CHF, diabetes, hypertension, malnutrition, or smoking ($p \geq 0.05$). Patients with PVT undergoing TACE had higher odds of variceal bleeding (OR 2.933, 95% CI 1.255–6.857), acute kidney injury (OR 2.478, 95% CI 1.451–4.232), and acute liver failure (OR 2.422, 95% CI 1.212–4.842). No significant differences were observed in spontaneous bacterial peritonitis, sepsis, liver transplantation, ICU admission, mechanical ventilation, vasopressor use, and inpatient mortality ($p \geq 0.05$). Length of stay was longer in the PVT group (7.8 versus 5.2 days, $p < 0.05$), while total hospitalization charges were similar between groups ($p \geq 0.05$). **Conclusion:** In patients with cirrhosis undergoing TACE for HCC, patients with alcohol use were less likely to have PVT. We found higher rates of variceal bleeding, acute kidney injury, acute liver failure, and overall length of stay in patients with PVT consistent with guideline recommendations favoring alternative systemic therapies in PVT. We recommend monitoring for these complications and further prospective studies to identify risk factors and safety of TACE in the setting of PVT.

4213 | NON-INVASIVE RISK STRATIFICATION TO GUIDE PRE-TREATMENT ENDOSCOPIC SCREENING AND PREDICT HEPATIC DECOMPENSATION IN HEPATOCELLULAR CARCINOMA PATIENTS RECEIVING SYSTEMIC THERAPY: A PROSPECTIVE COHORT STUDY

Laia Aceituno Sierra[1] Giselle Caballero[2] Shiva Babakhani[2] Ahmed Elsheaita[3] Farah Albader[3] Elena Valenzi[3] Ann Ma[3] Roxana Bucur[2] Arndt Vogel[4], [1]Toronto General Hospital, University Health Network, [2]University Health Network, HPB Surgical Oncology, Toronto, Ontario, Canada., [3]Division of Gastroenterology and Hepatology, Toronto General Hospital, Toronto, Canada., [4]University of Toronto

Background: Atezolizumab–bevacizumab (AB) is the first-line standard-of-care therapy for advanced hepatocellular carcinoma (HCC). Concerns regarding bevacizumab-associated variceal bleeding have led to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

recommendations for routine pre-treatment esophagogastroduodenoscopy (EGD) in all patients, potentially increasing procedural burden and delaying treatment initiation. Baveno VII criteria use liver stiffness measurement (LSM) and platelet count to identify cirrhosis patients at low risk of varices who may safely avoid screening EGD, although their applicability in advanced HCC remains unclear. We evaluated whether non-invasive liver assessment tools could safely guide pre-treatment EGD strategies and predict hepatic decompensation. **Methods:** This prospective observational single-centre study included adult HCC patients initiating systemic therapy at Princess Margaret Cancer Centre, Toronto. Patients were stratified using Baveno VII criteria into low-risk (LR: LSM <15 kPa and platelets $\geq 150\times10^9$/L) or high-risk (HR: LSM ≥ 15 kPa and/or platelets $<150\times10^9$/L). HR patients underwent pre-treatment EGD, while LR patients proceeded directly to therapy. Primary endpoints were variceal bleeding and hepatic decompensation during follow-up. **Results:** 50 patients were included, 37 patients (70%) were classified as HR and 13 (30%) as LR according to Baveno VII criteria. Baseline HR patients had significantly higher LSM values and lower platelet counts compared with LR patients (27.0 vs. 9.0 kPa, $p<0.001$; 155 vs. 217 $\times10^9$/L, $p=0.013$). Portal vein thrombosis was more frequent in the HR group (51% vs. 15%, $p=0.053$). Varices were identified in 11/35 HR patients (35%), including 5 patients with high-risk stigmata. One HR patient (2%) developed post-AB variceal bleeding. No bleeding events occurred in the LR group. During follow-up, seven patients (14%) developed hepatic decompensation. Patients who decompensated had higher baseline bilirubin and MELD-Na scores and more frequently had prior decompensation and pre-existing varices. CP score did not significantly differ between groups, whereas ALBI grade 2 was associated with increased risk of decompensation (OR 6.25, 95% CI 1.06–36.74). MELD-Na demonstrated the highest discriminative performance for predicting decompensation (AUC 0.81, 95% CI 0.70–0.93). **Conclusion:** Baveno VII–based non-invasive stratification safely identified HCC patients receiving AB who could avoid pre-treatment EGD without bleeding complications, while MELD-Na outperformed other liver assessment tools for predicting hepatic decompensation. These findings support incorporation of non-invasive liver assessment into pre-treatment evaluation pathways for HCC systemic therapy.

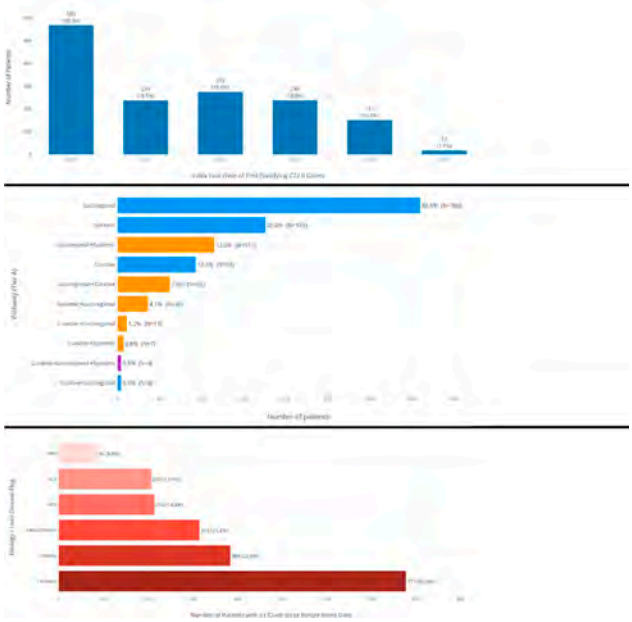
4214 | MAPPING REAL WORLD TREATMENT JOURNEYS OF HEPATOCELLULAR CARCINOMA IN THE IMMUNOTHERAPY ERA



Kavana Madhiraju Sanjay[1] Renu Dhanasekaran[1],
[1]Stanford University School of Medicine

Background: Hepatocellular carcinoma (HCC) systemic therapy has been transformed by the approvals of multiple immunotherapies as first line treatment, but the structure of real-world treatment journeys and how immunotherapy adoption has reshaped sequencing across curative, locoregional, and systemic modalities has not been quantified at scale. **Methods:** We conducted a retrospective cohort study of US adults with hepatocellular carcinoma (≥ 2 ICD-10 C22.0 claims ≥ 30 days apart) in the HealthVerity claims database (Jan 2020-Mar 2025), requiring ≥ 90 days continuous pre-index enrollment. Modality-anchored treatment journeys were constructed from procedure and pharmacy claims, with contamination control for non-liver-specific codes. We quantified pathway heterogeneity at three nested levels- Tier A (3 treatment classes), Tier B (7 modalities), Tier C (drug-level systemic) using normalized Shannon entropy with patient-level bootstrap 95% CIs (2,000 resamples). Temporal trends in first-line systemic agent use and immunotherapy positioning within the journey were tested with Cochran-Armitage and Kaplan-Meier methods. **Results:** Among 1,487 patients (median age 66 years; 74% male; 41% Medicare), 59% received ≥ 1 HCC-directed treatment. TACE was the most prevalent modality (32.5%), followed by systemic therapy (22.7%) and TARE (17.4%). Systemic therapy as the first treatment modality increased from 56% of systemic-treated patients in 2020 to 73% in 2023 ($z = +2.04$, $p = 0.041$). Durvalumab-based regimens rose from 0% of first-line systemic use in 2020-2021 to 42% by 2024 (Cochran-Armitage $z = +7.83$, $p<0.0001$), and sorafenib fell from 14% in 2020 to 0% from 2023 onward ($z = -4.52$, $p<0.0001$), while atezolizumab +bevacizumab maintained an overall share of approximately 31% with a modest rising trend ($z = +1.77$, one-sided $p = 0.038$). Nivolumab fell from 27% in 2020 to near-zero by 2024. Oral TKIs were infrequent across the dual-enrolled subset, with lenvatinib (4.4%) the most common, followed by cabozantinib (1.7%), sorafenib (1.4%), and regorafenib (0.9%). **Conclusion:** Real-world HCC treatment heterogeneity is concentrated at the drug-choice layer rather than in macro-sequencing, and the IO era has produced consolidation around dominant immunotherapy combinations, while shifting systemic therapy earlier in the patient journey. These findings reframe the post-immunotherapy treatment landscape and provide a quantitative baseline against which future sequencing trials and access

4215 | AGE-DEPENDENT SEX DIFFERENCES IN SURVIVAL AMONG PATIENTS WITH HEPATOCELLULAR CARCINOMA: A POPULATION-BASED ANALYSIS FROM THE TEXAS AND CALIFORNIA CANCER REGISTRIES

Mohammad Jarrah[1] Mohammed Al-Hasan[1] Zachary Whitham[1] Lauren Matevish[1] Ju Dong Yang[2] Fasiha Kanwal[3] Adam Yopp[1] Amit Singal[1] Nicole Rich[1], [1]University of Texas Southwestern Medical Center, [2]Cedars-Sinai Medical Center, [3]Michael E. DeBakey VA Medical Center

Background: Hepatocellular carcinoma (HCC) predominantly affects men, yet mechanisms underlying sex differences in HCC outcomes remain incompletely understood. Experimental models and observational studies suggest estrogen may protect against HCC progression. Prior population-based studies have largely relied on SEER datasets, which historically underrepresented patients from Texas and portions of California – states accounting for a substantial proportion of the U.S. HCC burden. Herein, we evaluated sex differences in overall survival (OS) among patients with HCC using population-based data from the Texas Cancer Registry (TCR) and California Cancer Registry (CCR). **Methods:** Patients diagnosed with HCC between 2004 and 2022 were identified from the TCR and CCR, using ICD code C22.0 and morphology codes 8170–8175. Patients diagnosed before age 18 years, non-HCC histology codes, or identified by death certificate or autopsy only were excluded. Associations between sex and OS were evaluated using Kaplan-Meier analysis and multivariable Cox proportional hazards models adjusting for age, race/ethnicity, SEER stage (localized, regional, distant), and treatment modality (surgical, locoregional, systemic). Age <50 was used as a surrogate for pre-menopausal status, and interaction between sex and age was assessed in multivariable models. **Results:** Among 95,237 patients with HCC (median age 64 years; 75.3% men), 44.4% were from TCR and 55.6% from CCR. The cohort was racially and ethnically diverse, including 40.8% White, 33.9% Hispanic, 14.1% Asian and 10.1% Black patients. Despite major changes in HCC epidemiology over time, including increasing MASLD-associated HCC, women consistently represented a minority of HCC cases across eras. Women more frequently presented with localized disease (54.4% vs 47.5%; $p<0.001$) and received surgery more often than men (8.0% vs 7.6%; $p<0.001$). Median OS was longer among women than men (13 vs. 11 months; $p<0.001$). After multivariable adjustment, female sex remained independently associated with lower mortality (aHR 0.88, 95% CI 0.87–0.90) (**Figure 1A**); this finding persisted across all stages ($p<0.001$ for all). Among women, those aged <50 years had substantially longer OS compared to women aged ≥ 50 years (27 vs. 13 months), corresponding to lower adjusted mortality (aHR 0.74, 95% CI 0.68–0.80) (**Figure 1B**). The survival advantage associated with female sex was greatest among women aged <50 years and attenuated with increasing age (**Figure 1C-D;** interaction $p<0.001$). **Conclusion:** In this large cohort, women with HCC demonstrated a survival advantage compared with men, particularly among younger women. The attenuation of this effect after age 50, together with the stable underrepresentation of women across eras, supports the presence of sex-related biologic differences in HCC susceptibility and progression.

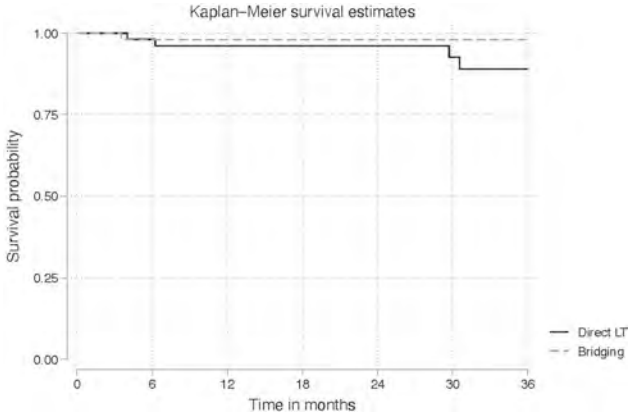
4216 | OVERALL SURVIVAL AMONG PATIENTS UNDERGOING DIRECT LIVER TRANSPLANTATION VERSUS BRIDGING LOCOREGIONAL THERAPY BEFORE TRANSPLANT FOR HEPATOCELLULAR CARCINOMA



Saleh Alqahtani[1] Saleh Alessy[2] Layan Alsubki[2] Amwaj Alanazi[2] Basmah Khoja[2] Habeeb Ibrahim Abdul Razack[3] Alwaleed Almojel[2] Fahad AlMugbel[2] Ali Alqahtani[2] Waleed Alomaim[2] Mohammed Alsager[4] Fuat Saner[2] May Alzahrani[5] Khalid AlNaamani[6] Dimitri Raptis[2] Dieter Broering[2] Saad Alghamdi[7] Faisal Abaalkhail[2], [1]King Faisal Specialist Hospital & Research Center, [2]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [3]King Saud University, Riyadh, Saudi Arabia, [4]King Saud Medical City, Riyadh, Saudi Arabia, [5]King Faisal Specialist Hospital and Research Center, Jeddah, Saudi Arabia, [6]The Medical City for Military and Security Services, Muscat, Oman, [7]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

Background: Locoregional therapy is commonly used as a bridging strategy before liver transplantation in patients with hepatocellular carcinoma to maintain transplant eligibility and reduce tumor progression while awaiting transplantation. We aimed to compare patients undergoing direct liver transplantation with those receiving bridging transarterial chemoembolization (TACE) or transarterial radioembolization (TARE) using real-world outcome data. **Methods:** We used data from the HCC registry, a large prospectively maintained registry established in 2020 at King Faisal Specialist Hospital & Research Center, a major tertiary referral center in Saudi Arabia. Adult patients with HCC who underwent liver transplantation were included. Patients were categorized into those who underwent direct liver transplantation without prior locoregional therapy and those who received bridging locoregional therapy with transarterial chemoembolization (TACE) or transarterial radioembolization (TARE) before transplantation. Baseline demographic, clinical, and tumor characteristics, including BCLC stage, Milan criteria, Child-Pugh class, and albumin-bilirubin (ALBI) grade, and the median time to transplant were compared between groups. Overall survival was assessed using Kaplan–Meier analysis and Cox proportional hazards models. **Results:** Among 696 patients with HCC, 138 (19.8%) underwent liver transplantation. Transplant recipients were younger at diagnosis than non-transplant patients (60.0 vs. 66.0 years, $p < 0.001$), while the sex distribution was comparable. The prevalence of MASLD/MASH was comparable between transplant and non-transplant patients (35.5% vs. 35.8%) and represented the leading etiology in both groups. Among the transplanted patients, 78 (56.5%) underwent direct transplantation and 60 (43.5%) received bridging locoregional therapy before transplantation. Age and sex distribution were similar between groups. BCLC stage and Milan criteria status were also similar. The median time from diagnosis to transplantation was longer among patients receiving bridging therapy (224.0 vs. 130.5 days; $P = 0.018$). Bridged patients had more favorable liver reserve by Child-Pugh class (Child-Pugh A: 71.7% vs. 44.9%; $P = 0.002$) and ALBI grade ($P = 0.012$). In Cox regression adjusted for age and sex, bridging therapy was not associated with a higher risk of death following transplantation (adjusted HR 0.23, 95% CI 0.02–2.19). **Conclusion:** Bridging locoregional therapy before liver transplantation was not associated with an increased risk of post-transplant mortality after adjusting for age and sex. However, the wide confidence interval and baseline differences in liver reserve highlight limited precision and potential

4217 | MEDICAL MANAGEMENT OF PATIENTS UNDERGOING ELECTIVE, LIVER-RELATED INVASIVE PROCEDURES – A NOVEL COLLABORATION MODEL BETWEEN HEPATOBILIARY SURGEONS AND HEPATOLOGISTS

Chiara Mangini[1] Federica Giunta[1] Cecilia Busato[1] Domenico Bassi[1] Riccardo Boetto[1] Carmine Gabriele Gambino[1] Riccardo Carandina[1] Matteo Ghisa[1] Caterina Soldà[2] Sabrina Cervesato[3] Michele Tessarin[4] Umberto Cillo[1] Sara Montagnese[1], [1]University of Padova, [2]Veneto Institute of Oncology IOV-IRCCS, Padova, Italy, [3]Universty of Padova, [4]Medical Management, Padova University Hospital

Background: To describe and evaluate a novel, joint surgical-hepatological management model for patients undergoing elective hepatobiliary procedures within the setting of a short medical hospitalization. **Methods:** Elective admissions to the Internal Medicine Ward 5 - Hepatology of Padova University Hospital for the above purpose between Feb 2023 (when the new system was implemented) and Dec 2025 were jointly scheduled and prioritized by a designated hepatologist and hepato-biliary surgeon, and managed by a specialist nurse. Outcomes of interest included length of the inpatient stay, complications and their management, plus estimated health costs. **Results:** 462 procedures (records of 74% male patients, 67 ± 12 years) were performed over the observation period, including 125 (27%) endoscopic retrograde cholangiopancreatographies (ERCP), 178 (39%) locoregional treatments (LRT) for liver lesions, 89 (19%) percutaneous transhepatic biliary drainages (PTBD), and 70 (15%) "other". 336 (73%) were first admissions and 126 (27%) were repeated admissions for scheduled multistep protocols. Most common underlying conditions were cirrhosis (33%), a history of liver transplantation (23%), and hepatobiliary malignancies (59%). Average inpatient stay was 2.4 ± 6.1 days, with 85% discharged within 72 hours. Complications occurred in 88 patients (19%), with significantly longer hospitalizations (6.7 ± 12.5 days vs 1.2 ± 0.6, $p < 0.001$), especially for PTBD (Figure). By way of comparison, 201 of the 3 most common procedures had been performed in the hepatobiliary surgery ward over the year 2022. Admissions were 16.8 per month in surgery and 13.2 in medicine, with pertinent, adjusted costs being € 18,085 in medicine and € 47,500 in surgery. **Conclusion:** Hepatological-surgical co-management of patients undergoing hepatobiliary procedures within the setting of an elective medical hospitalization is feasible, cost-effective and most likely scalable.

4218 | POPULATION-LEVEL OUTCOMES OF CUSE-GUIDED TREATMENT STAGE MIGRATION TO SURGICAL RESECTION IN BCLC-B AND BCLC-C HCC: A NATIONWIDE KOREAN REGISTRY ANALYSIS

Minseob Kim[1] Youngrok Choi[1] Suk Kyun Hong[1] Su Young Hong[1] Hye-Sung Jo[1] Kwang-Woong Lee[1] Eun-Woo Choi[2], [1]Seoul National University, College of Medicine, [2]Department of Surgery, Seoul National University College of Medicine, Seoul, Korea

Background: Surgical resection is the recommended curative option for hepatocellular carcinoma (HCC) at Barcelona Clinic Liver Cancer (BCLC) stage 0/A, whereas transarterial chemoembolization (TACE) and systemic therapy are recommended for intermediate (BCLC-B) and advanced (BCLC-C) disease, respectively. Whether selected BCLC-B or BCLC-C patients benefit from resection remains uncertain. Therefore, we investigated this in a nationwide Korean cohort. **Methods:** From 21,178 patients in the Korean Primary Liver Cancer Registry (2008–2021), we identified 1,713 with BCLC-B HCC (resection vs TACE) and 2,031 with BCLC-C HCC (resection vs systemic therapy). Inverse probability of treatment weighting (IPTW) was the primary analysis; propensity score matching (PSM), cause-specific Cox regression, restricted mean survival time (RMST), and era-stratified analysis were sensitivity analyses. **Results:** Pre-weighting imbalances across baseline covariates — most pronounced for tumor multifocality and (in BCLC-C) macrovascular invasion and distant metastasis — were balanced after IPTW (all standardized mean differences <0.1). Resection was associated with substantially better overall survival: hazard ratio (HR) 0.528 (95% CI 0.446–0.626) for BCLC-B and 0.327 (0.241–0.442) for BCLC-C. RMST gains in the matched cohort were 7.0 (4.3–9.7) and 22.3 (18.2–26.4) months, respectively. Cause-specific HRs for cancer death (0.506 [BCLC-B] and 0.332 [BCLC-C]) mirrored overall estimates. The benefit was preserved in the post-IMbrave era (HR 0.203, 0.105–0.392). **Conclusion:** In carefully selected BCLC-B and BCLC-C patients in this Korean nationwide cohort, surgical resection was associated with substantially better survival than the standard first-line option, supporting CUSE-guided multidisciplinary evaluation of surgical candidacy. The magnitude of effect likely reflects both real biological benefit in resectable patients and residual selection by unmeasured operability factors; prospective definition of resectability criteria is warrante

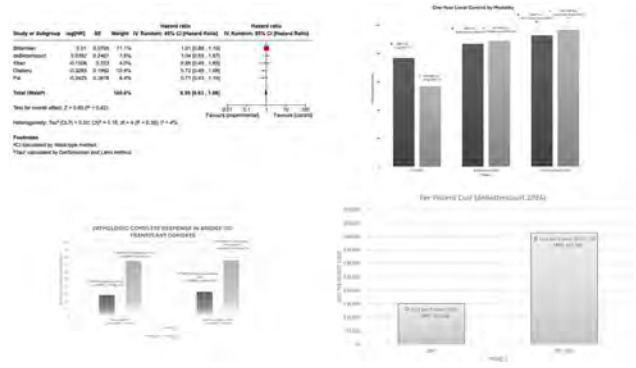
4219 | STEROTACTIC BODY RADIATION THERAPY VERSUS YTTRIUM-90 TRANSARTERIAL RADIOEMBOLIZATION FOR HEPATOCELLULAR CARCINOMA: A SYSTEMATIC REVIEW AND META-ANALYSIS



Bilind Ismail[1] Hasan Al-Obaidi[2] Hayder Alamily[2] Abdulkareem Jomaa[3] Muhammad Tausif[4] Zoha Khan[5] Hrishikesh Samant[6], [1]Willis Knighton Health, [2]University of Toledo, [3]University of Duhok College of Medicine, [4]Willis-Knighton Health, [5]Rawalpindi Medical University, [6]Ochsner Clinic Foundation

Background: Hepatocellular carcinoma (HCC) is the most common primary liver cancer. Considering the recent advances, locoregional therapy in the management of liver-confined disease is increasing. Among the various options, stereotactic body radiation therapy (SBRT) and yttrium-90 (Y90) transarterial radioembolization (TARE) are becoming popular for disease control and bridging to transplant. **Methods:** We performed a PRISMA 2020-compliant systematic review and meta-analysis of PubMed, EMBASE, MEDLINE, and Cochrane CENTRAL from 2010 to May 2026. Eligible studies directly compared SBRT and Y90 TARE for HCC at any BCLC stage. Primary outcomes were overall survival (OS) and local control. Secondary outcomes were progression-free survival (PFS), complete response in bridge-to-liver-transplant cohorts, grade ≥ 3 toxicity, and per-patient cost when reported. Pooled

estimates were calculated in RevMan. Risk of bias was assessed by ROBINS-I and certainty by GRADE. **Results:** Nine studies were included (N ≈ 12,747). Patient and disease characteristics differed widely across studies, which limits comparability. Five studies reported adjusted HRs for OS were Pai 2025 (n = 247), 0.71 (95% CI 0.43-1.20); Oladeru 2016 (n = 189), 0.72 (0.49-1.07); Khan 2026 (n = 9,084, indirect), 0.86 (0.45-1.66); Bitterman 2019 (n = 2,685), 1.01 (0.88-1.16); and deBettencourt 2024 (n = 84), 1.04 (0.65-1.67). The pooled random-effects HR for OS was 0.95 (95% CI 0.83-1.08, $I^2 = 4\%$), with no statistically significant difference between modalities. Local control varied widely (57-97%) without a consistent modality advantage after adjustment. PFS was similarly neutral (HR 0.96, 0.61-1.50). In bridge-to-transplant cohorts, Y90 TARE produced higher rates of complete tumor necrosis at explant, 75% vs. 28.5% (Mohamed 2016) and 76% vs. 33% (De la Garza-Ramos 2025). Grade ≥3 toxicity was uncommon and similar where it was reported. One institutional cost analysis suggested lower per-patient costs with SBRT ($15,148 vs. $41,360 for Y90), though downstream costs were not evaluated. Risk of bias was serious across all studies. GRADE certainty was very low for all outcomes. **Conclusion:** Across available comparative studies, SBRT and Y90 TARE showed no statistically significant differences in adjusted or pooled OS, local control, or PFS. The most consistent finding was in bridge-to-transplant populations, where Y90 TARE produced higher rates of complete tumor necrosis in both series that reported it. Limited cost data favored SBRT per patient, though downstream costs were not captured. In the absence of randomized evidence, treatment selection should be individualized based on transplant strategy, tumor burden, liver reserve, and multidisciplinary expertise. Ongoing trials including BIIRTH (NCT07293468) and NCT07530172 are actively enrolling and will provide the first randomized comparative data.

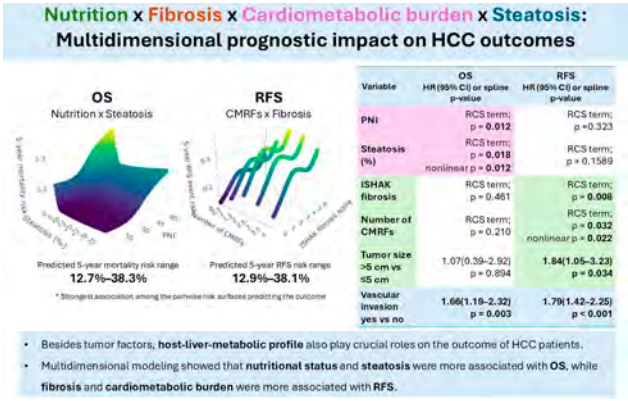
4220 | MULTIDIMENSIONAL PROGNOSTIC STRATIFICATION INTEGRATING NUTRITION, FIBROSIS, STEATOSIS, AND CARDIOMETABOLIC BURDEN FOR HEPATOCELLULAR CARCINOMA PATIENTS UNDERGOING CURATIVE RESECTION



Chun-Ting Ho[1] Shin-Yu Tsai[2] Chia-Jung Ho[3] Yi-Hsiang Huang[2] Ming-Chih Hou[2] Jaw-Ching Wu[4] Chien-Wei Su[2], [1]Taipei Veterans General Hospital/NYCU, [2]Taipei Veterans General Hospital, [3]Taichung Veterans General Hospital, [4]National Yang Ming Chiao Tung University

Background: Besides tumor factors, the prognosis of hepatocellular carcinoma (HCC) patients after curative resection can also be influenced by host factors, including nutritional reserve, fibrosis severity, hepatic steatosis, and cardiometabolic risk factors (CMRFs). However, their joint prognostic impact has not been well evaluated. We aim to comprehensively evaluate the joint prognostic impact of nutrition, fibrosis, steatosis, and cardiometabolic burden on HCC patients undergoing surgical resection. **Methods:** 1004 HCC patients undergoing curative resection at a tertiary center in Taiwan were analyzed. Four host–liver–metabolic domains were evaluated: nutritional status using the prognostic nutritional index (PNI), fibrosis severity using the ISHAK fibrosis grade, hepatic steatosis using histologic steatosis percentage, and cardiometabolic burden using the number of comorbid CMRFs. Multivariable Cox proportional (COX PH) hazardous models adjusted for age, gender, tumor size, tumor number, vascular invasion, Child–Pugh class, and viral etiology were performed to identify independent prognostic factors. Restricted cubic splines (RCS) were used to model potential nonlinear associations. Pairwise 3D risk surfaces/bands of the four domains were generated to visualize the 5-year outcome risks. **Results:** After a median follow-up of 55 months, 210 patients had died. The 5-year overall survival (OS) was 71.4%, and the 5-year recurrence-free survival (RFS) was 48.9%. The COX PH models for OS and RFS including the four domains were both statistically significant with good discrimination (likelihood ratio χ^2 = 103.64 and 106.44, both $p < 0.001$; approximate C-index = 0.716 and 0.673). Among the four domains, nutritional status was significantly associated with OS (χ^2 = 10.88, p = 0.012), and steatosis demonstrated a significant nonlinear association with OS (χ^2 = 10.10, p = 0.018; nonlinear p = 0.012). Vascular invasion was also associated with worse OS. Regarding RFS, Ishak fibrosis grade was identified as an independent risk factor (χ^2 = 11.72, p = 0.008), as well as

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

cardiometabolic burden (χ^2 = 6.88, p = 0.032), tumor size, and vascular invasion. In adjusted risk-surface visualization, the PNI and steatosis surface demonstrated the greatest discriminability for 5-year OS, whereas the fibrosis and CMRF surface showed the most prominent gradients for 5-year RFS event risk. **Conclusion:** Nutrition, fibrosis, steatosis, and cardiometabolic burden play important roles in the prognosis of HCC patients. While nutrition and steatosis were more closely associated with OS, fibrosis and cardiometabolic burden were more relevant to RFS. Adjusted 3D risk-surface visualization demonstrated a clinically interpretable and heterogeneous multi-dimensional prognostic landscape. These findings revealed the diverse impact of host-liver-metabolic factors on the outcome of HCC patients undergoing curative resection.

4221 | LONGITUDINAL PLASMA PROTEIN DYNAMICS ASSOCIATED WITH SURVIVAL IN INTERMEDIATE-STAGE HEPATOCELLULAR CARCINOMA TREATED WITH TACE FOLLOWED BY DURVALUMAB AND TREMELIMUMAB

Boqun Zhu[1] Harry Luu[1] Leya Chambo[1] Aida Kamalian[1] Abhay Moghekar[1] Hong Kelvin[1] Ana De Jesus-Acosta[1] Amy Kim[1], [1]Johns Hopkins University School of Medicine

Background: Combining transarterial chemoembolization with immune checkpoint blockade is an emerging strategy for intermediate-stage hepatocellular carcinoma (HCC), but biomarkers that guide patient selection and predict clinical outcomes remain limited. We evaluated longitudinal plasma protein changes to identify candidate biomarkers associated with 1-year survival and overall survival (OS) in patients with Barcelona Clinic Liver Cancer (BCLC) stage B disease treated with TACE followed by dual immunotherapy. **Methods:** In a phase II trial (NCT03638141), 20 patients with unresectable, transplant-ineligible BCLC stage B HCC were enrolled, and included in this analysis. Patients received TACE followed by durvalumab and tremelimumab. Plasma samples were collected at baseline (W0, pre-treatment), Week 2 after TACE (W2), Week 8 after 1 cycle of immunotherapy (W8), and end of treatment (EOT). Samples were profiled for 92 immune-oncology proteins (Olink's proximity extension assay). Protein abundance was reported as normalized protein expression (NPX) values. Plasma protein dynamics were evaluated according to 1-year survival status and overall survival (OS). For survival analyses, protein change was defined as W8 minus W0 NPX values. Patients were stratified into high- and low-change groups using the median change value for each marker. **Results:** Among 20 patients, four patients had died by 1 year after TACE. Compared with 1-year survivors, patients who died within 1 year had higher W8 plasma levels of GZMB, GZMA, IL18, and VEGFA. These patients also demonstrated greater increases in GZMB, GZMA, IL18, and VEGFA from W0 to W8 compared to1-year survivors (Fig 1). Patients were further stratified into high- and low-GZMB/GZMA/IL18 groups using their median W0-to-W8 change. High increases in GZMB, GZMA, or IL18 were each associated with significantly worse overall survival compared with low-change groups. **Conclusion:** Early increases in GZMB, GZMA, and IL18 from W0 to W8 identified a high-risk group with higher 1-year mortality and worse overall survival. These findings may indicate robust but ineffective immune activation rather than effective tumor control early after treatment and may enable early risk stratification for poor outcomes.

4222 | TRANSARTERIAL CHEMO- VERSUS RADIO-EMBOLIZATION FOR EARLY AND INTERMEDIATE STAGE HEPATOCELLULAR CARCINOMA (HCC): A CLINICAL AND COST COMPARISON ANALYSIS IN A NATIONAL COHORT

Meena Tadros[1] Courtney Williamson[2] Shalini Bansal[3] David Kaplan[1], [1]University of Pennsylvania, [2]Corporal Michael J Crescenz Philadelphia VA Medical Center, [3]The Mount Sinai Hospital

Background: Trans-arterial chemo- and radioembolization (TACE and TARE) are primary treatment modalities for early- and intermediate-stage hepatocellular carcinoma (HCC). Prior studies, primarily from tertiary academic centers, comparing outcomes and cost for TACE and TARE have shown mixed results. We aimed to directly compare TACE and TARE clinical and cost effectiveness in a non-tertiary setting in a national Veterans Affairs (VA) cohort. **Methods:** We reviewed patients with HCC diagnosed from 1/1/2021 to 4/1/2021 who underwent first-line (1L) TACE or TARE for HCC within the VA system. Severity of liver disease, tumor characteristics including Barcelona Clinic Liver Cancer (BCLC) staging, ECOG performance status, treatment history/response (LI-RADs), clinical outcomes and costs (VA HERC and DSS) were collected. Survival was evaluated by Kaplan-Meier methodology, with adjustment for unbalanced baseline covariates. **Results:** We identified 121 patients who received 1L TACE (n = 94) or TARE (n = 27). Median age was 69.4, 99.2% were male, 59.5% were White, 19.8% Black and 12.4% Hispanic. Predominant underlying liver disease was ALD ± HCV with 22% MASH. Child-Pugh A5/A6/B7/B8+ status was 58/19/12/11%. There was no statistical difference in BCLC Stage between TACE and TARE patients, with similar median tumor number. Patients selected for TARE had larger size of the largest tumor (4.0 vs. 2.7 cm, p = 0.0009, and total tumor diameter (4.6 vs. 2.9 cm, p = 0.0055). ALBI grade was more likely to be 2A among TARE patients (p = 0.04). Pre-treatment AFP was also higher for patients undergoing TARE (44.5 vs.10.0 p = 0.0049). During follow-up, response rates by LI-RADs were similar among TACE and TARE patients, with LR-TR nonviable status achieved in 46.2%. The median total number of treatments received did not differ, p = 0.84. Median survival was 960d (95% CI 810-1650) for TACE and 570d (95% CI 360-NA) for TARE, p = 0.44. In unadjusted Cox analysis and analyses adjusted for tumor size, AFP, and ALBI grade, there was no significant difference in the risk of mortality between TACE and TARE. There was no significant difference in the likelihood of worsening Child-Pugh or ALBI score during 1 year of follow-up. Median cost of healthcare in the first year of follow-up did not differ between TACE and TARE, $136K vs. $141K, however there was trend towards higher inpatient cost for TACE patients $24.9K vs. $8.5K, p = 0.07 (Table 1). **Conclusion:** In this preliminary cohort with ongoing data collection, there were no significant differences in survival, liver function, or total healthcare costs when TACE or TARE was first line therapy for early or intermediate stage HCC. Further analysis with propensity matching, stage stratification, and generalized linear modeling for cost to assess the average marginal cost of treatment choice is planned.

Table 1. Baseline Characteristics of Patients Receiving Locoregional Therapy for HCC and Subsequent Costs (n=121)

Variable		Overall	TACE	TARE	p-value
n		121	94	27	
Age at Treatment (years) (median [IQR])		69.40 [65.60, 73.90]	69.00 [65.67, 73.80]	70.30 [65.90, 74.10]	0.70

4223 | CONSISTENT GASTROENTEROLOGY/LIVER CLINIC FOLLOW-UP IS THE STRONGEST PREDICTOR OF HEPATOCELLULAR CARCINOMA SURVEILLANCE AMONG ADULTS WITH CIRRHOSIS

Robert Wong[1] Bolin Niu[2] Mandana Khalili[3] Paulo Pinheiro[4] Mae Thamer[5] Onkar Kshirsagar[5] Yi Zhang[5] Ronnie Fass[2] Jasmine Davis[4] Lisa Quirk[6] George Therapondos[7] Amit Singal[6] Patricia Jones[8], [1]Stanford/VA Palo Alto Healthcare System, [2]MetroHealth Medical Center, [3]University of California, San Francisco, [4]University of Miami, [5]Medical Technology and Practice Patterns Institute, [6]University of Texas Southwestern, [7]Ochsner Health System, [8]University of North Carolina at Chapel Hill

Background: Guideline-concordant surveillance for hepatocellular carcinoma (HCC) in patients with cirrhosis improves HCC detection at an earlier stage. However, HCC surveillance remains underutilized in real-world settings, contributing to a more advanced tumor stage at diagnosis. We evaluated gaps in HCC surveillance prior to HCC diagnosis, and whether modifiable factors could be identified to improve surveillance. **Methods:** Adults with cirrhosis who were diagnosed with HCC from 3/1/2018 – 2/29/2024 across four U.S. safety-net health systems were evaluated. HCC surveillance in the 12 months prior to HCC diagnosis was assessed by the 1) proportion having semiannual surveillance imaging and 2) proportion of time covered (PTC), estimated by dividing the number of covered months (6 months of coverage applied to each completed surveillance exam) that fell within this 12- month period by 12. Adjusted multivariable logistic regression and linear regression models evaluated predictors of semiannual surveillance and PTC, respectively. **Results:** A total of 622 adults with HCC were identified (mean age 61.8y, 74.6% men, 46.0% Hispanic, 28.8% non-Hispanic white, 16.1% African American, 1.0% Asian, 33.3% Medicare, 25.4% Medicaid, 12.2% uninsured/indigent care). At HCC diagnosis, 14% had very early BCLC stage 0 and 62.9% within Milan criteria. In the 12 months prior to HCC diagnosis, 12.5% received semiannual surveillance, which was higher in men (vs. women), highest in adults age 40-49y, and highest in those with Medicaid or uninsured/indigent care (Figure). Overall, mean PTC was 16.9% (mean 2.03 months), which was higher in men vs. women, highest in adults age 40-49y, highest in Asians, and highest in those with indigent care or uninsured (Figure). On multivariable regression, only linkage to GI/Liver clinic ($\geq$1 visit within past 12 months) was significantly associated with semiannual HCC surveillance. Compared to patients who did not have GI/Liver visit, those who did had significantly greater odds of semiannual surveillance (aOR 7.08, 95% CI 3.94-12.70) and significantly greater PTC (3.80 vs. 1.80 months in those without GI/Liver clinic follow up, $p < 0.01$) prior to HCC diagnosis. **Conclusion:** Among a multi-center safety-net cohort of cirrhosis patients who developed HCC, major gaps in surveillance were observed. Patients who were engaged into GI/Liver care were significantly more likely to have had HCC surveillance prior to HCC diagnosis, emphasizing the importance of improved engagement with primary care and ensuring consistent GI/Liver follow-up in those with access to liver care.

Figure. Proportion Receiving Semiannual Surveillance and Proportion Time Covered by Surveillance in the 12 Months Preceding HCC Diagnosis

4224 | CLINICAL PREDICTORS OF IMMUNE CHECKPOINT INHIBITOR RESPONSE IN ADVANCED CHOLANGIOCARCINOMA: ANALYSIS FROM A MULTI-SITE TERTIARY CARE CENTER

Sarah Khan[1] Diana Segovia[1] Jessie Hohenstein[1] Qian Shi[1] Chen Wang[1] Lewis Roberts[2], [1]Mayo Clinic-Rochester, [2]Mayo Clinic Rochester

Background: Cholangiocarcinoma (CCA) is a highly lethal malignancy whose prognosis remains dismal, partly due to unpredictable response to systemic therapies including first-line immune checkpoint inhibitors (ICI). This analysis aims to characterize predictors of ICI response in advanced CCA. **Methods:** Patients with CCA treated across the tri-site Mayo Clinic from 2018-2025 were evaluated. Clinical variables were investigated, including patient characteristics, tumor molecular data and oncologic course. ICI response was classified per RECIST criteria using 3–6-month surveillance imaging scans, with development of a disease-controlled cohort (DC) (stable disease, partial or complete response) and non-responder cohort (progressive disease). **Results:** Our final cohorts included 60 ICI responders (DC; 65.9%) and 31 non-responders (NR; 34.1%). The cohort was predominantly Caucasian (96.7%), of median age 65.6 years and with slight female predominance (56.0%). Median overall survival from diagnosis was 4.3 years in DC versus 1.4 years in NR ($p = 0.05$), with 43.3% of DC versus 96.8% of NR dying during follow-up ($p < 0.001$; figure 1A). Median progression-free survival was 2.5 years for DC vs 0.9 years for NR ($p < 0.001$, figure 1B). CCA subtypes included intrahepatic ($n = 55$), perihilar ($n = 28$), and distal CCA ($n = 8$), without significant difference between groups. The dominant first-line regimen was durvalumab-based (76.7% DC vs. 77.4% NR), followed by pembrolizumab (16.7% DC vs 16.1% NR), and no significant difference in regimens between cohorts ($p = 0.896$). Compared to metastatic disease (M1), patients with M0 disease were more likely to be DC (75.5% vs 24.5%, $p = 0.04$). DC patients more frequently had surgical resection (79.4% vs 20.6%, $p = 0.04$, figure 1C) and second-line immunotherapy (21.1% vs. 0%, $p = 0.006$). Survival difference persists between DC and NR when comparing non-surgical canidates. No differences were present in microsatellite instability or histologic grade. Patients with IDH1 mutations were less likely to respond to ICI, while those with CDKN2A mutations were more likely (OR 0.20, $p = 0.04$ for IDH1 and OR 7.20, $p = 0.072$ for CDKN2A). Multivariable regression identified M1 disease as a predictor of non-response (M1 OR 0.26, $p = 0.02$). Models adjusting for pre-treatment tumor size, multifocal disease, M1, tumor mutation burden and serum CA19-9 achieved AUC 0.73 (95% CI 0.51-0.95) and 0.79 (95% CI 0.65-0.94) for extrahepatic and intrahepatic ICI response prediction (figure 1D). **Conclusion:** Our analysis identifies important predictors of ICI response including M1 status and IDH1 mutations. Models revealed these characteristics were more predictive than most molecular tumoral characteristics, though sample size is a limitation. These findings are critical for improving precise prognostication of CCA patients.

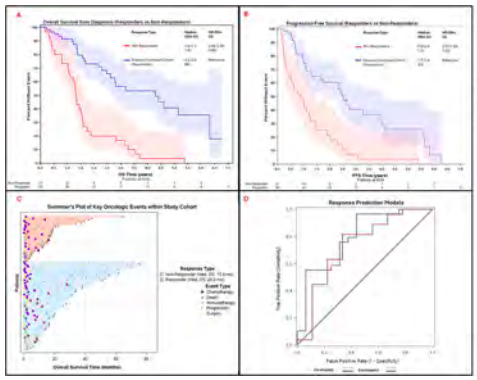

Figure 1:
A. Overall survival comparison by immune checkpoint inhibitor response type between disease-controlled cohort (DC, i.e., responders) vs non-responders (NR).
B. Progression-free survival comparison of DC vs NR.
C. Swimmer's plot detailing oncologic courses of DC and NR.
D. Areas under the curve for clinical models predicting ICI response for intrahepatic and extrahepatic (perihilar and distal) CCA.

4225 | TRENDS IN INTRAHEPATIC CHOLANGIOCARCINOMA MORTALITY AND SHIFTING COMORBIDITY PROFILE IN THE UNITED STATES, 1999–2020: A POPULATION-BASED MULTIPLE CAUSE OF DEATH ANALYSIS

Kanachai Boonpiraks[1] Kyle Yuquimpo[1] Nizar Talaat[1], [1]University of Kansas Medical Center

Background: Intrahepatic cholangiocarcinoma (ICC) is the second most common primary liver malignancy, with rising US incidence and mortality. The comorbidity profile of ICC decedents has not been systematically characterized, despite growing concern that metabolic dysfunction-associated steatotic liver disease (MASLD) may be an emerging risk factor for liver cancer. Hence, we aim to evaluate liver-related co-lisitng deaths to gain proper population-level insight. **Methods:** We conducted a retrospective, population-based mortality study using the CDC WONDER Multiple Cause of Death databases (1999–2020 finalized and 2018–2023 expanded for fatty liver). We identified all decedents with ICC (ICD-10 C22.1) as underlying cause. Age-adjusted mortality rates (AAMR) per 100,000 (2000 US standard population) were calculated and stratified by sex, race, and Hispanic origin. Joinpoint regression model was used to estimate annual percent change (APC) with 95% confidence interval (CI). We identified ICC deaths co-listing diabetes (E10–E14), cirrhosis (K74), chronic hepatitis C (B18.2), alcoholic liver disease (K70), or fatty liver disease (K76.0), and assessed temporal trends in proportions. **Results:** A total of 107,149 ICC deaths occurred from 1999–2020. AAMR rose from 0.9 to 1.9 per 100,000 (APC 3.67%, 95% CI 3.29–4.00, $p < 0.001$), with no joinpoints. African American individuals had the steepest racial increase (APC 4.08%), while Asian/Pacific Islanders maintained the highest absolute AAMR. Males had consistently higher absolute mortality rates than females. The comorbidity profile shifted markedly throughout the following period as shown in Figure 1. Cirrhosis co-listing nearly tripled (0.98% to 2.89%) with acceleration after 2008 (APC 7.48%, $p = 0.011$). Alcoholic liver disease grew at 9.66%/year ($p = 0.015$). Hepatitis C showed an interesting trend of significant rise through 2014 then a decline from 2014-2017, followed by a rebound. Diabetes increased modestly (APC 1.12%, $p < 0.001$). Fatty liver disease data was absent before 2017. However, it rose from 14 to 42 annual ICC deaths during 2017–2023 putting it as the steepest comorbidity trend observed in the study (APC 18.40%, 95% CI 12.63–26.47, $p < 0.001$). **Conclusion:** ICC mortality continues to rise in the US with significant racial disparities. The comorbidity profile of ICC decedents is shifting toward metabolic and alcohol-associated liver disease, most strikingly with fatty liver disease. This could reflect the growing population burden of MASLD. These findings support heightened clinical awareness of MASLD-related liver cancer risk and may inform surveillance strategies.

Figure 1. Relative trends in intrahepatic cholangiocarcinoma (ICC) mortality and co-listed comorbidities, United States, 1999–2023

Each line is the joinpoint-modeled trend, indexed to 100 at that series' first analyzed year (ICC mortality, diabetes & cirrhosis 1999; hepatitis C 2003; alcoholic liver disease 2010; fatty liver disease 2017). Comorbidity lines show the proportion of ICC deaths co-listing each condition (1999–2020); fatty liver shows the crude ICC death rate co-listing K76.0 (2011–2023, provisional). Indexing places all series on one scale so relative change is directly comparable.

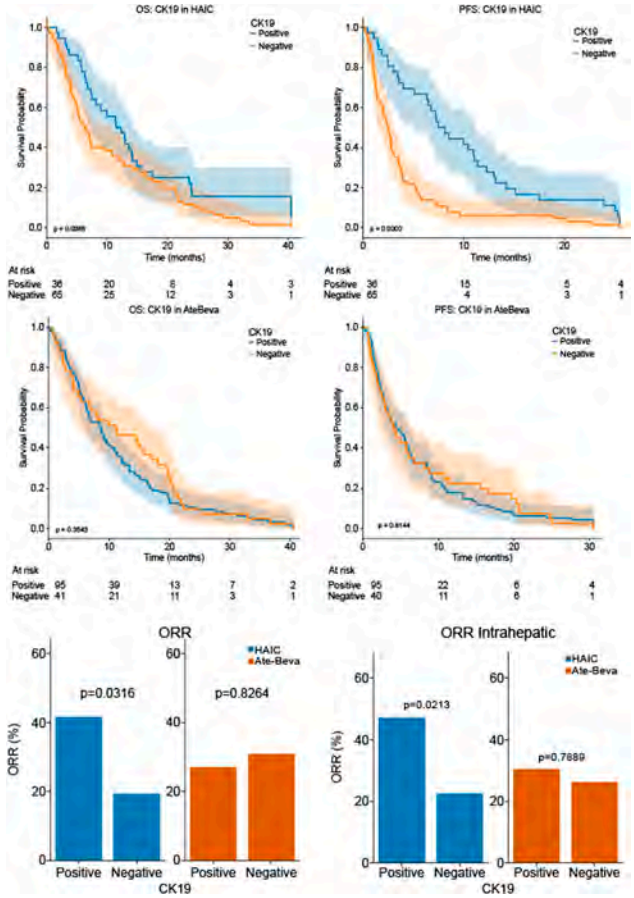
4226 | CYTOKERATIN 19 EXPRESSION STRATIFIES OUTCOMES WITH HEPATIC ARTERIAL INFUSION CHEMOTHERAPY BUT NOT ATEZOLIZUMAB PLUS BEVACIZUMAB IN ADVANCED HEPATOCELLULAR CARCINOMA



Pil Soo Sung[1], [1]Seoul St Mary's Hospital

Background: Cytokeratin 19 (CK19)-positive hepatocellular carcinoma (HCC) exhibits biliary/progenitor features and aggressive biology, raising uncertainty regarding the optimal therapeutic strategy for this subgroup. We evaluated the prognostic and predictive value of CK19 expression according to treatment modality in patients with advanced HCC treated with hepatic arterial infusion chemotherapy (HAIC) or atezolizumab plus bevacizumab. **Methods:** We retrospectively analysed consecutive patients with advanced HCC who received atezolizumab plus bevacizumab or HAIC between January 2020 and July 2025. Only patients with available tumour biopsy and immunohistochemical assessment of CK19 were included. Overall survival (OS) and progression-free survival (PFS) were compared by CK19 status within each treatment group using Kaplan-Meier analysis and log-rank testing. Objective response rate (ORR), including overall and intrahepatic responses, was evaluated by radiologic assessment, excluding non-evaluable cases. Categorical variables were compared using chi-square tests. **Results:** We included 136

patients treated with atezolizumab plus bevacizumab (CK19-positive n = 95; CK19-negative n = 41; median follow-up 8.7 months) and 101 treated with HAIC (CK19-positive n = 36; CK19-negative n = 65; median follow-up 7.4 months). In the atezolizumab plus bevacizumab group, OS and PFS did not differ by CK19 status (OS p = 0.3643; PFS p = 0.8144), and ORR was similar for both overall (p = 0.8264) and intrahepatic responses (p = 0.7889). In contrast, in the HAIC group, CK19-positive tumours showed improved OS and PFS compared with CK19-negative tumours (OS p = 0.0365; PFS p < 0.0001). ORR was higher in CK19-positive than CK19-negative tumours after HAIC for both overall response (41.7% vs 19.4%, p = 0.0316) and intrahepatic response (47.2% vs 22.6%, p = 0.0213). **Conclusion:** CK19 expression identifies a subgroup of advanced HCC with differential outcomes following HAIC, whereas outcomes with atezolizumab plus bevacizumab were not stratified by CK19 status. CK19 assessment may support biomarker-informed selection of HAIC in advanced HCC, warranting prospective validation.

Disclosures: Pil Soo Sung:Nothing to Disclose.

4227 | COST-EFFECTIVE AGE THRESHOLDS FOR HEPATOCELLULAR CARCINOMA SURVEILLANCE IN PATIENTS WITH CIRRHOSIS ACROSS ETIOLOGIES AND COMORBIDITIES

Szu-Yu Kao[1] David Hutton[2] Neehar Parikh[3] Amit Singal, [1]Siemens Medical Solutions, [2]University of Michigan, [3]University of Michigan Medical Center

Background: The net benefit of hepatocellular carcinoma (HCC) surveillance likely varies by liver disease etiology, liver disease severity, and burden of non-liver comorbidity. However, in contrast to other cancer screening programs, stopping rules based on age and comorbiditity have not been defined. We aimed to determine ages to start and stop HCC surveillance in Child-Pugh A cirrhosis, including any variation in thresholds across etiology and comorbidity, through cost-effectiveness analysis. **Methods:** We developed a microsimulation model for cirrhosis, following 1 million patients with Child-Pugh A cirrhosis in semiannual cycles over their lifetimes. The population was stratified into 12 subgroups based on cirrhosis etiology (viral, MASLD, alcohol with active use) crossed with Charlson Comorbidity Index (CCI) categories (0, 1-2, 3-4, ≥5). Etiology affected HCC incidence and all-cause mortality, and higher CCI increased all-cause mortality. We compared 15 semiannual surveillance strategies across starting ages of 50-70 and stopping ages of 60-80, with a minimum 10-year duration. From a healthcare-sector perspective, we estimated lifetime direct medical costs and quality-adjusted life-years (QALYs) in each subgroup vs. no surveillance as the comparator. A strategy was cost-effective if it produced the most QALYs while keeping the incremental cost-effectiveness ratio (ICER) below a willingness-to-pay threshold of $150,000 per QALY gained. **Results:** Surveillance strategies with earlier starting ages and longer durations detected more HCC cases than those with later starting ages and shorter durations. Early-stage HCC detection rose from 12-13% without surveillance to as high as 66% with surveillance. However, early-stage detection was lower among patients with high comorbidity (CCI ≥3) than those with lower comorbidity (CCI 0 or 1-2), particularly for strategies with later starting ages and shorter durations. Surveillance was cost-effective for patients with low comorbidity. The cost-effective durations of surveillance differed by etiology. Specifically, across low comorbidity subgroups, the cost-effective starting age was 50 and the stopping age ranged from 70 to 80, with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

ICERs varying between $137,653 and $149,929 per QALY gained (**Table**). Surveillance was not cost-effective for patients with high comorbidity, regardless of etiology. **Conclusion:** Cost-effective HCC surveillance age thresholds in Child-Pugh A cirrhosis depend on liver disease etiology and comorbidity. Surveillance was cost-effective for patients with low comorbidity, with varying starting and stopping ages by etiology, but not for those with high comorbidity, in whom competing mortality outweighed the benefit. These findings support risk-stratified rather than one-size-fits-all HCC surveillance recommendations based on patient comorbidity and age.

4228 | SYSTEM-LEVEL BOTTLENECKS ACROSS THE HCC CARE CASCADE IN LATIN AMERICA

Pablo Coste[1] Luis Díaz[2] Marco Arrese[2] Wagner Ramirez[1] Francisco Vargas Navarro[3] Maria Fernanda Lynch-Mejia[1] Federico Piñero[4] Manuel Mendizabal[5] Maria Reig[6] Jeffrey Lazarus[7] Margarita Anders[8] Josemaría MenendezDutra[9] Juan Pablo Arab[10], [1]Liver Unit, Hospital Rafael Ángel Calderón Guardia, LiverLab CR, San José, Costa Rica, [2]Pontificia Universidad Católica de Chile, Santiago, Chile, [3]Hospital RA Calcderón Guardia, [4]Hepatology and Liver Transplant Unit, Hospital Universitario Austral, Buenos Aires, Argentina, [5]Hospital Universitario Austral, [6]Director, Liver Cancer Unit, Consultant Liver Unit - Hospital Clínic Barcelona, [7]University of Barcelona, [8]Hepatology and Liver Transplantation Unit. Alemán Hospital, Buenos Aires, Argentina., [9]Liver Transplantation National Program, Hospital Militar, Montevideo, Uruguay., [10]Virginia Commonwealth University

Background: Hepatocellular carcinoma (HCC) outcomes depend on healthcare system performance across the care cascade, yet operational assessments of system-level capacity remain scarce in Latin America. **Methods:** We conducted a multinational cross-sectional analysis including 20 Latin American countries. Twenty variables were operationalized into six predefined domains: fibrosis detection, surveillance, diagnosis, multidisciplinary care (MDT), curative treatment, and non-curative treatment. Data were compiled through expert-based country validation and publicly available healthcare system indicators. Variables were coded using a predefined ordinal scale reflecting implementation and accessibility, and normalized into 0–100 domain scores. System-level bottlenecks across the HCC care cascade were evaluated descriptively. **Results:** Marked heterogeneity in HCC care capacity was observed across the region, with total scores ranging from 0 to 85.4. Higher-performing systems demonstrated preserved diagnostic and treatment capacity, whereas lower-performing countries exhibited widespread deficiencies across all domains. Upstream deficiencies in fibrosis detection and linkage to care persisted even among higher-performing systems with otherwise preserved downstream therapeutic capacity. In contrast, curative treatment access, particularly liver transplantation, represented the principal limitation among intermediate-performing systems. A progressive gradient of healthcare system capacity was observed across the HCC care cascade. **Conclusion:** HCC care capacity across Latin America appears constrained primarily by upstream deficiencies in fibrosis detection and surveillance, even in systems with preserved downstream therapeutic capacity. These findings support integrated system-level strengthening strategies centered on early detection and structured HCC care pathways.

Figure 1. HCC care cascade performance across Latin America. Domain-specific scores (0–100) are shown for each country across six domains: fibrosis detection, surveillance, diagnosis, multidisciplinary care (MDT), curative treatment, and non-curative treatment. Countries are ordered by overall performance (total score). Colors represent level of system capacity (red: low [0–39]; yellow: intermediate [40–69]; green: high [≥70]). The primary bottleneck for each country is defined as the lowest-scoring domain, in case of ties, the most upstream domain was selected. A clear gradient of system performance is observed, ranging from countries with preserved downstream capacity but persistent upstream deficiencies to those with widespread limitations across all domains.

4229 | IMPACT OF PRIOR AND CURRENT TREATMENT RESPONSES ON SURVIVAL OUTCOMES DURING SEQUENTIAL SYSTEMIC THERAPY AFTER ATEZOLIZUMAB PLUS BEVACIZUMAB IN UNRESECTABLE HEPATOCELLULAR CARCINOMA

Ji won Yang[1] Sung Won Chung[2] Jeayeon Park[3] Byeong Geun Song[4] Jihyun An[5] Eun Sun Jang[6] Su Jong Yu[7] Ju Hyun Shim[2], [1]Department of Gastroenterology, Liver Center, Asan Medical, [2]Department of Gastroenterology, Liver Center, Asan Medical Center, University of Ulsan College of Me, [3]Department of Gastroenterology, Ajou University School of Medicine, Suwon, Republic of Korea, [4]Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, R, [5]Department of Gastroenterology, Hanyang University Guri Hospital, Hanyang University College of Medi, [6]Seoul National University College of Medicine, [7]Seoul National University Hospital

Background: As survival outcomes improve, sequential systemic therapies after atezolizumab plus bevacizumab (Atezo/Bev) failure are increasingly performed in patients with unresectable hepatocellular carcinoma (uHCC). However, real-world treatment patterns and prognostic factors during subsequent systemic treatment lines remain unclear. We evaluated sequential treatment patterns and prognostic factors associated with survival outcomes during subsequent systemic therapies following Atezo/Bev failure in patients with uHCC. **Methods:** In this retrospective cohort study, we evaluated second- and third-line treatment patterns and survival outcomes in patients with uHCC who received at least one dose of Atezo/Bev (May 2022–December 2023) and subsequent systemic therapies. Overall survival (OS) and progression-free survival (PFS) were compared according to prior and current treatment responses (PD vs. non-PD) among patients who underwent at least one response evaluation during each treatment line. Prognostic factors associated with survival outcomes after subsequent systemic therapies were analyzed using Cox proportional hazards models. **Results:** Among 466 patients who received subsequent treatment after first-line Atezo/Bev, 388 and 148 patients were included in the second- and third-line systemic therapy cohorts, respectively. In the second-line setting, Lenvatinib was the most used systemic therapy (> 50%) and showed significantly longer PFS than sorafenib, while OS was comparable between two groups. Second-line non-PD group showed significantly longer OS and PFS than PD group (mOS: 9.6 vs. 3.9 months; mPFS: 5.3 vs. 1.4 months; *Ps* < 0.001). In the third-line settings, tyrosine kinase inhibitors (TKIs) predominated and showed comparable survival outcomes with immune checkpoint inhibitors (ICIs) (mOS: 6.1 vs. 4.0 months; mPFS: 1.6 vs. 1.7 months; *Ps=NS*). Furthermore, third-line non-PD group also showed significantly higher survival outcomes (mOS: 9.0 vs. 4.5 months; mPFS: 4.8 vs. 1.4 months; *Ps* < 0.001). In Cox proportional models, survival outcomes during sequential systemic therapy were more strongly associated with response to the current treatment line than with prior treatment response. **Conclusion:** In this Korean real-world study, TKIs remained the predominant subsequent systemic therapies after first-line Atezo/Bev for uHCC. Subsequent systemic therapies may be more strongly influenced by response to the current treatment line than with prior treatment response. Active sequential systemic therapy may

therefore provide a survival benefit, irrespective of the initial response of first-line Atezo/Bev.

4230 | RISK FACTORS AND OUTCOMES ASSOCIATED WITH MIXED HEPATOCELLULAR-CHOLANGIOCARCINOMA (HCC-CCA) IDENTIFIED AT TIME OF LIVER TRANSPLANT

Mahip Grewal[1] Yuan Zhang[1] Meaghan Phipps[1],
[1]Columbia University Irving Medical Center

Background: Frequently misdiagnosed on imaging, mixed hepatocellular-cholangiocarcinoma (HCC-CCA) cases are heterogeneous and rare. HCC-CCAs often exhibit intermediate outcomes, though such findings are confounded by diagnostic delays and a lack of standardized management. The purpose of this study was to investigate the prevalence, risk factors, and outcomes associated with HCC-CCA. **Methods:** A retrospective analysis of patients with HCC or HCC-CCA confirmed on explant at a large academic medical center from 1998 – 2025 was conducted. Via chart review, data pertaining to patient characteristics, pre-liver transplant (LT) diagnostics, tumor characteristics, and post-LT outcomes were collected. **Results:** On explant, there were 728 patients with HCC and 24 patients with HCC-CCA. 21 of the HCC-CCA patients were pre-operatively diagnosed with HCC; the others were transplanted for cirrhosis without a tumor diagnosis. HCC and HCC-CCA patients were similar with respect to demographics, MELD score, time on the waitlist, and rates of pre-LT locoregional therapy. The mean maximum CA 19-9 level among HCC-CCA patients was low at 17; the mean AFP level was 254 among HCC-CCA patients versus 388 among HCC patients (p = 0.47). Among those ultimately found to have HCC-CCA, 4 patients (17%) had pre-LT lesional biopsy consistent with HCC alone. MRI was the final imaging modality pre-LT for 80% of HCC patients and 76% of HCC-CCA patients (p = 0.52). On explant, 41% of HCC-CCA cases met Milan criteria versus 70% of HCC cases (p = 0.003). A significantly higher proportion of HCC-CCA tumors were moderately or poorly differentiated (p = 0.002), and HCC-CCA tumors exhibited higher rates of microvascular (p = 0.02) and lymphatic (p < 0.001) invasion. In Kaplan Meier analyses, recurrence-free survival (p < 0.0001) and overall survival (p = 0.002) were significantly shorter in the HCC-CCA cohort than the HCC cohort (Figure 1). **Conclusion:** Over nearly 3 decades, approximately 3% of patients transplanted for HCC were incidentally found to have HCC-CCA. Despite high rates of MRI imaging and even lesional biopsy, in some cases, no patients were diagnosed with HCC-CCA prior to LT. Current diagnostic methods are suboptimal in identifying HCC-CCA, which is associated with worse post-LT outcomes.

Connelly[1] Pushpa Neppala[1] Oren Shaked[1] Flavio Rocha[1] Skye Mayo[1] Nima Nabavizadeh[1] Adel Kardosh[1] Parmede Vakil[1] Ruchi Thanawala[1] Julie Doberne[1] Willscott Naugler[1] Erin Maynard[1] C. Kristian Enestvedt[1], [1]Oregon Health & Science University

Background: Multidisciplinary tumor boards (MDTBs) guide treatment for hepatocellular carcinoma (HCC). Few prior studies have attempted to computationally model these complex evaluations and treatment recommendations. **Methods:** We analyzed 1,115 individual HCC cases presented in MDTB at our NCI designated comprehensive cancer center between 2016-2024. Seven consolidated treatment categories were predicted (liver transplant, resection, chemoembolization, radioembolization, systemic therapy, combined local therapy—encompassing locoregional treatments with consolidative treatment of external beam radiation or ablation—and palliative care). Multinomial logistic regression and XGBoost (gradient boosted trees) statistical modeling were compared. Clinician-expressed decisional confidence in the MDTB recommendation was graded and incorporated as a variable in the models. Performance was assessed with overall accuracy, area under the receiver operator curve (AUC), and per-class Brier Scores. Shapley Additive Explanations (SHAP) analysis was used to identify key variables contributing to model performance. All analyses were performed in Python 3.13. **Results:** The 1,115 patients were predominantly male (70.5%) with a median age of 65 years. Most patients were BCLC Stage A (53.5%). The most common primary recommendations were radioembolization (23.4%), combined local therapy (22.8%), and liver transplant (15.1%). Multinomial logistic regression modeling achieved 28.7% accuracy in predicting treatment recommendations. The XGBoost model improved accuracy to 51.1% with strong discriminative performance across treatment classes (one-vs-rest AUC 0.76–0.96; Fig. 1), compared to a theoretical chance performance for seven-class prediction of 14.3%. Per-class Brier scores were lowest for palliative care (0.029) and surgery (0.057), reflecting high specificity for these classes, and highest for radioembolization (0.147) and combined local therapy (0.138), the two largest and most overlapping categories. SHAP analysis showed that the size of the dominant lesion, BCLC stage, MELD score, and platelet count were among the most influential variables. **Conclusion:** Complex MDTB treatment recommendations for patients with HCC can be modeled by machine learning with reasonable accuracy and strong discriminative performance. Incorporating these tools into clinical practice may allow for more efficient and consistent MDTB discussions but will require careful refinement and validation.

4232 | SAFETY AND EFFICACY OF STEREOTACTIC BODY RADIATION THERAPY VS RADIOFREQUENCY ABLATION IN PATIENTS WITH HEPATOCELLULAR CARCINOMA. A SYSTEMATIC REVIEW AND META-ANALYSIS

Rahmat Ali[1] Sheraz Ali[2] Hurriyah Ramzan[3] Khawar Ali[4] Tahira Irshad[4] Silla Naeem[4] Mahnoor Usman[4] Ali Nawaz[4] Muhammad Farhan Zafar Baloch[4] Ahsan Ali[5] Khadija Tanvir[4] Waseem Sajjad[4], [1]University Of Connecticut School of Medicine, [2]King Edward Medical University, [3]Dow University of Health Sciences, Karachi, Pakistan, [4]King Edward Medical University, Lahore, Pakistan, [5]Faisalabad Medical University, Faisalabad, Pakistan

Background: Hepatocellular carcinoma (HCC) remains a leading cause of cancer mortality worldwide. While radiofrequency ablation (RFA) is the standard local

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

therapy for early-stage HCC, stereotactic body radiation therapy (SBRT) has emerged as a non-invasive alternative, particularly for tumors in anatomically challenging locations. Comparative evidence on the efficacy and safety of SBRT versus RFA remains inconclusive. This systematic review and meta-analysis aimed to compare both modalities in terms of survival, local control, and treatment-related toxicity. **Methods:** Following PRISMA guidelines, PubMed, Embase, MEDLINE, and Cochrane databases were searched up to 2025. Randomized controlled trials and cohort studies directly comparing SBRT and RFA in HCC patients were included. Pooled odds ratios (OR) or mean differences (MD) with 95% confidence intervals (CI) were calculated using Review Manager (RevMan). Heterogeneity was assessed using the I^2 statistic, and study quality was evaluated using the ROB-2 tool and Newcastle–Ottawa Scale. **Results:** Seventeen studies (one RCT, sixteen cohorts) involving 10182 HCC patients were included. The SBRT group has 2468 patients, and the RFA group has 7714 patients. Pooled analysis showed no significant difference in overall survival (OR = 1.02, 95% CI 0.62–1.67) or progression-free survival (OR = 1.58, 95% CI 0.84–3.01). Local control and recurrence rates were comparable. SBRT demonstrated significantly lower liver-related mortality (OR = 2.08, p = 0.02) and reduced post-procedural pain (OR = 0.15, p < 0.0001), whereas RFA showed higher complete response rates (OR = 0.21, p = 0.02) but increased liver-related toxicity (OR = 2.74, p = 0.01). Overall treatment-related complications did not differ significantly between modalities. **Conclusion:** SBRT and RFA yield comparable long-term oncologic outcomes in HCC. SBRT offers advantages in pain reduction and lower liver-related mortality, while RFA may achieve higher complete response in small, peripherally located tumors. Both modalities remain effective and safe; treatment selection should be individualized based on tumor characteristics, liver function, and anatomical feasibility. Further randomized trials with standardized protocols are warranted.

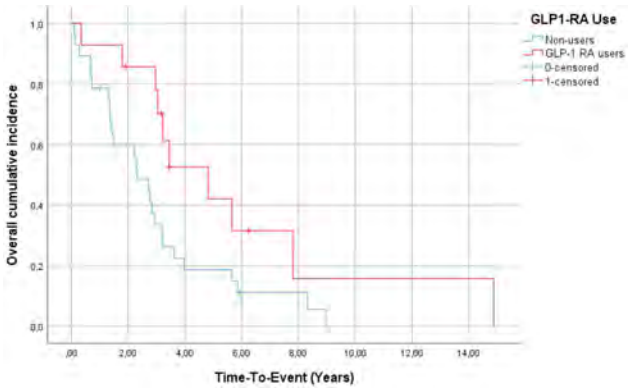
4233 | GLP-1 RECEPTOR AGONIST EXPOSURE AND OUTCOMES IN HEPATOCELLULAR CARCINOMA ACROSS THE LIVER TRANSPLANT CONTINUUM: A SINGLE-CENTER, EXPLORATORY ANALYSIS



Talal Alhejaili[1] Lameyaa Alsheekh[1] Lujain Alrabghi[2] Xin Tong Ma[2] Chiara Becchetti[3] Mohammad Qasim Khan[4], [1]Department of Medicine, Division of Gastroenterology, Western University, London, ON, Canada, [2]Department of Medicine, Division of Internal Medicine, Western University, London, ON, Canada, [3]Hepatology and Gastroenterology Unit, ASST Grande Ospedale Metropolitano Niguarda, Milan, Italy, [4]Western University, London, ON, Canada

Background: GLP-1 receptor agonists (GLP-1 RAs) have shown favorable metabolic and liver-related effects in type 2 diabetes mellitus with potential to reduce hepatocellular carcinoma (HCC) risk. However, their impact on outcomes in patients with HCC, particularly across the liver transplant (LT) spectrum, are not fully elucidated. We evaluated the association between GLP-1 RA exposure and clinical outcomes in patients with HCC and T2DM before and after LT. **Methods:** We conducted a retrospective, matched cohort of adults with HCC and T2DM, comparing GLP-1 RA users with non-users in a 1:2 ratio. Two separate analyses were performed. In the pre-LT cohort, GLP-1 RA users were matched to non-users to evaluate outcomes since HCC diagnosis, accounting for liver transplant, death, and loss to follow-up as competing events. In the post-LT cohort, LT recipients with prior GLP-1 RA exposure were matched to non-exposed controls to assess HCC recurrence following LT. Demographic, clinical, tumor, treatment, and outcomes-related data were extracted from electronic medical records. Time-to-event analyses and non-parametric tests were used as appropriate. **Results:** Overall, 84 patients were included, comprising 14 GLP-1 RA-exposed patients matched to 28 controls across the two settings. In the pre-LT setting, age, sex, and tumor burden were comparable between groups. MASLD was the predominant underlying liver disease in both groups (43%). Primary HCC treatment modalities among GLP-1 RA users included ablation (57%)

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

and transarterial chemoembolization (TACE) (38%), compared with 43% and 50% in controls, respectively. Complete response rates were 50% in the GLP-1 RA group and 65% in controls, while progression occurred in 29% and 12%, respectively. Despite similar LT rates (21% vs 21%), GLP-1 RA exposure was associated with lower mortality in time-to-event analyses (50% vs. 83%; log-ran p = 0.033) (Figure 1). In the post-LT cohort, patients were again similar in baseline characteristics. Only two cases of recurrent HCC were observed, both occurring within 5 years post-LT and exclusively among the non-exposed group. **Conclusion:** In this exploratory, single-center, matched cohort study, GLP-1 RA exposure in patients with HCC and T2DM was not associated with worse oncologic outcomes and may have been associated with lower pre-transplant mortality. Post-LT recurrence was rare and occurred only among non-exposed patients. Larger, multicenter studies are needed to confirm these findings and further define the implications of GLP-1 RA use in HCC.

4234 | HEPATOCELLULAR CARCINOMA IN WOMEN: DISTINCT ETIOLOGIC PATTERNS AND AGE-RELATED SURVIVAL OUTCOMES COMPARED WITH MEN

Saleh Alqahtani[1] Duna Barakeh[2] Saleh Alessy[2] Amwaj Alanazi[2] Mussadique Jhatial[2] Mehwish Hussain[3] Layan Alsubki[2] Ahad Alseraihi[4] Fahad AlMugbel[2] Ali Alqahtani[2] Habeeb Ibrahim Abdul Razack[5] Mohammed Shouki Bazarbashi[2] Adnan Alzanbagi[6] Khalid AlNaamani[7] Waleed Alomaim[2] Tatyana Kushner[8] Dieter Broering[2] Saad Alghamdi[3] Faisal Abaalkhail[2], [1]King Faisal Specialist Hospital & Research Center, [2]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [3]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia, [4]Ministry of Health, Riyadh, Saudi Arabia, [5]King Saud University, Riyadh, Saudi Arabia, [6]King Abdullah Medical City, Makkah, Saudi Arabia, [7]Armed Forces Hospital, Muscat, Oman, [8]Weill Cornell Medicine, New York, USA

Background: Hepatocellular carcinoma (HCC) in women may differ from that in men in disease characteristics, with potential age-related effects on presentation and survival. However, female-specific HCC patterns remain incompletely explored in Saudi Arabia. We aimed to characterize the clinical features, etiologies, and survival outcomes of female patients with HCC across different age groups and compare outcomes between female and male patients. **Methods:** Data were obtained from a comprehensive institutional database of all patients diagnosed with HCC between January 2020 and April 2026 at two major tertiary referral centers in Saudi Arabia. Demographic, etiologic, and clinical data were analyzed using descriptive statistical methods. Female patients were categorized into three age groups (< 55, 55–64, and ≥ 65 years). Overall survival was estimated using the Kaplan-Meier method, with mortality data supplemented by the National Death Registry maintained by the Ministry of Health. **Results:** Among 693 patients with HCC, 205 (29.6%) were female, with a median age at diagnosis of 65 years, comparable to males. Smoking history (current or former) was uncommon among females (3.0% vs 22.3% of males, P < 0.001). Etiologic distribution differed by sex (P < 0.001): hepatitis C virus was most frequent among females (38.5%), whereas metabolic dysfunction-associated steatotic liver disease/steatohepatitis was most frequent among males (35.9%); hepatitis B virus etiology was less common in females than males (10.2% vs. 27.5%). Liver cirrhosis was more frequent in females than males (91.7% vs. 85.9%, P = 0.033), while Child-Pugh class distribution was similar (Child–Pugh A: 56.1% vs. 60.0%, P = 0.281). Tumor stage at presentation was similar between females and males (early-stage BCLC 0–A: 41.0% in both groups, P = 0.865), as was first-line locoregional therapy use (48.8% vs. 43.2%, P = 0.616) in females and males. Survival analysis showed that females had higher overall survival probabilities than males (at 36 months: 0.53; 95% CI 0.42 - 0.62 vs 0.50; 95% CI 0.44-0.56), with the most favorable estimated outcomes observed among the female patients aged < 55 years (< 55 years) compared with older age groups (55–64 and ≥ 65 years). **Conclusion:** Female patients with HCC in Saudi Arabia demonstrate distinct etiologic patterns and broadly similar stage and treatment characteristics compared with males. Females had higher overall survival, particularly among those aged < 55 years, highlighting

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

a potential age-related survival advantage that warrants further investigation.

Figure 1: Stage at diagnosis by gender

4235 | RADIOTHERAPY COMBINED WITH ATEZOLIZUMAB PLUS BEVACIZUMAB IN HEPATOCELLULAR CARCINOMA WITH MAIN PORTAL VEIN TUMOR THROMBOSIS: REFINED ANALYSIS WITH IPTW ADJUSTMENT IN A MULTICENTER REAL-WORLD COHORT

Hyun Young Woo[1] Young Joo Park[2] Ki Youn Yi[2] Junsik Yoon[3] Yeowool Kang[4] Woo Sun Rou[5] Jeongeun Song[6] Joonho Jeong[7] Yu Rim Lee[8] Jae hyun Yoon[9] Young Mi Hong[10] Sangyoun Hwang[11] Hyun Jin Cho[12] Yang Hyun Baek[4] Soo Young Park[8] Won Young Tak[13] Sung Bum Cho[14] Jeong Heo[15], [1]College of Medicine, Pusan National University and Pusan National University Hospital, [2]Pusan National University Hospital, [3]Busan Paik Hospital, Inje University College of Medicine, [4]Dong-A University College of Medicine, [5]Chungnam National University College of Medicine, [6]Daegu Catholic University Medical Center, Catholic University of Daegu School of Medicine, [7]Ulsan University Hospital, University of Ulsan College of Medicine, [8]School of Medicine, Kyungpook National University, Kyungpook National University Hospital, [9]Chonnam National University Hospital, School of Medicine, [10]College of Medicine, Pusan National University, Pusan National University Yangsan Hospital, [11]Dongnam Institute of Radiologic & Medical Sciences, [12]Gyeongsang National University, [13]School of Medicine, Kyungpook National University, [14]Chonnam National University Hwasun Hospital and Chonnam National University Medical School, [15]Pusan National University College of Medicine, Busan, Republic of Korea

Background: Our previous study demonstrated that RT combined with atezolizumab plus bevacizumab (Ate/bev) improved OS in high-risk HCC patients including Vp4 PVTT. However, that analysis included heterogeneous high-risk features without accounting for RT timing or baseline confounders. Here, we performed a refined analysis in HCC patients with main PVTT (MPVTT), incorporating RT timing classification and inverse probability of treatment weighting (IPTW). **Methods:** This multicenter retrospective cohort study included 183 HCC patients with MPVTT who received Ate/bev across five tertiary hospitals in Korea (July 2020–December 2023). Patients receiving RT before or after Ate/bev completion (n = 14) were excluded, yielding 169 patients: RT group (n = 95) and Ate/bev-only group (n = 74). Median RT dose was 35 Gy in 12 fractions. Tumor response was assessed per mRECIST. Primary endpoint was OS; secondary endpoints were TTP, ORR, and DCR. IPTW was applied to adjust for selection bias. Subgroup analysis was performed in patients without extrahepatic spread (EHS). **Results:** The RT group had younger age (62 vs. 66 years), better ECOG PS 0 (60% vs. 46%), higher Child-Pugh A (94% vs. 78%), and lower EHS rate (45% vs. 54%). The RT group showed significantly higher DCR (82.2% vs. 53.3%, p < 0.001) and numerically higher ORR (32.2% vs. 18.3%, p = 0.09). Median TTP (6.1 vs. 2.5 months, p < 0.001) and OS (9.9 vs. 6.0 months, p < 0.001) were significantly longer in the RT group. On univariate Cox analysis, RT significantly improved OS (HR 0.638, 95% CI 0.453–0.898, p = 0.010) and TTP (HR 0.598, 0.412–0.869, p = 0.007). After IPTW adjustment, RT

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

independently predicted prolonged TTP (HR 0.672, 0.512–0.883, p = 0.004) with a trend toward improved OS (HR 0.787, p = 0.10). In the no-EHS subgroup (RT n = 52, No-RT n = 34), RT independently predicted OS (HR 0.505, 0.294–0.868, p = 0.013; median 11.0 vs. 6.7 months, p = 0.010) and TTP (6.9 vs. 3.0 months, p = 0.035). **Conclusion:** RT combined with Ate/bev independently predicted prolonged TTP after IPTW adjustment and improved OS in MPVTT patients without EHS. These results extend our previous findings and support RT as a meaningful adjunct to Ate/bev, particularly in locoregionally confined MPVTT. Prospective trials are warranted.

★ 4236 | MACHINE PERFUSION AND HEPATOCELLULAR CARCINOMA RECURRENCE AFTER LIVER TRANSPLANTATION: A SYSTEMATIC REVIEW AND META-ANALYSIS

Patricia Viana[1] Gabriel Chiacchio[2] João Vitor Carneiro[3] Paulo Martins[1], [1]University of Oklahoma, [2]Centro Universitário Tocantinense Presidente Antônio Carlos, [3]Pontifical Catholic University of Paraná

Background: Hepatocellular carcinoma (HCC) recurrence following liver transplantation (LT) remains a significant clinical challenge, affecting 10–20% of recipients. Ischemia-reperfusion injury (IRI) has been implicated as a modifiable risk factor for tumor recurrence, and machine perfusion (MP) strategies have emerged as a potential means of mitigating IRI. We conducted a systematic review and meta-analysis to compare tumor recurrence outcomes in patients undergoing LT for HCC with and without MP. **Methods:** MEDLINE, Embase, and the Cochrane databases were searched for studies comparing any modality of MP (hypothermic oxygenated perfusion and normothermic machine perfusion with static cold storage in adult LT recipients with HCC were eligible for inclusion. Binary outcomes were synthesized using odds ratios (OR) and time-to-event outcomes using hazard ratios (HR), both calculated with random-effects models. Statistical analyses were performed using R (version 4.3.1). The study protocol was prospectively registered on PROSPERO. **Results:** Four observational cohort studies (spanning from 2020 to 2025) met inclusion criteria, encompassing 1,525 patients, of whom 621 (40.7%) received MP. Median follow-up ranged from 12 to 64 months. Reconstructed Kaplan–Meier analysis demonstrated superior recurrence-free survival in the MP group, with an estimated 5-year RFS of approximately 90% versus 65–70% in the SCS group. On pooled time-to-event analysis, MP was independently associated with a significant reduction in recurrence risk (HR 0.26; 95% CI 0.18–0.38; p = 0.001). Moreover, MP was associated with a significantly lower risk of HCC recurrence compared with SCS (OR 0.30; 95% CI 0.10–0.92; p = 0.007). **Conclusion:** This first meta-analysis evaluating the association between MP and HCC recurrence after LT demonstrates that MP is associated with significantly lower recurrence rates and improved recurrence-free survival. As MP adoption expands globally, prospective randomized trials are warranted to confirm these findings and define optimal perfusion strategies for oncologic benefit in LT.

Figure 1. Recurrence-free survival: machine perfusion was associated with a significantly lower risk of HCC recurrence compared with SCS

★ 4237 | MIP-3α AND IP-10 AS PROMISING BIOMARKERS FOR HEPATOCELLULAR CARCINOMA IN HIV AND VIRAL HEPATITIS COINFECTED PATIENTS: A PILOT AND VALIDATION COHORT STUDY

Johana Acuña[1] Casper Rokx[2] Ângelo Zambam de Mattos[3] Anthonie Groothuismink[2] Ibrahim Irfanullah[4] Andre Boonstra[5] Jose Debes[6], [1]Universidade Federal de Ciências da Saúde de Porto Alegre, [2]Erasmus MC, Erasmus University, Rotterdam, the Netherlands, [3]Federal University of Health Sciences of Porto Alegre, [4]University of Minnesota, Minneapolis, USA, [5]Erasmus University Medical Center, [6]University of Minnesota

Background: Hepatocellular carcinoma (HCC) has higher mortality in individuals co-infected with HIV and HCV or HBV, presenting additional complexities for screening and surveillance. There is a lack of data across the globe related to surveillance of HCC in this population. **Methods:** We evaluated a pilot cohort of 129 patients from Latin America (Brazil) and a validation cohort of 80 from Europe (the Netherlands) each divided into three groups: HCC + viral hepatitis + HIV; viral hepatitis + HIV; and HIV only. Thirteen immunological markers-TNFα, IL-6, IP-10, IL-10, VEGF-A, BCA-1, IFN-γ, MIP-3α, MDC, MCP-4, TECK, MIG, and HGF- were measured in serum samples. Values below the lower limit of quantification (LLOQ) replaced by LLOQ/2 and false discovery rate (FDR) correction applied. **Results:** In both cohorts, male sex predominated in HCC and coinfected groups (Latin America: 60% and 62%; Europe: 93% and 100%, respectively); HCC group had higher prevalence of cirrhosis than coinfected group (Latin America: 80% vs. 9%; Europe: 86% vs. 16%). In the pilot cohort, IP-10 was the marker with the greatest differentiation, with a median of 113.1 pg/mL in the HCC group — approximately 33-fold higher than coinfected (3.4 pg/mL) and HIV groups (3.3 pg/mL)— reaching statistical significance ($q = 0.049$ for both comparisons). MIP-3α also showed consistently elevated levels in HCC patients, with a median of 20.9 pg/mL, representing a 5.2-fold increase over the coinfected (4.0 pg/mL; $q = 0.039$) and a 4.1-fold increase over HIV groups (5.2 pg/mL; $q = 0.049$). BCA-1 showed the strongest statistical separation ($q = 0.001$ for both comparisons), with a median of 33.3 pg/mL in the HCC group — approximately 10-fold higher than in both control groups (3.35 pg/mL each), where values equivalent to LLOQ/2 indicated that the vast majority of patients without HCC had undetectable levels of this marker.In the validation cohort, MIP-3α was the only marker to reach statistical significance, with HCC group median levels 2.8-fold higher than the coinfected group (49.9 vs 18.1 pg/mL) and 3.5-fold higher than the HIV group (14.4 pg/mL; $q = 0.050$). IP-10 levels in HCC group were also consistently higher than in both control groups, showing the same directional trend observed in the pilot cohort, although without reaching post-FDR significance. BCA-1 did not show a consistent trend in this cohort. Cirrhotic and non-cirrhotic patients showed no significant differences in any marker in either cohort. **Conclusion:** MIP-3α was the only marker to reach statistical significance in both cohorts, emerging as the most robust discriminator of HCC in this cohort. IP-10 and BCA-1 present relevant findings that deserve further exploration. Overall, immune markers could play an important role in surveillance for HCC in individuals with HIV.

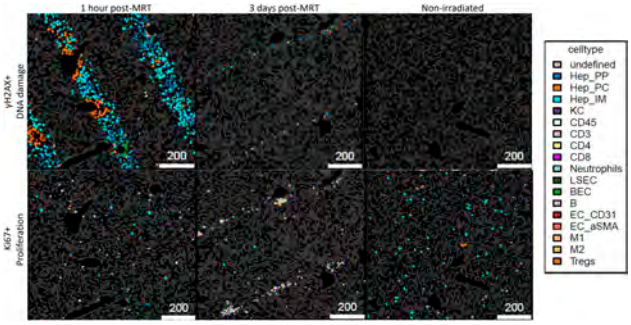
4238 | SUBMILLIMETRE SPATIALLY FRACTIONATED RADIOTHERAPY (μSFRT) PROMOTES REGENERATIVE RESPONSES AND PRESERVES LIVER ARCHITECTURE FOLLOWING HIGH-DOSE IRRADIATION



Cheuk Ting Wu[1] Nahoko Shintani[2] Tural Yarahmadov[3] Verdiana Trappetti[2] Cristian Fernandez-Palomo[2] Deborah Keogh-Stroka[3] Valentin Djonov[2], [1]Institute of Anatomy, [2]Insitute of Anatomy, University of Bern, [3]DBMR, University of Bern

Background: Radiation-induced liver disease (RILD) limits radiotherapy efficacy in hepatocellular carcinoma (HCC). Submillimetre spatially fractionated radiotherapy (μSFRT), including microbeam (MRT) and minibeam (MBRT) modalities, delivers highly heterogeneous dose distributions that spare normal tissue despite ablative peak doses. Early clinical MBRT in palliative patients has demonstrated tumour response and symptom relief with favourable normal tissue tolerability, supporting further investigation in liver

malignancies. The mechanisms underlying normal tissue sparing and absence of RILD following µSFRT remain undefined. **Methods:** C57BL/6 mice received synchrotron-generated MRT (50 µm beam width, 400 µm spacing, ~400 Gy peak dose). Liver tissue and serum were collected 1 hour to 6 days post-irradiation for assessment of DNA damage, cell death pathways, proliferation, and liver injury markers. Imaging Mass Cytometry (IMC) with a custom hepatic-immune panel characterized spatial cellular dynamics. Long-term histological analyses were performed up to 6 months post-irradiation. Comparative studies using MBRT (~50 Gy peak, 200 µm beams/800 µm spacing) and conventional broadbeam radiotherapy (CONV-RT) via a CIX FLASH orthovoltage irradiator are ongoing. **Results:** MRT induced highly localized DNA damage confined to beam paths with minimal systemic liver injury. Classical apoptosis, necroptosis, ferroptosis, and pyroptosis were minimally activated; instead, poly (ADP-ribose) accumulation and apoptosis-inducing factor (AIF) upregulation, consistent with a parthanatos-like cell death mechanism. IMC revealed transient reductions in periportal and intermediate hepatocyte populations with localized immune cell enrichment at peak-dose regions, largely resolving within 6 days. Long-term analyses demonstrated preserved hepatic architecture without fibrosis at 6 months following MRT. Preliminary Masson's Goldner staining revealed markedly reduced fibrosis in MBRT-treated livers (50 Gy peak) compared to CONV-RT at matched (50 Gy) and lower (25 Gy) doses, with the difference most pronounced at equivalent doses. **Conclusion:** µSFRT induces spatially compartmentalised cell death and coordinated immune-regenerative responses that restore liver homeostasis without chronic injury. Parthanatos-like signalling may represent a mechanistically distinct, tissue-protective death pathway activated by extreme dose heterogeneity. Preliminary histological evidence of reduced fibrosis across both MRT and MBRT versus CONV-RT supports a potential µSFRT class effect on long-term liver protection, implicating regenerative reprogramming as central to RILD prevention. Ongoing orthotopic HCC studies will define the relationship between normal tissue preservation and tumour control.

4239 | REAL-WORLD OUTCOMES OF ATEZOLIZUMAB PLUS BEVACIZUMAB ACCORDING TO ETIOLOGY IN UNRESECTABLE HEPATOCELLULAR CARCINOMA

Yeowool Kang[1] Jun Sik Yoon[2] Jung Eun Song[3] Joonho Jeong[4] Yu Rim Lee[5] Jae hyun Yoon[6] Young Mi Hong[7] Sang Youn Hwang[8] Hyun Young Woo[9] Soo Young Park[5] Sung-Bum Cho[10] Yanghyun Baek[11],
[1]Department of Internal Medicine, Dong-A University, [2]Department of Internal Medicine,Busan Paik Hospital, Inje University College of Medicine, [3]Department of Internal Medicine, Catholic University of Daegu School of Medicine, [4]Department of Internal Medicine, Ulsan University Hospital, University of Ulsan College of Medicine, [5]Department of Internal Medicine, School of Medicine, Kyungpook National University, [6]Department of Internal Medicine, Chonnam National University Hospital, School of Medicine, Gwangju, [7]Department of Internal Medicine, College of Medicine, Pusan National University Yangsan Hospital, [8]Department of Internal Medicine, Dongnam Institute of Radiologic & Medical Sciences, Busan, Korea, [9]Department of Internal Medicine, College of Medicine, Pusan National University Hospital, [10]Department of gastroenterology and hepatology, Chonnam National University Hwasun Hospital, [11]Department of Internal Medicine, Dong-A University College of Medicine

Background: Atezolizumab plus bevacizumab is the preferred first-line systemic therapy for unresectable hepatocellular carcinoma (uHCC). Because HCC exhibits substantial etiologic and immunologic heterogeneity, treatment responsiveness to immune checkpoint inhibitors may differ according to underlying liver disease. However, vascular endothelial growth factor inhibition may attenuate these biologic differences. We evaluated survival outcomes and treatment-related adverse events according to HCC etiology in a large real-world multicenter cohort treated with atezolizumab plus bevacizumab. **Methods:** We conducted a multicenter retrospective cohort study including patients with uHCC who received first-line atezolizumab plus bevacizumab between January 2022 and December 2024 across participating tertiary referral centers in Korea. Patients were classified into viral HCC (HBV or HCV infection) and non-viral HCC groups, including alcohol-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

related liver disease, metabolic dysfunction-associated steatotic liver disease, and cryptogenic liver disease. Overall survival (OS), progression-free survival (PFS), treatment response, and immune-related adverse events (irAEs) were compared between groups using Kaplan–Meier and multivariable Cox regression analyses. **Results:** A total of 1,020 patients were included, comprising 743 patients with viral HCC and 277 with non-viral HCC. Patients with non-viral HCC were older and had higher rates of obesity, hypertension, and diabetes mellitus, whereas viral HCC had a higher proportion of Child-Pugh class B disease. Median OS was comparable between viral and non-viral HCC (11.9 vs. 12.7 months; p = 0.83), as was median PFS (5.9 vs. 6.3 months; p = 0.088). In multivariable Cox regression analyses, viral etiology was not independently associated with OS (HR 1.15, 95% CI 0.97–1.37; p = 0.11) or PFS (HR 1.16, 95% CI 0.99–1.35; p = 0.067), showing no statistically significant difference between the two groups. Objective response rates were comparable between viral and non-viral HCC (23% vs. 29%; p = 0.086). Impaired liver function, poor performance status, macrovascular invasion, and elevated AFP were the strongest predictors of survival. The incidence of irAEs was generally comparable between groups (18.4% vs. 13.7%, p = 0.10). **Conclusion:** In this large real-world multicenter cohort, atezolizumab plus bevacizumab demonstrated broadly similar efficacy and safety across viral and non-viral etiologies of uHCC. Treatment outcomes were primarily determined by liver function, performance status, and tumor burden rather than underlying disease etiology. These findings suggest that atezolizumab plus bevacizumab may provide consistent clinical benefit across diverse HCC etiologies.

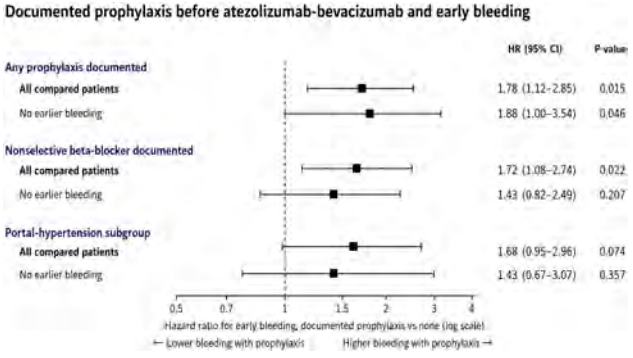
4240 | DOCUMENTED VARICEAL PROPHYLAXIS AND BLEEDING AFTER ATEZOLIZUMAB-BEVACIZUMAB: A MARKER OF PORTAL HYPERTENSION SEVERITY, NOT PROPHYLAXIS FAILURE



EzzElDien A. Ibrahim[1] Mahmoud Majed Mansour[1] Akram Alnounou[2] Yazan Alnairah[3] Abdallah Al Ghnaimat[4] Fouad Jaber[5] Islam Mohamed[1] Ahmad Hassan Ali[1] Nikki Duong[6] Khulood T Ahmed[1], [1]University of Missouri, Columbia, Missouri, USA, [2]Western Michigan University Homer Stryker M.D. School of Medicine,, [3]Jordanian Royal Medical Services,Amman, Jordan, [4]Hashemite University, Jordan, [5]Baylor College of Medicine, [6]Stanford University, Palo Alto, CA

Background: Portal hypertension assessment is integral to treatment planning before atezolizumab-bevacizumab for unresectable hepatocellular carcinoma (HCC), given bevacizumab-associated hemorrhagic risk. In electronic health record (EHR) data, documented variceal prophylaxis may reflect clinician-recognized high-risk portal hypertension rather than adequate risk mitigation. We evaluated the association between documented variceal prophylaxis and early bleeding after treatment initiation. **Methods:** We identified adults in the TriNetX Global Collaborative Network initiating first-line atezolizumab-bevacizumab for HCC, classified by documented variceal prophylaxis status, defined as nonselective beta-blocker (NSBB) prescription or endoscopic intervention in the 180 days preceding treatment initiation. Propensity score matching (1:1) was performed on 30 covariates encompassing demographics, liver function, portal hypertension indicators, oncologic characteristics, medications, and laboratory values. Primary outcomes over days 1–180 were variceal-only bleeding and a composite of variceal and upper gastrointestinal (GI) bleeding. Sensitivity analyses restricted the exposure to NSBBs alone, excluded prior bleeders, and enriched both arms for documented portal hypertension. **Results:** Among 3,095 patients initiating first-line atezolizumab-bevacizumab, 326 (10.5%) had documented prophylaxis and 2,769 (89.5%) did not; 280 matched pairs were formed. Variceal-only bleeding was numerically higher in the prophylaxis group before matching, though post-match event counts were small. For the composite variceal/upper-GI bleeding endpoint after matching, events occurred in 47 of 280 (16.8%) vs 28 of 280 (10.0%) patients (risk ratio [RR] 1.68, 95% CI 1.08–2.60; hazard ratio [HR] 1.78, 95% CI 1.12–2.85). After excluding patients with prior bleeding, estimates remained elevated but borderline: 27 of 233 (11.6%) vs 15 of 229 (6.6%) (RR 1.77, 95% CI 0.97–3.24; HR 1.88, 95% CI 1.00–3.53; log-rank P = 0.046). In the NSBB-only

sensitivity analysis, the inclusive HR was 1.72 (95% CI 1.08–2.74), attenuating to 1.43 (95% CI 0.82–2.49) when restricted to incident events. Portal-hypertension-enriched estimates remained directionally consistent but imprecise (HR 1.68, 95% CI 0.95–2.96; incident HR 1.43, 95% CI 0.67–3.07). **Conclusion:** Patients with documented variceal prophylaxis before atezolizumab-bevacizumab experienced higher rates of early bleeding, likely reflecting underlying portal hypertension severity rather than prophylaxis failure. This signal persisted after excluding prior bleeders and adjusting for portal hypertension markers, suggesting that documented prophylaxis may identify a subgroup with incompletely mitigated hemorrhagic risk. Prospective studies integrating portal hemodynamics and variceal grading are needed to refine patient selection and monitoring.

4241 | RACIAL AND ETHNIC DIFFERENCES IN STAGE AT PRESENTATION, PRIMARY-SITE SURGERY, AND SURVIVAL FOR HEPATOCELLULAR CARCINOMA: A SEER ANALYSIS, 2000–2022

Kesava Manikanta Achuta[1] Vatsal Khanna[2] Abhishek Vadher[3] Sujata Kambhatla[3], [1]Garden city hospital, Michigan State University, [2]HFH, Providence, [3]Garden City Hospital, MSUCOM

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer death in the United States, and surgery remains central to curative-intent management. Racial and ethnic disparities in HCC survival have been reported, but whether these differences are driven by later presentation, lower treatment receipt, or both has not been fully characterized. We evaluated racial/ethnic differences in stage at presentation, surgery, survival in adults with HCC using population-based data. **Methods:** Adults with primary liver HCC diagnosed 2000–2022 were identified from SEER Research Data. Race/ethnicity was categorized as White (n = 61,374), Black (n = 14,739), API (n = 20,056), AI/AN (n = 1,616), and Hispanic (n = 25,849). Advanced-stage analysis was limited to 80,961 patients with known summary stage. Recorded primary-site surgery was defined using SEER RX Summ–Surg Prim Site codes. Multivariable logistic regression evaluated advanced-stage presentation and surgery receipt. Stepwise Cox regression assessed survival using three sequential models: demographic-adjusted (age, sex, year), tumor-adjusted (stage, grade, tumor size, histology), and treatment-adjusted (surgery, chemotherapy, radiation). **Results:** Among 123,934 patients, advanced-stage disease was more common in Black than White patients (50.6% vs 46.0%; adjusted OR 1.20, 95% CI 1.15–1.26). Recorded surgery was lower in Black (19.0%), AI/AN (20.4%), and Hispanic (19.8%) versus White patients (24.2%). Adjusted odds of surgery were lower for Black (OR 0.72, 95% CI 0.69–0.76), AI/AN (OR 0.77, 95% CI 0.67–0.88), and Hispanic patients (OR 0.73, 95% CI 0.70–0.76), but higher for API patients (OR 1.39, 95% CI 1.34–1.45). Surgery gaps persisted among localized/regional disease (stage-by-race interaction $p < 0.001$). In stepwise survival models, Black-White mortality attenuated from HR 1.17 (95% CI 1.14–1.19) to HR 1.08 after tumor adjustment and HR 1.01 after treatment adjustment, indicating approximately half of excess mortality was explained by tumor factors and the remainder by treatment receipt. **Conclusion:** Black patients had higher odds of advanced-stage presentation and lower odds of surgery. The Black–White mortality disparity attenuated from HR 1.17 to HR 1.01 after sequential adjustment for tumor factors and treatment, suggesting later presentation and lower treatment receipt may largely explain the survival gap. Lower surgery among Black, Hispanic, and AI/AN patients persisted among localized/regional disease, a treatment-access signal not explained by stage alone. API patients had higher surgery odds and lower mortality, supporting system-level rather than biological factors. SEER lacks data on insurance, liver disease severity, and transplant evaluation; findings represent

4242 | PIVKA-II SERUM LEVELS ENHANCE PROGNOSTIC STRATIFICATION BEYOND BCLC STAGING IN NEWLY DIAGNOSED HEPATOCELLULAR CARCINOMA: A MULTICENTRE COHORT STUDY

Francesco Damone[1] Gian Paolo Caviglia[2] Francesco Faita[3] Piero Colombatto[1] Filippo Oliveri[1] Marta Guariglia[2] Gabriele Ricco[4] Silvia Gaia[5] Daniela Cavallone[1] Veronica Romagnoli[1] Emanuela Rolle[6] Patrizia Carucci[6] Ferruccio Bonino[3] Maurizia Brunetto[7], [1]Hepatology Unit, Pisa University Hospital, Italy, [2]Department of Medical Sciences, University of Turin, Turin, Italy, [3]Biostructure and Bio-imaging Institute of National Research Council of Italy, [4]Hepatology Unit, Pisa University Hospital, Italy;, [5]Unit of Gastroenterology, Città della Salute e della Scienza - Molinette Hospital, Turin, Italy, [6]Unit of Gastroenterology, Città della Salute e della Scienza - Molinette Hospital, Turin, Italy;, [7]Department of Clinical and Experimental Medicine, Pisa University and Hepatology Unit, Pisa Universi

Background: Current prognostic tools for Hepatocellular Carcinoma (HCC), including the Barcelona Clinic Liver Cancer (BCLC) staging system, rely on liver function, tumour burden and performance status, yet fail to capture tumour biological heterogeneity and aggressiveness. This multicentre cohort study investigated whether baseline serum Protein induced by Vitamin K Absence-II (PIVKA-II) levels could complement BCLC staging to enhance prognostic accuracy. **Methods:** A cohort of 605 consecutive patients with newly diagnosed HCC, enrolled between 2010 and 2024 at two Italian tertiary referral centres, was analysed. PIVKA-II was incorporated as a continuous variable. The primary endpoint was Overall Survival (OS). Prognostic performance was evaluated by comparing two Cox proportional hazards models: one based on BCLC stage alone and the other additionally incorporating baseline PIVKA-II. Discrimination and calibration were assessed using time-dependent AUC, Brier score, and C-index at 24, 36, and 60 months. Internal validation was performed through a 70/30 train–test split approach. **Results:** BCLC stage distribution was as follows: 83 patients BCLC-0, 284 BCLC-A, 151 BCLC-B, and 87 BCLC-C. Median OS for the overall cohort was 29.0 months, with stage-specific medians ranging from 47.9 months (BCLC-0) to 10.7 months (BCLC-C) ($p < 0.001$). Adding PIVKA-II to the BCLC model substantially improved prognostic discrimination at mid- and long-term timepoints: time-dependent AUC at 36 months was 80.8% versus 75.7% ($p = 0.006$), rising to 79.3% versus 73.1% at 60 months ($p = 0.002$). Calibration also marginally improved with PIVKA-II integration, as evidenced by lower Brier scores at 36 months (18.9% vs 19.2%) and 60 months (19.8% vs 20.1%). Overall discriminative ability favoured the integrated model (C-index: 0.71 vs 0.68). **Conclusion:** Baseline PIVKA-II serum levels offer meaningful prognostic value beyond BCLC staging in patients with newly diagnosed HCC, significantly enhancing mid- and long-term survival prediction. These results support the design of prospective studies aimed at incorporating tumour biomarkers into established staging frameworks, in line with a precision medicine approach to HCC management.

[1]University of Missouri, Columbia, [2]University of Missouri- Columbia Hospital, [3]Moorehouse School Of Medicine, [4]Zucker School of Medicine at Hofstra/ Northwell at Vassar brothers medical center, [5]Piedmont Athens Regional Medical Center

Background: Metabolic syndrome–associated hepatocellular carcinoma (HCC) is increasingly recognized as a major etiologic subtype of liver cancer, yet comparative outcomes relative to viral hepatitis– associated HCC remain unclear. We evaluated clinical outcomes among HCC patients with metabolic syndrome versus viral hepatitis using a multicenter electronic health record database. **Methods:** We performed a retrospective propensity score–matched comparative effectiveness study using the TriNetX Research Network. Adult patients with HCC and metabolic syndrome were matched1:1 to patients with HCC associated with chronic viral hepatitis (HBV/HCV) based on demographics, cirrhosis status, obesity, diabetes mellitus, smoking history, and cardiovascular comorbidities. Primary outcome was all-cause mortality. Secondary outcomes included hepatic decompensation, portal hypertension, liver-related hospitalization, metastatic disease, liver transplantation, and systemic therapy utilization. Hazard ratios (HRs) with 95% confidence intervals (CIs) were calculated using Cox proportional hazards models. **Results:** After propensity matching, 41,882 patients were included in each cohort. During a median follow-up of 5.8 years, metabolic syndrome–associated HCC demonstrated significantly higher all-cause mortality compared with viral hepatitis–associated HCC (38.6% vs 32.4%; HR 1.29, 95% CI 1.23–1.35; $p < 0.001$), with progressive divergence in overall survival over time (log-rank $p < 0.001$) (Fig. 1). Patients with metabolic syndrome–associated HCC additionally demonstrated increased risks of hepatic decompensation (22.1% vs 18.4%; HR 1.24, 95% CI 1.18–1.31), portal hypertension (27.8% vs 23.3%; HR 1.21, 95% CI 1.15–1.27), liver-related hospitalization (41.2% vs 35.9%; HR 1.26, 95% CI 1.21–1.32), and metastatic disease at presentation (18.7% vs 14.1%; HR 1.38, 95% CI 1.29–1.47) (Fig. 2). Conversely, these patients were less likely to undergo liver transplantation (4.9% vs 8.7%; HR 0.58, 95% CI 0.52–0.65) or receive systemic therapy (21.4% vs 25.9%; HR 0.81, 95% CI 0.76–0.86). Increased mortality persisted among patients with obesity (HR 1.33), diabetes mellitus (HR 1.27), and non-cirrhotic disease (HR 1.41) (all $p < 0.001$). Sensitivity analyses excluding alcohol-associated liver disease continued to demonstrate worse survival in the metabolic syndrome cohort (HR 1.22, 95% CI 1.16–1.29; $p < 0.001$). **Conclusion:** Metabolic syndrome–associated HCC was associated with worse survival, increased hepatic complications, and lower transplantation utilization compared with viral hepatitis–associated HCC. These findings highlight important etiologic differences in HCC presentation and outcomes and support the need for improved surveillance and risk stratification strategies.

4244 | HEPATOCELLULAR CARCINOMA IN A LARGE CORRECTIONAL HEALTHCARE SYSTEM: BURDEN, MANAGEMENT, AND OUTCOMES

Raakhi Menon[1] Mahnur Haider[2] Hari Movva[1] Hisham Alsharif[1] Muhammad Mushtaq[1] Biai Digbeu[1] Gwen Baillargeon[1] Jessica Khan[1] Olugbenga Ojo[1] Owen Murray[1] Sreeram Parupudi[1], [1]University of Texas Medical Branch, [2]Georgetown University

Background: Incarcerated populations have a high prevalence of hepatocellular carcinoma (HCC) risk factors, particularly chronic hepatitis C virus (HCV) infection, yet data on HCC characteristics, management, and outcomes in correctional settings remain limited. We describe the burden of HCC within the Texas Department of Criminal Justice (TDCJ). **Methods:** Retrospective study of individuals, 18 years or older, incarcerated in TDCJ (January 2015–December 2023). HCC was identified via ICD-9/10 codes and confirmed by chart review using standardized imaging criteria (LI-RADS) and/or histopathology. Stage classified as early (solitary ≤ 3 cm, no vascular invasion or metastasis), intermediate (multifocal or > 3 cm, no vascular invasion or metastasis), or advanced (vascular invasion and/or metastasis). Clinical characteristics were compared by HCV viral clearance status (undetectable HCV RNA). **Results:** 408 HCC cases were confirmed; 395 (96.8%) diagnosed during incarceration. Cohort was predominantly male (97.8%); 45.1% incarcerated 3–5 years, 35.2% > 5 years. Cirrhosis present in 88.7%, mostly viral hepatitis (93.4%). At diagnosis, median MELD-Na was 9.0 (IQR 8–12), 51.9% were ALBI grade 2, and 30.4% had decompensated cirrhosis. Stage: early 18.1%, intermediate 32.4%, advanced 22.5%; 27.0% unstaged. HCC-directed therapy received by 71.3%: 54.2% chemoembolization, 20.9% ablation,10.8% systemic therapy and 10.0% surgical resection. Median time to first treatment

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

was 61 days (IQR 34–108). Mortality was 49.8%; median time from diagnosis to death was 365 days (IQR 152–831). Of 331 patients with HCV testing, 312 (94.3%) had chronic HCV; 111 (27.2%) received antiviral therapy, of whom 84 (75.6%) achieved HCV viral clearance. One-third (31.5%) initiated HCV treatment after HCC diagnosis. Most prescribed regimens: sofosbuvir/velpatasvir (45%), glecaprevir/pibrentasvir (30%), ledipasvir/sofosbuvir (18%). Compared to those without HCV viral clearance, patients with viral clearance were more often incarcerated >5 years (63.3% vs. 29.7%; $p < 0.001$), had lower hepatic fibrosis by APRI ($p = 0.002$), and trended toward earlier HCC stage (25.6% vs. 17.1%) and lower mortality (41.1% vs. 50.9%), although these did not reach statistical significance (Table 1). **Conclusion:** Correctional healthcare systems face substantial barriers to care and remain understudied. Chronic HCV was the predominant etiology of liver disease, highlighting the high burden of HCV mediated HCC among incarcerated individuals. Despite patients receiving HCC-directed therapy, nearly half died, many presenting with intermediate or advanced-stage disease. Patients achieving HCV viral clearance had significantly less hepatic fibrosis and longer incarceration duration. Correctional healthcare systems represent critical opportunities for HCV treatment, cirrhosis care, and HCC surveillance, and require dedicated resources to address this burden.

Table 1. Clinical characteristics by HCV viral clearance status among individuals with documented chronic HCV and available HCV RNA testing (n=312)

Variable	Achieved viral clearance (n=90)	No viral clearance (n=222)	P-value
Age, median (IQR)	60 (56.25-63)	58 (53.5-61)	0.268
Male sex, n (%)	87 (96.7%)	216 (97.3%)	0.7207
Race, n (%)			0.7466
White	38 (42.2%)	86 (38.7%)

4245 | A POST-RESECTION RECURRENCE MODEL (REC SCORE) INTEGRATING TUMOR SIZE AND CD8⁺TIM-3⁺ T-CELL DIFFERENTIAL IN EARLY-STAGE HEPATOCELLULAR CARCINOMA

Qing Zhao[1] Jie Wang[2] Wei Wu[2] Qi Xia[2], [1]Zhejiang University, [2]The First Affiliated Hospital, Zhejiang University School of Medicine

Background: Early-stage hepatocellular carcinoma (HCC) frequently recurs after curative resection, yet individualized prediction tools remain limited. **Methods:** We retrospectively enrolled 59 patients with early-stage HCC who underwent hepatectomy and completed ≥ 3-year follow-up. Clinical-pathological parameters, peripheral immune profiling by flow cytometry and tumor tissue immunofluorescence were compared between recurrent and non-recurrent patients. Independent predictors from multivariable Cox regression were integrated into the Recurrence Estimation after Curative resection (REC) score. Discrimination and risk stratification were evaluated by area under the receiver operating characteristic (ROC) curve and Kaplan-Meier (KM) analysis. **Results:** Recurrent patients exhibited higher levels of alpha-fetoprotein (AFP) and protein induced by vitamin K absence or antagonist-II (PIVKA-II), larger tumor size, poorer differentiation, and a greater pre-post change in the proportion of CD8⁺TIM-3⁺ T-cell (all $p < 0.05$) compared to non-recurrent patients. Tumor size (HR 1.17, 95%CI 1.02-1.30) and pre-post change of CD8⁺TIM-3⁺ T-cell proportion (HR 1.55, 95%CI 1.03-2.21) were independently associated with recurrence and constructed the predictive REC score. The REC score achieved an AUC of 0.79, outperforming AFP (AUC 0.65) and albumin-bilirubin (ALBI) (AUC 0.58). With the optimal cutoff (0.533), REC stratified patients into low-risk (n = 37, 3-year RFS > 91.90%) and high-risk (n = 22, 3-year RFS < 50.00%) groups (log-rank $p < 0.01$). **Conclusion:** This exploratory study suggests that integrating tumor burden with dynamic T-cell dysfunction may provide promising insights into predicting post-resection recurrence in early-stage HCC. However, theses preliminary findings require validation in larger, more diverse cohorts due to the small sample size and statistical limitations.

4246 | MULTIMODAL SEQUENCING IDENTIFIES SYNERGISTIC MECHANISMS DRIVING RESISTANCE TO NEOADJUVANT NIVOLUMAB TREATMENT IN HCC

Irene Ng[1] Fanhong Zeng[2] Jiax Guo[1] Zheng Zeng[1] Vanilla Zhang[2] Daniel Ho[2], [1]The University of Hong Kong, [2]University of Hong Kong

Background: The tumor immune microenvironment (TIME) critically modulates therapeutic responses to immune checkpoint inhibitors (ICIs) in hepatocellular carcinoma (HCC). Relative to the other solid tumors, HCC is characterized by more pronounced intratumoral heterogeneity and has comparatively poorer responsiveness to ICI blockade treatment. Importantly, the correlation of the underlying mechanism of TIME and the molecular underpinnings of immunotherapy resistance in HCC remains elusive. **Methods:** We employed an integrative multi-omics approach, including spatially resolved transcriptomics, single-cell and bulk RNA sequencing, and lipidomics to delineate the spatiotemporal dynamics and mechanistic basis of resistance to anti-PD-1 therapy in patient HCC tumors. **Results:** Our analyses revealed a profoundly immunosuppressive TIME in non-responsive patients, marked by sparse immune cell infiltration within the tumor niche, in contrast to the immune-inflamed TIME observed in the responders. Multidimensional profiling further uncovered dysregulated and enhanced lipogenesis and aberrant lipid accumulation in tumor cells of the non-responder cases. Notably, tumor-associated macrophages (TAMs), exhausted CD8 T cells, and lipid-enriched tumor cells co-localize at the tumor-immune interface, forming a physical and functional barrier that precludes effective immune cell infiltration into the tumor niche. We also identified a pivotal TAM-tumor cell crosstalk via ADM-RAMP1-EBP signaling axis, orchestrating lipid metabolism reprogramming and contributing to the attenuated PD-1 therapeutic efficacy. To evaluate the therapeutic potential of the combined actions of EBP inhibition and anti-PD1 immune checkpoint blockade, we utilized an orthotopic liver injection HCC mouse model. While anti-PD1 or EBP inhibitor monotherapy effectively suppressed tumor growth, the combination of both agents showed a robust synergistic effect in further abrogating the tumor growth. **Conclusion:** Collectively, these findings provide a comprehensive mechanistic framework for anti-PD1 resistance, unveiling actionable biomarkers and a translational vulnerability to enhance precision therapeutics in HCC.

4247 | LIPID NANOPARTICLE-TARGETED SIRNA THERAPEUTICS FOR CHOLANGIOCARCINOMA

Brandon Wilbanks[1] Danielle Carlson[1] Jayla Millender[1] Shelby Yee[1] Hidemi Nishi[1] Enis Ozmert[1] Emily Siegler[1] Leonard Di Filippo[1] Gregory Gores[1] Sai Yerneni[1] Rory Smoot[1], [1]Mayo Clinic

Background: Cholangiocarcinoma (CCA) is a highly lethal primary hepatic malignancy arising from the biliary epithelium. Resection is curative for some patients, though most are not eligible due to advanced disease at the time of presentation. Current treatment strategies rely on systemic treatment with chemotherapeutics or small molecule inhibitors, leaving many potential therapeutic targets unexplored due to the systemic toxicity of their inhibitors. No approach for tumor-selective inhibition is available. **Methods:** We performed an in vitro screen with unique 96 lipid nanoparticles (LNPs) composed of varied combinations of ionizable lipids and phospholipids to discover an LNP with selective cholangiocarcinoma delivery properties. This screen and subsequent in vivo validation with mice bearing orthotopically implanted tumors (panel A) identified an LNP that delivers nucleic acid payloads to tumors without off-target deposition in all other tissues except for spleen. We then used this LNP for delivery of siRNAs targeting Mcl-1 and Bcl-xL to selectively induce apoptosis in tumors. After implanting CCA cells and allowing 19 days of orthotopic tumor development, mice were treated 3X weekly for two weeks and then observed to humane endpoint. **Results:** LNP-targeted siRNA treatment with anti-Mcl-

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

1 and Bcl-xL knockdown ("siCombo") extended survival in CCA-bearing mice (panels B-D), slowed tumor growth rates, and reduced intraperitoneal metastatic burden (panel E). We observed no long-term damage in spleen as a result of off-target delivery. All mice in control groups met humane endpoint criteria (20% body weight loss or 15% weight gain with visible ascites) before study termination (43 days post-implant) while half of siRNA-treated animals survived. **Conclusion:** LNP-targeted siRNA therapies represent a promising new modality for CCA treatment. Importantly, this platform enables knockdown of target genes that are otherwise undruggable due to systemic toxicity of small molecule inhibitors. We are exploring additional therapeutic targets and methods for extended target knockdown with chemically modified siRNAs.

4248 | UNDERTREATMENT AND DISPARITIES IN HCC TREATMENT AMONG OLDER PATIENTS WITH HEPATOCELLULAR CARCINOMA (HCC): A U.S. POPULATION-BASED STUDY

Danfeng Ren[1] Taotao Yan[1] Joanne Kimiko Liu[2] Nicholas Chien[2] Bowu Chen[3] Hong Fan[2] Xiaonan Su[4] Ramsey Cheung[2] Mindie Nguyen[2], [1]The First Affiliated Hospital of Xi'an Jiaotong University, [2]Stanford University Medical Center, [3]Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, [4]Zhejiang Provincial Clinical Research Center for Digestive Diseases, The First Affiliated Hospital

Background: HCC disproportionately affects older adults who may have more barriers to treatment, which may lead to poorer survival outcomes. However, population-based data on treatment utilization, disparities and its evolution over time in this population remain limited. The current study evaluated changes by HCC diagnosis year in the overall treatment rates, treatment types and overall survival (OS) of older patients with HCC using a U.S. national population-based database. **Methods:** We conducted a retrospective cohort study of 40,996 adults aged ≥65 years who were diagnosed with HCC from 2007 to 2021 using the Surveillance, Epidemiology, and End Results (SEER)-Medicare database. Temporal trends in treatment utilization were assessed using Joinpoint regression to estimate average annual percentage change (AAPC). **Results:** Only 49.7% of the study cohort received HCC treatment of any type. Initial treatments were surgery in 9.6%, local ablation in 6.0%, other locoregional therapy in 26.7%, and systemic therapy in 7.4%. Treatment rates declined with increasing age (54.8%, 47.6%, and 31.1% for ages 65-74, 75-84, and ≥85 years) and more advanced HCC stage (61.3%, 47.6%, and 30.0% for localized, regional, and distant HCC), respectively, with significant disparities across sociodemographic and clinical subgroups (Figure 1A). However, treatment rates increased over time (32.4% in 2007 to 64.2% in 2021; AAPC 4.84%, 95% CI 4.14%–5.31%) but mostly in nonsurgical treatments (AAPC: 5.34% for local ablation, 5.85% for other locoregional therapy and 7.45% for systemic therapy, $P<0.001$ for all), with consistent increase across major subgroups, especially in patients aged ≥85 years (18.0% in 2007 to 49.3% in 2021; AAPC 8.85%, 95% CI 6.24%–11.50%) though they remained the least treated in 2021. Multivariable analysis adjusting for age, sex, race and ethnicity, urbanicity, insurance status, socioeconomic status (SES), liver disease etiology and severity, Charlson Comorbidity Index, tumor stage at diagnosis and diagnosis period showed lower odds of treatment with age ≥85 vs 65–74 (aOR 0.41, 95% CI 0.37–0.44), distant vs localized stage (aOR 0.27, 95% CI 0.25–0.28), and non-Hispanic Black vs White (aOR 0.63, 95% CI 0.58–0.69), while higher odds were observed with compensated cirrhosis vs noncirrhosis (aOR 2.76, 95% CI 2.60–2.93), viral vs nonviral etiology (aOR 1.81, 95% CI 1.71–1.91), highest vs lowest SES quintile (aOR 1.78, 95% CI 1.65–1.93). Treated (vs untreated) patients had longer median OS overall (24.0 vs 3.0 months, $P<0.001$) and in each age subgroup including those older than 85 (all $P<0.001$) (Figure 1B). **Conclusion:** Among older adults with HCC, though treatment rates have increased over time, these gains were mainly with nonsurgical palliative treatment and nearly half still untreated, with substantial age, racial and ethnic, geographic, and socioeconomic disparities.

4249 | TRANSCRIPTOMIC SHANNON DIVERSITY STRATIFIES PROGNOSIS AND MARKS AN ONCOFETAL SUBTYPE IN GRADE 1 HEPATOCELLULAR CARCINOMA

Haley Arbore[1] Jia-Jun Liu[1] Silvia Liu[1] Panayiotis Benos[2] Juliane Beier[1] Gavin Arteel[1], [1]University of Pittsburgh, [2]University of Florida

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related mortality worldwide, yet histologic grading does not fully capture molecular heterogeneity, particularly in well-differentiated tumors. Transcriptomic Shannon diversity is a per-sample measure of transcript abundance evenness that has been proposed as a pan-cancer index of tumor heterogeneity. Its prognostic relevance in HCC and its relationship to tumor biology have not been established. This study examines whether Shannon diversity predicts survival in a grade-dependent manner and whether it relates to oncofetal dedifferentiation in well-differentiated HCC. **Methods:** Shannon diversity indices were computed from TCGA-LIHC bulk RNA-seq data across all tumors (n = 374), and quartile boundaries (Q1-Q4) were established from this full cohort distribution. Differential gene expression analysis was performed using DESeq2 (Q4 vs Q1, Q2, and Q3). Ingenuity Pathway Analysis was applied to Q4 vs Q1 DEGs. Overall survival was evaluated by Kaplan-Meier and Cox regression across all tumor grades. A hepatocyte differentiation score was computed as the mean log2(CPM+1) expression of 24 mature hepatocyte marker genes. Spearman correlation was used to assess the relationship between Shannon diversity and hepatocyte differentiation across tumor grades. **Results:** Shannon diversity independently predicted mortality after adjusting for T stage and tumor grade (OR = 1.16 per unit, $p < 0.001$). Grade 1 was the only grade at which Shannon diversity significantly stratified survival; Q4/G1 tumors had 62.5% mortality compared to 15.8% in Q1/G1. High Shannon diversity (Q4) was associated with significantly worse overall survival compared to Q1 in Grade 1 tumors (log-rank $p < 0.001$). No significant survival association was found in Grade 2 ($p = 0.489$) or Grade 3/4 ($p = 0.823$). DEG analysis identified 944 significant genes in Q4 vs Q1, the majority downregulated. IPA showed suppression of mature hepatocyte programs including the urea cycle, LXR/RXR activation, metallothionein signaling, and acute phase response, with concurrent activation of ID3 and SPINK1 pathways. Q4 tumors had significantly lower hepatocyte differentiation scores than Q1 ($p = 3.6 \times 10^{-6}$), and Shannon diversity was inversely correlated with hepatocyte differentiation in Grade 1 ($r = -0.516$, $p = 5.5 \times 10^{-5}$), Grade 2 ($r = -0.447$, $p = 4.2 \times 10^{-10}$), and Grade 3/4 ($r = -0.403$, $p = 1.2 \times 10^{-6}$). **Conclusion:** High Shannon diversity in Grade 1 HCC identifies a clinically aggressive subgroup with loss of hepatocyte identity and oncofetal transcriptional activation. The prognostic value of Shannon diversity is restricted to well-differentiated HCC, where it captures molecular heterogeneity not reflected by histologic grade alone, and points to oncofetal reprogramming as a driver of poor outcomes in early-stage disease.

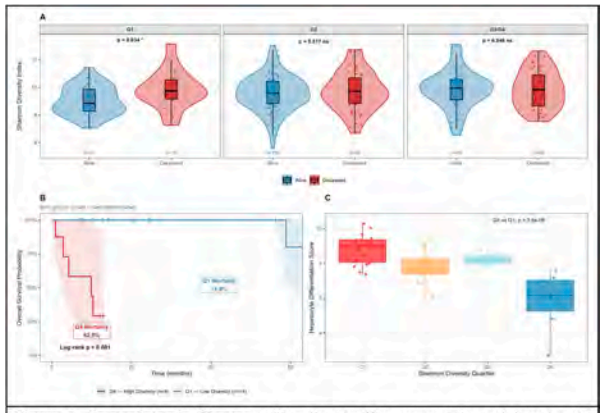

Figure 1. Transcriptomic Shannon diversity stratifies prognosis and hepatocyte identity in Grade 1 HCC. (A) Shannon diversity compared between deceased and surviving patients by tumor grade (TCGA-LIHC, n=364). Grade 1 is the only grade with a significant dead/alive difference (9.93 vs. 9.52, Mann-Whitney p=0.034); no significant difference was observed in Grade 2 (p=0.517) or Grade 3/4 (p=0.946). **(B)** Kaplan-Meier survival curves for Grade 1 tumors stratified by Shannon quartile (Q4 vs. Q1). Despite identical histologic grade, Q4 tumors exhibit 62.5% mortality vs. 15.8% in Q1 (log-rank p<0.001). Tick marks indicate censored observations. **(C)** Hepatocyte differentiation score (mean log2(CPM+1) of 24 mature hepatocyte marker genes) by Shannon quartile in Grade 1 tumors. Q4 tumors show a stepwise reduction compared to Q1 (Wilcoxon $p = 3.6 \times 10^{-6}$), indicating progressive loss of hepatocyte gene expression with increasing transcriptomic diversity.

4250 | HEPATIC ADENOMATOSIS: A SYSTEMATIC REVIEW OF DEFINITIONS, DIAGNOSTIC EVALUATION, MANAGEMENT, AND OUTCOMES

Thomas Stirrat[1] Shankar Thiru[2] Stella Kim[2] Soham Apte[3] Deeptha Bejugam[2] Michael Flatley[4] Amol Rangnekar[5] Rachel Redfield[6], [1]University of California Los Angeles (UCLA), [2]Georgetown University School of Medicine, [3]Kentucky College of Osteopathic Medicine, [4]University of Colorado Internal Medicine Residency Program, [5]Georgetown University Hospital, [6]MedStar Georgetown University Hospital

Background: Hepatic adenomatosis (HA), the multifocal phenotype of hepatocellular adenoma, is inconsistently defined and managed. We performed a systematic review to synthesize definitions, imaging use, pathology reporting, management strategies, and outcomes. **Methods:** MEDLINE/PubMed, Embase, Web of Science, and CINAHL were searched from inception through August 25, 2025. Human case reports/series with original clinical data and diagnostic confirmation by imaging and/or histopathology were included. Data were abstracted using standardized fields and synthesized descriptively. **Results:** Fifty-four reports describing 55 patients were included; 53/54 studies (98.1%) were single-case reports. Most patients were female (45/55, 81.8%), with median age 34 years. Definitions most often used a $\geq$10-lesion threshold (37/54, 68.5%). Among cases with quantifiable lesion burden, the median lesion count was 15; median largest-lesion diameter was 80 mm (range 13-170), and 37/46 (80.4%) measured $\geq$5 cm. MRI was reported in 34/51 (66.7%), but hepatobiliary-phase MRI was reported in only 2/51 (3.9%). Histologic/molecular subtype reporting was sparse. Management included observation (34/53, 64.2%), resection (32/53, 60.4%), transplantation (6/53, 11.3%), embolization (4/53, 7.5%), and ablation (1/53, 1.9%). Indications for active intervention included size $\geq$5 cm (21/41, 51.2%), malignancy/diagnostic concern (17/41, 41.5%), hemorrhage/risk (11/41, 26.8%), and symptoms (10/41, 24.4%). Follow-up documented hemorrhage in 5/55 (9.1%) and malignant transformation in 6/55 (10.9%), likely reflecting publication/severity bias. **Conclusion:** HA literature remains fragmented by variable definitions, incomplete imaging protocols, limited molecular profiling, and sparse follow-up. A pragmatic research framework should standardize HA as $\geq$10 adenomas in a non-cirrhotic liver while emphasizing hepatobiliary-contrast MRI, targeted biopsy/molecular profiling of index lesions, hormone withdrawal, and risk-adapted intervention.

Hepatic adenomatosis: key abstract outcomes

Variable	Value
Reports / patients included	54 / 55
Female patients	45/55 (81.8%)
Median age	34 years
≥10-lesion definition used	37/54 (68.5%)
Median lesion count	15
Median largest-lesion diameter	80 mm
Largest lesion ≥5 cm	37/46 (80.4%)
MRI reported	34/51 (66.7%)
Hepatobiliary-phase MRI reported	2/51 (3.9%)
Hemorrhage / malignant transformation	5/55 (9.1%) / 6/55 (10.9%)

Disclosures: Thomas Stirrat:Nothing to Disclose, Shankar Thiru:Nothing to Disclose, Stella Kim:Nothing to Disclose, Soham Apte:Nothing to Disclose, Deeptha Bejugam:Nothing to Disclose, Michael Flatley:Nothing to Disclose, Amol Rangnekar:Nothing to Disclose, Rachel Redfield:Nothing to Disclose.

4251 | DIAGNOSTIC PERFORMANCE OF MRI VS. CONTRAST ENHANCED ULTRASOUND FOR DETECTION OF HCC IN PATIENTS WITH INDETERMINATE LIVER NODULES

Amit Singal[1] Guruveer Bhamra[1] Emma Jones[1] David Fetzer[1] Sruthi Yekkaluri[1] Takeshi Yokoo[1] So Yeon Kim[1] Lisa Quirk[1] Kayleen Sorto[1] Nicole Rich[2], [1]UT Southwestern Medical Center, [2]University of Texas Southwestern Medical Center

Background: Patients with indeterminate liver nodules (ILNs), i.e., LI-RADS 3 and 4 observations, have a 35-70% risk of developing hepatocellular carcinoma (HCC) and require close surveillance. Multi-phase CT or MRI are the most common surveillance modalities, and the role of contrast-enhanced ultrasound (CEUS) is unknown. **Methods:** We conducted an interim analysis of a prospective cohort of patients with cirrhosis and LR-3 or LR-4 observations to compare the performance of MRI and CEUS for diagnosing HCC (NCT06184152).

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Patients were enrolled from 2 large health systems in Dallas, TX between November 2023 and April 2026. We excluded patients with a history of liver cancer, liver transplant, or extra-hepatic malignancy. Patients underwent both contrast MRI and CEUS every 3-6 months. Exams were performed within one month of each other and interpreted per LI-RADS v2018 criteria, blinded to the other exam results. Patients were followed until HCC diagnosis, death, transplant, ILNs resolving on both studies, or 2 years of stability. Cases with discordant findings were resolved by multi-phase CT, biopsy, or clinical diagnosis per tumor board. The primary outcome was patient-level sensitivity for HCC detection, and a secondary outcome was specificity. **Results:** Of 135 enrolled patients, 89 completed follow-up and were included in this analysis. Median age was 61 years (IQR 50-67), and 56.2% were male. Patients were diverse regarding race/ethnicity (47% Hispanic, 38% non-Hispanic White, 9% Black, 6% Asian/other) and cirrhosis etiology (38%, ALD, 28% MASLD, 15% post-SVR HCV). Most patients (83%) had Child Pugh A cirrhosis. There were 48 patients with LR-3 (median 1.2 cm (IQR 0.8-1.8) and 41 with LR-4 (median 1.7 cm (IQR 1.2-2.4). Most (66.3%) had a unifocal ILN, 21.4% had 2 ILNs, and the rest had 3 or more ILNs. During a median follow-up of 7 months (IQR 2.9-12), 31 patients (34.8%) developed HCC. Among these, 83.9% were early stage (BCLC stage A), 9.7% BCLC stage B, and 6.5% BCLC stage C. 54.8% of HCC were detected by MRI alone, 19.4% by both CEUS and MRI, and 9.7% by CEUS alone. Compared to MRI, CEUS had a significantly lower sensitivity (74% [95%CI 55-88] vs. 29% [95%CI 14-48], $p = 0.01$) but comparable specificity (97% [95%CI 89-100] vs 95% [95%CI 86-99]), yielding a higher diagnostic odds ratio (84.8 vs. 7.9). Findings were similar in the subset of patients with early-stage HCC. Of 18 ILNs that resolved prior to 2 years, 6 first resolved on CEUS, 6 on MRI, and 6 on both simultaneously. **Conclusion:** In a prospective cohort of patients with ILNs, MRI had superior sensitivity than CEUS for HCC detection, although CEUS may be complementary in some cases.

4252 | COMPARABLE LONG-TERM ONCOLOGICAL OUTCOMES AFTER CONVERSION THERAPY FOLLOWED BY RESECTION VERSUS UPFRONT RESECTION IN INTERMEDIATE-STAGE HEPATOCELLULAR CARCINOMA

Seohyun Ryu[1] Jaehong Jeong[1] Hye Won Lee[1],
[1]Yonsei University College of Medicine, Seoul, Korea

Background: Hepatocellular carcinoma (HCC) at Barcelona Clinic Liver Cancer (BCLC) stage B poses a therapeutic challenge, as current guidelines generally recommend surgical resection for early-stage disease, while selected patients with intermediate-stage HCC may also be considered for curative-intent surgery. Recent advances in therapies have enabled conversion to curative-intent resection in intermediate-stage patients. We therefore compared long-term oncological outcomes between patients who underwent upfront resection and those who underwent curative-intent resection following conversion therapy. **Methods:** Between January 2004 and December 2025, 2,455 patients with clinically diagnosed HCC who underwent surgical resection were retrospectively screened. Patients presenting with initial BCLC stage B disease on pre-treatment imaging were included. Conversion therapy consisted of locoregional treatment, systemic therapy, or their combination before resection. Propensity score matching (PSM) was performed based on age, sex, initial tumor size and count, etiology, and albumin-bilirubin grade. Recurrence-free survival (RFS) and hazard ratios (HRs) were estimated using Kaplan-Meier and Cox regression. **Results:** Of 176 patients with initial BCLC stage B, 114 underwent upfront surgical resection and 62 underwent curative-intent resection following conversion therapy. In the entire cohort, 7-year RFS did not differ significantly between groups (HR 1.41, 95% confidence interval [CI] 0.98–2.04, $p = 0.066$). After 1:1 PSM, 90 patients were included in the matched cohort, and RFS was comparable between the two treatment groups (HR 0.97, 95% CI 0.59–1.59, $p = 0.904$). On multivariable analysis, pre-operative alpha-fetoprotein non-response (HR 1.56, 95% CI 1.01–2.41, $p = 0.046$), tumor number

≥3 (HR 1.83, 95% CI 1.22–2.73, p = 0.003), and prothrombin time–international normalized ratio (HR 1.42, 95% CI 1.13–1.79, p = 0.003) were associated with worse RFS. **Conclusion:** In selected patients with intermediate-stage HCC who ultimately underwent curative-intent resection, conversion therapy followed by resection showed long-term recurrence-free survival comparable to upfront resection. These findings support further evaluation of conversion therapy as a strategy to expand curative surgical opportunities in this population.

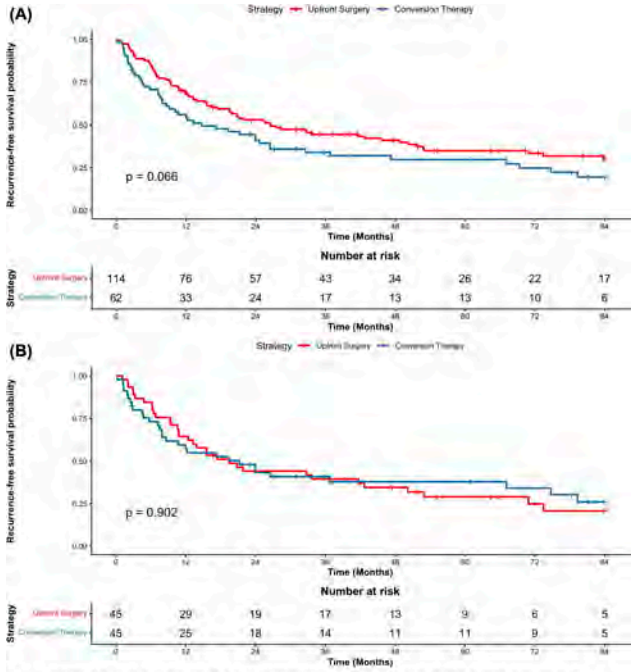

Fig 1. Kaplan-Meier curves for (A) 7-year recurrence-free survival in the entire cohort and (B) propensity score-matched 7-year recurrence-free survival in patients with intermediate-stage hepatocellular carcinoma.

4253 | CLINICAL CHARACTERISTICS OF PATIENTS MAINTAINING ATEZOLIZUMAB PLUS BEVACIZUMAB TREATMENT BEYOND TWO YEARS IN HEPATOCELLULAR CARCINOMA: A MULTICENTER RETROSPECTIVE COHORT STUDY

Young Mi Hong[1] Junsik Yoon[2] Yu Rim Lee[3] Jae hyun Yoon[4] Hyun Young Woo[5] Sangyoun Hwang[6] Yeowool Kang[7] Joonho Jeong[8] Sung Bum Cho[9] Jeongeun Song[10], [1]Pusan National University School of Medicine, [2]Department of Internal Medicine, Busan Paik Hospital, Inje University College of Medicine, [3]Department of Internal Medicine, School of Medicine, Kyungpook National University, [4]Department of gastroenterology and hepatology, Chonnam National University Hospital, [5]Department of Internal Medicine, College of Medicine, Pusan National University, [6]Department of Internal Medicine, Dongnam Institute of Radiologic & Medical Sciences, [7]Department of Internal Medicine, Dong-A University College of Medicine, [8]Department of Internal Medicine, Ulsan University Hospital, University of Ulsan College of Medicine, [9]Department of gastroenterology and hepatology, Chonnam National University, [10]Department of Internal Medicine, Daegu Catholic University Medical Center

Background: Atezolizumab plus bevacizumab (Atezo/Bev) has become a standard first-line treatment for unresectable hepatocellular carcinoma (HCC). While durable responses and long-term survival have been increasingly reported, the clinical characteristics of patients maintaining long-term Atezo/Bev treatment remain poorly understood. We aimed to investigate the characteristics and treatment outcomes of patients who maintained Atezo/Bev therapy beyond two years. **Methods:** We retrospectively analyzed patients with unresectable HCC treated with Atezo/Bev across multicenter cohorts. Patients who maintained Atezo/Bev treatment for ≥ 2 years were identified and compared with those who did not. Baseline liver function, tumor burden, inflammatory biomarkers, and treatment response were analyzed. **Results:** Among 943 patients treated with Atezo/Bev, 73 patients (7.7%) maintained treatment beyond two years. Patients maintaining long-term treatment showed more favorable baseline characteristics, including lower intrahepatic tumor extent (< 50%), lower ALBI grade, lower neutrophil-to-lymphocyte ratio (NLR), and lower AFP and PIVKA-II levels. Tumor response was strongly associated with long-term treatment maintenance. In the ≥ 2-year treatment group, complete response was observed in 17.8%, partial response in 43.8%, and stable disease in 38.4% of patients, indicating that durable disease control was observed even in patients without complete response. **Conclusion:** A subset of patients with HCC can maintain Atezo/Bev treatment beyond two years in real-world practice. Favorable liver function, lower inflammatory status, and lower intrahepatic tumor burden were associated with prolonged treatment maintenance. Importantly, durable disease control, including prolonged stable disease without complete response, may represent a key feature associated with long-term clinical benefit during Atezo/Bev treatment.

4254 | CLINICAL FEATURES AND SURVIVAL RATE OF PATIENTS WITH NON-CIRRHOTIC HEPATOCELLULAR CARCINOMA

Hunter Miller[1] Adrienne Gefre[1] Robert Vierkant[1] Perapa Chotiprasidhi[1] Karina Sato Espinoza[1] Lewis Roberts[1] Kirk Wangensteen[1], [1]Mayo Clinic

Background: Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related deaths worldwide. Non-cirrhotic HCC (NC-HCC) accounts for nearly 15-20% of HCC cases. However, there remains a gap in understanding the clinicopathologic characteristics, treatment patterns, and outcomes of NC-HCC in rigorously phenotyped patient cohorts. This study analyzed the electronic health records (EHR) of 539 patients with HCC to compare the clinical characteristics, treatment patterns, and outcomes of patients with NC-HCC and cirrhotic HCC (C-HCC). **Methods:** Initially, 1,400 patients were identified through the Mayo Clinic Hepatobiliary Cancer Registry. Following EHR abstraction, 226 were classified as NC-HCC and 313 as C-HCC for comparison. 72 cases were excluded due to mixed HCC-cholangiocarcinoma, fibrolamellar HCC, F3 fibrosis, or insufficient clinical data. Demographic, etiologic, laboratory, tumor, treatment, and survival characteristics were compared between cohorts. Mann-Whitney U, chi-squared or Fisher exact testing were used for respective continuous and categorical variables. Survival was analyzed using Kaplan-Meier methodology with log-rank and Gehan-Breslow-Wilcoxon testing. **Results:** A total of 226 patients with NC-HCC and 313 patients with C-HCC were included. Compared to C-HCC, patients with NC-HCC demonstrated lower median Fib-4 scores (1.90 vs 6.40), higher platelet counts (256.5 vs 95.5 $\times 10^9$/L), and lower MRI elastography stiffness (2.7 vs 5.9 kPa) (all $P < 0.0001$). NC-HCC patients had lower rates of hepatitis C (5.8% vs 37.4%), steatohepatitis (16.4% vs 34.5%), and alcohol-associated liver disease (7.1% vs 32.9%), while idiopathic HCC was more common in NC-HCC (23.5% vs 2.9%)(all $P < 0.0001$).Patients with NC-HCC more frequently presented with solitary tumors (67.7% vs 48.6%), whereas multifocal disease (>5 tumors) was more common in C-HCC patients (1.3% vs 8.0%). NC-HCC had higher rates of Grade 3 tumors (20.8% vs 8.9%), greater T3 tumor stage (22.1% vs 4.2%), and less T1 stage (15.3% vs 23.6%). Nodal and metastatic staging did not significantly differ.With regards to initial treatment, NC-HCC patients were more likely to undergo resection (44.2% vs 6.7%), whereas baseline liver transplantation (0.4% vs 8.3%) and chemoembolization (12.4% vs 38.3%) were more common in C-HCC patients (all $P < 0.0001$). Ultimately, liver transplantation occurred much more frequently in C-HCC patients (1.8% vs 51.1%, $P < 0.0001$). 5-year overall survival was significantly lower in NC-HCC compared to C-HCC patients (50.1% vs 64.5%, $P = 0.0013$). **Conclusion:** Non-cirrhotic HCC is a distinct clinical subtype characterized by minimal fibrosis, more advanced tumors at presentation, different treatment patterns, and worse survival. The genetic and environmental factors underlying NC-HCC remain unclear. This study establishes a well-characterized NC-HCC cohort for future genomic and risk stratification studies.

4255 | SURVIVAL OUTCOMES OF CONVERSION CURATIVE THERAPY FOLLOWING ATEZOLIZUMAB–BEVACIZUMAB IN ADVANCED HEPATOCELLULAR CARCINOMA

Chao-Hung Hung[1] Ying-Hsin Chen[1] Wei-Feng Li[1] Yen-Hao Chen[1] Jing-Houng Wang[1], [1]Kaohsiung Chang Gung Memorial Hospital

Background: The prognostic value of curative therapies—including liver transplantation, hepatectomy, and local ablation—in patients with advanced hepatocellular carcinoma (HCC) following atezolizumab plus bevacizumab treatment remains unclear. This study evaluated the feasibility of curative therapy and compared survival outcomes between patients who did and did not undergo curative interventions following atezolizumab plus bevacizumab, using a propensity score–matched analysis. **Methods:** We retrospectively analyzed 318 consecutive patients with advanced HCC who received atezolizumab plus bevacizumab between 2020 and 2024. Overall survival (OS) and progression-free survival (PFS) were defined as the primary and secondary endpoints, respectively, and were estimated using the Kaplan–Meier method and assessed with multivariate Cox proportional hazards regression. **Results:** The objective response rate to atezolizumab plus bevacizumab was 34.6%. Thirty-six patients (11%) subsequently underwent curative therapy, including liver transplantation (n = 8, 2.5%), hepatectomy (n = 11, 3.5%), and local ablation (n = 17, 5.3%). Patients receiving curative therapy demonstrated significantly improved OS ($p < 0.001$) and PFS ($p < 0.001$) compared with those who did not, with benefits persisting after propensity score matching. Multivariate Cox regression identified curative therapy as an independent predictor of OS (hazard ratio [HR] 0.204; 95% confidence interval [CI] 0.094–0.444; $p < 0.001$). **Conclusion:** Curative therapy following atezolizumab plus bevacizumab confers substantial survival benefits in selected patients with advanced HCC.

4256 | CLINICAL CHARACTERISTICS AND DIAGNOSIS OF DOUBLE-NEGATIVE HEPATOCELLULAR CARCINOMA WITH AFP AND PIVKA-II

Yanhui Shi[1] Wenjun Du[2] Shiyu Wang[1] Weihua Cao[1] Wen Deng[1] Minghui Li[1], [1]Department of Hepatology Division 2, Beijing Ditan Hospital, Capital Medical University, Beijing, [2]Department of Liver Diseases,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Shandong Public Health Clinical Center, Shandong University, Jinan

Background: This study elucidates the clinical and imaging features of double-negative hepatocellular carcinoma (HCC), identify independent hazard factors for double-negative tumor markers in HCC patients, construct a risk prediction model, and analyze the challenges and countermeasures in the current diagnostic paradigm centered on serum biomarkers and imaging. **Methods:** A total of 535 patients diagnosed with HCC between January 2019 and June 2024 were consecutively enrolled and randomized into a training (n = 361) and a testing cohort (n = 174) at a 7:3 ratio. Based on serum AFP and PIVKA-II levels, patients were categorized into double-negative and non-double-negative groups. Demographic, clinical, laboratory (including liver and coagulation functions), and contrast-enhanced CT/MRI features were systematically collected and compared between the two groups. Statistical analyses were performed using SPSS 26.0 and R 4.1.0. A risk prediction model was constructed and validated using receiver operating characteristic (ROC) curves, while decision curve analysis (DCA) was utilized to assess its clinical net benefit. **Results:** In the training set, double-negative HCC accounted for 29.4% (106/361) of cases. The univariate analysis revealed that the two tumor markers negative group was diagnosed at a younger age than the non-double-negative group, a meaningly lower prevalence of cirrhosis (83.0% vs. 94.1%, P < 0.001) and a greater percentage of younger patients (42.5% vs. 18.4%, P < 0.001). Etiologically, metabolic-associated fatty liver disease (MAFLD) was much more common in the double-negative group (17.0% vs. 2.8%, P < 0.001). Imaging features indicated that the double-negative group had smaller tumor diameters (2.3 [1.6, 3.8] cm vs. 5.3 [2.8, 10.2] cm, P < 0.001) and a greater prevalence of solitary tumors (72.6% vs. 48.6%, P < 0.001). Binary logistic regression study identified younger age, MAFLD etiology, and smaller tumor diameter as independent predictors of double-negative status. A nomogram-based risk prediction model was established using these factors, attaining a training set region beneath the ROC curve (AUC) of 0.812 and a validation set AUC of 0.798. DCA showed that the model had great clinical applicability, and calibration curves (CC) showed good consistency between anticipated and observed values. **Conclusion:** "Young age, metabolic association, and small tumor size" are independent hazard factors for AFP and PIVKA-II double-negative HCC. The anticipated outcome model based on these factors demonstrates good discriminative ability and clinical applicability. For high-risk young populations with metabolic risk factors or non-viral backgrounds, it is recommended to optimize imaging screening strategies and enhance the role of high-resolution multimodal imaging in clinical diagnostic pathways to compensate for the limitations of traditional serological markers in this subgroup.

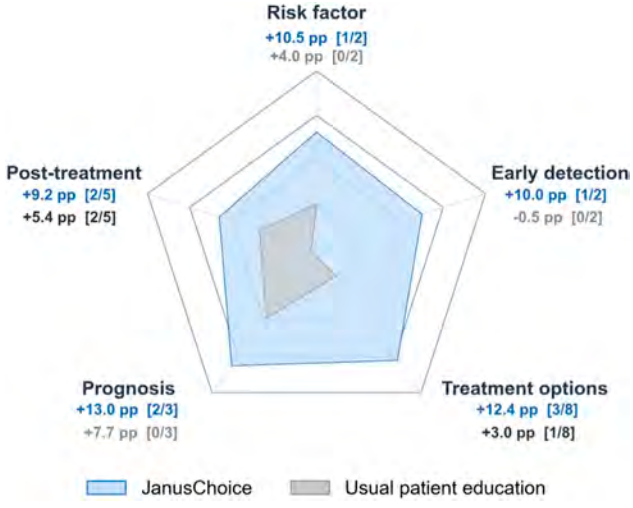
4257 | ETIOLOGY AS A BIOMARKER CONTEXT RATHER THAN A DRIVER-MUTATION CLASSIFIER IN HEPATOCELLULAR CARCINOMA

Motoyuki Otsuka[1], [1]Okayama University

Background: Hepatocellular carcinoma (HCC) develops through diverse etiologic backgrounds, including HBV, HCV, and nonviral liver diseases. However, whether etiology should be used to define distinct molecular subtypes or to contextualize genomic biomarker interpretation remains unclear. We reappraised nationwide comprehensive genomic profiling data to determine whether viral and nonviral backgrounds primarily shape core oncogenic drivers, biomarker phenotypes, or the clinical utility of tissue- and liquid-based genomic testing. **Methods:** We analyzed 551 patients with HCC registered in the Japanese C-CAT database, a nationwide repository of clinical cancer gene panel testing/comprehensive genomic profiling data. Patients were classified into HBV-related, HCV-related, and nonviral/noncholestatic HCC. Pathogenic or likely pathogenic alterations detected by clinical comprehensive genomic profiling were evaluated across three interpretive layers: recurrent driver alterations, biomarker-associated phenotypes including tumor mutation burden (TMB) and homologous recombination repair (HRR)-related alterations, and the detection of druggable alterations by tissue- versus liquid-based profiling. **Results:** Etiology had limited impact on the core driver framework of HCC. TERT splice-site alterations represented the dominant genomic event across etiologic groups, and major drivers such as TP53 and CTNNB1 showed broadly comparable distributions. Only modest etiology-associated signals were observed, including enrichment of AXIN1 alterations in HCV-related HCC and DDR2 alterations in HBV-related HCC. In contrast, etiology was more informative for biomarker interpretation. TMB was generally low in HCC, but nonviral/noncholestatic HCC showed significantly lower TMB than HCV-related HCC, suggesting a less mutation-burdened biomarker phenotype in nonviral tumors. HRR-related alterations, including ATM, BRCA2, CHEK2, and BRCA1, were not associated with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.



increased TMB, indicating that HRR alteration status should not be used as a surrogate for hypermutation in HCC. Tissue-based profiling detected more oncogenic alterations overall, whereas liquid biopsy retained a comparable yield for druggable alterations. Despite the identification of druggable genomic findings, matched therapy was implemented in only a minority of patients. **Conclusion:** HCC etiology does not appear to define fundamentally separate driver-mutational diseases. Rather, etiology functions as a clinically relevant context for interpreting genomic biomarkers, particularly TMB, HRR-related alterations, and liquid biopsy results. These findings support an etiology-aware precision oncology framework in HCC, in which treatment strategies may remain broadly unified across etiologies, while biomarker interpretation and clinical trial stratification should account for the underlying liver disease background.

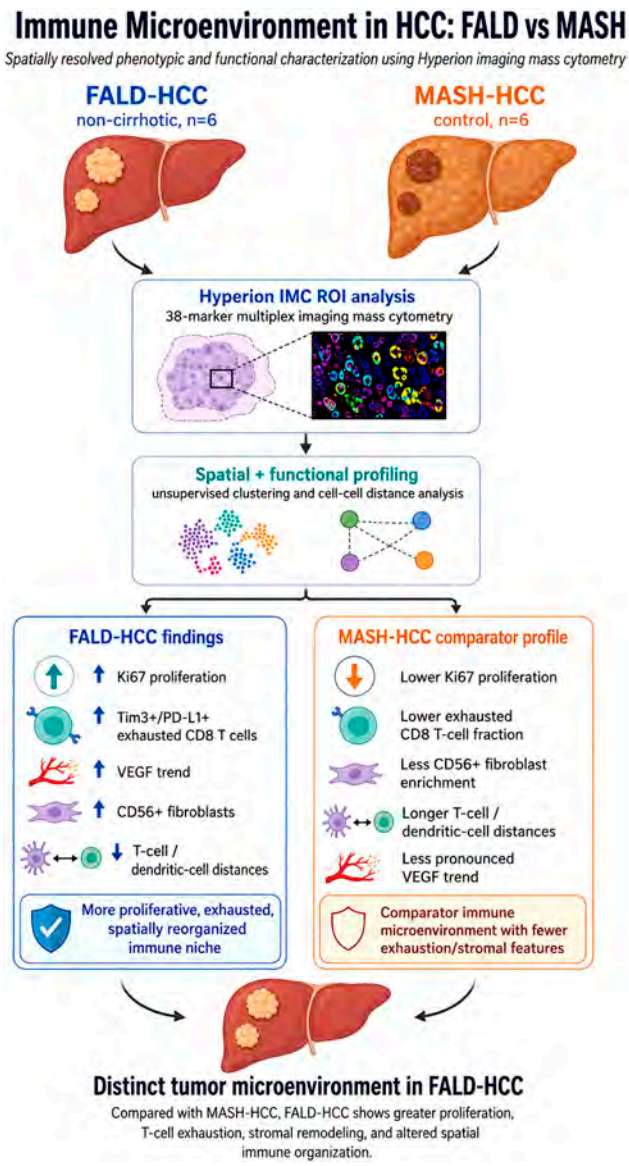
4258 | A RETRIEVAL-AUGMENTED AI CHATBOT IMPROVES HEALTH LITERACY IN NEWLY DIAGNOSED EARLY-STAGE HEPATOCELLULAR CARCINOMA: A MULTICENTRE RANDOMISED CONTROLLED TRIAL

Chun-Ying Wu[1] Li-Lin Liang[1] Che-Lun Hung[1], [1]National Yang MIng Chiao Tung University, Taiwan

Background: Patients with newly diagnosed early-stage hepatocellular carcinoma (HCC) face complex curative-intent treatment decisions under time pressure, with limited health literacy a prevalent unmet need. Whether AI chatbots can address this gap, particularly for socioeconomically vulnerable patients, remains untested. **Methods:** In a multicentre randomised controlled trial across five tertiary hospitals in Taiwan (NCT06384950), 150 patients with BCLC stage 0/A HCC were randomly assigned to usual patient education or usual education plus JanusChoice, a retrieval-augmented chatbot delivered through the LINE messaging platform. **Results:** JanusChoice produced a 7.1-percentage-point net gain in liver cancer literacy (P = .016), with concentrated improvements in treatment-options and prognosis domains. Two of five consultation-quality dimensions improved significantly. User experience exceeded the scale midpoint (P = .008). Lower-income, retired or unemployed, and AI-naive participants derived the largest benefits. **Conclusion:** Messaging-platform-delivered RAG chatbots can improve patient literacy in early-stage HCC, with benefits concentrated in populations typically underserved by digital health interventions.

Disclosures: Chun-Ying Wu:Nothing to Disclose, Li-Lin Liang:Nothing to Disclose, Che-Lun Hung:Nothing to Disclose.

4259 | SPATIALLY RESOLVED PHENOTYPIC AND FUNCTIONAL CHARACTERIZATION OF THE IMMUNE MICROENVIRONMENT IN MASH- AND FONTAN-ASSOCIATED HEPATOCELLULAR CARCINOMA



Papawee Sutthirat[1] Christine Nguyen[2] Brenna Novotny[1] Chen Wang[1] Timucin Taner[1] Nidhi Jalan-Sakrikar[1] Vijay Shah[1] Moira Hilscher[1] Maarouf Hoteit[3] Yuli Kim[4], [1]Mayo Clinic Rochester, [2]Mayo Clinic Rocheste, [3]Penn Medicine, [4]Divisions of Cardiology at Penn and Children's Hospital of Philadelphia

Background: Fontan associated liver disease (FALD) is associated with an increased risk of hepatocellular carcinoma (HCC). Approximately half of HCC in FALD occurs in the absence of cirrhosis. The occurrence of HCC in the absence of cirrhosis or overt inflammatory activity suggests a unique pathophysiology. In this study, we characterized

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

the immune microenvironment of HCC in FALD and metabolic-dysfunction associated steatohepatitis (MASH). **Methods:** Multiplex imaging mass cytometry (Hyperion) was performed on tumor and adjacent non-tumor regions from non-cirrhotic FALD-HCC (n = 6) and MASH-HCC (n = 6). A 38-marker panel captured parenchymal, epithelial, stromal, endothelial, and immune cells, with functional markers of proliferation, angiogenesis, cytotoxicity, and exhaustion. Two-step unsupervised clustering was used to define major lineages and then functional states, with T-cell phenotyping focused on CD4+ and CD8+ subsets. ROI-level data were aggregated by patients to avoid pseudo-replication. Cell proportions, Ki67+, VEGF+, T-cell phenotypes, and nearest-neighbor distances were compared across tumor ROIs. **Results:** FALD-HCC demonstrated increased multiple cells proliferation compared with MASH-HCC. Ki67 expression was significantly higher in macrophages ($p = 0.041$), dendritic cells ($p = 0.011$), T cells($p = 0.014$), and endothelial cells($p = 0.013$), while B cells and hepatocyte/tumor cell did not significantly differ. Exhausted $CD8^+$ T cells, defined by Tim3, HLA-DR, or PD-L1 expression, were increased in FALD-HCC compared with MASH-HCC, whereas central memory, naïve, and terminal effector $CD8^+$ T-cell proportions are not significantly differ. $VEGF^+$ cell frequency show non-significant upward trends in FALD-HCC, most notably in endothelial cells($p = 0.065$), with additional non-significant trends in macrophage and hepatocyte/tumor cells. FALD-HCC also show enrichment of $CD56^+$ fibroblasts, suggesting a stromal population may contribute to fibrosis–tumor crosstalk. Spatial nearest-neighbor analysis reveal alter tumor immune architecture in FALD-HCC, with $CD8^+$ T cells positione closer to tumor cells by ~20.2 µm and closer to dendritic cells by ~24.5 µm compare with MASH-HCC. $CD4^+$ T cells were also position closer to dendritic cells in FALD-HCC by ~42.8 µm. **Conclusion:** FALD-HCC exhibits a distinct tumor microenvironment compare with MASH-HCC, characterize by increase immune and endothelial proliferation, greater $CD8^+$ T-cell exhaustion, $CD56^+$ fibroblast enrichment, pro-angiogenic VEGF trends, and closer T-cell proximity to dendritic cells and tumor cells. These spatial findings provide insight beyond cell proportions alone and suggest that FALD-HCC may harbor a permissive, spatially organize immune niche that promotes persistent T-cell stimulation and exhaustion. Further studies are warrant to define how Fontan-associated hepatic immune remodeling contributes to HCC pathophysiology.

4260 | YTTRIUM-90 SIRT CLINICAL DECISION-MAKING AND OUTCOMES IN UNRESECTABLE HEPATOCELLULAR CARCINOMA PATIENTS WITH ELEVATED LUNG SHUNT FRACTION

Jingqin Ma[1] Minjie Yang[1] Wen Zhang[1] Yaozu Liu[1] Jianjun Luo[1] Zhiping Yan[1], [1]Department of Interventional Radiology, Zhongshan Hospital, Fudan University

Background: Yttrium-90 selective internal radiation therapy (SIRT) provides potent local control and downstaging for unresectable hepatocellular carcinoma (uHCC). However, elevated lung shunt fraction (LSF) in Chinese patients poses severe radiation pneumonitis risks, potentially exacerbated by immunotherapy. This study evaluated multidisciplinary team (MDT)-guided triage, dosimetry, and outcomes in uHCC patients with high LSF ($\geq$10%) assessed via ^{99} Tc-MAA MAPPING. **Methods:** Clinical data of 45 uHCC patients with baseline LSF$\geq$10% between June 2024 and December 2025 were reviewed. Based on MDT consensus, patients were triaged into three pathways: direct SIRT (N = 14), conversion SIRT (SIRT preceded by 2 cycles of HAIC plus lenvatinib, N = 8), and conventional TACE (N = 23). Baseline anatomy, parameter evolution, and 6-month outcomes were compared. **Results:** The overall baseline mean LSF was 17.89% (range: 10.06%-43.40%). The direct SIRT group had a significantly lower baseline LSF than the conversion SIRT and TACE groups (12.49% vs 22.33% vs 20.32%, P < 0.05). In the conversion group, upfront HAIC plus Lenvatinib significantly reduced the mean LSF from 22.33% to 7.75% (P < 0.001), enabling safe SIRT for all 8 patients. The overall mean tumor volume was 846.07 ml, with the direct SIRT group showing a significantly lower tumor burden than the conversion SIRT and TACE groups (381.74 ml vs 1109.13 ml vs 1037.21 ml, P < 0.05). No significant difference was found in mean tumor absorbed dose between direct and conversion SIRT (239.29 Gy vs 224.29 Gy, P = 0.8799), though the conversion group required a significantly higher mean prescribed activity (4.70 GBq vs 3.43 GBq, P < 0.05). At 6 months, the objective response rates (ORR) of direct and conversion SIRT were comparable, both being significantly superior to TACE (71.4% vs 75.0% vs 60.9%, P < 0.05). Notably, 2 conversion patients (25.0%) successfully achieved radical surgical resection. **Conclusion:** For uHCC with high tumor burden and baseline LSF, upfront HAIC plus lenvatinib effectively remodels microvasculature and minimizes lung shunting. This conditioning strategy ensures lung safety and allows higher prescribed activity, yielding excellent ORR and surgical conversion opportunities.

4262 | REAL-WORLD IMPACT OF HEPATOCELLULAR CARCINOMA SURVEILLANCE ON SURVIVAL: A PROSPECTIVE BRAZILIAN COHORT

Diego Vieira[1] Rodrigo Cambraia[1] Geraldo Pereira[1] Lucy Ana Fonseca[1] Marcelo Chaves França[1] Rosangela Teixeira[1], [1]Hospital das Clínicas (EBSERH/UFMG), School of Medicine, Federal University of Minas Gerais

Background: Hepatocellular carcinoma (HCC) surveillance is recommended for patients with cirrhosis and selected high-risk populations, playing a pivotal role in early tumor detection and improved outcomes. However, evidence regarding the real-world impact of surveillance on tumor burden, hepatic reserve, and overall survival (OS) remains limited. This study evaluated the effect of structured HCC surveillance on tumor stage, hepatic reserve, and OS in cirrhosis-associated HCC patients. **Methods:** Patients from a tertiary HCC referral center were prospectively enrolled between 2019 and 2024. HCC diagnosis was established by contrast-enhanced CT or MRI according to LI-RADS criteria. Patients were stratified into: (1) HCC detected through structured surveillance with biannual ultrasound plus alpha-fetoprotein (AFP), and (2) HCC diagnosed outside surveillance protocols. The primary outcome was HCC-related mortality. OS was estimated using the Kaplan–Meier method and compared with the log-rank test. For intergroup comparisons were employed chi-square, Fisher's exact, Student's t, or Mann–Whitney U tests, as appropriate. The study was approved by the local Ethics Committee, and all participants provided written informed consent. **Results:** A total of 206 patients were prospectively included, of whom 73 (35.4%) were diagnosed under surveillance and 133 (64.6%) outside surveillance protocol. Patients undergoing surveillance had lower baseline AFP levels (7.8 vs. 59.0 ng/mL; p = 0.002), lower prevalence of AFP > 20 ng/mL (41.1% vs. 56.9%; p = 0.03), and higher frequency of early-stage HCC (BCLC 0/A) (71.0% vs. 35.5%; p < 0.001). Surveillance was also associated with smaller tumors (31.5 vs. 54.0 mm; p < 0.001), higher prevalence of ALBI grade I (70.4% vs. 32.5%; p < 0.001), compensated cirrhosis (91.0% vs. 68.8%; p < 0.001), lower HCC-related mortality (20.5% vs. 45.4%; p < 0.001), and longer OS (48.1 vs. 29.7 months; p < 0.001). **Conclusion:** HCC surveillance was associated with earlier-stage diagnosis, lower tumor burden, better hepatic reserve, and

longer OS. These findings support surveillance as an effective strategy to improve eligibility for curative-intent therapies and optimize long-term outcomes in real-world practice.

4263 | A HOSPITAL-INTEGRATED ONCOLOGY PLATFORM FOR RISK-ADAPTED MULTIDISCIPLINARY REVIEW OF HEPATOCELLULAR CARCINOMA

Cheng Huang[1] Jiabin Cai[1] Dian Wang[2] Cunying Pu[3] Jitthye Kee[4] Qiang Gao[1] Jian Zhou[1] Jia Fan[1] Huichuan Sun[1], [1]Department of Hepatobiliary Surgery and Liver Transplantation Zhongshan Hospital, Fudan University, [2]Roche Diagnostics (Shanghai) Ltd, Shanghai, China, [3]Roche Diagnostics (Shanghai) Ltd., Shanghai, China, [4]Roche Diagnostics (Shanghai) Ltd., Shanghai , China

Background: Risk-adapted management of hepatocellular carcinoma (HCC) depends on multidisciplinary review of tumor status, liver reserve, prior treatment, pathology, genomic findings and longitudinal outcomes. In routine care, these data are often dispersed across hospital systems and external reports, delaying review and making recurrence risk assessment less consistent. We assessed whether a hospital-integrated oncology platform could assemble structured longitudinal patient summaries and support recurrence risk assessment in an HCC multidisciplinary team (MDT) setting. **Methods:** This retrospective implementation study included 2,465 patients with HCC treated at Zhongshan Hospital, Fudan University from January 2020 to December 2022 who had follow-up data available. The Oncology Hub (OH, provided by Roche Diagnostics China), a commercially available integrated oncology platform, connected HIS/EMR, LIS, PACS, pathology and genomics systems, and external reports through FHIR/RESTful APIs, ETL, OCR and LLM-assisted semantic parsing. Outcomes included MDT operation logs recorded from March 25, 2025 to May 5, 2026, timed workflow samples, quality review of system-generated summaries, patient-like-me retrieval and internal validation of a recurrence risk model. **Results:** Over 13.3 months, 316 patients were discussed in 58 MDT sessions (5.45 cases/session). Mean case-preparation time was 24 min 55 s. Data aggregation through the platform, including OCR processing and timeline generation, averaged 9 min 55 s and had a median of 7 min 37 s (IQR, 4 min 42 s), compared with a manual review benchmark of approximately 15 min per case; MDT recording required 5-10 min per case. System-generated summaries were produced in 1 min 18 s. Quality review showed physician modification and key-information omission rates of 6.92% and 6.47%, respectively. Patient-like-me analytics aligned 2,281 evaluable patients and displayed top-matched cases with similarity scores, CNLC stage, treatment history, disease-free survival, overall survival and recurrence status. In 630 patients used for internal validation, the recurrence risk model achieved an AUC of 0.742 and accuracy of 0.70; for recurrent cases, precision, recall and F1-score were 0.63, 0.59 and 0.61. **Conclusion:** In a tertiary HCC MDT program, implementation of the Oncology Hub platform organized fragmented clinical data into longitudinal profiles and comparable outcome trajectories for risk-adapted review. Further multicenter evaluation should determine whether this approach improves MDT recommendation consistency, follow-up planning and patient outcomes.

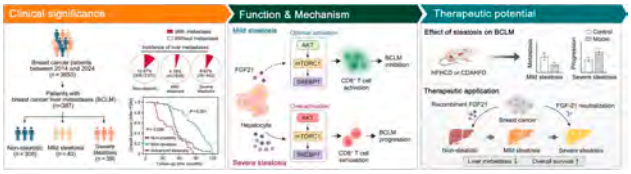
4264 | HEPATOCYTE FGF21 DICTATES OPPOSING FATES OF BREAST CANCER LIVER METASTASIS IN A STEATOSIS-SEVERITY-DEPENDENT MANNER



Junli Liu[1] Qiyue Hong[2] Jiaxing Yin[1] Yihui Yu[3] Wenchao Li[2] Xiaowen Wang[2] Keke Zhang[1] Xinya Yu[3] Kunpeng Hu[2] Hengdong Qu[1], [1]State Key Laboratory of Bioactive Molecules and Druggability Assessment, Jinan University, [2]The Third Affiliated Hospital of Sun Yat-Sen University, [3]Jiangxi Ganbei Integrated Traditional Chinese and Western Medicine Hospital

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is highly prevalent in patients with breast cancer; however, whether pre-existing hepatic steatosis differentially modulates breast cancer liver metastasis (BCLM) remains undefined. **Methods:** We retrospectively analyzed 3,653 breast cancer patients diagnosed across multiple centers in China (2014–2024), of whom 387 (11%) developed liver metastasis. Steatosis severity was determined by biopsy or imaging and graded as mild (5–33% fat) versus severe ($\geq$34% fat). To validate the causal effect of MASLD on BCLM, mice were fed a high-fat high-cholesterol diet (HFHCD) or a choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD), followed by intra-splenic or left ventricular

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

injection of syngeneic E0771 or 4T1 breast cancer cells. Single-cell transcriptomics, hepatocyte secretomics, and FGF21 supplementation or neutralization were employed to dissect the underlying mechanisms and therapeutic potential. **Results:** MASLD was independently associated with a lower overall risk of liver metastasis ($p < 0.001$), with mild steatosis conferred stronger protection against BCLM than severe steatosis. Survival analyses showed that mild steatosis prolonged both liver metastasis-free survival (LMFS) and overall survival (OS) (both $p < 0.01$), whereas severe steatosis markedly shortened LMFS and post-metastasis OS (OSLM), leading to significantly worse OS ($p < 0.05$ for LMFS; $p < 0.01$ for OSLM and OS). These findings remained robust after 1:1 propensity score matching (all $p < 0.01$). In murine models, MASLD markedly reduced liver metastatic colonization; however, only mild steatosis prolonged mouse survival, while severe steatosis showed the opposite trend, faithfully recapitulating the clinical observations. Mechanistically, single-cell transcriptomics and secretomics identified hepatocyte-derived FGF21 as a steatosis-severity-dependent effector. Compared with normal livers, FGF21 secretion was moderately elevated (2.5-fold) in mild steatosis but markedly increased (7.8-fold) in severe steatosis. Functionally, moderately elevated FGF21 activated optimal AKT/mTORC1/SREBP1 signaling, which enhanced infiltration of IFN-γ^+/granzyme B^+ $CD8^+$ T cells and suppressed tumor cell engraftment. In contrast, pathologically high FGF21 drove sustained AKT/mTORC1/SREBP1 activation, induced $CD8^+$ T-cell cholesterol overload and exhaustion and consequently promoted BCLM progression. Therapeutically, low-dose recombinant FGF21 administration to non-steatotic mice reduced BCLM, whereas FGF21 neutralization in mice with severe steatosis markedly prolonged survival in BCLM-bearing mice. **Conclusion:** FGF21 exerts a dual, dose-dependent role in BCLM depending on steatosis severity. Modulating FGF21 levels may represent a promising therapeutic strategy for concurrently managing MASLD and BCLM.

4265 | FECAL MICROBIOTA TRANSPLANTATION IN ADDITION TO LENVATINIB IN ADVANCED HEPATOCELLULAR CARCINOMA: A DOUBLE-BLIND, PLACEBO-CONTROLLED PILOT RANDOMIZED TRIAL

Ayush Agarwal[1] Arnav Aggarwal[1] Vishal Chauhan[1] Shubham Jain[1] Sarthak Saxena[2] Sejal Kotwani[1] Shubham Garg[1] Sanchita Gupta[1] Shivanand Gamanagatti[1] Ankur Goyal[1] Raju Sharma[1] Bipin Tiwari[1] Samagra Agarwal[1] Sagnik Biswas[1] Shalimar[1], [1]All India Institute of Medical Sciences, New Delhi, [2]All India Institute of Medical Sciences, Delhi

Background: Objective response rates to systemic therapies in advanced hepatocellular carcinoma (HCC) remain low. Adjunctive faecal microbiota transplantation (FMT) has been reported to improve immunotherapy response in malignant melanoma. We aimed to assess the safety and efficacy of FMT in combination with lenvatinib in advanced HCC. **Methods:** In this double-blind placebo-controlled pilot randomised trial, treatment naïve adult patients with advanced HCC (Barcelona Clinic Liver Cancer Stage C) were randomly assigned (1:1) to receive either FMT or placebo (equal volume of normal saline), along with systemic therapy with oral weight-based lenvatinib. FMT/placebo instillation in duodenum was done via endoscopy 1 week prior to starting lenvatinib. FMT was sourced from 2 healthy donors and processed by independent research staff. Radiological, serological and questionnaire-based assessments were performed at 3 and 6 months. Outcomes included response (RECIST1.1), overall survival (OS), progression-free survival (PFS), adverse events and quality of life (EORTC QLQ-C30 and QLQ-HCC18). **Results:** 20 patients were randomised; 19 were included in analysis (9 in FMT arm, 10 in placebo arm). Baseline characteristics were comparable (mean age: 56.0 ± 9.5 years; 85% males; median AFP 6692 [IQR 1667-25904], mean ALBI score −2.3 ± 0.1). Major etiologies of liver disease were hepatitis C (42.1%) and hepatitis B (36.8%). Cirrhosis was present in 84.2% patients. Extrahepatic metastases were present in 8 (42.1%) patients and portal venous thrombosis in 15 (78.9%) patients. Of 12 patients with radiological assessment at 3 months, 6 (50%) had stable disease (3 per group); the remainder had progressive disease. At 6 months, 2 FMT patients had stable disease and 2 control arm patients had progressive disease ($p = 0.33$). The OS (104 [IQR 84-176] vs 134 [IQR 19-180] days, $p = 0.51$) and PFS (100 [IQR 84-167] vs 90 [IQR 90-91] days, $p = 0.63$) were similar in FMT and control arms. Adverse events, including ascites (26.3%) and hand foot syndrome (15.8%), were similar in both arms. Serious adverse events occurred in 7 patients in FMT

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

arm vs 6 patients in placebo arm (77.7% vs 60%, p = 0.6). Nutritional issues and pain symptom scales were lower in FMT arm at 1 week (p = 0.016 and 0.029 respectively), while global health and functional scale scores were similar in both arms. **Conclusion:** Fecal microbiota transplantation in addition to lenvatinib is safe in advanced hepatocellular carcinoma.

4266 | MULTI-ANCESTRY ASSOCIATION OF *PNPLA3* RS738409 WITH INCIDENT HEPATOCELLULAR CARCINOMA IN CIRRHOTIC PARTICIPANTS OF THE ALL OF US RESEARCH PROGRAM

Hyunseok Kim[1] Walid Ayoub[1] Alexander Kuo[2] Paul Martin[2] Aarshi Vipani[2] Yun Wang[2] Yee Hui Yeo[2] Stephen Pandol[2] Debiao Li[2] David Cohen[2] Shelly Lu[2] Suthat Liangpunsakul[3] Juan Pablo Arab[4] JuDong Yang[2], [1]Cedars-Sinai Medical Center, [2]Cedars Sinai Medical Center, [3]Indiana University Medical Center, [4]Virginal Commonwealth University Medical Center

Background: *PNPLA3* rs738409 G-allele is an established hepatocellular carcinoma (HCC) risk factor in predominantly European (EUR)-ancestry cohorts. The variant exhibits striking allele frequency variation across populations, yet validation in multi-ancestry US cirrhosis cohorts remains limited. **Methods:** We identified All of Us cohort participants with whole-genome sequencing and ICD-coded cirrhosis at EHR consent (baseline), excluding pre-existing HCC. Genetic ancestry was inferred from WGS; EUR, AFR, and AMR labels correspond predominantly to participants self-identifying as non-Hispanic White, non-Hispanic Black, and Hispanic/Latino, respectively. Incident HCC required ≥ 2 diagnosis codes ≥ 30 days apart, with a 6-month landmark exclusion to remove likely prevalent disease. Cox proportional hazards regression was adjusted for age, sex, hierarchical primary etiology (HCV/HBV/Alcohol/MASLD/Other), genetic ancestry, and first three principal components. Pre-specified secondary analyses tested *PNPLA3* × ancestry and *PNPLA3* × etiology interactions; sensitivity analyses examined severity-restricted subsets. **Results:** Among 4,098 cirrhotic participants (EUR 2,269; AMR 960; AFR 807; other 62), 56 incident HCC events occurred over median 3.8 years (crude incidence 0.43/100 person-years; 1.51/100 in decompensated HCV-cirrhosis). *PNPLA3* GG homozygote frequency differed markedly by ancestry (AMR 36%, EUR 10%, AFR 3%). Each G-allele was associated with a 70% increase in HCC hazard (HR 1.70, 95% CI 1.15-2.51, p = 0.008). Within AMR cirrhotics, HCC incidence increased monotonically with genotype (CC 0.00, CG 0.37, GG 0.76/100 person-years). The association was directionally consistent across etiologies (HCV: HR 1.35; alcohol: HR 1.45; MASLD: HR 1.44) without interaction (p = 0.83) and persisted in severity-restricted sensitivity analyses (decompensated HR 1.38, p = 0.077; FIB-4 high or decompensated HR 1.41, p = 0.030). The effect was attenuated in AFR participants (interaction p = 0.24), consistent with recent reports of weakened *PNPLA3*-HCC association in AFR. Addition of *PNPLA3* improved discrimination (c-statistic 0.74 -> 0.76, p-value < 0.01). *MBOAT7* (HR 1.38, p = 0.09) and *MARC1* (HR 0.63, p = 0.10) showed directionally consistent but non-significant associations. **Conclusion:** In a US multi-ancestry cirrhosis cohort, *PNPLA3* rs738409 G-allele dosage was associated with incident HCC, with effect consistent across EUR and AMR ancestries, major cirrhosis etiologies, and disease severity strata. The substantially higher GG homozygote frequency in AMR participants, combined with monotonic genotype-stratified incidence in this group, suggests *PNPLA3* genotyping may have clinical utility for risk stratification in Hispanic/Latino cirrhotic populations. Validation in larger cohorts and assessment of incremental utility beyond established clinical risk scores are warranted.

4267 | AN ARTIFICIAL INTELLIGENCE MODEL FOR PREDICTING RESPONSE TO ATEZOLIZUMAB–BEVACIZUMAB IN HCC: MULTICENTER REAL-WORLD

Yu Rim Lee[1] Sung-Bum Cho[2] Hyun Young Woo[3] Jae Hyun Yoon[4] Jun Sik Yoon[5] Yeowool Kang[6] Jeong Eun Song[7] Young Mi Hong[8] Sang Youn Hwang[9] Joonho Jeong[10] Jeong Heo[3] Yang Hyun Baek[6] Young Oh Kweon[1] Soo Young Park[1] Won Young Tak[11], [1]Kyungpook National University, [2]Chonnam National University, [3]Pusan National University, [4]Chonnam National University Hospital, [5]Busan Paik Hospital, [6]Dong-A University Hospital, [7]Daegu Catholic University School of Medicine, [8]Pusan National University School of Medicine, [9]Dongnam Institute of Radiologic & Medical Sciences, [10]University of Ulsan College of Medicine, [11]School of Medicine, Kyungpook National University

Background: Atezolizumab plus bevacizumab (atezo/bev) has been established as an effective first-line treatment for unresectable hepatocellular carcinoma (HCC). Although various prognostic markers and prediction models have been proposed to estimate treatment outcomes in patients with HCC, clinically validated biomarkers remain limited. Therefore, we aimed to develop a machine learning–based model to predict treatment outcomes following atezo/bev therapy using demographic, laboratory, and imaging data from a large, multicenter real-world population. **Methods:** From May 2020 to October 2025, this retrospective cohort study included 1,114 patients with HCC from 10 tertiary hospitals who were treated with atezo/bev. Machine learning models, including random forest, were developed using baseline and follow-up parameters obtained after treatment initiation. **Results:** Among a total of 1,114 patients, 773 (69.4%) died at a median of 8.4 months during the study period (median 10.7 months). Age, modified ALBI grade, tumor size, CRP level, and main portal vein invasion at baseline were identified as significant predictors based on SHAP (SHapley Additive exPlanations) values. A random forest model trained using these five baseline factors and longitudinal variables, including follow-up NLR, AFP, and PIVKA-II levels, demonstrated superior performance compared with other machine learning models (AUROC, 0.765 [95% CI, 0.739–0.795]). Furthermore, compared with existing models, including the CRAFITY score, CRAFITY plus early AFP response model, and mALBI-based prognostic model, the proposed model demonstrated markedly improved discriminatory performance (AUROCs: 0.616 [0.580–0.650], 0.592 [0.554–0.629], and 0.627 [0.595–0.659], respectively). **Conclusion:** This model may serve as an adjunctive tool in clinical practice by assisting physicians in predicting treatment response and helping patients better understand their prognosis.

Table. Prognostic accuracy of prediction models to predict the survival of HCC patients : Comparison with existing models

Model	Key variables	Performance
Random Forest	Key5 = NL3 + AFP3 + PIVKA3	0.765 (0.739–0.795)
CRAFITY score	CRP ≥1 mg/dL, AFP ≥100 ng/mL	0.616 (0.580-0.650)
CRAFITY + Early AFP response	CRAFITY score + AFP response (≥75% decrease at 6–8 weeks)	0.592 (0.554-0.629)
mALBI-based prognostic model	mALBI (1 / 2a / 2b) + AFP, NLR	0.627 (0.595-0.659)

4268 | SARCOMATOID DIFFERENTIATION AND SURVIVAL OUTCOMES IN HEPATOCELLULAR CARCINOMA: A POPULATION-BASED SEER ANALYSIS

Kesava Manikanta Achuta[1] Rutwik Pradeep Sharma[2] Tharun Gopannagari[1] Narissa Nursjamsi[1] Hari Conjeevaram[3] Sujata Kambhatla[1], [1]Garden city hospital, Michigan State University, [2]Sparrow Hospital, U of M, [3]University of Michigan Medical Center

Background: Sarcomatoid hepatocellular carcinoma is a rare histologic variant with poor outcomes. It

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

remains unclear whether its survival disadvantage is explained by advanced presentation or persists after adjustment for tumor and treatment factors. We used contemporary SEER data to evaluate whether sarcomatoid histology identifies an aggressive phenotype and independently predicts mortality. **Methods:** Adults with primary liver hepatocellular carcinoma diagnosed from 2000-2022 were identified using SEER Research Data (17 registries, November 2024 submission). Conventional and sarcomatoid hepatocellular carcinoma were defined by ICD-O-3 codes 8170/3 and 8173/3. Overall survival was assessed using Kaplan-Meier analysis and Cox regression. Sensitivity analyses included cancer-specific survival, Fine-Gray competing-risk analysis, restricted mean survival time, and inverse probability of treatment weighting (IPTW). **Results:** Among 126,290 patients, 126,190 (99.92%) had conventional HCC and 100 (0.08%) had sarcomatoid HCC. Median overall survival was 11 months versus 3 months respectively. Sarcomatoid histology was associated with worse overall survival in unadjusted analysis (HR 2.01, 95% CI 1.64-2.46), core-adjusted analysis (HR 1.72, 95% CI 1.41-2.10), and fully adjusted analysis (HR 1.49, 95% CI 1.22-1.83). It was also associated with cancer-specific mortality (HR 1.58, 95% CI 1.28-1.96) and competing-risk-adjusted cancer death (sub distribution HR 1.50, 95% CI 1.26-1.78). Sarcomatoid hepatocellular carcinoma was associated with advanced stage, poor or undifferentiated grade, larger tumor size, and an aggressive phenotype (OR 7.19, 95% CI 3.42-18.49). Restricted mean survival time showed 12.4 fewer months alive over 60 months. Propensity-weighted analysis supported worse survival (HR 1.88, 95% CI 1.49-2.39), although residual imbalance remained. **Conclusion:** Stage, grade, and tumor size explained part of the survival disadvantage, but excess mortality persisted after adjustment. SEER lacks liver disease severity data, including Child-Pugh class, MELD score, portal hypertension, cirrhosis etiology, viral hepatitis status, and baseline liver function tests. This supports sarcomatoid differentiation as a clinically meaningful marker of aggressive tumor biology rather than a finding explained only by later-stage presentation. Given the rarity of this subtype, population-level analyses may define prognosis, support careful histologic reporting, and guide future studies evaluating treatment response and risk stratification in contemporary cohorts. **Conclusion:** Sarcomatoid hepatocellular carcinoma is rare but associated with aggressive clinicopathologic features and substantially worse survival. Recognizing sarcomatoid differentiation may improve prognostic counseling and support focused study in modern treatment-era cohorts.

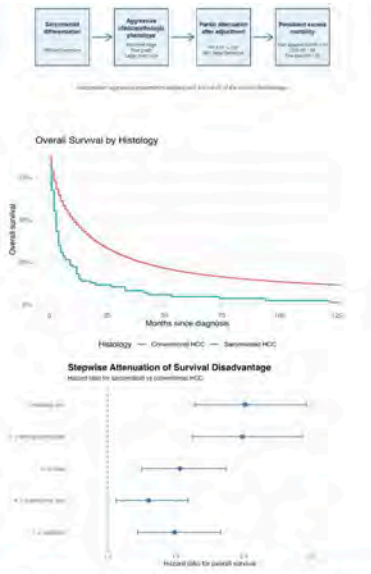

Table 1. Primary survival models for sarcomatoid versus conventional HCC.

Outcome	Adjustment	HR	95% CI	P value
Overall survival	Unadjusted	2.01	1.64-2.46	<0.001
Overall survival	Core adjusted	1.72	1.41-2.10	<0.001
Overall survival	Fully adjusted	1.49	1.22-1.83	<0.001
Cancer-specific survival	Fully adjusted	1.58	1.28-1.96	<0.001

Hazard ratios above 1 indicate higher mortality for sarcomatoid HCC compared with conventional HCC. Full covariate results are provided in Supplementary Table 9.

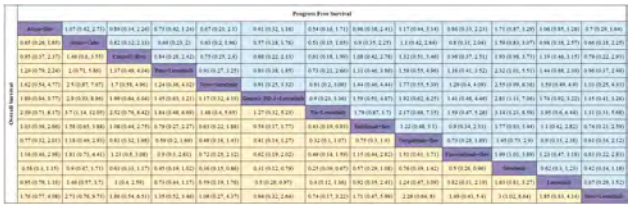
4269 | COMPARISON OF EFFICACY AND SAFETY OF PD-1/PD-L1 INHIBITORS COMBINED WITH TARGETED THERAPY IN HEPATOCELLULAR CARCINOMA: A NETWORK META-ANALYSIS



Tianyu Ma[1] Ruyu Liu[1], [1]Beijing Ditan Hospital, Capital Medical University

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related death worldwide, with most patients diagnosed at advanced stages where systemic therapy is the mainstay. Immune checkpoint inhibitors (ICIs) combined with targeted therapy have significantly improved outcomes in advanced HCC; however, whether PD-1 inhibitors and PD-L1 inhibitors differ in efficacy and safety when paired with targeted agents remains unclear due to the lack of head-to-head comparisons. This network meta-analysis aims to comprehensively compare the efficacy and safety of

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

PD-1-based versus PD-L1-based combination regimens for advanced HCC, providing evidence to guide clinical decision-making. **Methods:** We performed a network meta-analysis of 28 studies (13 regimens). PubMed, Embase, Cochrane Central, and Web of Science were searched. Outcomes included overall survival (OS), progression free survival (PFS), objective response rate (ORR), disease control rate (DCR), and adverse events. Pooled hazard ratios (HRs) with 95% confidence intervals (CIs) were calculated using Bayesian models. **Results:** Among all included studies, tislelizumab plus lenvatinib showed the potential for the best OS (P = 44.7%). PD-1 plus lenvatinib was significantly superior to atezolizumab plus bevacizumab for ORR (HR 0.17, 0.06 0.41) and DCR (HR 0.19, 0.06 0.49). No significant differences in OS or PFS were observed between PD-1 based and PD-L1 based combinations. PD-1 plus lenvatinib ranked among the top two regimens in most subgroups (AFP > 400 ng/mL, BCLC C, ECOG 0, female). Sintilimab plus bevacizumab ranked first for OS in BCLC B patients (P = 41.2%). Most regimens increased the risk of hypothyroidism and proteinuria versus sorafenib. **Conclusion:** PD-1 plus lenvatinib may benefit patients with high AFP or female sex. PD-1 inhibitor plus lenvatinib significantly improved ORR and DCR versus atezolizumab plus bevacizumab in first line advanced HCC, with tislelizumab plus lenvatinib ranking best for OS. No significant differences in OS or PFS were observed between PD-1 based and PD-L1 based regimens.

4270 | BURDEN, TRENDS, AND PREDICTIONS OF LIVER CANCER IN ASIA: ESTIMATES OF 2005-2023 AND PROJECTIONS TO 2035

Yujiao Deng[1] Yixin Guo[1] Qiaoman Fei[1] Xiao Yuan[1] Xubing Zhou[1] Chongyu Zhang[1] Dou Qu[1] Qian Wang[1] Huan Deng[1] Gaixia He[1] Meijuan Han[1] Qi Shang[1] Yuan Wang[1] Fanpu Ji[1], [1]The Second Affiliated Hospital of Xi'an Jiaotong University

Background: Asia bears the heaviest burden of liver cancer (LC) globally. Analysis of its disease burden, variation and predictions of future trends is crucial for reducing its burden. **Methods:** Using GBD 2023 study, we calculated age-standardized incidence (ASIR), prevalence (ASPR), death (ASDR), disability-adjusted life years (DALYs) rates (ASDALYR) and their average annual percent change (AAPC) in Asia and ite subregions and countries. We conducted a Prophet model to predict ASRs between 2024 to 2035 based on the data from 2005 to 2023. Temporal and spatial trends, Das Gupta's standardization, spearman correlation, decomposition method and predictive analysis was used to decompose and explain the regional difference. **Results:** From 2005 to 2023, East Asia carried the highest burden of LC and kept decreasing (Figure 1). High-income Asian Pacific (HIAP) always had the highest ASIR, ASPR, ASDR of LC, with the fastest decrease. South Asia always had the lowest ASRs. ASIR decreased in all Asian areas but increased in South Asia. ASDR, ASPR, ASDALYR decreased in HIAP, Central and East Asia, but increased in South and Southeast Asia. ASRs is projected to increase in South and Southeast Asia in 2035. Mongolia had the highest ASRs. China always carried the highest ASPR of LC in East Asia. In HIAP and Southeast Asia, the countries with the highest ASR are South Korea and Thailand respectively. ASRs of LC due to hepatitis B (LCB) kept the highest in East Asia, ASRs of LC due to hepatitis C (LCC) was the highest in HIAP. ASR (except for ASPR) of LCC and LCB decreased the fastest in Central Asia and increased only in South Asia, while ASPR decreased the fastest in HIAP. Notably, only HIAP successfully achieved the WHO-targeted declining trend in LC ASIR. The peak age for the LC and LCB burden of male is earlier than that for females. The epidemiologic changes mainly contributed to the burden decrease, whereas age structure mainly affected the increase. In 2005, ASIR, ASPR, and ASDR of LC, ASPR of LCB in Asian countries were positively correlated with sociodemographic index (SDI). However, by 2023, these correlations no longer existed. **Conclusion:** The imbalance in the burden of LC in the Asian region persists and remains severe. East Asia always carried the highest disease burden of LC and LCB. HIAP always had the highest ASRs of LC, with the fastest decrease. China always carried the highest ASPR of LC. ASRs of LC is no longer correlated with SDI in Asian countries.

4271 | CLINICAL OUTCOMES FOR CONTEMPORARY COHORT OF PATIENTS WITH HCC LISTED FOR LIVER TRANSPLANTATION

Manasa Narasimman[1] Neil Mehta[2] Parissa Tabrizian[3] Ju Dong Yang[4] Neehar Parikh[5] Ang Gao[1] Lisa Quirk[1] Naomy Kim[6] Madeline Smith[7] Rashmita Raghunathan[7] Willis Tang[2] Zoe Berman[2] Jasmine Gamez[2] Amit Singal[1], [1]UT Southwestern Medical Center, [2]University of California, San Francisco, [3]Mount Sinai, [4]Cedars-Sinai Medical Center, [5]University of Michigan Medical Center, [6]Cedars Sinai, [7]University of Michigan

Background: Liver transplantation (LT) is a preferred curative option for patients with early-stage hepatocellular carcinoma (HCC). Changes in eligibility (e.g., downstaging), waitlist priority policies, and types of bridging therapy (e.g., use of immune checkpoint inhibitors), can lead to changes in risk of waitlist dropout and recurrence. We characterized clinical outcomes in a contemporary multi-center cohort of patients with HCC listed for LT in the U.S. **Methods:** We conducted a multi-center retrospective cohort study to characterize patterns and outcomes among patients with HCC listed for LT between January 2019 and July 2023 across 5 sites in the HCC-Live Consortium. We excluded patients with patients with cholangiocarcinoma (including known mixed HCC-CCA) and unknown treatment history prior to listing. We used Fine and Gray competing risk analysis to characterize time to waitlist dropout and time to post-LT recurrence, with death as a competing risk for both models; for waitlist dropout analysis, patients were censored at LT. **Results:** We identified 900 eligible patients, with median age 63 (IQR 57.6 – 67.0), 73.6% male, and 51.3% non-Hispanic White. Liver disease etiology included 27.0% post-SVR, 12.6% viremic HCV, 22.9% MASLD, 18.4% ALD, 12.1% HBV. At diagnosis, most patients (68.6%) had unifocal HCC, 20.7% had 2 lesions, and remainder had 3+ lesions. Median HCC diameter was 2.7 (IQR 2.0 – 3.8) cm, with 24 (2.7%) having vascular invasion. Waitlist dropout occurred in 308 (34.2%) patients, with 102 (33.1%) due to tumor progression. Median time to dropout was 32.5 months, with 6-, 12-, and 18-month dropout probabilities of 0.06 (95%CI 0.04 – 0.08), 0.15 (0.12 – 0.17), and 0.24 (0.20 – 0.28). Waitlist dropout was associated with older age (HR 1.03, 95%CI, 1.00 – 1.06) and presence of ascites (HR 1.81, 95%CI 1.18 – 2.79). Waitlist dropout did not differ by tumor burden at diagnosis (number of HCC: HR 1.02, 95%CI 0.88 – 1.18 and maximum diameter: HR 1.02, 95%CI 0.95 – 1.10), AFP at diagnosis (continuous: HR 1.00, 95%CI 1.00 – 1.00), or bridging modality (vs. TACE: ablation (HR 0.97, 95%CI 0.64 – 1.46); resection (HR 0.81, 95%CI 0.50 – 1.29); TARE/SBRT (HR 0.89, 95%CI 0.62 – 1.27). Of 550 patients who underwent LT, 56 (10.1%) experienced HCC recurrence, with 12- and 24-month probabilities of 0.03 (95%CI 0.02 – 0.05) and 0.07 (95%CI 0.05 – 0.09). Recurrence was associated with male sex (HR 2.38, 95%CI 1.08 – 5.22), microvascular invasion on explant (HR 7.99, 95%CI 4.27 - 15.0), and AFP at transplant (HR 1.01, 95%CI 1.01 – 1.02). Rejection was observed in 77 (14.0%) patients, with no significantly associated factors. **Conclusion:** In contemporary patients with HCC listed for LT, waitlist dropout occurs in over one-third of patients, often due to tumor progression, while post-LT recurrence rates remain acceptably low.

4272 | DEVELOPMENT AND EXTERNAL VALIDATION OF A SIMPLIFIED PREDICTION MODEL FOR EARLY HCC RECURRENCE: THE SPARE SCORE

Jaehong Jeong[1] Dai Hoon Han[1] Hye Won Lee[1],
[1]Yonsei University College of Medicine, Seoul, Korea

Background: Early HCC recurrence after curative resection significantly limits survival. Existing predictive models are often limited by inflexible categorical systems, complex variables, or insufficient external validation. We aimed to develop and externally validate the SPARE (Simplified Prediction model for Advanced Recurrence Evaluation) score to provide continuous probabilities for predicting 2-year HCC recurrence. **Methods:** The development cohort included patients undergoing first-line surgical resection for HCC at Severance Hospital (Jan 2004–Jan 2025). An independent validation cohort was collected from Gangnam Severance Hospital (Dec 2004–Aug 2024). A logistic regression nomogram, the SPARE score, was developed using multivariable analysis. Its predictive performance was externally validated and compared to ERASL-pre and ERASL-post models. **Results:** The development and external validation cohorts included 2,099 and 372 patients, respectively. The final simplified model consisted of five core variables: age, sex, log (alpha-feto protein), tumor diameter, and microvascular invasion. In the external validation cohort, the SPARE score achieved an AUC of 0.663, demonstrating statistically non-inferior and numerically comparable performance to the highly complex ERASL-post (AUC 0.633, $P = 0.222$) and ERASL-pre (AUC 0.629, $P = 0.276$) models. Applying predefined statistical tertiles calculated from the SPARE score (low risk: $\leq 21.1\%$, intermediate risk: 21.1–38.4%, high risk: $> 38.4\%$) successfully stratified the external cohort into distinct risk groups with perfectly separated recurrence-free survival curves (log-rank $P < 0.001$). **Conclusion:** The SPARE score predicts 2-year HCC recurrence using only five clinical variables while achieving non-inferior predictive performance compared to complex existing models. It provides robust continuous probabilities, enabling simple and intuitive clinical risk stratification.

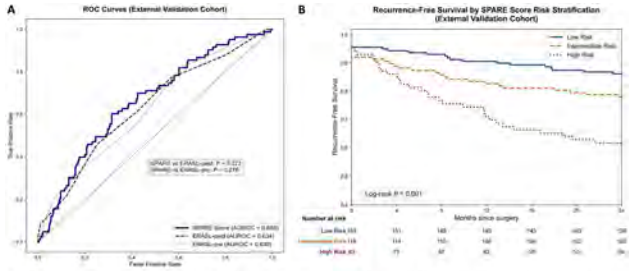

Figure 1. Predictive Performance and Risk Stratification of the SPARE Score. (A) Receiver-operating-characteristic (ROC) curves predicting 2-year early HCC recurrence, comparing the SPARE score to existing ERASL models. (B) Kaplan-Meier recurrence-free survival curves demonstrating successful risk stratification using predefined SPARE score tertiles. Abbreviations: ERASL, Early Recurrence After Surgery for Liver cancer; HCC, hepatocellular carcinoma; SPARE, Simplified Prediction model for Advanced Recurrence Evaluation.

4273 | HIGH RISK OF HCC PERSISTS BEYOND 2 YEARS IN PATIENTS WITH INDETERMINATE LIVER NODULES

Janvi Patel[1] Sruthi Yekkaluri[1] So Yeon Kim[1] Nicole Rich[2] Amit Singal[1], [1]UT Southwestern Medical Center, [2]University of Texas Southwestern Medical Center

Background: Patients with indeterminate liver nodules (ILNs, i.e., LR-3 and LR-4) have a high risk of developing hepatocellular carcinoma (HCC). However, LI-RADS recommends that these lesions are downgraded after 2 years of stability, so patients can then return to ultrasound-based surveillance. However, clinical outcomes, including the risk of HCC, after the 2-year landmark have not been well described. **Methods:** We conducted a retrospective cohort study of patients with ILNs diagnosed at two academic medical centers between August 2013 and December 2021. We included those patients who had a newly diagnosed LR-3 or LR-4 lesion with 2 years of stability; we excluded patients who developed HCC, had the ILN resolve, or were transplanted within the 2-year period. We collected all subsequent imaging receipt and results. We used Fine-Gray subdistribution hazard models to characterize time to HCC after the 2-year landmark, with liver transplantation and death as competing events. Fine-Gray multivariable regression, with backward selection, was used to identify factors associated with incident HCC. **Results:** Of 53 eligible patients (44 with LR-3 and 9 with LR-4 lesions), median age was 59 years and 56.6% were male. Patients were diverse regarding race (18.9% White, 56.6% Hispanic, 22.6% Black) and liver etiology (24.5% hepatitis C, 34.0% MASLD, 18.9% alcohol-associated). The median size of the ILN was 1.0 cm (IQR 0.9 – 1.2) at diagnosis, which was similar median (1.0 cm, IQR 0.9 – 1.5) at the 2-year landmark. Despite stability, radiologists only downgraded the ILN in 10 (18.9%) cases. During a median follow-up of 37.7 months after the 2-year landmark, 15 developed HCC, 2 underwent transplant, and 5 died. The overall HCC incidence after the 2-year landmark was 9.3 per 100 person-years, with a cumulative incidence of 10.3% (95%CI 3.7 – 20.7) during year 2-3, 14.8% (95%CI 6.4 – 26.4) during year 3-4, and 19.5% (95%CI 9.5 – 32.2) during year 4-5. Stratified by ILN, the cumulative incidence was 9.9% (95%CI 3.1 – 21.5) during year 2-3 and 12.6% (95CI 4.5 – 25.1) during years 3-4 for patients with LR-3 lesions and 12.5% (95%CI 0.5 – 44.5) during year 2-3 and 25.0% (95CI 3.0 – 57.9) during years 3-4 for patients with LR-4 lesions. The only factor associated with HCC in multivariable analysis was Child Pugh B cirrhosis at diagnosis (sHR 16.8, 95%CI 2.1 – 137.0). Male sex was associated with increased HCC risk but this did not achieve statistical significance (sHR 4.76, 95%CI 0.99 – 25.0). **Conclusion:** Patients with ILNs have a persistent high risk of HCC beyond 2 years after initial diagnosis, arguing against current recommendations to downgrade these lesions. Our data suggest a need for continued surveillance using multi-phase CT or MRI beyond 2 years.

4274 | BEYOND TACE REFRACTORINESS: HEPATIC RESERVE AS THE DECISION ANCHOR FOR TRANSITION TO ATEZOLIZUMAB-BEVACIZUMAB IN UNRESECTABLE HEPATOCELLULAR CARCINOMA

Hyo Jin Nam[1] Soe Thiha Maung[2] Sung Won Chung[1] Ji won Yang[3] Won-Mook Choi[1] Jonggi Choi[4] Roongruedee Chaiteerakij[5] Danbi Lee[1] Ju Hyun Shim[1] Kang Mo Kim[1] Young Suk Lim[1] Han Chu Lee[1], [1]Asan Medical Center, [2]Faculty of Medicine, Chulalongkorn University, [3]Asan Medical Center, University of Ulsan College of Medicine, [4]University of Ulsan, Asan Medical Center, [5]Chulalongkorn University

Background: In unresectable hepatocellular carcinoma (HCC), repeated transarterial chemoembolization (TACE) may impair hepatic reserve before formal TACE refractoriness is recognized. We evaluated whether hepatic reserve at the pre-final-TACE better identifies the optimal transition window to atezolizumab-bevacizumab (Atezo/Bev) than refractoriness alone. **Methods:** This retrospective single-center cohort included 154 patients with unresectable HCC who received sequential TACE followed by Atezo/Bev. TACE refractoriness was defined according to Japan

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Society of Hepatology criteria and assessed at Atezo/Bev initiation. Overall survival (OS) and radiologic progression-free survival (PFS) were measured from Atezo/Bev initiation. Pre-final-TACE ALBI grade/score, INR, cumulative TACE count, and integrated decision models were evaluated. **Results:** Patients underwent a median of 4 TACE sessions, and 117 (76.0%) met refractoriness criteria at Atezo/Bev initiation. Among 148 patients with paired pre-final-TACE ALBI data, 121 (81.8%) already had ALBI grade 2/3 at the last TACE. A refractoriness-only model yielded a C-index of 0.535 for PFS and 0.536 for OS in the complete-case subset. In the key cross-classification analysis, non-refractory patients with pre-final-TACE ALBI grade 2/3 had worse PFS than refractory patients with preserved ALBI grade 1 (adjusted hazard ratio 2.75, 95% confidence interval 1.35–5.64; $p = 0.006$). In exploratory analyses, pre-final-TACE ALBI > -2.36 and INR values entering the 1.10–1.20 range as clinically relevant warning signals. A composite rule incorporating ALBI > -2.36, INR category, and TACE > 4 yielded a higher C-index than refractoriness alone (C-index 0.619 for PFS and 0.698 for OS). **Conclusion:** TACE refractoriness alone is an insufficient anchor for transition timing. Dynamic hepatic reserve assessment at the last TACE, particularly ALBI and INR, should be incorporated to identify patients who may benefit from timely transition to Atezo/Bev before irreversible reserve loss.

4275 | METABOLIC DYSFUNCTION–ASSOCIATED STEATOTIC LIVER DISEASE AND RISK OF HEPATOCELLULAR CARCINOMA IN NON-CIRRHOTIC PATIENTS: A PROPENSITY-MATCHED COHORT STUDY

Eunice Aregbesola[1] Ibukunoluwa Oshobu[2] Eunice Omeludike[3] Abisola Ajayi[4] Winifred Iklaki[5], [1]University of Missouri, Columbia, [2]University of Missouri-Columbia Hospital, [3]Piedmont Athens Regional Medical Center, [4]Moorehouse School of Medicine, [5]University of Missouri - Columbia

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD) is increasingly linked to hepatocellular carcinoma (HCC), including in patients without cirrhosis. We evaluated the association between MASLD and incident HCC in non-cirrhotic patients using a multicenter electronic health record database. **Methods:** We performed a retrospective propensity score–matched cohort study using the TriNetX Research Network. Adult patients with MASLD without prior cirrhosis, viral hepatitis, alcoholic liver disease, hepatic decompensation, or pre-existing HCC were matched 1:1 to controls without MASLD based on demographics and metabolic comorbidities. The primary outcome was incident HCC. Secondary outcomes included progression to cirrhosis, hepatic decompensation, liver-related hospitalization, and all-cause mortality. Hazard ratios (HRs) with 95% confidence intervals (CIs) were calculated using Cox proportional hazards models. **Results:** After propensity matching, 84,216 patients were included in each cohort with balanced baseline characteristics. During a median follow-up of 6.2 years, MASLD patients demonstrated significantly higher incidence of HCC compared with controls (1.12% vs 0.41%; HR 2.41, 95%CI 2.08–2.79; $p < 0.001$), with progressive divergence in cumulative HCC incidence over time (log-rank $p < 0.001$) (Fig. 1). MASLD was additionally associated with increased risks of progression to cirrhosis (6.84% vs 1.91%; HR 3.87, 95% CI 3.61–4.15), hepatic decompensation (2.16% vs 0.74%; HR 2.98, 95% CI 2.63–3.37), portal hypertension (HR 2.76, 95% CI 2.41– 3.15), liver-related hospitalization (8.92% vs 4.63%; HR 1.94, 95% CI 1.82–2.07), and all-cause mortality (12.7% vs 10.9%; HR 1.18, 95% CI 1.11–1.25) (Table 1). Elevated HCC risk persisted across patients with obesity (HR 2.27), diabetes mellitus (HR 2.61), and metabolic syndrome (HR 2.48) (all $p < 0.001$), and remained significant even among MASLD patients without obesity or diabetes (HR 1.89, 95% CI 1.42–2.51). Sensitivity analyses excluding patients who developed cirrhosis during follow-up continued to demonstrate increased HCC risk in the MASLD cohort (HR 1.76, 95% CI 1.39–2.24; $p < 0.001$). **Conclusion:** MASLD was independently associated with significantly increased risk of HCC in non-cirrhotic patients. These findings suggest hepatocarcinogenesis may occur prior to cirrhosis in MASLD and highlight the need for improved risk stratification and surveillance strategies.

4276 | AGE-STRATIFIED INCIDENCE, TUMOR CHARACTERISTICS, TREATMENT PATTERNS, AND SURVIVAL IN FIBROLAMELLAR CARCINOMA: A POPULATION-BASED ANALYSIS OF SEER DATA (2000–2023)

Nicholas Thomas[1] Krishna Chandrasekhara[1] Chandni Bhagtaney[1] Prasun Jalal[1], [1]Baylor College of Medicine

Background: Fibrolamellar Carcinoma (FLC) is a rare tumor believed to account for 1-5% of all liver cancers. Uniquely, FLC is not associated with liver disease and is typically found in non-cirrhotic parenchyma. As a result, FLC characteristically affects younger patients with a bimodal age distribution, exhibiting peaks at 15-19 and 65-75 years of age. No previous literature has looked at the differences in FLC presentation, treatment, and prognosis between these age groups. **Methods:** 366 cases of FLC were identified between 2000–2023 from the Surveillance, Epidemiology, and End Results (SEER) database using ICD-O-3 histology code 8171/3. Groups were compared based on sex, year of diagnosis, tumor size, histologic grade, stage at diagnosis, surgical resection (any hepatic resection vs. no surgery), receipt of chemotherapy, and cancer-specific survival (CSS). The chi-squared test was applied for categorical variables, and the Kruskal-Wallis Test was applied for non-normally distributed continuous variables. For comparisons of CSS, the log-rank test was used to evaluate differences between Kaplan-Meier curves. **Results:** Consistent with existing literature, a bimodal age distribution was found, with a large and small incidence peak at 15-19 and 65-69 years of age, respectively. Likelihood of metastasis (regional or distant) at diagnosis was highest for patients < 20 years old (66% of cases), compared to only 46% for patients > 60. However, tumor size did not differ significantly across age groups ($p = 0.14$), indicating that it was not a primary contributor to the observed differences in cancer staging. Treatment approaches differed significantly by age group ($p < 0.001$), with the highest rates of surgical resection seen in patients 15-19 years old (74%) before declining to 20% of patients > 80 years old. Chemotherapy rates followed a similar decline, with 71% of patients < 15 receiving chemotherapy, compared to 24% of patients 70-79 years old. CSS was significantly different across age groups ($p = 0.00036$), with patients diagnosed at an older age having a worse prognosis, even after multivariate analysis. **Conclusion:** Younger FLC patients demonstrated better rates of cancer-specific survival despite higher rates of metastasis at diagnosis. This is likely reflected in the treatment approach (greater rates of surgical resection and chemotherapy in this population) rather than tumor burden, as tumor size did not differ across age groups. Differences in treatment might be explained by the higher prevalence of comorbidities and functional decline among older patients.

4277 | COMPREHENSIVE SAFETY AND EFFICACY EVALUATION OF IMMUNOTHERAPY COMBINATION APPROACHES VERSUS TYROSINE-KINASE INHIBITOR MONOTHERAPY AS FIRST-LINE TREATMENT OF HEPATOCELLULAR CARCINOMA: A NETWORK AND INDIVIDUAL PATIENT DATA (IPD) META-ANALYSIS

Maen Abdelrahim[1] Abdullah Esmail[2] Yazan Hamdaneh[2] Zaid Al-Abed[2] Ebtesam Al-najjar[2] Nour Mustafa[2], [1]Houston Methodist Neal Cancer Center, Houston, Tx, [2]Section of GI Oncology, Department of Medicine, Houston Methodist Cancer Center, Houston, TX 77030

Background: Hepatocellular carcinoma (HCC) represents the most common primary liver cancer and a significant cause of global cancer-related mortality, with a lot of patients diagnosed at advanced or unresectable stages. Historically, tyrosine-kinase inhibitor (TKI) monotherapies such as sorafenib and lenvatinib served as the primary systemic standard of care. However, the emergence of immune checkpoint inhibitor (ICPI)-based combinations has significantly transformed the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

treatment landscape. We aim to perform a comparative analysis of ICPI-based combination treatment versus TKI monotherapy among advanced HCC patients. **Methods:** This study utilized a reconstructed individual patient data (IPD) pooled analysis derived from nine phase 3 randomized clinical trials, adhering to PRISMA-IPD reporting guidelines. A total of 6,161 patients were included in the analysis, which categorized treatment into five primary strategies: ICPI monotherapy, ICPI plus bevacizumab, dual ICPI (duplet), ICPI plus TKI, and TKI monotherapy as the control group. The primary endpoint was overall survival (OS), with secondary endpoints including progression-free survival (PFS) and the incidence of grade 3 or higher adverse events (AEs). **Results:** The analysis demonstrated that ICPI-based combinations provided a significant survival advantage over TKI monotherapy. Key hazard ratios (HR) for OS compared to TKIs were 0.76 (95% CI: 0.67–0.85, $p < 0.001$) for dual ICPI, 0.76 (95% CI: 0.68–0.85, $p < 0.001$) for ICPI plus TKI, and 0.70 (95% CI: 0.61–0.81, $p < 0.001$) for ICPI plus bevacizumab. Median OS was numerically highest for ICPI plus TKI at 19.68 months and dual ICPI at 19.58 months, compared to 14.84 months for the TKI group. Among FDA-approved regimens, Nivolumab plus Ipilimumab (NivoIpi) achieved the longest median OS of 24.08 months. From a safety standpoint, the ICPI plus TKI group had the highest incidence of grade 3/4 AEs at 69.1%. Conversely, TKI monotherapy showed a 50.1% incidence, while dual ICPI therapy exhibited the most favorable safety profile at 32.7%. **Conclusion:** ICPI-containing combination therapies are superior to TKI monotherapy for the first-line treatment of advanced HCC, providing marked improvements in survival outcomes. Dual ICPI therapy represents the most balanced approach between efficacy and safety, achieving high survival with the lowest rates of severe toxicity. Among approved options, NivoIpi demonstrated the strongest survival signal, while DurvaTreme offered the highest tolerability, supporting a personalized treatment approach based on individual patient risk factors and hepatic reserve.

4278 | COMPARISON OF TUMOR CONTROL AND TOXICITY ASSOCIATED WITH SBRT AND TARE THERAPY FOR HCC

Alisa Likhitsup[1] Neehar Parikh[2], [1]University of Michigan, [2]University of Michigan Medical Center

Background: Treatment of hepatocellular carcinoma (HCC) with Stereotactic Body Radiation Therapy (SBRT) vs Transarterial radioembolization (TARE) has been shown to be effective for tumor control; however, the comparative safety and efficacy of the approaches are not well described. We aimed to compare tumor control and risk of hepatic decompensation following SBRT or TARE. **Methods:** We included patients from single institution with diagnosis of HCC, based on AASLD guidelines, who underwent SBRT or TARE between July 2018 and June 2023. Records were reviewed for demographics, Barcelona Clinic Liver Cancer (BCLC) tumor stage/ tumor burden, laboratory, and symptoms of hepatic decompensation. Radiation side effects were evaluated by changes in Albumin-Bilirubin (ALBI) grades and Child-Pugh (CP) progression at 3-month, 6-month, and 12-month intervals from index radiation treatment compared to baseline (before index treatment). **Results:** We included 59 patients were included, 42 treated with SBRT and 17 treated with ARE, with a median age 68 (64,72) years, 71% male, 95% White, 93% with cirrhosis (39% viral hepatitis, 31% MASLD, 14% alcohol, and 5% others), average tumor burden (n) 1.6 (1.1) lesions, average tumoral size 3.8 (2.9) cm, average follow up time 30 (range 4, 88) months. Tumor numbers, tumor size, and BCLC stages were more advanced, and AFP level was higher among patients who received TARE compared with SBRT. Age, sex, race, and cirrhosis etiologies were similar. MELD scores, CP scores, and ALBI grades were comparable at baseline (Table 1). Compared to CP score and ALBI grades at baseline, at 3 months, CP progression developed 24%, and ALBI grades increased in 14% among SBRT group, whereas CP progression was 29% and ALBI grades increased in 18% among TARE group ($p = 0.65$ for CP and $p = 0.75$ for ALBI). At 6 months, 29% had CP progression and 12% had ALBI grades increased, and were similar among the groups ($p = 0.95$ for CP and 0.99 for ALBI). At 12 months, the SBRT group had 10% CP progression, and 21% increased ALBI grades, whereas 12% and 18% of TARE group had CP progression and ALBI grades increased, respectively ($p = 0.80$ for CP and 0.75 for ALBI). Tumor control rates at 3 months was similar (83% SBRT and 82% TARE, $p = 0.70$). HCC recurrence rates were 12% at 6 months and 14% at 12 months among SBRT group, and 47% at 6 months and 18% at 12 months among TARE group. Death occurred 45% among SBRT (10% HCC progression and 12% liver-related death) and 59% among TARE (29% HCC progression and 35% liver-related death). Overall, 12% received liver transplantation. Median survival 31(19, 57) months among SBRT and 20(9, 38) months among TARE ($p = 0.09$). **Conclusion:** A significant proportion of patients with HCC developed CP and ALBI progression within 3-6 months of treatment with SBRT/TARE, with

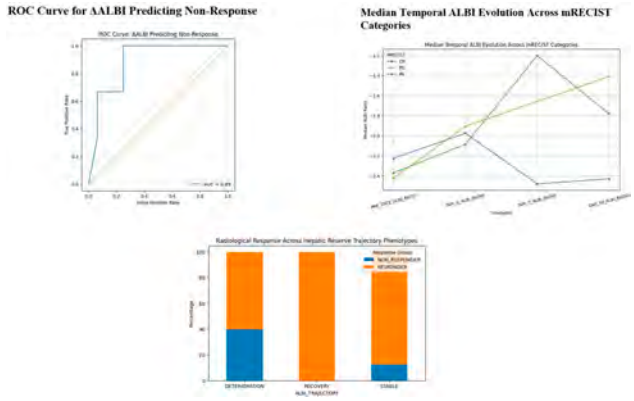
4279 | FROM LIVER RESERVE TO LIVER RESPONSE: HEPATIC ADAPTATION PHENOTYPES FOLLOWING TACE AND THEIR ASSOCIATION WITH MRECIST RESPONSE IN HEPATOCELLULAR



Anthieya Jude[1] Mrinalni J[1], [1]Sree balaji medical college and hospital

Background: Transarterial chemoembolization is the standard locoregional therapy for intermediate-stage hepatocellular carcinoma, with treatment response assessed only on follow-up imaging. Baseline ALBI and MELD scores reflect pre-treatment hepatic reserve, while dynamic post-TACE changes in these markers may carry prognostic information beyond baseline values. This study evaluated whether post-TACE ALBI and MELD trajectories correlate with mRECIST response and whether hepatic adaptation phenotyping enables earlier outcome stratification. **Methods:** This preliminary analysis includes 96 patients from an ongoing retrospective cohort study with an anticipated final enrollment of 250 patients. Adult HCC patients undergoing TACE with complete pre- and post-procedural laboratory data were included. ALBI and MELD scores were calculated at baseline, Day 7, and Day 30 post-TACE, with laboratory assessments accepted within a ±2 day window. Dynamic changes in ALBI and MELD at Day 30 were derived and used as the primary exposure variables. Patients were subsequently classified into three hepatic adaptation phenotypes — Recovery, Stable, and Deterioration — based on their post-TACE ALBI trajectories. A Hepatic Recovery Score was additionally derived from persistent worsening of both ALBI and MELD at Day 30. Radiological response was assessed per mRECIST criteria **Results:** In this preliminary cohort of 96 patients, change in ALBI at Day 30 was significantly associated with radiological response ($p = 0.044$) and demonstrated strong discrimination for non-response (AUC = 0.89). Change in MELD showed a directional trend ($p = 0.068$; AUC = 0.77). Response rates declined progressively across adaptation phenotypes from 100% in Recovery to 60% in Deterioration, with the Hepatic Recovery Score demonstrating a consistent dose-response gradient across non-response rates of 14.1%, 27.3%, and 37.5%. Traditional tumour biomarkers showed no meaningful association — AFP ($p = 0.092$) and PIVKA-II ($p = 0.608$) were uninformative. Baseline ALBI similarly showed no significant association ($p = 0.376$), confirming the limited utility of static pre-procedural assessment. Early stress markers at 24 hours showed limited value (AUC = 0.54), reflecting transient ischaemic injury rather than sustained treatment response biology. These findings will be validated in the complete cohort. **Conclusion:** The liver's adaptive response to TACE carries significantly

more prognostic information than its baseline state. Dynamic ALBI and MELD trajectories outperformed static scores and tumour biomarkers in predicting mRECIST response, and hepatic adaptation phenotyping identified clinically meaningful response gradients using data already routinely collected. Validation in the complete cohort is ongoing.

4280 | PSC-ASSOCIATED CHOLANGIOCARCINOMA IS DIAGNOSED WITH EARLIER-STAGE DISEASE AND IMPROVED SURVIVAL COMPARED TO NON-PSC CHOLANGIOCARCINOMA

Sarah Khan[1] Niharika Bhattacharjee[2] Mosbah Aouad[2] Diana Segovia[1] Jessie Hohenstein[1] Qian Shi[1] Chen Wang[1] Ravishankar Iyer[2] Lewis Roberts[3], [1]Mayo Clinic- Rochester, [2]University of Illinois- Urbana Champagne, [3]Mayo Clinic Rochester

Background: Primary sclerosing cholangitis (PSC) is a well-established risk factor for cholangiocarcinoma (CCA), but outcomes may differ compared to de novo CCA due to surveillance, referral patterns, and access to transplantation. We compared clinicopathologic features, treatment, recurrence, and survival in PSC-associated versus non-PSC CCA at a multi-site tertiary referral center. **Methods:** We performed a retrospective analysis of 115 CCA patients diagnosed from 2015 to 2025 (PSC-CCA n = 30, non-PSC CCA n = 85), who consented to participate within our registry and biorepository. Clinical, pathologic, treatment, and overall survival data were compared using Mann-Whitney U, Fisher's exact, and chi-square tests with Benjamini-Hochberg correction. **Results:** Compared to non-PSC patients with CCA, PSC-CCA patients were predominantly male (73.3% vs. 43.5%, p = 0.009), younger (median age 55.9 vs 65.6, p < 0.0005), and had higher rates of cirrhosis (56.7% vs. 7.1%, p < 0.0001) and ulcerative colitis (63.3% vs. 4.7%, p < 0.0001). PSC-CCA was more frequently perihilar in subtype (perihilar PSC-CCA vs non-PSC CCA 76.7% vs. 29.4%, p < 0.0001). PSC-CCA tumors were smaller at diagnosis (median 2.0 vs. 5.2 cm, p < 0.0001) with earlier T stage (T1a/T1b: 46.7% vs. 13.0%, p = 0.003), less nodal involvement (N0: 66.7% vs. 37.6%, p = 0.023), and lower rates of distant metastasis (M1: 13.3% vs. 48.2%, p = 0.002). PSC-CCA patients had better ECOG performance status (ECOG 0: 76.7% vs. 47.6%, p = 0.011) and more frequently underwent curative surgery (73.3% vs 36.5% p = 0.001; figure 1A). Within this cohort, liver transplantation was performed exclusively in PSC-CCA cases (43.3% vs. 0%, p < 0.0001), and post-surgical recurrnce was significantly lower in PSC-CCA (38.1% vs. 76.9%, p = 0.003). Among patients with PSC, 29.0% of patients underwent non-transplant hepatectomy, with recurrence occurring in 88.0% of this population. Of PSC-CCA cases, 36.7% were detected due to screening, 36.7% due to symptoms, and 23.3% were diagnosed with PSC at CCA diagnosis. Most PSC cases were referrals for liver transplant evaluation (70.0%). The median overall survival was significantly longer in PSC-CCA relative to de novo counterparts (31.5 vs. 18.7 months, p = 0.005; figure 1B). **Conclusion:** PSC-associated CCA presents and is detected at an earlier stage with smaller tumors, fewer metastases, and greater eligibility for curative-intent therapy including transplantation. This results in markedly improved survival and lower post-surgical recurrence compared to non-PSC counterparts. Our experience strongly supports maintaining a high degree of suspicion for CCA in IBD patients, rigorous structured CCA surveillance in PSC and expedient transplantation evaluation in this population.

4281 | DEVELOPMENT OF A GALLBLADDER STROMAL CELLULAR DENSITY ALGORITHM AND ASSOCIATION WITH THE SPECTRUM OF DISEASE

Jill Koshiol[1] Ilona Argirion[2] Karun Mutreja[3] Scott Lawrence[3] Petra Lenz[3] Rime Jebai[3] Allan Hildesheim[4] Ruth Pfeiffer[3] Catterina Ferreccio[5] Juan Araya[6], [1]1Division of Cancer Epidemiology and Genetics, NCI, NIH, [2]Georgetown University Medical Center, [3]Division of Cancer Epidemiology and Genetics, NCI, NIH, [4]Agencia Costarricense de Investigaciones Biomedicas, San Jose, Costa Rica, [5]Instituto de Salud Pública de Chile, [6]Hospital Dr. Hernan Henríquez Aravena, Temuco, Chile

Background: Gallbladder cancer (GBC) incidence is high in Chile. Gallstones are a major risk factor, but most people with gallstones never develop GBC. In a cohort designed to evaluate the determinants of progression from gallstones to cancer, we developed a stromal cellular density (SCD) algorithm to help characterize non-epithelial tissue composition on digital H&E slide images and assess SCD across the spectrum of disease. **Methods:** Using digital H&E slide images from the Chile Biliary Longitudinal Study (BiLS), we created an algorithm with 5 steps (tissue detection, QC to identify good tissue, liver detection and removal, epithelia and non-epithelia detection, account cells in non-epithelia) in HALO (Indica Labs, Arizona) to estimate SCD as the area of cells in non-epithelial region/area of non-epithelia. The training set included 41 images with 204 annotated regions and the test set 349 images with 2025 annotated regions (1060 non-epithelial, 965 epithelial). After evaluating precision (positive predictive value), recall (sensitivity), and the F1 Score [2*(precision*recall/(precision + recall)], we ran the algorithm on 37,553 independent images with pathologist-determined slide-level worst diagnosis from Chile BiLS. We excluded images with >50% artifact area and <30mm^2 usable tissue, leaving 33,544 images for analysis. We fit linear regression models to log(SCD) with slide level outcome as the independent variable, with independence working correlation and robust standard errors to account for repeated observations adjusted for age at cholecystectomy, waist-to-height ratio, and ethnicity. **Results:** The precision, recall, and F1-score were 0.94, 0.92, and 0.92 overall; 0.91, 0.84, and 0.87 for epithelial tissue; and 0.97, 0.99, and 0.98 for stromal tissue. A pathologist qualitatively confirmed performance on 600 of the 37,553 independent images from Chile. Compared to images with a slide-level diagnosis <intestinal metaplasia (IM), the betas were 0.07 (95% confidence interval [CI]: 0.03-0.11) for IM, 0.10 (0.04-0.16) for low-grade dysplasia (LGD), 0.18 (0.085-0.28) for high-grade dysplasia (HGD), and 0.33 (0.21-0.46) for GBC ($p < 0.001$). Making pairwise comparisons across the spectrum of disease, the p-values were 0.002 for IM vs. <IM, 0.4 for LGD vs. IM, 0.1 for HGD vs. LGD, and 0.05 for GBC vs. HGD. **Conclusion:** The SCD algorithm showed robust performance on gallbladder H&E slide images from Chile. The increase in SCD across the spectrum of gallbladder disease suggests that SCD could help characterize micro-environmental changes across disease progression and support investigation of associations with GBC risk factors.

Medicine, [3]Department of Gastroenterology and Hepatology, University of Texas Medical Branch, Galveston, TX

Background: Immune checkpoint inhibitors (ICIs) are standard care for advanced hepatocellular carcinoma (HCC), but emerging evidence suggests that HCC arising from metabolic dysfunction-associated steatotic liver disease (MASLD) responds poorly to ICIs, owing to a dysbiosis-shaped, pre-exhausted immune microenvironment. Large real-world comparative data remain limited. We compared mortality and hepatic decompensation in MASLD-HCC versus non-MASLD HCC. **Methods:** We conducted a retrospective cohort study using the TriNetX Research Network (112 healthcare organizations). Adults with HCC who initiated an ICI (atezolizumab, durvalumab, tremelimumab, nivolumab, pembrolizumab, or ipilimumab) after HCC diagnosis were identified. The MASLD-HCC cohort required ICD-10 diagnostic codes for nonalcoholic steatohepatitis (K75.81) or hepatic steatosis (K76.0) and excluded viral, alcohol-related, autoimmune, cholestatic, and hereditary liver disease; the comparator was ICI-treated HCC without these steatotic codes. Patients receiving chemotherapy, tyrosine kinase inhibitors, or radiotherapy after ICI initiation were excluded to isolate ICI-based treatment. Cohorts were 1:1 propensity score-matched on demographics, cardiometabolic/hepatic comorbidities, and portal vein thrombosis. Follow-up began one day after first ICI administration, and all-cause mortality and hepatic decompensation (ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, bleeding esophageal varices, or hepatorenal syndrome) were assessed using risk ratios (RR) and Kaplan-Meier hazard ratios (HR). **Results:** Of 4,879 ICI-treated HCC patients, 578 had MASLD-HCC and 4,301 had non-MASLD HCC. After matching, 541 patients per cohort were balanced (all standardized differences <0.1; similar median follow-up, 213 vs 204 days). MASLD-HCC patients had significantly higher all-cause mortality (59.1% vs 48.1%; RR 1.23, 95% CI 1.10-1.38; $p<0.001$) and shorter median survival (241 vs 360 days; HR 1.25, 95% CI 1.06-1.47; log-rank $p=0.007$). Hepatic decompensation was also more frequent in MASLD-HCC (51.8% vs 43.8%; RR 1.18, 95% CI 1.04-1.34; $p=0.009$), with shorter median time to decompensation (168 vs 326 days; HR 1.24, 95% CI 1.05-1.48; log-rank $p=0.013$). **Conclusion:** In this large, propensity-matched real-world cohort, MASLD-HCC patients treated with ICIs had significantly higher mortality and more frequent, earlier hepatic decompensation than non-MASLD HCC patients. These findings support the hypothesis that the MASLD immunometabolic milieu limits ICI efficacy and underscore the need for etiology-specific strategies, including microbiome-targeted approaches.

Table 1. Propensity-matched cohort characteristics and clinical outcomes: MASLD-HCC vs non-MASLD HCC treated with immune checkpoint inhibitors

TriNetX Research Network (112 healthcare organizations). 1:1 propensity score matching: 541 patients per cohort. Median follow-up after matching: 213 days (MASLD-HCC) vs 204 days (non-MASLD HCC).

A. Selected baseline characteristics after 1:1 propensity score matching

Characteristic	MASLD-HCC (n=541)	Non-MASLD HCC (n=541)	P value	Std. diff.

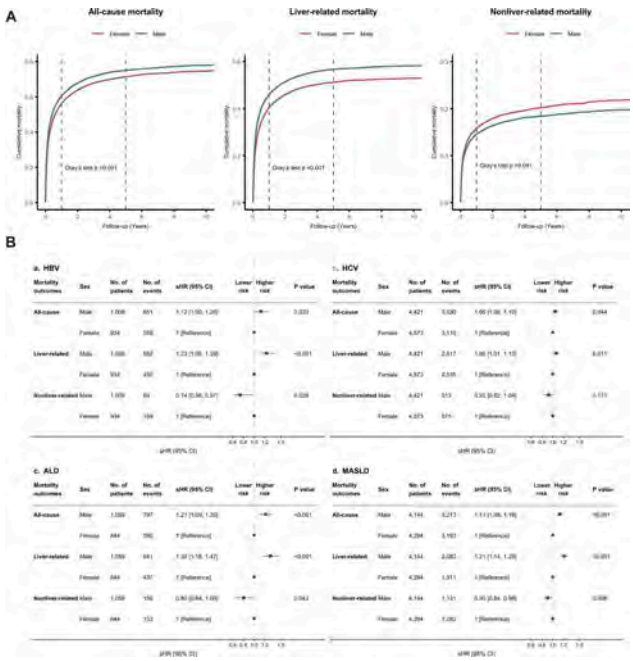
4283 | SEX DIFFERENCES IN ALL-CAUSE, LIVER-RELATED AND NONLIVER-RELATED MORTALITY AMONG PATIENTS WITH HEPATOCELLULAR CARCINOMA: A POPULATION-BASED LONGITUDINAL STUDY



Bowu Chen[1] Xiaonan Su[2] Danfeng Ren[3] Ramsey Cheung[4] Mindie Nguyen[4], [1]Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine, [2]The First Affiliated Hospital, Zhejiang University School of Medicine, [3]The First Affiliated Hospital of Xi'an Jiaotong University, [4]Stanford University Medical Center

Background: Males generally have higher HCC risk across most chronic liver diseases. However, sex differences in clinical outcomes after HCC diagnosis

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

are less well characterized. This study aimed to fill in this gap by comparing long-term all-cause, liver-related, and nonliver-related mortality between male and female patients with HCC. **Methods:** We conducted a population-based retrospective cohort study of patients with HCC who had at least one hospitalization for any cause from the California Department of Health Care Access and Information database from 1/2005 to 12/2019 using 1:1 propensity score matching (PSM, caliper 0.1) to balance background differences between the male and female study groups. We evaluated long-term mortality obtained from California State Death Statistical Master File records which included deaths occurring in both inpatient and outpatient settings. Associations between sex and mortality were evaluated using Fine-Gray competing risk models (competing events: liver transplantation (LT) or alternate cause of death as applicable). Robustness was assessed with demographic (age, race, ethnicity) and clinical (etiology, comorbidity, cirrhosis, liver decompensation) subgroup analyses and multiple sensitivity analyses including stricter-caliper (0.01) PSM, inverse probability of treatment weighting (IPTW) as alternate matching method, exclusion of deaths within 3 months, and analyses without treating LT as a competing event. **Results:** We analyzed a total of 44,340 adult patients with HCC (29.1% female) after excluding HIV infection, LT before HCC, or residence outside California. PSM yielded 12,569 female-male pairs with balanced baseline characteristics (standardized mean difference [SMD] $\leq$ 0.1). Compared with females, males had higher 5-year cumulative all-cause (75.1%, 95% CI 74.3–75.9 vs. 71.4%, 95% CI 70.5–72.2) and liver-related (56.7%, 95% CI 55.8–57.6 vs. 51.2%, 95% CI 50.3–52.1) mortality, but lower nonliver-related mortality (18.4%, 95% CI 17.7–19.1 vs. 20.2%, 95% CI 19.5–20.9) (Figure 1A). In Fine-Gray models, male sex was associated with higher risks of all-cause (subdistribution hazard ratio [sHR] 1.12, 95% CI 1.09–1.15) and liver-related mortality (sHR 1.18, 95% CI 1.14–1.22), but lower risk of nonliver-related mortality (sHR 0.89, 95% CI 0.85–0.95), all $P < 0.001$. Findings were consistent across sensitivity and subgroup analyses. Additionally, disparities varied by etiology with the higher sHR for liver-related mortality in males with ALD (sHR 1.30), HBV (sHR 1.23), and MASLD (sHR 1.21) and lowest with HCV (sHR 1.06) (Figure 1B). **Conclusion:** Among patients with HCC, male patients had higher all-cause and liver-related mortality while females had higher nonliver-related mortality. Sex disparities should be taken into consideration in future disease monitoring and treatment decision-making for patients with HCC.

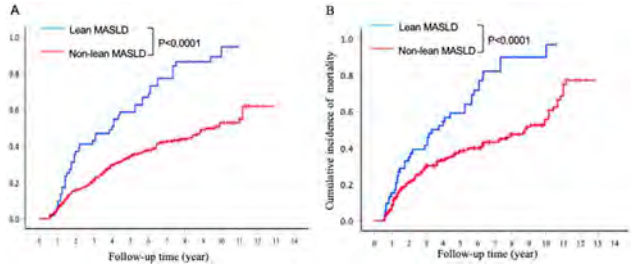
4284 | ASSOCIATION OF LEAN MASLD WITH CLINICAL PROGNOSIS IN HEPATOCELLULAR CARCINOMA AFTER CURATIVE RESECTION IN MASLD AND/OR HEPATITIS B VIRUS PATIENTS



Chih Wen Lin[1] Yaw-Sen Chen[2] Yu-Wei Huang[2] Steven Lin[3] James Lin[4] Yao-Chun Hsu[2] Chih-Che Lin[5] Ming-Lung Yu[6], [1]Lin Da Clinic and E-Da Hospital, I-Shou University, [2]E-Da Hospital, I-Shou University, [3]New York University, [4]Wentworth institute of technology, [5]Kaohsiung Chang Gung Memorial Hospital, [6]Kaohsiung Medical University

Background: The prevalence of metabolic dysfunction–associated steatotic liver disease (MASLD) is increasing in worldwide. The prevalence of concomitant MASLD and hepatitis B virus (HBV)-related hepatocellular carcinoma (HCC) is also increasing. Our previous study showed patients with concomitant MASLD and HBV are at a significantly greater risk of HCC recurrence and mortality after curative hepatectomy than those with MASLD or HBV alone. Patients with MASLD are at increased risk of both hepatic and extrahepatic adverse outcomes.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

However, the evidence regarding lean MASLD and hepatic prognosis remains controversial. This study explored the effect of lean MASLD on clinicopathological features and long-term clinical prognoses in patients with MASLD-related and/or HBV-related HCC after curative hepatectomy. **Methods:** The study retrospectively collected the data of 653 patients with HCC who had undergone curative hepatectomy between 2011 and 2022. We assessed the association of histologically confirmed MASLD. The endpoint is HCC recurrence and mortality after curative resection. Lean MASLD was defined as body mass index (BMI) < 23 kg/m². **Results:** Of 653 patients, 320 (49.0%), 103 (15.8%), and 230 (35.2%) had concomitant MASLD and HBV, MASLD only, and HBV only, respectively. The median follow-up period was 5.1 years. Patients with concomitant MASLD and HBV were at a significantly increased risk of HCC recurrence (P = 0.013 and P = 0.041) and mortality (P = 0.044 and P = 0.026) than those with MASLD or HBV alone. Fifth-three patients (12.5%) were lean MASLD. In multivariable analyses, lean MASLD, GOT > 40 serum aspartate aminotransferase ≥ 40 U/L, tumor size ≥ 5 cm, Lymph node invasion, and cirrhosis were significantly associated with increased HCC recurrence. Furthermore, lean MASLD, type 2 diabetes mellitus, tumor size ≥ 5 cm, Lymph node invasion, microvascular invasion, AJCC stage III-IV and tumor recurrence were significantly associated with increased mortality. Patients with lean MASLD were at a significantly increased risk of HCC recurrence (P < 0.0001) and mortality (P < 0.0001) than those with non-lean MASLD. **Conclusion:** Patients with lean MASLD were at a significantly increased risk of HCC recurrence and mortality than those with non-lean MASLD in MASLD and/or HBV related HCC patients after curative hepatectomy.

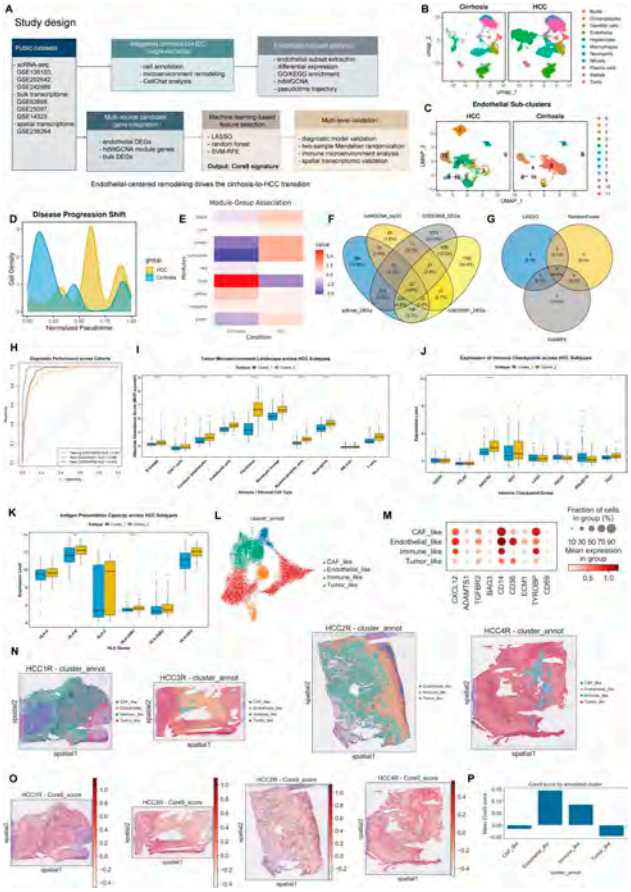
4285 | ENDOTHELIAL REMODELING AND A CORE9 VASCULAR-IMMUNE SIGNATURE DURING THE CIRRHOSIS-TO-HCC TRANSITION



Jiahao Yuan[1] Min Cong[1], [1]Liver Research Center, Beijing Friendship Hospital, Capital Medical University

Background: Hepatocellular carcinoma (HCC) commonly develops in cirrhotic liver, but endothelial programs accompanying malignant transition remain poorly defined. We aimed to characterize endothelial remodeling across the cirrhosis-to-HCC continuum and identify an endothelial-associated signature with diagnostic and microenvironmental relevance. **Methods:** Three public human liver single-cell RNA-seq datasets were integrated to build a cirrhosis-to-HCC atlas. Endothelial cells were extracted for subclustering, differential expression, cell-cell communication, hdWGCNA, and pseudotime analyses. Candidate genes were prioritized by integrating endothelial single-cell signals, co-expression modules, and two bulk transcriptomic cohorts, followed by LASSO, random forest, and SVM-RFE feature selection. Spatial localization, Mendelian randomization (MR)-based prioritization, diagnostic performance, and tumor microenvironment associations were evaluated in independent datasets. **Results:** The integrated atlas revealed marked remodeling of the cirrhosis-to-HCC microenvironment, with endothelial cells showing compositional expansion and transcriptional displacement. Endothelial reclustering resolved inflammatory, sinusoidal, lymphatic-like, metabolic, and proliferative states. hdWGCNA and pseudotime analyses indicated disease-biased co-expression modules and progressive endothelial state transitions. Multi-source integration and machine-learning convergence identified a nine-gene endothelial-associated Core9 signature comprising CXCL12, ADAMTS1, TGFBR2, BAG3, CD14, CD36, ECM1, TYROBP, and CD69. MR-based prioritization highlighted CD36 and CD69 as dynamic candidates with genetic support. Spatial transcriptomic validation localized the Core9 program preferentially to endothelial-like niches in HCC tissues. The Core9

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

model showed strong diagnostic performance across cohorts, with AUCs of 0.927, 0.989, and 0.953. Core9-defined HCC subtypes differed in immune infiltration, immune checkpoint expression, and HLA-related antigen-presentation profiles. **Conclusion:** Endothelial remodeling is a consistent feature of cirrhosis-to-HCC progression. The Core9 signature captures a spatially enriched vascular-immune remodeling program with diagnostic value and potential utility for microenvironmental stratification in HCC.

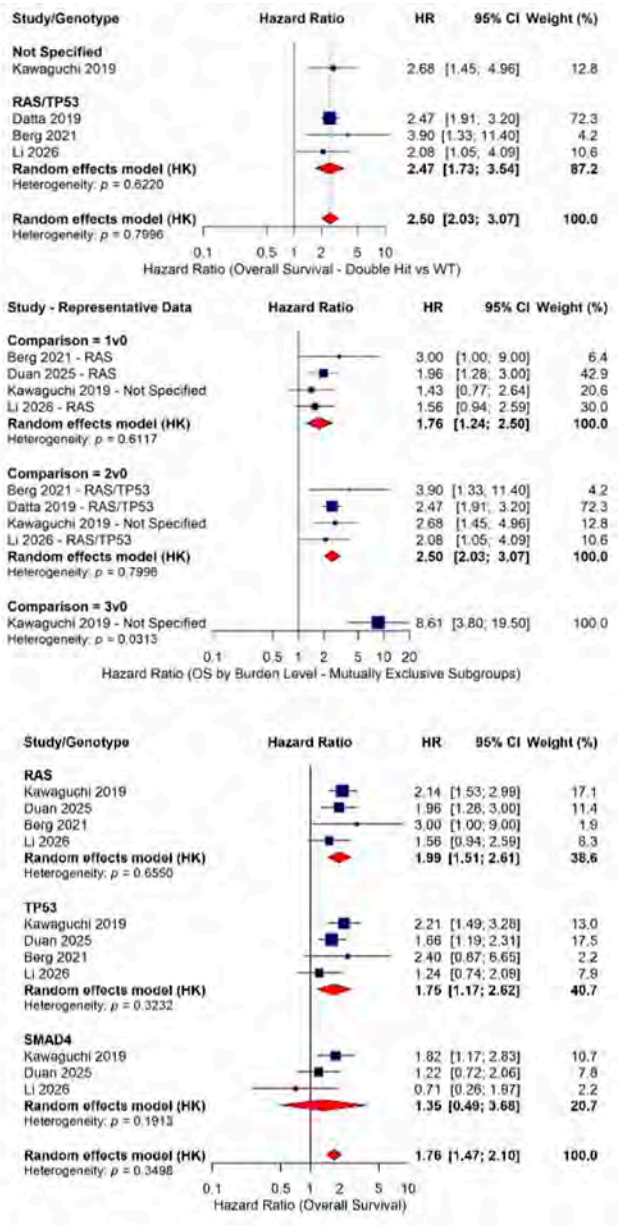
4286 | COMBINED RAS, TP53, AND SMAD4 MUTATIONS AS A PROGNOSTIC MODEL FOR PATIENTS UNDERGOING RESECTION OF COLORECTAL LIVER METASTASES: A SYSTEMATIC REVIEW AND META-ANALYSIS



Ahmed Sayed Ahmed[1] Abdullah Ahmed[2] Mariam Ismail[3] Asmaa Soliman[4] Sanaa Farahat[3] Sapana Verma[1] Reham Zayed[5] Elise Hokr[1] Erlind Erlind[1] Kyungran Justina Cho[6] Chase Wehrle[1] Khalil Mazhar[1] Kim Jaekeun[1] Federico Aucejo[1], [1]Department of Surgery Transplantation Center, The Cleveland Clinic Foundation, OH, USA, [2]Hameed Latif Teaching Hospital, Lahore, Pakistan, [3]Faculty of Medicine, Delta University for Science and technology, Gamasa, Egypt, [4]Faculty of Medicine, Zagazig University, Sharqia, Egypt, [5]Department of Gastroenterology, Hepatology and Nutrition, The Cleveland Clinic Foundation, OH, USA, [6]Department of Gastroenterology, The Cleveland Clinic Foundation, OH, USA

Background: Predicting outcomes after resection of colorectal liver metastases (CRLM) remains difficult, and existing prognostic tools do not adequately account for combined mutational burden. RAS, TP53, and SMAD4 mutations each carry prognostic weight individually, but their cumulative effect has not been systematically quantified. This meta-analysis aimed to define the prognostic impact of combined RAS, TP53, and SMAD4 mutations in patients undergoing curative-intent CRLM resection. **Methods:** A systematic review and meta-analysis were conducted in accordance with PRISMA guidelines, with searches performed across PubMed, Scopus, and Embase. Studies were eligible if they reported hazard ratios (HR) for overall survival (OS) or recurrence-free survival (RFS) according to somatic mutational status of RAS, TP53, and/or SMAD4 in patients undergoing curative-intent CRLM resection. Patients were categorized by mutational burden: single-hit (1 mutation vs. wild-type), double-hit (2 mutations vs. wild-type), or triple-hit (3 mutations vs. wild-type). Pooled HRs were derived using a random-effects model with Hartung-Knapp adjustment. Heterogeneity was quantified using the I^2 statistic. **Results:** Five studies met inclusion criteria. A stepwise increase in mortality risk with rising mutational burden was observed across all analyses ($p < 0.0001$). For OS, the pooled HR for single-hit mutations was 1.56 (95% CI 1.28–1.91, $I^2 = 0\%$), rising to 2.50 for double-hit genotypes (95% CI 2.03–3.07, $I^2 = 0\%$), and peaking in the triple-hit group (HR 8.61, 95% CI 3.80–19.50; Kawaguchi et al.). In genotype-specific analysis of single-hit mutations, RAS (HR 1.99, 95% CI 1.51–2.61) and TP53 (HR 1.75, 95% CI 1.17–2.62) were independent predictors of worse OS, while isolated SMAD4 mutation did not reach significance (HR 1.35, 95% CI 0.49–3.68). A parallel escalating pattern was seen for RFS in the Kawaguchi cohort, with HRs of 1.18, 1.81, and 3.72 for 1-hit, 2-hit, and 3-hit genotypes, respectively. Heterogeneity was low across the primary burden analyses ($I^2 = 0\%$). **Conclusion:** Combined RAS, TP53, and SMAD4 mutational burden shows a consistent, stepwise relationship with survival after CRLM resection. The strength of this dose-response pattern across studies supports incorporating multi-gene mutational profiling into clinical prognostic models, with potential implications for patient

4287 | GENOMIC DETERMINANTS OF RECURRENCE AFTER CURATIVE-INTENT THERAPY FOR HEPATOCELLULAR CARCINOM

Laia Aceituno Sierra[1] Javier Ruiz Ramirez[2] Elena Valenzi[3] Giselle Caballero[4] Giselle Caballero[4] Shiva Babakhani[4] Roxana Bucur[4] Trevor Pugh[2] Anand Ghanekar[4] Arndt Vogel[5], [1]Toronto General Hospital, University Health Network, [2]Princess Margaret Cancer Centre, University Health Network, Toronto, Ontario, Canada, [3]Division of Gastroenterology and Hepatology, Toronto General Hospital, Toronto, Canada, [4]University Health Network, HPB Surgical Oncology, Toronto, Ontario, Canada, [5]University of Toronto

Background: Recurrence after curative-intent therapy for hepatocellular carcinoma (HCC) remains a major challenge, and current risk stratification is largely clinicopathologic. We aimed to define genomic predictors of recurrence and characterize biological differences between resection and transplantation using an integrated gene- and pathway-level framework. **Methods:** We analyzed 158 patients with HCC undergoing resection (87) or liver transplantation (71) with tumor genomic profiling. Gene-level associations with recurrence were assessed using Fisher's exact test with Benjamini–Hochberg correction. Recurrence-free survival (RFS) was evaluated using Kaplan–Meier and Cox proportional hazards models. Pathway-level analyses were performed using curated oncogenic pathways. **Results:** Among the included patients, the median age was 63.7 years, and 83.2% were male. Recurrence occurred in 27.2% of cases and was more frequent following resection than transplantation (36.8% vs. 15.5%, $p = 0.004$). The most commonly observed genomic alterations were TERT (46.8%), TP53 (43.0%), and MAP2K4 (29.1%). Distinct genomic differences by treatment modality were evident, with *TP53*, *FLCN*, and *MAP2K4* alterations enriched in resection specimens. At the pathway level, RTK/growth factor, RAS/MAPK, Hippo, and PI3K/AKT/mTOR signaling were significantly enriched in resection (FDR $q < 0.1$), although no pathway independently predicted recurrence after multiple testing correction. TP53 alterations (43%) were associated with worse RFS (log-rank $p = 0.042$), with a particularly strong effect observed in the transplant subgroup ($p = 0.014$). In multivariable analysis, a combined TP53 + ARID1B model provided the best prediction of recurrence (HR 2.13, 95% CI 1.07–4.21, $p = 0.03$; model concordance 0.66). **Conclusion:** Preliminary results show that

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

TP53-driven biology, particularly when co-occurring with ARID1B alterations, might help to identify patients at increased risk of recurrence. Further analysis needs to be completed.

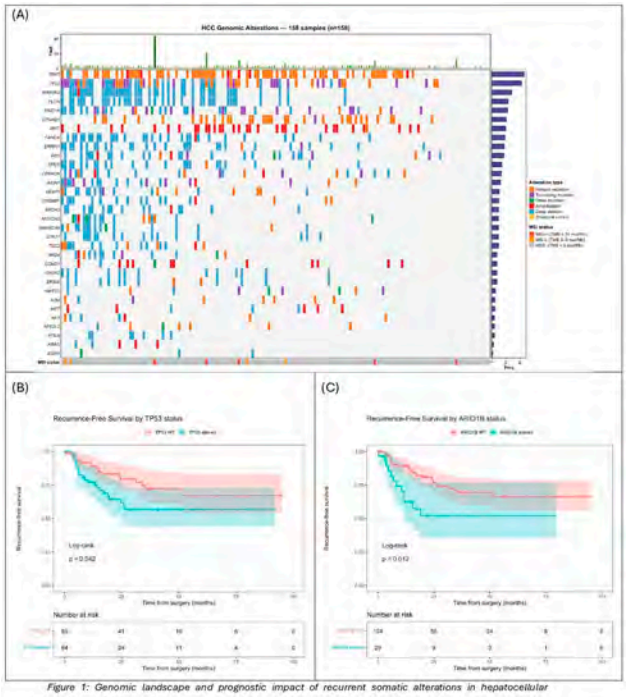

Figure 1: Genomic landscape and prognostic impact of recurrent somatic alterations in hepatocellular carcinoma. (A) Oncoprint representation of the most frequently altered showing mutation types, copy number alterations, tumor mutational burden, and microsatellite instability status.(B) Kaplan–Meier analysis of recurrence-free survival according to TP53 alteration status. (C) Kaplan–Meier of recurrence-free survival according to ARID1B alteration status.

4288 | CLINICAL IMPACT OF TP53 MUTATIONS AND TUMOR-INFILTRATING LYMPHOCYTES IN UNRESECTABLE INTRAHEPATIC CHOLANGIOCARCINOMA

Hiroki Inada[1] Daiki Maeda[1] Fumiya Otsuka[1] Satoshi Narahara[1] Hideaki Miyamoto[1] Takehisa Watanabe[1] Katsuya Nagaoka[1] Hiroko Setoyama[1] Haruki Uojima[1] Yasuhito Tanaka[1], [1]Kumamoto University

Background: The clinical utility of predictive biomarkers for immune checkpoint inhibitor (ICI)-based combination therapy in unresectable intrahepatic cholangiocarcinoma (ICC) remains unclear. We previously reported that TP53 mutations influence the tumor immune microenvironment and serve as a prognostic factor in ICC patients treated with ICIs. In this study, we investigated the tumor cell characteristics driven by TP53 mutations and evaluated tumor-infiltrating lymphocytes (TILs). **Methods:** We retrospectively analyzed 41 patients with ICC who received gemcitabine, cisplatin, and durvalumab (GCD) or GC plus pembrolizumab (GCP) at our institution and affiliated hospitals between December 2022 and March 2026. TILs were evaluated using hematoxylin and eosin staining and classified into three groups: High (>40%), Intermediate (11–40%), and Low (<10%). Spatial transcriptomic analysis using Xenium was performed to characterize TP53-mutant tumor cells. **Results:** The median age was 72 years (range, 44–83 years). Treatment regimens included GCD in 35 patients and GCP in 6 patients, and 29 patients (64%) received first-line therapy. Comprehensive genomic profiling was performed in 37 patients (90%). TIL classification was High in 3 patients (7%), Intermediate in 8 (20%), Low in 26 (63%), and unevaluable in 4 (10%). Median progression-free survival (PFS) was 21.2 months in the High group, 3.5 months in the Intermediate group, and 5.4 months in the Low group, demonstrating favorable PFS in the TIL-High group. Median PFS in TP53-mutant ICC was 4.1 months (95% CI, 2.5–6.3), which was significantly shorter than that in TP53 wild-type ICC (6.9 months; 95% CI, 4.4–10.7; $p = 0.021$). Spatial transcriptomic analysis revealed enrichment of cell cycle-related pathways, including HALLMARK_G2M_CHECKPOINT and HALLMARK_E2F_TARGETS, whereas inflammatory response pathways were suppressed in TP53-mutant ICC. Furthermore, SOX2 expression was significantly elevated in TP53-mutant tumor cells ($p < 0.001$), suggesting activation of cancer stem cell programs. **Conclusion:** TIL-High ICC cases demonstrated favorable PFS following ICI-based combination therapy. TP53-mutant ICC showed activation of cell cycle- and cancer stem cell-related pathways along with suppression of inflammatory response-related genes, suggesting that these tumor cell characteristics may contribute to impaired antitumor immunity and resistance to ICI therapy.

4289 | EVOLVING LANDSCAPE OF HEPATOCELLULAR CARCINOMA RECURRENCE AFTER CURATIVE RADIOFREQUENCY ABLATION IN THE ANTIVIRAL ERA: AN ETIOLOGY- AND ERA-STRATIFIED HAZARD ANALYSIS

Makoto Moriyama[1] Naoto Fujiwara[2] Takuma Nakatsuka[1] Tatsuya Minami[1] Mitsuhiro Fujishiro[1] Ryosuke Tateishi[1], [1]The University of Tokyo, [2]Mie university

Background: Following the introduction of direct-acting antivirals (DAAs) and the widespread use of nucleos(t)ide analogues (NAs), the etiologic landscape of hepatocellular carcinoma (HCC) has shifted toward non-viral etiologies. However, comparative long-term recurrence patterns among non-B, non-C (NBNC), hepatitis B virus (HBV), and hepatitis C virus (HCV)-related HCC in the DAA era remain poorly defined. **Methods:** In this single-center, retrospective study, consecutive patients who underwent radiofrequency ablation (RFA) as initial curative treatment for HCC (complete response on imaging) between January 2000 and December 2023 were enrolled. Patients were stratified into four groups: NBNC, HBV (the majority of whom were on NA therapy either before or after initial HCC treatment), pre-2014 HCV, and post-2014 HCV (the era of approved interferon-free DAA regimens in Japan). Cumulative recurrence rates were estimated using the Kaplan-Meier method and compared by pairwise log-rank tests with Bonferroni adjustment, using NBNC as the reference group. Annualized recurrence hazard rates were estimated using natural cubic splines weighted by the number at risk. **Results:** Among 1,629 patients who underwent curative RFA (NBNC n = 338; HBV n = 194; pre-2014 HCV n = 964; post-2014 HCV n = 133), 1,340 recurrences were observed over a median follow-up of 1.67 years. Cumulative recurrence rates at 5/10 years were: 88.1%/94.3% in pre-2014 HCV, 74.2%/86.6% in NBNC, 68.4%/78.6% in HBV, and 62.8%/77.0% in post-2014 HCV. Compared with NBNC, pre-2014 HCV had higher recurrence ($p = 1.3 \times 10^{-5}$), whereas post-2014 HCV had lower recurrence ($p = 0.026$); HBV showed no significant difference ($p = 0.066$). Within the HCV cohort, the post-2014 cohort had substantially lower cumulative recurrence than the pre-2014 cohort ($p = 2.0 \times 10^{-8}$). Annualized hazard analysis showed that the pre-2014 HCV cohort displayed a biphasic trajectory, with an initial peak of 64.7%/year at 2.5 years and a secondary rise to 23.8%/year at 7 years. NBNC exhibited a similar biphasic pattern, with an early peak of 42.1%/year at 2.2 years and a late rise to 16.2%/year at 7 years. In contrast, the post-2014 HCV (peak 34.9%/year at 1.8 years; 5-year hazard 12.7%/year) and HBV (peak 27.3%/year at 1.6 years; 5-year hazard 14.1%/year) cohorts showed attenuated, unimodal trajectories with progressive decline. **Conclusion:** The introduction of DAAs has significantly reduced the cumulative recurrence of HCV-related HCC. In the DAA era, however, NBNC-related HCC now exhibits a higher cumulative recurrence rate than DAA-era HCV-related HCC. Annualized hazard analysis further revealed that NBNC-related HCC displays a bimodal recurrence pattern resembling that of pre-DAA HCV-related HCC, underscoring the need for sustained long-term surveillance even in patients without early recurrence.

4290 | DIVERGENT AGE-STRATIFIED TRENDS IN HEPATOCELLULAR CARCINOMA MORTALITY IN THE UNITED STATES, 1999–2024

Moksha Prasoona Avvaru[1] Shashank Trivedi[2] Mythily Rao Ponaganti[3] Sri Ram Charan Gundapaneni[4] Suhas Kataveni[5] Gaurav Sharma[6], [1]Harnett Health, [2]Rochester General Hospital, NY, [3]SBH health system, [4]UCF/HCA Florida Ocala Hospital, [5]HCA Citrus, Florida, [6]JNU Medical School, Jaipur

Background: The epidemiology of hepatocellular carcinoma (HCC) in the United States has evolved substantially over the past two decades amid changing hepatitis C virus prevalence, advances in antiviral therapy, and increasing metabolic liver disease burden. However, contemporary age-stratified national mortality trends remain incompletely characterized. **Methods:** We performed a retrospective serial cross-sectional analysis using the CDC WONDER Multiple Cause of Death database from 1999–2024. Deaths with HCC listed as the underlying cause of death were identified using ICD-10 code C22.0. Age-adjusted mortality rates (AAMRs) per 100,000 population were analyzed for adults aged <55 (25-54) years and ≥ 55 years. Temporal trends were evaluated using Joinpoint regression analysis with calculation of annual percent changes (APCs) and corresponding 95% confidence intervals. **Results:** HCC mortality trajectories diverged substantially by age beginning around 2010. Among adults aged <55 years, mortality initially increased from 1999–2004 (APC +4.20%, $p=0.017$), followed by a sustained decline from 2010–2024 (APC −5.97%, $p<0.001$). Age-adjusted mortality rates in this group decreased from a peak of 1.18 per 100,000 in 2005 to 0.48 per 100,000 in 2024. In contrast, adults aged ≥ 55 years demonstrated persistent increases in HCC mortality throughout the study period, including continued growth after 2014. Mortality rates in this cohort increased from 6.72 per 100,000 in 1999 to 12.47 per 100,000 in 2024, with ongoing significant increases observed from 2017–2024 (APC +0.91%, $p=0.002$). **Conclusion:** HCC mortality trends in the United States have diverged markedly by age over the past two decades. While adults aged <55 years experienced sustained mortality declines after 2010, adults aged ≥ 55 years continued to demonstrate progressive increases in HCC mortality. These findings suggest an increasing concentration of HCC burden among aging populations and highlight the evolving epidemiology of chronic liver disease in the United States.

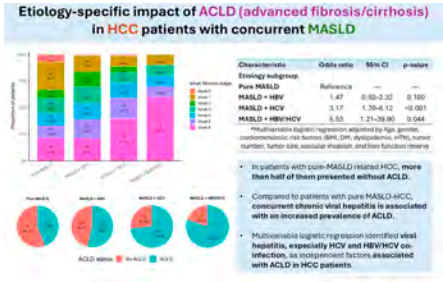
4291 | ETIOLOGY-SPECIFIC CONTRIBUTIONS TO ADVANCED CHRONIC LIVER DISEASE IN HEPATOCELLULAR CARCINOMA PATIENTS WITH CONCURRENT METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE



Chun-Ting Ho[1] Shin-Yu Tsai[2] Yi-Hsiang Huang[2] Ming-Chih Hou[2] Jaw-Ching Wu[3] Chien-Wei Su[2], [1]Taipei Veterans General Hospital/NYCU, [2]Taipei Veterans General Hospital, [3]National Yang Ming Chiao Tung University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a rising etiology for hepatocellular carcinoma (HCC), with heterogeneous pathophysiology related to or independent from advanced chronic liver disease (ACLD). Also, other etiologies including viral hepatitis can also lead to liver fibrosis and carcinogenesis. Our study aimed to investigate the burden and etiological impact on ACLD among HCC patients with concurrent MASLD. **Methods:** 478 treatment-naïve HCC patients with concurrent MASLD who underwent curative resection at a tertiary center in Taiwan with available pathological specimens and complete clinical data were included. Patients were divided into ACLD and non-ACLD groups according to their ISHAK fibrosis grade from the surgical specimen using a cut-off of four. Subgroup analysis was performed in patients with pure-MASLD without viral hepatitis, concurrent MASLD and chronic hepatitis B (CHB), MASLD and chronic hepatitis C (CHC), and finally MASLD with CHB and CHC co-infection. Multivariable logistic regression was performed to determine factors associated with the presence of ACLD. **Results:** Among all patients, 257 (53.8%) had ACLD. The prevalence of ACLD differed significantly across etiology-specific

subgroups and increased progressively with concomitant chronic viral hepatitis: 43.9% in pure MASLD-related HCC, 53.6% in MASLD and CHB, 73.2% in MASLD and CHC, and 80.0% in MASLD and CHB/CHC co-infection. In multivariable logistic regression adjusted by age, gender, tumor factors and cardiometabolic risk factors (CMRFs), presence of viral hepatitis, especially CHC and CHB/CHC co-infection, were identified as independent factors associated with ACLD in HCC patients, along with female gender and smaller tumor size. Individual CMRFs, such as diabetes, obesity, dyslipidemia, and hypertension, were not independently associated with ACLD. **Conclusion:** The burden of ACLD among HCC patients with concurrent MASLD varies significantly by etiology. While chronic viral hepatitis was independently associated with a higher prevalence of ACLD in HCC patients with MASLD, more than half of pure MASLD-related HCC patients presented without ACLD, indicating distinct pathophysiology features.

4292 | MIXED SARCOMATOID HEPATOCELLULAR CARCINOMA/ CHOLANGIOCARCINOMA: A CONCERNING COMBINATION

Martin Sharpe[1] Jason Eng[2], [1]Ohio State University Medical Scientist Training Program, [2]The Ohio State University College of Medicine

Background: Mixed sarcomatoid hepatocellular carcinomas/cholangiocarcinomas (sHCC/ICC) are an exceptionally rare, primary malignant cancer of the liver. Although their pathogenesis remains largely unknown, cases of sHCC/ICC often appear in patients that have been treated with locoregional therapies such as radiofrequency ablation or transarterial chemoembolization. sHCC/ICC carries a very poor prognosis due to its late presentation, lack of effective treatments, and high potential for metastases. Here, we report the case of a 54-year-old female referred to our clinic for decompensated MASH cirrhosis management. **Methods:** N/A **Results:** Standard HCC screening diagnostics, including RUQ ultrasound and serum AFP, both failed to suggest the presence of a malignancy. However, abdominal MRI ordered for transplant evaluation revealed a small focus initially suggestive of a LR-5 lesion (HCC) in segment 7. Surprisingly, serial imaging demonstrated radiographic changes that eventually suggested evolution to an LR-M (metastatic) lesion which led to a subsequent biopsy. Pathology demonstrating hallmark histopathological findings such as mixed epithelial and spindle cell features, with both components showing variable cytokeratin expression confirmed the diagnosis of a mixed sarcomatoid hepatocellular/cholangiocarcinoma. The patient underwent ablation of the lesion followed by imaging which demonstrated adequate treatment response. **Conclusion:** While exceedingly rare, *de novo* sarcomatoid carcinomas can develop in patients with cirrhosis. This case highlights a unique instance in which a patient with no prior risk factors associated with this type of cancer developed a mixed cell-type variant which was identified early in its formation, providing an opportunity for aggressive treatment.

4293 | TEMPORAL TRENDS IN INCIDENCE, TREATMENT, AND SURVIVAL IN FIBROLAMELLAR CARCINOMA: IMPACT OF THE DNAJB1–PRKACA FUSION DISCOVERY ERA USING SURVEILLANCE, EPIDEMIOLOGY, AND END RESULTS (SEER) 2000–2023 DATABASE

Krishna Chandrasekhara[1] Nicholas Thomas[1] Chandni Bhagtaney[1] Prasun Jalal[1], [1]Baylor College of Medicine

Background: Fibrolamellar carcinoma (FLC) is a rare, aggressive liver cancer predominantly affecting adolescents and young adults without underlying liver disease or cirrhosis. Historically misclassified as "HCC with fibrolamellar features," FLC's classification

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

was transformed in 2014 by the discovery of the DNAJB1–PRKACA fusion protein, arising from a chromosome 19 deletion juxtaposing DNAJB1 and PRKACA. Dysregulated PKA activity drives oncogenesis; the fusion is detected in essentially 100% of cases. This established FLC as molecularly distinct, prompted WHO criteria updates in 2019, and is an active clinical trial target, though no FDA-approved therapy exists. True incidence may be 5–8 times higher than reported. Prior SEER studies characterize survival without analyzing treatment trends or contextualizing within the fusion discovery era. **Methods:** SEER identified FLC cases (ICD-O-3 code 9173/3) from 2000–2023 (n = 366). Cases were classified pre-2014 (n = 191) or post-2014 (n = 175). Annual incidence was plotted through 2022 with segmented regression. Stage proportions used 3-year rolling means; surgical and chemotherapy rates used LOESS smoothers. CSS was time to FLC-attributable death per SEER. Kaplan–Meier curves compared eras by log-rank test; 5-year CSS computed for 2000–2018. A Cox model adjusted for age and stage isolated the independent era effect. Chi-square tests compared categorical variables; $p < 0.05$ was significant. **Results:** 366 FLC cases were identified (range 5–21/year) with a modest upward trend and no step-change at 2014. Stage was stable across eras ($p = 0.72$). Surgical resection (49% vs 57%, $p = 0.11$) and chemotherapy (51% vs 48%, $p = 0.60$) did not differ. Five-year CSS was 44.0% (95% CI 37.4–51.7%) pre-2014 and 48.9% (95% CI 40.7–58.7%) post-2014; the difference was not significant ($p = 0.27$). After age and stage adjustment, era HR was 0.92 (95% CI 0.67–1.27, $p = 0.626$); age (HR 1.22/decade) and advanced stage were independent adverse predictors (both $p < 0.001$). **Conclusion:** Incidence did not increase post-2014, possibly reflecting incomplete adoption of molecular testing or challenges disseminating advocated diagnostic criteria, meaning true FLC may be misclassified as HCC and distort incidence given FLC's rarity. The unadjusted survival difference (44.0% vs 48.9% at 5 years) was attenuated to null after age and stage adjustment (HR 0.92, $p = 0.626$), suggesting apparent improvements reflect a more favorable case mix rather than a true era effect. Age and stage remain the primary CSS determinants. Longitudinal monitoring following broader molecular testing adoption will be important to assess whether current rates underestimate true disease burden, and whether DNAJB1–PRKACA-targeted therapies under development, given the inherent lag from discovery to clinical maturity, ultimately translate into measurable survival gains.

4294 | TRENDS IN INCIDENCE, TREATMENT PATTERNS, AND OVERALL SURVIVAL OF INTRAHEPATIC CHOLANGIOCARCINOMA IN THE UNITED STATES, 2000-2022

Fadhil Jamil[1] Hyunseok Kim[2] Michael Luu[2] Paul Martin[2] Alexander Kuo[3] Walid Ayoub[3] Yun Wang[2] Aarshi Vipani[3] Nicole Rich[4] Neehar Parikh[5] Kambiz Kosari[2] Nicholas Nissen[2] Cristina Ferrone[6] Amit Singal[4] Ju Dong Yang[3], [1]American University of Antigua College of Medicine, [2]Cedars Sinai Medical Center, [3]Cedars-Sinai Medical Center, [4]University of Texas Southwestern Medical Center, [5]University of Michigan Medical Center, [6]Cedar Sinai Medical Center

Background: Intrahepatic cholangiocarcinoma (iCCA) represents the second most common primary liver cancer worldwide after hepatocellular carcinoma (HCC). With evolving epidemiology and treatment strategies, recent trends in iCCA incidence, tumor burden, treatment patterns, and overall survival in the United States warrant investigation. **Methods:** The Surveillance, Epidemiology, and End Results (SEER) database, including the SEER-21 and SEER-17 registries, was used to evaluate patients with iCCA. Using the SEER-21 registry, we calculated annual percent change (APC) and average annual percent change (AAPC) with Joinpoint regression analysis. Patient-level analyses were performed using the SEER-17 registry to evaluate tumor characteristics, treatment patterns, and overall survival (OS) among 17,833 patients diagnosed with iCCA between 2000 to 2022. Multivariable logistic regression identified factors associated with receipt of surgical treatment, while Cox regression analysis identified factors associated with OS. **Results:** iCCA incidence increased significantly from 2000 to 2022 (AAPC: 6.64%, 95% CI: 6.18% - 7.12%, $p < 0.001$) with a similar pattern between females (AAPC: 6.99%, 95% CI: 6.45% - 7.54%, $p < 0.001$) and males (AAPC: 6.32%, 95% CI: 5.65% - 6.99%, $p < 0.001$). Joinpoint analysis analyis identified an inflection point with a rapid increase in the incidence rates among individual younger than 50 years between 2020 and 2022 (APC: 21.13%, 95% CI: 1.56% - 35.93%, $p = 0.010$). Compared with 2000-2010, diagnosis during 2011-2019 was associated with higher odds of receiving surgical treatment (aOR: 1.29, 95% CI: 1.16-1.44, $p < 0.001$) (**Table**). Compared with non-Hispanic White patients, Hispanic (aOR: 0.69, 95% CI: 0.61-0.78, $p < 0.001$) and non-Hispanic Black patients (aOR: 0.70, 95% CI: 0.59-0.83, $p < 0.001$) had significantly lower odds of receiving surgical treatment. In multivariable analyses, recent diagnosis was independently associated with improved OS, with better survival among patients diagnosed in 2020-2022 (aHR: 0.76, 95% CI: 0.72-0.79, $p < 0.001$) compared to 2000-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

2010. Hispanic ethnicity (aHR: 1.10, 95% CI: 1.05-1.16, p < 0.001), non-Hispanic Black race (aHR: 1.08, 95% CI: 1.01-1.15, p = 0.017) and non-Hispanic American Indian/Alaska Native race (aHR: 1.22, 95% CI: 1.03-1.46, p = 0.024) were associated with worse OS after adjusting for diagnosis year, sex, age group, race/ethnicity, household income, rural-urban classification, tumor size, stage, and grade. **Conclusion:** iCCA incidence continues to rise in the United States with marked increase among patients younger than 50 years in recent years. Although survival has improved in recent years, disparities in treatment receipt and outcomes persist among racial and ethnic minority groups. Addressing these gaps is essential to improving equitable access to treatment and optimizing outcomes for patients with iCCA.

Table 1 - Factors associated with receipt of surgical treatment among all iCCA patients in SEER 17 database.

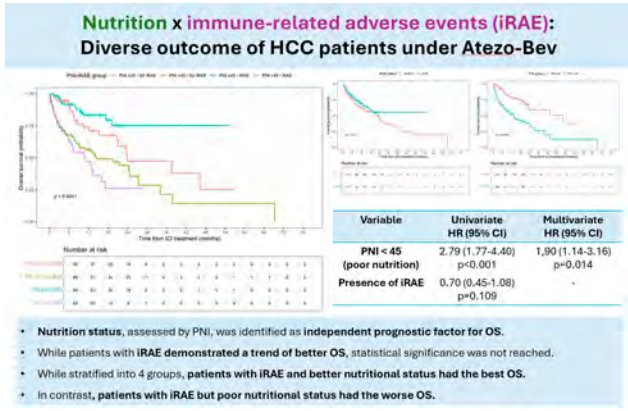
4295 | PROGNOSTIC IMPACT OF NUTRITIONAL STATUS AND IMMUNE-RELATED ADVERSE EVENTS IN HEPATOCELLULAR CARCINOMA PATIENTS TREATED WITH ATEZOLIZUMAB PLUS BEVACIZUMAB



Chien-Wei Su[1] Chun-Ting Ho[1] San-Chi Chen[1] Wei-Yu Kao[2] Yao-Yu Hiseh[3] Ming-Shun Wu[4] Chia-Chi Wang[5], [1]Taipei Veterans General Hospital, [2]Taipei Medical

University Hospital, [3]Shuang Ho Hospital, [4]Wan Fang Hospital, [5]Taipei Tzu Chi Hospital

Background: Both host nutritional status and immune-related adverse events (iRAEs) may influence outcomes in patients with hepatocellular carcinoma (HCC) receiving immunotherapy. However, the interaction between these two factors is not well studied. We aimed to evaluate the combined prognostic effects of baseline nutritional status and iRAE development on overall survival (OS) in HCC patients treated with atezolizumab plus bevacizumab. **Methods:** This multicenter retrospective study included 248 HCC patients treated with atezolizumab plus bevacizumab in Taiwan. Baseline nutritional status was assessed using the prognostic nutritional index (PNI), with poor nutrition defined as PNI < 45. Patients were further categorized according to the occurrence of iRAEs during treatment. Multivariable Cox proportional hazards models adjusted for age, sex, tumor stage, macrovascular invasion, and viral etiology were used to identify independent predictors of OS. Survival outcomes were analyzed using Kaplan-Meier methods and compared by log-rank tests. **Results:** After a median follow-up of 16.3 months, 102 deaths occurred, with an overall 5-year OS rate of 25.2% (95% confidence interval, CI: 14.3%–44.5%). On multivariable Cox PH analysis, poor nutritional status (PNI < 45) was identified as a significant, independent adverse prognostic factor for OS (hazard ratio, HR: 1.90; 95% CI: 1.14–3.16; p = 0.014), alongside macrovascular invasion, elevated alpha-fetoprotein (AFP) levels, and higher ALBI grade. Although the development of iRAEs was associated with a trend toward improved survival on univariable analysis (HR, 0.70; 95% CI, 0.45–1.08; p = 0.109), it was not independently associated with OS after adjustment. Notably, significant survival differences emerged when patients were stratified according to both nutritional status and iRAE occurrence (p < 0.001). Patients with preserved nutritional status who developed iRAEs achieved the best survival outcomes. In contrast, patients with poor baseline nutrition who developed iRAEs exhibited the worst OS among all subgroups. **Conclusion:** Baseline nutritional status is a critical determinant of survival in HCC patients receiving atezolizumab plus bevacizumab. Moreover, the prognostic implication of iRAEs appears to be highly dependent on host nutritional reserve. While iRAEs may reflect effective antitumor immune activation in well-nourished patients, their occurrence in malnourished patients is associated with markedly poor outcomes. These findings highlight the importance of nutritional assessment and optimization in patients undergoing combination immunotherapy for HCC.

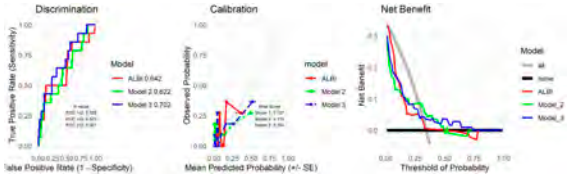
4296 | MODEL TO PREDICT EARLY HEPATIC DECOMPENSATION DURING IMMUNE CHECKPOINT INHIBITOR THERAPY FOR HEPATOCELLULAR CARCINOMA



David Kaplan[1] Courtney Williamson[2] Shalini Bansal[3] Stephen Valerio[4] Dex Underwood[4], [1]University of Pennsylvania, [2]Corporal Michael J. Crescenz VA Medical Center, [3]Mount Sinai School of Medicine, [4]AstraZeneca Inc.

Background: Immune checkpoint inhibitors (ICI) have significantly improved survival outcome for patients with unresectable hepatocellular (uHCC). However, due to high prevalence of pre-existing advanced liver dysfunction, a significant fraction of ICI-treated uHCC patients will experience early hepatic decompensation and liver-related death. The objective of this study was develop and internally validate a clinical prediction tool for early death or new/worsening decompensation under ICI therapy for uHCC. **Methods:** All U.S. Veteran patients who received first-line (1L) ICI therapies were identified in the U.S. Veterans Administration CDW between 10/2020 and 2/2024. Manual chart abstraction confirmed uHCC diagnosis, immediate pre-1L tumor characteristics (number, tumor diameters, macrovascular invasion, extrahepatic spread, prior LRT or resection), evidence of portal hypertension (ascites, endoscopy, imaging), spleen size, prior hepatic decompensations (ascites, variceal hemorrhage, encephalopathy), Child-Pugh, ALBI score, ECOG performance status, and baseline labs. Chart abstraction further

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

identified time to death and post-treatment decompensations including new/worsening ascites (clinical/imaging), variceal hemorrhage, hepatic encephalopathy, SBP (lab confirmed), and HRS. After 70%:30% random sampling, generalized linear models to predict 30-day death or decompensation were trained and internally validated for AUROC, calibration and decision-curve analysis to compare net benefit using ALBI score as a reference. **Results:** 367 patients undergoing 1L atezolizumab/bevacizumab (n = 245), STRIDE (n = 101), atezolizumab (n = 16) or durvulamab (n = 5) monotherapy were abstracted. Median age was 70 (IQR 66-74); 98.9% were male; 211 (57.5%) were white; etiology of liver disease was ALD/ALD+HCV/HCV/MASH/HBV in 16.3%/25.6%/33.5%/21.0%/1.1%; baseline CTP A/B/C 76.0%/23.4%/0.5%; median tumor number was 4 [IQR 1-5], largest tumor size 5.5cm [2.7 - 11.1cm], TTD 11.5cm [5.3 - >20cm] , 127 had MVI (34.6%, 13% VP4) and 84 extrahepatic spread (22.9%); and BCLC 0/A/B/C/D stage was 1.4%/7.1%/30.0%/59.9%/ 1.6%. 39 (10.6%) died or developed worsening decompensation within 30 days (9 variceal hemorrhage, 10 new/worsening ascites, 3 SBP, 0 HRS, 9 hepatic encephalopathy, with 25 deaths). After training, compared to ALBI, Model 3 based on age, MELD3.0, tumor number, largest tumor size, VP3/4 MVI, AST and splenomegaly showed superior discrimination, calibration and net-benefit for prediction 30-day outcomes (Figure 1). **Conclusion:** Death and worsening decompensation within 30 days of initiation of ICI therapy for uHCC is relatively frequent and can be reasonably predicted with a parsimonious set of readily available clinical and laboratory values. After external validation, such predictive models may be utilized to identify patients for whom poor liver reserve may mitigate benefits of ICI.

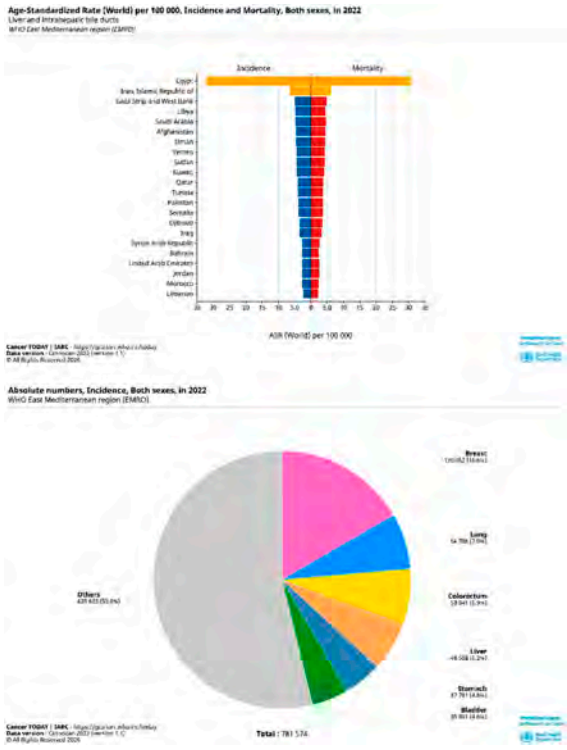
4297 | REVISITING THE BURDEN OF LIVER CANCER IN THE EASTERN MEDITERRANEAN REGION AND ITS PROJECTIONS TO 2050



Saleh Alessy[1] Mariam Zahwe[2] Basmah Khoja[1] Habeeb Razack[3] Ghadeer Jamjoum[4] Aldanah Althwanay[5] Lolwa Alobaid[6] Nouf Al-Turki[7] Mohammad Mawardi[8] May Alzahrani[8] Khalid AlNaamani[9] Isabelle Soerjomataram[2] Saleh Alqahtani[10], [1]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [2]The International Agency for Research on Cancer, Lyon, France, [3]King Saud University, Riyadh, Saudi Arabia, [4]King Abdulaziz University Hospital, Jeddah, Saudi Arabia, [5]Washington University at St.Louis, St.Louis, USA, [6]King Abdulaziz Medical City, Riyadh, Saudi Arabia, [7]King Abdulaziz University, Jeddah, Saudi Arabia, [8]King Faisal Specialist Hospital and Research Centre-Jeddah, Jeddah, Saudi Arabia, [9]The Medical City for Military and Security Services, Muscat, Oman, [10]King Faisal Specialist Hospital & Research Center

Background: Liver cancer remains a major cause of cancer-related mortality, despite being largely linked to modifiable risk factors, including viral hepatitis and metabolic liver disease. For the World Health Organization (WHO) Eastern Mediterranean Region (EMR), updated country-level burden estimates and projections to 2050 are needed to guide regional cancer-control planning. We aimed to assess the current burden and project future liver cancer incidence in the EMR through 2050 to inform regional cancer control efforts. **Methods:** We used cancer estimates from the International Agency for Research on Cancer GLOBOCAN 2022 dataset to assess liver cancer incidence and mortality across all 22 EMR countries. Cases, deaths, and age-standardized incidence rates (ASIRs) were summarized by country and sex. Future incidence projections to 2050 accounted for projected population growth and aging, and the annual incidence reduction required to maintain 2022 case counts was estimated. **Results:** In 2022, an estimated 48,568 new liver cancer cases occurred across the EMR, representing 6.2% of all regional cancer cases. Liver cancer ranked fourth overall and among males, and third among females. Egypt accounted for almost two-thirds (57.5%) of the estimated cases, followed by Pakistan (12.6%) and Iran (12.0%). The ASIR for liver cancer in Egypt was 32.0 per 100,000, a 5-fold higher rate than Iran, the second-highest-ranking country (ASIR, 6.4 per 100,000 persons). Liver cancer was the second leading cause of cancer-related death in males and females and third overall, accounting for 46,820 deaths (9.6% of all cancer deaths). A 3% annual reduction in incidence would be required across the region to maintain the same number of cases in 2050 as in 2022. **Conclusion:** Liver cancer remains a major and projected growing burden in the EMR, with most cases in Egypt, likely reflecting the historically high prevalence of hepatitis

C. Maintaining 2022 case counts by 2050 would require sustained incidence reductions, supporting integrated strategies for viral hepatitis elimination, prevention and management of metabolic dysfunction-associated steatotic liver disease, and regional cancer-control planning. Interpretation should consider variability in cancer-registry completeness, reliance on modeled GLOBOCAN estimates, and uncertainty in long-term demographic projections.

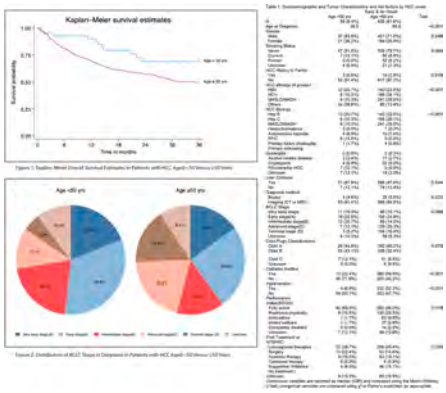
4298 | EARLY-ONSET HEPATOCELLULAR CARCINOMA IN A SAUDI TERTIARY REFERRAL-CENTER REGISTRY: PREVALENCE, ETIOLOGIES, STAGE DISTRIBUTION, AND SURVIVAL OUTCOMES



Saleh Alqahtani[1] Waleed Al Hamoudi[1] Lolwa Alobaid[2] Duna Barakeh[1] Amwaj Alanazi[1] Mussadique Jhatial[1] Mehwish Shahzadi[1] Ahmed Alyahya[3] Fahad AlMugbel[1] Ali Alqahtani[1] Hadi Kuriry[4] Hamdan Alghamdi[5] Khalid Alswat[6] Khalid AlNaamani[7] Waleed Alomaim[1] Dieter Broering[1] Saad Alghamdi[8] Faisal Abaalkhail[1] Saleh Alessy[1], [1]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [2]King Abdulaziz Medical City, Riyadh, Saudi Arabia, [3]Ministry of Health, Riyadh, Saudi Arabia, [4]King Fahad Specialist Hospital, Dammam, Saudi Arabia, [5]King Abdulaziz Medical City of National Guard Hospital, [6]King Saud University/KKUH, [7]The Medical City for Military and Security Services, Muscat, Oman, [8]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

Background: Trends in early-onset hepatocellular carcinoma (HCC) vary globally, and data from Saudi Arabia remain limited. Shifting global HCC etiologies highlight the need to characterize disease patterns in younger populations. We aimed to describe prevalence, etiologies, and survival outcomes of HCC in patients younger than 50 years in Saudi Arabia. **Methods:** Data were extracted from the King Faisal Specialist Hospital and Research Center HCC Registry, a tertiary referral-center registry receiving patients from across Saudi Arabia, for patients diagnosed between Jan 2020 and Apr 2026. Patients aged <50 years (younger group) were compared with those aged ≥ 50 years (older group). Demographic, etiologic, and clinical characteristics were analyzed descriptively. Overall survival up to 36 months was estimated using the Kaplan-Meier method, with mortality data supplemented through the National Death Registry. **Results:** Among 693 patients with HCC, 8.4% (n = 58) were <50 years. The median age at diagnosis was 36.5 years and 65.0 years in the two groups, respectively. Males were predominant in both groups. Family history of HCC was more frequent in younger patients (8.6% vs. 2.8%; P = 0.019). Metabolic dysfunction-associated steatotic liver disease and steatohepatitis (MASLD/MASH) were less common in the younger group (10.3% vs. 38.0%). Hepatitis B virus (HBV) prevalence was comparable between groups (20.7% vs. 22.5%), while hepatitis C virus (HCV) was less prevalent among younger patients (10.3% vs. 26.1%). Other etiologic categories were more frequent in younger patients (58.6% vs. 13.4%; $P < 0.001$), including progressive familial intrahepatic cholestasis (PFIC, 15.5%), autoimmune hepatitis (6.9%), cryptogenic disease (6.9%), and unknown etiology (12.1%). Cirrhosis prevalence was high and comparable between groups (87% in both). Younger patients showed a trend towards early-stage disease (BCLC 0-A; 51.8% vs. 40.0%; p = 0.086). Overall survival at 12 and 36 months was higher in the younger group (0.90 and 0.68) compared with the older group (0.69 and 0.49). Child-Pugh B/C was more frequent in younger patients, although not

statistically significant (55.2% vs. 38.9%; P = 0.075). **Conclusion:** Early-onset HCC accounted for 8.4% of registry cases and showed distinct etiologic and clinical characteristics, with reduced contribution from MASLD/MASH and HCV and a disproportionate burden of other etiologic categories, including PFIC, fibrolamellar HCC, autoimmune hepatitis, and cryptogenic disease. Younger patients demonstrated higher estimated survival despite comparable cirrhosis burden, supporting the need for age-specific surveillance and management strategies.

4299 | INCIDENCE AND ASSOCIATED RISK FACTORS OF HEPATOCELLULAR CARCINOMA IN PEOPLE WITH HIV: A SYSTEMATIC REVIEW AND META-ANALYSIS

Andrea Dalbeni[1] Rosa Lombardi[2] Felice Cinque[2] Marco Vicardi[3] Filippo Cattazzo[3] Vincenzo Di Maria[3] david sacerdoti[3] Giovanni Guaraldi[4] Giada Sebastiani[5], [1]Azienda Ospedaliera Universitaria Integrata Verona, [2]SC Medicina Indirizzo Metabolico, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico di Milan, [3]Liver Unit, Department of Medicine, University of Verona, Verona, Italy., [4]Department of Surgical, Medical, Dental and Morphological Sciences, University of Modena and Reggio, [5]Division of Experimental Medicine, McGill University, Montreal, Quebec, Canada.

Background: The epidemiology of hepatocellular carcinoma (HCC) in people with HIV (PWH) has evolved in the era of antiretroviral therapy (ART) and direct-acting antivirals for hepatitis C virus (HCV). HCC incidence estimates remain heterogeneous, and the contribution of distinct liver disease phenotypes to HCC in PWH is incompletely characterized. **Methods:** We conducted a PRISMA-guided systematic review and meta-analysis reporting HCC incidence among adults with HIV. PubMed, EMBASE, Cochrane Library, Web of Science, and Scopus were searched from January 1996 through December 2025. The primary outcome was pooled HCC incidence per 1,000 person-years (PY). Random-effects models were used to estimate pooled incidence rates overall. Study quality was assessed using the Newcastle-Ottawa Scale. **Results:** We included 13 studies comprising 153,071 PWH and 855 HCC cases over 957,920 PY of follow-up. The pooled HCC incidence was 1.18 per 1,000 PY (95% CI: 0.64-2.17), with high between-study heterogeneity (I^2 = 97.2%). Incidence was lower in African and Asian cohorts. HCC incidence was lowest with HIV mono-infection (0.12 per 1,000 PY; 95% CI: 0.05-0.29), increased in HCV coinfection (1.72 per 1,000 PY; 95% CI: 1.25-2.36), HBV coinfection (2.01 per 1,000 PY; 95% CI: 1.69-2.40), and triple infection (4.52 per 1,000 PY; 95% CI: 3.29-6.22). HCV-related cirrhosis conferred the highest risk overall (15.40 per 1,000 PY; 95% CI: 6.42-37.08). MASLD was also associated with elevated HCC incidence (1.97 per 1,000 PY; 95% CI: 1.17-3.11). CD4 cell count demonstrated a non-significant inverse association (β = -0.015 per cell/µL increase, p = 0.21), suggesting a possible contribution of immune dysfunction to hepatocarcinogenesis. Era-stratified analysis did not demonstrate a significant reduction in HCC incidence in contemporary compared to historical cohorts. **Conclusion:** Among PWH, HCC risk appears to be driven by underlying liver disease phenotype rather than HIV infection itself. Viral hepatitis coinfections, cirrhosis, alcohol-related liver disease, and MASLD were associated with markedly increased HCC incidence. These findings support phenotype-based HCC surveillance strategies in HIV care, with increasing consideration for MASLD.

4300 | THE EFFECT OF STATIN THERAPY ON THE OVERALL SURVIVAL OF PATIENTS WITH HEPATOCELLULAR CARCINOMA: A SINGLE-CENTER EXPERIENCE

Christos Triantos[1] Konstantinos Papantoniou[1] Vasileios Lekakis[2] Efthymios Tsounis[1] Evangelia Bourdalou[1] Nikitas Kimiskidis[1] Georgios Geramoutsos[1] Ploutarchos Pastras[1] Ioanna Aggeletopoulou[1] Odyssefs Ampazis[1] Georgia Diamantopoulou[1] Tryfon Spyridonidis[3] Konstantinos Katsanos[4] Konstantinos Thomopoulos[1], [1]Division of Gastroenterology, Department of Internal Medicine, University of Patras, 26504, Patras, [2]First Academic Department of Gastroenterology, Medical School of National and Kapodistrian Universit, [3]Nuclear Medicine Department, University Hospital of Patras, Rio, Greece, [4]Department of Interventional Radiology, University Hospital of Patras, Rio, Greece

Background: Statins exert pleiotropic anti-inflammatory, antifibrotic, and potential antineoplastic effects beyond lipid lowering. Although previous studies have suggested a protective role against hepatocellular carcinoma (HCC) development, their impact on survival after HCC diagnosis remains unclear. **Methods:** To evaluate the association between statin use and overall survival in patients with HCC, we conducted a retrospective single-center study including consecutive patients with HCC managed at a tertiary referral center from January 2000 onward. Demographic, clinical, laboratory, tumor-related, and treatment data were collected. Patients were classified according to statin use prior to HCC diagnosis. Overall survival (OS) was assessed using Kaplan–Meier analysis and compared with the log-rank test. Cox proportional hazards regression models were used to identify independent predictors of survival. **Results:** A total of 190 patients were included (90.5% male; median age 67 years), of whom 137 (72.1%) had cirrhosis. Among cirrhotic patients, 48 (35%) had hepatic decompensation at diagnosis. Statins were administered in 42 patients (22.1%). Baseline liver function, AFP levels, and treatment allocation were comparable between statin users and non-users, although statin users more frequently had diabetes mellitus and arterial hypertension. During follow-up, statin therapy was associated with significantly improved survival. Mean OS was 82.5 months in statin users versus 41.7 months in non-users, while median OS was 57 versus 31 months, respectively (log-rank $p < 0.001$). In univariate Cox analysis, statin use was associated with reduced mortality risk (HR 0.45, 95%CI 0.28–0.70, $p < 0.001$). Other adverse prognostic factors included hepatic decompensation, ascites, portal vein thrombosis, and extrahepatic metastases. In multivariate models adjusting for liver function, tumor burden, and therapeutic interventions, statin therapy remained independently associated with improved survival, with hazard ratios ranging from 0.19 to 0.44 across models (all $p < 0.05$). Advanced liver dysfunction and tumor stage also independently predicted worse outcomes. **Conclusion:** Statin therapy prior to HCC diagnosis was independently associated with significantly improved overall survival in a real-world cohort of HCC patients. These findings support a potential beneficial role of statins as adjunctive therapy in HCC and warrant prospective multicenter studies to further clarify their impact on prognosis and disease progression.

4301 | Y90 VS. SBRT AS HCC BRIDGING THERAPY TO LIVER TRANSPLANTATION: A REAL-WORLD COMPARATIVE ANALYSIS

Tarek Aridi[1] Luke Ghabril[1] Pedro Escobedo[1] Adel Hajj Ali[1] Patrick Ryan[1] Amna Yaqub[1] Naushair Hussain[1] Olivia Carlton[1] Lauren Nephew[1] Marco Lacerda[1] Chandrashekhar Kubal[1] John Holden[1], [1]Indiana University

Background: Hepatocellular carcinoma (HCC) bridging therapy aims to prevent tumor progression in patients awaiting orthotopic liver transplantation (OLT). Yttrium-90 radioembolization (Y90) and stereotactic body radiation therapy (SBRT) are well-established locoregional therapies used for bridging, yet comparative data on pre- and post-OLT outcomes remains limited. **Methods:** We conducted a single-center retrospective study of consecutive patients referred between January 1, 2008 and December 31, 2023 with a single HCC lesion (< 4cm in size) and no prior bridging therapy who received either Y90 or SBRT as initial bridging therapy to OLT. Outcomes were assessed through April 30, 2026.The primary study outcomes were pre-OLT time to progression (TTP). Secondary outcomes for the study included post-OLT tumor-free survival (TFS). Multivariable Cox regression, stratified by treatment arm and adjusted for age, sex, race, ethnicity, viral hepatitis, Child-Pugh score, AFP, tumor size, and ECOG performance status, was used to compare TTP and Pre-OLT survival. Kaplan-Meier analysis with log-rank testing was performed for primary and secondary outcomes. **Results:** A total of 119 patients met inclusion criteria: 71 patients received Y90 and 48 patients received SBRT. The treatment groups were well-matched at baseline. Among Y90 patients, mean dosimetry was 57.3 mCi. Among SBRT patients, 18 (38.3%) received 3 fractions and 29 (61.7%) received 5 fractions, with a mean total of 45.0 Gy. HCC size at time of evaluation was significantly greater in Y90 as compared to SBRT (28 vs 23 mm, p = 0.034). Pre-OLT deaths were similar between groups, 28/71 in Y90 (39.4%) and 22/48 in SBRT (45.8%) groups (p = 0.567). Pre-OLT progression occurred in 15/71 Y90 (21.1%) and 14/48 SBRT (29.2%) patients (log-rank p = 0.385). The median follow-up overall was 307 and 481 days in the Y90 and SBRT groups respectively (p = 0.090). In those who progressed, median TTP was significantly higher in the SBRT group (621 days) as compared to the Y90 group (257 days, p = 0.026). On multivariable analysis, treatment modality was not independently associated with TTP (adjusted HR 1.24 95% CI (0.51–3.01), p = 0.631). Among 58 transplanted patients (Y90 n = 38, SBRT n = 20), post-OLT recurrence was 5.3% versus 0.0% (p = 0.548), with no difference in tumor-free survival (log-rank p = 0.345). Multivariable Cox regression for post-OLT recurrence was not feasible because no recurrence events occurred in the SBRT group. **Conclusion:** Y90 and SBRT were associated with similar pre- and post-OLT outcomes as bridging therapies to transplant for HCC, with no significant difference in pre-OLT time to progression, pre-OLT survival, or post-OLT tumor-free survival seen after multivariable adjustment. Our findings suggest both modalities remain reasonable bridging approaches for carefully selected patients.

Variable	Y90 (n = 71) Median (IQR) or n(%)	SBRT (n = 48) Median (IQR) or n(%)	p-value
Age at OLT evaluation, yr	64.8 (59.6–67.8)	62.8 (58.6–67.1)	0.373

4302 | PATIENT EXPERIENCES WITH HEPATOCELLULAR CARCINOMA CARE: A QUALITATIVE STUDY

Zoe Zimmerman[1] Kyra Chism[2] Forough Heidarzad Pahlaviani[1] Mario Strazzabosco[1] Leah Ferrucci[3] Bubu Banini[1], [1]Yale School of Medicine, [2]Morehouse School of Medicine, [3]Yale School of Public Health, Yale Cancer Center

Background: Hepatocellular carcinoma (HCC) remains a highly lethal malignancy, with a 5-year survival rate of approximately 20%. Thus, understanding patients' experiences with HCC care may provide important insights for improving the quality and equity of care delivery. At present, significant differences exist in HCC incidence, treatment, and mortality, with racial and ethnic minority populations and individuals of lower socioeconomic status experiencing higher disease burden and poorer clinical outcomes. The purpose of this study is to explore the experiences of patients with HCC and identify barriers to and facilitators of high-quality, patient-centered care. **Methods:** We conducted a qualitative study involving semi-structured interviews of patients with HCC. Participants were recruited from HCC-specific and general GI oncology clinics across the Yale Cancer Center Smilow Network (YCCSN) from July 2025 to April 2026. Interviews were recorded and transcribed. We applied thematic analysis using an inductive approach. Three members of the study team independently coded a subset of transcripts and came to a consensus on the codebook, which was then iteratively refined as additional transcripts were coded. Finally, codes were grouped into themes. **Results:** We interviewed 22 patients with HCC. Participants were predominantly male (86%) and non-Hispanic/Latino (95%); 59% identified as white and 36% identified as black. Insurance coverage types included employer-based (9%), Medicare only (32%), Medicaid only (13%), private and public (36%), more than one public (5%), and no insurance (5%). Income distribution for <$20,000, $20,000-$34,999, $35,000-$49,999, $50,000-$74,999, $75,000-$100,000, and >$100,000 were 41%, 5%, 5%, 5%, 18%, and 27%, of the cohort, respectively. Five major themes were identified: 1) HCC diagnosis altered patients' lives; 2) communication quality shaped care experiences; 3) patients differed in decision-making preferences; 4) both disease and choice limited treatment options; and 5) social support facilitated care navigation. The impact of each theme (yellow boxes) along the care continuum is demonstrated by the figure. The study identified opportunities to improve patient-centered HCC care, including the need for transparency regarding diagnosis and treatment options; early assessment of patient preferences for involvement; prompt follow-up to explain test results; involvement of family members in care; and tailored education and navigation support for individuals with limited health literacy. **Conclusion:** Patients with HCC generally reported positive care experiences. Insurance coverage and care coordination were largely adequate, although financial challenges persisted for some patients. Areas for improvement included communication about HCC diagnosis and treatment and additional support for patients navigating HCC care.

4303 | ADDING ALPHA-FETOPROTEIN TO ALBI GRADE OR MELD 3.0 DOES NOT IMPROVE 6-MONTH HEPATIC DECOMPENSATION PREDICTION FOR CIRRHOTIC PATIENT WITH HEPATOCELLULAR CARCINOMA UNDERGOING TACE PROCEDURE

Rabia Afzaal[1] Hasan Bualbanat[1] David Hudson[1] Tamoor Afzaal[1], [1]Western University

Background: Post-transarterial chemoembolization (TACE) hepatic decompensation remains a critical consideration in patients with cirrhosis and hepatocellular carcinoma (HCC). Alpha-fetoprotein (AFP) reflects tumor biology and disease burden, but limited data exist on whether baseline AFP improves prediction of post-TACE decompensation beyond established liver reserve models. **Methods:** We conducted a retrospective analysis of an anonymized cohort of 280 patients with cirrhosis and HCC undergoing TACE. The primary outcome was any decompensating event within 6 months, including hepatic encephalopathy, spontaneous bacterial peritonitis, variceal bleeding, or ascites. Logistic regression models incorporating ALBI grade and MELD 3.0, each with and without log-transformed AFP, were compared. Model discrimination was

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

assessed using area under the receiver operating characteristic curve (AUROC) with DeLong testing. Reclassification performance was evaluated using continuous net reclassification improvement (NRI) and integrated discrimination improvement (IDI). **Results:** Decompensation occurred in 84/280 patients (30.0%) within 6 months of TACE. MELD 3.0 alone demonstrated the strongest discrimination for post-TACE decompensation (AUROC 0.81). Addition of AFP did not significantly improve discrimination for either ALBI grade (DeLong $p = 0.30$) or MELD 3.0 (DeLong $p = 0.64$). Reclassification analyses similarly demonstrated no clinically meaningful improvement with AFP incorporation. **Conclusion:** In this cohort of cirrhosis and HCC patients undergoing TACE, addition of baseline AFP to either ALBI grade or MELD 3.0 did not improve prediction of 6-month hepatic decompensation. MELD 3.0 alone provided the strongest discriminatory performance for post-TACE decompensation.

4304 | ANA AND SMA POSITIVITY ARE NOT ASSOCIATED WITH IMMUNE-RELATED ADVERSE EVENTS OR TREATMENT OUTCOMES IN ICI-TREATED HEPATOCELLULAR CARCINOMA

Pin-Jung Chen[1] Manaf Alsudaney[2] Ashley Kim[2] Priyanshi Shah[3] Hyunseok Kim[2] Paul Martin[2] Alexander Kuo[2] Walid Ayoub[2] Yun Wang[2] Aarshi Vipani[2] Emily Kaymen[1] Cristina Ferrone[4] Neil Mehta[5] Nguyen Tran[3] Paul Thevenot[6] Michael Li[5] Ju Dong Yang[2], [1]Samuel Oschin Comprehensive Cancer Institute, Cedars-Sinai Medical Center, [2]Karsh Division of Gastroenterology and Hepatology, Cedars-Sinai Medical Center, [3]Department of Medical Oncology, Mayo Clinic, Rochester, [4]Department of Surgery, Cedars-Sinai Medical Center, [5]Division of Gastroenterology and Hepatology, University of California, San Francisco, [6]Institute of Translational Research, Ochsner Clinic Foundation

Background: Immune checkpoint inhibitors (ICI) are standard-of-care for advanced hepatocellular carcinoma (HCC), yet immune-related adverse events (irAE) cause significant morbidity. Whether baseline antinuclear antibody (ANA) and smooth muscle antibody (SMA) predict irAE risk or treatment response in ICI-treated HCC has not been rigorously evaluated. **Methods:** We conducted a multi-institutional retrospective cohort study. Baseline ANA titer and SMA (positive defined as any reported positive or numeric value ≥ 20) were abstracted. Primary outcomes include any irAE and time to first irAE. Secondary outcomes include grade ≥ 3 irAE, hepatic irAE, objective response rate (ORR) [partial response (PR) + complete response (CR)], disease control rate (DCR), progression-free survival (PFS), and overall survival (OS). Site-adjusted and clinically adjusted logistic and Cox models were used to assess the association between autoantibodies and clinical outcomes. Site-adjusted models included institution as a covariate; clinically adjusted models additionally adjusted for age, sex, Child-Pugh score, and BCLC stage. **Results:** A total of 233 patients enrolled; median age 72 years, 75% male, 90% cirrhotic, 86% BCLC B/C. There was 183 patients (ANA-positive 69/183 [37.7%]) in the ANA-evaluable cohort. SMA-evaluable cohort incldued 189 patients (SMA-positive 57/189 [30.2%]). Baseline characteristics were balanced between ANA and SMA groups (all $p > 0.05$). ANA positivity was not associated with higher irAE rates (26.1% vs 34.2%; site-adj OR 0.59 [0.28–1.21], $p = 0.151$), grade ≥ 3 irAE (OR 0.85 [0.35–2.11], $p = 0.732$), or time to first irAE (HR 0.68 [0.38–1.22], $p = 0.198$). SMA positivity similarly showed no association with any irAE (36.8% vs 36.4%; OR 1.01 [0.51–1.96], $p = 0.988$), grade ≥ 3 irAE (OR 1.26 [0.49–3.22], $p = 0.626$), or hepatic irAE (OR 1.12 [0.41–3.05], $p = 0.829$). ORR was numerically lower with ANA positivity (23.4% vs 33.7%; fully adjusted OR 0.59 [0.27–1.32], $p = 0.200$) and SMA positivity (29.4% vs 35.4%; OR 0.59 [0.27–1.27], $p = 0.176$), but neither reached statistical significance. DCR, PFS, and OS were also non-significant for both antibodies (**Table**). In exploratory combined ANA/SMA phenotype analysis ($n = 139$), no phenotype group showed significantly different irAE rates vs the ANA−/SMA− reference (global χ^2 $p = 0.561$). **Conclusion:** In this multi-institutional study of 233 ICI-treated HCC patients, baseline ANA and SMA positivity did not independently predict irAE risk, severity, ORR, DCR, or survival. These null findings were consistent across primary, sensitivity, and combined phenotype analyses. Routine autoantibody screening does not guide irAE risk stratification or ICI candidacy decisions in HCC.

Autoantibody Status and Outcomes in ICI-Treated HCC (N = 233)

Outcome	ANA+ (n=69)	ANA− (n=114)	OR or HR (95% CI), p	SMA+ (n=57)	SMA− (n=132)	OR or HR (95% CI), p
TOXICITY

4305 | COMPARATIVE EFFICACY AND SAFETY OF FIRST-LINE SYSTEMIC THERAPIES IN ADVANCED BILIARY TRACT CANCER: A SYSTEMATIC REVIEW AND NETWORK META-ANALYSIS

Rahul Falodia[1] Maheen Afzal[2] Ubaid Ahmed[3], [1]All India Institute of Medical Sciences Jodhpur, [2]University of Alabama at Birmingham, Montgomery, [3]Dow University of Health Sciences, Karachi, Pakistan

Background: The standard of care for first-line treatment of advanced biliary tract cancer (BTC) has rapidly evolved with the introduction of immune checkpoint inhibitors and triplet chemotherapy regimens. In the absence of head-to-head randomized controlled trials (RCTs), we conducted a network meta-analysis (NMA) to evaluate the comparative efficacy and safety of these novel regimens. **Methods:** A systematic literature search identified Phase II/III RCTs evaluating first-line systemic therapies for advanced BTC. A Bayesian NMA was performed to synthesize indirect comparisons. The primary outcome was overall survival (OS). Secondary outcomes included progression-free survival (PFS), objective response rate (ORR), and grade ≥ 3 adverse events (AEs). Treatment ranking was assessed using the surface under the cumulative ranking curve (SUCRA). **Results:** Ten RCTs encompassing over 3,000 patients and 10 distinct treatment regimens were included. Compared with standard gemcitabine plus cisplatin (GemCis), the addition of durvalumab (HR 0.74, 95% CrI 0.63–0.87) and pembrolizumab (HR 0.83, 95% CrI 0.72–0.95) significantly improved OS. Triplet chemotherapy regimens, including GemCis plus nab-paclitaxel (HR 0.93) and GemCis plus S-1 (HR 0.79), did not show a statistically significant OS benefit over GemCis. For ORR, triplet regimens ranked highest, with GemCis plus S-1 and GemCis plus nab-paclitaxel showing greater response rates than immuno-oncology doublet regimens. Grade ≥ 3 adverse events were highest with mFOLFIRINOX and nab-paclitaxel–based regimens, while immuno-oncology doublet regimens maintained a safety profile comparable to standard GemCis. **Conclusion:** Chemo–immunotherapy combinations (durvalumab plus GemCis and pembrolizumab plus GemCis) represent the optimal first-line systemic options for improving overall survival in advanced BTC. However, for patients requiring rapid tumor downstaging, triplet chemotherapy regimens achieve higher objective response rates, albeit with increased toxicity.

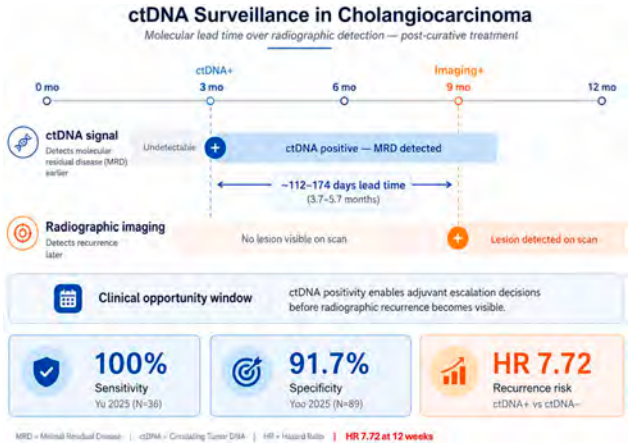
4306 | CIRCULATING TUMOR DNA AS A BIOMARKER FOR RECURRENCE DETECTION IN CURATIVELY TREATED CHOLANGIOCARCINOMA, A SYSTEMATIC REVIEW



Ahmed Sayed Ahmed[1] Abdullah Ahmad[2] Sanna Farahat[3] Asmaa Soliman[4] Erlind Allkushi[1] Elise Hokr[1] Mariam Ismail[3] Sapana Verma[1] Kyungran Justina Cho[5] Chase Wehrle[1] Kim Jaekeum[1] Khalil Mazhar[1] Federico Aucejo[1], [1]Department of Surgery Transplantation Center, The Cleveland Clinic Foundation, OH, USA, [2]Hameed Latif Teaching Hospital, Lahore, Pakistan, [3]Faculty of Medicine, Delta University for Science and Technology, Gamasa, Egypt, [4]Faculty of Medicine, Zagazig University, Sharqia, Egypt, [5]Department of Gastroenterology, The Cleveland Clinic Foundation, OH, USA

Background: Cholangiocarcinoma (CCA) carries a dismal prognosis, with 5-year recurrence rates exceeding 60% following curative-intent treatment. Conventional surveillance including cross-sectional imaging and serum CA19-9 demonstrates insufficient sensitivity for early relapse detection. Circulating tumor DNA (ctDNA) as a surrogate for molecular residual disease (MRD) represents a promising paradigm shift for post-surgical risk stratification and treatment response monitoring

Methods: Following a pre-registered PROSPERO protocol (CRD42026129755), PubMed, Embase, Scopus, and CENTRAL were systematically searched. Eligible studies enrolled adults with curatively treated CCA (resection or transplantation) who underwent post-treatment cell-free ctDNA analysis. Hazard ratios (HR) for survival outcomes and diagnostic accuracy metrics were extracted and narratively synthesized. **Results:** Three longitudinal cohort studies met inclusion criteria from 1,296 screened records. In the STAMP trial cohort (Yoo 2025, N = 89), post-operative ctDNA positivity independently predicted significantly worse recurrence-free survival at the pre-adjuvant chemotherapy baseline (HR 1.80, 95% CI 1.06–3.07; p = 0.029), 12 weeks into adjuvant therapy (HR 7.72, 95% CI 4.09–14.56; p < 0.001), and 24 weeks into adjuvant therapy (HR 5.24, 95% CI 2.75–9.97; p < 0.001). Diagnostically, Yu 2025 (N = 36) demonstrated a surveillance sensitivity of 100%, specificity of 84%, PPV of 73.3%, and NPV of 100%, with a median molecular lead time of 112.6 days preceding radiographic detection. Yoo 2025 yielded a sensitivity of 69.2%, specificity of 91.7%, PPV of 95.7%, and NPV of 52.4%, with a mean lead time of 174 days. In a small liver transplantation cohort (Abdelrahim 2025, N = 4), all diagnostic metrics reached 100% in the CCA subpopulation, though this finding requires cautious interpretation given the limited sample size **Conclusion:** Post-treatment ctDNA dynamics constitute highly sensitive and specific biomarkers for predicting relapse in curatively treated cholangiocarcinoma, consistently anticipating radiographic recurrence by three to six months. While the current evidence base remains limited to three cohort studies, these findings support prospective integration of ctDNA surveillance into post-treatment monitoring frameworks and future trials evaluating ctDNA-guided adjuvant escalation strategies.

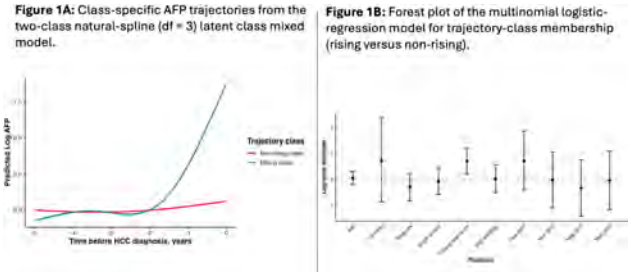
4307 | DISTINCT ALPHA-FETOPROTEIN TRAJECTORIES DURING THE FIVE YEARS PRECEDING HEPATOCELLULAR CARCINOMA DIAGNOSIS: A LATENT CLASS MIXED-MODEL ANALYSIS



Apichat Kaewdech[1] Chanavee Toh[2] Pimsiri Sripongpun[1] Naichaya Chamroonkul[1] Pisit Tangkijvanich[3] Teerha Piratvisuth[1] Suthat Liangpunsakul[4] Thammasin Ingviya[5] Paramee Thongsuksai[1], [1]Prince of Songkla University, [2]Faculty of Medicine, Prince of Songkla University, [3]Chulalongkorn University, [4]Indiana University School of Medicine, [5]Baylor College of Medicine

Background: Hepatocellular carcinoma (HCC) is frequently diagnosed at an advanced stage, and serum alpha-fetoprotein (AFP), the most widely used biomarker for HCC surveillance, exhibits substantial interpatient variability. We characterized longitudinal AFP trajectories during the five years preceding HCC diagnosis and identified clinical features associated with rising versus non-rising AFP patterns. **Methods:** We analyzed 529 patients with newly diagnosed HCC at Songklanagarind Hospital, each with at least three serum AFP measurements obtained within five years before diagnosis. Log-transformed AFP values were modeled using latent class mixed models (LCMMs) with natural cubic splines (degrees of freedom 3–5) and linear fixed and random effects for time. Optimal model complexity was selected based on Bayesian Information Criterion (BIC), entropy, and clinical interpretability. Multinomial logistic regression and Cox proportional hazards models were used to evaluate associations between AFP trajectory class, baseline characteristics, and overall survival. **Results:** A two-class natural spline model (df = 3) provided the most parsimonious and clinically interpretable solution (BIC = 9003). Class 1 ("non-rising," n = 440; 83.2%) demonstrated a near-flat AFP trajectory throughout the observation period, whereas Class 2 ("rising," n = 89; 16.8%) exhibited an exponential increase beginning approximately 18–24 months before diagnosis. Compared with the non-rising group, patients in the rising group were significantly more likely to present with tumors > 2 cm (78% vs 62%; p = 0.009). The rising trajectory group was also associated with shorter overall survival on log-rank analysis (p = 0.03), although this association attenuated after adjustment for Barcelona Clinic Liver Cancer (BCLC) stage. **Conclusion:** Two distinct AFP

trajectories were identified during the five years preceding HCC diagnosis. Most patients (approximately 83%) did not demonstrate meaningful AFP elevation, underscoring the need for complementary surveillance biomarkers. In contrast, the minority with a rising AFP trajectory may benefit from risk-stratified intensification of imaging surveillance.

4308 | CONDITIONAL SURVIVAL AFTER ABLATION FOR LOCALIZED HEPATOCELLULAR CARCINOMA AND THE ASSOCIATION OF TUMOR SIZE WITH PROGNOSIS

Henry Souto[1] George Ashji[1] Dustin Roberts[1], [1]Rutgers New Jersey Medical School

Background: Tumor size is an important prognostic factor in localized hepatocellular carcinoma and is routinely utilized in framing expectations for survival and treatment planning. However, survival estimates calculated at diagnosis may become less informative for patients who have already survived beyond the early high-risk period. This study uses a conditional survival approach to examine how baseline tumor size and other factors are associated with prognosis over time. **Methods:** Using SEER 2004-2017, we identified 6,088 adults with localized hepatocellular carcinoma treated with ablation only (transplant recipients were excluded), with known tumor size (≤ 2, 2.1-3, 3.1-5, >5 cm). Conditional survival was assessed at 1-, 2-, 3-, and 5-year landmarks, with time-to-event recalculated at each landmark. Cancer-specific mortality and overall mortality were analyzed. Cumulative incidence functions were estimated nonparametrically and stratified by tumor size, and multivariable Fine-Gray and Cox regression models were performed at each landmark, adjusting for tumor size, age, sex, race/ethnicity, diagnosis year, and grade. Analyses were performed in R version 4.2.2. **Results:** Five-year post-landmark conditional all-cause survival improved with longer survivorship, and differences by tumor size narrowed over time (Figure 1). Among tumors >5 cm, 5-year conditional survival increased from 26% at the 1-year landmark to 48% at the 5-year landmark; among tumors ≤ 2 cm, it increased from 48% to 56%. For overall mortality, the hazard ratio for >5 cm versus ≤ 2 cm tumors attenuated from 1.54 (95% CI 1.26-1.88, $p<0.001$) at the 1-year landmark to 1.16 (95% CI 0.88-1.53, $p=0.293$) at the 3-year landmark, remaining insignificant at the 5-year landmark. A similar pattern was shown in adjusted Fine-Gray subdistribution hazards for cancer-specific mortality. Older age was associated with higher mortality at all landmarks (HR per additional year 1.02-1.04, $p < 0.001$), while later diagnosis year was a significant predictor of decreased overall mortality across all landmarks (HR per additional year 0.94-0.97, $p < 0.001$). **Conclusion:** Conditional survival estimates capture the dynamic prognosis in HCC ablation patients over time, providing a more clinically meaningful foundation for survivorship counseling than risk stratification at the time of diagnosis. These findings are relevant to improving post-ablation surveillance strategies.

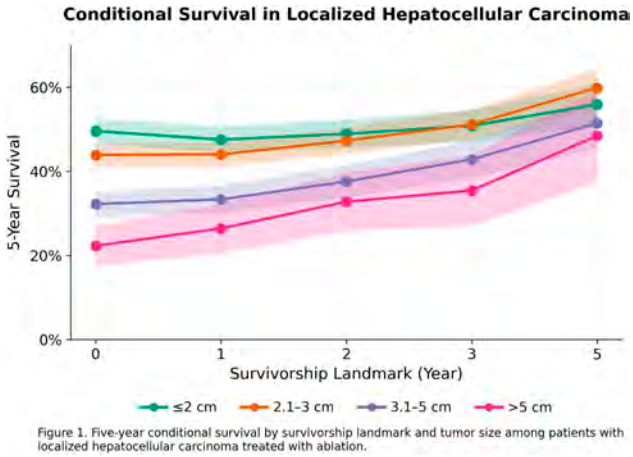

Figure 1. Five-year conditional survival by survivorship landmark and tumor size among patients with localized hepatocellular carcinoma treated with ablation.

4309 | PALLIATIVE MEDICINE UTILIZATION FOR OLDER ADULTS WITH HEPATOCELLULAR CARCINOMA REFERRED FOR LIVER TRANSPLANTATION

Gavisha Waidyaratne[1] Jason Benedict[1] Leanna Perez Eiterman[2] Laura Rush[2] Sean Kelly[1] Jessica Merlin[1] Ann McAlearney[2] Brittany Waterman[3], [1]The Ohio State University Wexner Medical Center, [2]The Ohio State College of Medicine, [3]The Ohio State Wexner Medical Center

Background: The incidence and prevalence of chronic liver disease and hepatocellular carcinoma (HCC) for older adults ($\geq$ 65 years) have continued to increase worldwide, with a subsequent increase in the proportion of older adults referred for liver transplantation (LT) evaluation. Evidence suggests that long term outcomes for older adults are similar to younger cohorts when stratified by stage and treatment, including LT. However, older adults with HCC often have more advanced disease at diagnosis and have been shown to receive less disease-directed treatment, including locoregional therapies, surgical resection, and LT, as compared with younger cohorts. Older adults with HCC referral for LT have considerable and often unmet palliative care (PC) needs related to prognostic uncertainty, high rates of LT deferral, morbidity, and mortality. Existing PC patterns and association with outcomes for these patients have not yet been fully described, which is an important step in developing the evidence base needed to guide PC integration for this high-need group. **Methods:** We conducted a retrospective chart review to describe PC utilization and health outcomes for older adults with ESLD referred for LT evaluation between 7/1/2015 and 6/30/2021. Outcomes were followed through 6/30/22. This project represents a subgroup analysis examining patients with HCC within the larger cohort. **Results:** Within the HCC subgroup (N = 102; 24% of total cohort of N = 421), formal LT evaluation was initiated for 76% of patients (N = 78), while in comparison, LT evaluation was initiated for 66% of the non-HCC cohort (N = 209) (p = 0.04). LT deferral occurred in 42% (N = 33) of the HCC group while in only 32% (N = 100) of the non-HCC group (p = 0.10). Of those approved for LT, successful completion of LT occurred in 41% (N = 32) of the HCC group and 47% (N = 130) of the non-HCC group (p = 0.37). Finally, death in the study period occurred in 48% of both the HCC (N = 49) and the non-HCC (N = 152) groups (p > 0.95). Within HCC patients, PC encounters occurred for 31 patients (30% vs. N = 77, 24% in the non-HCC group, p = 0.24). Those without PC referrals had higher rates of LT referral (80% vs 68%), higher rates of LT completion (75% vs 56%), and lower rates of LT deferral (37% vs 57%) as compared with those who had PC encounters. A larger proportion of patients died in the group who received PC (84% vs. 32%). **Conclusion:** As compared with the non-HCC cohort, the subgroup of older adults with HCC had higher rates of LT referral, lower rates of LT deferral, and lower rates of LT completion. Patients with HCC who encountered PC had lower rates of LT referral and completion, as well as higher rates of LT deferral. This finding suggests that PC referrals may be more commonly pursued for patients unable to complete the LT process. However, the temporal relationship between these LT outcomes and PC encounters is not defined in this dataset but will be examined in future studies.

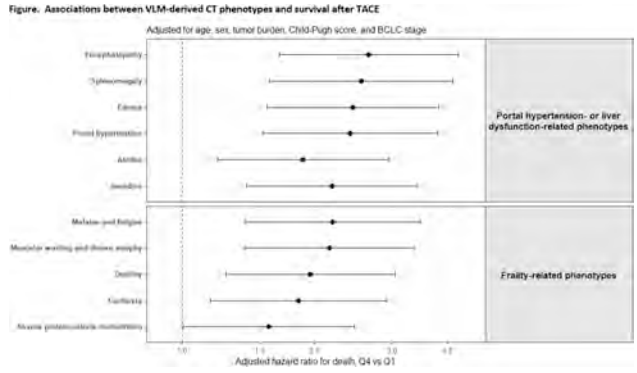
4310 | VISION-LANGUAGE MODEL–DERIVED COMPUTED TOMOGRAPHY PHENOTYPES ARE ASSOCIATED WITH SURVIVAL AFTER TRANSARTERIAL CHEMOEMBOLIZATION



Philip Vutien[1] George Ioannou[2] Amilcare Gentili[3] Chunnan Hsu[3], [1]University of Washington Medical Center, [2]University of Washington, [3]Veterans Affairs San Diego Healthcare System

Background: Accurate risk stratification of HCC patients after transarterial chemoembolization (TACE) remains challenging, as conventional staging systems incompletely capture liver function, portal hypertension, and patient frailty. Vision–language models (VLMs) such as Merlin can generate interpretable Computed Tomography (CT)-derived phenotypes aligned with clinically meaningful concepts. We evaluated whether VLM-derived CT phenotypes reflecting portal hypertension, liver dysfunction, and frailty are independently associated with overall survival after TACE. **Methods:** Using the publicly available WAW-TACE dataset, we analyzed 233 patients with hepatocellular carcinoma (HCC) with multiphase CT imaging $\leq$ 90 days before initial TACE, excluding those with metastatic disease, vascular invasion, or Child–Pugh class C. A pretrained VLM (Merlin) was applied to baseline CT imaging to generate probabilistic imaging-derived phenotypes that are associated with clinical diagnoses. Phenotype probabilities were stratified into quartiles and each phenotype was evaluated in separate Cox proportional hazards models for associations with overall survival adjusting for age, sex, tumor burden (number and

largest lesion diameter), Child–Pugh score, and Barcelona Clinic Liver Cancer stage. **Results:** Median age was 66 years, 48 (21%) were women, 149 (64%) had unifocal disease, and the median largest tumor diameter was 4.5 cm (IQR 3–6.2). During a median follow-up of 871 days (IQR 332–1,386), 170 (73%) patients died. VLM-derived CT phenotypes demonstrated strong, graded associations with overall survival. In multivariable analyses, the highest versus lowest quartile of portal hypertension–or liver-dysfunction related phenotypes - including splenomegaly (aHR 2.55, 95% CI 1.58–4.12), ascites (aHR 1.88, 95% CI 1.20–2.94), CT-correlates of encephalopathy (aHR 2.69, 95% CI 1.66–4.23), and jaundice (aHR 2.19, 95% CI 1.40–3.43) - was associated with increased mortality. Similarly, frailty-related features including cachexia (aHR 1.84, 95% CI 1.16–2.91) and muscular wasting (aHR 2.16, 95% CI 1.39–3.36), were independently associated with worse survival. **Conclusion:** VLM-derived CT phenotypes captured imaging signatures of portal hypertension, liver dysfunction, and frailty that were independently associated with overall survival after TACE. These findings suggest that VLM-based imaging phenotypes may provide complementary, noninvasive risk stratification and warrant further validation in larger multi-center cohorts.

4311 | WHEN TUMOR RESPONSE FAILS THE PATIENT: REAL-WORLD LIMITATIONS OF FUTIBATINIB IN FGFR2-REARRANGED INTRAHEPATIC CHOLANGIOCARCINOMA

Joshika Agarwal[1] Abul Hasan Shadali Abdul Khader[2] Jaison Lawrence Alexander Santhi[2] Rajesh Thirumaran[2], [1]Mercy Catholic Medical Center, [2]Mercy Catholic Medical Center, Darby, PA

Background: Biliary tumors, including intrahepatic cholangiocarcinoma (ICC), are rare tumors with a poor median survival of around one year. Patients are often asymptomatic, resulting in advanced-stage presentation, making tumor detection and treatment difficult. We present the case of an advanced ICC harboring fibroblast growth factor receptor (FGFR2 fusion), managed on a targeted therapy, Futibatinib, commonly known as Lytgobi. This case highlights the diverse real-world outcomes of the drug in comparison to results obtained in the clinical trial in 2022, which resulted in the drug's accelerated approval in the US. **Methods:** A 74-year-old male presented with one week of severe abdominal pain, fatigue, and weight loss. Vitals and labs, including AFP and CEA, were unremarkable. MRI abdomen revealed a 9.4 cm left hepatic lobe mass with intrahepatic bile duct dilation and lymphadenopathy. A liver biopsy was consistent with advanced cholangiocarcinoma. The patient was started on combination chemotherapy with gemcitabine, cisplatin, and pembrolizumab. Subsequent next-generation sequencing identified a fibroblast growth factor receptor (FGFR2) fusion, and therapy was switched to futibatinib, an irreversible FGFR 2 inhibitor. Over the course of treatment, the patient developed recurrent ascites requiring paracentesis with albumin replacement. He was still maintained on the escalating doses of futibatinib based on follow-up imaging displaying some response to the drug. However, due to progressive clinical decline, he was transitioned to hospice care despite the first four months of tolerance on futibatinib therapy. **Results:** The FOENIX-CCA2 trial, under its Phase 2, demonstrated an objective response rate of 42%, a median response duration of 9.7 months, and a median time to response of 2.5 months, along with a manageable adverse effect, including hyperphosphatemia, in patients with unresectable or metastatic ICC treated with futibatinib. In this case, the patient tolerated the medication well with mild side effects of nausea, vomiting, and constipation. However, ascitic fluid analysis that revealed an elevated serum–ascites albumin gradient (SAAG) > 1.1, indicating portal hypertension due to underlying cirrhosis and hepatic metastasis causing portal vein occlusion, further worsened by hypoalbuminemia, was the likely culprit for refractory ascites, rather than direct drug-related effects indicative of disease progression. **Conclusion:** Initial response to targeted molecular therapies does not preclude challenges, including hepatic decompensation that can outpace tumor response, limiting overall clinical benefit. The ongoing FOENIX-CCA3 trial is anticipated to emphasize such limitations for optimizing therapeutic outcomes.

4312 | CONSTRUCTION AND VALIDATION OF A NOMOGRAM FOR PREDICTING PROGRESSION-FREE SURVIVAL IN AFP-NEGATIVE HEPATOCELLULAR CARCINOMA PATIENTS BASED ON AGE, VASCULAR INVASION, PIVKA-II, AND GGT

Yanhui Shi[1] Wenjun Du[2] Shiyu Wang[3] Weihua Cao[3] Wen Deng[3] Xulong Zhang[4] Minghui Li[3], [1]Department of Hepatology Division 2, Beijing Ditan Hospital,Capital Medical University, Beijing, [2]Department of Liver Diseases, Shandong Public Health Clinical Center, Shandong University, Jinan, [3]Department of Hepatology Division 2, Beijing Ditan Hospital, Capital Medical University, Beijing, [4]HBV Infection, Clinical Cure and Immunology Joint Laboratory for Clinical Medicine, Capital Medical

Background: Alpha-fetoprotein (AFP) serves as a crucial prognostic indicator for individuals diagnosed with hepatocellular carcinoma (HCC). Drawing upon real-world clinical evidence, our research sought to develop and verify a progression-free survival (PFS) prediction model for AFP-negative HCC via LASSO-Cox regression, and to explore the risk factors for early progression in this population receiving standard treatment. **Methods:** Clinical data from 72 AFP-negative HCC patients receiving various standardized treatments (including curative and non-curative modalities) were retrospectively analyzed. LASSO and multivariable Cox regression identified prognostic factors to construct the nomogram. Model performance was evaluated via C-index, ROC, calibration, and decision curve analysis (DCA). Internal validation was conducted using bootstrap resampling, and external validation was performed in The Cancer Genome Atlas (TCGA) cohort. **Results:** Among the 72 patients, 65 experienced disease progression or death (62 progressions and 3 deaths), all of which were early endpoint events ($\leq$2 years). Among them, 36 patients experienced very early progression ($\leq$1 year). The median PFS for this cohort was 6.28 months. Subsequent multivariable Cox regression assessment identified Age (HR : 1.037, P = 0.035), PIVKA-II (HR : 2.326, P = 0.002), Vascular invasion (HR : 1.909, P = 0.024), and GGT (HR : 1.006, P = 0.003) as independent risk factors for early progression in AFP-negative HCC. An individualized nomogram was subsequently developed incorporating these independent risk factors. The model's C-index was 0.705 (95% CI: 0.644 - 0.767) in the training set. After internal validation and correction using the Bootstrap method, yielding an optimism-adjusted C-index of 0.688 (95% CI: 0.627–0.750) alongside a minimal optimism of 0.017. External validation results showed a model C-index of 0.622 (95% CI: 0.475–0.768). Time-dependent ROC curve assessments exposed that the areas under the curve (AUC) for predicting half-year and 12-month PFS in the internally corrected training dataset were 0.723 and 0.738, respectively. The calibration curve demonstrated good fit. DCA indicated that the nomogram provided a good net clinical benefit across a wide range of threshold probabilities. After grouping patients based on the nomogram risk scores, the disparity in PFS between the high and low-risk groups reached statistical significance, suggesting that the model has good risk stratification capability. **Conclusion:** The nomogram model based on Age, Vascular invasion, PIVKA-II and GGT can effectively predict PFS in AFP-negative HCC patients. It provides a strategy for clinicians to optimize treatment plans earlier, adjust follow-up strategies and enhance the prognosis of patients with AFP-negative HCC.

4313 | INTRAVENOUS AT-101 DEMONSTRATES FAVORABLE TOLERABILITY AND DIRECTIONAL TUMOR-GROWTH SUPPRESSION IN AN SK-HEP-1 MURINE XENOGRAFT MODEL OF HEPATOCELLULAR CARCINOMA

Stanley Lewis[1], [1]A28 Therapeutics, Inc

Background: Hepatocellular carcinoma (HCC) remains a major cause of global cancer mortality, necessitating continued development of novel therapeutic approaches. AT-101, a lytic peptide that targets the gonadotropin-releasing hormone receptor, was evaluated for anti-tumor efficacy in a murine SK-Hep-1 xenograft model of HCC. This study aimed to determine whether repeated intravenous dosing of AT-101 suppresses tumor growth compared with vehicle and the reference standard sorafenib. **Methods:** Male Nu/J mice (n = 31) were implanted subcutaneously with 3×10^6 SK-Hep-1 cells. When mean tumor volume reached approximately 75 mm³, animals were randomized into three treatment groups: AT-101 (n = 11, twice-weekly IV), vehicle control (n = 10, twice-weekly IV), and sorafenib (n = 10, daily oral gavage). Treatments were administered for three weeks. Tumor volumes were measured three times weekly. Body weight and detailed clinical observations were recorded at baseline, early study time points, and weekly thereafter. At study completion, animals were euthanized, and gross necropsy evaluations were performed. Terminal tumor weights were collected, and tumors were flash-frozen for potential future analyses. **Results:** AT-101–treated mice demonstrated lower mean terminal tumor volumes (124.12 mm^3) relative to both vehicle- (182.18 mm^3) and sorafenib-treated (145.39 mm^3) groups throughout the treatment period, although these differences did not reach statistical significance. Mean terminal tumor weights were likewise reduced in the AT-101 (0.069g) and sorafenib groups (0.084g) compared with vehicle (0.104g). Body weights remained stable across all treatment arms, with no evidence of systemic toxicity or treatment-related clinical abnormalities. Necropsy revealed two isolated liver findings—one AT-101–treated mouse with a small hard hepatic deposit and one vehicle-treated mouse with a pale mottled liver—both considered incidental and unrelated to treatment due to lack of recurrence or dose response. No adverse events or unscheduled deaths occurred. **Conclusion:** Repeated intravenous dosing of AT-101 was well tolerated and associated with a consistent trend toward reduced tumor growth in this SK-Hep-1 xenograft model of HCC. Although statistical significance was not achieved, the directionality of tumor reduction and favorable safety profile support further evaluation of AT-101 in dose-optimization, mechanistic, or combination-therapy studies.

4314 | CLINICAL FEATURES, TREATMENT PATTERNS, AND OUTCOMES OF YOUNG-ONSET HEPATOCELLULAR CARCINOMA: A TERTIARY COHORT ANALYSIS WITH A NATIONWIDE POPULATION-BASED STUDY

Eunju Kim[1] Jina Park[2] Sung Won Chung[2] Won-Mook Choi[2] Danbi Lee[2] Ju Hyun Shim[2] Kang Mo Kim[2] Young Suk Lim[2] Han Chu Lee[2] Jonggi Choi[3], [1]Chung-Ang University, [2]Asan Medical Center, [3]University of Ulsan, Asan Medical Center

Background: Hepatocellular carcinoma (HCC) in younger patients is uncommon, and its clinical characteristics and prognosis remain uncertain. We aimed to evaluate the clinical features, treatment patterns, and outcomes of young-onset HCC using large-scale datasets. **Methods:** This study included two cohorts: the Asan Medical Center (AMC) HCC registry (2009–2023) and the nationwide Korean Liver Cancer Association (KLCA) registry. Young-onset HCC was defined as age ≤ 40 years. Outcomes were compared between young (≤ 40 years) and non-young (> 40 years) patients, with additional analyses across three age groups (≤ 40, 41–65, > 65 years). Propensity score matching (PSM) was performed to adjust for baseline differences. Overall survival (OS), recurrence-free survival (RFS), treatment patterns, and treatment intensity were evaluated. In the KLCA cohort, survival analyses were limited to patients diagnosed between 2015 and 2021. **Results:** A total of 21,699 patients in the AMC cohort and 21,178 in the KLCA cohort were included. Young-onset HCC accounted for 955 (4.4%) and 627 (3.0%) cases, respectively. Before matching, younger patients had larger tumors, higher alpha-fetoprotein levels, and more advanced disease. After PSM, OS was comparable between groups in the AMC cohort (median 3.8 vs. 4.0 years; p = 0.890) and the KLCA cohort (median 3.7 vs. 2.9 years; p = 0.053). Stage-stratified analyses showed no significant differences in OS. RFS was also similar between groups in the AMC cohort. Initial treatment distribution and longitudinal treatment intensity were comparable, whereas patients aged > 65 years were less likely to receive curative treatments. **Conclusion:** Young-onset HCC shows more aggressive tumor features but comparable outcomes

4315 | REAL-WORLD OUTCOMES AND PREDICTORS OF RESPONSE TO FIRST-LINE STRIDE IN UNRESECTABLE HEPATOCELLULAR CARCINOMA: FOCUS ON VP4 PORTAL VEIN TUMOR THROMBUS

Chi-Jung Wu[1] Ming-Chieh Hsieh[1] Pei-Chang Lee[1] Chen-Ta Chi[1] I-Cheng Lee[1] Chieh-Ju Lee[1] Ming-Chih Hou[1] Yi-Hsiang Huang[1], [1]Taipei Veterans General Hospital

Background: While the STRIDE regimen (tremelimumab plus durvalumab) is a standard first-line treatment for unresectable hepatocellular carcinoma (uHCC), patients with Vp4 portal vein tumor thrombus (PVTT) remain severely underrepresented in landmark clinical trials. As a result, real-world evidence guiding the use of STRIDE in this ultra-high-risk cohort is highly limited. This study evaluated the real-world efficacy and safety of first-line STRIDE therapy in uHCC and sought to identify key clinical predictors of objective response. **Methods:** Between December 2023 and February 2026, 90 consecutive patients with advanced HCC receiving first-line STRIDE therapy at Taipe Veterans General Hospital were prospectively enrolled. Tumor response was assessed by RECIST v1.1; AEs were graded using CTCAE v5.0. Survival curves were calculated via the Kaplan–Meier method. Predictors of objective response were determined using multivariable logistic regression. **Results:** Of the 90 patients enrolled, 85.6% (n = 77) had Child–Pugh class A liver function, 90.0% (n = 81) had BCLC stage C disease, and 22.2% (n = 20) presented with Vp4 PVTT. Over a median follow-up of 6.6 months (ranged: 0.7-27.4), the median progression-free survival (PFS) was 3.7 months (95% CI: 1.5–5.9), while median overall survival was not reached. Survival outcomes did not differ significantly between patients with and without Vp4 PVTT. Notably, robust antitumor activity was preserved in the Vp4 PVTT subgroup, which achieved an objective response rate (ORR) of 40.0% and a disease control rate (DCR) of 65.0%. Multivariable analysis identified infiltrative tumor morphology (OR:6.42, 95% CI:1.66-24.80; p = 0.007) and a lower tumor burden score (within up-to-11 criteria) (OR:3.76, 95% CI:1.22-11.57; p = 0.021) as independent predictors of objective response. Grade $\geq$ 3 treatment-related AEs (TRAEs) reported in 20.0%. High-dose corticosteroids were required in 18.9% of patients, and 8.9% discontinued treatment due to toxicity. **Conclusion:** This real-world study confirms the favorable therapeutic index of first-line STRIDE in uHCC, extending its clinical utility to high-risk patients with Vp4 PVTT. Furthermore, the unexpected link between infiltrative morphology and improved objective response implies a unique immune susceptibility in this aggressive subgroup, offering a potential clinical selection tool for optimizing dual immunotherapy.

4316 | PALLIATIVE CARE IN THE MANAGEMENT OF HEPATOCELLULAR CARCINOMA

Newsha Nikzad[1] Arpan Patel[2] Thomas Hunold[3] Anjana Pillai[4], [1]The University of Chicago Medical Center, [2]University of California, Los Angeles, [3]University of Michigan, [4]University of Chicago

Background: Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer, and patients often present with advanced stage disease and poor overall survival despite surveillance recommendations. Patients with HCC experience substantial impairments in quality of life, including significant physical and emotional distress arising from the combined burden of malignancy and underlying chronic liver disease. However, the incorporation of palliative and hospice care in the management of HCC is limited, and the existing literature within this realm represents an opportunity for further optimization of care. **Methods:** This scoping review followed the PRISMA guidelines (PROSPERO protocol CRD42019123398). Our study focused on articles investigating attitudes towards, experiences with, and clinical outcomes related to palliative care (PC) or hospice care in patients with HCC. Studies indexed in Pubmed, Embase, and Cochrane Library and published between January 1, 1965 until January 24, 2026 that met inclusion criteria were analyzed. These studies were subsequently assessed for risk of bias with the Joanna Briggs Institute Critical Appraisal tools. **Results:** The 22 included studies consisted of 3 qualitative studies and 19

quantitative studies; the quantitative evidence was predominantly retrospective observational in design (14 cohort studies, 4 cross-sectional analyses, and 1 case series), with only 1 pilot randomized controlled trial. Most articles were at moderate to serious risk of bias. Outcomes were classified by five distinct categories: current practice trends, caregiver and patient perspectives; end-of-life outcomes and hospice; resource utilization and cost; and health disparities. Clinician accounts revealed infrequent and delayed specialty PC and hospice referrals for patients and limited training in PC among hepatologists, despite recognizing the importance of multidisciplinary supportive care. Patients expressed negative misconceptions about PC, but education on PC improved patient perceptions and referral to PC improved quality of life and decreased physical symptom burden, such as pain and pruritus. Notable disparities in access to palliative care and hospice were observed around insurance coverage and racial and ethnic background, such as Black and Hispanic patients having less frequent hospice utilization compared to White patients. Palliative and hospice care reduced inpatient expenditures overall and invasive interventions in terminal hospitalizations. **Conclusion:** The care of patients with HCC requires a standardized, multidisciplinary approach that individualizes palliative and hospice care for patients. Future research and integrated care models that focus on clinician education, patient-reported outcomes, and equity are essential to provide high quality care to this patient population.

4317 | PROGNOSTIC ROLE OF ABSOLUTE EOSINOPHIL COUNT IN PATIENTS WITH HEPATOCELLULAR CARCINOMA TREATED WITH ATEZOLIZUMAB PLUS BEVACIZUMAB

Jung Pyo Hong[1] Yeo Wool Kang[2] Jun Sik Yoon[3] Jeong Eun Song[4] Joon Ho Jeong[5] Yu Rim Lee[6] Jae Hyun Yoon[7] Young Mi Hong[8] Sang Youn Hwang[9] Hyun Young Woo[10] Yang Hyun Baek[2] Soo Young Park[6] Sung Bum Cho[11] Hyun Chin Cho[1], [1]Gyeongsang National University College of Medicine, [2]Dong-A University College of Medicine, [3]Inje University College of Medicine, [4]Catholic University of Daegu School of Medicine, [5]University of Ulsan College of Medicine, [6]School of Medicine, Kyungpook National University, [7]Chonnam National University Hospital, School of Medicine, [8]College of Medicine, Pusan National University, [9]Dongnam Institute of Radiologic & Medical Sciences, [10]College of Medicine, Pusan National University and Biomedical Research Institute, [11]Chonnam National University Medical School

Background: Atezolizumab plus bevacizumab is the standard first-line treatment for advanced hepatocellular carcinoma (HCC). However, predictive biomarkers for survival remain scarce. We investigated the prognostic value of baseline and early kinetic changes in absolute eosinophil count (AEC) in patients receiving this combination therapy. **Methods:** We analyzed a multicenter, retrospective cohort of 1,153 patients with HCC treated with atezolizumab plus bevacizumab. The optimal baseline AEC cut-off was determined as 54 /μL (equivalent to 0.95% of the median white blood cell count). We assessed overall survival (OS) and progression-free survival (PFS) using Kaplan-Meier methods and multivariable Cox proportional hazards models. Inverse probability of treatment weighting (IPTW) mitigated baseline confounding. A 3-week landmark analysis evaluated the impact of AEC kinetics ($\geq$ 86 /μL). **Results:** High baseline AEC ($\geq$ 54 /μL) was present in 920 patients (79.8%). Patients with high AEC demonstrated significantly improved OS (HR 0.63; 95% CI 0.52–0.75; $P < 0.001$) and PFS (HR 0.77; 95% CI 0.65–0.91; $P = 0.002$) in multivariable analysis compared to the low AEC group ($n = 233$). This survival benefit persisted after IPTW adjustment for OS (HR 0.70; 95% CI 0.54–0.91; $P = 0.007$). The prognostic advantage of high baseline AEC remained consistent across patients with preserved liver function (Child-Pugh A). In the landmark analysis ($n = 900$), maintaining or achieving an AEC $\geq$ 86 /μL at 3 weeks was significantly associated with superior OS ($P = 0.002$) and PFS ($P < 0.001$). **Conclusion:** Baseline AEC and its early kinetics serve as simple, universally accessible prognostic biomarkers for patients with HCC receiving atezolizumab plus bevacizumab.

4318 | ASSESSING PATIENT SYMPTOMS AND QUALITY OF LIFE AFTER LOCOREGIONAL THERAPY FOR HEPATOCELLULAR CARCINOMA

Garren Montgomery[1] Maria Krantz[1] Arsheya Patel[2] Kelly Durkin[1] Stacey Culp[1] Vivek Mendiratta[1] Lindsay Sobotka[1], [1]The Ohio State University Medical Center, [2]Gastro Health

Background: Locoregional therapies (LRT) including transarterial chemoembolization (TACE), radiofrequency ablation (RFA), stereotactic body radiation therapy (SBRT), and transarterial radioembolization (TARE) are often utilized in the management of hepatocellular carcinoma (HCC). While the efficacy of LRT is well-supported, there is limited data concerning the effect of LRT on patients' well-being. The aim of this study was to assess feasibility of collecting longitudinal health-related quality of life (HRQoL) measures in patients undergoing LRT using the Functional Assessment of Cancer Therapy-Hepatobiliary (FACT-Hep) questionnaire, and to describe early HRQoL patterns among these patients. **Methods:** Adult patients diagnosed with HCC who were recommended for LRT were eligible for enrollment. Patient demographics and details regarding liver disease history and HCC were collected by chart review. HRQoL was assessed using the FACT-Hep questionnaire at baseline (pre-LRT), 1 week post-LRT, and 1 month post-LRT. Feasibility outcomes included enrollment rate and FACT-Hep completion at each time point. FACT-Hep subscores were compared between patients receiving TARE or SBRT (Group 1) and those receiving TACE or ablation (Group 2) using a descriptive analysis. **Results:** Of 58 eligible patients, 21 were enrolled (36.2%). Eight patients did not complete the baseline or follow-up surveys (6 unable to be contacted and 2 canceled LRT due to illness). Thirteen patients completed the baseline survey and at least one of the post-LRT surveys. Of these, 85% completed the 1 week post-LRT survey and 92% completed the 1 month post-LRT survey. Ten patients were in Group 1 (6 TARE and 4 SBRT) and 3 were in Group 2 (2 TACE and 1 ablation). Median age was higher in Group 1 (62.5) compared to Group 2 (51). At baseline, Group 1 had lower mean physical well-being, emotional well-being, functional well-being, and hepatobiliary cancer subscores. At 1 week, Group 2 experienced larger declines in all FACT-Hep subscores compared to Group 1 (Table 1). By 1 month post-treatment, this difference was not as apparent, and individual trajectories in both groups trended towards improvements in each subscore (Figure 1). These observations were not powered for statistical comparison. **Conclusion:** Prospective longitudinal HRQoL assessment using the FACT-Hep questionnaire before and after LRT appears feasible. While enrollment is modest, for those who enroll survey completion rates at 1 week and 1 month are reasonable. Early descriptive trends suggest differing HRQoL trajectories between patients treated with TARE or SBRT (Group 1) and Ablation or TACE (Group 2), particularly at 1 week post treatment. A larger, adequately powered study is needed to assess if these differences are statistically significant.

4319 | SELECTION OF POSTOPERATIVE ADJUVANT THERAPY REGIMENS AND EFFICACY ASSESSMENT IN INTRAHEPATIC CHOLANGIOCARCINOMA

Zhongquan Sun[1] Weilin Wang[2] Yang Huang[2] Haotian Fu[2] Hongfan Ding[2], [1]Zhejiang University, [2]The Second Affiliated Hospital Zhejiang University School of Medicine

Background: Intrahepatic cholangiocarcinoma (iCCA) is a highly aggressive and heterogeneous malignancy, accounting for approximately 10%–15% of primary liver cancers. Radical surgical resection remains the only potentially curative treatment; however, prognosis remains poor even after curative resection owing to its aggressive biological behavior. Immune checkpoint inhibitors (ICIs) have demonstrated significant efficacy across various malignancies, whereas their role in the adjuvant setting for iCCA remains to be fully elucidated. This study aimed to evaluate the efficacy and safety of different postoperative adjuvant treatment strategies in patients with iCCA and to identify prognostic risk factors, thereby providing evidence to inform clinical decision-making. **Methods:** Clinical and pathological data of patients with iCCA who underwent curative resection between January 1, 2018 and June 30, 2025 were retrospectively collected from 10 tertiary hospitals in China, including The Second Affiliated Hospital, Zhejiang University School of Medicine. A total of 513 patients met the inclusion criteria. Patients were categorized into a non-adjuvant group and an adjuvant group according to whether postoperative adjuvant therapy was administered. Based on treatment regimens, the adjuvant group was further stratified into an oral chemotherapy group, a gemcitabine-based intravenous chemotherapy group, and an ICIs plus intravenous chemotherapy group. The primary endpoints were recurrence-free survival (RFS) and overall survival (OS). Independent prognostic factors were identified, and treatment-related adverse events were assessed. **Results:** Multifocal intrahepatic lesions, tumor diameter >5 cm, concomitant biliary stones, lymph node metastasis, vascular invasion, perineural invasion, and a narrow surgical margin (defined as a tumor-free margin <1 cm) were identified as independent risk factors for postoperative recurrence in patients with iCCA. Based on these factors, patients were stratified into recurrence risk groups.Patients with low recurrence risk derived greater survival benefits from oral chemotherapy with capecitabine or S-1, with improvements observed in both RFS and OS. In contrast, for patients with high recurrence risk, neither oral chemotherapy nor intravenous chemotherapy alone conferred significant survival benefits. However, ICIs combined with intravenous chemotherapy significantly improved RFS, indicating improved disease control, with an overall manageable safety profile. **Conclusion:** Postoperative adjuvant treatment strategies for patients with iCCA should be individualized. Oral chemotherapy with capecitabine or S-1 may provide greater survival benefits in patients with low recurrence risk, whereas ICIs combined with intravenous chemotherapy represents an effective and tolerable adjuvant treatment option for those with high recurrence risk.

4320 | GEMCITABINE-BASED CHEMOTHERAPY PLUS PD-1/PD-L1 INHIBITORS AND TYROSINE KINASE INHIBITORS FOR INITIALLY UNRESECTABLE INTRAHEPATIC CHOLANGIOCARCINOMA: A MULTICENTER, RETROSPECTIVE COHORT STUDY

Zhongquan Sun[1] Yuan Ding[2] Xin Han[2] Hongfan Ding[2] Haotian Fu[2], [1]Zhejiang University, [2]The Second Affiliated Hospital Zhejiang University School of Medicine

Background: Patients with initially unresectable intrahepatic cholangiocarcinoma have poor prognoses and the current first-line standard treatments remain unsatisfactory. Our study aimed to evaluate gemcitabine-based chemotherapy plus PD-1/PD-L1 inhibitors

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

and tyrosine kinase inhibitors (TKIs) for previous untreated unresectable intrahepatic cholangiocarcinoma. **Methods:** In this multicenter retrospective cohort study, 392 patients were included in the full cohort analysis. For the primary analysis, 88 patients received gemcitabine-based chemotherapy (GEMCIS or GEMOX), and 177 patients received the same chemotherapy backbones combined with PD-1/PD-L1 inhibitors and TKIs. The primary outcome was to evaluate overall survival (OS). The propensity score matching (PSM) method was utilized to reduce potential confounders. **Results:** Overall, 392 patients were included from 12 hospitals across China, with data from January 2016 to December 2024. In the full cohort analysis, the combination of GEMCIS/GEMOX with PD-1/PD-L1 inhibitors and TKIs significantly prolonged median OS compared to GEMCIS/GEMOX alone (26.7 vs. 15.3 months; hazard ratio [HR] 0.47, 95% CI: 0.35-0.63, $P < 0.001$). In the primary analysis, the combination strategy was associated with a median OS of 24.8 months (95% CI: 20.8-28.8) and median progression-free survival (PFS) of 11.0 months (95% CI: 8.5-13.5), with corresponding HRs of 0.56 (95% CI: 0.38-0.83, $P = 0.004$) for OS and 0.46 (95% CI: 0.32-0.66, $P < 0.001$) for PFS after PSM. Furthermore, in the combination cohort, the incidence of grade 3-4 hematological adverse events was 30%, compared with 27% in the chemotherapy cohort, with no significant difference observed ($P = 0.604$). Importantly, our treatment strategy increased the rate of conversion surgery to 42% for locally advanced disease, ultimately resulting in significantly improved overall outcomes (HR for OS: 0.17 [95% CI: 0.05-0.61]). **Conclusion:** Combining gemcitabine-based chemotherapy with PD-1/PD-L1 inhibitors and TKIs may provide a promising new first-line treatment option for patients with initially unresectable intrahepatic cholangiocarcinoma.

4321 | ASSOCIATION BETWEEN PNPLA3 I148M GENOTYPE AND TUMOR CHARACTERISTICS AND DISEASE SEVERITY IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

Dilara Turan Gokce[1] Halil Tuğrul Akarca[2] Rifat Furkan Aydın[2] Esra Tunç[3] Volkan Yılmaz[1] Özge Koç[1] Zeynep Melekoglu Ellik[1] Mesut Gümüssoy[1] Ramazan Erdem Er[1] Hale Gökcan[1] Ramazan İdilman[1], [1]Ankara University School of Medicine, Department of Gastroenterology, [2]Ankara University School of Medicine, Department of Internal Medicine, [3]Ankara University Institute of Hepatology

Background: The I148M (rs738409) polymorphism in the patatin-like phospholipase domain-containing protein 3 (PNPLA3) gene is a well-established genetic variant associated with disease progression, cirrhosis, and HCC. However, its role in HCC biology remains unclear. The aim of this study was to evaluate the association between the PNPLA3 rs738409 variant and tumor biology and clinical outcomes in patients with HCC. **Methods:** This single-center retrospective cohort study included patients diagnosed with HCC. Under a recessive genetic model, the PNPLA3 rs738409 variant was considered the risk genotype. Patients with HCC were categorized into two etiological groups: steatotic liver disease (SLD)–related HCC and viral hepatitis–related HCC. **Results:** A total of 105 patients were included. The mean age was 64.7 ± 7.9 years, and 78% were male. Viral hepatitis–related HCC was the most common etiology (57%), followed by SLD-related HCC (36%) in this HCC cohort. At diagnosis, cirrhosis was present in 94% of patients. Overall, 42% of patients had early-stage disease (BCLC 0–A). A single lesion was identified in 55% of patients, while portal vein invasion and extrahepatic involvement were observed in 12% and 9% of cases, respectively. Patients with SLD–related HCC were significantly older than those with viral-related HCC (median age 66.7 vs. 63.9 years, $p = 0.031$). In multivariable Cox regression analysis, SLD–related HCC was associated with a higher risk of mortality compared with viral hepatitis-related HCC (HR 0.45, 95% CI 0.24–0.85, $p = 0.014$). The frequency of the PNPLA3 rs738409 variant was significantly higher in patients with SLD-related HCC than in those with viral-etiology-related HCC (47.2% vs. 25.4%, respectively; $p = 0.016$). Patients carrying the PNPLA3 rs738409 variant had more advanced liver disease ($p = 0.025$), more advanced-stage HCC ($p = 0.013$), and higher ALBI scores ($p = 0.009$). Portal vein invasion was more frequent among PNPLA3 rs738409 variant carriers ($p = 0.028$), suggesting more aggressive tumor behavior. Additionally, carriers exhibited numerically greater tumor burden, including a slightly larger median total tumor diameter ($p = 0.30$), higher rates of multifocality ($p = 0.63$), and elevated serum AFP levels ($p = 0.39$). Kaplan–Meier analysis showed significant differences in overall survival among genotype groups (log-rank $p = 0.048$). **Conclusion:** In this cohort of patients with HCC, the epidemiological landscape of HCC risk factors has shifted from virus-related to steatotic liver disease. The PNPLA3 I148M GG genotype was more frequently observed in SLD-related HCC and was associated with more advanced liver disease, as well as tumor features consistent with a more aggressive

biological phenotype. These findings suggest that PNPLA3 may influence HCC biology and disease severity rather than acting as the sole independent prognostic marker.

4322 | INTERDEPENDENCE ACROSS THE HCC CARE CASCADE IN LATIN AMERICA: A MULTINATIONAL SYSTEM-LEVEL ANALYSIS

Pablo Coste[1] Luis Antonio Diaz[2] Marco Arrese[3] Francisco Vargas Navarro[1] Maria Fernanda Lynch-Mejia[4] Wagner Ramirez[1] Federico Piñero[5] Manuel Mendizabal[6] Maria Reig[7] Jeffrey Lazarus[8] Margarita Anders[9] Josemaría MenendezDutra[10] Juan Pablo Arab[11], [1]Liver Unit, Hospital Rafael Ángel Calderón Guardia, Liver Lab CR, San José, Costa Rica, [2]Pontificia Universidad Católica de Chile, [3]Pontificia Universidad Católica de Chile, Santiago, Chile., [4]Caja Costarricense de Seguro Social, [5]Hepatology and Liver Transplant Unit, Hospital Universitario Austral, Buenos Aires, Argentina, [6]Hospital Universitario Austral, [7]Liver Cancer Unit, Hospital Clínic Barcelona, Barcelona, España, [8]University of Barcelona, [9]Hepatology and Liver Transplant Unit, Hospital Alemán, Buenos Aires, Argentina, [10]Liver Transplant National Program, Hospital Militar, Montevideo, Uruguay, [11]Virginia Commonwealth University

Background: Hepatocellular carcinoma (HCC) outcomes depend on the integrity of the care cascade, yet structural relationships between healthcare system components remain poorly characterized in Latin America. **Methods:** We conducted a multinational cross-sectional analysis including 20 Latin American countries. Twenty variables were operationalized into six predefined domains: fibrosis detection, surveillance, diagnosis, multidisciplinary care (MDT), curative treatment, and non-curative treatment. Domain scores were normalized to a 0–100 scale. Correlations across domains were assessed using Spearman coefficients, and hierarchical clustering analysis was performed to identify system-level performance patterns across the HCC care cascade. **Results:** Substantial heterogeneity in HCC care capacity was observed across countries, with total scores ranging from 0 to 85.4. Strong correlations were identified across all domains ($\rho = 0.73–0.98$; $p < 0.001$), indicating marked interdependence throughout the care cascade. Fibrosis detection demonstrated strong associations with diagnosis ($\rho = 0.92$) and MDT performance ($\rho = 0.95$), while curative and non-curative treatment domains were highly correlated ($\rho = 0.98$). Hierarchical clustering revealed a continuum of healthcare system capacity rather than discrete categories. Higher-performing systems clustered with preserved downstream therapeutic capacity, whereas lower-performing systems demonstrated widespread limitations across multiple domains. Across all settings, deficiencies in fibrosis detection and linkage to care emerged as the most consistent limitation. **Conclusion:** HCC care performance in Latin America appears to reflect integrated healthcare system capacity rather than isolated domain-specific factors. These findings support system-level strengthening strategies centered on early detection and structured HCC care pathways.

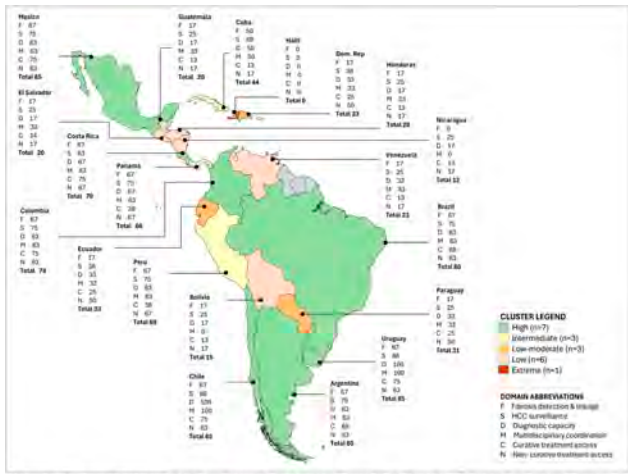

Figure 1. Clustered heatmap of HCC care cascade performance across Latin America. Countries are ordered according to hierarchical clustering based on six domain-level scores. Colors represent relative healthcare system capacity (red: low; yellow: intermediate; green: high). Clusters reflect progressive gradients of system-level performance across the HCC care cascade.

4323 | THE EASTERN MEDITERRANEAN LANDSCAPE OF LIVER CANCER CLINICAL TRIALS (1999–2022): EVIDENCE FROM THE WHO CLINICAL TRIALS DATABASE

Saleh Alessy[1] Atheer Almutairi[2] Maryam Alalawi[3] Basmah Khoja[4] Aldanah Althwanay[5] Ghadeer Jamjoum[6] Adnan Alzanbagi[7] Khalid AlNaamani[8] Saad Alghamdi[9] Saleh Alqahtani[10], [1]Saudi Electronic University, Riyadh, Saudi Arabia, [2]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [3]Columbia University, New York, USA, [4]King Faisal Specialist Hospital & Research Hospital, Riyadh, Saudi Arabia, [5]Washington University at St.Louis -Barnes Jewish Hospital, [6]King Abdulaziz University Hospital, Jeddah, Saudi Arabia, [7]King Abdullah Medical City, Makkah, Saudi Arabia, [8]The Medical City of Military and Security Services, Muscat, Oman, [9]King Faisal Specialist Hospital and Research Center, [10]King Faisal Specialist Hospital & Research Center

Background: Liver cancer clinical trials are critical for providing timely access to innovative prevention and treatment strategies and generating evidence to improve liver cancer control. The World Health Organization (WHO) Eastern Mediterranean Region (EMR) includes countries with a substantial liver cancer burden, yet regional participation in liver cancer clinical research has not been well characterized. We aimed to assess the liver cancer clinical trial landscape in the WHO EMR from 1999 to 2022 and benchmark regional trial activity against global patterns. **Methods:** We analyzed data from the WHO landscape of clinical trials on cancer, published in September 2025. This dataset includes information from the WHO International Clinical Trials Registry Platform and cancer prevalence, incidence, and mortality estimates from the International Agency for Research on Cancer GLOBOCAN 2022 database. Characteristics of liver cancer trials were summarized globally and for EMR countries by registration year, recruitment country, trial phase, and sponsor category. **Results:** Between 1999 and 2022, 4,199 liver cancer clinical trials were registered globally, with the cumulative count increasing from 11 trials in 1999. China had the highest number of trials (n = 1,860), followed by the United States (n = 752), and Japan (n = 698). Globally, most trials were sponsored by academic or research institutions (79%), whereas pharmaceutical and biotechnology sponsors accounted for only 7%. Overall, liver cancer trials represented 4.68% of all oncology clinical trials worldwide, despite liver cancer contributing to 9.02% of global cancer-related deaths in 2020. Within the WHO EMR, only 59 trials were registered by 2022, with trial activity increasing from a single trial in 2002, with Egypt contributing the largest share (n = 45), followed by Saudi Arabia (n = 12). Phase III studies represented the largest proportion of EMR trials (35.6%, n = 21), highlighting limited early-phase trial activity across the region. In contrast, industry sponsorship was proportionally higher in the EMR (20% vs 7% globally), although academic institutions remained the predominant sponsors (56% vs 79% globally). **Conclusion:** Despite the substantial global expansion of liver cancer clinical trials, the EMR contributed only 1.4% of global liver cancer trials, despite serving a population of nearly 745 million people. These findings highlight substantial geographic disparities in liver cancer clinical research, with trial activity concentrated in few countries and limited early-phase activity across the region. Targeted investment in regional trial networks, early-phase research capacity, and academic engagement may help address this gap. Interpretation should consider potential underregistration, incomplete registry updates, disease-classification uncertainty, and multicountry trial counting in the WHO database.

Saudi Arabia, [2]King Faisal Specialist Hospital & Research Center

Background: *ABCB4*-related diseases are exceedingly rare causes of liver cirrhosis in adults and can be associated with serious complications that require liver transplantation, such as hepatocellular carcinoma (HCC). Data on the outcomes of HCC in adults with *ABCB4*-related liver disease remain scarce because of the rarity of this condition. Here, we characterized the clinical presentation, tumor features, and management of patients with HCC arising in the setting of *ABCB4*-related liver disease. **Methods:** We retrospectively collected clinical, biochemical, radiological, and genetic data of adult patients (n = 5) with HCC arising in genetically confirmed *ABCB4*-related liver disease. Patients were identified from a large HCC registry at the King Faisal Specialist Hospital and Research Center in Saudi Arabia. **Results:** Five patients with ABCB4-related liver disease and HCC were identified. The median age at ABCB4-related liver disease diagnosis was 19 years, while the median age at HCC diagnosis was 23.0 years, and 60% were male. All patients had underlying cirrhosis, and none had a family history of HCC. Jaundice was present in all patients during the disease course, whereas ascites and prior variceal bleeding were observed in 2 patients (40%) and 1 patient (20%), respectively. Most patients had decompensated liver disease, with 3 patients (60%) classified as Child-Pugh B and 1 patient (20%) as Child-Pugh C. MRI identified hepatic lesions in all patients. At diagnosis, 2 patients (40%) had early-stage disease (BCLC A), 1 patient (20%) had intermediate-stage disease (BCLC B), and 2 patients (40%) had advanced-stage disease (BCLC C). Vascular invasion was observed in one patient (20%). Three patients (60%) were within Milan criteria. Initial treatment strategies included liver transplantation in two patients (40%), locoregional therapy in one (20%), best supportive care in one (20%), and one patient awaiting liver transplantation. **Conclusion:** HCC can develop at a remarkably young age in patients with ABCB4-related liver disease, frequently in the setting of cirrhosis and significant hepatic dysfunction. Despite the young age of the cohort, 2 of 5 patients presented with advanced HCC at diagnosis. These findings highlight the need for further awareness in ABCB4-related liver disease and the importance of careful HCC surveillance guidelines in patients with this rare condition.

Background: Hepatocellular carcinoma (HCC) is the fourth most common cancer in the Philippines. Despite established risk factors and advancements in treatment management, prognosis remains poor. Comprehensive analysis of factors will allow for optimized diagnosis and patient care. We present an initial evaluation of selected prognostic factors applied to a small cohort of HCC patients from the Philippines through Cox regression modeling. **Methods:** Baseline records from 120 newly diagnosed, treatment-naive HCC patients from six study sites across the Philippines were obtained. These include patient demographics, clinical data, and laboratory (hepatitis and hematological markers) parameters evaluated for overall survival. A subgroup of 52 patients was also evaluated for TP53 gene mutation. Univariate and multivariate Cox proportional hazards regression models were constructed. Continuous variables were transformed into categorical variables based on Martingale residual plots. Events of interest include death and TP53 gene mutation presence, respectively. Statistical analyses were all performed using STATA version 13.0. **Results:** The cohort is predominantly male (76%) aged 62 ± 10 years. Notable cohort characteristics include large BCLC Stage C (39.17%) and ALBI Grade 2 (45%) classifications, with wide ranged and high-valued AFP (23331.10 ± 71102.6) and PIVKA II (2302.83 ± 5020.84) ng/mL results. Univariate and multivariate analysis revealed HCC patients categorized as BCLC Stage D (HR 4.55; 95% CI 1.46 - 14.22; p = 0.009), assessed as ALBI Grade 2 (HR 2.65; 95% CI 1.24 - 5.65; p = 0.012) and Grade 3 (HR 6.00; 95% CI 2.10 - 17.13; p = 0.001), and patients with PIVKA II results > 2000 ng/mL (HR 3.48; 95% 1.64 - 7.38; p = 0.001) have an increased risk of death compared to their references, while holding other factors in the model constant. Subgroup analysis revealed that Hepatitis B positive HCC patients have an increased risk of TP53 gene mutation compared to Hepatitis B negative HCC patients (HR 5.60; 95% CI 1.16 - 27.09; p = 0.032). **Conclusion:** Our preliminary results are consistent with literature and further highlights the need to evaluate potential prognostic factors in HCC, warranting further exploration in a larger Philippine cohort. Strengthened screening and surveillance efforts, especially in high-risk populations, are highly recommended to detect early stages of HCC and reduce mortality rates.

4326 | COMPARISON OF TEMPORAL MORTALITY TRENDS IN YOUNG PATIENTS (2544) WITH COLORECTAL CANCER AND HEPATOCELLULAR CARCINOMA IN THE UNITED STATES, 1999-2024

Abigail Jacobs[1] Kate Backes[1], [1]Kansas City University

Background: Hepatocellular Carcinoma (HCC) is one of the leading causes of cancer-related mortality worldwide, with incidence and mortality rates continuing to rise, particularly in the United States.[1] In comparison, Colorectal Cancer (CRC) remains the third most diagnosed cancer globally and the second leading cause of cancer-related death.[2] Additionally, these numbers are increasingly rising in young people.[3] Currently, there has been limited studies to investigate the regional differences associated with these changing trends in the United States. The aim of this study was to compare the mortality trends of CRC and HCC in young people ages 25-45 across different geographical regions within the United States. **Methods:** Data from the Centers for Disease Control and Prevention (CDC) WONDER database were aggregated across multiple years at the regional level by sex, age group, and underlying cause of death. Descriptive statistics were used to summarize CRC and HCC mortality by sex,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

region, and age group. Statistical analysis was performed using aligned rank transformation (ART) ANOVA to compare differences in CRC and HCC mortality rates over time. ART ANOVA was selected because the data were not normally distributed. **Results:** From 1999-2024, overall mortality rates among adults ages 25-44 were higher in CRC compared to HCC. Colon cancer mortality rose in the 35–44 age group (2.34 to 2.52). This result differed from liver cancer mortality, where there was a decline seen in the 35–44 age group (0.93 to 0.81). Both HCC and CRC in the 25–34 group remained stable. Males had higher mortality for both cancers, though the male-female liver cancer gap is narrowing. Regionally, the South maintained the highest CRC burden while the West was the only region with a sustained upward colon cancer mortality trend. HCC rates are narrower across all regions (0.4 to 0.65). From 1999-2024, there was a significant difference in overall mortality rates among young adults between CRC and HCC ($p < 0.001$). However, there was not significant difference in the rates of CRC and HCC across years ($p > 0.05$). The interaction between cancer type and year was also not significant, indicating the differences in mortality rates between CRC and HCC remained consistent over time ($p > 0.05$). **Conclusion:** Our findings proved that there is a difference in mortality rates of HCC and CRC in young patients ages 25-44, but the differences have remained stable over time (1999-2024). The differences in mortality rates among regions warrants further investigation into underlying behavioral and demographic factors. Overall, these findings suggest that while CRC mortality is generally more common in younger patients, the relative mortality rates of HCC and CRC remain stable over time and highlights the need for prevention strategies in young adults.

4327 | A NOVEL INJECTABLE SMART-POLYMER CHEMOEMBOLIC PLATFORM AS A SAFER ALTERNATIVE TO LIPIODOL FOR TRANSARTERIAL CHEMO EMBOLIZATION IN HEPATOCELLULAR CARCINOMA

Riham Soliman[1] Mitsuhiro Ebara[2] Ayman Hassan[3] Talal Amer[4] Ahmed Nabil[2] Gamal Shiha[5], [1]Egyptian Liver Research Institute and Hospital (ELRIAH), Sherbin, El Mansoura, Egypt., [2]National Institute for Materials Science (NIMS), Tsukuba, Ibaraki 305-0044, Japan, [3]Higher Technological Institute of Applied Health Sciences, Sherbin, Mansoura, Egypt, [4]Interventional radiology Department, Faculty of Medicine, Mansoura, Egypt, [5]Internal Medicine Department, Faculty of Medicine, Mansoura University, Egypt.

Background: Lipiodol remains the standard carrier for transarterial chemoembolization (TACE) in hepatocellular carcinoma (HCC), despite recognized limitations including persistent vascular occlusion, hepatic ischemic injury, and chronic inflammatory changes. We evaluated a novel injectable smart-polymer embolic platform as a potential next-generation alternative to Lipiodol for locoregional doxorubicin delivery **Methods:** In this controlled preclinical proof-of-concept study, 140 rats underwent portal venous administration of saline control, Lipiodol alone, polymer alone, Lipiodol–doxorubicin mixture, polymer–doxorubicin mixture, or doxorubicin control. Animals were sacrificed serially on days 1, 2, 7, and 14. Outcomes included serial doppler ultrasonography , serum biochemistry, and blinded histopathologic assessment using a semiquantitative injury score evaluating necrosis, lipid droplets, leukocyte infiltration, edema, fibrosis, and portal congestion. **Results:** No significant systemic biochemical toxicity signals were identified across treatment groups (all $p > 0.05$). However, marked differences emerged on imaging and histopathology. Lipiodol-containing formulations demonstrated the greatest hepatic injury, characterized by extensive sinusoidal lipid entrapment, coagulative necrosis, inflammatory infiltration, portal congestion, and persistent portal vein thrombosis. Peak injury occurred at day 2 in the Lipiodol-alone group (necrosis score 3; leukocyte infiltration score 3), with persistent vascular compromise through day 14. The Lipiodol–doxorubicin group demonstrated the most sustained chronic injury pattern, including persistent lipid deposition, edema, fibrosis, and vascular congestion.In contrast, the smart-polymer–doxorubicin formulation demonstrated substantially milder early hepatic injury, with minimal necrosis and reduced inflammatory changes. Although transient portal venous thrombosis was observed at day 7, restoration of portal vein patency and near-normal hepatic architecture occurred by day 14. Polymer-alone and saline groups maintained largely preserved hepatic architecture throughout the study period. Doxorubicin alone preserved portal venous patency but was associated with early systemic illness and ascites. **Conclusion:** This injectable smart-polymer embolic platform demonstrated significantly lower hepatotoxicity and improved vascular reversibility compared with Lipiodol-based formulations. Unlike Lipiodol, which induced persistent thrombosis and sustained hepatic injury, the smart-polymer formulation enabled restoration of portal venous patency with reduced histologic damage. These findings identify injectable smart-polymer embolization as a promising next-generation chemoembolic platform warranting

further translational evaluation in arterial HCC models.

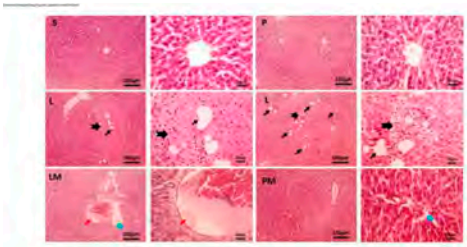

Fig1: Microscopic examination of hematoxylin and eosin (H&E)-stained liver sections one day post-injection demonstrated preserved hepatic architecture in the Polymer-only (P) group, comparable to the Saline (S) group, with normal hepatocytes, central veins, sinusoids, and portal tracts. In contrast, sections from the Lipiodol (L) group revealed multiple lipid droplets (thin black arrows) entrapped within the sinusoids, associated with focal areas of coagulative necrosis infiltrated by neutrophils (thick black arrows). In the Lipiodol Mix (LM) group, liver sections showed portal congestion (red arrows) and edema (thick blue arrows). Meanwhile, the Polymer Mix (PM) group exhibited only very mild portal edema (thick blue arrows). Magnifications: ×100 (scale bar = 100 μm) and ×400 (scale bar = 50 μm).

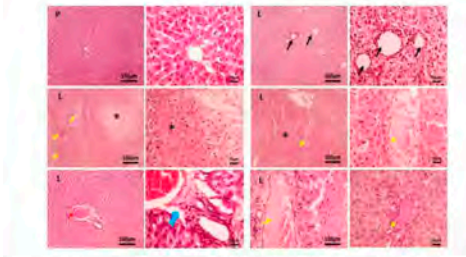

Figure 2: Microscopic examination of hematoxylin and eosin (H&E)-stained liver sections in the Polymer (P) group, two days post-injection, demonstrated preserved hepatic architecture with normal hepatocytes, central veins, sinusoids, and portal tracts. In contrast, liver sections from the Lipiodol (L) group at the same time point revealed multiple lipid droplets (thin black arrows) within the sinusoids, surrounded by leukocytic infiltration, along with fresh portal thrombi (yellow arrows). Additionally, extensive areas of coagulative necrosis infiltrated by neutrophils (*), portal congestion (red arrows), and edema (thick blue arrows) were observed. Magnifications: ×100 (scale bar = 100 μm) and ×400 (scale bar = 50 μm).

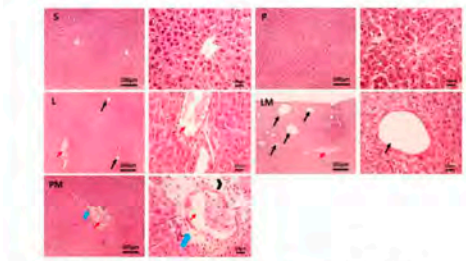

Fig 3: Microscopic examination of hematoxylin and eosin (H&E)-stained liver sections 7 days post-injection demonstrated preserved hepatic architecture in the Polymer (P) group, comparable to the Saline (S) group, with normal hepatocytes, central veins, sinusoids, and portal tracts. In the Lipiodol (L) group, multiple lipid droplets (thin black arrows) were observed within the sinusoids, accompanied by portal congestion (red arrows). Similarly, the Lipiodol Mix (LM) group showed large lipid droplets (thin black arrows) entrapped within the sinusoids, along with vascular congestion (red arrows). In the Polymer Mix (PM) group, liver sections exhibited portal congestion (red arrows), edema (thick blue arrows), and leukocytic infiltration (arrowheads). Magnifications: ×100 (scale bar = 100 μm) and ×400 (scale bar = 50 μm).

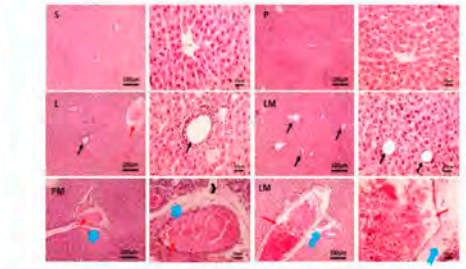

Figure 4: Microscopic examination of hematoxylin and eosin (H&E)-stained liver sections 14 days post-injection demonstrated preserved hepatic architecture in the Polymer (P) group, comparable to the Saline (S) group, with normal hepatocytes, central veins, sinusoids, and portal tracts. In the Lipiodol (L) group, multiple lipid droplets (thin black arrows) were observed within the sinusoids, surrounded by leukocytes, along with portal congestion (red arrows). In the Lipiodol Mix (LM) group, liver sections revealed multiple lipid droplets (thin black arrows) entrapped within the sinusoids, accompanied by portal congestion (red arrows) and edema (thick blue arrows). Similarly, the Polymer Mix (PM) group exhibited portal congestion (red arrows) and edema (thick blue arrows). Magnifications: ×100 (scale bar = 100 μm) and ×400 (scale bar = 50 μm).

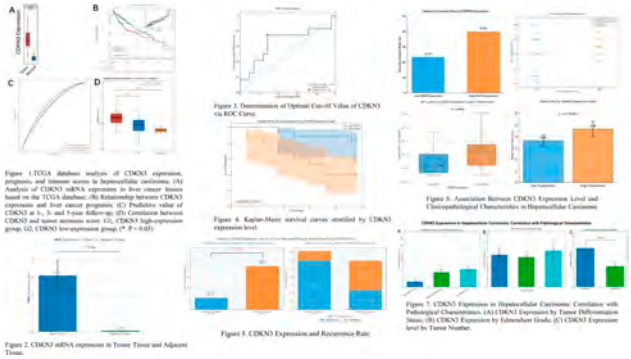
4328 | EXPRESSION AND CLINICAL SIGNIFICANCE OF CDKN3 IN HEPATITIS B-RELATED HEPATOCELLULAR CARCINOMA



Ning Lin[1] Guangming Li[2] Gongming Zhang[2] Yifan Han[1] Qingya Wang[1] Haiyang Zhou[3] Ying Liu[3] Mengqi Li[4] Yanyan Yu[1] Xiaoyuan Xu[1], [1]Peking University First Hospital, [2]Beijing YouAn Hospital, Capital Medical University, [3]Beijing iGandan Foundation, [4]Beijing Ditan Hospital, Capital Medical University

Background: Hepatocellular carcinoma (HCC) has a persistently high incidence in China, with hepatitis B virus (HBV) infection serving as the primary risk factor. Cell cycle dysregulation is involved in the progression of HCC. As a cell cycle regulatory molecule, cyclin-dependent kinase inhibitor 3 (CDKN3) plays a role in a variety of malignant tumors. This study aimed to investigate the expression pattern and clinical prognostic significance of the cell cycle regulator CDKN3 in hepatitis B-related HCC. **Methods:** Transcriptomic and clinical data of 371 HCC samples were retrieved from The Cancer Genome Atlas (TCGA) database to analyze the relationship between CDKN3 expression and patient prognosis. Additionally, 33 patients with hepatitis B-related HCC who received radical resection were enrolled from Beijing You'an Hospital were enrolled (Ethics Approval No.: LL-2024-127-K). CDKN3 expression in paired tumor and adjacent nontumor tissues was detected, and the optimal cut-off value of CDKN3 expression was determined using receiver operating characteristic (ROC) curves. Chi-square test, Kaplan-Meier survival analysis, and multivariate logistic regression were applied to evaluate the correlations of CDKN3 expression with clinicopathological characteristics and postoperative recurrence. **Results:** Both TCGA data analysis and clinical sample validation verified that CDKN3 was significantly upregulated in hepatitis B-related HCC tissues ($P < 0.05$). High CDKN3 expression was closely associated with aggressive pathological phenotypes, including poor tumor differentiation, advanced Edmondson grade, and vascular invasion. Multivariate analysis identified CDKN3 as an independent risk factor for 2-year postoperative recurrence in hepatitis B-related HCC patients ($P < 0.01$), with an AUC value of 0.659 for recurrence prediction. The optimal cut-off value of CDKN3 expression was determined as 3.85 based on the ROC curve. Accordingly, patients were stratified into the low-expression group (n = 18) and high-expression group (n = 15). Patients with elevated CDKN3 expression had a markedly higher 2-year recurrence rate and shorter

recurrence-free survival (P < 0.05). **Conclusion:** CDKN3 is abnormally overexpressed in hepatitis B-related HCC. It serves as a reliable indicator for evaluating postoperative recurrence risk and clinical prognosis, which has great potential to be a novel prognostic biomarker and therapeutic target for hepatitis B-related HCC.

4329 | SOCIOECONOMIC DISPARITIES IN TREATMENT PATTERNS AND SURVIVAL OUTCOMES AMONG PATIENTS WITH HEPATOCELLULAR CARCINOMA: A NATIONWIDE POPULATION-BASED COHORT

Heejoon Jang[1] Yookyoung Lim[2], [1]SMG-SNU Boramae Medical Center, [2]Boramae Medical Center

Background: While overall survival of hepatocellular carcinoma (HCC) has improved with advances in treatment, whether survival gains have been distributed equitably across socioeconomic strata remains unknown. We aimed to evaluate income-based disparities in treatment patterns and survival outcomes in a nationwide population-based cohort of patients with HCC. **Methods:** Using the Korean National Health Insurance Service database, we identified 35,050 adult patients newly diagnosed with HCC between January 2009 and December 2024. Income level was categorized into quintiles based on insurance premium–derived household income. The primary outcome was overall survival. Inverse probability of treatment weighting (IPTW) was applied to balance baseline covariates across income groups, and weighted Cox proportional hazards models were used to estimate adjusted hazard ratios (HRs) for mortality. **Results:** Lower-income patients were less likely to receive early-stage treatments — including surgical resection, liver transplantation, and radiofrequency ablation (Q1: 29.3% vs. Q5: 33.9%) — and more likely to receive chemotherapy (Q1: 8.9% vs. Q5: 6.7%), suggesting later-stage presentation at diagnosis among lower-income patients. The proportion of untreated patients was highest in Q1 (19.8%). Compared with Q1, patients in Q5 had significantly lower all-cause mortality, with a dose-response relationship observed across quintiles (adjusted HR 0.74, 95% CI 0.70–0.78). Additionally, income levels tended to decline following HCC diagnosis, suggesting that the disease itself may further widen pre-existing socioeconomic disparities. **Conclusion:** Despite universal health insurance coverage in Korea, lower-income patients with HCC were less likely to receive curative-intent treatment and experienced significantly higher mortality. Income levels further declined following diagnosis, potentially creating a vicious cycle that widens existing disparities. Although HCC surveillance programs are established, strengthening their outreach and utilization among low-income populations is essential to improve early detection and access to curative treatment.

4330 | NEUTROPHIL-TO-LYMPHOCYTE RATIO AND EXTRAHEPATIC SPREAD PREDICT RESPONSE AND SURVIVAL IN UNRESECTABLE HEPATOCELLULAR CARCINOMA

Sung Won Lee[1] Dong Yun Kim[2] Heechul Nam[1] Do Young Kim[2], [1]The Catholic University of Korea, [2]Yonsei University

Background: Identifying patients unlikely to respond to atezolizumab plus bevacizumab (AB) remains a critical challenge in unresectable hepatocellular carcinoma (uHCC). We aimed to develop and externally validate a simple risk scoring system using baseline neutrophil-to-lymphocyte ratio (NLR) and extrahepatic spread (EHS) to predict treatment outcomes. **Methods:** We included 304 patients with uHCC receiving first-line AB from multiple Korean centers, forming discovery (n = 220) and validation (n = 84) cohorts. Study outcomes included objective response rate (ORR) assessed by modified Response Evaluation Criteria in Solid Tumors , overall survival (OS), and progression-free survival (PFS). Multivariable analysis identified high NLR (> 4.575) and EHS as independent predictors of nonresponse. The NLR-EHS score assigned 2 points for high NLR and 1 point for EHS (range, 0–3). **Results:** In the discovery cohort, the score achieved an area under the receiver operating characteristic curve (AUC) of 0.749 (95% CI, 0.688–0.810) for predicting nonresponse, with ORR decreasing progressively: 67.3%, 47.7%, and 8.2% for low- (0), moderate- (1-2), and high- (3) risk groups, respectively ($p < 0.001$). External validation confirmed comparable discrimination (AUC, 0.705; 95% CI, 0.603–0.806), with a consistent ORR gradient of 77.8%, 54.2%, and 22.2% across risk groups ($p < 0.001$). The score maintained prognostic value for OS in both discovery (HR 1.28; $p = 0.003$) and validation cohorts (HR 1.45; $p = 0.007$). High-risk patients had notably inferior median OS (6.9 vs. 17.1 months in validation). **Conclusion:** The NLR-EHS score is a simple, practical tool for stratifying nonresponse risk and survival in uHCC patients receiving AB, facilitating early identification of high-risk patients who may benefit from alternative strategies.

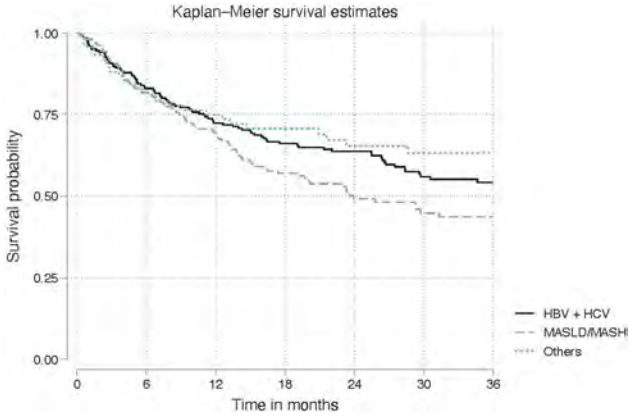
4331 | OVERALL SURVIVAL AMONG PATIENTS WITH HEPATOCELLULAR CARCINOMA RECEIVING SYSTEMIC THERAPY BY UNDERLYING ETIOLOGY: VIRAL VERSUS MASLD/MASH-RELATED DISEASE



Saleh Alqahtani[1] Saleh Alessy[2] Layan Alsubki[2] Amwaj Alanazi[2] Basmah Khoja[2] Alwaleed Almojel[2] Fahad AlMugbel[2] Waleed Alomaim[2] Mona Ismail[3] Marwan AlHajeli[4] Mohammed Alsager[5] Dimitri Raptis[2] Dieter Broering[2] Saad Alghamdi[6] Faisal Abaalkhail[2] Ali Alqahtani[2], [1]King Faisal Specialist Hospital & Research Center, [2]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [3]Imam Abdulrahman bin Faisal University, Dammam, Saudi Arabia, [4]King Abdulaziz University, Jeddah, Saudi Arabia, [5]King Saud University, Riyadh, Saudi Arabia, [6]King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

Background: In recent years, systemic therapy options for hepatocellular carcinoma (HCC) have expanded substantially. However, treatment response and outcomes may vary according to the underlying etiology of liver disease, particularly between metabolic dysfunction–associated steatotic liver disease or its progressive form (MASLD/MASH)-related and viral-related HCC. We aimed to characterize the allocation of systemic therapy among patients with HCC and assess overall survival by etiology, including viral-related, MASLD/MASH-related, and other etiologies. **Methods:** We used data from the HCC registry, a large prospectively maintained registry established in 2020 at King Faisal Specialist Hospital & Research Centre, a major tertiary referral center in Saudi Arabia. Adult patients diagnosed with HCC between January 2020 and December 2025 were included. Systemic therapy exposure was defined as receipt of systemic therapy at baseline or within the first year after diagnosis. Descriptive statistics were used to summarize patient characteristics and treatment allocation. Overall survival among patients receiving systemic therapy was assessed using Kaplan–Meier analysis and Cox proportional hazards models to compare etiology groups. **Results:** Of the 696 patients in the cohort, 18.0% (n = 125) received systemic therapy either as first-line treatment or during another treatment episode within their first year after diagnosis. Most treated patients had intermediate-to-terminal-stage disease, with 60% classified as BCLC stages B, C, or D . The distribution of HCC etiologies was comparable between patients who received systemic therapy and those who did not, with MASLD/MASH being the most common etiology in both groups (35.2% vs. 35.9%), followed by HCV (26.4% vs. 25.2%) and HBV (23.2% vs. 21.7%) (p = 0.939). Patients who received systemic therapy were more likely to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

present with advanced tumor burden, including tumors outside the Milan criteria (60.0% vs 34.3%, p < 0.001) and metastatic disease at diagnosis (24.8% vs 9.3%, p < 0.001), compared with patients who did not receive systemic therapy. After adjusting for sex and BCLC stage, patients with MASLD/MASH-related HCC had a higher risk of mortality than those with viral-related HCC (adjusted HR 1.43, 95% CI 1.05–1.95). **Conclusion:** Among patients receiving systemic therapy for HCC, MASLD/MASH was the major underlying etiology and was associated with worse overall survival compared with viral-related HCC after adjusting for sex and BCLC stage. These findings highlight potential etiologic differences in outcomes among patients treated with contemporary systemic therapies.

4332 | CHANGING LANDSCAPE OF SYSTEMIC THERAPY IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

Danfeng Ren[1] Taotao Yan[1] Xianhua Mao[2] Bowu Chen[3] Hong Fan[2] Ramsey Cheung[2] Mindie Nguyen[2], [1]The First Affiliated Hospital of Xi'an Jiaotong University, [2]Stanford University Medical Center, [3]Shuguang Hospital Affiliated to Shanghai University of Traditional Chinese Medicine

Background: The landscape of systemic therapy utilization for hepatocellular carcinoma (HCC) has changed substantially in recent years, but real-world data on its evolving role is limited. **Methods:** We conducted a retrospective cohort study using the Merative™ MarketScan Research Database to identify adults aged 18 to 90 years with HCC diagnosed from 2008 to 2023. We estimated age-standardized HCC treatment rates by year of HCC diagnosis, overall and by treatment type (systemic and nonsystemic) and their average annual percentage changes (AAPCs) using Joinpoint regression. Among patients who received systemic therapy, treatment patterns were categorized as systemic therapy alone or systemic therapy with other HCC treatments, whether before or after systemic therapy. **Results:** We analysed a total of 45,047 patients with HCC; of these, 5,557 patients (12.3%) received systemic therapy. The use of systemic therapy increased from 8.0% in 2008 to 21.3% in 2022 (AAPC 6.69%, 95% CI 5.14%–8.26%), especially when used alone (AAPC 9.88%, 95% CI 6.86%–12.29%) (Figure 1A). Meanwhile, there was also an increase in the overall treatment rate for HCC from 39.3% in 2008 to 48.5% in 2022 (AAPC 1.42%, 95% CI 0.84%–1.86%) while there was a small decline in nonsystemic treatment (AAPC -0.90%, 95% CI -1.58% to -0.24%) (Figure 1A). Early on (2008–2012), sorafenib was the dominant systemic therapy (98.3%), but the landscape became more diverse afterwards, with atezolizumab+bevacizumab as the most common regimen (36.4%) (Figure 1B). Among patients who received both systemic therapy and other HCC treatments, the majority (70.0% [1,923/2,746]) received other HCC treatments only before systemic therapy initiation, with most of the remaining only after systemic therapy initiation (22.9% [628/2,746]) and transarterial chemoembolization (TACE) as the predominant nonsystemic treatment modality (65.7% [1,264/1,923] and 86.9% [546/628] of patients, respectively). Only 7.1% (195/2,746) received other HCC treatment both before and after systemic therapy initiation. **Conclusion:** HCC treatment rates increased over time, driven largely by increasing use of systemic therapy, especially as stand-alone therapy. When used in combination with other HCC treatment, the most commonly used modality was TACE, regardless of timing. The findings highlight recent therapeutic advances in HCC care and underscore the importance of multimodal HCC management.

4333 | ARTIFICIAL INTELLIGENCE IN HEPATOCELLULAR CARCINOMA ABLATION: A PILOT ANALYSIS OF STUDIES ON CLINICALTRIALS.GOV

Vikram Sivakumar[1] Mohammad Salman[1] Gianluca Ramirez[1] Kat Light[1] Adam Webb[2], [1]Medical College of Georgia, [2]Memorial Health System

Background: Artificial intelligence (AI) applications have played an important role in diagnostic radiology and oncology; however, their integration into interventional oncology (IO) is still maturing. Hepatocellular carcinoma (HCC), as the primary indication for percutaneous ablation, offers an avenue for AI to play a greater role in procedural planning, guidance, and treatment response, expanding beyond diagnostic measures. Understanding the current landscape of AI-integrated clinical studies focusing on HCC ablation is essential to identify translational barriers and opportunities for growth in IO. **Methods:** We systematically searched ClinicalTrials.gov using Boolean operators combining AI-related terms (artificial intelligence, machine learning, deep learning, radiomics) with IO procedural terms (ablation, microwave ablation, cryoablation, radiofrequency ablation). Inclusion criteria required explicit integration of AI technologies in HCC ablation studies. We extracted and analyzed trial characteristics including ablation modality, AI application type, primary endpoints, study design, sponsorship, enrollment targets, imaging platforms, and geographic distribution. **Results:** Eight studies met inclusion criteria; all were observational, single-center, and academically sponsored. Median planned enrollment was 250 (mean: 489). Geographic distribution showed concentration in China (n = 6, 75%), with single studies in France and the Netherlands. Ablation modalities varied: microwave and radiofrequency (25% each), irreversible electroporation (13%), multiple modalities (13%), and unspecified thermoablation (25%). AI applications included treatment simulation (50%), outcome prediction (25%), and radiomics-based biomarker development (25%). Primary endpoints lacked standardization: local tumor control (38%), algorithm performance metrics (25%), and overall survival, progression-free survival, and imaging response (mRECIST) each at 13%. Imaging platforms included multimodal approaches (38%), CT (25%), with MRI and ultrasound each at 13%. **Conclusion:** The clinical study landscape shows important translational gaps. Despite extensive preclinical literature, clinical trial activity remains limited. The concentration of studies in one region limits generalizability and highlights low industry engagement in AI for IO. Studies prioritize prognostic modeling over intraprocedural guidance. Most AI tools remain investigational, emphasizing the need for long-term prospective studies with standardized endpoints and regulatory alignment to advance implementation in HCC ablation. **Disclosures:** Vikram Sivakumar:Nothing to Disclose, Mohammad Salman:Nothing to Disclose, Gianluca Ramirez:Nothing to Disclose, Kat Light:Nothing to Disclose, Adam Webb:Nothing to Disclose.

4334 | THE MAGNITUDE OF HEPATOCELLULAR CARCINOMA IN SAUDI ARABIA: RESULTS FROM A COMPREHENSIVE CLINICAL REGISTRY

Saleh Alessy[1] Waleed Al Hamoudi[1] Lolwa Alobaid[2] Maram Alotaiby[3] Ahmed Alyahya[3] Duna Barakeh[1] Amwaj Alanazi[1] Mussadique Jhatial[1] Mehwish Hussain[1] Fahad AlMugbel[1] Ali Alqahtani[1] Malak Abedalthagafi[4] Marwan AlHajeili[5] Waleed Alomaim[1] Mohammad Mawardi[6] Dieter Broering[1] Saad Alghamdi[7] Faisal Abaalkhail[1] Saleh Alqahtani[1], [1]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [2]King Abdulaziz Medical City, Riyadh, Saudi Arabia, [3]Ministry of Health, Riyadh, Saudi Arabia, [4]Tufts Medical Center and Tufts University School of Medicine, Massachusetts, MA, United States, [5]King Abdulaziz University, Jeddah, Saudi Arabia, [6]King Faisal Specialist Hospital & Research Center, Jeddah, Saudi Arabia, [7]King Faisal Specialist Hospital and Research Center

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related morbidity and mortality worldwide, with substantial regional variations in its epidemiology, etiology, clinical presentation, and outcomes. Understanding the patterns and underlying causes of HCC in Saudi Arabia is critical for developing targeted prevention and management strategies. This study aimed to describe the prevalence, clinical characteristics, and survival outcomes of HCC in Saudi Arabia using a large clinical registry. **Methods:** Data were collected from the HCC registry, at King Faisal Specialist Hospital and Research Center (KFSHRC), a tertiary referral center estimated to manage about 30% of HCC cases in the country. Cases diagnosed between 2020 and 2026 were identified from oncology services and multidisciplinary tumor boards. Data collected included demographics, etiologies, and clinical presentations, as well as mortality data linked

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

through the National Death Registry at the Ministry of Health. **Results:** Our analysis included 693 cases, of which 70% were male (2.3:1 male-to-female ratio), and the median age at diagnosis was 64.0 years. Metabolic dysfunction-associated steatotic liver disease and steatohepatitis (MASLD/MASH) were the most common etiologic category, accounting for 35.6% of cases, followed by hepatitis C virus (24.8%) and hepatitis B virus (22.4%). A history of smoking (current or former) was reported in 16.6% of patients, diabetes in 56.7%, and hypertension in 48.5%. Most patients (94.2%) were diagnosed by imaging. Early-stage disease (BCLC stage 0 or A) was observed in 40.9%, while 12.4% had no underlying cirrhosis[BAN1] [SAA2] . Locoregional therapy was the most common first treatment at KFSHRC (44.9%), followed by surgery (15.3%) and systemic therapy (13.3%). Overall survival at 12 and 36 months was 71.4% and 51.0%, respectively. **Conclusion:** The KFSHRC registry provides valuable insights into the epidemiology and survival outcomes of HCC in Saudi Arabia. MASLD/MASH were the leading etiologic category of HCC, surpassing both HBV and HCV, reflecting a major etiological transition in Saudi Arabia. The relatively high proportion of early-stage HCC in this registry may reflect referral bias, as KFSHRC is the country's largest transplant center, leading to an over-representation of patients suitable for curative interventions.

4335 | ESTABLISHMENT OF A PATIENT-DERIVED RAT MODEL OF HEPATOCELLULAR CARCINOMA FOR ENDOVASCULAR LOCOREGIONAL THERAPY AND SYSTEMIC THERAPY

Austin Zhang[1] Yohan Kim[1] Eleanna Kaffe[2] Ariful Islam[2] George McClung[2] Kelley Weinfurtner[2] David Tischfield[2] Terence Gade[2], [1]Perelman School of Medicine, University of Pennsylvania, [2]University of Pennsylvania

Background: Locoregional therapies (LRT), such as transarterial chemoembolization, and systemic therapies, such as immune checkpoint inhibitors, represent major treatment modalities for hepatocellular carcinoma (HCC), yet animal models that enable the study of these approaches in combination are lacking. Although patient-derived xenograft models of HCC exist in mice, their vasculature is too small to accomodate LRT. The rat is the smallest animal in which clinically relevant LRT techniques can be performed, while also being more practical than larger animals for studying treatments at scale. This study aims to establish a patient-derived orthotopic xenograft (PDOX) rat model of HCC for the preclinical study of combination LRT and systemic therapies. **Methods:** First, rat HCC PDOXs were generated by orthotopic implantation of tumor fragments from human HCC biopsy-derived PDX tumors, initially expanded in immunodeficient mice, into immunodeficient SRG rats (Rag2/Il2rg 2xKO). Tumor size was monitored weekly via T2 MRI. Rats with tumors $\geq 180mm^3$ were randomized into treatment groups including transarterial embolization (TAE), performed in an angio suite using a Siemens Artis Pheno robotic C-arm, 1.7Fr microcatheter, and 40-120µm particle embolic, with post-procedure MRI follow-up. Second, rats with humanized livers and immune system chimerism were generated in immunodeficient RRGS rats (Rag1/Il2rg 2xKO, hSIRPα). Conditioning with retrorsine (30mg/kg) was performed at age 4 weeks. At 8 weeks, myeloablation via irradiation (4Gy) was followed by 80% partial hepatectomy and intrasplenic injection of 3×10^6 human hepatocytes and 3×10^5 human CD34+ hematopoietic stem cells. Human liver and immune chimerism were assessed at 14 weeks via proteomics and flow cytometry, respectively. **Results:** Engraftment rates across 4 patient lines reached 70-100%. Growth curves showed variable kinetics reflecting inter-patient tumor heterogeneity. TAE was reproducibly performed, with embolized tumors showing reduced growth compared to controls. Liver chimerism assessment across

174 rat-only or human-only proteins showed equal abundance of each, demonstrating ~50% chimerism. Flow cytometry revealed ~25% abundance of hCD45 cells, confirming partial immune chimerism. **Conclusion:** This novel rat HCC PDOX model enables endovascular locoregional intervention and longitudinal imaging, while partial humanization of the liver and immune system provide a foundation for evaluating combination locoregional and systemic therapies. As such, it represents a promising preclinical platform for translational studies of HCC treatment. Given the importance of endothelial and immune microenvironments in HCC, this work lays the foundation for a translational model that better recapitulates the heterogeneity of human disease encountered in clinical practice, thereby enabling preclinical study of combination LRT and systemic therapy.

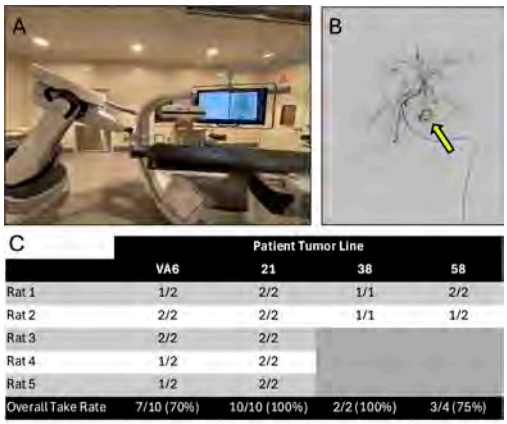

Fig. HCC PDOX Data: embolization procedure, tumor engraftment, growth kinetics, post-embolization response.
(A) Angio suite and C-arm used for embolization procedure. (B) Digital subtraction angiography performed during embolization procedure with tumor location denoted by arrow. (C) Take rates for tumors of 4 different patient lines implanted into SRG rats to generate HCC PDOX, numerator denoting successfully engrafted tumors and denominator denoting how many tumors were implanted into each rat. (D) Tumor growth curves based on MRI volumetric segmentation. (E) Growth rates of embolized (n=5) vs non-embolized tumors (n=2).

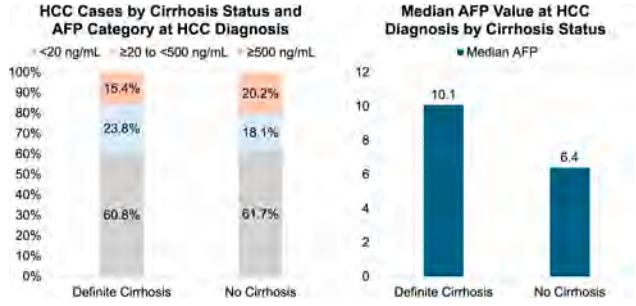
4336 | HIGH SERUM ALPHA-FETOPROTEIN VALUES (≥500 NG/ML) ARE MORE COMMON AT DIAGNOSIS IN NON-CIRRHOTIC THAN CIRRHOTIC HEPATOCELLULAR CARCINOMA



Nicole Kim[1] Philip Vutien[1] Bret Mecham[2] Vyshnika Sriskantharajah[2] Elliott Lowy[2] Kristin Berry[2] George Ioannou[2], [1]University of Washington, [2]Veterans Affairs Puget Sound Health Care System

Background: Elevated serum alpha-fetoprotein (AFP) values correlate with more advanced stage hepatocellular carcinoma (HCC) and poor prognosis. We aimed to examine serum AFP values at HCC diagnosis by cirrhosis status and etiology of liver disease. **Methods:** We identified U.S. Veterans diagnosed with incident HCC between 1/1/2014 and 10/26/2025. Cirrhosis status was categorized as “definite” based on ICD-codes for cirrhosis and/or related complications within 1 year of the HCC diagnosis date, “probable” based on not meeting criteria for definite cirrhosis but having a FIB-4 score >3.25 or a transient elastography liver stiffness measurement >12.5 kPa within 2 years before or 6 months after the HCC diagnosis date, and “no cirrhosis” based on not meeting criteria for definite and probable cirrhosis. Serum AFP values obtained on or within 6 months before or after the date of HCC diagnosis were reviewed. Descriptive statistics were used to compare median and categories of AFP values by cirrhosis status and etiology of liver disease. **Results:** A total of 25,625 U.S. Veterans diagnosed with HCC during 2014-2025 had an AFP value around the time of their HCC diagnosis. Of these patients, 81%, 3.7%, and 15.6% had definite, probable, and no cirrhosis respectively. Patients without cirrhosis had a lower median AFP value at HCC diagnosis than those with definite or probable cirrhosis (6.4 vs. 10.1 vs. 35.1 ng/mL; $p<0.001$, Figure), and a similar proportion of patients with definite and no cirrhosis had an AFP value <20 ng/mL at the time of HCC diagnosis (61% vs. 62%). However, a greater proportion of patients with non-cirrhotic HCC than those with definite cirrhosis and HCC had an AFP value ≥500 ng/mL at the time of HCC diagnosis (20.2% vs. 15.4%; $p<0.001$, Figure). These findings persisted across liver disease etiologies, including hepatitis C, metabolic-dysfunction associated steatotic liver disease, and alcohol-related liver disease ($p<0.001$). **Conclusion:** A very high proportion (20.2%) of patients with non-cirrhotic HCC have

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

very high AFP values ≥500 ng/mL at the time of diagnosis. This suggests late diagnosis at advanced stages of HCC and is associated with poor prognosis. These findings support the need to develop rational HCC surveillance strategies to enhance early detection of non-cirrhotic HCC.

4337 | HEPATOCELLULAR CARCINOMA IN AUTOIMMUNE LIVER DISEASES: A SINGLE-CENTRE CASE SERIES

Shubham Jain[1] Arnav Aggarwal[2] Ayush Agarwal[2] Sarthak Saxena[3] Sudipta Nandi[2] Ankush Garg[2] Vishal Singh Chauhan[2] Samagra Agarwal[2] Sagnik Biswas[4] . Shalimar[2], [1]All India Institute of Medical Sciences, New Delhi, [2]All India Institute of Medical Sciences , New Delhi, [3]All India Institute of Medical Sciences, Delhi, [4]All India Institute of Medical Sciences New Delhi

Background: Hepatocellular carcinoma (HCC) is a rare but increasingly recognised complication of autoimmune liver diseases (AILD). Despite growing recognition of AILD-associated HCC, data regarding its clinical presentation, tumour characteristics, treatment outcomes, and survival remain limited. We aimed to evaluate the clinicopathological profile and overall survival outcomes of patients with AILD-associated HCC in a tertiary care centre. **Methods:** We conducted a retrospective observational study of 13 patients with AILD-related HCC treated at a tertiary care centre. We analysed demographic, biochemical, radiological, staging, treatment, and outcome data. The Barcelona Clinic Liver Cancer (BCLC) staging system was used to assess tumour burden. Overall survival (OS) was calculated from the date of HCC diagnosis until death or the last follow-up. **Results:** Among the 13 patients, underlying aetiologies included autoimmune hepatitis (AIH) in 9 (69.2%), primary biliary cholangitis (PBC) in 2 (15.4%), AIH-PBC overlap syndrome in 1 (7.7%), and AIH-primary sclerosing cholangitis overlap syndrome in 1 patient (7.7%). Six patients (46.2%) had HCC at the time of initial AILD diagnosis, while 7 (53.8%) developed HCC during follow-up. The median duration from AILD diagnosis to HCC development was 66 months [interquartile range (IQR) 51.5–126.5]. BCLC stage A was the most common stage at presentation. The median tumour size was 3.05 cm [IQR 2.3–6.5] while one had an infiltrative lesion. Portal vein thrombosis and extrahepatic metastases were infrequent. Treatment modalities included transarterial chemoembolization (TACE) in 4 patients (30.8%), transarterial radioembolization (TARE) in 1 (7.7%),microwave ablation (MWA) in 2 (15.4%), percutaneous acetic acid injection (PAI) in 2 (15.4 %), stereotactic body radiation therapy (SBRT) in 1 (7.7 %), lenvatinib-based systemic therapy in 2 (15.4%) and immunotherapy in 2 (15.4%) according to tumour stage and hepatic function with median Child–Turcotte–Pugh (CTP) score at HCC diagnosis being 7 [IQR 6–9] . No patient received a transplant during the follow-up. Kaplan–Meier survival analysis demonstrated poor overall survival following HCC diagnosis. Median overall survival was 4.5 months [IQR 2–12], with an estimated survival probability of approximately 54% at 6 months, declining to 31% at 12 months. **Conclusion:** In our cohort, AILD-related HCC was linked to poor survival after diagnosis, even with locoregional and systemic therapies. This aligns with findings from earlier case series of AIH and overlap syndrome related HCC and highlights the need for regular surveillance and better risk assessment in patients with AILD for earlier HCC detection.

4338 | BASELINE ALPHA-FETOPROTEIN PREDICTS SURVIVAL IN PATIENTS WITH HEPATOCELLULAR CARCINOMA: A PROSPECTIVE BRAZILIAN COHORT STUDY

Rodrigo Cambraia[1] Diego Vieira[1] Geraldo Pereira[1] Osvaldo Flávio Couto[1] Lincoln Cordeiro da Mata[1] Antônio Orlando Neto[1] Rosangela Teixeira[2], [1]Hospital das Clínicas (EBSERH/UFMG), School of Medicine, Federal University of Minas Gerais, [2]Federal University of Minas Gerais

Background: Although alpha-fetoprotein (AFP) is widely used for hepatocellular carcinoma (HCC) surveillance and diagnosis, the prognostic significance of lower AFP thresholds remains insufficiently validated in real-world cohorts. This study evaluated the prognostic value of baseline AFP levels in patients with HCC. **Methods:** Patients with HCC were prospectively enrolled between 2019 and 2024. Diagnosis and staging were established according to LI-RADS and Barcelona Clinic Liver Cancer (BCLC) classification. Clinical and imaging data were collected at baseline and reassessed every 3–4 months or as clinically indicated. Overall survival (OS) was estimated using the Kaplan–Meier method and compared by log-rank test. Variables with $p \leq 0.20$ in univariate analyses were included in multivariable Cox proportional hazards models. The study was approved by the local Ethics Committee, and all participants provided written informed consent. **Results:** A total of 206 patients were included (mean age: 67.4 ± 9.6 years; 76.7% male), with a median follow-up of 16.0 months (IQR: 8.0–30.0). Baseline AFP levels were ≤20 ng/mL in 102 patients (49.5%) and >20 ng/mL in 104 (50.5%). During follow-up, 74 HCC-related deaths (35.9%) occurred. Estimated mean OS for the entire cohort was 38.3 months (95% CI: 34.5–42.0). Early-stage HCC (BCLC 0/A) was more frequent among patients with AFP ≤20 ng/mL (60.2% vs. 36.5%). AFP >20 ng/mL was associated with higher HCC-related mortality (67.6% vs. 40.9%; $p < 0.001$) and shorter OS (30.3 vs. 46.3 months; $p < 0.001$). Additional predictors of worse survival included advanced BCLC stage ($p < 0.001$) and ALBI grade II/III ($p = 0.001$). In univariate analyses, AFP >20 ng/mL was associated with impaired liver function (Child-Pugh B/C: 29.7% vs. 15.9%; $p = 0.03$), larger tumors (55.5 mm vs. 41.5 mm; $p = 0.02$), and higher prevalence of portal vein tumor thrombosis (14.1% vs. 2.1%; $p = 0.003$). In multivariable analysis, AFP >20 ng/mL remained independently associated with HCC-related mortality (adjusted hazard ratio [aHR]: 2.07; 95% CI: 1.21–3.50; $p = 0.008$). Likewise, BCLC stage B (aHR: 2.06; 95% CI: 1.10–3.86; $p = 0.02$), BCLC stage C/D (aHR: 2.69; 95% CI: 1.35–5.33; $p = 0.005$), and ALBI grade II/III (aHR: 1.89; 95% CI: 1.09–3.27; $p = 0.02$) were independently associated with poorer survival. **Conclusion:** Baseline AFP >20 ng/mL was independently associated with worse survival in HCC, conferring mortality risk comparable to advanced tumor stage and impaired liver function. These findings suggest that relatively low AFP thresholds may improve prognostic stratification and identify patients with more aggressive tumor biology.

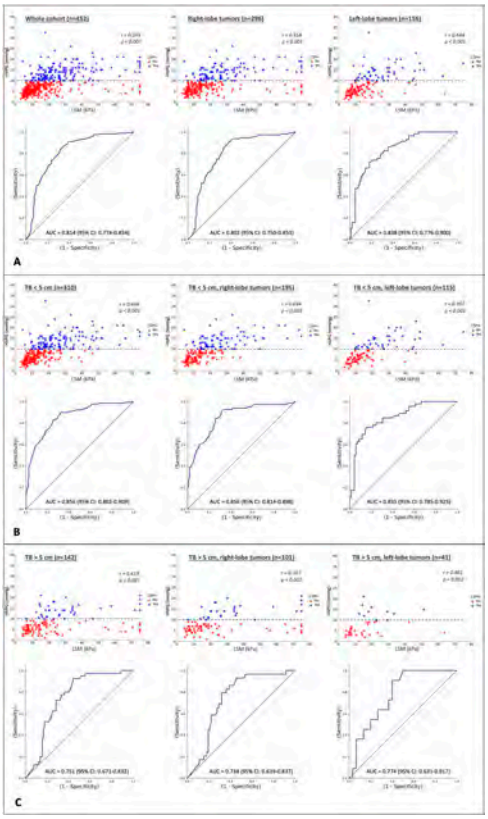
4339 | NONINVASIVE PREDICTION OF CLINICALLY SIGNIFICANT PORTAL HYPERTENSION IN HEPATOCELLULAR CARCINOMA: A TUMOR-ADJUSTED MODEL



Coskun Demirtas[1] Catherine Mezzacappa[2] Riccardo Sartoris[3] Pierre-Emmanuel Rautou[4] Mario Romero-Cristóbal[5] Rafael Banares Canizares[5] Cosmina Sutac[6] Bogdan Procopet[6] Manon Allaire[7] Dominique Thabut[7] Elba Llop[8] Juan Carlos Garcia-Pagan[9] Muthukumarassamy Rajakannu[10] Eric Vibert[10] Tamar Taddei[11] Guadalupe Garcia-Tsao[11], [1]Marmara University School of Medicine, [2]Yale School of Medicine, [3]AP-HP, University Hospitals Paris Nord Val-de-Seine, [4]Université Paris-Cité, Inserm, Centre de recherche sur l'inflammation, [5]Liver Unit, Hospital General Universitario Gregorio Marañón, Instituto de Investigación Sanitaria, [6]"Prof. Dr. Octavian Fodor" Regional Institute of Gastroenterolog, [7]AP-HP Sorbonne Université, Hôpital Universitaire Pitié-Salpêtrière, [8]Hospital Universitario Puerta de Hierro Majadahonda, [9]Hospital Clinic, [10]Centre Hépato-Biliaire, AP-HP Hôpital Paul Brousse, [11]Yale University

Background: Noninvasive assessment of clinically significant portal hypertension (CSPH) using liver stiffness measurement (LSM) and platelet count (per Baveno VII criteria) may be influenced by tumor-related factors in patients with hepatocellular carcinoma (HCC). We evaluated the relationship between LSM and hepatic venous pressure gradient (HVPG) and developed a tumor-adjusted model for CSPH prediction in HCC. **Methods:** In this multicenter study, 452 patients with compensated cirrhosis and HCC who underwent LSM by vibration-controlled transient elastography (VCTE) and HVPG measurement within three months across six tertiary centers were retrospectively analyzed. The correlation between LSM and HVPG was assessed using Spearman correlation analyses, including stratification by tumor characteristics. CSPH was defined as HVPG ≥10 mmHg. A tumor-adjusted predictive model (Baveno-HCC) was developed in a derivation cohort (n = 316) and validated in an independent cohort (n = 136). Model discrimination, calibration, and clinical utility were evaluated using AUROC analysis, calibration plots, Hosmer-Lemeshow testing, and decision curve analysis. **Results:** LSM correlated moderately with HVPG overall ($r = 0.593$, $p < 0.001$; AUC = 0.814), with substantially reduced performance in patients with tumor burden >5 cm, particularly with right-lobe involvement ($r = 0.357$; AUC = 0.738). Baveno

VII criteria maintained high rule-out performance (negative predictive value >90%, sensitivity >87%) across subgroups but showed limited rule-in accuracy in patients with tumor burden >5 cm (positive predictive value [PPV] 50.0% and specificity 70.4%). The Baveno-HCC model, incorporating LSM, platelet count, spleen size, and tumor burden, improved rule-in performance of CSPH, with higher PPV and specificity while preserving rule-out accuracy. Improvements were most pronounced in patients with tumor burden >5 cm, with PPV increasing from 46.2% to 84.6% in the derivation cohort and from 56.3% to 100.0% in the validation cohort, and with specificity improving from 72.6% to 95.8% in the derivation cohort and from 65% to 100.0% in the validation cohort. Indeterminate classifications were also reduced (41.8% to 38.7%). The Baveno-HCC model demonstrated strong discrimination (AUROC = 0.884 in the derivation cohort; 0.860 in the validation cohort) with improved calibration and net benefit on decision curve analysis. **Conclusion:** Tumor burden and location affect LSM-based CSPH assessment in HCC. The proposed Baveno-HCC model, incorporating readily available clinical variables, improves CSPH prediction and supports more accurate risk stratification and clinical decision-making in patients with HCC.

4340 | AN EDGE-DEPLOYABLE REPVIT FRAMEWORK FOR ZERO-SHOT SEGMENTATION AND AUTOMATED CLASSIFICATION OF FOCAL LIVER LESIONS ON B-MODE ULTRASOUND

Elangovan Krishnan[1] Kavin Elangovan[2] Nayanika Tummala[3] Jansi Sethuraj[4] Ramya Elangovan[5] Namratha Cherukuru[3] Gautam Maddineni[6] Giulio Quarta[3] Tarun Sharma[3] Mushtaq Jaghuri[2], [1]Indian Institute of Technology Bombay, [2]AIM, [3]NYMC ST Mary's General Hospital St Clares, [4]The University of Texas Health Science Center at Houston, [5]Johns Hopkins University, [6]Creighton University

Background: Hepatocellular carcinoma (HCC) is the most prevalent primary liver malignancy, accounting for over 900,000 new cases annually worldwide. B-mode ultrasound remains the frontline screening modality, yet radiological differentiation from benign hemangioma is unreliable, particularly in cirrhotic liver parenchyma. Contemporary deep learning classifiers achieve high benchmark accuracy but rely on computationally intensive architectures, including multi-branch attention networks and vision transformers, that are impractical for point-of-care or resource-limited deployment. Lightweight, edge-deployable models that preserve diagnostic fidelity without GPU dependency represent an unmet clinical need. **Methods:** We developed a two-stage diagnostic pipeline employing Re-parameterised Vision Transformer (RepViT) architectures. Stage 1 used LiteMedSAM, a promptable foundation segmentation model, to isolate focal liver lesions and eliminate background parenchymal confounders. Stage 2 applied a RepViT classifier to the segmented lesion masks to distinguish HCC from hemangioma. Models were trained and internally validated on SMC-LUD, a high-quality

public dataset of 5,385 histopathologically and radiologically confirmed B-mode ultrasound images from 1,021 patients (Samsung Medical Centre, 2015–2024), with patient-level train/validation/test partitioning (70:20:10). External validation was conducted on the TCIA B-mode liver dataset. Performance was assessed by AUROC, sensitivity, specificity, F1, and F2 scores. **Results:** Stage 1 segmentation yielded a Dice Similarity Coefficient of 0·89. On internal validation, the RepViT classifier achieved an accuracy of 95%, sensitivity 94%, specificity 96%, AUROC 0·98, F1-score 95%, and F2-score 95%, while requiring less than 1 second per image on a standard CPU without GPU acceleration. **Conclusion:** A lightweight, two-stage RepViT pipeline achieves clinically competitive HCC-versus-hemangioma classification on B-mode ultrasound with edge device deployability, offering a practical solution for real-time liver lesion triage in resource-limited settings. Limitations include single-centre training data and a binary classification scope; prospective multicentre validation and extension to additional focal liver lesion subtypes are warranted.

4341 | A CASCADED MULTI-TASK AI MODEL FOR TUMOR GRADE, FIBROSIS STAGE, AND MICROVASCULAR INVASION ASSESSMENT IN HEPATOCELLULAR CARCINOMA WHOLE SLIDE IMAGE

Yan Miao[1] Philip Yu[2] Tak-Siu Wong[3] Regina Lo[1] Rex Wan-Hin Hui[1] Ho-Ming Cheng[1] Lung Yi Mak[1] Man-Fung Yuen[1] Wai-Kay Seto[1], [1]The University of Hong Kong, [2]Education University of Hong Kong, [3]Pamela Youde Nethersole Eastern Hospital

Background: Hepatocellular carcinoma (HCC) pathology reports usually include tumor grading, background fibrosis staging, and microvascular invasion (MVI). All of them facilitate postoperative risk assessment and clinical management. Most artificial intelligence models for liver pathology predict these findings separately, although pathologists assess tumor morphology, fibrosis and vascular invasion simultaneously during the same slide review. We developed CIPHER, a cascaded multi-task model that predicts these three HCC characteristics from hematoxylin and eosin (H&E) whole slide images (WSIs) in a single workflow. **Methods:** The present study included 2,246 H&E WSIs from 319 surgically resected HCC patients at Queen Mary Hospital, Hong Kong. Two board-certified pathologists with more than 10 years of experience annotated tumor grade as G1, G2, or G3, fibrosis as F0-F1, F2-F3, or F4, and MVI as present or absent. Each WSI was divided into tissue-containing patches after color-based quality filtering, and each retained patch received annotation-based labels while preserving its slide coordinates. Up to 1,000 patches per slide were sampled with class-aware weights to reduce dominance by common tissue regions. CIPHER used a pretrained pathology foundation model, UNI, with task-adapted tumor and fibrosis encoders, followed by a transformer-based slide aggregator. Three prediction classifiers at the end of the pipeline were arranged as a clinical cascade: grade first, then fibrosis informed by the grade probabilities, and MVI informed by both grade and fibrosis probabilities. Task masks were used during training so that each slide contributed only to prediction tasks with available reference labels. **Results:** Experiments were performed on a held-out test set. Microvascular invasion was present in 26.1% (n = 586) of slides. For tumor grading, Area Under the Curve (AUC) was 0.967 (95% CI 0.931-0.992), sensitivity was 0.887 (0.746-0.977), specificity was 0.930 (0.870-0.979), positive predictive value (PPV) was 0.870 (0.714-0.962), and negative predictive value (NPV) was 0.918 (0.857-0.967). For fibrosis stage, AUC was 0.985 (0.966-0.997), sensitivity was 0.891 (0.785-0.983), specificity was 0.974 (0.943-0.999), PPV was 0.903 (0.794-0.993), and NPV was 0.983 (0.957-0.997). For MVI status, AUC was 0.982 (0.965-0.995), sensitivity was 0.946 (0.885-0.988), specificity was 0.944 (0.906-0.976), PPV was 0.886 (0.812-0.949), and NPV was 0.974 (0.945-0.994). **Conclusion:** CIPHER predicted three slide-level HCC findings in a single workflow that follows how a pathologist interprets liver histology in a real-world setting, with strong diagnostic performances for tumor grading, fibrosis staging, and MVI. A cascaded multi-task design that respects the clinical reading order may help bring AI assistance closer to routine HCC sign-out.

4342 | LIVER AND PREGNANCY OUTCOMES ASSOCIATED WITH HEPATIC ADENOMAS IN PREGNANCY: A SINGLE-CENTER RETROSPECTIVE COHORT STUDY

Clara McNatt[1] Maria Anzola-Schnell[2] Scarlet Yang[2] Tatyana Kushner[2], [1]Weill Cornell Medicine - Division of GI and Hepatology, [2]Weill Cornell Medicine

Background: Hepatocellular adenomas (HCAs) are at risk of growth, bleeding, and rupture in the context of pregnancy. Current guidelines recommend resection or embolization of HCAs > 5cm prior to conception, yet risks of adverse pregnancy outcomes (APOs) in this population remain poorly understood. **Methods:** We performed a single-center retrospective cohort study of HCAs diagnosed before or during pregnancy since 2010. Medical records were reviewed for demographics, HCA characteristics, treatment, and pregnancy outcomes. **Results:** We identified a total of 24 patients with HCAs diagnosed before or during pregnancy. Median age at diagnosis was 29.5 years, median BMI was 23.9, 21% were Hispanic, 54% white, 16% Black, and 21% Other. HCAs ranged in size from 0.6cm-14.8cm (median 4.0cm) (Table). Ten (42%) patients underwent surgery (partial hepatectomy or sectionectomy) or embolization, which was performed a median of 3.5 years prior to pregnancy. Among HCAs resected, median size was 6.8cm. Thirteen (54%) patients had HCAs that were not treated surgically; of those, median size was 2.6cm (Table). Four (31%) of these patients experienced growth during pregnancy, including two who developed new HCAs; 3 of these 4 patients had at least one lesion measuring over 5cm at baseline, and 2 had multiple lesions. Two patients experienced hemorrhagic complications: one was a case of intratumoral hemorrhage, which was monitored until delivery, and one was a rupture at 26 weeks requiring prompt surgical removal. Both patients delivered at term without complication. Rates of APOs were similar between patients who had pre-pregnancy resection and those who did not. Among those post-resection, 6 had APOs: 2 had GDM, 2 had ICP, 1 had gHTN, and 1 had PEC with severe features. Among those without pre-pregnancy resection, 2 had GDM and 2 had PEC, 1 with severe features. **Conclusion:** Our real-world retrospective cohort showed that 69% of HCAs did not show intra-pregnancy growth, and only 31% did. Patients with larger (>5cm) or multiple HCAs at baseline were more likely to exhibit growth during pregnancy. Pregnancy outcomes were similar between patients with remaining HCAs and those post-resection. Hemorrhage occurred in only two cases, perhaps suggesting a lower risk of complication than previously thought. This study reinforces current guidelines to resect adenomas greater than 5cm prior to pregnancy

4343 | VALIDATION OF A BIOMARKER-DERIVED INDEX IN PREDICTING HCC DEVELOPMENT IN PATIENTS WITH LI-RADS 3 OR 4 LESIONS

Jeff Liang[1] Ashley Kim[1] Mai Abdusamad[1] Naomy Kim[1] Zoe Berman[2] Jasmine Gamez[2] Lixia Wang[1] Hyunseok Kim[1] Yun Wang[1] Aarshi Vipani[1] Walid Ayoub[1] Paul Martin[1] Alexander Kuo[1] Tsuyoshi Todo[1] Irene Kim[1] Georgios Voidonikolas[1] Todd Brennan[1] Steven Wisel[1] Justin Steggerda[1] Kambiz Kosari[1] Nicholas Nissen[1] Tyler Sandow[3] Rola Saouaf[1] Paul Thevenot[3] Neil Mehta[2] Ju Dong Yang[1], [1]Cedars-Sinai Medical Center, [2]University of California, San Francisco, [3]Ochsner Medical Center

Background: LI-RADS 3 (LR3) and LI-RADS 4 (LR4) lesions pose a diagnostic dilemma and management often requires a multidisciplinary discussion. In a prior study, we developed an index based on the biomarkers, AFP- **L** 3%, **A** FP, and **D** CP—termed the LAD score—that had good performance for detecting viable hepatocellular carcinoma (HCC) after HCC treatment. In this study, we aim to evaluate the accuracy of the LAD score in predicting the progression of LR3 and LR4 lesions to HCC. **Methods:** We identified patients with cirrhosis or chronic hepatitis B infection who had the biomarkers AFP, AFP-L3%, and DCP measured between January 2020–January 2026. We analyzed patients with CT or MRI features of LR3 or 4. The LAD score, obtained within 3 months from imaging, is calculated from the following formula:-0.3695 + 0.6915×log(AFP) + 0.0414×AFP-L3% + 1.180×log(DCP)Positivity is defined as a score $\geq$ 0.927. Diagnosis of HCC was determined by characteristic imaging findings (LR-5) on subsequent imaging or histology. Patients taking Coumadin and those with existing HCC were excluded, although patients who achieved remission after HCC treatment were included. Multivariate Cox regression and AUROC of the LAD score in predicting progression to HCC were calculated, and a Kaplan-Meier plot was used to estimate the incidence of HCC diagnosis over time. **Results:** A total of 201 patients were included. The mean age was 62 years, and 59% were male. HCV and alcohol were the predominant etiologies of HCC (57%). 67% and 33% had LR3 and LR 4 lesions, respectively. Roughly one-quarter of the patients had a history of previously treated HCC with no residual tumor at the time of imaging and blood collection.A total of 56 (28%) patients had a positive LAD score and 66 (33%) patients developed HCC with a median follow-up of 5.0 months. After adjusting for demographic covariates, patients with a positive LAD score were significantly more likely to develop HCC than those with a negative LAD score (HR 3.65, 95% CI 2.18-6.12, $P < 0.01$). The LAD score predicted HCC development in the subset of patients with LR3 (HR 2.24, 95% CI 1.12-4.48, $P = 0.02$), LR4 (HR 9.42, 95% CI 3.15-28.1, $P < 0.01$), and with (HR 2.41, 95% CI 1.10-5.27, $P < 0.01$)/without (HR 5.61, 95% CI 2.84-11.1, $P < 0.01$) prior history of HCC (Figure). The AUROC of the LAD score for predicting HCC development was 0.69 (95% CI: 0.59-0.79) and 0.79 (95% CI: 0.67-0.92) for patients with LR3 and LR4 lesions, and 0.75 (95% CI: 0.62-0.88) and 0.76 (95% CI: 0.66-0.86) for patients with, without prior history of HCC, respectively. **Conclusion:** We found that a positive LAD score is associated with HCC development in patients with LR3 and LR4 lesions. These findings suggest that the LAD score may be a useful adjunct in predicting HCC among patients with indeterminate liver lesions (LR-3/4).

★ 4344 | SPLENIC STIFFNESS MEASUREMENT TO PREDICT THE ESOPHAGEAL VARICES IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

Sayan Malakar[1] Mayank Agarwal[2] Virendra Singh[1] Sumit Rungta[3] Tushar Kundu[2] Amandeep Singh[4] Jahnvi Dhar[1] Nitesh Bassi[5] Upasna Rajput[1] Anmol Anmol[1], [1]Punjab Institute of Liver and Biliary Sciences, [2]King George Medical University, [3]KGMU, [4]Punjab Institute of Liver and Billiary Sciences, [5]Punjab Institute of Liver and Bilary Sciences

Background: The presence of clinically significant portal hypertension (CSPH) and its complications pose significant challenges in hepatocellular carcinoma (HCC) management. Presence of high risk esophageal varices (HREV) can be associated with bleeding following immune-check-point inhibitor therapy. Liver resection is contraindicated the presence of CSPH in patients with HCC. Hence, non-invasive tests to detect CSPH in HCC is worth exploring. Hepatic venous pressure gradient (HVPG) measurement is the gold standard; however, it is an invasive test and requires expertise. Hence, we aimed to explore the role of splenic stiffness measurement (SSM) to predict EV in patients with HCC. **Methods:** This cross-sectional study included 220 patients with HCC who underwent transient elastography evaluation for SSM and liver stiffness measurement (LSM). Patients with ascites, overt hepatic encephalopathy, history of variceal bleeding and splenic space occupying lesions were excluded. Patients were categorised according to the presence or absence of EV and high-risk EV (HREV). Receiver operating characteristic (ROC) curve analysis was performed to determine the diagnostic accuracy of LSM and SSM for predicting EV and HREV. **Results:** The age at presentation was 53.9 ± 11.5 years [male: 181 (82.3%]. The most common etiology of HCC was chronic hepatitis C [83 (37.7%)]. Among 220 patients with HCC, 167 (75.9%) had EV, and 18 (8.2%) had HREV. Patients with EV had significantly higher LSM [48.59 ± 19.84 kPa vs 26.33 ± 11.80 kPa; $p < 0.001$] and SSM [57.50 ± 16.03 kPa vs 42.87 ± 13.50 kPa; $p < 0.001$]. SSM demonstrated superior diagnostic performance compared with LSM for predicting EV [area under the receiver operating curve (AUROC): 0.89 and 0.8] and HREV [AUROC: 0.93 and 0.72], respectively (Table 1 and figure 1). An SSM cut-off of 49.5 kPa has a sensitivity of 88.5% and a specificity of 86.7% for predicting EV in patients with HCC. **Conclusion:** SSM is a better tool to predict EV and HREV in patients with HCC.

4345 | TARGETING HYPOGLYCOSYLATED MUC1 USING SCFV TO DEVELOP NOVEL RADIOTHERANOSTIC AGENTS FOR CHOLANGIOCARCINOMA

Piyushkumar Gondaliya[1] Dylan Zinn[2] Irene Yan[2] Julia Driscoll[2] Christian Ogaugwu[2] Vijayalakshmi Kancharla[2] Wenhui Fu[2] Joshua Knight[2] Adinarayana Kunamneni[2] Hancheng Cai[2] Tushar Patel[2], [1]Mayo Clinic, [2]Mayo Clinic Florida

Background: Cholangiocarcinoma (CCA) is an aggressive malignancy that is challenging to diagnose and to treat. Hypoglycosylated mucin-1 (MUC1) is highly expressed on CCA cells and exposes tumor-specific epitopes that can be selectively targeted. We developed novel single-chain variable fragment antibodies (scFvs) against hypoglycosylated MUC1 and evaluated their therapeutic and radiodiagnostic potential in CCA **Methods:** BALB/c mice were immunized with a MUC1 variable number tandem repeat (VNTR) peptide, and a high-diversity scFv library was generated from splenocyte RNA. Ribosome display technology was used to isolate high-affinity MUC1-binding scFvs. Binding specificity was assessed by ELISA, flow cytometry, and immunocytochemistry in human CCA cell lines (HuCCT1, SNU1079, and KMCH). Functional effects on tumor cell viability were evaluated using MTS assays. Biodistribution and tumor tropism were assessed in orthotopic xenograft mouse models using fluorescently labeled scFvs. scFv-8 was radiochemically conjugated with Gallium-68 (68Ga), and its diagnostic potential was evaluated in orthotopic CCA-bearing mice by ex vivo tissue radioactivity analysis. **Results:** Two novel lead candidates (scFv-8 and scFv-10) were identified by ribosome display and demonstrated selective binding to hypoglycosylated MUC1-positive CCA cells with negligible binding to MUC1-negative controls. Both scFvs reduced CCA cell viability in vitro and suppressed tumor growth in orthotopic xenograft models. Biodistribution studies demonstrate detectable tumor localization with limited off-target tissue retention. Based on its favorable binding and in vivo distribution profile, scFv-8 was selected for further development as a radiodiagnostic and was successfully conjugated with 68Ga. 68Ga-labeled scFv-8 retained MUC1-binding activity following radiolabeling. Ex vivo tissue radioactivity analysis demonstrated localization of radiolabel within orthotopic tumors. **Conclusion:** These findings demonstrate the feasibility and utility of hypoglycosylated MUC1-targeted molecular imaging and the potential for developing precision-targeted therapy. They established a foundation for the development of novel theranostic agents using humanized scFv to hypoglycosylated MUC1 for the diagnosis and treatment of CCA.

4346 | PERFORMANCE OF ASAP, LG2M, AND GP73 FOR HCC DETECTION IN PATIENTS WITH CIRRHOSIS

Mohammad Jarrah[1] Mohammed Al-Hasan[1] Mariadelcarmen Yanez[1] Maria Yow[1] Fouzia Ahmed[1] Nicole Rich[1] Sneha Deodhar[1] Amit Singal[1], [1]University of Texas Southwestern Medical Center

Background: The sensitivity of ultrasound plus alpha-fetoprotein (AFP) for early-stage hepatocellular carcinoma (HCC) detection remains suboptimal, prompting growing interest in blood-based biomarkers as an alternative strategy. The ASAP [age, sex, AFP, PIVKA-II] score has shown promising performance in prior studies, although further validation in contemporary Western populations is needed. **Methods:** We conducted a case-control study with cases defined as patients with HCC and controls as patients with cirrhosis but without HCC. Blood specimens were collected within 6 months following HCC diagnosis (cases) and during routine visits for cirrhosis (controls). AFP, PIVKA-II, LG2m, and GP73 were measured using the Abbott Alinity platform, and ASAP scores were calculated. The diagnostic performance

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

of each individual biomarker and ASAP was assessed by ROC curves and AUROC values. Sensitivity and specificity for detection of early-stage HCC (BCLC stage 0 or A) were compared between ASAP and ultrasound plus AFP using McNemar's Chi-square test, with a positive ultrasound defined as a liver lesion ≥ 1 cm within 6 months of blood collection. **Results:** Among 294 patients (median age 61 years, 67.7% men), 50.7% had HCC (69.1% BCLC 0/A). Liver disease etiology in our cohort included HCV (29.9% viremic HCV; 15.3% post-SVR), ALD (24.5%), and MASLD (16.0%). The diagnostic performance of individual biomarkers for early-stage HCC was moderate to poor (AUROC: AFP 0.76, PIVKA-II 0.79, LG2m 0.53, and GP73 0.57), while ASAP had an AUROC of 0.82. ASAP, at a cutoff of ≥ 0.526, demonstrated a sensitivity of 88.3% for early-stage HCC, with specificity of 54.5%. Sensitivity was higher in men (94.7% vs. 71.4%) and viremic HCV (97.4% vs. 76.9%), whereas specificity was higher in younger individuals (58.5% vs. 37.0%), women (65.6% vs. 46.4%), and those with Child Pugh A cirrhosis (67.5% vs. 37.1%). ASAP, at a cutoff of ≥ 0.804 per Youden's index, demonstrated a sensitivity of 68.0% for early-stage HCC and specificity of 83.4%. In a paired analysis ($n = 178$), ASAP had comparable sensitivity to ultrasound plus AFP (85.5% vs. 90.3%; $p = 0.51$) but lower specificity (53.4% vs. 93.1%; $p < 0.001$). Paired analysis results were consistent across subgroups by age, sex, etiology, and Child-Pugh. **Conclusion:** ASAP demonstrated high sensitivity but suboptimal specificity for early-stage HCC detection. Optimization of ASAP's threshold in Western populations may be needed to better balance sensitivity and specificity.

4347 | SERUM GLYCAN PROFILING AUGMENTS THE GAAD SCORE FOR EARLY-STAGE HEPATOCELLULAR CARCINOMA DETECTION

Yujie Feng[1] Ming Chen[2] Rui Ma[2] Ziqiang Li[3] Haiguang Xin[3] Qing Guo[3] Honglian Gui[3] Qing Xie[4], [1]Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, [2]Shanghai Jiao Tong University School of Medicine, [3]Department of Infectious Diseases, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, [4]Ruijin Hospital

Background: In China, hepatocellular carcinoma (HCC) is a major public health burden, with chronic viral hepatitis as the leading cause. Curative therapy yields over 90% 5-year survival for early-stage HCC, yet timely detection remains an unmet clinical challenge. Conventional diagnostics have clear limitations: nearly 40% of HCC lesions show atypical imaging features, while AFP and PIVKA-II/DCP exhibit insufficient sensitivity, especially for early-stage HCC. The GAAD score, integrating gender, age, AFP and DCP, improves diagnostic performance but still exhibits suboptimal sensitivity. While dysregulated serum glycoprotein glycosylation participates in HCC progression, robust clinical validation is currently lacking. This study aimed to evaluate whether fluorescence-labeled capillary electrophoresis-based Glycan Test (GT) could augment the performance of GAAD and conventional biomarkers. **Methods:** This cross-sectional study enrolled patients from Shanghai Ruijin Hospital, stratified into an HCC group and a high-risk cohort with chronic hepatitis or liver cirrhosis. HCC cases were further stratified by CNLC and BCLC staging, with diagnoses confirmed pathologically or clinically. Serum AFP and DCP were tested; the Elecsys GAAD score was calculated via logistic regression at a validated cutoff of 2.57. All samples underwent parallel GT profiling. ROC analysis, Cohen's kappa, DCA and stage-stratified analysis compared performance of standalone GT, standalone GAAD and the GAAD-GT combination. **Results:** A total of 171 participants were enrolled (median age 58.1 years; 65.5% male), including 59 chronic hepatitis (34.5%), 48 liver cirrhosis (28.1%) and 64 HCC patients (37.4%). As a standalone biomarker, GT outperformed AFP, DCP and GAAD, with sensitivity 81.25%, accuracy 91.23% and kappa 0.807. AFP, DCP and GAAD showed lower sensitivity (59.38%, 62.50%, 75.00%), accuracy (79.53%, 82.46%, 88.89%) and kappa consistency (0.538, 0.603, 0.753). GT specificity reached 97.20%, comparable to GAAD. AUC values were 0.844 (AFP), 0.861 (GAAD), 0.892 (GT), 0.913 (DCP). The GAAD-GT combination increased AUC to 0.94. DCA confirmed favorable clinical utility of the combined model across wide threshold probabilities. Subgroup analysis showed standalone GT

achieved sensitivities of 80.49% and 78.43% for BCLC and CNLC early-stage HCC, while standalone GAAD reached 70.73% and 68.63%. The GAAD-GT combination increased the sensitivity to 90.24% and 88.24%. For advanced HCC, the model yielded sensitivities of 91.30% and 100% under BCLC and CNLC criteria. **Conclusion:** GT presents reliable diagnostic performance for HCC across clinical stages, superior to standalone AFP, DCP and GAAD. Combining GT with GAAD further improves accuracy, with the greatest advantage in early detection of HCC. This novel cost-effective serological strategy warrants prospective validation for early HCC detection in high-risk populations.

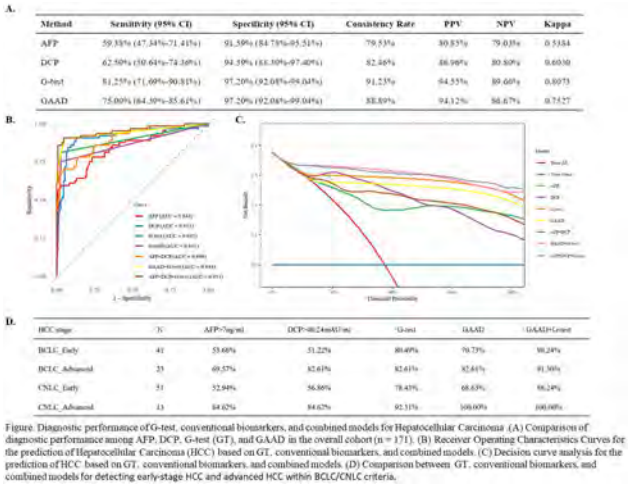

Figure. Diagnostic performance of G-test, conventional biomarkers, and combined models for Hepatocellular Carcinoma. (A) Comparison of diagnostic performance among AFP, DCP, G-test (GT), and GAAD in the overall cohort (n = 171). (B) Receiver Operating Characteristics Curves for the prediction of Hepatocellular Carcinoma (HCC) based on GT, conventional biomarkers, and combined models. (C) Decision curve analysis for the prediction of HCC based on GT, conventional biomarkers, and combined models. (D) Comparison between GT, conventional biomarkers, and combined models for detecting early-stage HCC and advanced HCC within BCLC/CNLC criteria.

4348 | MRI-TRAINED SELF-SUPERVISED LEARNING TO IMPROVE RECURRENCE PREDICTION IN HEPATOCELLULAR CARCINOMA POST-TRANSPLANTATION

Shreeja Patel[1] Conor Conor Donnelly[2] Lars Chen[3] Dorry Segev[4] Michal Mankowski[3] Karim Halazun[5], [1]NYU Langone Health, [2]NYU Langone Department of Surgery, [3]NYU Center for Surgical and Transplant Applied Research, [4]NYU Center for Surgical and Transplant Applied Resarch, [5]NYU Langone Transplant Institue

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related mortality worldwide, with increasing incidence in Western populations. Current criteria for selecting patients with HCC for liver transplantation relies on absolute tumor size and number of lesions. However, this approach simplifies the extent and heterogeneity of HCC burden. Given demand for organs continues to outpace supply, optimization of candidate selection for transplantation in the setting of HCC to ensure maximum organ utility is critical. This study aimed to compare the performance of a trained and untrained imaging-based artificial intelligence in HCC recurrence prediction after liver transplantation. **Methods:** We assembled an MRI-specific dataset comprising approximately 330,000 unlabeled abdominal scans drawn from LLD-MMRI4, AMOS5, CHAOS6, and LiverHccSeg. A DINOv2 model was pre-trained using these specific images. We then identified all patients who underwent liver transplantation for HCC between 2014 and 2024 at a single academic health system as our experimental population. An untrained general-purpose DINOv2 model (trained only on ImageNet) and the pre-trained DINOv2 model were independently asked to evaluate the final pre-transplant MRI of our experimental population and predict recurrence. Model performance was evaluated using survival-specific metrics, including the concordance index (C-index) for time-to-event analysis, and area under the receiver operating characteristic curve (AUC-ROC), precision, recall, and specificity for binary classification. **Results:** In 109 patients who underwent transplantation for HCC at this single center, there were 9 recurrences. For survival analysis, the concordance index (C-index) of the general-purpose model was 0.6815 ± 0.1988 (mean ± SD), compared with the MRI-pretrained model 0.7558 ± 0.2556. In classification-based evaluation, the general-purpose model yielded an AUC-ROC of 0.5559 ± 0.0406, precision of 0.0640 ± 0.0175, and recall of 0.5286 ± 0.2124. By contrast, the MRI-pretrained model was slightly improved to AUC-ROC (0.5766 ± 0.1038) and recall (0.5571 ± 0.1623), although not statistically significant [Table 1]. **Conclusion:** We demonstrate that an abdominal MRI–trained self-supervised learning (SSL) model, which learns image representations from large collections of unlabeled abdominal MRI and relies solely on routine pre-transplant imaging, achieves higher discrimination for post-transplant HCC recurrence than a general-purpose image-recognition model. This proof-of-concept suggests that MRI-specific SSL may provide a practical approach to improving recurrence risk stratification among liver transplant candidates with HCC. Our findings demonstrate the potential of leveraging transformers like DINOv2 to adapt artificial intelligence to aid imaging-guided clinical decision making in transplant hepatology.

4350 | DEVELOPMENT AND INDEPENDENT VALIDATION OF AN ARTIFICIAL INTELLIGENCE MODEL FOR HEPATOCELLULAR CARCINOMA DETECTION USING PORTAL VEIN DOPPLER ULTRASOUND WAVEFORMS

Ibrahim Irfanullah[1] Wenjie Zhang[2] Angelo Mattos[3] Fernanda Branco[3] Giovanna Dumoncel[3] Ju Sun[2] Jose Debes[2], [1]Carle Illinois College of Medicine, [2]University of Minnesota, [3]Universidade Federal de Ciências da Saúde de Porto Alegre

Background: Hepatocellular carcinoma (HCC) surveillance relies on ultrasonography, a modality that is operator-dependent and demonstrates suboptimal sensitivity for early-stage disease. These limitations are particularly relevant in resource-limited settings, where HCC burden is high and access to specialized expertise may be restricted. We developed an artificial intelligence (AI)-based approach utilizing Doppler ultrasound waveforms to identify physiologic vascular changes associated with HCC and sought to validate this approach in an independent patient cohort. **Methods:** We analyzed Doppler ultrasound examinations from a U.S.-based development cohort of 228 patients (85 HCC, 143 cirrhotic controls) and an independent Brazilian validation cohort of 116 patients (18 HCC, 98 cirrhotic controls). HCC diagnoses were confirmed by cross-sectional imaging and/or histopathology. Doppler waveforms from the main portal vein (MPV), hepatic artery, and inferior vena cava were analyzed using deep learning models based on a VGG16 architecture. These vessels are routinely assessed during liver ultrasonography and can be identified with minimal additional operator training. Model performance was evaluated using area under the receiver operating characteristic curve (AUROC). **Results:** The development and validation cohorts had median ages of 60 and 67 years, respectively, and included 60% and 58% male participants. Among evaluated vessels, the MPV demonstrated the strongest individual performance for HCC detection. In the development cohort, MPV alone achieved an AUROC of 0.77, increasing to 0.84 when combined with AFP. Most models demonstrated improved performance when analyses were restricted to tumors < 5 cm, with the MPV-only model achieving an AUROC of 0.82. In the independent validation cohort, MPV alone achieved an AUROC of 0.65, while the highest-performing model combined MPV and age, achieving an AUROC of 0.70. **Conclusion:** AI analysis of routine MPV Doppler ultrasound waveforms can differentiate patients with HCC from cirrhotic controls and retained discriminatory ability in an independent Brazilian validation cohort. Performance improved further when combined with AFP and in patients with tumors < 5 cm. This approach leverages routinely acquired ultrasound data and may provide a scalable, low-cost adjunct to current HCC surveillance strategies. Larger multicenter studies are warranted to assess generalizability and clinical implementation.

Background: A fundamental and underappreciated tension persists in applied medical artificial intelligence: the settings where automated hepatocellular carcinoma (HCC) triage is most urgently needed, communities where B-mode ultrasound constitutes the sole accessible imaging modality and specialist radiological expertise is absent, are precisely those least equipped to run prevailing deep learning classifiers. Architectures optimised for benchmark accuracy impose GPU requirements that render them inoperable on edge or mobile hardware, concentrating diagnostic benefits in well-resourced health systems. **Methods:** We developed a two-stage minimum-footprint pipeline: LiteMedSAM, operating from bounding-box prompts, segmented focal liver lesions and generated perilesional crops (10–20% margin), which a fine-tuned MobileNetV4-Conv-Small network then classified as HCC or hemangioma. Internal validation used SMC-LUD, 5,385 B-mode images from 1,021 patients (Samsung Medical Center, 2015–2024), all HCC cases histopathologically confirmed and hemangioma cases radiologically verified by two independent board-certified radiologists, with strict patient-level partitioning (70:20:10) , and external validation used the TCIA liver dataset. Outcomes included AUROC, sensitivity, specificity, F1-score, F2-score, and Dice Similarity Coefficient. **Results:** LiteMedSAM yielded a Dice Similarity Coefficient of 0·87 at zero-shot inference, improving to 0·89 after fine-tuning. MobileNetV4-Conv-Small achieved 91·0% accuracy and 92·0% F1-score on standard lesion crops; perilesional-margin cropping improved both metrics to 93·0%, with AUROC 0·958. Complete two-stage inference required under one second on edge devices, with a total model footprint under 20 MB, a deliberate accuracy–efficiency trade-off quantifiably justified by the deployment context. **Conclusion:** LiteMedSAM yielded a Dice Similarity Coefficient of 0·87 at zero-shot inference, improving to 0·89 after fine-tuning. MobileNetV4-Conv-Small achieved 91·0% accuracy and 92·0% F1-score on standard lesion crops; perilesional-margin cropping improved both metrics to 93·0%, with AUROC 0·958. Complete two-stage inference required under one second on edge devices, with a total model footprint under 20 MB, a deliberate accuracy–efficiency trade-off quantifiably justified by the deployment context.

4352 | FASTVIT-SA12 AND SA24 WITH LITEMEDSAM FOR SEGMENTATION-ASSISTED, EDGE-DEPLOYABLE CLASSIFICATION OF HEPATOCELLULAR CARCINOMA ON B-MODE ULTRASOUND

Kavin Elangovan[1] Nayanika Tummala[2] Elangovan Krishnan[3] Ramya Elangovan[4] Jansi Sethuraj[5], [1]AIM, [2]NYMC St Marys St Clares, [3]Indian Institute of Technology Bombay, [4]Johns Hopkins University, [5]The University of Texas Health Science Center at Houston

Background: Hepatocellular carcinoma (HCC) is diagnosed in approximately 905,000 individuals annually, with a 5-year survival below 20% in most regions. B-mode ultrasound is widely accessible for surveillance, yet focal liver lesion characterisation without specialist input remains unreliable. Contemporary deep learning classifiers demonstrate high diagnostic accuracy but depend on GPU-intensive architectures incompatible with mobile or edge deployment. Hybrid vision transformers engineered specifically for on-device inference represent a structurally distinct and underexplored solution to this constraint. **Methods:** A two-stage pipeline was constructed pairing LiteMedSAM, prompted with bounding boxes to segment liver lesions and extract perilesional crops (10–20% margin), with independently fine-tuned FastViT-SA12 and FastViT-SA24 classifiers (Apple). Both models were trained and internally validated on SMC-LUD: 5,385 B-mode images from 1,021 patients, all HCC cases histopathologically confirmed and hemangioma cases radiologically verified by two independent board-certified abdominal radiologists, patient-level split 70:20:10. External validation used the TCIA liver dataset. Primary outcomes: AUROC, sensitivity, specificity, F1-score, F2-score, and Dice Similarity Coefficient (DSC). **Results:** LiteMedSAM segmentation yielded a DSC of 0·90 (zero-shot) and 0·93 (fine-tuned). FastViT-SA12 achieved 93·0% accuracy and F1-score on standard crops, improving to 95·0% with perilesional-margin cropping; AUROC was 0·96. FastViT-SA24 reached 96·0% accuracy and AUROC 0·98, performance commensurate with heavier architectures benchmarked on SMC-LUD, while both variants completed inference in under one second per image on edge devices. **Conclusion:** FastViT-SA24, guided by LiteMedSAM segmentation, achieves excellent HCC classification with full edge deployability; FastViT-SA12 provides a leaner alternative for settings where model footprint is the primary constraint. Both variants deliver lesion-level spatial interpretability. Limitations include single-centre training data and binary classification scope; prospective multicentre validation is required before clinical adoption.

4353 | EARLY HCC DETECTION USING MULTI-EXPERT MACHINE LEARNING ON CELL-FREE WHOLE GENOME BISULFITE SEQUENCING DATA

Mythili Subharam[1] Ryan Koehler[2], [1]OmicXHealth, [2]VerdAscend Sciences

Background: Standard HCC surveillance with AFP/Ultrasound has limited sensitivity for early-stage disease and targeted, narrow panel liquid biopsy approaches also fall short in detecting BCLC 0/A stage HCC, where it is treatable. Early-stage HCC is characterized by low tumor-derived cfDNA fraction, where tumor-shedding-dependent markers are unreliable. We developed a multi-expert machine learning (ML) platform employing cell-free whole genome bisulfite sequencing (cfWGBS) with six independently trained ML classifiers integrated through a biologically informed rules engine with etiology-aware adjudication. **Methods:** Six ML classifiers were independently trained on domain-specific published datasets in a Mixture of Experts (MoE) architecture, ensuring orthogonal signals. Five methylation-based classifiers target distinct biomarker sets: (1) Sensitivity Expert for HCC signal gating (2) Malignancy Expert targeting pan-GI malignancy biomarkers (3) HCC Tumor Markers for focal HCC promoter silencing detectable at low tumor fraction (4) Early Stage Detector targeting liver cell death-associated loci (5) Tumor Burden Hypomethylation for HBV-specific hypomethylated blocks. A sixth classifier interrogates cfDNA fragmentation, a structurally orthogonal modality. Both signal types are extracted from plasma moderate-depth whole genome bisulfite sequencing (WGBS) and integrated through a hierarchical rules engine with multi-signal corroboration and etiology-aware adjudication. Thresholds are biologically grounded, not ROC-optimized. Evaluated in a 30-plasma biosample cohort (14 HCC: Stage1A n = 2, Stage2 n = 10, Stage3/4 n = 2; 16 CLD(14 Cirrhosis/HBV, and 2 normal). **Results:** Sensitivity 14/14 (100%); Specificity 15/16 (94%). One HCV/Cirrhosis sample generated a false malignancy signal attributed to active viral hepatitis. Stage1A detection (2/2) was driven by the Early Stage Detector, operating independently of tumor-derived cfDNA. Low-shedding HCC was identified via HCC Tumor Markers where tumor burden signal was absent. No single-expert dependency was identified, each HCC call required corroboration from at least two experts.**Conclusion:** This MoE WGBS platform demonstrates proof-of-concept in a challenging cohort inclusive of active viral hepatitis (HCV), NASH, HBV and Cirrhosis. Orthogonal detection mechanisms address biological heterogeneity limiting single-mechanism approaches. Biologically grounded thresholds and etiology-aware adjudication reduce cohort-specific calibration dependence. Current cohort size is small but independent blinded validation (n = 100, major academic medical center) is underway to confirm if the results hold in a larger validation cohort. This approach may offer a clinically translatable path toward blood-based HCC surveillance that maintains specificity while improving early-stage detection across etiologically diverse high-risk populations.

4354 | NON-CONTRAST MAGNETIC RESONANCE IMAGING FOR HEPATOCELLULAR CARCINOMA SURVEILLANCE IN PATIENTS WITH CIRRHOSIS: A COST-UTILITY ANALYSIS

Dong Ho Lee[1] Seokyung Hahn[2] Yeonggyeong Jang[2], [1]Seoul national university hospital, [2]Seoul National University College of Medicine

Background: Ultrasound (US) is the standard surveillance modality for hepatocellular carcinoma (HCC) in at-risk populations, but its sensitivity for early-stage detection is limited. Non-contrast abbreviated MRI (NC-MRI) offers higher sensitivity; however, its cost-effectiveness remains uncertain. We aimed to

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

evaluate the cost-effectiveness of biannual NC-MRI and an alternating NC-MRI/US strategy compared with US in patients with cirrhosis, identifying specific HCC incidence thresholds for clinical benefit. **Methods:** A Markov model simulated a cohort of 10,000 patients with cirrhosis (age 50 years) over a 30-year horizon. Three strategies were compared: (1) biannual US, (2) biannual NC-MRI, and (3) alternating NC-MRI and US at 6-month intervals. Model inputs, including sensitivity for detecting very early and early-stage HCC (NC-MRI 86%, US 47%, alternating 83.9%) and transition probabilities, were derived from the literature. Outcomes were expressed as incremental cost-effectiveness ratios (ICERs) per quality-adjusted life-year (QALY). Deterministic and probabilistic sensitivity analyses were performed. **Results:** At a base-case annual HCC incidence of 3%, biannual NC-MRI and the alternating strategy yielded higher QALYs (8.60 and 8.58, respectively) than US (8.22). The corresponding ICERs were $9,625/QALY for biannual NC-MRI and $3,467/QALY for the alternating strategy. At a willingness-to-pay threshold of $20,000/QALY, biannual NC-MRI was cost-effective when the annual HCC incidence exceeded 1.57%, whereas the alternating strategy was cost-effective when incidence exceeded 0.70%. Probabilistic sensitivity analysis indicated an >80% probability of cost-effectiveness for both NC-MRI-based strategies at a WTP of $50,000/QALY. **Conclusion:** NC-MRI–based surveillance is cost-effective for HCC in patients with cirrhosis, particularly at annual incidence rates ≥1.57% at a $20,000/QALY threshold. An alternating NC-MRI/US strategy offers a more efficient option at lower risk thresholds (≥0.70%), supporting its incorporation into risk-stratified surveillance strategies.

4355 | PATTERN OF ADHERENCE TO LI-RADS REPORTING STANDARDS IN A CANADIAN PROVINCE; RETROSPECTIVE STUDY

Miray Eskandar[1] Sayli Devdikar[2] Robert Balshaw[3] Signy Holmes[1] Maged Nashed[4], [1]University of Manitoba, [2]CancerCare Manitoba, [3]George and Fay Yee Centre for Healthcare Innovation; University of Manitoba, [4]CancerCare Manitoba; University of Manitoba

Background: The radiological diagnostic algorithm, Liver Imaging Reporting & Data System (LI-RADS) is a comprehensive system for standardizing reporting of liver imaging. The lack of adherence to its standards may lead to delayed diagnoses of hepatocellular carcinoma (HCC). **Methods:** In this retrospective study, we aimed to determine whether diagnostic radiologists were compliant in reporting on the four LI-RADS criteria and final category score. We also sought to identify factors that might influence the pattern of LI-RADS reporting. We collected demographic and diagnostic radiological details of patients diagnosed with HCC in Manitoba, by either CT or MRI, between January 2011 and December 2021. **Results:** 725 patients were identified with a median age at diagnosis of 67 years. 10% of scans reported a LI-RADS category and 25% reported all four criteria. There has been a significant increase in reporting both category and criteria over time (P = < 0.001 for both). MRI-based reporting of category and criteria was significantly more frequent than CT-based reporting (P = < 0.001 for both). Specialist radiologists were less likely [OR 0.42; CI 0.22, 0.79] to report category compared to non-specialists but there was no difference in the frequency of reporting criteria between specialist and non-specialist radiologists. **Conclusion:** Compliance with the standardized LI-RADS reporting system in Manitoba has been improving over the years. Nevertheless, it is still suboptimal, and efforts should be made to enhance diagnostic radiologists' compliance with the recommended standards.

Figure 2. Predicted probability of LI-RADS category (A) and criteria (B) reporting over time (2011-2021) by specialist vs non-specialist radiologists when MRI or CT is used for diagnosis. N.b. The logistic regression models included the main effects of year, specialist and imaging.

4356 | DEEP LEARNING-ASSISTED IMAGE ANALYSIS FOR MORPHOLOGIC PHENOTYPING AND TREATMENT MONITORING OF CIRCULATING TUMOR CELLS IN HEPATOCELLULAR CARCINOMA

Hirotaka Nomiya[1] Takuto Nosaka[1] Yosuke Murata[1] Yu Akazawa[1] Tomoko Tanaka[1] Tatsushi Naito[1] Kazuto Takahashi[1] Yasunari Nakamoto[1], [1]University of Fukui

Background: Circulating tumor cells (CTCs) are promising liquid biopsy biomarkers in hepatocellular carcinoma (HCC). We previously showed that dynamic changes in CD90-positive CTCs were associated with tumor shrinkage and survival (Cancers 2025). However, morphologic evaluation of HCC CTCs has not been established. We quantified CTC morphology using deep learning–based detection and segmentation and examined its association with tumor burden and treatment-related change. **Methods:** Peripheral blood was collected before treatment and at 8–12 weeks after treatment initiation from 18 patients with unresectable HCC receiving atezolizumab plus bevacizumab (n = 14) or durvalumab plus tremelimumab (n = 4); BCLC stage B/C was 12/6. Paired pre/post samples were available in 8 patients. After CD45-positive leukocyte depletion, samples were stained with DAPI/CD45/PanCK and images were acquired by confocal microscopy (FV1200) and whole-slide microscopy (VS200). TruAI (Olympus) was trained on spike-in and HCC samples and used for CTC detection and segmentation. CTCs were defined as DAPI-positive, CD45-negative, PanCK-positive cells with preserved nuclear morphology. Area, circularity, solidity, and aspect ratio were extracted. Each CTC was classified as solitary or non-solitary, and the non-solitary CTC fraction was calculated. Morphologic phenotypes were defined by principal component analysis and Ward clustering. **Results:** The workflow showed linearity in spike-in experiments and agreement with flow cytometry ($R^2 = 0.71$, $P < 0.01$). A total of 714 CTCs from 30 objects were analyzed. Unsupervised clustering identified two morphologic phenotypes. Phenotype 1 showed a large, elongated cells with irregular contour, whereas Phenotype 2 showed a smaller, rounder cells with smoother contour. Phenotype 1 had a larger area than Phenotype 2 (573.83 vs 472.80, $P < 0.05$), with differences in circularity, solidity, and aspect ratio (all $P < 0.01$). In the baseline cohort, Phenotype 1 (n = 8) tended to show larger maximal tumor size (88.21 vs 27.98 mm), higher AFP (25.05 vs 5.90 ng/mL), and higher DCP (898.50 vs 173.50 mAU/mL) than Phenotype 2 (n = 10). In paired samples, CTC count decreased after treatment ($P < 0.05$), the non-solitary CTC fraction showed a decreasing trend ($P = 0.055$), and the PC1 score derived from non-solitary CTC morphology shifted from 0.2 to -1.0, indicating reduced morphologic irregularity after treatment. **Conclusion:** Deep learning–assisted image analysis enabled morphologic phenotyping of HCC CTCs. A large, elongated, irregular phenotype was associated with higher tumor burden and serum tumor markers, and treatment was accompanied by reductions in CTC count and non-solitary morphologic irregularity. Complementing subset-based and molecular profiling, this morphology-based approach may extend multimodal liquid biopsy for characterizing tumor aggressiveness and monitoring treatment-associated change in HCC.

4357 | LITEMEDSAM AND EFFICIENTNETV2-B0: A SEGMENTATION-GUIDED, EDGE-DEPLOYABLE PIPELINE FOR SONOGRAPHIC CLASSIFICATION OF HEPATOCELLULAR CARCINOMA AND HEMANGIOMA

Nayanika Tummala[1] Elangovan Krishnan[2] Kavin Elangovan[3] Jansi Sethuraj[4] Ramya Elangovan[5] Namratha Cherukuru[1] Gautam Maddineni[6] Giulio Quarta[1] Mushtaq Jaghuri[3], [1]NYMC ST Mary's General Hospital St Clares, [2]Indian Institute of Technology Bombay, [3]AIM, [4]The University of Texas Health Science Center at Houston, [5]Johns Hopkins University, [6]Creighton University

Background: Hepatocellular carcinoma (HCC) accounts for approximately 830,000 deaths annually and is routinely detected during B-mode ultrasound surveillance. Reliably distinguishing HCC from benign hepatic hemangioma on ultrasound remains diagnostically challenging, particularly in the setting of cirrhotic parenchymal heterogeneity. Contemporary deep learning classifiers achieve high benchmark accuracy but depend on computationally intensive, GPU-reliant architectures impractical for point-of-care or resource-limited deployment. Lightweight, lesion-focused models combining automated segmentation with efficient classification, operable on standard CPU hardware, represent an unmet clinical priority. **Methods:** A two-stage diagnostic pipeline was developed. In Stage 1, LiteMedSAM received bounding-box prompts to generate lesion segmentation masks, from which lesion-centered crops with a 10–20% perilesional margin were extracted. In Stage 2, an ImageNet-pretrained EfficientNetV2-B0 classifier was fine-tuned on cropped lesion images. The model was trained and internally validated on SMC-LUD, a publicly available dataset of 5,385 B-mode

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

ultrasound images from 1,021 patients (Samsung Medical Center, 2015–2024), all HCC cases histopathologically confirmed and hemangioma cases radiologically verified by two independent board-certified abdominal radiologists, with strict patient-level partitioning (70:20:10). External validation was conducted on the TCIA B-mode liver dataset. Primary outcomes were AUROC, sensitivity, specificity, F1-score, F2-score, and Dice Similarity Coefficient (DSC). **Results:** Zero-shot LiteMedSAM segmentation yielded a DSC of 0·89; fine-tuned segmentation improved to 0·91 model performance on ultrasound. EfficientNetV2-B0 on standard lesion crops achieved 92% accuracy and F1-score; the perilesional-margin strategy attained 95% accuracy. HCC sensitivity was 93%, hemangioma sensitivity 94%, and AUROC 0·95. These results are commensurate with heavier architectures benchmarked on SMC-LUD while requiring less than 1 second per image on standard edge devices.**Conclusion:** A two-stage LiteMedSAM–EfficientNetV2-B0 pipeline achieves clinically competitive HCC classification, lesion-level spatial interpretability, and edge deployability. This framework offers a reproducible, resource-efficient tool for real-time liver lesion triage in resource-limited settings. Limitations include single-centre training data and binary classification scope; prospective multicentre validation across heterogeneous ultrasound platforms is required before clinical translation.

4358 | LARGE LANGUAGE MODEL EXTRACTION OF TRANSPLANT-RELEVANT IMAGING FEATURES FROM MULTIPHASE MRI RADIOLOGY REPORTS IN HEPATOCELLULAR CARCINOMA

Usamah Chaudhary[1] Farzad Tahmasebi Arashloo[1] Nicole Rich[2] Amit Singal[1], [1]UT Southwestern, [2]University of Texas Southwestern Medical Center

Background: Accurate characterization of hepatocellular carcinoma (HCC) on multiphase MRI is critical for diagnosis, staging, transplant eligibility, and longitudinal monitoring. However, extracting structured features from free-text radiology reports remains labor-intensive and limits large-scale retrospective research. Large language models (LLMs) show strong performance in medical text interpretation, but their ability to extract granular HCC imaging features and determine transplant-relevant criteria remains incompletely characterized. We evaluated GPT-5.5 for extracting clinically relevant HCC imaging features from multiphase MRI reports. **Methods:** We performed a retrospective study of patients with HCC who underwent multiphase liver MRI. Free-text radiology reports were provided to GPT-5.5 using a standardized structured extraction prompt without fine-tuning. The model extracted predefined features, including number of hepatic lesions and LR-3/LR-4/LR-5 observations, lesion size, arterial phase hyperenhancement (APHE), washout, capsule appearance, tumor in vein, cirrhosis, portal hypertension, ascites, and Milan criteria eligibility. Ground-truth labels were established by manual physician review. **Results:** A total of 348 lesions (132 LR3, 62 LR4, 154 LR5) across 152 MRI reports from 112 unique patients were analyzed. Compared to manual physician review, GPT-5.5 demonstrated high overall extraction performance. The model correctly identified and classified 344 of 348 lesions as LR-3, LR-4, or LR-5, yielding lesion-level classification accuracy of 98.9%. Two lesions, one LR-5 and one LR-3, were missed; one LR-5 was mislabeled LR-4, and one LR-4 was mislabeled LR-5. Among correctly identified lesions, diameter was extracted accurately in all cases. Lesion-level feature extraction was strong, with high accuracy for APHE (98.9%), washout appearance (99.4%), capsule appearance (100%), and vascular invasion (100%). Milan criteria were assessed with 93.4% accuracy. The model also performed well in identifying advanced liver disease features, including portal hypertension (100%), ascites (100%), and extrahepatic metastatic disease or lymph node involvement (94.1%). When stratified by our internal structured report format, lesion classification improved to 99.4%, with all lesion APHE, washout, and capsule appearance correctly identified. Milan criteria accuracy improved to 97.6%. Average processing time per report was 2.59 seconds. **Conclusion:** A GPT-5.5 large language model demonstrated excellent performance extracting clinically meaningful and transplant-relevant imaging features from free-text multiphase MRI radiology reports in patients with HCC. These findings suggest LLM-assisted extraction may enable scalable structured HCC imaging datasets for clinical research, transplant evaluation, and longitudinal outcome studies.

4359 | ETIOLOGICAL SPECTRUM AND IMAGING MODALITIES IN PANCREATOBILIARY DISORDERS IN SUB-SAHARAN AFRICA (SSA): A SYSTEMATIC REVIEW AND META-ANALYSIS (SRMA)

Emeka Stanley Obi[1] Joshua Kalu[2] Olamide Asifat[3] Chimezirim Ezeano[4] Ihunanya Kanu[5] Uwakmfonabasi Umoudoh[6] Adedeji Adenusi[7] Anthony Ude[8] Nneoma Abajue[9] Onyinyechukwu Onyewuchi[10], [1]Brookdale University Hospital and Medical Center, [2]Suny Downstate Medical Center, [3]Georgia Southern University, [4]Advocate Aurora Healthcare, [5]Baptist Memorial Hospital- Golden Triangle, [6]NYCHHC/Lincoln Medical Center, [7]One Brooklyn Health-Interfaith Medical Center, Brooklyn, NY., [8]Department of Radiology CHUKWUEMEKA ODUMEGWU OJUKWU UNIVERSITY (COOU), [9]Regions Healthcare, Mgbirichi, Imo State, [10]Department of Clinical Services, Clinix Healthcare Diagnostics, Awka, Nigeria

Background: Pancreatobiliary disorders contribute substantially to gastrointestinal morbidity, but their etiologic distribution and diagnostic imaging patterns remain poorly characterized in SSA, worsened by limited access to advanced imaging which further influence diagnostic pathways and reported disease patterns. This systematic review and meta-analysis synthesized available evidence on imaging-diagnosed pancreatobiliary etiologies in SSA settings. **Methods:** We conducted a systematic review and random-effects meta-analysis of proportions. Eight databases were searched from January 2010 for studies of adults evaluated for obstructive jaundice in sub-Saharan Africa by ultrasound, CT, MRCP, or ERCP. 472 of 487 results were excluded, and of 15 screened, 5 studies (731 patients; Kenya, Nigeria, Ethiopia) met eligibility; risk of bias was assessed with QUADAS-2. Extracted data included country, sub-region, imaging modality, sample size, benign and malignant etiologies, and specific pancreatobiliary diagnoses. Pooled proportions were estimated using logit-transformed random-effects models with REML. Heterogeneity was quantified by I^2 and τ^2. Exploratory subgroup analyses by sub-region and imaging modality where conducted where data permitted, and sequential leave-one-out sensitivity analyses for primary and diagnosis-specific outcomes reported in ≥ 3 studies, were performed. **Results:** Benign and malignant etiologies were identified in 445 and 286 cases, respectively. The pooled proportion of benign etiologies was 62.3% (95% CI: 32.5%-85.1%; I^2 = 95.5%) and 37.7% malignant (95% CI: 14.9%-67.5%). Diagnosis-specific pooling showed pancreatic tumor/cancer at 22.0% of cases (95% CI: 11.8%-37.1%; I^2 = 83.8%), biliary stricture at 11.5% of cases (95% CI: 8.1%-16.2%; I^2 = 0%), and gallbladder cancer at 3.4% of cases (95% CI: 0.3%-27.7%). Subgroup analyses showed no statistically significant East–West African difference. By imaging modality, MRCP-based studies yielded higher benign etiology proportions than ERCP (79.3% vs. 48.6%), while ERCP yielded higher malignant proportions (51.4% vs. 20.7%). **Conclusion:** Benign etiologies appeared to predominate among imaging-detected pancreatobiliary disorders although malignant causes remained substantial. Pancreatic tumor/cancer and biliary stricture were important diagnosis-specific findings. Modality-based subgroup analyses suggested different etiologic distributions across imaging pathways, but these patterns likely reflect clinical indication, referral pathway, and disease severity rather than comparative diagnostic superiority. Substantial heterogeneity highlights the need for standardized, prospective, multicenter studies with complete diagnostic accuracy data to guide imaging strategies, procurement, training, and region-specific clinical decision-making

4360 | CENTRAL MRI LI-RADS INTER-READER AGREEMENT IN ALTUS, A PROSPECTIVE MULTICENTER HCC SURVEILLANCE STUDY

Alvin Silva[1] Binu John[2] Mark Camardo[3] Amit Singal[4] Neehar Parikh[5] Ju Dong Yang[6] Lewis Roberts[7] Paul Elias[3] Elle Kielar Grevstad[3] Paul Limburg[3],
[1]Department of Radiology, Mayo Clinic, Scottsdale, AZ, [2]Division of Gastroenterology and Hepatology, Miami VA Medical Center, Miami, Florida, [3]Abbott, Madison, WI, [4]University of Texas Southwestern Medical Center, Dallas, [5]University of Michigan, Ann Arbor, MI, [6]Cedars-Sinai Medical Center, Los Angeles, CA, [7]Department of Internal Medicine, Mayo Clinic, Rochester, Minnesota

Background: CT/MRI LI-RADS standardizes imaging diagnosis of hepatocellular carcinoma (HCC); however, most inter-reader agreement studies have been retrospective and performed using curated datasets. We report the first inter-reader reproducibility study of LI-RADS v2018 from a large, prospective, multicenter HCC surveillance study utilizing consecutive cross-sectional imaging examinations. **Methods:** ALTUS (NCT05064553) was a multi-center U.S. study of 2,463 adults with cirrhosis or chronic HBV evaluating the performance of a multi-target HCC blood test with central CT/MRI LI-RADS v2018 assessment as reference. Two blinded, fellowship-trained abdominal radiologists—randomly paired from a pool of six—independently assigned LI-RADS categories to 1,605 MRI exams, with a single, experienced fellowship-trained radiologist adjudicating any discrepancies. Inter-reader concordance was evaluated for overall LI-RADS classification, individual major features, and observation number and size using percent agreement, Gwet's AC2, and intraclass correlation coefficient (ICC). **Results:** Overall LI-RADS concordance was 75.4% (95% CI, 73.2-77.4) with AC2 of 0.90 (0.89-0.92), driven largely by high agreement (93.5%, 92.0-94.8) on LR-Neg (n = 1237) images (Fig. 1). LR-3 (n = 85) and LR-4 (n = 20) concordance was 22.4% (14.8-32.3) and 20.0% (8.1-41.6), respectively. A majority (89.4%, 59/66) of LR-3 discrepancies were LR-Neg, LR-1, or LR-2, whereas 31.3% (5/16) of LR-4 discrepancies were LR-3, and 25.0% (4/16) were malignant (2 LR-5, 2 LR-M). LR-5 (n = 25) concordance was 56.0% (33.6-66.4), with 9.1% (1/11) of discrepancies being LR-3, 27.3% (3/11) LR-4, and 9.1% (1/11) LR-M. LR-5 major feature concordance for arterial phase hyperenhancement, enhancing capsule, and non-peripheral washout were 68.0%, 60.0%, and 48.0%, respectively. Concordance on observation count was 15.8% (12.4-19.8). For index observation size, ICC was 0.79, with a median absolute difference between paired readers of 0.3 cm (median observation size 1.5 vs 1.2 cm). **Conclusion:** In this large prospective multicenter cohort, LI-RADS classification demonstrated high agreement in negative examinations, with lower concordance across indeterminate categories where imaging assessment is inherently challenging. Differences in categorization in these settings reflect the complexity of real-world surveillance imaging and may have management implications, underscoring the importance of reader calibration and adjudicated central review in clinical and research settings.

Note: Discordant Non-HCC includes LR-Neg, LR-1, and LR-2

Figure 1. Summary of inter-reader concordance and discordance by LI-RADS category.

4361 | LONGITUDINAL UPDATING OF THE HEPATOCELLULAR CARCINOMA RISK SCORES IMPROVES THE PREDICTION OF HCC DEVELOPMENT IN PATIENTS WITH CHRONIC HEPATITIS B

Volkan Yilmaz[1] Ali Eren Turkan[2] Beyza Doganay[3] Dilara Turan Gokce[4] Fatih Karakaya[5] Özge Koç[4] Mesut Gümüssoy[6] Zeynep Melekoglu Ellik[6] Hale Gokcan[6] Atilla Halil Elhan[3] Ramazan Idilman[7]

[1]Department of Gastroenterology, Yalova Training and Research, [2]Ankara University School of Medicine, Department of Internal Medicine, Ankara, Türkiye, [3]Department of Biostatistics, Ankara University School of Medicine, Ankara, Türkiye, [4]Ankara University, [5]Department of Gastroenterology, Medicana International Ankara Hospital, Ankara, Türkiye, [6]Department of Gastroenterology, Ankara University School of Medicine, Ankara, Türkiye, [7]Ankara University School of Medicine

Background: Hepatitis B virus-related disease remains the most common cause of liver-related morbidity and mortality. The present study aimed to develop and validate an accurate risk score for predicting hepatocellular carcinoma (HCC) in patients with chronic hepatitis B (CHB) who were treated with nucles(t)ide analogs. **Methods:** This was a single-center, observational study that included cirrhotic Caucasian patients with CHB. All patients received nucles(t)ide analogs at the physician's discretion and achieved sustained virological suppression. Most of the Turkish patients with HBV are infected with genotype D. The aMAP, PAGE-B, and ALBI scores were utilized to predict the development of HCC. Baseline risk scores were categorized into clinically interpretable risk groups according to predefined cutoffs. For aMAP, patients were classified as low risk (<50), medium risk (50–60), and high risk (>60). For PAGE-B, categories were defined as low risk (<9), medium risk (10–17), and high risk (≥ 18). ALBI categories were defined as low risk (<-2.6), medium risk (-2.6 to -1.39), and high risk (>-1.39). **Results:** A total of 340 cirrhotic patients were included in the analysis. The median age was 54.0 years, and the majority were male (79%). At admission, nearly half of the patients exhibited decompensation, and 43 patients had been diagnosed with HCC. The median aMAP, PAGE-B, and ALBI scores of these 43 patients with HCC were 64.9 (interquartile range [IQR], 8.2), 19.0 (IQR, 4.0), and -2.0 (IQR: -0.84), respectively. During the median follow-up period of 60 months (IQR: 24-118 months), de novo HCC was developed in 52 patients. Patients who developed HCC were older and more frequently male than those who did not develop HCC. Baseline mean aMAP (67 ± 5 vs 60 ± 8), PAGE-B (19.9 ± 2.7 vs 16.2 ± 4.9), and ALBI scores (-1.84 ± 0.61 vs -2.24 ± 0.66) were all significantly higher in the HCC group than in the non-HCC group (all $p < 0.001$), indicating a higher baseline risk profile among patients who subsequently developed HCC. In Cox regression analyses, all three scores were significantly associated with HCC development. PAGE-B showed the highest hazard ratio, whereas aMAP demonstrated the highest discriminative performance. Longitudinal, time-dependent Cox regression analyses incorporating repeated measurements showed that all three scores remained significantly associated with HCC development over time (all $p < 0.001$). Time-dependent models also demonstrated consistently higher discriminative performance compared with baseline-only models. **Conclusion:** In conclusion, the aMAP, PAGE-B, and ALBI scores are objective, straightforward, and reliable in accurately predicting HCC development in patients with cirrhosis due to CHB. We suggest that longitudinal updating of these risk scores improves HCC prediction compared with a single baseline assessment.

Table 1 -Baseline Cox regression analyses

Score	HR(%95 CI)	C-index	AIC	P value
Baseline aMAP	3.38 (2.14–5.34)	0.765	351	<0.001
Baseline PAGE-B	3.46 (2.04–5.86)	0.752	354	<0.001
Baseline ALBI	1.92 (1.42–2.61)	0.711	387	<0.001
Baseline ALBI*	1.92 (1.38–2.67)	0.776	[illegible]	<0.001

*: adjusted for age and sex

Table 2- Time-dependent Cox regression analyses

Score	HR(%95 CI)	C-index	AIC	P value
aMAP	3.67 (2.56–5.25)	0.808	430.3	<0.001
PAGE-B	4.07 (2.60–6.38)	0.775	435.3	<0.001
ALBI	2.37 (1.73–3.26)	0.754	448.1	<0.001
ALBI*	2.32 (1.65–3.27)	0.809	444.1	<0.001

*: adjusted for age and sex

4362 | ◆ CLINICAL RISK SIGNATURE-GUIDED REVERSE-ENGINEERING APPROACH TO IDENTIFY REPURPOSED DRUGS FOR HCC CHEMOPREVENTION

Hiroaki Kanzaki[1] Nevena Slovic[2] Courtney Katz[1] Hiroyuki Suzuki[1] Ece Janet Dinc[3] Hai-Cheng Huang[1] Sheza Siddiqui[1] Jingxuan Chen[1] Purva Gopal[1] Adam Yopp[1] Amit Singal[1] Joachim Lupberger[4] Emilie Crouchet[2] Thomas Baumert[5] Yujin Hoshida[1], [1]University of Texas Southwestern Medical Center, [2]University of Strasbourg, [3]UT Southwestern Medical Center, [4]Inserm U748, [5]INSERM

Background: Despite promising preclinical data, the clinical translation of experimental HCC chemoprevention strategies has been unsuccessful, as evidenced by a series of failed clinical trials. This gap suggests that biological hypotheses derived from experimental models may not be clinically relevant. Clinically well-validated HCC risk biomarkers may serve as clues to identify therapies that can elicit clinically meaningful chemopreventive effects. We previously identified and validated a hepatic transcriptome-based biomarker (prognostic liver signature [PLS]) predictive of incident HCC in multiple cohorts of chronic liver disease patients. We utilized the PLS as a probe to computationally and experimentally screen compounds that likely elicit clinically meaningful chemopreventive effects. **Methods:** We conducted an in silico primary screen of 13,945 FDA-approved drugs and bioactive compounds to identify those that favorably modulate the high-risk PLS. Selected compounds underwent an in vitro secondary screen in a PLS-inducible cell culture model (cPLS system). The prioritized compounds from this 2-step screen were subsequently evaluated in the choline-deficient, L-amino acid-defined, high-fat diet (CDA/HFD) rat model of MASH fibrosis-driven HCC development. The clinical relevance of the selected compounds was assessed using organotypic ex vivo culture of precision-cut liver slices (PCLS) from patients with various liver diseases. **Results:** The PLS-guided in silico primary screen identified 159 compounds that favorably modulate the high-risk PLS, of which 52 compounds were selected for the in vitro secondary screen based on their potential for clinical translation. In the secondary screen using the cPLS system, 12 compounds were prioritized for their shared favorable effects on HCV- and free fatty acid-induced high-risk PLS. Among them, aripiprazole, chloroquine, and minoxidil were selected as repurposed drugs for subsequent in vivo validation in CDA/HFD rats. These drugs were well tolerated, without recognizable hepatic or systemic adverse effects. As predicted, the number of liver tumor nodules was reduced to varying degrees, preferentially in male rats, accompanied by a relative reduction in liver fibrosis and a favorable modulation of the PLS and our previously reported Fibrosis Progression Signature (FPS). Hepatic transcriptome profiling revealed varying degrees of suppression of inflammatory, fibrogenic, and oncogenic pathways among the drugs. Clinical PCLS culture showed improved PLS in 50%–75% of the patients, suggesting the proportion of patients who might benefit from these therapies, and warranting the exploration of predictive biomarkers of response. **Conclusion:** The clinical HCC risk signature-guided reverse-engineering strategy identified multiple repurposed drugs as promising candidate HCC chemoprevention therapies for subsequent clinical evaluation.

★ 4363 | ◆ INTRATUMORAL *KLEBSIELLA PNEUMONIAE* DRIVES ANTI-PD-L1 RESISTANCE IN HEPATOCELLULAR CARCINOMA BY PROMOTING 7-DEHYDROCHOLESTEROL-MEDIATED FERROPTOSIS EVASION

Liqiu Li[1] Hongli Liu[2] Xuying Xu[1] Wenjuan Yang[1] Yongxiang Yi[3], [1]Kunshan Hospital of Traditional Chinese Medicine, [2]The Second Hospital of Nanjing, [3]Nanjing Drum Tower Hospital

Background: Immune checkpoint blockade targeting the PD-1/PD-L1 axis has expanded therapeutic options for hepatocellular carcinoma (HCC), although limited response rates and treatment resistance remain major barriers. Ferroptosis is an iron-dependent form of regulated cell death characterized by lipid peroxidation and closely linked to antitumor immunity. The contribution of intratumoral microbiota to ferroptosis regulation and anti-PD-L1 efficacy in HCC remains insufficiently defined. Here, we examined whether tumor-resident *Klebsiella pneumoniae* (*K. pneumoniae*) promotes anti-PD-L1 resistance by reprogramming cholesterol metabolism and suppressing ferroptosis. **Methods:** Intratumoral *K. pneumoniae* colonization was evaluated in human HCC specimens and immunocompetent mouse HCC models. The therapeutic response to anti-PD-L1 antibody was assessed in K. pneumoniae-colonized Hepa1-6 tumors. Bacterial PBP1B-deficient *K. pneumoniae*, recombinant PBP1B, TLR4/NF-κB and SREBP2 inhibition, SC5D/DHCR7 manipulation, and 7-dehydrocholesterol supplementation were used to dissect the mechanistic pathway. Ferroptosis was examined by lipid peroxidation, 4-HNE, MDA, C11-BODIPY, GPX4, SLC7A11, and ACSL4 analyses. CD8⁺ T-cell function, IFN-γ-dependent cytotoxicity, and tumor immune infiltration were assessed by flow cytometry, immunostaining, and T cell–tumor cell co-culture assays. **Results:** Intratumoral *K. pneumoniae* was enriched in HCC tissues and was associated with reduced ferroptotic activity and an immunosuppressive tumor microenvironment. In immunocompetent HCC models, *K. pneumoniae* colonization markedly impaired the antitumor efficacy of anti-PD-L1 therapy. Mechanistically, *K. pneumoniae*-derived PBP1B persistently activated TLR4/NF-κB signaling in HCC cells, promoted SREBP2 nuclear translocation, upregulated SC5D, suppressed DHCR7, and drove the accumulation of 7-dehydrocholesterol. This metabolic rewiring attenuated membrane lipid peroxidation, increased GPX4 and SLC7A11 expression, reduced ACSL4 expression, and conferred ferroptosis evasion. Disruption of PBP1B, TLR4/SREBP2 signaling, or 7-dehydrocholesterol accumulation restored ferroptosis, enhanced CD8⁺ T cell/IFN-γ-mediated tumor cell killing, and resensitized *K. pneumoniae*-colonized tumors to anti-PD-L1 therapy. **Conclusion:** Our findings reveal tumor-resident K. pneumoniae as a microbial determinant of anti-PD-L1 resistance in HCC. *K. pneumoniae*-derived PBP1B rewires cholesterol metabolism through TLR4/NF-κB–SREBP2 signaling, resulting in 7-dehydrocholesterol accumulation, ferroptosis evasion, and weakened CD8⁺ T-cell immunity. This bacteria–metabolism–ferroptosis circuit may represent a targetable vulnerability for improving immune checkpoint blockade in HCC.

4364 | ◆ CD4⁺ T CELLS MEDIATE ANTITUMOR IMMUNITY IN NOVEL PD1-RESITANT PSC-ASSOCIATED CHOLANGIOCARCINOMA MODEL

Pinzhu Huang[1] Zaur Abilov[1] Chandra Sekar Shankar[1] Yoshiko Nanki[1] Jered Garrison[1] Victor Turkowski[1] Yury Popov[1], [1]Beth Israel Deaconess Medical Center, Harvard Medical School

Background: Patients with primary sclerosing cholangitis (PSC) are at high risk to develop cholangiocarcinoma (CCA), yet the underlying immune mechanism remain obscure. We established a novel syngeneic, immunocompetent murine CCA model arising in PSC-like fibroinflammatory microenvironment (SB CCA.*Mdr2-/-)* that recapitulates high susceptibility to CCA in human PSC. Here, we interrogated the relative contributions of T cell subsets in PSC-CCA antitumor immunity. **Methods:** Intrahepatic CCA was induced in PSC-like *Mdr2-/-* mice via hydrodynamic tail vein injection of sleeping beauty transposon-transposase system with activated forms of AKT (myr-AKT) and Yap (YapS127A). PD1, PD-L1, CD4, and CD8 cells were quantified in CK7+ CCA stroma. Role of adaptive immunity in tumor

progression was interrogated in *Mdr2-/-;Rag1-/-* and via selective CD4 and CD8 antibody-mediated cell depletion in vivo. TGFb receptor 1 inhibitor (ALK5i) and therapeutic antibody against PD-1 or integrin β8 (C6D4 mAb) were administered 1-4 weeks post transduction (n = 5-12/group). **Results:** In our SB CCA.*Mdr2-/-* model, all CCA tumors expressed PD-L1 + and were immunologically "hot" with robust stromal PD-1+, CD8+ and CD4+ immune infiltration. Introduction of CCA in immunodeficient *Mdr2-/-;Rag1-/-* mice (lacking T and B cells) demonstrated dramatically accelerated tumor growth and shortened survival, suggesting adaptive immunity restrains tumorigenesis in our system. Intriguingly, in the immunocompetent SB CCA.*Mdr2-/-* model selective depletion of $CD4^+$, but not $CD8^+$, T cells markedly accelerated tumors. Administration of anti-PD-1 mAB therapy resulted in increased stromal CD8+, but not CD4+ cells, but had no impact on tumor growth. Likewise, significant increase in tumor-infiltrating CD4+, but not CD8+ lymphocytes was associated with therapeutic anti-tumor response to both pan-TGFb (ALK5i) or selective TGF inhibition via integrin β8. **Conclusion:** We generated immunocompetent, PD1-resistant PSC-associated CCA model that recapitulate predisposition to biliary cancer in human PSC. CD4+, rather than CD8+ T cells play indispensable role in antitumor immunity in the settings of chronic sclerosing cholangitis in SB CCA.*Mdr2-/-* model. Therapeutic strategies enhancing $CD4^+$ T-cell responses may represent a promising approach for PSC-associated CCA.

4365 | ◆ P38 MAPK-DEPENDENT YAP ACTIVATION PROMOTES SPONTANEOUS LIVER FIBROSIS AND HEPATOCARCINOGENESIS IN HEPATOCYTE-SPECIFIC TAK1-DEFICIENT MICE

Tiantian Chang[1] Jieun Kim[1] Takashi Tsuchiya[1] Michael Pimienta[2] Ekihiro Seki[1], [1]Cedars-Sinai Medical Center, [2]PIH Health Good Samaritan Hospital

Background: Transforming growth factor (TGF)-β-activated kinase 1 (TAK1) activates nuclear factor-κB (NF-κB), p38, and c-Jun N-terminal kinase (JNK), which regulate cell death, proliferation, and carcinogenesis. Hepatocyte-specific deletion of TAK1 results in spontaneous development of hepatocellular carcinoma (HCC), accompanied by liver inflammation and fibrosis. Yes-associated protein (YAP), a key effector of the Hippo signaling pathway that regulates cell proliferation and apoptosis, also functions as a major oncogenic driver in HCC. Previous studies have suggested that p38 can regulate YAP expression and activity. However, it remains unclear whether hepatocyte p38 signaling promotes HCC and fibrosis through YAP activation. **Methods:** We generated hepatocyte-specific TAK1 knockout mice ($TAK1^{\Delta Hep}$) and hepatocyte-specific TAK1/p38 double-knockout mice ($TAK1/p38^{\Delta Hep}$). $TAK1^{flox/flox}$ and $p38^{\Delta Hep}$ mice were used as controls, respectively. A YAP inhibitor (VT-103) was administered intraperitoneally to 9-month-old $TAK1^{flox/flox}$ and $TAK1^{\Delta Hep}$ mice. Liver injury, inflammation, fibrosis, and HCC development were assessed. In vitro, the p38 inhibitor SB203580 and the YAP inhibitor VT-103 were applied to the liver cancer cell lines, Hep3B and Huh7. **Results:** Levels of phospho-p38 and YAP were markedly increased in the livers from 9-month-old $TAK1^{\Delta Hep}$ mice, which developed severe liver fibrosis and HCC. In contrast, $TAK1/p38^{\Delta Hep}$ mice were protected from these pathological changes, exhibiting reduced liver fibrosis and diminished tumor development. Moreover, immunohistochemical staining suggested that total and nuclear YAP expression was reduced in the livers from $TAK1/p38^{\Delta Hep}$ mice, supporting YAP as a downstream effector of p38 signaling. For in vitro studies, Hep3B and Huh7 cells were treated with either the p38 inhibitor SB203580 or the YAP inhibitor VT-103. Western blot and immunohistochemical analyses demonstrated that treatment with SB203580 reduced YAP expression and activity in both liver cancer cell lines, further supporting YAP as a downstream effector of p38 signaling. In addition, YAP inhibition with VT-103 reduced the expression of the downstream target genes, CTGF and CYR61, and suppressed cancer cell proliferation, migration, and invasion. Finally, $TAK1^{\Delta Hep}$ mice were treated with the YAP inhibitor VT-103, and YAP blockade significantly attenuated spontaneous HCC development and hepatic fibrosis. **Conclusion:** Hepatocyte-specific p38 ablation mitigates spontaneous liver injury, inflammation, fibrosis, and hepatocarcinogenesis in hepatocyte-specific TAK1-deficient mice through suppression of YAP expression and activity. These findings highlight the p38–YAP signaling axis as a potential therapeutic target for HCC and liver fibrosis.

4366 | LOSS OF SPHINGOSINE KINASE 2 SUPPRESSES AKT/YAP-DRIVEN INTRAHEPATIC CHOLANGIOCARCINOMA DEVELOPMENT

Yun-Ling Tai[1] Nan Wu[1] Grayson Way[1] Meiyi Song[1] Derrick Zhao[1] Sareh Bayatpour[1] Chen Chen[1] Hongkun Lu[1] Lianyong Su[1] Xuan Wang[1] Phillip Hylemon[1] Emily Gurley[1] Huiping Zhou[1], [1]Virginia Commonwealth University

Background: Intrahepatic cholangiocarcinoma (iCCA) is an aggressive primary liver malignancy with a poor prognosis and limited therapeutic options. Sphingosine kinase 2 (SphK2), a key regulator of sphingolipid metabolism, has been implicated in cancer progression; however, its role in iCCA remains unclear. We assessed whether SphK2 loss suppresses AKT/YAP-driven iCCA and its relevance in human datasets. **Methods:** Wild-type (WT) and SphK2 knockout (KO) mice (both sexes,n = 6-10) underwent hydrodynamic tail-vein injection of AKT, YAP, and Sleeping Beauty transposase to induce iCCA. Mice were sacrificed 7 weeks post-injection, and tumor burden alongside serum liver chemistries were assessed. Immunohistochemistry and qPCR were used to evaluate biliary/progenitor and proliferation-associated markers. Transcriptomic profiling was performed by RNAseq with pathway enrichment analysis. Targeted sphingolipid and bile acid profiling were performed by LC-MS/MS. Public human iCCA transcriptomic datasets were analyzed for *SPHK2* expression. **Results:** Loss of SphK2 significantly reduced tumor burden, with KO mice developing fewer and smaller tumors compared with WT across both male and female cohorts. Serum AST, ALT, ALP, and total bilirubin levels were significantly reduced in KO mice. Histologic and molecular analyses demonstrated reduced expression of biliary/progenitor markers (CK19, EpCAM, CK7, and SOX9) and the proliferation marker Ki67 in KO mice. Transcriptomic analysis revealed suppression of tumor-associated pathways, specifically ECM-receptor interaction, focal adhesion, and PI3K-AKT signaling. Targeted LC-MS/MS demonstrated significantly elevated total ceramides, long-chain ceramide species, and conjugated bile acids with altered 12α-hydroxylation ratios in WT tumor-bearing mice, whereas SphK2 KO mice maintained both sphingolipid and bile acid profiles markedly closer to non-tumor baseline. Analysis of public human iCCA datasets (TCGA-CHOL and GSE107943) demonstrated significantly elevated SPHK2 expression in tumor tissues compared with adjacent non-tumor liver. **Conclusion:** Loss of SphK2 markedly suppresses AKT/YAP-driven iCCA development, attenuates hepatic injury, and disrupts tumor-associated transcriptional and metabolic reprogramming. Consistently elevated SPHK2 expression in human iCCA cohorts supports its translational relevance and identifies SphK2 as a promising therapeutic target.

★ 4367 | CHILDHOOD OBESITY–INDUCED KUPFFER CELL DYSFUNCTION PROMOTES LIVER CANCER SUSCEPTIBILITY LATER IN LIFE

Yuta Myojin[1] Chi Ma[2] Kylynda Bauer[2] Gabriel Prata[2] Mohamed-Reda Benmebarek[2] Patrick Huang[2] Kohei Kamizono[3] Lorenz Kocheise[2] Rajiv Trehan[2] Hayato Hikita[3] Takahiro Kodama[3] Firouzeh Korangy[2] Tim Greten[2], [1]The University of Osaka, National Cancer Institute, [2]National Cancer Institute, [3]The University of Osaka

Background: Childhood obesity has been epidemiologically associated with an increased risk of hepatocellular carcinoma (HCC) later in life; however, the underlying biological mechanism remains poorly understood. **Methods:** C57BL/6 mice were fed a short-term Western diet (SWD) after weaning and then returned to standard chow to model transient juvenile obesity. Liver tumor susceptibility was evaluated using three models: orthotopic liver tumor implantation, intravenous metastasis to the liver, and DEN-induced hepatocarcinogenesis. Bone marrow chimera experiments and Kupffer cell depletion were used. Immune remodeling

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

was characterized by flow cytometry, single-cell RNA sequencing, and in vivo SIINFEKL-specific cytotoxic T-cell assays. Spatial immune organization and cell-cell relationships were analyzed using CosMx spatial molecular imaging. **Results:** Although body weight and hepatic steatosis improved after the dietary intervention, mice exposed to SWD during the juvenile period showed significantly increased tumor burden in orthotopic liver tumor, liver metastasis, and DEN-induced carcinogenesis models. In contrast, subcutaneous tumor growth was not increased, indicating that transient juvenile obesity enhanced hepatic tumor susceptibility. Bone marrow chimera and depletion experiments suggested that this phenotype was driven predominantly by persistent alterations in liver-resident immune cells. SWD induced durable remodeling of Kupffer cell states, including altered inflammatory and antigen-presenting programs, and impaired liver antigen-dependent $CD8^+$ T-cell cytotoxicity in vivo. Spatial analysis further demonstrated that, in SWD livers, $CD8^+$ T-cell cytotoxic programs were attenuated in proximity to Kupffer cells, whereas in regular diet controls, $CD8^+$ T cells located near Kupffer cells exhibited increased cytotoxicity. **Conclusion:** Transient obesity during the juvenile period leaves a long-lasting hepatic immune imprint characterized by altered Kupffer cell states and impaired local $CD8^+$ T-cell effector function. This persistent liver-specific immune remodeling promotes HCC susceptibility. These findings provide a mechanistic link between childhood obesity and adult liver cancer risk and highlight liver-resident immune reprogramming as a potential target for prevention and therapeutic intervention.

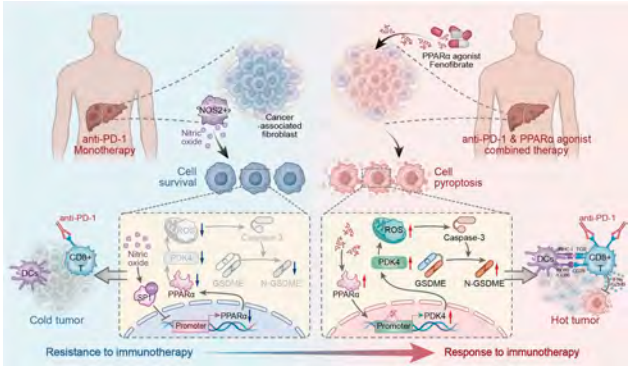
4368 | FENOFIBRATE OVERCOMES FIBROINFLAMMATION-DRIVEN RESISTANCE TO PD-1 BLOCKADE IN HEPATOCELLULAR CARCINOMA



Peng Chen[1] Zheyu Dong[1] Yuanbo Zhao[2] Huajin Pang[3], [1]Nanfang Hospital, Southern Medical University, [2]Zhujiang Hospital: Zhujiang Hospital of Southern Medical University, [3]Interventional Treatment Center, Zhujiang Hospital, Southern Medical University

Background: Resistance to immune checkpoint blockade remains a major challenge in hepatocellular carcinoma (HCC). Because most HCCs arise in chronically inflamed and fibrotic livers, we investigated whether the fibroinflammatory liver microenvironment (FILM) promotes immune resistance and explored therapeutic strategies to restore anti-tumor immunity. **Methods:** Human HCC cohorts, anti-PD-1-treated specimens, bulk RNA-seq, single-cell RNA-seq, spatial transcriptomics, orthotopic and spontaneous HCC models, and humanized patient-derived xenograft models were integrated to define mechanisms of FILM-associated immunotherapy resistance and evaluate therapeutic interventions. **Results:** FILM was associated with inferior survival and reduced responsiveness to anti-PD-1 therapy in HCC patients. Consistently, HCC established in independent FILM models exhibited profound resistance to PD-1 blockade and markedly reduced GSDME cleavage despite preserved total GSDME expression. Restoration of cleaved GSDME re-sensitized FILM tumors to anti-PD-1 therapy and enhanced dendritic-cell activation and cytotoxic $CD8^+$ T-cell responses. Multi-omics analyses identified tumor-intrinsic PPARα suppression as a central feature of FILM-associated immune resistance. Mechanistically, FILM-associated $NOS2^+$ macrophages induced SP1 S-nitrosylation and transcriptional repression of PPARα, thereby suppressing the PDK4–ROS–caspase-3 pathway and disabling GSDME-dependent pyroptotic immunogenic cell death. Conversely, pharmacologic activation of PPARα restored pyroptosis and anti-tumor immunity. Both the selective PPARα agonist GW7647 and the FDA-approved agonist fenofibrate significantly enhanced anti-PD-1 efficacy in orthotopic and spontaneous HCC models. In humanized immune-system PDX models, fenofibrate potentiated anti-PD-1 responses selectively in PPARα-positive tumors. Importantly, concomitant fenofibrate use was associated with prolonged progression-free survival and greater tumor shrinkage in an exploratory cohort of anti-PD-1-treated HCC patients. **Conclusion:** FILM drives anti-PD-1 resistance through suppression of a tumor-intrinsic NOS2–SP1–PPARα–PDK4 axis that restrains GSDME-dependent pyroptotic immunogenicity. Pharmacologic activation of PPARα with fenofibrate

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

4369 | DUAL INHIBITION OF INOS AND COX2 REMODELS MYELOID PROGRAMS TO IMPROVE RESPONSE TO PD-L1 BLOCKADE IN HEPATOCELLULAR CARCINOMA

Qianru Wu[1] Yuzhen Li[1] Timothy Billiar[1], [1]University of Pittsburgh

Background: Immune evasion in hepatocellular carcinoma (HCC) is driven in part by a suppressive tumor microenvironment shaped by tumor-infiltrating monocytes and macrophages. We investigated whether combined pharmacologic inhibition of inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX2) could remodel the HCC immune microenvironment and enhance antitumor response to PD-L1 blockade. **Methods:** An orthotopic murine HCC model was established by intrahepatic injection of 6×10^5 RIL-175 cells into mice. Mice received vehicle control, anti-PD-L1 antibody, the selective iNOS inhibitor 1400W plus the COX2 inhibitor celecoxib, or 1400W plus celecoxib combined with anti-PD-L1. After three weeks, tumors and plasma samples were collected for downstream analyses. Tumor response was evaluated by gross liver morphology, H&E histology, and survival. Flow cytometry was used to assess T-cell exhaustion-associated markers and intracellular cytokine production. Single-cell RNA sequencing was performed to characterize tumor-infiltrating immune populations, with focused reanalysis of monocyte/macrophage-lineage cells and treatment-associated functional programs. CODEX multiplex imaging with HALO spatial analysis was used to evaluate immune-cell localization and cellular proximity within tumor and stromal regions. **Results:** Triple therapy with 1400W, celecoxib, and anti-PD-L1 induced marked tumor regression and significantly improved survival compared with vehicle control, anti-PD-L1 alone, or 1400W plus celecoxib. Flow cytometry showed improved T-cell function, with reduced exhaustion markers and increased CD4+ IL-2 and CD8+ IFNγ production. Focused scRNA-seq analysis suggested that 1400W/celecoxib-based treatment remodeled tumor-infiltrating monocyte/macrophage programs, shifting away from SPP1/TAM-like states toward antigen-presenting and IFN-responsive states. Plasma cytokine profiling revealed increased IFNγ, IP-10/CXCL10, and other immune-activating cytokines following treatment. CODEX spatial analysis demonstrated increased proximity and clustering of inflammatory macrophages with CD4+ and CD8+ T cells in tumor and stromal regions, supporting improved myeloid–T-cell organization within the TME. **Conclusion:** Combined inhibition of iNOS and COX2 remodels the HCC tumor immune microenvironment and enhances antitumor response to PD-L1 blockade. Triple therapy with 1400W, celecoxib, and anti-PD-L1 induced tumor regression, significantly improved survival, enhanced T-cell effector function, increased systemic immune-activating cytokines, and shifted monocyte/macrophage programs away from SPP1/TAM-like states toward antigen-presenting, IFN-responsive states. Together, these data support a model in which iNOS/COX2 inhibition reshapes the myeloid compartment and promotes a T-cell-supportive immune microenvironment in HCC.

4370 | SILIBININ INHIBIT THE METASTASIS OF HCC BY INTERFERING WITH THIOREDOXIN-INDUCED GLYCOLYSIS

Jin Shang[1], [1]Sichuan Cancer Hospital

Background: Metastasis is the main cause of high morality of hepatocellular carcinoma (HCC). We previously found that RNA-binding protein Thioredoxin(Trx) regulates alternative splicing and promotes metastasis of HCC via interacting with LINC00152. It's worth noticing that Trx could be up-regulated by glycolysis to maitain NADP/NADPH homeostasis. Aerobic glycolysis is an emerging hallmark of many human cancers. The aim of this study was to explore whether interfering of Trx-induced glycolysis could inhibit the metastasis of HCC. **Methods:** Trx-related metabolism reprograming was first analyzed by Whole transcriptome sequencing between HCC with metastasis and HCC without metastasis. Next, bioinformatic analysis was conducted

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

based on the single-cell transcriptome data derived from HCC patients in different stages to explore the metabolism reprograming in HCC cell sutsets. Finally, the impact of 79 glycolysis inhibition drugs approved by the FDA drug repository on Trx expression was screened by Western blot. The effect of glycolysis inhibitor on the metastasis ability of hepatocellular carcinoma cells was observed by transwell experiment. Lactate dehydrogenase (LDH) and NADPH were detected to verify the metabolism reprogramby glycolysis inhibitor. **Results:** We screen glycolysis inhibition drugs approved by the FDA drug repository, we found that among 79 drugs, a total of 54 kinds of drugs could decrease the expression of Trx more than half, in which we found that the hepatitis treatment commonly used drug silibinin could significantly reduce the expression of Trx, The inhibition of Trx expression by silibinin was further verified by Western method, and Transwell method showed that the metastatic ability of MHCC97L-Trx was decreased under silibinin treatment. Experiments on glucose metabolism showed that silibinin could significantly reduce LDH production and NADPH level, and the level of glycolysis could be significantly reduced by silibinin. Finally, under the treatment of silibinin, the expression levels of ALDOB, a glucose metabolic enzyme that inhibits the pentose phosphate pathway, were significantly increased, suggesting that silymarin mainly inhibits the expression of Trx by inhibiting the pentose phosphate pathway of glycolysis. As a potential inhibitor of Trx, the clinical application of silibinin in targeted therapy or combination therapy in the future is worth further exploration. **Conclusion:** Silibinin showed promising suppressive effects on HCC metastasis via inhibting Trx-induced glycolysis, indicating that glycolysis inhibitors are potential targeted drugs for Trx, the clinical application of silibininin future targeted therapy and combination therapy for hepatocellular carcinoma is worthy of further exploration.

4371 | ATTENUATED BACTERIAL THERAPY SUPPRESSES HEPATOCELLULAR CARCINOMA AND RESHAPES THE INTRATUMORAL IMMUNE LANDSCAPE

Xinlei Guo[1] Lujie Liu[1] Weiqi Ai[1] Duminduni Angappulige[1] Shan Xu[1] Jianxun Song[1], [1]Texas A&M University Health Science Center

Background: Hepatocellular carcinoma (HCC) is characterized by a profoundly immunosuppressive tumor microenvironment that limits the efficacy of current immunotherapies. Strategies capable of reprogramming intratumoral immunity and restoring effective anti-tumor responses are urgently needed. **Methods:** A spontaneous murine HCC model was established by hydrodynamic tail vein injection of oncogenic plasmids (MYC, sgTrp53, and sgPten) using the Sleeping Beauty transposase system. Mice were treated with attenuated *Brucella*-derived bacterial strain lacking virulent genes (1×10^8 CFU) or PBS control on day 5 after tumor induction. Tumor burden was monitored longitudinally by bioluminescence imaging (BLI) on day 5, 10 and 15. Tumors were harvested on day 15 for comprehensive immune profiling by flow cytometry, including cytotoxic $CD8^+$ T cells, macrophage subsets, regulatory T cells (Tregs), and T cell exhaustion markers. **Results:** Attenuated bacterial therapy significantly suppressed tumor progression compared with controls, as demonstrated by reduced tumor-associated bioluminescence. Immune profiling revealed marked remodeling of the intratumoral immune landscape. Treatment increased cytotoxic $CD8^+$ T cell activity, as indicated by elevated IFN-γ and TNF-α production, and expanded M1-like macrophage populations ($CD11b^+F4/80^+CD80^+CD86^+$), consistent with a pro-inflammatory and anti-tumor phenotype. Conversely, immunosuppressive components were reduced, including intratumoral Tregs ($CD4^+CD25^+FOXP3^+$). In addition, bacterial therapy alleviated T cell exhaustion, with decreased PD-1 and CTLA-4 expression on both $CD8^+$ and $CD4^+$ T cells, indicating improved effector function within the tumor microenvironment. **Conclusion:** Attenuated bacterial therapy suppresses HCC progression and promotes coordinated reprogramming of intratumoral immunity. These findings highlight microbial-based immunotherapy as a promising strategy to overcome immune suppression in HCC and support further translational investigation of this approach in liver cancer. **Keywords** : Hepatocellular carcinoma (HCC); Bacterial immunotherapy; Tumor microenvironment; Antitumor immunity

Background: STIL (SCL/TAL1 interrupting locus) is a key regulator of centrosome duplication and mitosis. Although its overexpression is associated with the progression of multiple tumors, its biological functions and molecular mechanisms in hepatocellular carcinoma (HCC) remain to be systematically elucidated. This study aims to characterize the expression profile, functional roles, and downstream pathways of STIL in HCC, and to explore its potential as a novel target for precision therapy. **Methods:** STIL expression and clinical relevance in HCC were analyzed using GEPIA, GEO, and UALCAN. PPI networks were built with STRING and GeneMANIA, and GSEA was performed on the TCGA-LIHC cohort. STIL was knocked down in Hep3B and SK-HEP-1 cells via shRNA lentivirus. Cell proliferation, apoptosis, migration, and invasion were assessed by MTT, Celigo, flow cytometry, wound healing, and Transwell assays. In vivo tumorigenicity was evaluated using a subcutaneous xenograft nude mouse model. Microarray profiling combined with IPA identified downstream pathways, validated by qPCR and Western blot. STIL-interacting proteins were identified by Co-IP coupled with LC-MS/MS, followed by rescue experiments to clarify their functional roles. **Results:** TCGA analysis showed STIL was significantly overexpressed in 25 cancers including HCC, validated by GEO datasets and tissue microarray immunohistochemistry. High STIL expression correlated with advanced stage, lymph node metastasis, poor differentiation, TP53 mutation, and poor prognosis (OS: HR = 1.6, P = 0.013; DFS: HR = 1.5, P = 0.007), particularly in males. GSEA revealed enrichment of ribosomal and protein synthesis pathways in the STIL-high group. STIL knockdown inhibited proliferation ($P < 0.01$), migration and invasion ($P < 0.05$), and promoted apoptosis (4.2% vs 8.5%, $P < 0.001$). In vivo, sh-STIL tumors showed reduced volume and weight (0.864 ± 0.35 g vs 1.158 ± 0.20 g, P = 0.034). Mechanistically, IPA identified the HGF/c-MET axis as the most significantly inhibited pathway upon STIL knockdown (Z-score = −2.496), with downstream molecules (IL6ST, RAF1, JAK1, STAT3, JUN, RRAS, ITGA2, PTGS2) downregulated at the mRNA level, and IL6ST and STAT3 concordantly decreased at the protein level. Co-IP/MS identified 174 candidate STIL-interacting proteins and confirmed specific binding between STIL and ribosomal protein RPS15A. RPS15A overexpression partially rescued STIL knockdown-induced apoptosis (8.9% to 5.9%, $P < 0.05$), indicating STIL regulates HCC apoptosis via RPS15A interaction. **Conclusion:** STIL is highly expressed in HCC and correlates with poor prognosis. It promotes HCC progression via a dual mechanism: activating the HGF/c-MET/STAT3 pathway to drive proliferation and invasion, while binding RPS15A to suppress apoptosis. STIL represents a promising prognostic biomarker and therapeutic target for HCC.

4373 | FAM17 LIMITS SENESCENCE-ASSOCIATED TRANSCRIPTIONAL ELONGATION TO PROMOTE HEPATOCELLULAR CARCINOMA

Taofei Zeng[1] Hao He[1] Jiuxiang Chang[1] Weiqiao Chen[1] Jiayi Geng[1] Yabin Huang[1] Dalong Yin[1], [1]The First Affiliated Hospital of USTC

Background: Cellular senescence is accompanied by extensive transcriptional remodeling, including altered RNA polymerase II elongation. However, whether Pol II pause release actively instructs senescence-associated transcription in hepatocellular carcinoma remains unresolved. **Methods:** Candidate regulators of senescence-associated transcription were identified by integrating public HCC RNA-seq and ATAC-seq datasets with transcriptomic profiles from senescence models. ATAC-seq and CUT&Tag were used to map chromatin accessibility, Pol II occupancy, Pol II Ser2/Ser5 phosphorylation and histone modifications. FAM17-interacting proteins were identified by IP–MS and validated by co-immunoprecipitation. The in vivo function of FAM17 was assessed using *Alb-Cre; Fam17$^{fl/fl}$* mice, followed by single-cell RNA sequencing and flow

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

cytometry to characterize tumor immune microenvironment remodeling. **Results:** Integrative multiomic screening identified FAM17 as a candidate regulator of senescence-associated transcription in HCC. FAM17 was induced during senescence but functionally restrained senescence execution, as its depletion triggered cellular senescence and SASP activation. Loss of FAM17 increased chromatin accessibility at TP53, CDKN1A and CDKN1B, promoted Pol II pause release and enhanced elongating Pol II accumulation at these loci, together with H3K4me3 enrichment at adjacent super-enhancers. Mechanistically, FAM17 interacted with PHF and promoted PHF degradation, thereby restraining PHF-dependent Pol II pause release and transcriptional elongation through the PHD1 domain. Consistently, hepatocyte-specific FAM17 loss in *Alb-Cre;Fam17$^{fl/fl}$* mice enhanced senescence-associated transcription and secretory programs, suppressed liver tumorigenesis, and remodeled the tumor immune microenvironment, characterized by increased NK-cell infiltration and reduced myeloid-cell abundance. Therapeutically, GalNAc-conjugated siFAM17 recapitulated the antitumor effects of genetic FAM17 loss, promoting tumor senescence, reducing liver tumor burden and prolonging survival. **Conclusion:** FAM17 functions as a suppressor of senescence-associated transcription by coupling PHF degradation to Pol II pause-release control. Targeting FAM17 reactivates tumor senescence and suppresses HCC progression, providing a liver-directed therapeutic strategy for HCC.

4374 | LIPIDOMIC SIGNATURE OF HEPATOCELLULAR CARCINOMA

Héloïse Giudicelli[1] Valérie-Ann Raymond[2] Caroline Daneault[3] Isabelle Robillard[3] Simon Turcotte[2] Matthieu Ruiz[3] Marc Bilodeau[2], [1]Université de Montréal, Sorbonne Université, [2]Université de Montréal, [3]Université de Montréal, Institut de cardiologie de Montréal

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related death. In the liver, disrupted lipid homeostasis can lead to steatosis and Metabolic Dysfunction–Associated SteatoHepatitis (MASH), a preneoplastic condition to HCC. Metabolic reprogramming is a cancer hallmark and lipid metabolism may play a key role in hepatocarcinogenesis, especially in steatotic liver disease. This study aimed to characterize lipidomic differences across HCC, adjacent cirrhotic tissue, steatotic liver and healthy liver. **Methods:** We analyzed HCC arising from MASH (n = 10) and non-MASH cirrhosis (n = 10), along with matched adjacent non-tumoral liver (MASH n = 10; non-MASH cirrhosis n = 10). Non-cirrhotic samples included steatotic (> 20% steatosis, n = 10) and healthy liver (n = 10) from resections for benign tumors or colorectal metastases. Lipidomic profiling was performed using high-performance liquid chromatography–mass spectrometry (HPLC). Linear regression (adjusted for age and sex, without multiple testing correction) or paired t-tests (for the comparisons of tissues from the same individual) identified significant changes ($p < 0.05$; FC > 1.25 or < 0.8). Gene expression was assessed by qPCR. **Results:** Compared with healthy liver, HCC showed 698 lipid features significantly altered, of which, for now, we annotated 192 features across 5 lipid categories: fatty acyls (FA), glycerophospholipids (GP), sphingolipids, sterol lipids, and glycerolipids. More precisely, in terms of major subclasses, HCC displayed increased acylcarnitines (CAR), triacylglycerols (TG) enriched in very-long-chain unsaturated FA and steryl esters (SE), but reduced diacylglycerophoscholines (PC) and ceramides (CER). Beyond elevated CAR, used as surrogates of impaired fatty acid β-oxidation (FAO), we observed in HCC a downregulation of specific markers of FAO: ACAA2($p < 0{,}001$), ACSL1 ($p = 0{,}002$), ECH($p < 0{,}001$), CPT2 ($p = 0{,}006$). The same trend was observed in HADHA and ACSS2 expression. MASH-HCC exhibited increased CAR and mono-(LPC) and di-acylglycerophosphocholines (PC) while TG are down-regulated compared to MASH adjacent liver. Non-MASH-HCC exhibited increased CAR, TG enriched in very-long-chain unsaturated FA and SE compared to adjacent cirrhotic liver. Compared to non-MASH-HCC, MASH-HCC had lower CAR, SE, and CER. Steatotic liver versus healthy liver showed 1267 altered lipid features, and particularly decreased CAR, CER and major subclasses of GP but increased TG enriched in long-chain saturated FA. **Conclusion:** In conclusion, these findings highlight a survival-driven metabolic reprogramming in HCC, where suppressed fatty acid oxidation—evidenced by acylcarnitine accumulation—potentially limits reactive oxygen species production. Additionally, the distinct remodeling of acylcarnitines, ceramides, and sterols in MASH-HCC underscores a clear metabolic continuum spanning from steatosis to tumorigenesis.

4375 | TEAD INHIBITION BY IAG933 AS A FERROPTOSIS-SENSITIZING THERAPEUTIC STRATEGY IN CHOLANGIOCARCINOMA

Hidemi Nishi[1] Brandon Wilbanks[1] Erik Jessen[1] Shelby Yee[1] Meina Cai[1] J. Pedro Fincatto Safi[1] Danielle Carlson[1] Amro Abdelrahman[1] Enis Hikmet Ozmert[1] Jack Sample[1] Nathan Werneburg[1] Rory Smoot[1], [1]Mayo Clinic Rochester

Background: Cholangiocarcinoma (CCA) is an aggressive biliary tract malignancy with limited therapeutic options and poor prognosis. Dysregulation of the Hippo–YAP/TAZ–TEAD pathway contributes to tumor progression and therapeutic resistance. IAG933 is a novel pan-TEAD inhibitor that suppresses YAP/TAZ–TEAD transcriptional activity. Previously, we demonstrated that IAG933 exhibits synergistic effects with Gemcitabine/Cisplatin (GemCis) and the pan-RAS inhibitor RMC6236. Recent chromatin profiling studies further suggested that TEAD inhibition induces tumor-selective enhancer remodeling and ferroptosis-associated transcriptional priming. We therefore investigated whether combination therapy with the GPX4 inhibitor RSL3 enhances ferroptosis-mediated anti-tumor effects in CCA. **Methods:** Human CCA cell lines (HuCCT1 and RBE) and murine CCA cell lines (SB1 and FAC) were treated with IAG933 alone or in combination with GemCis, RMC6236, or RSL3. Cell viability assays were used to determine IC_{50} values and calculate Combination Index (CI) scores. TEAD activity was evaluated using luciferase reporter assays and qRT-PCR of canonical target genes. RNA-seq, CUT&RUN, and chromatin accessibility analyses were integrated to evaluate enhancer remodeling, YAP chromatin occupancy, and ferroptosis-associated transcriptional responses following TEAD inhibition. **Results:** IAG933 significantly suppressed TEAD-dependent transcription and reduced expression of canonical YAP/TEAD target genes. IC_{50} values ranged from approximately 500–1400 nM across CCA cell lines. Combination treatment with GemCis or RMC6236 demonstrated synergistic effects (CI < 1). Integrated chromatin analyses revealed marked loss of H3K27ac at tumor-specific enhancer loci in CCA cells, whereas normal cholangiocyte chromatin architecture remained relatively preserved. Transcriptomic analyses demonstrated induction of ferroptosis-associated genes, including SOD2, ACSL4, SLC7A11, and NFE2L2, suggesting that TEAD inhibition primes CCA cells for ferroptosis. MitoSOX staining demonstrated increased mitochondrial ROS levels following IAG933 treatment. Sequential combination treatment with IAG933 and RSL3 demonstrated concentration-dependent synergistic effects in HuCCT1 cells, particularly within intermediate-dose ranges where CI values were consistently below 1. Pretreatment with IAG933 followed by RSL3 exposure reduced viability compared with either agent alone. **Conclusion:** IAG933 induces tumor-selective chromatin remodeling and ferroptosis-associated transcriptional priming in cholangiocarcinoma. Combination treatment with GemCis, RMC6236, and the ferroptosis inducer RSL3 demonstrated synergistic effects across multiple CCA models. These findings support TEAD inhibition-based ferroptosis combination therapy as a promising therapeutic strategy for YAP/TEAD-dependent cholangiocarcinoma.

4376 | WNT RECEPTOR FZD10 MARKS CAR-INDUCED TUMOR-ASSOCIATED HEPATOCYTE POPULATION WITH CANCER STEM CELL-LIKE FEATURES

Elena (Yu) Sun[1] Maxim Pyatkov[1] David Waxman[1], [1]Boston University

Background: Constitutive androstane receptor (CAR, *Nr1i3*) is a hepatocyte-expressed nuclear receptor that mediates widespread transcriptional responses to xenobiotics, promotes steatosis, and with prolonged exposure, induces mouse hepatic tumorigenesis. Mice were treated with TCPOBOP, a selective CAR agonist xenobiotic, to identify early CAR-induced gene responses that drive liver tumor formation, with the goal of interdicting liver disease progression at an early stage. **Methods:** snRNA-seq, ChIP-seq and ATAC-seq datasets were analyzed for male CD1 mouse livers exposed to TCPOBOP persistently, with liver tumors first detected at 14 wk and becoming extensive by 20-22 wk. smFISH validated localization and co-expression. Human HCC data were analyzed using UALCAN. DAVID and Ingenuity Pathway Analysis (IPA) identified enriched pathways and upstream regulators. **Results:** *Fzd10* was rapidly (within 3 hr) and strongly (>90-fold) induced by TCPOBOP in mouse liver. ATAC-seq sites proximal to *Fzd10* responded to TCPOBOP by chromatin opening, were linked to *Fzd10* expression by multiomic analysis, and acquired enhancer histone marks (H3K27ac, H3K4me1). A subset of these *Fzd10*-proximal enhancers showed strong CAR binding, indicating that *Fzd10* is a direct CAR target gene.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Fzd10 and Sox4 RNAs co-localize within an snRNA-seq pericentral hepatocyte subcluster where CAR is enriched, in both high and low Fzd10- and Sox4-expressing subpopulations. The Sox4 locus was increasingly accessible (snATAC-seq) in Fzd10+ cells, suggesting that Fzd10 and Sox4 define a common cancer stem cell-like population. smFISH validated the expression and co-localization of both gene transcripts. DAVID analysis indicated cancer-associated pathway enrichment, and IPA identified Tbx3, a Wnt/β-catenin target that maintains cancer stemness, as an activated upstream regulator in Fzd10+ and Sox4+ hepatocytes. Hepatocyte re-clustering using 433 tumor-specific gene features, including 32 well-defined liver cancer markers representing distinct tumorigenic programs, revealed high- and low-expression patterns aligned with Fzd10-high and Fzd10-low subclusters, suggesting shared tumor-related transcriptional programs. Human HCC data showed FZD10 overexpression and association with aggressive tumor features. **Conclusion:** CAR induces both Fzd10-high and Fzd10-low pericentral hepatocytes, which may represent distinct tumor-associated reprogramming events. Fzd10+ hepatocytes are proposed to acquire cancer stem cell-like and tumor-associated features through increased Wnt/β-catenin signaling. These findings support Fzd10 as an early marker and a potential therapeutic target for CAR-driven HCC.

4377 | EEF1E1 DRIVES IMMUNE EVASION IN HEPATOCELLULAR CARCINOMA BY SUSTAINING EGFR SIGNALING

Dongbo Chen[1] Liying Ren[2] Hongsong Chen[3], [1]Peking University People's Hospital, [2]Peking University People's Hospital, Peking University Hepatology Institute, [3]Peking University Third Hospital, Beijing, China

Background: Although immune checkpoint inhibitors have recently achieved promising advances, their clinical benefits in hepatocellular carcinoma (HCC) remain limited. Therefore, it is urgent to identify novel biomarkers that can predict which patients are more likely to benefit from immunotherapy and guide rational combination treatment strategies. Our previous studies identified EEF1E1 as a recurrence-associated gene in HCC. However, its role in the tumor immune microenvironment (TIME) remains unclear. **Methods:** Immunohistochemistry (tissue microarray, n = 141), RNA sequencing, and spatial transcriptomic analyses were performed to evaluate the expression pattern and prognostic significance of EEF1E1 in HCC tissues. In vitro and in vivo functional assays were conducted to investigate the oncogenic function role of EEF1E1. Single-cell RNA sequencing combined with multiparameter flow cytometry was used to analyze the impact of EEF1E1 on the TIME. Co-immunoprecipitation and signaling pathway–related experiments were performed to validate the interaction between EEF1E1 and epidermal growth factor receptor (EGFR). **Results:** EEF1E1 was significantly upregulated in HCC tissues and identified as an independent risk factor for poor prognosis in HCC patients. Functional experiments demonstrated that EEF1E1 promoted HCC cell invasion, migration, and epithelial–mesenchymal transition (EMT) both in vitro and in vivo, while remodeling the TIME toward an immunosuppressive phenotype characterized by increased infiltration of $PD\text{-}1^{+}$ $CD8^{+}$ T cells. Mechanistically, EEF1E1 interacted with EGFR at the protein level and prevented EGFR degradation through the endosome–lysosome pathway, thereby promoting EGFR accumulation and sustained activation of the EGFR–STAT signaling pathway. Consistent with this mechanism, treatment with the EGFR inhibitor osimertinib reduced $PD\text{-}1^{+}$ $CD8^{+}$ T-cell infiltration in mouse models. Moreover, the combination of osimertinib and anti–PD-1 antibody exhibited significantly superior antitumor efficacy compared with either monotherapy alone. Notably, tumors with high EEF1E1 expression derived the greatest benefit from the combination therapy. **Conclusion:** EEF1E1 drives aggressive biological behaviors and mediates immune evasion in HCC by sustaining EGFR signaling activity. Furthermore, EEF1E1 may serve as both a prognostic and predictive biomarker, providing a theoretical basis for combination therapy with PD-1 inhibitors and EGFR inhibitors in HCC.

Sydney, Australia, [5]Department of Tissue Pathology and Diagnostic Oncology, Royal Prince Alfred Hospital, Australia, [6]A.W. Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, Sydney, Australia, [7]A.W. Morrow Gastroenterology and Liver Centre, Royal Prince Alfred Hospital, Sydney NSW, Australia

Background: In 2020, Hepatocellular carcinoma (HCC) was the sixth most frequent cancer and third leading cause of cancer-related deaths worldwide. Technological advances provide insight into the human tumour microenvironment (TME) and its influence on clinical outcomes. These studies have advanced our knowledge considerably, however, cancers with unique TMEs such as HCC do not adhere to these classifications for immune cells or Cancer-associated Fibroblasts (CAFs). **Methods:** A total of 39 patients undergoing liver resection for HCC at a single tertiary hospital from 2021 to 2024 were included. We interrogated the HCC TME in tumour and adjacent non-tumour (NT) regions using multi-omic technologies including single-cell RNA sequencing (scRNAseq, n = 10), high-dimensional imaging (IMC (n = 16) & Lunaphore COMET) and spatial transcriptomics (Xenium, n = 35). **Results:** scRNAseq analysis of dissociated HCC tumour identified a new CAF phenotype with attributes of fibroblasts (ACTA2/aSMA, COL3A1/type I/II collagens) and endothelial cells (ECs) (CD31/PECAM1, CDH5/VE-cadherin, PLVAP, CD34). Due to this unique profile, we designated these cells "*endothelial-like*-CAFs" or ***'el-CAF'***. Using multiple high-dimensional tissue imaging platforms we confirmed the presence of *el*-CAFs in the HCC TME. Interestingly, this data showed *el*-CAFs present in higher proportions in tumour compared to adjacent NT tissue. Ligand-receptor (L-R) analysis revealed *el*-CAFs may interact with myeloid cells, CD4 Tregs, B cells, CD8 T cells and ECs. Amongst these, the greatest potential interaction was with ECs through multiple L-R pairs such as, CX3CL1/ITGAV, ENG/CDH5, TGFb3/TGFbR2 or ENG, and COL4A1-2/ITGA1. These interactions suggest *el*-CAFs have multiple roles within the TME including promotion of leukocyte adhesion and activation, facilitating tumour cell adhesion and spread, supporting angiogenesis and endothelial mesenchymal transition (endMT). Spatial transcriptomics confirmed cell proximity and L-R communication between *el*-CAFs and ECs independent of cell densities. Moreover, quantitation of *el*-CAF showed higher numbers in HCC tumours containing vessels-encapsulating tumour clusters (VETC) compared to VETC-negative tumour tissue or VETC+ adjacent NT tissue. **Conclusion:** We have identified a novel CAF, *el*-CAF, with attributes of both fibroblasts and ECs, suggesting these cells result from endMT within highly vascularised HCC tumours. In particular, *el*-CAFs were most abundant in tumours with abnormal vascular pathology, VETC, suggesting *el*-CAFs are associated with abnormal and dysfunctional vasculature that has a unique role in metastasis and poor patient outcomes in HCC. These findings challenge existing dogma by redefining stromal cell archetypes in HCC and advancing a new, tumour type-specific framework for understanding TME organisation and function.

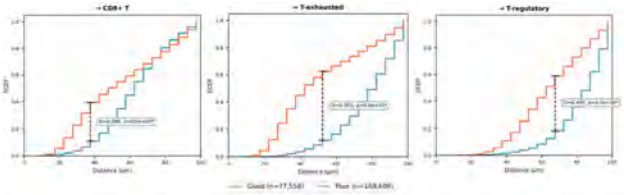
4379 | CD8⁺ T CELL EXHAUSTION DRIVEN BY SUSTAINED JAK/STAT–IFN-Γ SIGNALING DEFINES RESISTANCE TO ATEZOLIZUMAB PLUS BEVACIZUMAB IN HEPATOCELLULAR CARCINOMA: A XENIUM SPATIAL TRANSCRIPTOMIC STUDY



Young-Sun Lee[1] Sungjun Jang[2] Eunho Choi[2] Yang Jae Yoo[2] Seong Hee Kang[2] Sun Young Yim[2] Taehyung Kim[2] Young Kul Jung[2] Ji Hoon Kim[2] Yeon Seok Seo[2] Hyung Joon Yim[2] Jong Eun Yeon[2], [1]Korea University College of Medicine, [2]Korea university

Background: Atezolizumab plus bevacizumab is the standard first-line systemic therapy for advanced hepatocellular carcinoma (HCC), but objective responses are achieved in only a minority of patients, and the spatial features of the tumor microenvironment (TME) that govern response remain incompletely defined. We applied in situ spatial transcriptomics to dissect the cellular architecture and signaling programs distinguishing responders from non-responders. **Methods:** We retrospectively assembled tissue microarrays from primary resected HCC specimens of 14 patients who subsequently received atezolizumab plus bevacizumab for post-operative recurrence, and stratified them by RECIST v1.1 best response: responders (complete or partial response; n = 5) and non-responders (stable or progressive disease; n = 9). Spatial transcriptomic profiling was performed on the 10× Genomics Xenium platform, followed by unsupervised clustering and annotation of 15 cell populations, differential expression and pathway enrichment analyses, and nearest-neighbor distance analysis between malignant hepatocytes and immune subsets. **Results:** Responder tumors retained well-differentiated hepatocyte identity, with preserved cytochrome P450 expression (CYP17A1, CYP1A2) and enrichment of androgen

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

and xenobiotic metabolism pathways. Non-responder tumors exhibited loss of metabolic hepatocyte programs, upregulation of the invasion-associated laminin LAMC2, and POSTN-high cancer-associated fibroblast–driven stromal remodeling. Despite robust expression of the T cell–recruiting chemokines CXCL9 and CXCL10, $CD4^+$ and $CD8^+$ T cells in non-responders displayed high LAG3, consistent with a terminally exhausted phenotype, and tumor-associated macrophages expressed MARCO, indicating immunosuppressive polarization. Pathway analysis demonstrated concurrent activation of E2F targets, VEGF signaling, and—most prominently—sustained JAK/STAT and interferon-γ signaling, a configuration mechanistically linked to terminal T cell exhaustion. Nearest-neighbor analysis revealed that exhausted T cells, regulatory T cells, and total $CD8^+$ T cells were positioned significantly closer to malignant hepatocytes in non-responders than in responders (Kolmogorov–Smirnov test, $p < 0.001$; KS statistic $D = 0.505$, 0.405, and 0.286, respectively). **Conclusion:** These findings nominate sustained type II interferon signaling and tumor-proximal exhausted-cell niches as candidate biomarkers and therapeutic targets—via LAG3 blockade, intensified anti-angiogenic pressure, or JAK inhibition—for overcoming primary resistance to atezolizumab plus bevacizumab.

4380 | UNCOVERING THE ROLE OF VISCOELASTICITY IN LIVER CANCER COLLECTIVE INVASION IN THE CIRRHOTIC LIVER

Vidushi Bansal[1], [1]*Stanford University*

Background: Hepatocellular carcinoma (HCC) is highly invasive and carries a poor prognosis. While increased bulk stiffness during cirrhosis is a well-established driver of tumor progression, the cirrhotic liver microenvironment is highly architectural and mechanically heterogeneous. We showed that regenerative areas—where dysplastic nodules arise—exhibit increased viscoelasticity characterized by fast stress relaxation, independent of bulk stiffness change. How these localized viscoelastic matrix properties impact early collective HCC cell invasion remains poorly defined. This study characterizes how matrix stress relaxation drives collective invasion modes and identifies key downstream mechanosensitive transcriptomic regulators. **Methods:** We used a 3D collagen-alginate interpenetrating network (CAiPN) to decouple stiffness from viscoelasticity. Epithelial (Huh7) and mesenchymal (SNU449) spheroids were embedded in CAiPNs (~2.5 kPa) tuned for fast/slow stress relaxation. Tracks were captured via live-imaging. Patient-derived organoids (PDOs) with stroma were established via air-liquid interface, embedded in CAiPNs , and profiled via spatial transcriptomics across the invasive front. Blockades against integrin β1, Rac1, RhoA, and CK666 validated mechanisms. **Results:** Both Huh7 and SNU449 spheroids exhibited significantly enhanced invasion in fast stress-relaxing CAiPNs compared to slow stress-relaxing counterparts at equal stiffness. Huh7 spheroids invaded through cohesive, multicellular protrusions, whereas SNU449 spheroids migrated via rapid cell streaming. While matrix metalloproteinase (MMP) inhibition showed minimal impact, blocking integrin β1 and Arp2/3 (CK666) completely abrogated viscoelasticity-induced invasion. Crucially, spatial transcriptomic profiling of patient-derived organoids identified transgelin-2 (TAGLN2) as a highly significant mechanosensitive hit, demonstrating intense upregulation specifically at the leading edge of collectively invading cells in fast stress-relaxing matrices. The invading cells in the organoids expressed a metabolic shift toward aerobic glycolysis, whereas there were elevated glycolytic gene patterns in mouse RNA-seq data and increased lactic acid production observed under high viscoelastic conditions. **Conclusion:** Matrix viscoelasticity, rather than stiffness alone, determines early collective HCC invasion. The integrin β1 axis upregulates cytoskeletal TAGLN2 and coordinates localized metabolic reprogramming at the invasive margin. Targeting viscoelastic mechanosensing or downstream effectors like TAGLN2 provides a compelling framework to impede collective invasion.

4381 | MELK INHIBITION ACTIVATES THE NLRP3 INFLAMMASOME AND PYROPTOSIS TO INDUCE RADIOFREQUENCY ABLATION MEDIATED IMMUNOGENIC CELL DEATH IN THE HCC

Bufu Tang[1] Xiaojie Zhang[2] Jinhua Luo[2], [1]Zhongshan Hospital Fudan University, [2]Wenzhou Medical University

Background: Residual hepatocellular carcinoma cells after radiofrequency ablation (RFA) often create an immunosuppressive microenvironment that promotes tumor recurrence. This study aimed to develop a pH-responsive superparamagnetic iron oxide nanoparticle platform, SPIO/OTS167@cRGD-phSiNPs, for targeted delivery of the MELK inhibitor OTS167 to residual tumor regions, and to use real-time MRI monitoring to evaluate its combined effects with RFA in inducing immunogenic cell death (ICD) and reversing immunosuppression. **Methods:** cRGD-modified pH-sensitive nanoparticles (SPIO/OTS167@cRGD-phSiNPs) were constructed and characterized by transmission electron microscopy, dynamic light scattering, and in vitro release assays. In vitro, HCC-LM3 and SK-HEP1 cell lines were used, and in vivo, mouse subcutaneous and orthotopic liver cancer models based on Hepa1-6 cells were established to evaluate the nanoparticles' targeting ability, biodistribution, antitumor efficacy in combination with RFA, and immunoregulatory mechanisms. Western blotting, flow cytometry, immunofluorescence, and single-cell RNA sequencing were employed to analyze MELK expression, ROS levels, NLRP3 inflammasome activation, dendritic cell maturation, and $CD8^+$ T-cell infiltration. **Results:** SPIO/OTS167@cRGD-phSiNPs had a particle size of approximately 100 nm, exhibited favorable pH-responsive drug release properties, and showed strong tumor-targeting capability. In vitro, the nanoparticles combined with hyperthermia significantly suppressed MELK expression, increased ROS levels, activated the NLRP3/GSDMD pathway to induce pyroptosis, and promoted CRT exposure and HMGB1 release, thereby enhancing dendritic cell maturation and $CD8^+$ T-cell cytotoxicity. In tumor-bearing mice, treatment with RFA combined with the nanoparticles significantly inhibited tumor growth and prolonged survival, and further synergized with PD-L1 blockade to strengthen the antitumor immune response. **Conclusion:** This study developed a theranostic nanoparticle platform that combines diagnostic and therapeutic functions. By targeting and inhibiting MELK, it enhances pyroptosis and immunogenic cell death in residual tumors after RFA, reverses the immunosuppressive microenvironment, and provides a new strategy for combined local and systemic immunotherapy of liver cancer.

4382 | SPATIAL TRANSCRIPTOMIC PROFILING OF RESPONSE TO EGFR INHIBITION WITH ERLOTINIB FOR HCC CHEMOPREVENTION

Hai-Cheng Huang[1] Hiroaki Kanzaki[1] Jingxuan Chen[1] Kenneth Tanabe[2] Yujin Hoshida[1], [1]University of Texas Southwestern Medical Center, [2]Massachusetts General Hospital and Harvard Medical School

Background: Our previous preclinical study showed that EGFR inhibition in myofibroblasts attenuates liver fibrosis and reduces HCC nodules in rodent models of cirrhosis-driven hepatocarcinogenesis. Building on these findings, a recent phase I clinical trial of a 7-day erlotinib treatment in patients with cirrhosis confirmed target engagement, evidenced by reduced phospho-EGFR (p-EGFR) staining, at 25 mg/day (Gastro Hep Adv, 3;426, 2024). Furthermore, our clinically validated hepatic transcriptomic signature predictive of long-term HCC risk (Prognostic Liver Signature [PLS]) was favorably modulated at 50 mg/day. Identifying clinical and molecular correlates of this therapeutic response will provide mechanistic insights and inform the design of subsequent clinical trials and translation. **Methods:** Using paired pre- and post-treatment FFPE liver tissues from a p-EGFR/PLS responder and a non-responder in the phase I trial, we performed spatial transcriptome profiling with the Visium HD assay. We assessed therapeutic changes in cell-type proportions, EGFR signaling, related genes, and relevant molecular pathways, and compared these changes between the responder and non-responder. These molecular modulations were also compared with bulk tissue-based transcriptome profiles. **Results:** The paired biopsy and surgical tissues were successfully assayed to generate high-quality spatial transcriptome data. In the responder, the proportion of myofibroblasts decreased from 5.58% to 0.06% with erlotinib treatment, whereas the proportion of myofibroblasts in the non-responder was low (0.65%) and unchanged with treatment (0.62%). This result suggests that erlotinib reduced myofibroblasts in the responder, and the pre-treatment proportion of myofibroblasts may be associated with the p-EGFR/PLS response. The fibrotic area in the tissue decreased in the responder (39.7% to 30.2%), whereas minimal change was observed in the non-responder (53.0% to 50.3%), suggesting that underlying fibrogenic activity is associated with the erlotinib response. The

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

EGFR pathway gene set was suppressed in myofibroblasts in the responder, whereas such an effect was not observed in the non-responder. These results collectively support our hypothesis that erlotinib elicits a p-EGFR/PLS-improving effect via EGFR inhibition in myofibroblasts. Modest suppression of the EGFR pathway gene set was also observed in macrophages in the responder, suggesting the involvement of this cell type in the response. **Conclusion:** Spatially resolved, cell type-specific transcriptome profiling provides insights into the mechanism of action and identifies correlates of response to erlotinib in patients with cirrhosis.

4383 | DOWNREGULATION OF MICRORNA-1297 MEDIATES HYPOXIA-INDUCED LENVATINIB RESISTANCE IN HEPATOCELLULAR CARCINOMA BY TARGETING THYMOSIN-β10

Takayuki Kogure[1] Mari Satoh[1] Kennichi Satoh[1], [1]Tohoku Medical and Pharmaceutical University

Background: Hypoxia in the tumor microenvironment is a key driver of acquired drug resistance. Consistently, VEGF inhibition by lenvatinib induces significant intratumoral hypoxia. This study investigated the mechanisms underlying lenvatinib resistance, focusing on the role of microRNAs (miRNAs) in hepatocellular carcinoma (HCC) under hypoxic conditions. **Methods:** Human HCC cell lines (PLC/PRF/5, HepG2, and Huh7) were cultured under hypoxia (1% O_2, 5% CO_2, 94% N_2) or normoxia (95% air, 5% CO_2). Cell proliferation was assessed via metabolic assays, and apoptosis was evaluated morphologically and by caspase-3/7 activity. Genome-wide miRNA profiling was performed to identify resistance-associated miRNA alterations. An Argonaute2-based RNA-binding protein immunoprecipitation (RIP) assay combined with mRNA profiling was used to identify miRNA targets, which were further validated using a 3'-UTR luciferase reporter assay. **Results:** Lenvatinib inhibited HCC cell proliferation dose-dependently; however, its IC_{50} increased significantly under hypoxia. Lenvatinib-induced apoptosis was reduced by 22.4% and 19.6% in PLC/PRF/5 and HepG2 cells, respectively, under hypoxia, and caspase-3/7 activation was suppressed. Genome-wide profiling identified 42 upregulated miRNAs in PLC/PRF/5 cells treated with lenvatinib under normoxia, 28 of which were downregulated under hypoxia. We focused on miR-1297, which showed the most significant change. Under hypoxia, forced expression of miR-1297 significantly sensitized cells to lenvatinib, reducing viability (PLC/PRF/5: 76.6%, HepG2: 67.1%) compared with negative controls (88.3%, 75.3%). RIP assays and TargetScan analysis identified *TMSB10* mRNA as a target containing complementary sequences to the seed region of miR-1297. Forced expression of miR-1297 reduced thymosin-β10 protein levels by 46.3% and 33.4% in PLC/PRF/5 and HepG2 cells, respectively. Silencing *TMSB10* mRNA partially restored lenvatinib cytotoxicity under hypoxia, reducing cell viability by 14.7% and 13.5%. A 3'-UTR reporter assay confirmed that co-transfection of miR-1297 with a firefly luciferase vector containing the 3'-UTR of *TMSB10* mRNA decreased luciferase activity by 64.4% compared to the negative control. **Conclusion:** Downregulation of miR-1297 may contribute to hypoxia-induced lenvatinib resistance by upregulating thymosin-β10, a protein associated with cell survival and proliferation. These observations suggest that the miR-1297/thymosin-β10 axis could be a potential therapeutic target for overcoming lenvatinib resistance.

Virgen Del Rocío/C, [4]Instituto de Biomedicina de Sevilla (IBiS), [5]Ibis- Biomedicine Institute of Sevilla, [6]Servicio de Aparato Digestivo, Hospital Universitario Virgen del Rocío, Sevilla, [7]Virgen del Rocio University Hospital

Background: CD147 is a transmembrane glycoprotein that has been linked to liver cancer. It is well known that extracellular vesicles (EVs) are nano-sized, membranous structures secreted into the extracellular space to mediate intercellular communication and carry markers derived from their cell of origin. The lack of reliable biomarkers for HCC management makes them excellent candidates for study in this context. **Aims:** To explore CD147 expression in liver cancer and to evaluate the clinical utility of circulating CD147-positive extracellular vesicles as a non-invasive diagnostic tool for hepatocellular carcinoma (HCC) management. **Methods:** A) CD147 gene expression was evaluated in liver cancer cell lines and CD147+ EVs release was confirmed in vitro studies. B) *CD147* mRNA expression was analysed in a cohort of 25 HCC patients undergoing transplantation or resection (6 cirrhotic patients, 12 non-cirrhotic patients who developed HCC, and 7 cirrhotic patients with HCC). Total mRNA was isolated from tumoral and non-tumoral tissue, and gene expression was determined by qPCR. In addition, CD147 protein expression was analysed by immunohistochemistry. C) CD147-EVs were quantified in cohort of 96 patients.; non-cirrhotic liver disease (8), 38 patients with cirrhosis (F4) and 50 with HCC.EVs were characterized by size (0.2-1µm) and CD147 expression and phosphatidylserine cell surface by flow cytometry in plasma heparin samples. **Results:** *CD147* gene expression was upregulated in HepG2 cells compared to Huh7.5 (fold change: 2.06 ± 0.15: p = 0,.002) and CD147+EVs constituted around 70% of the total EVs released by HepG2. Gene expression levels were significantly higher in tumor tissue compared to non-tumor tissue, regardless of fibrosis stage (HCC vs. non-F4: fold-change 3.74 ± 0.53; p < 0.001 and HCC vs. F4: 2.08 ± 0.32; p = 0.004). This upregulation were also observed at protein levels in HCC compared to cirrhosis and non-cirrhotic tissue. C) In our cohort, 90.6% were men, with a mean age of 64.6 ± 9.5 years. Main etiologies were alcohol consumption and HCV infection. AFP, ALT, and GGT levels were significantly increased in HCC group vs. F4 (p < 0.001, p = 0.05 and p = 0.02 respectively). The level of EVs AV+-CD147+ U/µl was significantly increased in HCC patients vs cirrhotic patients (1096 ± 211 vs. 6374 ± 1294 U/µl; p = 0.002), demonstrating an AUC of 0.82 (0.715-0.915; p < 0.0001) for HCC diagnosis (spec: 80%; sens: 70.8%, NPV 83.3% and PPV 74.3% (cut off: 1111.21U/µl)). In the multivariate analysis, age, AFP serum levels and AV+CD147+ EVs (OR: 12.7 (2.06-78.81) p = 0.006) were independently associated with HCC diagnosis. **Conclusion:** CD147 expression levels are increased in liver cancer cell lines and HCC tumor tissue, (independently of the liver fibrosis stage). HepG2 cells release CD147+EVs, confirming their origin. Additionally, circulating levels of AV-CD147 EVs represent a promising non-invasive diagnostic tool for HCC.

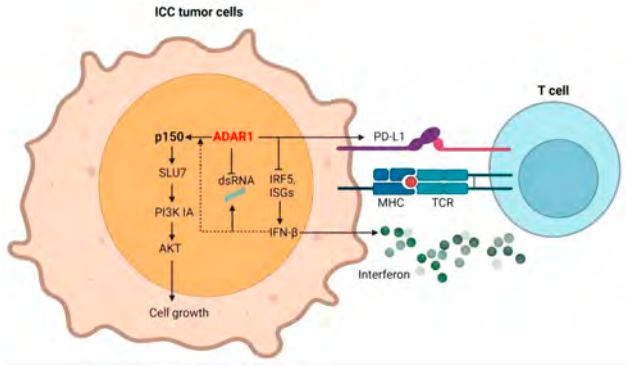
4385 | TARGETING DICKKOPF-1 UNLOCKS SYNERGISTIC ANTITUMOR IMMUNITY WITH PD-L1 BLOCKADE IN HEPATOCELLULAR CARCINOMA



Seung Up Kim[1] Yuri Cho[2], [1]Yonsei University, [2]National Cancer Center, Goyang, Korea

Background: Dickkopf-1 (DKK1), a secreted Wnt antagonist, is frequently overexpressed in hepatocellular carcinoma (HCC) and has been implicated in tumor progression. However, its role in immune regulation and therapeutic response remains unclear. We investigated the immunomodulatory function of DKK1, its association with programmed death-ligand 1 (PD-L1), and the potential benefit of DKK1 inhibition combined with anti–PD-L1 therapy. **Methods:** We employed patient samples, human HCC cell lines with DKK1 knock-out (KO) or overexpression, and a syngeneic murine HCC model. PD-L1 expression was assessed by immunohistochemistry, western blotting, and qRT-PCR. T-cell activity was evaluated through Jurkat co-culture assays and cytokine secretion. The pharmacologic DKK1 inhibitor WAY-262611 was tested alone or in combination with anti–PD-L1 *in vitro* and *in vivo*. **Results:** High DKK1 expression correlated with increased PD-L1 levels in human HCC tissues and cell lines, while DKK1 KO reduced PD-L1 expression. Co-culture experiments revealed that DKK1 suppressed Jurkat T-cell viability and IFN-γ production. Treatment with WAY-262611 downregulated PD-L1 expression and reduced tumor cell migration. *In vivo*, Hepa1-6 DKK1 tumors displayed enhanced growth suppression when treated with combined DKK1 inhibition and anti–

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

PD-L1, compared with either agent alone ($P < 0.05$). Dual blockade significantly increased $CD8^+$ T-cell infiltration and reduced immune evasion. **Conclusion:** DKK1 promotes immune escape in HCC by upregulating PD-L1 and impairing T-cell function. Pharmacologic inhibition of DKK1 augments the antitumor efficacy of PD-L1 blockade, suggesting that DKK1 is a promising therapeutic target and biomarker for immunotherapy combinations in HCC.

4386 | THE ROLE OF ADAR1 IN THE PROGRESSION OF INTRAHEPATIC CHOLANGIOCARCINOMA

Yi Tong[1] Guoteng Qiu[2] Zeyuan Qiang[1] Haichuan Wang[1], [1]West China Hospital, Sichuan University, [2]Sichuan Provincial People's Hospital, University of Electronic Science and Technology of China

Background: Intrahepatic cholangiocarcinoma (ICC) is an aggressive malignancy with limited treatment options. The role of ADAR1-mediated RNA editing in ICC progression remains unclear. **Methods:** ADAR1 expression and A-to-I RNA editing levels were evaluated in ICC tissues and cell lines. Functional assays and orthotopic murine models were used to assess tumor progression. RNA sequencing was performed to identify downstream pathways associated with ADAR1 signaling. **Results:** ADAR1 was significantly upregulated in ICC and positively correlated with A-to-I editing activity. ADAR1 overexpression enhanced ICC proliferation and tumor growth in vitro and in vivo. Transcriptomic analyses demonstrated suppression of interferon-related pathways, including IRF5 and interferon-stimulated genes. Increased ADAR1 expression was additionally associated with reduced CD8+ T-cell infiltration and elevated PD-L1 expression, suggesting an immune-evasive tumor phenotype.SLU7 expression was also markedly elevated in ICC models and positively correlated with ADAR1 expression. **Conclusion:** ADAR1 promotes ICC progression and is associated with immune modulation and altered expression of interferon-related pathways. The positive correlation between ADAR1 and SLU7 suggests a potential link between RNA editing and tumor-intrinsic signaling in ICC. Targeting ADAR1 may represent a promising therapeutic strategy for ICC.

4387 | TRANSCRIPTOMIC PROFILING REVEALS INTRINSIC MULTI-MECHANISM PD-1 RESISTANCE IN VINYL CHLORIDE-ASSOCIATED HCC

Haley Arbore[1] Pooja Muddasani[1] Olivia Bannister[1] Jiang Li[1] Tyler Yasaka[1] Silvia Liu[1] Gavin Arteel[1] Junyan Tao[1] Satdarshan (Paul) Monga[1] Juliane Beier[1], [1]University of Pittsburgh

Background: Vinyl chloride (VC) is an established hepatic carcinogen associated with HCC. Beyond high-dose occupational exposure, sub-OSHA level VC exposure enhances CLD progression and accelerates HCC development in our mouse models. This VC-driven HCC exhibits a unique transcriptomic signature that clusters a subset of human TCGA-LIHC tumors with disproportionately poor survival despite lower pathologic burden, suggesting an aggressive, etiology-driven phenotype. Whether VC exposure shapes the tumor transcriptome to confer intrinsic immunotherapy resistance is unknown. **Methods:** RNA sequencing was performed on tumors from a VC-exposed Met/β-catenin mouse model. Concordantly upregulated genes were identified by cross-referencing mouse DEGs with TCGA-LIHC tumor DEGs (DESeq2, $\log_2FC > 0.5$, $p < 0.05$, $n = 512$). These were intersected with genes trending toward non-responders in an independent human HCC immunotherapy cohort (GSE202069; $n = 17$, 8 responders and 9 non-responders, anti-PD-1 therapy, Illumina NovaSeq 6000), yielding a 63-gene resistance signature. Prognostic validation used TCGA-LIHC ($n = 338$, 116 events) as a completely independent cohort with Cox models adjusted for age and stage. Immune infiltration was

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

assessed using CIBERSORT and quanTIseq deconvolution. **Results:** The signature was enriched for VC-specific genes (59% VC-specific, 25% VC-amplified, 14% tumor-general). High signature expression independently predicted worse overall survival in external validation (HR = 1.705, 95% CI 1.163-2.498, Cox p = 0.006, log-rank p = 0.0008). Sixteen of 63 genes were individually prognostic after multiple testing correction, dominated by mitotic kinases and chromosomal instability markers including PBK (HR = 1.530), TROAP (HR = 1.444), and ESPL1 (HR = 1.402). The prognostic effect was directionally consistent across tumor grades G1-G3 and reached significance in G3 (HR = 2.26, p = 0.033). Immune deconvolution revealed Treg enrichment ($\rho = 0.310$, adj.p < 0.001), M0 macrophage enrichment ($\rho = 0.239$), and neutrophil enrichment ($\rho = 0.255$) in high-signature tumors without significant cytotoxic immune depletion, indicating active immunosuppression rather than immune desert. Comparison with the immunotherapy cohort confirmed non-responder genes were enriched among VC-downregulated DEGs (OR = 2.42, p < 0.001), and VC mouse tumors scored deeply negative on a net PD-1 response prediction score. **Conclusion:** A 63-gene VC-associated transcriptomic signature predicts worse survival and implicates Treg-mediated immunosuppression and tumor-intrinsic proliferative resistance as co-drivers of anti-PD-1 resistance in VC-exposed HCC. This signature may improve patient stratification in immunotherapy trials and inform treatment selection in a disease where PD-1 checkpoint inhibitors represent the current standard of care.

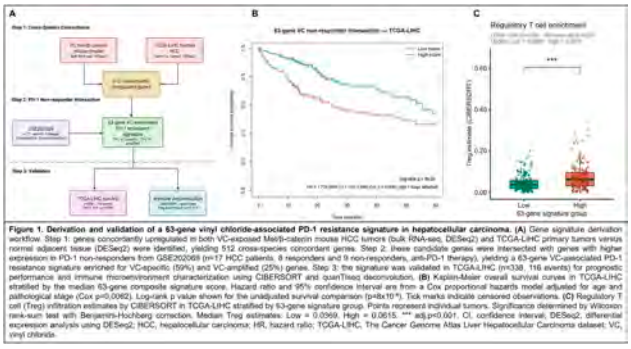

Figure 1. Derivation and validation of a 63-gene vinyl chloride-associated PD-1 resistance signature in hepatocellular carcinoma. (A) Gene signature derivation workflow. Step 1: genes concordantly upregulated in both VC-exposed Met/β-catenin mouse HCC tumors (bulk RNA-seq, DESeq2) and TCGA-LIHC primary tumors versus normal adjacent tissue (DESeq2) were identified, yielding 512 cross-species concordant genes. Step 2: these candidate genes were intersected with genes with higher expression in PD-1 non-responders from GSE202069 (n=17 HCC patients, 8 responders and 9 non-responders, anti-PD-1 therapy), yielding a 63-gene VC-associated PD-1 resistance signature enriched for VC-specific (59%) and VC-amplified (25%) genes. Step 3: the signature was validated in TCGA-LIHC (n=338, 116 events) for prognostic performance and immune microenvironment characterization using CIBERSORT and quanTIseq deconvolution. **(B)** Kaplan-Meier overall survival curves in TCGA-LIHC stratified by the median 63-gene composite signature score. Hazard ratio and 95% confidence interval are from a Cox proportional hazards model adjusted for age and pathological stage (Cox p=0.0062). Log-rank p value shown for the unadjusted survival comparison (p=8x10⁻⁴). Tick marks indicate censored observations. **(C)** Regulatory T cell (Treg) infiltration estimates by CIBERSORT in TCGA-LIHC stratified by 63-gene signature group. Points represent individual tumors. Significance determined by Wilcoxon rank-sum test with Benjamini-Hochberg correction. Median Treg estimates: Low = 0.0369, High = 0.0615. *** adj.p=0.001. 4388 | FIVE HEPATOCELLULAR CARCINOMA CELL LINES WITH DISTINCT LIPID METABOLIC PROFILES DURING HEPATOCARCINOGENESIS

Héloïse Giudicelli[1] Valérie-Ann Raymond[2] Laure Voisin[2] Sylvain Meloche[2] Marc Bilodeau[2], [1]Université de Montréal, Sorbonne Université, [2]Université de Montréal

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related mortality worldwide. Impaired liver lipid homeostasis can lead to Metabolic dysfunction–Associated SteatoHepatitis (MASH), a preneoplastic condition for HCC. This study aimed to (i) characterize lipid metabolism alterations in five human HCC cells lines; (ii) identify specific lipid transporters that modulate fatty acid (FA) flux in HCC cells, as future therapeutic target. **Methods:** Cells were cultured in high-glucose DMEM with 10% FBS (complete medium) or in nutrient free DMEM (blank medium) supplemented with linoleic acid (LA) at 400µM. Gene expression was analyzed by quantitative PCR. Cell viability was assessed by MTT assay. Intracellular triglyceride (TG) content was measured with Cobas system or Oil Red O staining. Mitochondrial respiratory function was assessed using a high-resolution respirometer (Seahorse). Cultured primary human hepatocytes (PH) were used as controls. Among 20 human HCC cell lines, we selected five cell lines using principal component analysis: (i) HepaRG as the main alternative to PH, (ii) JHH2 and SNU-387, which displayed β-oxidative genes expression similar to PH, (iii) PLC-PRF5 (PP5) and Huh7, which exhibited lower β-oxidative profile. Data are presented as mean ± standard error and multifactorial ANOVA was used for statistics (p < 0.05). **Results:** LA treatment increased TG storage in HuH7 and PP5 compared to HepaRG and SNU-387 (p < 0.05). In blank medium, cell viability was reduced in HuH7 (p < 0.05) and not restored by LA supplementation, in contrast to glucose or glutamine. In complete medium, LA reduced viability at 48 hours in Huh7 (p < 0.05), suggesting lipotoxicity, but not in PP5/HepaRG/SNU-387. Metabolic effects peaked at 48 hours. In Huh7 and PP5, expression of β-oxidation genes (ACSL1, CPT2, LCAD, ECH, ACAA1/2) was decreased compared to PH (p < 0.05). In SNU-387 and JHH-2, expression of ACLS1, ACSS2, CPT1/2, ECH and HADAH genes was similar as PH. In Huh7, genes

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

involved in FA desaturation (SCD1, FADS1) and elongation (ELOVL6) were upregulated compared with PH ($p < 0.05$). PLIN2 was overexpressed in JHH2 and SNU-387 and repressed in Huh7 and PP5 compared to PH. Transcriptional regulation showed increased SREBP (Huh7) and PPARγ (all) while ChREBP decreased (all) ($p < 0.05$). FA synthesis (ACAC, ACLY, FASN) was not altered (all). Basal and maximal respiration rate were increased in JHH2 and Huh7, moderate in SNU 387 and decreased in HepaRG and PP5 ($p < 0,001$). Transporters FATP2/5, FABP4, and CD36 were decreased in all cell lines compared to PH, while FABP1 expression was maintained in Huh7 and PP5. **Conclusion:** HCC cell lines display distinct lipid metabolic reprogramming, without following a uniform pattern. Impaired FA transport and utilization underscore the need for stratified therapeutic approaches targeting lipid metabolism in HCC

4389 | SMP30/POLA1 DOWNREGULATION IN MALE MEDIATES GENDER DIFFERENCES IN LIVER INJURY AND TUMORIGENESIS OF HEPATOCELLULAR CARCINOMA

Tae-Un Kim[1] Jin-Kyu Park[1], [1]Kyungpook National University

Background: Hepatocellular carcinoma (HCC) exhibits well-established gender disparity, with higher incidence and poorer prognosis in males compared with female. However, the underlying molecular mechanisms remain incompletely understood. Senescence marker protein-30 (SMP30), a calcium-binding protein known to decline with aging, has been reported to regulate hepatocellular homeostasis and carcinogenesis. In this study, we investigated the role of SMP30 in gender disparities of HCC progression through regulation of DNA replication process. **Methods:** Male and female mouse HCC tissues were analyzed to identify potential genes associated with gender disparities in HCC progression, with particular focus on X chromosome–linked candidates independent of hormonal effects. SMP30 and DNA polymerase alpha (Pola1) expression were selected via gene chip profiling and analyzed in both HCC tissues and HEPG2 cell line with quantitative PCR and western blotting. Cycloheximide chase assay and polysome profiling were conducted to evaluate protein stability and translational regulation. SMP30 mice HCC tissues were analyzed to further confirm regulatory effects of SMP30 on Pola1 expression. **Results:** HCC liver tissues of male mice showed elevated liver injury and tumorigenesis compared with female mice. Gene chip assay showed marked elevation of oxidoreductase activity and DNA repair gene expression, especially Pola1. Relationship between SMP30 and Pola1 was investigated. SMP30 knockdown significantly reduced Pola protein expression without marked changes in total Pola1 mRNA levels, suggesting post-transcriptional regulation. Cycloheximide chase assays demonstrated no significant difference in POLA degradation between control and SMP30-deficient cells, indicating that enhanced proteolysis was unlikely to account for the observed reduction. Polysome profiling revealed decreased association of Pola1 mRNA with polysomes following SMP30 knockdown, consistent with selective translational suppression rather than global translational inhibition. HCC liver tissue of SMP30 KO mice showed severe tumorigenesis and decreased Pola expression compared with wild-type HCC mice. **Conclusion:** The present study suggests SMP30 as a potential mediator of sex disparity in HCC through selective translational regulation of Pola1. Reduced SMP30 expression may impair DNA replication homeostasis by suppressing Pola1 translation, thereby promoting replication stress and hepatocarcinogenesis. This study provides a novel mechanistic framework connecting aging-related proteins, translational regulation, and gender-associated differences in liver cancer biology.

4390 | STUDY ON BIOMARKERS OF IMMUNE CHECKPOINT INHIBITOR COMBINATION THERAPY-RELATED ADVERSE EVENTS IN HEPATOCELLULAR CARCINOMA PATIENTS BASED ON MULTI-OMICS INTEGRATION

Dachuan Cai[1] Yiheng Tang[1], [1]The Second Affiliated Hospital of Chongqing Medical University

Background: Immune checkpoint inhibitors (ICIs) combined with targeted drug therapy have played a pivotal role in the treatment of advanced hepatocellular carcinoma (HCC). However, beyond their antitumor effects, traditional chemotherapeutic agents, macromolecular or small-molecule targeted drugs, and ICIs can all induce off-target adverse reactions, known as treatment-related adverse events (trAEs). Hepatocellular carcinoma typically arises in the context of chronic liver disease, where underlying liver conditions may cause symptoms overlapping with AEs or exacerbate their severity. By analyzing proteomic and

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

metabolomic data, we aimed to screen for biomarkers capable of early identification of trAEs in these patients. **Methods:** This study employed a nested case-control design. Plasma samples were collected from patients who met the inclusion and exclusion criteria. Proteomics and metabolomics technologies were utilized to profile proteins and metabolites. Candidate biomarkers were selected through an integrative analysis of proteomic and metabolomic data, taking into account fold changes, P-value rankings, and correlations within common biological pathways. **Results:** Integrated analysis of proteomics and metabolomics data revealed eight common pathways, including thyroid hormone synthesis, central carbon metabolism in cancer, and protein digestion and absorption. Seven differentially expressed proteins and six differentially expressed metabolites were annotated to these shared pathways. Based on a combination of fold change, P-value ranking, and correlations within the common pathways, the following proteins were selected: TTR, APOL1, ICAM1, CNDP1, COL12A1, and PON1, EPB42, EXT2, LAMP2, along with metabolites: glutathione, urocanic acid, and citric acid. **Conclusion:** Through integrated proteomic and metabolomic analysis, this study demonstrated that candidates possess diagnostic value for treatment-related adverse events in patients with primary liver cancer undergoing immune checkpoint inhibitor (ICIs) combination therapy. However, further validation in large-scale cohorts is required to confirm their clinical utility.

4391 | IRAK4 IS A POTENTIAL THERAPEUTIC TARGET IN BILIARY TRACT CANCER

Vivian Ortiz[1] Huaping Li[2] Richard Kurupi[2] Kian-Huat Lim[2], [1]Washington University in St. Louis, [2]Division of Oncology, Department of Medicine, Washington University in St. Louis

Background: Biliary tract cancer (BTC) is the second most common hepatic malignancy after hepatocellular carcinoma that arises from biliary epithelia with 5-year survival ranging from 2–23%. Despite the addition of immunotherapy to the backbone treatment of gemcitabine and cisplatin, the increase in survival and progression-free survival is only modest. New therapies are needed to prolong survival in patients with this malignancy. Interleukin-1 receptor–associated kinase 4 (IRAK4) is a pivotal serine/threonine kinase in the NF-κB and MAPK pathway whose inhibition has shown sensitization to immune checkpoint inhibitors in mice with pancreatic adenocarcinoma. Thus, we hypothesize that IRAK4 is upregulated in response to gemcitabine and cisplatin treatment, and its inhibition leads to anti-tumor response. **Methods:** Human and mouse BTC cell lines were incubated with gemcitabine and cisplatin (GC). Transcriptomic analysis and protein expression were assessed by bulk RNA sequencing, Western Blot and reverse phase protein array were done. Synergy analysis between gemcitabine, cisplatin and IRAK4 inhibitor CA-4948 was employed using Alamar blue and Incucyte. **Results:** Incubation of GC leads to protein activation of activated IRAK4 and NF-κB as well as transcriptional activation of NF-kB. Preliminary RPPA analysis also show upregulation of p-p38 and HSP27 in addition to p- NF-kB. Addition of CA-4948 to gemcitabine and cisplatin in human and mouse BTC cell lines increases apoptosis activation. **Conclusion:** IRAK4 is a potential additive therapeutic target for treatment of BTC. Further in vivo studies are underway to evaluate efficacy of CA-4948 effect in combination with GC and unveil its cytotoxic mechanism in BTC.

4392 | IMPACT OF ACSM5 ON FATTY ACID METABOLISM IN HEPATOCELLULAR CARCINOMA

Lei Yang[1] Shaoning Jiang[1] Kien Pham[1] Chen Liu[1], [1]Yale University

Background: Hepatocellular carcinoma (HCC) is characterized by dysregulated lipid metabolism, which plays a critical role in tumor progression and prognosis. We and others have reported that Acyl-CoA synthetase medium-chain family member 5 (ACSM5) is down-regulated in HCC and is closely associated with poor prognosis; however, the underlying mechanisms remain unclear. In this study, we investigated the role of ACSM5 in fatty acid metabolism and its potential impact on HCC progression. **Methods:** Stable ACSM5-overexpressing Huh7 cells (Huh7-ACSM5) were established to evaluate alterations in fatty acid metabolism. Cell pellets were collected and subjected to mass spectrometry-based fatty acid analysis. Huh7 and Huh7-ACSM5 cells were further treated with different fatty acids, including palmitic acid (PA), linoelaidic acid (LA), arachidonic acid (AA), and oleic acid (OA), to assess lipid accumulation. In addition, the expression levels of STAT3 activation and TGFB were analyzed. **Results:** Huh7-ACSM5 cells exhibited lower total fatty acid levels compared with Huh7 control cells. Mass spectrometry analysis demonstrated an overall reduction in fatty acid content in ACSM5-overexpressing cells. Saturated fatty acids were markedly decreased, whereas unsaturated fatty acids remained relatively stable. Specifically, levels of C14:0, C16:0, C16:1n7, C18:2n6t, and C20:4n6 were reduced in Huh7-ACSM5

cells, while C18:1n9 levels were increased. These alterations resulted in a lower proportion of saturated fatty acids in ACSM5-overexpressing cells. Among the fatty acid treatments, LA treatment induced the most significant lipid accumulation, accompanied by increased STAT3 activation and elevated TGFB expression, suggesting a potential mechanism contributing to HCC progression and poor prognosis. **Conclusion:** Our findings demonstrate that ACSM5 plays an important role in regulating fatty acid metabolism in HCC. Reduced ACSM5 expression in cancer cells promotes lipid accumulation and STAT3 activation, thereby contributing to HCC progression. In contrast, restoration of ACSM5 significantly reduced lipid accumulation, particularly under LA treatment conditions, and modulated signaling pathways associated with tumor progression. These results provide new insights into the molecular mechanisms underlying HCC pathogenesis and suggest ACSM5 as a potential therapeutic target for HCC treatment.

4393 | ◆ PERFUSATE SOLUBLE PD-L1 TRACKS ISCHAEMIC INJURY BURDEN DURING LIVER NORMOTHERMIC MACHINE PERFUSION: AN INTEGRATED HUMAN, RAT, AND COMPUTATIONAL ANALYSIS

Sally Campbell[1] Fangyu Zhou[1] Omar Alomar[1] Cliona O'Farrelly[2] William Chapman[1], [1]Washington University, St Louis, [2]Trinity College Dublin

Background: Soluble PD-L1 (sPD-L1) is detectable in human liver perfusate during normothermic machine perfusion (NMP), but its upstream drivers and functional role remain undefined. CD274 (encodes PD-L1) has been identified as the strongest gene-level predictor of NMP graft quality, and PD-1/PD-L1 signalling limits ischaemia-reperfusion injury (IRI) in murine models. We asked whether perfusate sPD-L1 reflects an active, injury-proportional response that scales with donor ischaemic burden. **Methods:** Three complementary analyses were performed. First, sPD-L1 was measured by ELISA on serial perfusate from 38 human donor livers undergoing NMP, linked to donor type, functional warm ischaemia time [fWIT; SBP < 50 mmHg → NRP (normothermic regional perfusion) start], cold ischaemia time (CIT), NRP modality, viability criteria, and early allograft dysfunction (EAD). Second, sPD-L1 was measured on rat NMP perfusate from lean (n = 4) and steatotic (n = 4) donor livers, sampled at 30 min and 4 h of perfusion, following 15 min in-situ hepatic ischaemia. Third, an integrated transcriptomic analysis across six published datasets spanning healthy human liver, steatosis, human NMP, human IRI, and rat orthotopic liver transplantation (OLT) was used to define cellular sources and regulators of CD274. **Results:** Human cohort (38 grafts): perfusate sPD-L1 rose progressively from a median 15 pg/mL at 0–30 min to 403 pg/mL at 10–13 h. Within DCDs (n = 22), longer fWIT was associated with higher 4-h sPD-L1: DBD 91, DCD-low-fWIT 108, DCD-high-fWIT 131 pg/mL (p = 0.027 for DBD vs high-fWIT). The signal was strongest with the pure asystolic window (declaration to NRP start, p = 0.003). After adjusting for CIT, age, BMI and sex (n = 32), high-fWIT vs DBD remained significant (β = +0.39, p = 0.044). sPD-L1 did not discriminate viability or binary EAD on time-adjusted endpoints. Rat NMP: sPD-L1 rose in all livers from 30 min to 4 h with a steeper trajectory in steatotic versus lean donors, paralleling the human ischaemic-burden gradient. Computational analysis: hepatocytes, macrophages and neutrophils showed increased CD274 at end-NMP; CD274, ADAM17 (PD-L1 sheddase) and PD-1 were each upregulated in IRI+ versus IRI− tissue (p = 0.025, 0.045, 0.009). Rat OLT showed coordinated CD274 + ADAM17 induction alongside broad injury-response signalling (Type I/II IFN, TNF/NF-κB, IL-1, TLR/DAMP), all normalising in long-term survivors. **Conclusion:** Perfusate sPD-L1 during liver NMP is a kinetic, injury-proportional response. Transcriptomic data reveal coordinated CD274 / ADAM17 induction alongside broad injury-response signalling, a programme normalising in long-term survivors. Higher trajectories in DCDs (especially long-fWIT) and in steatotic rat livers identify ischaemic burden as the dominant driver, framing sPD-L1 as a candidate dynamic biomarker of graft injury during NMP and post-transplant, with the PD-L1 axis as a potential therapeutic target.

4394 | ◆ SURGICAL STRESS-INDUCED HEPATIC REGULATORY T CELLS PROMOTE THE DEVELOPMENT OF COLORECTAL LIVER METASTASES

Ti Yang[1] Grace Wu[1] Xingping Huang[1] Xiaorong Guo[1] Preethi Jayakumar[1] Ameilia solan[1] Ephraim Ansa-Addo[2] Hai Huang[3], [1]The Feinstein Institute for Medical Research, [2]The Ohio State University Wexner Medical Center, [3]Feinstein Institutes for Medical Research

Background: Complete surgical resection remains central to curative treatment of colorectal liver metastases (CRLM), yet up to 50-60% of patients undergoing liver resection subsequently recur within five years. One of the mechanisms that drives recurrence is the reshaping of the hepatic immune microenvironment during surgical stress or ischemia-reperfusion (I/R) injury. Regulatory T cells (Tregs) promote wound healing and repair in injured tissues but are also known to restrain antitumor immunity. Moreover, whether I/R-induced alterations in Tregs contribute to subsequent tumor metastatic growth has not yet been elucidated. **Methods:** In this study, Wild-type mice (8-12 weeks) were injected with murine MC38 colon carcinoma cells expressing firefly luciferase. 70% hepatic I/R was performed with 60 minutes of ischemia time. CD25 antibody injections were used to deplete Tregs. Foxp3^{DTR} mice, followed by diphtheria toxin -mediated ablation of Treg cells. Treg numbers were confirmed by flow cytometry (percentage of Foxp3^{+} /CD4^{+}). Tumor growth was quantified by bioluminescence, tumor-to-body weight ratio, and number of macroscopic nodules. Single-cell RNA sequencing (scRNA-seq) was performed to identify transcriptomic changes in Tregs from I/R vs. sham livers. **Results:** Compared to sham mice, greater tumor growth was observed after I/R at 1- to 3-weeks post-surgery on bioluminescence. The number of hepatic Tregs was greater in tumor-bearing mice subjected to I/R versus sham surgery. After depletion of Tregs, reduced tumor growth was observed by bioluminescence at 1, 2, and 3 weeks post-surgery. Analysis of the top differentially expressed genes in I/R Tregs yielded significant upregulation of genes implicated in an immunosuppressive microenvironment, as confirmed by experiments; moreover, we identified that the OX40^{high} GITR^{high} Treg subpopulation was significantly enriched in the I/R group. After we neutralized the two markers *in vitro*, the Teff proliferation capacity recovered. **Conclusion:** Hepatic I/R drives the expansion of immunosuppressive hepatic Tregs, thereby promoting CRLM outgrowth. Treg depletion before I/R and during tumorigenesis attenuates this effect. Single-cell profiling further revealed an expanded OX40^{high} GITR^{high} effector Treg subset after I/R, and functional blockade of these molecules restored effector T-cell proliferation, supporting this population as a promising therapeutic target in postoperative CRLM.

4395 | ◆ LIVER ABO RE-ENDOTHELIALIZATION FOLLOWING TRANSPLANTATION – FACT OR FICTION?

Anna Beck[1] Byoung Uk Park[1] Oyedele Adeyi[2] Srinath Chinnakotla[1] Claudia Cohn[1], [1]University of Minnesota, [2]Univ of Alabama, Birmingham

Background: Transplant patients may receive organs with major and minor ABO-mismatches. Endothelial cells of the transplanted organ express ABO antigens, making them a potential target for attack from the patient's isohemagglutinins. It has been hypothesized that transplanted organs undergo a process of re-endothelialization to protect the transplant. Re-endothelialization replaces the organ's native endothelial cells with new cells of patient origin, thus, the ABO of the organ's vascular lining would transform from native-type to patient-type over time. We sought to characterize this process by staining serial biopsies from patients who received ABO-mismatched organs. This study will allow us to better understand the timing and extent of re-endothelialization post-transplant. **Methods:** We analyzed the ABO endothelial status of 6 pediatric liver transplant patients, with surgery occurring from December 2010 to April 2023. All transplants were from whole livers except patient 6, who received a split liver. Biopsy follow-up time ranged from 4 months to 129 months. The number of biopsies taken per patient ranged from

one to six. They were evaluated with immunohistochemical stains using anti-A and anti-B antibodies with appropriate control slides. Native hepatectomy specimens were also evaluated and served as additional controls. Stained slides were read for ABO status, as well as scored for intensity of staining and percent of each vascular compartment staining (hepatic artery, portal vein, central vein, and sinusoids). **Results:** Results are summarized in Table A. Native explants showed ABO staining consistent with that of the recipient's blood type, while all follow-up allograft biopsies demonstrated staining consistent with the donor's blood type. This pattern was observed in all follow-up biopsies for each patient, with the strongest and most reliable staining seen in the hepatic artery and portal vein compartments, while staining of the central vein and sinusoidal compartments was more variable. **Conclusion:** Post-transplant endothelial ABO antigen expression reflects donor ABO type, with the strongest and most reliable staining seen in the portal vascular endothelium. Sinusoidal and central venous expression is more variable and may show reduced staining over time or by compartment. Re-endothelialization of donor endothelium to recipient ABO type was not observed in our population.

Table A. Summary of ABO Staining in Liver Explants and Transplant Biopsies

	Blood Type	Donor Type	Explant / Control	Transplant Bx	Re-endothelialized ?	Time from transplant to latest biopsy
Patient 1	O+	A	O	A	No	34 months
Patient 2	O+	B	O	B	No	12 months
Patient 3	A-	B	A	B	No	22 months
Patient 4	A-	A1B	A	AB	No	129 months
Patient 5	AB+	AB	AB	AB	No	4 months
Patient 6	O+	B	O	B	No	11 months

4396 | ◆ SLC6A8-MEDIATED CREATINE TRANSPORT IN HEPATIC STELLATE CELLS IS ESSENTIAL FOR LIVER REGENERATION AND POST-SURGICAL HEPATIC RECOVERY

Thi Linh Nguyen[1] Ning Wang[2] Jieun Lee[1] Alfin Mohammad Abdillah[1] Ji Sun Moon[1] Ho Yeop Lee[1] Hyo Ju Jang[1] Aulia Reski Widyaningrum[1] Hyon-Seung Yi[1], [1]Chungnam National University School of Medicine, [2]Zhejiang University School of Medicine

Background: This study investigated the role of creatine metabolism and the impact of its deficiency on liver regeneration. The liver's ability to restore mass and function following injury or surgical resection is essential for recovery in patients with liver disease. Although multiple metabolic pathways have been implicated, the contribution of creatine metabolism remains poorly understood. **Methods:** A two-thirds partial hepatectomy (PH) model in mice was used to evaluate the role of creatine in hepatic regeneration. Creatine deficiency was induced by administering β-guanidinopropionic acid (β-GPA), a creatine analogue, while controls received standard drinking water. Liver regeneration was assessed by measuring the expression of proliferation markers and metabolic genes. Single-cell RNA sequencing was performed to identify key cell populations involved in creatine transport. To further examine the effects of creatine deficiency in a clinically relevant setting, a liver transplantation model was established in Sprague–Dawley rats. The relationship between creatine levels and post-surgical liver recovery in recipients was evaluated using CT-based imaging. **Results:** Expression of the creatine transporter gene Slc6a8 increased during the S and G2/M phases of liver regeneration, paralleling the induction of proliferation markers such as PCNA and Ki67. Inhibition of creatine uptake by β-GPA treatment significantly suppressed hepatocyte proliferation, as evidenced by decreased PCNA and Ki67 expression. Single-cell RNA sequencing revealed that Slc6a8 is predominantly expressed in hepatic stellate cells (HSCs) and is upregulated upon their activation. Conditional knockdown of the creatine transporter in HSCs using the Cre-loxP system markedly impaired regenerative capacity compared with floxed controls. Furthermore, β-GPA treatment induced upregulation of oxidative phosphorylation genes, indicating a metabolic shift toward mitochondrial energy utilization under creatine-deficient conditions. Consistent with these findings, β-GPA administration substantially delayed liver regeneration in a reduced-size rat liver transplantation model. Notably, creatine levels were strongly and positively correlated with regenerative capacity across all post-surgical time points. **Conclusion:** Creatine deficiency impairs hepatic regenerative processes and alters hepatic energy metabolism. Genetic disruption of creatine transport in HSCs further compromises the liver's ability to restore its mass and function. Clinical data demonstrated a strong positive correlation between creatine levels and regenerative potential following liver surgery. Collectively, these findings establish creatine metabolism as an underrecognized determinant of hepatic recovery and highlight its potential as a therapeutic target for improving outcomes after liver injury or transplantation.

4397 | NORMOTHERMIC MACHINE PERFUSION (NMP) VERSUS STATIC COLD STORAGE (SCS) IN LIVER TRANSPLANTATION: AN UPDATED SYSTEMATIC REVIEW AND META-ANALYSIS OF RANDOMIZED CONTROLLED TRIALS

Paramveer Love[1] Alexander Moersch[1] Rabia Afzaal[1] David Hudson[1] Karim Qumosani[1] Mohammad Khan[1] Anouar Teriaky[2] Tamoor Afzaal[1], [1]Western University, [2]London Health Sciences Centre

Background: Donor organ shortage in liver transplantation has driven increased use of higher-risk grafts and extended-criteria donors. Normothermic machine perfusion (NMP) maintains the graft at physiological temperature with oxygenated perfusion and may reduce early allograft dysfunction (EAD), biliary complications, and hospital resource use compared with static cold storage (SCS). We performed an updated systematic review and meta-analysis of all available randomized control trials (RCT). **Methods:** MEDLINE, Embase and CENTRAL were searched from inception to March 2026 (PROSPERO CRD420261330445). Search strategy was developed in conjunction with a medical librarian. Eligible studies were RCTs of adult deceased-donor liver transplantation comparing any normothermic preservation strategy (ex situ NMP, ischemia-free liver transplantation, or controlled oxygenated rewarming) with SCS. Two reviewers independently performed screening, extraction and Cochrane RoB 2 assessment. Continuous data was analyzed using mean difference with random-effects model. Dichotomous outcomes were pooled as risk ratios (RR) using DerSimonian–Laird random-effects models and continuous outcomes as mean differences (MD). Heterogeneity was quantified using I^2. **Results:** Seven RCTs (2018–2026) enrolling 984 recipients (476 NMP, 508 SCS) were included. NMP significantly reduced EAD (15.9% vs 25.6%; RR 0.60, 95% CI 0.41–0.87; p = 0.007; I^2 = 33%; k = 7). Non-anastomotic strictures (4.0% vs 9.0%; RR 0.54, 95% CI 0.25–1.15; p = 0.110; k = 5) and overall biliary complications (6.1% vs 14.6%; RR 0.64, 95% CI 0.26–1.58; p = 0.330; k = 4) were numerically lower with NMP but did not reach significance. Anastomotic strictures (RR 1.05, 95% CI 0.58–1.91; k = 3), 1-year mortality (RR 1.15, 95% CI 0.64–2.05; k = 5) and 1-year graft loss (RR 1.03, 95% CI 0.47–2.29; k = 4) were comparable. ICU length of stay favoured NMP (MD −0.55 days, 95% CI −0.84 to −0.26; p < 0.001; k = 3); hospital length of stay did not differ (MD +1.06 days, 95% CI −1.24 to +3.37; p = 0.366; k = 5). **Conclusion:** NMP reduces early allograft dysfunction by approximately 40% and is associated with shorter ICU stay compared with SCS, with consistent point-estimate reductions in biliary complications and comparable 1-year survival.

★ 4398 | IMPACT OF NORMOTHERMIC MACHINE PERFUSION IN DONATION AFTER BRAIN DEATH LIVER TRANSPLANTATION

Mohammad Almokdad[1] Atsushi Nishimagi[1] Rikako Oki[1] Jack Avedikian[2] Mohamed Adhnan[2] Abbas Al-Kurd[2] Ahmed Nassar[2] Atsushi Yoshida[2] Marwan Abouljoud[2] Shunji Nagai[2], [1]Henry Ford Hospital, [2]Henry Ford Hospital Transplant Institute

Background: Normothermic machine perfusion (NMP) has shown clear benefits in donation after circulatory death (DCD) liver transplantation, particularly in reducing early allograft dysfunction (EAD). However, its role in donation after brain death (DBD) liver transplantation remains limited and inconsistent. In this study, we aimed to evaluate the impact of NMP on early outcomes and to characterize its role in DBD liver transplantation (LT). **Methods:** First, a retrospective single centered study was performed including a total of 230 DBD liver transplantations performed between January 2022 and December 2025. Patients were divided based on preservation technique into static cold storage (Non-NMP) (N = 177) and NMP(N = 53) groups. The primary outcome was EAD. Secondary outcomes were peak ALT/AST, ICU stay, hospital stay, and 180-day graft and patient survival. Multivariable logistic regression was used to identify independent factors of EAD. Second, historical comparison analysis was conducted to evaluate the impact of NMP introduction in transplant practice, in which waiting time, donor and procedural characteristics

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

in the NMP era (2022-2025) were compared with a pre-NMP cohort (2017-2021; N = 339). **Results:** Recipient characteristics were comparable between both groups, with NMP group having a lower MELD score (22 vs 28.5, p = 0.002). Donor age was higher in the NMP group (57 vs 48, p = 0.001), while cold ischemia time was significantly shorter (117 vs 404 minutes, p < 0.001). Total operation time was higher in the NMP group (416 vs 387 minutes, p = 0.04). There was no significant difference in the rate of EAD between NMP and non-NMP group (20.8% vs 14.1%, p = 0.24), and NMP was not independently associated with EAD on multivariable analysis (odds ratio, 0.23 [95% confidence interval, 0.03-2.08], p = 0.29). As for the second historical comparison analysis, the NMP era showed a higher proportion of donors aged > 70 years old (8.3% vs 1.5%, p < 0.001), a greater frequency of multiple same-day transplants (16% vs 5.3%, p < 0.001) and a significantly shorter waitlist time (median days, 20 vs 85, p < 0.001). Although non-NMP group had a higher MELD score (median, 27 vs 21, p = 0.002), the NMP group showed a significantly shorter waitlist time. **Conclusion:** In conclusion, NMP did not reduce EAD or 180-day survival in standard DBD transplantation, however it enabled the acceptance of higher-risk grafts, including older donors, and expansion of access for those who needed retransplantation. Notably, waiting time significantly reduced by approximately 76% in the NMP era. These findings support the use of NMP in DBD liver transplant as a tool for donor pool expansion and improved transplant access especially for challenging surgical cases, contributing to a marked reduction in waitlist time in the NMP era, without compromising post-transplant outcome.

4399 | PHARMACOLOGIC MODULATION OF CELL METABOLISM AND HIBERNATION AS A STRATEGY TO REDUCE ISCHEMIA DURING ORGAN PRESERVATION

Dylan Zinn[1] Piyushkumar Gondaliya[1] Irene Yan[1] Julia Driscoll[1] Christine Mehner[1] Tushar Patel[1], [1]Mayo Clinic Florida

Background: Hepatic ischemia and reperfusion injury (IRI) is a significant concern during liver surgery and transplantation. Preservation strategies such as cold storage are typically used to reduce the metabolic activity of organs, thereby protecting them from IRI. However, prolonged cold storage can result in cold-induced injury, which is exacerbated during organ rewarming. Hibernation in mammals is characterized by a shift to use of glycerol as an energy substrate. To explore whether modulation of metabolism under normothermic conditions could be used to mimic the preservation effects of cold storage, we developed CellNap, a metabolic modulator that uses glycerol as an alternative energy source to glucose. **Methods:** The effects of CellNap on metabolic activity, nutrient homeostasis and metabolic phenotype were assessed in primary human hepatocytes. Cell viability, proliferation, metabolic activity, glucose consumption, and protein translation were assessed using trypan blue exclusion, MTS assay, glucose monitoring, and L-AHA incorporation click chemistry respectively. Studies were performed at 4°C, 21°C, or 37°C to mimic hypothermia, room temperature, and normothermia respectively. Metabolic activity was assessed using Seahorse XF analysis after 24 or 48 hrs to measure OCR, ECAR, glycoPER, metabolic phenotype, and mitoOCR/glycoPER ratios. The effects of systemic pre-administration of CellNap were evaluated using a murine hepatic IRI model after 90 mins of partial ischemia followed by 3 or 6 hrs reperfusion in C57BL/6J mice. Liver injury was assessed by serum markers, histology, necrotic area, and immunohistochemistry. **Results:** CellNap decreased metabolic activity, glucose consumption, and protein translation, indicating reduced nutrient demand and suppression of biosynthetic processes. Whilst cell proliferation was significantly reduced, CellNap preserved hepatocyte viability at 4°C, 21°C, and 37°C. Compared with controls at 21°C, Cell Nap treated hepatocytes had improved viability whilst proliferation and metabolic activity were stable across conditions. Metabolic activity analysis confirmed reduced basal and compensatory glycolysis, lower OCR and ECAR, and an increased mitoOCR/glycoPER ratio, suggesting a less energetic phenotype with a shift toward oxidative phosphorylation. In vivo, CellNap reduced ALT and AST levels, reduced the area of necrosis, and decreased cleaved caspase-3 staining at 3 and 6 hrs after reperfusion, consistent with a reduction of hepatic IRI. **Conclusion:** CellNap leads to a suppression of metabolism whilst preserving cell viability and thereby promotes a hibernation-like state in hepatocytes. These data support the use of pharmacological modulation of cell metabolism to reduce hepatic ischemia-reperfusion injury and improve liver preservation during surgery and transplantation.

4400 | ◆ ROLE OF SARCOPENIA AND FRAILTY MEASURES IN IMPROVING WAITLIST MORTALITY PREDICTION IN LIVER-TRANSPLANT CANDIDATES: A RETROSPECTIVE COHORT STUDY

Michael Garas[1] Shivangi Gupta[2] Robin van de Meeberg[3] Ben Bull[4] May Kang[5] Christopher Welman[6] Leon Adams[1] George Garas[1] Gerry MacQuillan[7] Michael Wallace[8] Briohny Smith[8] Luc Delriviere[7] Angus Jeffrey[8] Chloe Attree[7] Gary Jeffrey[7], [1]University of Western Australia, [2]Sir Charles Gairdner Hospital, Western Australia, [3]The Kids Research Institute Australia, 15 Hospital Ave, Nedlands, 6009, WA, Australia, [4]Department of Physiotherapy, Sir Charles Gairdner Hospital, Western Australia, [5]Dietetics and Nutrition, Sir Charles Gairdner Hospital, Western Australia, [6]Department of Medical Imaging, Fiona Stanley Hospitals Group, Murdoch, Australia, [7]Western Australian Liver Transplant Service, Sir Charles Gairdner Hospital, Western Australia, [8]Sir Charles Gairdner Hospital

Background: Sarcopenia and frailty are common in Liver Transplant (LT) candidates and associated with adverse events. Skeletal Muscle Index (SMI) and Intramuscular Adipose Tissue (IMAT) are CT measures of sarcopenia assessing muscle quantity and quality, whereas frailty is assessed using the Liver Frailty Index (LFI). While frailty has been shown to improve prognostic ability of MELD 3.0, the additional benefit of sarcopenia measures remains unclear, particularly in cohorts with hepatocellular carcinoma (HCC). This project evaluated the utility of frailty and sarcopenia measures in improving prediction of waitlist mortality in LT candidates. **Methods:** Patients waitlisted for LT from a single centre between 2018-2025 were retrospectively identified. Baseline biochemistry, CT and physiotherapy assessment for LFI were obtained ±4 weeks from LT evaluation. SMI and IMAT were calculated at the L3 vertebral level. Primary outcome was waitlist mortality defined by death on waitlist or within 30 days of delisting. Models with MELD 3.0 and risk factors were developed using cox proportional hazards models, then assessed and internally validated using optimism corrected concordance indices and Net Reclassification Indices (NRI). **Results:** Among 215 patients evaluated for LT, 160 (76%) were listed. Median age was 55 years; 108 (67.5%) were male. Median MELD 3.0 score was 18 , LFI 3.86, SMI 44 cm²/m², and IMAT 6.7%. After a median follow up of 110 days, 14 (8.75%) experienced waitlist mortality. Addition of LFI to MELD 3.0 improved discrimination (c-index 0.82 to 0.90). NRI showed an 11.4% improvement at 3 months. Frailty and MELD 3.0 remained statistically significant when accounting for aetiology and HCC status. The addition of SMI or IMAT had no further benefit. **Conclusion:** In LT candidates, including those with HCC, LFI improved prediction of waitlist mortality beyond MELD 3.0 alone. Further addition of SMI or IMAT provided no significant benefit.

Model	Original Concordance -Index	Corrected Concordance-index	Akaike Information Criterion	Net Reclassification Index
MELD 3.0	0.84	0.82	151.35	-
MELD 3.0 + LFI	0.91	0.90	104.54	0.114 (-0.152 – 0.401)
MELD 3.0 + Sarcopenia	0.86	0.82	121.88	0.095 (-0.034 – 0.274)
MELD 3.0 + SMI	0.84	0.82	150.42	0.035 (-0.057 – 0.176)
MELD 3.0 + IMAT	0.84	0.81	153.04	-0.016 (-0.039 – 0.000)
MELD 3.0 + LFI + Sarcopenia	0.92	0.90	97.02	0.114 (-0.152 – 0.411)
MELD 3.0 + LFI + SMI	0.92	0.90	104.56	0.217 (0.033 – 0.431)
MELD 3.0 + LFT + IMAT	0.91	0.89	106.50	0.113 (-0.146 – 0.361)

Table 1: Model comparison of additional variables vs MELD 3.0 alone for the prediction of waitlist mortality in liver transplant candidates. LFI = Liver Frailty Index; SMI = Skeletal Muscle Index; IMAT = Intramuscular Adipose Tissue.

evaluation. Current 2025 AASLD/AST guidance considers active intravenous drug use a contraindication to LT and discourages inhaled substance use but allows centers to establish their own substance-specific policies, resulting in substantial practice variation. This study provides an updated national survey of LT center policies on controlled substances during transplant candidacy evaluation. **Methods:** We distributed a structured survey on alcohol-associated transplant protocols to one hepatologist at each active adult LT center in the United States, selecting medical directors or transplant hepatologists with expertise in their center practices. Respondents were asked the minimum abstinence duration of non-alcohol substances required for transplant candidacy. We defined federally controlled substances to include stimulants, non-prescription opioids, misused prescription opioids, and hallucinogens. We separately considered inhaled/edible cannabis, which is controlled state-by-state. Frequencies were averaged across all federally controlled substances and separately across cannabis. Responses were further analyzed by US census geographic region, center volume, and median MELD at transplant (MMaT) as characterized by the SRTR database. **Results:** Among 117 centers, 78 with representation from all 11 UNOS regions responded (67% response rate). For stimulants, opioids, and hallucinogens, 42% required 6 months of abstinence, 15% required 1 year, and 10% required no minimum. Among centers selecting "Other" (30%), most reported case-by-case decisions or reliance on psychosocial or addiction medicine evaluation. In contrast, most reported no minimum requirement for inhaled (64%) or edible cannabis (81%), with no statistical difference when stratified by cannabis legality. Regional analysis showed the Northeast (N = 18) had the most stringent centers, with > 70% requiring at least 6 months of abstinence for non-cannabis substances. Centers with 150+ annual transplants (N = 23) were most permissive, with 12% requiring no abstinence period and none requiring ≥ 1 year; however, centers with higher MMaT (MELD 30-34, N = 47) tended to require longer abstinence, with 33% requiring 6 months to 1 year versus 22% for lower MMaT (MELD 25-29, N = 31). **Conclusion:** LT centers across the United States demonstrate substantial variation in controlled substance abstinence requirements during candidacy evaluation, with differing policies when stratified by region, center volume, and MMaT. These center characteristics may play a multifactorial role in determining center-specific practices. Further work evaluating how these policies influence patient perceptions, psychosocial interventions, and transplant outcomes can help shape future LT selection guidance.

4402 | ◆ EXPANDING THE DCD LIVER DONOR POOL: THE IMPACT OF NORMOTHERMIC MACHINE PERFUSION ON BILIARY INTERVENTIONS AND RESOURCE SAVINGS

Mingyi Zhang[1] Nicole Loo[2] Andrew Keaveny[2] Liu Yang[2] Denise Harnois[2] Kristopher Croome[2] Omar Mousa[2], [1]Mayo Clinic, [2]Mayo Clinic Florida

Background: Donation after circulatory death (DCD) liver grafts have historically been underutilized because of concerns for early allograft dysfunction, ischemic cholangiopathy, and graft loss after static cold storage (SCS). Normothermic machine perfusion (NMP) may mitigate these risks, safely expanding the marginal graft pool while demonstrating early perioperative resource savings. However, delayed biliary complications after NMP may impose a downstream resource burden that is not captured by index-admission outcomes. This study aims to compare early perioperative resource utilization against biliary intervention burden in DCD liver transplantation using NMP versus SCS. **Methods:** This is a retrospective review of 333 DCD liver transplants preserved with either SCS (n = 167) or NMP (n = 166). Donor, graft, recipient

demographics, intraoperative characteristics, resource utilization, 1-year clinical and biliary outcomes were compared between groups. Early resource utilization outcomes included operative time, index length of stay, ICU admission, and blood product transfusion. Clinical and biliary outcomes through 1 year included primary nonfunction, graft loss, patient survival, biliary complications, anastomotic strictures, ERCP utilization, and biliary stent placement. **Results:** Compared to SCS, NMP was used for significantly higher-risk DCD grafts, including older donors (59.5 vs 39.0 yrs), higher BMI (29.6 vs 26.6), longer warm ischemia (14.0 vs 9.0 min), higher DRI (3.89 vs 2.98), and greater steatosis (24.1% vs 6.0%) [all $p < 0.001$]. Despite this higher-risk graft profile, NMP improved early outcomes: lower PNF (0.0% vs 3.6%), less post-reperfusion syndrome, lower ICU admission (30.7% vs 44.9%), and fewer transfusions [all $p < 0.05$]. Index LOS ($p = 0.66$) and operative time ($p = 0.31$) were similar. However, NMP required fewer pRBCs (3.7 ± 2.8 vs 6.5 ± 6.0), FFP (2.8 ± 3.0 vs 5.5 ± 5.3), and platelets (0.9 ± 1.1 vs 1.7 ± 2.0) [all $p \leq 0.05$]. Total blood products were 8.7 ± 6.7 vs 15.5 ± 13.2 units/transplant ($p < 0.001$), saving 680 units per 100 transplants. However, NMP had higher rates of anastomotic strictures (32.5% vs 18.6%, $p < 0.001$), ERCP need (35.5% vs 26.9%, $p < 0.001$), and stenting (34.9% vs 20.4%, $p < 0.05$). Non-anastomotic strictures were low (5.4% vs 9.0%, $p = 0.31$). One-year graft loss (4.2% vs 7.7%, $p = 0.17$) and survival (96.9% vs 95.2%, $p = 0.40$) were comparable. **Conclusion:** NMP enabled using older, higher-risk DCD grafts while improving early outcomes and reducing transfusions, without compromising operative time, LOS, graft loss, or survival. However, these early benefits were accompanied by significantly higher rates of anastomotic strictures, ERCP, and stenting. Economic evaluations of NMP must extend beyond index-admission metrics to include delayed biliary interventions to reveal the true cost of expanding the donor pool.

Outcome Metric	SCS (n=167)	NMP (n=166)	P value

4403 | ◆ PROSPECTIVE SILENT TRIAL OF A MULTI-AGENTIC AI LIVER TRANSPLANT COMMITTEE FOR OBJECTIVE DECISION-MAKING IN TRANSPLANT CANDIDACY

Yingji Sun[1] Ghazal Azafar[1] Peter Maksymowksy[1] Peregrina Peralta[1] Irene Chen[2] Jin Ge[2] Divya Sharma[3] Elmar Jaeckel[1] Mamatha Bhat[4], [1]University Health Network, [2]University of California, San Francisco, [3]York University, [4]Toronto General Hospital

Background: Liver transplant (LT) selection committee decisions are complex and may be influenced by subjectivity despite their significant impact on patient outcomes. We previously demonstrated that a multi-agent artificial intelligence (AI) system composed of large language models (LLMs) simulating LT committee specialists could accurately identify patients likely to benefit from transplantation. We developed a dashboard and conducted a prospective silent trial to evaluate the feasibility of implementing this AI Selection Committee (AI-SC) in clinical practice. **Methods:** We included adult LT candidates discussed at weekly University Health Network Liver Transplant Program listing meetings. Cohort 1 comprised patients reviewed retrospectively between June 2022 and May 2025, while Cohort 2 included candidates evaluated prospectively between August and December 2025. In the multi-agentic sysmtem, an agent was first prompted as an AI medical scribe to generate standardized clinical vignettes from electronic health records. For the prospective silent trial, we developed an interactive dashboard that ingested the PowerPoint slides presented during committee meetings as input to the medical scribe agent. The AI-SC consisted of six large language model agents representing a hepatologist, surgeon, cardiologist, social worker, anesthesiologist, and psychiatrist. Institutional transplant guidelines were incorporated through retrieval-augmented generation. For each candidate, the AI-SC generated a listing recommendation (list vs. decline), specialty-specific rationales, and cosine similarity analyses. Cohort 1 vignettes were reviewed for accuracy and hallucinations. AI-SC recommendations in both cohorts were compared with those of the clinical transplant selection committee. **Results:** Fewer than 10% of AI-generated vignettes in cohort 1 ($n = 500$) contained hallucinated information, primarily due to missing or incomplete source data. 88 vignettes were eligible for analysis after excluding cases with insufficient written clinical information. The AI-SC accurately identified

contraindications to liver transplant and effectively assessed transplant candidacy with an accuracy of 86.4% (95% CI, 79.0–93.8%), sensitivity of 91.0% (95% CI, 84.0–97.0%), and specificity of 58.0% (95% CI, 30.0–87.0%). Across the prospective cohort (n = 89), the AI-SC demonstrated an accuracy of 85.4%, sensitivity of 88.0%, and specificity of 71.4%. Discordant decisions were predominantly attributable to incomplete clinical documentation and abbreviations not recognized by the system. **Conclusion:** A multi-agent LLM framework can simulate LT selection committee deliberations and generate listing recommendations with high concordance to clinical decisions. These findings support the feasibility of AI-assisted decision support for improving the objectivity, consistency, and equity of LT candidate assessment.

4404 | ◆ MELD-RISE (RISK OF INCREMENTAL SCORE ELEVATION): QUANTIFYING INCREASES IN MORTALITY RISK CONFERRED BY CHANGES IN MELD

Xiaohan Ying[1] Russell Rosenblatt[2], [1]NewYork Presbyterian/Weill Cornell, [2]Weill Cornell Medicine

Background: The Model for End-Stage Liver Disease (MELD) score has guided liver transplantation (LT) allocation since 2002, prioritizing candidates based on estimated short-term mortality risk. Despite its widespread adoption and iterative refinements, MELD remains a static, cross-sectional measure that captures disease severity at a single point without accounting for trajectory. In this study, we developed and validated a novel trajectory-based scoring system (MELD-RISE) that incorporates MELD changes to improve prediction of 90-day WL mortality in the contemporary allocation era. **Methods:** We used the UNOS STAR file and included adult LT candidates listed from 2/4/20-12/31/25 with at least 3 MELD assessments. We excluded candidates listed with status 1A, multiorgan, exception points, prior LT, and initial MELD > 23 (median MELD of our cohort). The cohort was split randomly 70:30 into derivation and validation groups. Competing-risk regression including *a priori* covariates (age, sex, diagnosis, function according to performance status, region) estimated waitlist (WL) mortality and LT. The primary outcome was 90-day WL mortality. A score incorporating change in MELD was created. Discrimination was assessed using the area under the curve (AUC). **Results:** Of the 20,738 patients included in the derivation cohort, 55.5% were transplanted, 16.2% remained on the WL, and 10.2% died. The characteristics of the validation cohort (8,685) were similar to the derivation cohort. After competing risk regression, change in MELD over the last 3 measurements was associated with a significant increase in WL mortality (sHR 1.08, 95% CI: 1.06-1.09). A MELD-RISE score was created: MELD-RISE = last MELD + 0.94 * [MELD change over last 3 measurements]. Essentially, for each point of MELD score change over 3 checks, the risk of WL mortality was equal to an extra MELD point (**Figure 1**). Using the validation cohort, however, AUC was lower than using the last MELD score itself (0.81 vs 0.82, p < 0.001). **Conclusion:** In this study, we developed and validated a novel trajectory-based score integrating both the most recent MELD and the magnitude of MELD changes. Each one-point increase in MELD conferred a mortality hazard equivalent to nearly one additional point to the most recent MELD score. This suggests that the rate and direction of MELD changes carry independent prognostic weight not captured by a static, cross-sectional score. Additionally, this further quantifies the impact of a rise in MELD – a clinical situation that is known to result in increased mortality above the score itself. The incorporation of this trajectory-based approach may be warranted to better identify and prioritize patients whose true mortality risk is underestimated by the current scoring system.

4405 | ◆ PROPENSITY-MATCHED ANALYSIS OF 10-YEAR GRAFT AND PATIENT SURVIVAL AFTER LIVER TRANSPLANTATION WITH HEPATITIS B VIRUS-POSITIVE DONOR ORGANS

Rachael Mahle[1] Leandro Sierra[2] Katherine Cooper[1] Karin Andersson[1] Daniel Sikavi[1] Doan Dao[1] Eric Przybyszewski[1] Xing Li[1] Irun Bhan[1] Deepika Devuni[3] Raymond Chung[1] Arthur Kim[1] Camille Kotton[1] Heidi Yeh[1] Shimul Shah[1] Emily Bethea[1], [1]Massachusetts General Hospital, [2]Cleveland Clinic Foundation, [3]UMass Memorial Health

Background: Hepatitis B virus (HBV)-positive donor grafts represent an important opportunity to expand the liver donor pool to increase access to transplantation. However, data on long-term outcomes across the spectrum of donor HBV serologic profiles remain limited. We evaluated short- and long-term graft and recipient outcomes across HBV-infected (HBsAg+ and/or NAT+), HBV-exposed (HBcAb+; HBsAg-, NAT-), and HBV-naïve (HBcAb-, HBsAg-, NAT-) donor grafts. **Methods:** We conducted a retrospective cohort study using the United Network for Organ Sharing/Organ Procurement and Transplantation Network (UNOS/OPTN) national registry (2000-2025). Three pairwise propensity-matched comparisons across donor HBV serologic profiles were performed. Patient and graft survival at 1, 5, and 10 years were assessed by Kaplan-Meier estimation. Sensitivity analyses included Cox proportional hazards regression, Royston-Parmar flexible parametric models, restricted mean survival time, 30-day landmark analysis, and Fine-Gray competing-risk models. **Results:** Among 138,485 recipients, 130,684 (94.4%) received HBV-naïve, 7,404 (5.2%) HBV-exposed, and 397 (0.3%) HBV-infected donor grafts. After propensity matching, recipients of HBV-naïve and HBV-infected donor grafts showed comparable graft and patient survival at 1 and 5 years. However, at 10 years, HBV-infected donor grafts were associated with lower graft survival (66.8% vs 56.5%; P = 0.043) and patient survival (71.6% vs 60.4%; P = 0.046). Recipients of HBV-exposed donor grafts demonstrated statistically significant lower graft and patient survival compared with HBV-naïve donor graft recipients at all time points; however, the absolute differences between groups ranged from 1.3% to 2.3%. No significant differences were observed between recipients of HBV-exposed and HBV-infected grafts. **Conclusion:** In this national propensity-matched analysis, HBV-infected donor grafts showed comparable short- and intermediate-term outcomes compared to HBV-naïve donor grafts, with differences emerging only at long-term follow-up. While HBV-exposed donor grafts were associated with a reduction in graft and patient survival compared with HBV-naïve donor grafts, the absolute differences were small and may have limited clinical significance. These findings support ongoing expansion of HBV-positive donor utilization and highlight the need for long-term post-transplant monitoring.

4406 | VERY LOW MELD SCORES ON THE WAITLIST: HIGHER WAITLIST MORTALITY

Hanna Abuhay[1] Alexander Zhao[2] Russell Rosenblatt[1], [1]Weill Cornell Medicine, [2]Joan and Sanford I. Weill Medical College of Cornell University

Background: Patients with low MELD scores are often perceived to have favorable prognosis and may not be considered for liver transplantation (LT) at many centers. However, outcomes among patients listed with very low MELD scores remain poorly defined. We evaluated outcomes in patients listed for LT with MELD ≤ 10 without access to MELD exception points or living donation. **Methods:** Adults listed for LT between 2015–2025 with MELD ≤ 10 in the UNOS STAR file were identified. In order to isolate patients with poor access to LT, patients with hepatocellular carcinoma, MELD exception points, multi-organ transplant listing, or LDLT were excluded. Competing risk regression models were used to evaluate predictors of waitlist (WL) mortality, LT, and delisting due to clinical improvement, with covariates selected a priori. **Results:** Among 6,120 patients, mean age was 57 years and mean MELD at listing was 9. Alcohol-associated liver disease (ALD) (32.2%) was the most common etiology. Despite low MELD scores, 69.4% had ascites and 53.6% had hepatic encephalopathy (HE). Mean WL time was 677 days. During follow-up, 14.7% died on the WL, 28.3% underwent LT, 23.4% were delisted due to clinical improvement, 19.3% were delisted for other reasons, and 14.3% remained listed. At WL removal, mean MELD at LT was 13, 14 at mortality, and 9 at delisting/still waiting. On competing risk regression, older age was associated with increased WL mortality (SHR 1.03, 95% CI 1.03–1.04, $p < 0.001$), while ALD was associated with lower WL mortality (SHR 0.62, 95% CI 0.49–0.78, $p < 0.001$) and higher likelihood of clinical improvement (SHR 1.72, 95% CI 1.43–2.08, $p < 0.001$). Male sex, higher MELD, and HE were associated with lower likelihood of improvement. Older age, male sex, higher MELD, ascites, and HE were associated with LT. **Conclusion:** Patients listed for LT with MELD ≤ 10 without access to living donation or MELD exception points represent a clinically heterogeneous cohort with substantial underlying hepatic decompensation and surprisingly high WL mortality despite low laboratory MELD scores. Although nearly 1 in 4 improved sufficiently for delisting, particularly in ALD, over 1 in 4 underwent LT and nearly 1 in 6 died on the WL, highlighting the fact that MELD incompletely captures disease burden in this population.

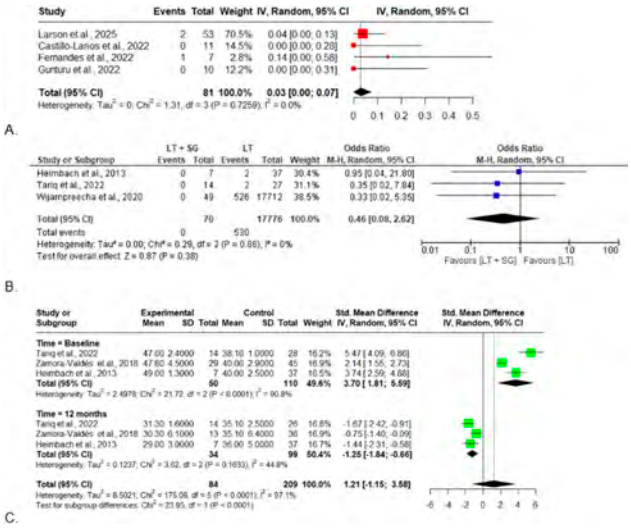
4407 | THE SAFETY AND EFFICACY OF COMBINED LIVER TRANSPLANT AND SLEEVE GASTRECTOMY: A SYSTEMATIC REVIEW AND META-ANALYSIS



Muaaz Masood[1] Amita Kasar[1] Mala Jain[2] Richard Kozarek[1] Asma Siddique[1], [1]Virginia Mason Franciscan Health, [2]Westchester Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is currently the most common etiology of chronic liver disease and the most common indication for liver transplantation (LT) in the United States. The rate of obesity in patients undergoing LT has increased. Additionally, there is a risk for recurrent and de novo MASLD following LT. Several studies have revealed that a combined LT and sleeve gastrectomy (SG) may be effective. This is the first systematic review and meta-analysis to our knowledge to evaluate the safety and efficacy of combined LT and SG. **Methods:** We performed a comprehensive search from four databases including PubMed, Scopus, Google Scholar and ScienceDirect. All analyses were performed using a random-effects model. Statistical analysis was conducted using R version 4.5.1 and Review Manager (RevMan) 5.4. For comparative outcomes, pooled effect sizes were calculated using standardized mean differences (SMDs). The odds ratio was calculated for mortality. Statistical significance was defined as $p < 0.05$. Between-study heterogeneity was assessed using the I2 statistic, characterized as low (25%), moderate (50%), or high (75%) heterogeneity.

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Results: Four studies with a total of 81 patients were included in the meta-analysis of perioperative mortality following LT + SG (A). The pooled mortality rate was 3% (95% CI 0–7%), with no heterogeneity (I2 = 0%). Three studies with 17,846 patients compared post-operative complications between LT + SG and LT alone. In the LT + SG group, no complications were reported (0/70), whereas in the LT only group, 530 events occurred (B). The pooled odds ratio was 0.46 (95% CI 0.08–2.62), which indicated no significant difference between groups (p = 0.38). The pooled mean body mass index (BMI) was determined at baseline and at 12 months (C). The pooled mean BMI decreased from 45.54 (95% CI 43.14–47.95; I2 = 93%) at baseline to 30.57 at 12 months following LT + SG (95% CI 29.41–31.72; I2 = 43.3%). Subgroup differences between the time points were statistically significant (Chi2 = 128.43, p < 0.0001), which suggested sustained improvements in BMI. **Conclusion:** Our study demonstrated that combined LT + SG is safe and is not associated with increased perioperative mortality compared to LT alone. There was no significant differences in reported complications among LT + SG patients which suggests that the addition of SG does not affect postoperative outcomes in select patients. Subgroup analysis revealed sustained improvements in BMI which were statistically significant. Studies also revealed a trend towards improvement in metabolic comorbidities. LT + SG remains an option for patients who are not able to take medications for obesity due to barriers, e.g. medication side effects, cost, insurance coverage, and patients with inadequate response to medical therapy. Additional studies are warranted to explore outcomes with LT + SG.

4408 | UTILIZATION TRENDS IN HEPATITIS B VIRUS POSITIVE DONORS FROM 2000-2024

Rachael Mahle[1] Leandro Sierra[2] Katherine Cooper[1] Karin Andersson[1] Daniel Sikavi[1] Doan Dao[1] Eric Przybyszewski[1] Xing Li[1] Irun Bhan[1] Deepika Devuni[3] Raymond Chung[1] Arthur Kim[1] Camille Kotton[1] Heidi Yeh[1] Shimul Shah[1] Emily Bethea[1], [1]Massachusetts General Hospital, [2]Cleveland Clinic Foundation, [3]UMass Memorial Health

Background: The global burden of liver disease is driving a growing demand for liver transplantation, which remains a resource-limited field. HBV-positive donor grafts have been used to expand access to suitable organs. In this study, we evaluated HBV-positive donor graft utilization patterns, stratified by HBV-naïve (HBcAb-, HBsAg-, NAT-), HBV-exposed (HBcAb+; HBsAg- and NAT-), and HBV-infected donors (HBsAg+ or NAT+). **Methods:** This retrospective cohort study (2000-2024) used the United Network for Organ Sharing/Organ Procurement and Transplantation Network (UNOS/OPTN) registry. Transplanted grafts were identified by linkage to recipient records, while donors without a matched liver transplant recipient were classified as discarded. Pearson's chi-square test was used to compare discard rates across donor groups, and logistic regression was used to estimate odds ratios (ORs) for graft discard using HBV-naïve donors as the reference group. Era-stratified analyses (2000-2014 vs 2015-2024) were used to assess temporal trends in utilization. **Results:** Among 208,087 deceased donors with classifiable HBV serologic profiles, discard rates were similar across donor categories: 33.4% for HBV-naïve, 38.3% for HBV-exposed, and 37.0% for HBV-infected donors. After adjusting for donation year, HBV-exposed donors had modestly increased odds of discard compared with HBV-naïve donors (OR 1.25, 95% CI 1.21-1.30; P < 0.001), while the difference for HBV-infected donors was not significantly different (OR 1.07, 95% CI 0.90-1.26; P = 0.463). Era-stratified analyses showed that from 2000-2014, HBV-infected donors had substantially higher discard rates than HBV-naïve donors (45.7% vs 28.5%; OR 2.12, P < 0.001). However, in 2015-2024, discard rates became similar between groups (34.2% vs 37.7%; OR 0.86, P = 0.13). There was significant regional variation in HBV-positive donor utilization, with the highest transplant rates in OPTN Regions 7 and 11 and the lowest in Regions 5 and 6. **Conclusion:** Utilization of HBV-positive liver grafts has increased substantially in the US. In the last decade, HBV-infected donors had similar discard rates to HBV-naïve donors. These findings may suggest growing national acceptance of HBV-positive donor grafts. Ongoing regional differences in utilization represents an opportunity to improve equitable use of HBV-positive donor organs.

4409 | INCRETIN-BASED THERAPIES AS A BRIDGE TO LIVER AND OTHER SOLID ORGAN TRANSPLANTATION: A SYSTEMATIC REVIEW AND META-ANALYSIS

Ahmed Mohammad[1] Noor Mawaz-Khan[2] Areej Hasan[3] Shreya Narayanamoorrthy[2] Mohammad Qasim Khan[4], [1]Department of Medicine, Western University, [2]Faculty of Health Sciences, Western University, [3]Faculty of Science, McMaster University, [4]Department of Epidemiology, Department of Medicine, Division of Gastroenterology, Western University

Background: Obesity is a major barrier to solid organ transplantation (SOT), limiting transplant candidacy, waitlist activation, and access to transplantation. Incretin-based therapies (IBTs), including GLP-1 receptor agonists (GLP-1 RAs) and GIP/GLP-1 RAs are effective weight-loss therapies, but their effectiveness as a bridge-to-transplant remains uncertain. We evaluated the effectiveness of IBTs on anthropometric and transplant-related outcomes among adults undergoing evaluation for SOT. **Methods:** We conducted a systematic review and meta-analysis of studies evaluating IBTs in adult SOT candidates with obesity-related barriers to transplantation. Outcomes included absolute weight change, percentage total body weight loss (%TBWL), body mass index (BMI) change, waitlist activation, and receipt of transplantation, and exposure characteristics describing how IBTs were used. Random-effects meta-analyses were performed for continuous anthropometric outcomes. Sensitivity analyses explored treatment duration, transplanted organ type, and study-level heterogeneity. **Results:** Nineteen studies across liver, kidney, heart, lung, and combined-organ transplant populations were included. Semaglutide was the most reported agent followed by tirzepatide, liraglutide, and dulaglutide. Treatment duration ranged from approximately 3 to 15 months. In single-arm pooled analyses, IBTs were associated with significant reductions in absolute body weight across 12 studies (mean change −10.51 kg, 95% CI: −13.66 to −7.36 kg), BMI across 12 studies (mean change −3.34 kg/m², 95% CI −4.36 to −2.32 kg/m²), and %TBWL across 8 studies (mean change −9.01%, 95% CI −10.99 to −7.03%). Despite substantial heterogeneity across anthropometric outcomes, treatment effects were directionally consistent across sensitivity analyses. Transplant-related outcomes were synthesized narratively. Across studies, IBTs were associated with improved transplant candidacy, increased waitlist activation, and progression to transplantation. Comparative studies demonstrated higher likelihood of waitlisting (aHR 1.66, 95% CI 1.28 to 2.13) and transplantation (aOR 2.51, 95% CI 1.72 to 3.67) among IBT users versus non-users. Multiple single-arm cohorts further demonstrated that clinically meaningful proportions of previously ineligible candidates subsequently achieved waitlisting or transplantation following IBT-associated weight loss. **Conclusion:** IBTs are associated with clinically meaningful reductions in weight and BMI among transplant candidates with obesity-related barriers. These therapies may improve access to transplantation by facilitating waitlist activation and progression to transplant. Prospective controlled studies are needed to define optimal implementation strategies and long-term post-transplant outcomes.

4410 | LIVING LIVER DONATION IS FINANCIALLY AND OCCUPATIONALLY SAFE: NATIONAL EVIDENCE REASSURING DONORS ON INSURANCE AND EMPLOYMENT OUTCOMES

Sri Harsha Boppana[1] Subhash Gurappa[2] Sachin Sravan Kumar Komati[2] Gautam Maddineni[3] Raja Chandra Chakinala[4] Venkata Sunkesula[5] Pradeep Yarra[6] Kamran Qureshi[7], [1]Nassau University Medical Center, [2]Florida International University, [3]Creighton university, [4]Guthrie Robert Packer Hospital, [5]Case Western Reserve University, [6]UT Health San Antonio, [7]Saint Louis University

Background: Living liver donation saves lives and expands transplant access, yet unfounded concerns about financial harm — including insurance loss and income disruption — continue to deter potential donors. Robust national data are needed to reassure candidates that donation does not jeopardize their financial security or occupational stability. We aimed to comprehensively characterize insurance, employment, and disability outcomes after living liver donation in a contemporary national cohort and identify modifiable risk factors for work disruption. **Methods:** Retrospective cohort study using OPTN/UNOS STAR data (2014–2024). Adult living liver donors aged 18–65 were assessed for donation-attributed health insurance loss, life insurance loss, work disruption (employed at donation, not employed at follow-up), and transition to disability status. Multivariable logistic regression identified independent predictors of work disruption, adjusting for donor demographics, donation type, liver complications, and hospital readmission. **Results:** Among 5,159 adult living liver donors (median age 36; 56.3% female), donors were young, healthy, and economically active: 86.1% were employed and 94.6% were insured at donation. Donation-attributed insurance loss was exceedingly rare: only 34 of 5,050 donors (0.67%) lost any coverage — health insurance in 25 and life insurance in 12. Although liver complications occurred in 738 donors (14.3%) and hospital readmissions in 621 (12.0%), nearly 9 in 10 employed donors successfully maintained employment after donation. Work disruption occurred in 504 of 4,461 baseline-employed donors (11.3%). On multivariable analysis, readmission — not hepatic complications — was the primary independent predictor of work disruption (OR 1.79, 95% CI 1.36–2.36; hepatic complications OR 1.02, p = 0.92). Donor sex, age, and graft type were not significant predictors. Long-term transition to disability status remained low across the cohort. **Conclusion:** This large national study provides compelling reassurance that living liver donation is financially and occupationally safe for the overwhelming majority of donors. Insurance loss affected fewer than 1 in 150 donors, employment was preserved in nearly 9 of 10 working donors, and transition to disability was uncommon. The principal driver of work disruption was readmission rather than hepatobiliary complications, identifying a specific and preventable target for perioperative support. These findings should be actively shared with prospective donors and their families during evaluation to address financial concerns, reduce donation hesitancy, and promote broader expansion of living liver donation.

EXTRAHEPATIC PORTAL VEIN OBSTRUCTION

David Grabski[1] Riccardo Superina[2] Lisa Keys[1] Jordan Perrott[1], [1]Lurie Children's Hospital, [2]Ann and Robert H. Lurie Children's Hospital of Chicago

Background: Meso-Rex bypass (MRB) is the preferred physiologic treatment for extrahepatic portal vein obstruction (EHPVO) in children. Despite increasing acceptance of MRB, many patients with EHPVO experience significant delays in surgical referral possibly due to a concern for technical feasibility in younger children with smaller vessels. We sought to determine whether age at operation influences the degree of physiologic portal venous inflow restoration achieved following MRB. **Methods:** We analyzed a prospectively maintained cohort of children undergoing primary MRB for EHPVO between 1997 and 2026 at a quaternary pediatric referral center. Intraoperative shunt flow was measured using a vascular flow probe and normalized to patient-specific predicted physiologic portal venous inflow derived from body surface area and cardiac output. This calculation generates a Meso-Rex Flow Ratio (measured flow/ideal portal flow). Linear regression was used to evaluate the relationship between age at surgery and achieved flow ratio. Previously established associations between flow ratio and bypass durability were used to contextualize clinical significance. **Results:** A total of 148 children underwent primary MRB and met inclusion criteria. Median age at operation was 6.3 years (IQR 3.4–10.6 years). Age at surgery demonstrated a significant inverse association with achieved Meso-Rex Flow Ratio (β = -0.016, p = 0.001), with younger children consistently achieving higher normalized portal venous inflow following reconstruction. Children undergoing MRB at younger ages frequently achieved portal inflow approaching or exceeding predicted physiologic requirements, whereas older children demonstrated progressively lower flow ratios. Prior analyses within this cohort demonstrated that higher flow ratios are associated with improved primary bypass patency and reduced need for postoperative intervention. These findings suggest that earlier intervention may confer a physiologic advantage by maximizing restoration of hepatopetal portal flow. **Conclusion:** Younger age at MRB is associated with superior restoration of physiologic portal venous inflow. These data directly challenge the perception that younger children are technically disadvantaged candidates for MRB and instead support earlier evaluation and referral before prolonged portal venous deprivation occurs.

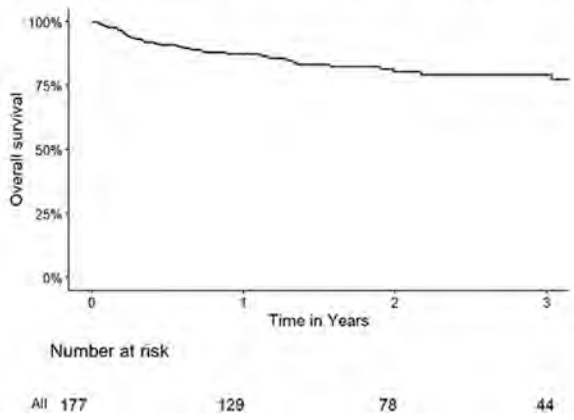
4412 | LIVER TRANSPLANTATION IN RECIPIENTS AGED 75 YEARS AND OLDER IN THE ACUITY-CIRCLE ALLOCATION ERA

Irena Helenowski[1] Eyad Razzak[2] Kush Patel[2] Scott Cotler[2] Eric Kallwitz[2], [1]Loyola University Chicago, [2]Loyola University Health System



Background: Liver transplantation (LT) is increasingly considered in older individuals, especially those with MASLD and hepatocellular carcinoma (HCC). There is no established recipient age threshold which serves as a contraindication to LT. The purpose of this study was to perform a descriptive analysis of LT recipients aged 75 and older. **Methods:** Liver transplant recipients aged ≥75 years in the UNOS database from Feb 2020–December 2024 were included in this analysis. Descriptive data were included and patient and graft survival was estimated using Kaplan-Meier survival curves. **Results:** In the era included, there were 177 LT recipients aged ≥75 years. The annual number increased from 18 transplants in 2020 to 51 transplants in 2024. Fifty-five transplant centers transplanted at least one patient aged 75 and older. Recipients 75 and older were largely non-Hispanic, white (n = 127, 71.8%) and male (n = 118, 66.7%). The most common transplant

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

indications were HCC (n = 74, 41.1%) and MASLD (n = 40, 22.6%). The Karnofsky score was < 40% in 61 recipients (34.5%) and 67 (37.9%) recipients had a BMI < 25 kg/m2. Fifty-one recipients were in an ICU (28.8%) at time of transplant, and 11 (6.2%) had a history of grade 3-4 encephalopathy. Only 16 recipients (9%) received dialysis within one week of registration and 24 recipients (14%) received dialysis within one week of transplant. The distribution of recipient MELD scores was 25.4% MELD 6-11, 10.7% MELD 12-14, 11.9% MELD 15-17, 10.2% MELD 18-21, 13.6% MELD 22-25, 9.6% MELD 26-29, 10.7% MELD 30-34 and 7.9% MELD 35-40. Livers from donors aged 70 and older were used in 13.1% of recipients, whereas roughly 25% (n = 44) received a donor aged 18-39 years. Donation after cardiac death livers were utilized in 25.4% of cases. Donor location was 39.6% local, 29.4% regional and 31.1% national. Median cold ischemic time in donors was 6.6 hours. Overall patient survival is shown in the Figure. Notably patient survival at one year was 87.31%; 95% CI 82.49, 92.41 and at 3 years was 79.33; 95% CI 72.85,86.39. Five-year patient survival data were limited by a small sample size, but was 60.23; 95% CI 43.67,83.07. Graft survival was fairly similar to patient survival at 1 year (86.30; 95% CI 81.36, 91.55) and 3 years (78.42, 95% CI 71.91, 85.52). **Conclusion:** Selected recipients aged 75 and older had acceptable 1 year (87.3%) and 3 year (79.3%) survival. While LT in recipients aged 75 and older was uncommon, 55 centers performed at least one transplant in this age group. These data suggest that chronological age alone should not serve as an absolute contraindication to LT. Further data are needed to identify optimal selection criteria in this group and additional long term survival data are needed.

Figure. 1 and 3 year overall survival in transplant recipients aged 75 and older

4413 | REGIONAL IMPACT OF NEW LIVER TRANSPLANT CENTER ENTRY: A NATURAL EXPERIMENT

Holly Huang[1] John Roberts[1] Hillary Braun[1] Garrett Roll[1] Jennifer Lai[1] Jin Ge[1], [1]University of California, San Francisco

Background: Prior studies of liver transplant competition identified associations between competitive states and transplant outcomes but could not establish how programs respond to competition changes. In this retrospective cohort study, we used a quasi-experimental approach to evaluate the impact of a single new center opening on regional transplant volume, transplant efficiency, market share, donor utilization, and recipient case-mix. **Methods:** Using United Network for Organ Sharing (UNOS) registry data (February 14, 2022–December 31, 2024), we identified competing centers as those drawing ≥80% of transplanted livers from the same organ procurement organization (OPO) network as the new center. We analyzed transplant volume, efficiency (transplants per OPO deceased donor), and market share (transplants per OPO-recovered liver) in the regional cohort (competing plus new center; n = 8) and competing cohort (n = 7) in equal 526-day pre- and post-entry windows using Poisson regression and differences-in-differences (DiD) analysis, with UNOS Region 5 centers as external control. We compared regional donor and recipient characteristics pre- and post-entry using Mann-Whitney U and chi-square tests. **Results:** Regional transplant volume increased by 14% (931 pre vs. 1,058 post; rate ratio [RR] 1.14, 95% CI 1.04–1.24, p = 0.004; table 1), comparable to that of the external control (RR 1.10, p < 0.01); DiD confirmed no significant difference from control trends (incidence rate ratio [IRR] 1.02, 95% CI 0.92–1.14, p = 0.71). Among competing centers, volume did not change significantly (RR 1.07, 95% CI 0.98–1.17, p = 0.12; table 1), and DiD found no significant growth displacement (IRR 0.96, 95% CI 0.86–1.08, p = 0.52). Competing centers maintained transplant efficiency (RR 0.96, p = 0.37) but lost market share (RR 0.91, 95% CI 0.83–1.00, p = 0.042) while regional and external control shares remained stable; despite this, they increased absolute procurement from shared OPOs by 64 livers (compared to only +4 from other OPOs). Across regional cohort, donor profiles shifted markedly post-entry: the Donor Risk Index (DRI) increased (median 2.26 vs. 2.51, p < 0.01), cold ischemia time lengthened (6.75 vs. 7.57 h, p < 0.01), deceased cardiac donor (DCD) use nearly doubled (8.6% vs. 15.6%, p < 0.01), and machine perfusion use more than doubled (12.9% vs. 26.9%, p < 0.01). Recipient Model for End-Stage Liver Disease (MELD) scores at listing and transplant were unchanged, and the overall recipient case-mix was stable. **Conclusion:**

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

New liver transplant center entry did not significantly suppress incumbent transplant volume. The region adapted by accepting higher-risk donors while maintaining recipient acuity, and the adoption of machine perfusion may reflect a structural response to this shift. These findings suggest a new transplant center does not harm existing programs when donor supply is sufficient or organ utilization can be improved.

Table 1. Transplant volume: Poisson regression, transplants per 526-day period

Analysis	Pre N	Post N	Pre Rate*	Post Rate*	Rate Ratio	95% CI	P value
Competing centers (n=7)	931	999	1.77	1.90	1.073	0.981–1.173	0.122
Competing centers + new entrant (n=8)	931	1058	1.77	2.01	1.136	1.041–1.241	0.004
UNOS Region 5 centers (excluding competing and new centers; n=17)	2461	2716	4.68	5.16	1.104	1.045–1.165	<0.01
National cohort (n=144 pre, n=143 post)	14410	16212	27.40	30.82	1.125	1.100–1.151	<0.01

4414 | MELD-CYSC: A DE NOVO 90-DAY WAITLIST MORTALITY SCORE INCORPORATING CYSTATIN C IMPROVES RISK PREDICTION BY CAPTURING FRAILTY IN A 14-CENTER US LIVER TRANSPLANT CONSORTIUM

Giuseppe Cullaro[1] Taryn Liu[1] Jennifer Lai[2] Benjamin Cho[2] Brian Lee[3] Sean Lee[4] Sydney Whittaker[5] Stevan Gonzalez[6] Daniel Woodfin[7] Zachary Fricker[8] Todd Frederick[9] Hugo Vargas[10] Sharon Lechtig-Wasserman[11] Douglas Simonetto[12] Miguel Gomez[12] Hani Wadei[13] Ibrahim Alhayani[13] Clara Tow[14] Yixuan Du[14] Justin Belcher[15] Kavish Patidar[16] R. Mark Ghobrial[17] Eric Orman[18] Andres Duarte-Rojo[19] Seong Park[20] Elizabeth Verna[21] Andrew Allegretti[5], [1]Columbia University, [2]UCSF, [3]Keck School of Medicine, [4]USC, [5]MGH, [6]Baylor Scott and White All Saints Medical Center Fort Worth, [7]Burnett School of Medicine at TCU, [8]Beth Israel Deaconess Medical Center, [9]CPMC, [10]Mayo Clinic Arizona, [11]Mayo Arizona, [12]Mayo Clinic Rochester, [13]Mayo, [14]Albert Einstein College of Medicine, [15]Yale, [16]Houston Methodist, [17]Houston Methodist JC Walter Transplant Center, [18]Indiana University, [19]Northwestern Medicine, [20]Northwestern University, [21]Columbia University Medical Center

Background: Serum creatinine (sCr)–based scores, including MELD 3.0, underestimate waitlist mortality in sarcopenic and frail liver transplant candidates. Cystatin C (cysC) is a muscle-independent glomerular filtration marker. We hypothesized that incorporating cysC into MELD 3.0 would improve risk prediction. **Methods:** This substudy of the HRS-HARMONY consortium assembled 14 US LT centers that protocolized the measurement of cysC at the time of LT evaluation. 2,592 candidates with paired cysC and sCr at listing were randomly split 80:20 (stratified by site and 90-day outcome) into derivation (n = 2,083) and held-out validation (n = 509) cohorts. In the derivation cohort, we newly derived MELD-CYSC for 90-day waitlist mortality using multivariable Cox regression with stepwise selection. Candidate predictors were female sex, bilirubin, INR, albumin, sodium, sCr, cysC, and the cysC − sCr difference [Δ(cysC−sCr)]. Transformations and bounds were data-driven (penalized splines, log- vs. linear-fit), with sCr and cysC capped at their upper bounds on renal replacement therapy. MELD-CYSC was compared to MELD 3.0 by Harrell's C, calibration slope, and net reclassification (NRI). In candidates with Liver Frailty Index (LFI), we tested Spearman correlation with Δ(cysC−sCr) and ran a Cox mediation analysis testing whether adding LFI attenuated Δ(cysC−sCr)'s coefficient for 90-day mortality. **Results:** Derivation 2,083 (69 90-day events); validation 509 (13 90-day events). Median age 57y; 40% women; 8% RRT at listing; 72% ascites; 58% HE; alcohol 44%, MASLD 32%. Median (IQR): sCr 0.98 (0.7–1.5), cysC 1.5 (1.1–2.2), Δ(cysC−sCr) 0.5 (0.2–0.7), total bilirubin 2.4 (1.2–5.1), INR 1.50 (1.2–1.8), albumin 3.3 (2.8–3.8), sodium 136 (133–139); MELD 3.0 19 (14–25); MELD-CYSC 18 (13–24). The final MELD-CYSC included bilirubin, INR, sCr, and Δ(cysC−sCr) **(Panel 1a).** In validation, MELD-CYSC discriminated 90-day waitlist mortality numerically better than MELD 3.0 (ΔC +0.03, p = 0.04). MELD-CYSC was substantially better calibrated than MELD 3.0 (calibration slope 1.06 vs 0.18, p < 0.001); MELD-CYSC correctly reclassified 22% of candidates (p < 0.001) driven by appropriate downward reclassification of survivors **(Panel 1b).** Among 1,299 candidates with measured LFI, Δ(cysC−sCr) correlated significantly with LFI (r 0.22, p < 0.001). When LFI was added to the MELD-CYSC variable set, Δ(cysC−sCr)'s hazard ratio fell from 1.58 to 1.20 while LFI itself emerged as the strongest predictor (HR 2.28 per unit, p = 0.002), consistent with LFI-measured frailty mediating the delta's prognostic signal. **Conclusion:** MELD-CYSC improves discrimination, calibration, and reclassification of 90-day waitlist mortality compared with MELD 3.0. The contribution of Δ(cysC−sCr) to WLM prediction is partially explained by LFI, suggesting muscle impairment as a biological mechanism through which cysC improves risk stratification beyond

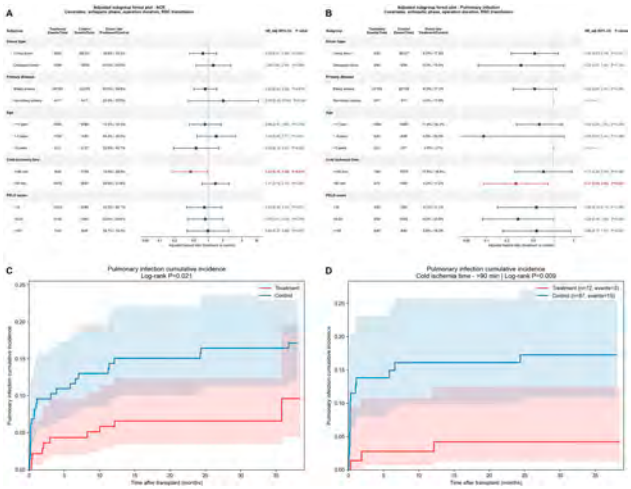
4416 | XENOPAX PLUS INTRAOPERATIVE STEROID IMMUNOSUPPRESSION IN PEDIATRIC LIVER TRANSPLANTATION: A SINGLE-CENTER RETROSPECTIVE STUDY



Shunqi Cao[1] Chong Dong[1], [1]Tianjin First Central Hospital

Background: Pediatric liver transplantation (LT) requires balanced immunosuppression to prevent acute cellular rejection (ACR) while limiting infections. Anti-CD25 induction improves outcomes; we evaluated xenopax, a novel humanized IL-2 receptor antagonist, combined with intraoperative methylprednisolone for early ACR and complication prevention. **Methods:** Single-center retrospective study of 283 consecutive pediatric LT recipients (age $\leq$6 years) undergoing first ABO-compatible LT between September 2021 and September 2023. All received intraoperative methylprednisolone (10mg/kg) and postoperative tacrolimus monotherapy.Xenopax group (n = 137): 1mg/kg on days 0 and +14. Basiliximab group (n = 146): 10mg (< 35kg) or 20mg($\geq$35kg) on days 0 and +4. Baseline characteristics were well balanced. Primary observation outcome : the incidence of ACR.Secondary outcome: infection. Analyses: Cox regression, Kaplan–Meier. **Results:** Median follow-up was 36.57 months (range 4.9–51.13 months). One-year ACR rates were similar (20.4% vs 25.3%, P = 0.402). However, in patients with cold ischemia time (CIT) $\leq$90 minutes, xenopax had a significantly decreased ACR risk trend (HR = 0.43, 95% CI: 0.19-0.99, P = 0.046). Xenopax also significantly reduced pulmonary infection (7.3% vs 17.1%, P = 0.020; Log-rank P = 0.021), with pronounced benefit in the CIT > 90 minutes subgroup (HR = 0.27, 95% CI 0.09–0.83, P = 0.022; Log-rank P = 0.009). **Conclusion:** Xenopax plus intraoperative steroids provides non-inferior ACR prophylaxis relative to basiliximab in pediatric LT, with a

favorable safety profile marked by lower pulmonary infection risk—especially in patients with CIT >90 minutes. Patients with CIT ≤90 minutes may derive particular benefit for rejection prevention. This regimen is a promising induction strategy for pediatric liver transplantation.

4417 | COMPREHENSIVE OR EXCLUSIVE: A 10-YEAR EXAMINATION OF AGE-RELATED OUTCOMES AND DISPARITIES IN LIVING LIVER DONATION

Lindsay Beaman[1] Claire Cywes[2] Audrey Bankes[2] Alyssa Abbott[1] Robert Daniels[2] Ali Hamandi[2] Frank Lee[3] Weslyn Bunn[3] Tayyab Diwan[3], [1]Mayo Clinic Biomedical Ethics Research Program, [2]Mayo Clinic Alix School of Medicine, [3]Mayo Clinic

Background: Young adults (YAs, ages 18-25) are recognized as a vulnerable population in living donation due to age-related psychosocial concerns—such as perceived maturity, financial instability, and risk for later onset of psychiatric disorders. Thus, many transplant centers have adopted age-specific donation policies, including requiring additional psychosocial evaluations for YA donor candidates. This study aimed to examine the relationship between age and liver donor (LD) evaluation outcome and identify antecedent factors associated with denial for LD. **Methods:** All adult living LD candidates from 2014-2023 at a single institution were included. Groups were created based on age (18-25 versus greater than 25). Chi-square and Kruskall-Wallis were used to determine demographic differences and multivariable logistic regression was employed to assess the association between age group and LD. Covariables included the presence of medical or psychiatric comorbidities, area deprivation index (ADI), and presence of social issues. **Results:** There were 401 adults evaluated for living LD; 43 (10.7%) were YA. Overall, YA were denied at similar rates to older candidates (58.1% vs 61.5%, $p=0.674$). However, older candidates experienced more medical comorbidities (28.6% vs 51.1%, $p=0.012$) yet were denied at similar rates for this reason (18.6% vs 24.9%, $p=0.365$). Meanwhile, YA experienced significantly more psychosocial comorbidities (96.9% vs 79.3%, $p=0.016$) and were denied more often for this reason (9.3% vs 1.7%, $p=0.002$). On multivariable analysis, only the presence of medical comorbidities was associated with decreased likelihood of living LD (OR 0.423, 95% CI 0.259-0.690, $p=0.001$). Age, ADI, psychiatric comorbidities, and presence of social issues were not independently associated with LD. **Conclusion:** Our results indicate that despite greater rates of medical suitability, YAs experience similar rates of approval as older adults. This finding suggests that YAs may face unique barriers that are unaddressed by current age-specific selection practices, given that YAs were denied more often for psychosocial reasons. As such, concerns arise about the utilization of certain psychosocial measures—such as relationship status as a proxy for social support—and whether current evaluation practices may systematically disadvantage YAs whose support networks may be equally as robust but fail to be captured by the nature of the assessment. This poses critical questions about whether current practice truly ensures age-related assumptions do not lead to unnecessary denials and how we can best support this unique group of LD candidates.

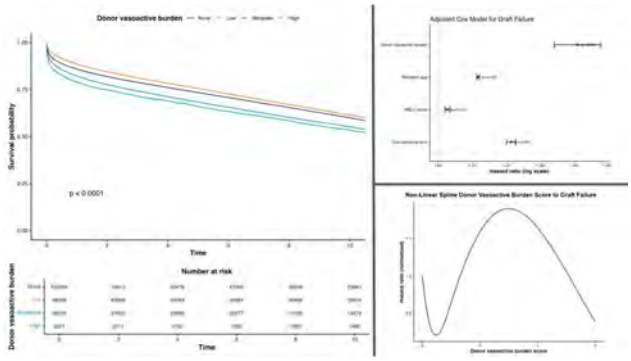
4418 | NONLINEAR ASSOCIATION BETWEEN DONOR VASOACTIVE BURDEN AND GRAFT FAILURE AFTER LIVER TRANSPLANTATION: A NATIONAL UNOS REGISTRY ANALYSIS



Narissa Nursjamsi[1] Elsa Sasongko[2] Kesava Manikanta Achuta[1] Abed Dabaja[1] Bashar Hmoud[1], [1]garden city hospital/msucom, [2]Faculty of Medicine, Universitas Padjadjaran

Background: Liver transplant numbers have increased yearly in the USA with up to 10% of grafts being non-functional at 1 year post transplant. While both donor and recipient factors contribute to outcomes, the impact of

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

donor hemodynamic instability prior to procurement remains poorly characterized as a determinant of graft outcomes. **Methods:** This retrospective cohort study utilized the UNOS STAR 2010-2025 database. Adult liver transplant recipients were identified, excluding those ≤ 18 years old and transplanted before 2010. Variables collected include recipient demographics, MELD score, graft status, time to graft failure, recipient status, donor vasoactive exposure, and cold ischemia time. Donor vasoactive exposure are categorized as burden scores were classified into none (no exposure), low (1 agent), moderate (2-3 agents), and high (> 4 agents). Cold ischemia time was grouped as < 6 hours, 6-10 hours, and > 10 hours. The primary outcome was graft failure after liver transplantation. Graft survival was evaluated using Kaplan-Meier (KM) analysis with group comparisons using log-rank testing. Multivariable Cox models adjusted for recipient age, MELD score, and ischemic time. Restricted cubic spline analysis was performed to evaluate non-linear association between donor vasoactive burden score and graft failure. **Results:** Using UNOS STAR 2010-2025 data, 234,981 adult liver transplant recipients met the inclusion criteria (Mean age 53 years old, MELD score 21, and ischemic time 6.6 hours). KM analysis showed distinct separation in graft survival across donor vasoactive burden groups, with highest burden showed the worst outcomes and low burden showed most favorfable survival (log-rank p < 0.0001). On multivariable Cox analysis, donor vasoactive burden remained independently associated with graft failure (HR 1.04, p < 0.001) and showed the strongest predictor compared with age, MELD score, and ischemia time. Restricted cubic spline analysis confirmed a significant non-linear association between donor vasoactive burden and graft failure, with lowest risk at low burden followed by a progressive increase at higher levels. **Conclusion:** Donor vasoactive burden is an underrecognized,independent prognostic marker with a non-linear association with graft failure. As an immediate available donor metric, it may improve risk stratification and guide recipient selection and perioperative planning.

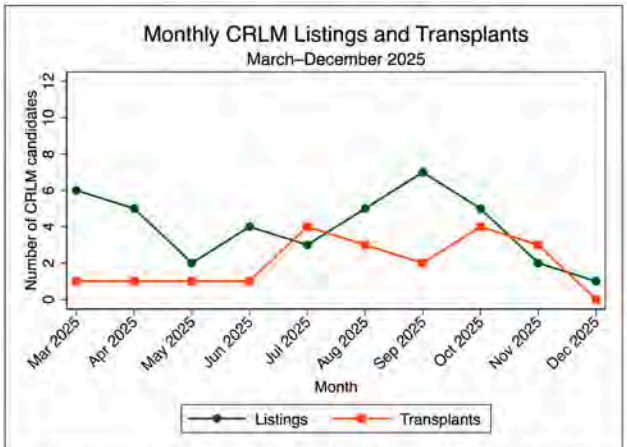
4419 | EARLY NATIONAL EXPERIENCE WITH LIVER TRANSPLANTATION FOR COLORECTAL LIVER METASTASES FOLLOWING NATIONAL LIVER REVIEW BOARD GUIDANCE



Benjamin Rosenthal[1] Therese Bittermann[1] Peter Abt[1] Samir Abu-Gazala[1] Maarouf Hoteit[1], [1]University of Pennsylvania

Background: Selected patients with unresectable colorectal liver metastases (CRLM) may achieve favorable outcomes after liver transplantation (LT). Candidates with unresectable or recurrent CRLM may be considered for LT if they have disease stability and no extrahepatic disease or local recurrence. The National Liver Review Board (NLRB) recommended CRLM exception scores of the center's median MELD at transplant (MMAT) minus 20, with a minimum score of 15. We hypothesize that utilization and outcomes vary across listing centers. **Methods:** This is a retrospective cohort study using UNOS/OPTN registry data to identify CRLM patients following implementation of NLRB guidance on February 27, 2025, through December 31, 2025. The primary exposure was center MMAT, calculated from all adult LT during study period, categorized into tertiles. Candidate-level variables included exception application status and waitlist outcome. Center level variables include number of CRLM listings and transplant yield, calculated as CRLM transplants divided by CRLM listings. Comparisons were performed using chi-squared, Fisher's exact and Kruskal-Wallis tests. **Results:** We identified 91 CRLM exception applications for 50 patients, two of whom applied for exception points at two centers. Patients were 76.9% White, had median ages of 48 (IQR 43-54), were 32.7% female and had median laboratory MELD of 7 (IQR 6-9). Twenty of 26 centers listed ≤2 candidates and only 2 centers listed >4 candidates. 57% of initial applications were approved, and 85% of patients submitted ≤2 applications. At the time of analysis, 25 candidates (48%) remained on the waitlist and 20 (39%) underwent LT at 10 centers. Among the 20 transplanted, 3 (15%) received living donor transplants, 17 (85%) received deceased donor transplants, 6 (35%) of which were from donors after circulatory death (DCD). Transplantation varied across MMAT tertiles: 67% of candidates at low-MMAT centers underwent transplant, compared to 21% and 18% at intermediate- and high-MMAT centers (p = 0.003). In center level analysis, mean center transplant yield was 84% per listing at low MMAT centers, compared to 33% and 8% among intermediate- and high-MMAT centers (p = 0.006). There was no association

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

between donor age and use of DCD donors between MMAT tertiles. **Conclusion:** We identify variable access to transplant for CRLM depending on the listing center MMAT. These early findings suggest that assigning CRLM exception priority at a fixed MELD score may create geography-dependent access to transplantation. Longer follow-up is needed, but these data raise concern that current policy may not achieve equitable access.

	Low MELD center MMAT 18-21, N=5 centers	Intermediate MELD center MMAT 22-25, N=9 centers	High MELD center MMAT 26.5-30, N=12 centers	Total N=26 centers	p-value

4420 | GLP-1 RECEPTOR AGONISTS ARE ASSOCIATED WITH LOWER 1-YEAR MORTALITY FOLLOWING HEPATECTOMY IN PATIENTS WITH TYPE 2 DIABETES: A PROPENSITY-MATCHED TRINETX COHORT STUDY

Shahzaib Zindani[1] Muhammad Qasim Chaudhry[1] Huzaifa Ansari[2] Zayed Rashid[3] Faiz Jajja[1] Syed Naqvi[1], [1]New York Medical College/Landmark Medical Center, [2]Dow University of Health Sciences, [3]Conemaugh Memorial Medical Center

Background: GLP-1 receptor agonists (GLP-1 RAs) have demonstrated cardioprotective, anti-inflammatory, and hepatoprotective properties beyond glycemic control. Hepatectomy carries substantial perioperative risk in patients with type 2 diabetes mellitus (T2DM), yet the impact of preoperative GLP-1 RA use on postoperative survival remains unknown. We evaluated postoperative outcomes in T2DM patients on GLP-1 RAs versus other antidiabetic agents undergoing hepatectomy. **Methods:** Using the TriNetX Research Network (111 healthcare organizations), adults with T2DM undergoing hepatectomy (January 2018–December 2024) with antidiabetic exposure within one year prior were identified. GLP-1 RA users (semaglutide, liraglutide, exenatide, dulaglutide, lixisenatide; GLP-1 RA-only) were compared to users of metformin, sulfonylureas, SGLT2 inhibitors, or DPP-4 inhibitors (GLP-1 RA-naive). Propensity score matching (1:1) on age, sex, race, ethnicity, BMI, ischemic heart disease, obesity, CKD, and nicotine dependence yielded 484 patients per cohort. Outcomes assessed at 1 year included all-cause mortality, readmission, surgical complications, pneumonia, MI, stroke, thrombus, pulmonary embolism, and UTI. **Results:** A total of 7,912 patients were identified pre-matching (GLP-1 RA: n = 484; other antidiabetics: n = 7,428). The GLP-1 RA cohort was younger (mean age 59.0 vs. 64.4 years), predominantly female (60.7% vs. 42.5%), and more commonly White (70.0% vs. 49.2%), with higher rates of obesity (43.0% vs. 18.6%) and CKD (36.4% vs. 22.5%) at baseline. After 1:1 propensity score matching (n = 484 per cohort), cohorts were well-balanced (mean age 59.0 vs. 59.6 years; female 60.7% vs. 60.5%; White 70.0% vs. 72.7%). GLP-1 RA use was associated with significantly lower 1-year all-cause mortality (18.2% vs. 23.8%; risk difference −5.6%, 95% CI −10.7 to −0.5; RR 0.77, 95% CI 0.60–0.98; OR 0.71, 95% CI 0.52–0.97; p = 0.033). Kaplan-Meier analysis confirmed superior 1-year survival (81.1% vs. 74.9%; log-rank p = 0.033; HR 0.74, 95% CI 0.56–0.98). Rates of readmission, surgical complications, pneumonia, MI, stroke, thrombus, pulmonary embolism, and UTI were similar between groups (all p > 0.05). **Conclusion:** In a propensity-matched real-world cohort, preoperative GLP-1 RA use was associated with a 26% reduction in 1-year all-cause mortality following hepatectomy in T2DM patients, without differences in major surgical or cardiorenal complications. These findings highlight a potentially important perioperative survival benefit of GLP-1 RAs in patients undergoing major hepatic resection, and support the need for prospective trials to validate these results.

4421 | UNOS-BASED TRENDS IN NMP UTILIZATION AND OUTCOMES FOR DCD AND DBD LIVER TRANSPLANTATION BETWEEN 2021-2025

Ozge Ozgur[1] Shanmukh Lingamsetty[2] Umnia Shnawa[2] Malak Elsawy[2] Ahmet Gurakar[3] Behnam Saberi[4], [1]University of Pittsburgh Medical Center, [2]BIDMC, Harvard Medical School, [3]Johns Hopkins University, [4]BIDMC Harvard Medical School

Background: Liver transplantation increasingly relies on extended criteria donors, including donation after circulatory death (DCD) grafts, to expand the donor pool and meet rising organ demand. This has driven the need for advanced preservation strategies to mitigate ischemia–reperfusion injury. Normothermic machine perfusion (NMP) has emerged as a transformative platform to assess, resuscitate, and optimize donor liver quality prior to transplantation. **Methods:** We performed a retrospective cohort study of adult liver transplant recipients using deceased donor grafts from the UNOS database (2021–2025). Grafts were stratified into four groups: DBD without NMP, DCD without NMP, DBD + NMP, and DCD + NMP. The primary outcome was recipient survival up to 3 years, analyzed using Kaplan–Meier methods with log-rank testing and pairwise comparisons. **Results:** A total of 45,789 liver transplants were included. Over time, there was a marked shift in practice toward increased use of both DCD grafts and NMP. DBD without NMP remained the largest group (67.6%) but declined from 88.3% in 2021 to 42.8% in 2025. In contrast, DCD + NMP increased from 0.3% to 25.9%, and DBD + NMP from 0.3% to 15.6%. DCD without NMP also increased modestly from 11.2% to 15.8% (Figure 1A). Kaplan–Meier analysis demonstrated significant differences in recipient survival across groups (log-rank $p < 0.001$), with modest separation of survival curves. Pairwise comparisons showed that DBD + NMP differed significantly from DBD without NMP ($p < 0.001$), DCD without NMP ($p = 0.005$), and DCD + NMP ($p < 0.001$). No significant differences were observed between DBD without NMP and DCD without NMP ($p = 0.21$), DBD without NMP and DCD + NMP ($p = 0.34$), or DCD without NMP and DCD + NMP ($p = 0.51$) (Figure 1B). **Conclusion:** The use of normothermic machine perfusion increased rapidly across both DBD and DCD liver transplantation, alongside a concurrent rise in DCD graft utilization. Although overall survival differed across groups, this was primarily driven by outcomes in the DBD + NMP cohort, while survival among DBD without NMP, DCD without NMP, and DCD + NMP remained comparable. These findings suggest that expanding use of DCD grafts and NMP has not been associated with a uniform survival benefit or harm in early post-transplant outcomes. However, interpretation of long-term survival is limited by the recent adoption of NMP and shorter follow-up in later cohorts. Continued longitudinal assessment is needed to define durable outcomes of these evolving preservation strategies.

4422 | EVOLVING ACCESS AND OUTCOMES AMONG HIGH-MELD LIVER TRANSPLANT CANDIDATES IN THE UNITED STATES

Elias Rady[1] Ahmad Anouti[1] Lauren Matevish[1] Pojsakorn Danpanichkul[2] Sarah Lieber[1] Lisa VanWagner[1] Arjmand Mufti[1] Parsia Vagefi[1] Madhukar Patel[1], [1]University of Texas Southwestern Medical Center, [2]Texas Tech University Health Sciences Center

Background: Liver transplant allocation in the U.S. has increasingly prioritized medical urgency, yet the contemporary impact of these policy shifts on access to transplantation, donor-quality, and post-transplant outcomes among patients with high MELD scores (≥ 30) remains poorly understood. **Methods:** We analyzed United Network for Organ Sharing (UNOS) adult deceased donor liver transplant data across three eras (2010–2015, 2016–2020, 2021–2025), stratified by listing MELD score category (30–35, 36–40, >40). Outcomes included waitlist transplant rate and mortality (Fine-Gray competing risk models), transplant by 30 days, allocation distance and high-risk donor receipt (multivariable logistic regression), delta-MELD trajectory, and post-transplant survival (Kaplan-Meier and adjusted Cox models). **Results:** Among 102,419 adult liver transplants, the proportion of high-MELD recipients increased from 26.9%

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(N = 7,429/27,641) in 2010–2015 to 31.7% (N = 13,128/41,364) in 2021–2025. Etiology shifted substantially, with alcohol-related liver disease rising from 24.3% to 55.0% and viral hepatitis declining from 22.6% to 3.2% (both $p < 0.001$). Among MELD 30–35 candidates, 30-day transplantation increased from 56.8% to 78.7%, while 90-day waitlist mortality declined from 19.6% to 6.6%. Comparable improvements were seen among MELD 36–40 (30-day transplantation: 65.5% to 83.6%; 90-day mortality: 22.7% to 9.1%) and MELD > 40 candidates (30-day transplantation: 61.6% to 78.5%; 90-day mortality: 31.1% to 13.3%). Among MELD ≥ 30, multivariable analyses demonstrated increased likelihood of waitlist transplantation in 2016–2020 (sHR 1.29, 95% CI 1.25–1.33) and 2021–2025 (sHR 1.66, 95% CI 1.61–1.71) compared with 2010–2015, alongside substantially lower waitlist death (HR 0.61, 95% CI 0.57–0.65 and HR 0.51, 95% CI 0.48–0.54, respectively; all $p < 0.001$). In the 30 days before transplant, median ΔMELD declined by 2 points between 2010-2015 and 2020-2025 across all MELD categories. Median allocation distance for MELD > 40 recipients increased from 106 to 222 nautical miles, while allocation ≥ 250 nautical miles became significantly more common in 2021–2025 (OR 2.44, 95% CI 2.29–2.60). High-risk donor utilization was also more likely in the contemporary era (OR 1.34, 95% CI 1.22–1.47). One-year post-transplant survival improved from 89.2% to 94.2%, 88.5% to 92.7%, and 87.0% to 90.5% in MELD 30–35, 36–40, and > 40, respectively. However, adjusted interaction modeling demonstrated attenuation of survival gains among MELD > 40 recipients in the modern era (interaction HR 1.54, 95% CI 1.30–1.81, $p < 0.001$). **Conclusion:** High-MELD LT has expanded with marked reductions in waitlist mortality and improved post-transplant survival, but improved access was accompanied by broader geographic sharing, and significant waitlist mortality persists, particularly among MELD > 40 candidates.

★ 4423 | EXAMINING TOPICS, SENTIMENT, AND MEETING DYNAMICS IN LIVER TRANSPLANT CANDIDATE SELECTION PRACTICES: AN LLM-POWERED ANALYSIS

Sue Hyon Kim[1] Sy Hwang[1] Jacqueline Theroux[1] Abbie Jin[1] Douglas Schaubel[1] Megan Saucke[2] Brian Fisher[2] Esra Alagoz[2] Michael Lucey[2] Ethan Weinberg[1] Brian Lee[3] Danielle Mowery[1] Marina Serper[4], [1]University of Pennsylvania, [2]University of Wisconsin, [3]Keck School of Medicine, [4]University of Pennsylvania Health System

Background: Although prior studies have raised concerns about inconsistent liver transplant (LT) selection practices, we lack understanding whether the nature of discussion during liver transplant selection committee (LTSC) meetings influences listing decisions. Our study aim was to evaluate LTSC practices including topics, sentiments, and meeting dynamics, and link them to waitlist decisions. **Methods:** We analyzed transcripts of 27 LTSC meetings at two centers (> 1,000 pages of ~50 hours of discussion), using a large language model (LLM) to extract features for downstream statistical analysis. We included patient discussions that resulted in a decision, excluding re-evaluations of waitlisted patients and those with predetermined decisions pending preoperative clearance. Human experts annotated a representative 30% subset to establish the reference standard for LLM training and evaluation. Iterative prompt engineering was conducted using GPT-OSS-120b hosted on Microsoft Azure Databricks, a HIPAA-compliant cloud-based environment. Multivariable logistic regression was used to evaluate associations between patient characteristics, topics, sentiments, and meeting dynamics with waitlist decisions as the outcome; results with $p < 0.05$ are reported. **Results:** We included 175 LT candidate evaluations (58.3% male; mean age 54 years; 74.3% White). The mean MELD score was 20 ± 9. Alcohol-associated liver disease (ALD) was the most common primary indication for LT (58.3%), followed by viral or autoimmune hepatitis (26.3%) and metabolic dysfunction-related liver disease (15.4%); 40.0% of evaluations resulted in waitlist acceptance, 38.3% in deferral, and 21.7% in decline.There were variations in key topics discussed across etiology-decision groups (**Figure 1**). Initial introduction sentiments were mostly neutral across etiologies (67.4 - 74.1%) with a notable negative shift for 40.2% of discussions for patients with ALD. Most

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

discussions were collegial (90.9%) with occasional tangential conversations (27.4%). Stigmatizing language was identified more often in ALD (23.5%) than non-ALD discussions (11%). We dichotomized waitlist outcomes (accept vs. defer or decline) and prioritized clinical features and meeting dynamics for logistic regression. Patients with concurrent hepatocellular carcinoma diagnosis were more likely to be accepted for LT (OR = 4.60). ALD etiology (vs. non-ALD, OR = 0.30) and discussions focused on chronic comorbidities (OR = 0.25) were associated with lower odds of acceptance. While initial introduction sentiments did not influence the final decision, negative overall sentiment was strongly associated with reduced odds of listing (OR = 0.02); discussions with tangential conversations were more likely to result in acceptance (OR = 4.10). **Conclusion:** Findings suggest that LT selection is an inconsistent process, influenced by biases toward certain etiologies and interpersonal dynamics.

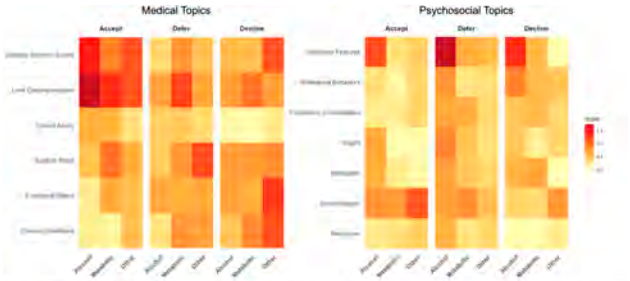

Figure 1. The LLM validated against human-annotated gold standards assigned decision weights to discussion topics (Low=0, Moderate=1, High=2). The heatmap shows greater variation in cases where decisions were to defer or decline. Medical topics predominated discussions of patients with metabolic dysfunction-related, viral, or autoimmune liver disease, whereas psychosocial topics carried more weight for patients with alcohol-associated liver disease who were deferred or declined.

4424 | OUTCOMES OF LIVER TRANSPLANTATION USING DONORS AGED 70 YEARS AND OLDER: A

Michael Friedman[1] Dylan Russell[2] Navpreet Kaur[2] Linda Sher[3], [1]Keck School of Medicine of USC, [2]Keck Medicine of USC, [3]Keck Medical Center of USC

Background: Donor age is an established risk factor for inferior liver transplant outcomes, yet a persistent organ shortage has increased utilization of older donors in the US over the last decade. We examined patient and graft survival following liver transplantation from donors aged ≥ 70 years using a contemporary national registry to review the outcomes from this growing trend. **Methods:** We analyzed 72,120 adult recipients of whole deceased-donor liver transplants from the OPTN/UNOS STAR database from January 2015–December 2025 with multiorgan, living donor, pediatric, and those with previous transplants excluded. Recipients of organs from donors ≥ 70 years (n = 3,373) were compared with those from donors aged 18–69 years (n = 68,747). Primary outcomes were graft survival and patient survival. Death was a censoring event ensuring that it was not double counted in graft and patient survival. Unadjusted comparisons used Kaplan-Meier curves with the log-rank test. Adjusted analyses used multivariate Cox proportional hazards regression with 17 covariates. Fine-Gray subdistribution hazard regression addressed the competing risk of death in graft failure analyses. Propensity score matching (1:1 nearest-neighbor) served as a sensitivity analysis. **Results:** Donors aged ≥ 70 years represented 4.7% of the cohort. Five-year patient survival was 77.8% for donor-age ≥ 70 versus 81.7% for donors aged 18–69 (log-rank $p < 0.001$). Five-year graft survival was 74.7% versus 79.8% (log-rank $p < 0.001$). On multivariate analysis, receipt of an organ from a donor ≥ 70 was associated with a higher hazard of death (HR 1.17, 95% CI 1.07–1.28, $p < 0.001$) and graft failure (HR 1.30, 95% CI 1.20–1.41, $p < 0.001$). After propensity score matching, the excess graft failure risk persisted (HR 1.17, 95% CI 1.05–1.31, $p = 0.006$), whereas the patient survival difference was attenuated and non-significant (HR 1.08, 95% CI 0.96–1.22, $p = 0.195$). **Conclusion:** In a contemporary national cohort, liver transplantation from donors ≥ 70 years is associated with significantly reduced graft survival after accounting for recipient characteristics, transplant factors, and era. However, patient survival is not significantly reduced in donors ≥ 70 years in matched cohorts, which suggests that these organs should be reserved for recipients who would benefit most from more accessible organs with a higher failure rate.

4425 | BARRIERS AND FACILITATORS TO EARLY LIVER TRANSPLANT REFERRAL IN ALCOHOL-ASSOCIATED LIVER DISEASE: A MULTI-SITE QUALITATIVE STUDY WITHIN THE INTEGRATE COLLABORATIVE

Natasha Schaefer Solle[1] Sarah Lieber[2] Avesh Thuluvath[3] Aida vanMossel[1] Hemangi Dhole[2] Anne Fernandez[4] Jessica Mellinger[5] David Goldberg[1] Elizabeth Verna[6] Lisa VanWagner[2], [1]University of Miami, [2]University of Texas Southwestern, [3]Columbia Univesity, [4]Rutgers University, [5]Henry Ford Health-Michigan State University, [6]Columbia University

Background: Alcohol-associated liver disease (ALD) is the leading indication for liver transplantation (LT) in the United States. Although evidence supports early LT (eLT), defined as LT with <6 months of abstinence, many eligible patients are not referred for LT, resulting in potentially preventable mortality. As part of the INTEGRATE cohort, a multi-site, multidisciplinary research collaborative examining eLT across the care continuum, this study identifies barriers and facilitators influencing referral for eLT in ALD. **Methods:** Semi-structured qualitative interviews were conducted with healthcare providers across four INTEGRATE sites (Florida, Texas, New York, and Michigan). Eligible participants included physicians and advanced practice providers (APPs) providing ALD care, including referring patients to transplant centers for LT evaluation. Interviews were conducted virtually by an experienced qualitative researcher, audio recorded, and transcribed verbatim. Data were analyzed using constant comparative methods with an inductive thematic approach. Recruitment continued until thematic saturation was achieved. **Results:** Twenty-four providers participated with a mean age of 49 years (range 28–73) with a mean of 17 years of clinical experience (range 1- 40). A majority were physicians (83%), with APPs comprising 17% of the cohort. Participants were predominantly male (67%) and practiced across private and academic settings. Six themes emerged as key influences of eLT referral. (1) Disease severity as the primary trigger: Referral was driven by decompensation, complications, and MELD thresholds. (2) Psychosocial determinants: Patient motivation, insight, and social support shaped perceived LT candidacy. (3) Deference to LT center: Providers reported a low threshold for referral, often deferring eligibility decisions to transplant centers. (4) Structural barriers: Transportation, lack of insurance, fragmented care coordination, and patient non-adherence limited referral completion. (5) Center-level variability: Differences in eligibility criteria contributed to inconsistent referral patterns. (6) Shifting paradigms: Providers described decreasing reliance on the 6-month abstinence rule and increasing acceptance and referral of patients regardless of alcohol abstinence. **Conclusion:** Early LT referral for ALD is shaped by a complex interplay of clinical severity, psychosocial judgments, and structural determinants. While providers increasingly support early referral, significant barriers persist at patient and system levels, contributing to heterogeneity in referring practices. Interventions targeting care coordination, behavioral health integration, and structural barriers are needed to optimize timely referral and improve outcomes.

4426 | DOES ALLOGRAFT TYPE IMPACT OUTCOMES IN PATIENTS WHO UNDERGO TRANSPLANT FOR PSC?

Yael Nobel[1] Russell Rosenblatt[2], [1]Columbia University Irving Medical Center, [2]Weill Cornell Medicine

Background: Graft selection for liver transplant (LT) in primary sclerosing cholangitis (PSC) is complicated by the high risk of biliary strictures, arising from conditions ranging from recurrent disease to a graft-related processes like ischemic cholangiopathy (IC). DCD allografts are associated with IC and have traditionally been used with caution in PSC. While machine perfusion has reduced non-anastomotic biliary stricture rates after DCD in LT broadly, its impact in PSC, and the impact of allograft type more generally, remain unknown. Therefore, we analyzed the association of allograft type with clinical outcomes after LT for PSC. **Methods:** The UNOS STAR file was queried for adults listed for LT from 2010–2024 with PSC. Graft types were living donor (LD), donation after brain death (DBD), DCD alone, or DCD with machine perfusion (DCD+MP). Three analyses were performed comparing outcomes based on graft type: 1. Patient survival from time of listing, 2. Short-term (1 year) patient and graft survival following LT, and 3. Long-term (after 1 year) patient and graft survival following LT. Cox proportional hazards regressions were performed with DBD as the reference group, adjusting for *a priori* selected covariates including recipient age, sex, MELD, exception points, and cholangiocarcinoma. A sensitivity analysis was performed using patients with primary biliary cholangitis (PBC) to assess if cholestatic diseases had similar outcomes. **Results:** 7,003 patients with PSC were included: 838 (12.0%) LD, 3,571 (51.0%) DBD, 251 (3.6%) DCD alone, 191 (2.7%) DCD+MP, and 2,152 (30.7%) who were not transplanted. LD recipients were younger with lower MELD scores and less severe disease at listing. In Analysis 1, from time of listing, receipt of any LT was associated with markedly improved survival compared to no LT (HR 144, 95%CI 78–269). The unadjusted survival advantage of LD compared to deceased donor LT did not persist after multivariable adjustment. In Analysis 2, after LT pairwise unadjusted log rank testing between graft types showed improved graft survival with DCD+MP vs. DCD alone ($p = 0.04$; Figure 1). However, there were no significant differences in graft or patient survival after adjusting for covariates. Finally, in Analysis 3, starting from 1 year post-LT, the unadjusted patient survival advantage of LD over DBD ($p = 0.01$) was again not significant after adjustment. Of note, only 60% of patients who received DCD+MP were included in the landmark analysis due to the recency of use. Findings were similar in the PBC sensitivity analysis. **Conclusion:** In this large national registry cohort, receiving a transplant by any means, not the allograft type, was independently associated with improved patient survival after LT for PSC. These findings do not support exclusion of DCD allografts in PSC recipients. Machine perfusion may improve early graft survival in DCD recipients, warranting further study.

Figure 1. Graft survival within one year post-transplant based on allograft type (Analysis 2). LDLT: living donor liver transplant. DBD: Donation after brain death organ. DCD: Donation after cardiac death organ. DCD+MP: Donation after cardiac death organ with machine perfusion.

4427 | COMPARATIVE OUTCOMES OF OPEN, HYBRID, LAPAROSCOPIC, AND ROBOTIC HEPATECTOMY FOR LIVING LIVER DONORS: A NETWORK META-ANALYSIS

Puneet Bansal[1] Mohammed Quazi[2] Eric Welwin[3] Abdul Awan[4] Muhammad Ahmad Nadeem[5] Chase Wehrle[5] Federico Aucejo[5] Jaekeun Kim[5] Choon Kwon[5] Mazhar Khalil[5], [1]Cleveland Clinic Foundation, [2]Department of Family and Community Health, West Virginia University, [3]City College of New York School of Medicine, [4]Nishtar Medical University, [5]Digestive Disease and Surgery Institute, Cleveland Clinic

Background: Living donor hepatectomy is essential to expanding the donor pool in liver transplantation but exposes otherwise healthy individuals to the risks of major hepatic resection, making donor safety paramount. Minimally invasive techniques have been increasingly adopted to reduce surgical morbidity, yet a comprehensive comparison across all available approaches is lacking, as existing data are largely derived from pairwise studies. We aimed to evaluate perioperative and postoperative outcomes across open, hybrid, laparoscopic, and robotic donor hepatectomy. **Methods:** Four databases were searched from inception to December 2025 for studies comparing open, laparoscopic, and robotic hepatic donor resections. A Bayesian network meta-analysis assessed differences in perioperative outcomes, post-operative complications, and hospital stay. **Results:** Thirty-one studies were included. Robotic hepatectomy was associated with longer operative time compared with open, hybrid, and laparoscopic approaches. Laparoscopic hepatectomy demonstrated higher conversion rates to open surgery than robotic surgery (OR [95% CrI]: 5.47 [1.19-52.89]). Estimated intraoperative blood loss was lower with robotic hepatectomy compared with open surgery, though no significant differences were observed relative to laparoscopic or hybrid approaches. Hospital stay was significantly longer after open hepatectomy compared with laparoscopic, with no differences compared to hybrid or robotic approaches. Robotic hepatectomy had lower odds of overall postoperative complications compared with open (OR [95% CrI]: 0.34 [0.18-0.65]), with no significant differences compared with hybrid or laparoscopic approaches. No significant differences were observed in bile leak, wound complications, Clavien-Dindo grade ≥ III complications, or reoperation rates amongst all modalities. **Conclusion:** Minimally invasive donor hepatectomy demonstrated favorable perioperative and postoperative outcomes compared with open surgery. Despite longer operative times, robotic approaches were associated with lower blood loss and fewer complications, supporting their selective use with appropriate patient selection and institutional expertise. These findings can help inform surgical approach selection while preserving donor safety as the foremost priority, though prospective and randomized studies are warranted to confirm these comparative benefits given the observational nature of the included evidence.

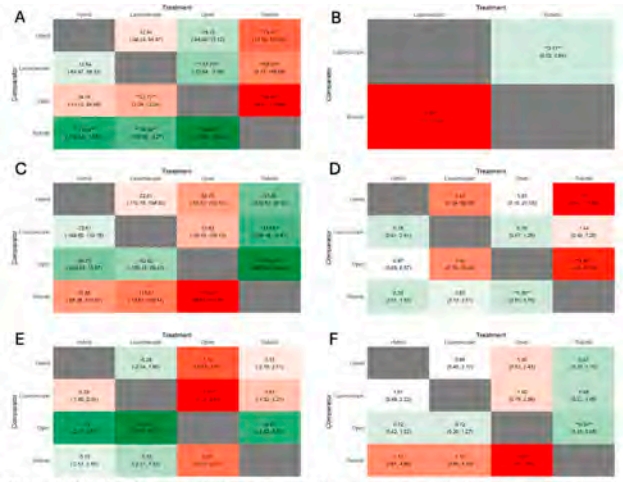

Figure 1. Pairwise Bayesian network meta-analysis comparing donor outcomes across surgical approaches for living donor hepatectomy. Heatmaps display pooled effect estimates with 95% credible intervals for each pairwise comparison, with the column-defined treatment compared against the row-defined comparator. Double asterisks indicate significance. Panels depict operative time **(A)**, conversion **(B)**, estimated blood loss **(C)**, bleeding events **(D)**, length of stay **(E)**, and overall complications **(F)**.

Plata, [5]Translational Research Institute, Academic Health System, Hamad Medical Corporation, Doha, Qatar

Background: Hepatectomy remains associated with significant postoperative morbidity and mortality. Modifiable factors have emerged as critical predictors of adverse outcomes. Prehabilitation aims to enhance physiological reserve to withstand surgical stress. Despite growing application, its specific impact on outcome after hepatectomy remains to be fully synthesized. **Methods:** A systematic review and meta-analysis of prehabilitation in HPB surgery was conducted following PROSPERO and PRISMA guidelines using PubMed, EMBASE, and Cochrane CENTRAL. Eligible interventions required ≥ 1 week of preoperative unimodal or multimodal prehabilitation. Outcomes included mortality, overall complications, major complications (Clavien-Dindo ≥ 3), global pulmonary morbidity, readmission, and length of stay. Random-effects meta-analyses were performed using Mantel-Haenszel and inverse variance methods. Effect estimates were expressed as Risk Ratio (RR), Odds Ratio (OR) for rare events such as mortality, and Mean Difference (MD) with 95% confidence intervals (CI). Heterogeneity was assessed via I^2. Here, we only report the hepatectomy subgroup analysis. **Results:** Eleven studies on prehabilitation for hepatectomy were included. Extractable data from 8 studies demonstrated that 197 of 263 patients completed the program (compliance 74.9%). Diet and exercise were the most frequent unimodal interventions; most programs were predominantly home-based. Prehabilitation significantly reduced pulmonary morbidity (RR 0.72; 95% CI 0.54–0.95; $P = 0.02$; $I^2 = 0\%$). No significant differences were observed in overall complications (RR 0.73; 95%CI 0.49–1.09; $P = 0.13$; $I^2 = 72\%$), major complications (RR 0.59; 95%CI 0.26–1.37; $P = 0.22$; $I^2 = 24\%$), readmission (RR 0.90; 95%CI 0.52–1.56; $P = 0.71$; $I^2 = 9\%$), or LOS (MD -0.72 days; 95%CI -1.77–0.34; $P = 0.18$; $I^2 = 65\%$). Mortality was a rare event across studies, with no significant difference observed between groups (OR 1.01; 95%CI 0.21–4.86; $P = 0.99$; $I^2 = 0\%$). **Conclusion:** Prehabilitation prior to hepatectomy is safe, shows strong compliance, and significantly reduces postoperative pulmonary morbidity. A protective trend toward fewer overall and major complications was observed, though it did not reach statistical significance. Limitations include the high heterogeneity of prehabilitation programs and the lack of consistent outcome reporting across studies. Larger, standardized RCTs are warranted to firmly establish its broader impact on surgical outcomes.

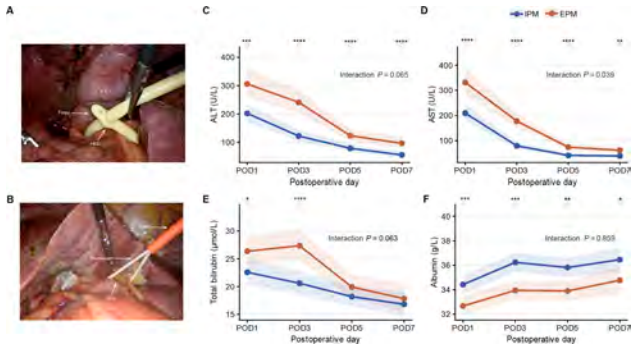
4429 | FOLEY CATHETER-BASED INTRAPERITONEAL VERSUS TOURNIQUET-STYLE EXTRAPERITONEAL PRINGLE MANEUVERS IN LAPAROSCOPIC HEPATECTOMY: PERIOPERATIVE OUTCOMES AND EARLY POSTOPERATIVE LIVER FUNCTION RECOVERY



Shenao Zhang[1] Lei Wu[2] Zhihong Chen[3] Haosheng Jin[4] Shi Ning[4] Shunan Zhou[4], [1]School of Medicine South China University of Technology, [2]Guangdong Cardiovascular Institute, [3]Department of Liver Surgery, Peking Union Medical College Hospital, [4]Department of Hepatobiliary Surgery, Guangdong Provincial People's Hospital

Background: Effective bleeding control during parenchymal transection is critical for laparoscopic liver resection (LLR). Intermittent Pringle occlusion is widely used for inflow control, but whether different occlusion configurations influence early postoperative hepatocellular injury remains unclear. This study compared Foley catheter–based intraperitoneal Pringle maneuver (IPM) with tourniquet-style extraperitoneal Pringle maneuver (EPM) in terms of perioperative outcomes,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

and early postoperative liver function recovery. **Methods:** In this retrospective cohort study (October 2024–February 2026), 110 patients undergoing LLR were classified by predominant inflow occlusion technique: Foley catheter-based IPM or tourniquet-style EPM, with 55 patients in each group.Intraoperative outcomes, postoperative recovery, 30-day complications, and post-hepatectomy liver failure (PHLF) were compared. Postoperative alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBil), and albumin (ALB) levels on postoperative days (POD) 1, 3, 5, and 7 were analyzed using propensity score-weighted linear mixed-effects models (LMMs). Overlap weighting (OW) was the primary analysis, and inverse probability of treatment weighting was used as a sensitivity analysis. **Results: Results:** : Occlusion frequency, cumulative occlusion time, operative time, and blood loss were similar between groups. IPM was associated with a lower postoperative drainage volume than EPM (688.0 vs. 1093.0 mL, $P < 0.001$) and a shorter drainage duration ($P = 0.032$). Within the OW cohort, the IPM group exhibited lower AST and ALT levels at POD1, 3, 5, and 7 (all $P < 0.01$), alongside consistently higher ALB levels throughout the observation period (all $P < 0.05$). TBil levels in the IPM group were lower on POD 1 and 3 ($P < 0.05$) , but no statistical differences were observed on POD 5 and 7. In OW, the group-by-time interaction was significant for AST ($P = 0.039$). Major complications (1.82% vs. 0%) and PHLF (14.55% vs. 18.18%) did not differ significantly. **Conclusion:** Compared with EPM, Foley catheter-based IPM was associated with a more favorable early postoperative biochemical profile, with the most prominent statistical evidence observed for AST. These findings support Foley catheter-based IPM as an advantageous and feasible inflow occlusion technique in LLR.

4430 | LIVER TRANSPLANTATION IN THE ELDERLY: OUTCOMES AND EXPANDING TRANSPLANT CANDIDACY IN PATIENTS AGED 75 AND OLDER

Kevin Harris[1] Mohammed Abusuliman[1] Nirajan Budhathoki[1] Dilip Moonka[1], [1]Henry Ford Health

Background: Liver transplantation (LT) is an effective treatment for patients with end stage liver disease. In recent years, there has been an increase in organ availability in part due to normothermic machine perfusion and improved therapy for hepatitis C. We looked at LT outcomes in patients 75 years and older, using the United Network for Organ Sharing (UNOS) registry to determine if this is a potential population for expansion. **Methods:** The UNOS database was queried for patients ≥ 18 y/o undergoing initial, liver alone, deceased donor LT from 1/1/2015 to 6/30/2025. Patients were grouped by age: 18–49, 50–59, 60–69, 70–74, and 75+ years. Groups were compared for patient and donor characteristics and for graft survival using Kaplan-Meier analysis with log-rank test and multivariate analysis. **Results:** A total of 96,218 LT were performed between 1/1/2015 and 6/30/2015. 73,521 patients met criteria. Of these patients, 332 were ≥ 75 y/o (0.45%) and six patients were 80 or older. There has been consistent growth in LT in patients ≥ 75 y/o over the years of the analysis from 16.7 LT per year from 2015-2018 to 52.3 from 2023-2025. When compared to younger patients, patients ≥ 75 y/o were less likely to be black (3.3% vs 9.7%), less likely to have alcoholic cirrhosis (11% vs. 43%) and more likely to have MASH (25% vs 7.3%) and HCC (51% vs 5.9%). Patients ≥ 75 y/o were more likely to have a Karnofsky score of 70-100% (41% vs 25%) and had a lower laboratory MELD at transplant (17 vs 30). Patients ≥ 75 y/o were more likely to have cold ischemia time of ≥ 8 hours (30% vs 23%) and to have received a donation after circulatory death liver (20% vs. 12%). All differences were significant at $P < 0.001$. In patients ≥ 75 y/o, one year graft survival was 85.2% (95% CI: 81.2 - 89.4), three-year graft survival was 76.2% (95% CI: 71.1 - 81.7) and five-year graft survival was 70.1 (95% CI: 64.0 – 76.8) (Table 1). On multivariate analysis, there was no statistically significant difference in survival between patients ≥ 75 y/o and those 70-74 with a hazard ratio of 0.87 (95% CI: 0.69 – 1.10: $P = 0.238$) but there were significant differences with all other age groups: 60-69 y/o (HR 0.76: 95% CI: 0.60 – 0.96: $P = 0.022$) ages 50-59 (HR 0.62: 95% CI:0.49 – 0.79: $P < 0.001$), ages 18-49 (HR 0.61: 95% CI 0.48 – 0.78: $P < 0.001$). On univariate and multivariate analysis, no one patient or donor variable was associated with worse outcomes in patients ≥ 75 y/o presumably because of low numbers. **Conclusion:**

Liver transplantation in patients over the age of 75 is feasible with acceptable one- and three-year graft survival. Patients in this age group had favorable patient characteristics but not donor characteristics. Despite the acceptable graft survival, liver transplantation in patients over the age of 75 is rare. With increasing organ availability, liver transplantation should be considered a viable treatment option in select patients above the age of 75.

	Age Group				
Survival, % (95% CI)	18-49	50-59	60-69	70-74	75+
1-year	93.2 (92.8 – 93.5)	92.3 (92.0 – 92.7)	90.6 (90.3 – 91.0)	89.3 (88.3 – 90.3)	85.2 (81.2 – 89.4)
3-year	87.7 (87.1 – 88.2)	86.8 (86.3 – 87.3)	83.3 (82.8 – 83.8)	79.4 (77.9 – 80.9)	76.2 (71.1 – 81.7)
5-year	82.5 (81.8 – 83.2)	81.2 (80.6 – 81.8)	76.2 (75.6 – 76.9)	71.7 (69.9 – 73.6)	70.1 (64.0 – 76.8)
10-year	64.8 (62.0 – 67.9)	61.9 (59.9 – 63.9)	51.7 (49.6 – 53.9)	37.9 (30.8 – 46.7)	insufficient data

4431 | LIVER TRANSPLANT ALLOCATION BY MILAN CRITERIA EXCLUDES ELIGIBLE HCC PATIENTS WITHOUT SURVIVAL BENEFIT – A POST-HOC ANALYSIS OF THE SILVER STUDY

Paul Kupke[1] Kathrin Schmitt[1] Moritz Wohlfahrt[1] Benedikt Wagner[1] Laura Kupke[1] Philipp Kreiner[1] Veronika Müller[1] Niklas Bogovic[1] Miklos Acs[1] Edward Geissler[1] Hans Schlitt[1] Jens Werner[1], [1]University Hospital Regensburg

Background: Selection criteria for liver transplant allocation are crucial for benefit-risk assessment of every patient evaluated for liver transplantation (LTx). Currently, Milan criteria are the key decision tool in several countries to assess whether a patient with hepatocellular carcinoma (HCC) is eligible for LTx. In this post-hoc analysis of the SiLVER Study, we analysed the performance of Milan criteria compared to the broader criteria UCSF, Up-to-7 and MT 2.0 to assess whether there is need to reform the selection process of HCC patients evaluated for LTx. **Methods:** Outcomes of 485 patients of the multicentre and randomized SiLVER Study were analysed determined by recurrence-free survival (RFS), overall survival (OS) and freedom of tumor (FoT). **Results:** All three more broadly inclusive criteria outperformed Milan in all three analysed outcome categories in terms of classification accuracy. Up-to-7 classified patients with the highest accuracy, especially regarding FoT with a correct classification of 78.8%, versus Milan at 67.4%. Simultaneously, categorizing patients inside the broader defined scores did not result in worse outcomes, compared to patients classified inside Milan. **Conclusion:** Our data suggest that Milan criteria exclude patients with HCC evaluated for LTx too strictly without an oncological or survival benefit, questioning Milan criteria as sole selection tool in many regions doing liver transplants.

4432 | ANALYZING GROUP DYNAMICS OF TUMOR BOARD DISCUSSION DURING MULTIDISCIPLINARY MANAGEMENT OF HEPATOCELLULAR CARCINOMA

Norine Chan[1] Whitney Welsh[1] Allison Martin[1] Michela Fabricius[1] Andrew Muir[2] Peter Allen[1] Lisa McElroy[1], [1]Duke University Hospital, [2]Duke University

Background: Consensus management is the standard of care for hepatocellular carcinoma (HCC) and occurs through multidisciplinary tumor board conferences (MDC), which are associated with improved patient survival. Despite known impacts of group discourse, team composition, and interpersonal dynamics on decision-making, there has been limited exploration of group interactions during MDC-based HCC discussions. This study aims to characterize patterns of group dynamics during MDC discussions of HCC. **Methods:** We performed a prospective, single-center qualitative study of HCC cases during virtual weekly hepatopancreatobiliary (HPB) MDCs, which were recorded from January to April 2026. Team-based coding of all transcripts was performed with three analysts simultaneously and content analysis was used to identify dominant themes. **Results:** Across 14 MDCs, a total of 226 patients were discussed, of which 63 (27.9%) were HCC cases. 90 clinical team members participated during the study period, consisting of gastroenterologists/hepatologists (26.7%), advanced practice providers (16.7%), transplant/HPB surgeons (14.4%), medical oncologists (12.2%), fellows/residents (10%), diagnostic radiologists (8.9%), interventional radiologists (IRs) (6.7%), radiation oncologists (3.3%), and pathologists (1.1%). Three main interaction patterns were identified: clinician deference, direct naming, and group priming. Clinician deference occurred in settings

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

of treatment decision-making, additional imaging requests, and subject expertise. Deference was typically observed across specialties with hepatologists being the most common initiators (50%). Surgeons were deferred to most often (50%) followed by medical oncologists (25%). Direct clinician naming was a mechanism of engagement for treatment discussion, clinical expertise, attendance confirmation, and referral to colleagues. IRs were named most often (37.5%); in contrast, hepatologists named others in 31% of cases but were only named in 6.9% of cases. Surgeons exhibited comparable frequencies of being named (31.9%) and naming others (39.4%). During complex discussions, group priming was used by hepatologists and diagnostic radiologists to convey clinical ambiguity. Surgeons used priming less often but were more likely to declaratively communicate their assessments. **Conclusion:** Surgeons, interventional radiologists, and medical oncologists were found to be dominant influences during tumor board discussion of HCC. Hepatologists, despite being highly represented in MDC participation, were infrequently engaged directly and more likely to introduce uncertainty and deference in their clinical assessments. Understanding group dynamics among professional roles can inform development of standardized MDC guidelines and practices that mitigate potential bias, ensure balanced participation, and promote a culture of engagement across specialties.

4433 | WHAT PATIENTS ARE SAYING: AN ANALYSIS OF LIVER TRANSPLANT DISCUSSIONS ON REDDIT

Mahinaz Mohsen[1] Rohan Karkra[1] Ziad Mohsen[2] Charmi Patel[1] Taha Shakarchi[3] Yash Shah[1] Lan Nguyen[4] Ahmed Al-Khazraji[1] Paul Gaglio[5], [1]Rutgers New Jersey Medical School, [2]Rutgers University, [3]Lahey Hospital & Medical Center, [4]University at Buffalo, [5]Rutgers NJ Medical School

Background: Liver transplant patients, donors, and caregivers face significant informational and emotional burdens across all stages of the transplant journey, with prior studies documenting persistent unmet informational and psychosocial needs extending well into the post-transplant period. Despite this, gaps remain in understanding patient and caregiver experiences beyond formal clinical interactions. Social media platforms such as Reddit host unsolicited, real-world narratives that may capture these unmet needs at scale. Understanding how these communities engage online may inform targeted improvements in transplant education and care delivery. **Methods:** Reddit posts were scraped from three liver transplant-related subreddits (r/Transplant, r/LiverDisease, r/FattyLiver-NAFLD). Of 16,912 posts collected, the top 3,000 by engagement score were retained, then filtered to 983 posts containing substantive liver transplant discussion (January 2023–May 2025). Each post was classified across ten dimensions using Claude (Anthropic), including: author perspective, transplant stage, sentiment, emotional tone, presence of care gaps, and medical team sentiment. **Results:** Of 983 posts, 55.3% were authored by transplant recipients and 12.3% by caregivers, and 73.1% were pre-transplant. Nearly half (45.0%) of posts were negative in sentiment, while only 17.4% were positive. Sentiment shifted significantly ($p < 0.05$) across stages: pre-transplant posts were predominantly negative, peri-transplant posts showed a reversal with positive sentiment prevailing, and post-transplant posts demonstrated equalization of positive and negative sentiment (Fig 1A). Anxiety was the dominant emotional tone (61.4%, Fig 1B), with pre-transplant anxiety significantly higher (70.2%, Fig 1C) than peri- or post-transplant stages (~28% each, $p < 0.05$). Among negative posts, fear of the unknown was the leading driver (54%, Fig 1D), followed by emotional/psychological distress (16%) and healthcare system frustration (12%). Care gaps were identified in one in four posts overall (25.8%), with higher prevalence in the post-transplant period (29.1%, $p < 0.05$, Fig 1E). **Conclusion:** Social media data represents an underutilized resource for identifying gaps in transplant care. Our findings corroborate prior reports of persistent unmet informational and psychosocial needs in the liver transplant population, and extend them by demonstrating that these gaps are detectable at scale in unsolicited social media data. Fear of the unknown was the dominant driver of negative sentiment, suggesting that proactive patient education, particularly pre-transplant, represents the highest-yield intervention target. The persistence of care gaps into the post-transplant period, despite emotional recovery, points to a specific window where follow-up care is inadequate.

4434 | LIVER TRANSPLANTATION RESTORES PRODUCTIVE LIFE: WORKING-FOR-INCOME AT ONE YEAR REFLECTS FIRST-YEAR SUCCESS AND HERALDS SUPERIOR LONG-TERM SURVIVAL

Sri Harsha Boppana[1] Subhash Gurappa[2] Sachin Sravan Kumar Komati[3] Gautam Maddineni[4] Raja Chandra Chakinala[5] Venkata Sunkesula[6] Pradeep Yarra[7] Kamran Qureshi[8], [1]Nassau University Medical Center, [2]sg001@fiu.edu, [3]sachinkomati23@gmail.com, [4]Creighton university, [5]Guthrie Robert Packer Hospital, [6]Case Western Reserve University, [7]UT Health San Antonio, [8]Saint Louis University

Background: Liver transplantation (LT) offers recipients not only survival but the prospect of returning to productive, working life. Whether working-for-income at 1 year independently drives improved long-term survival or reflects the success of the first post-transplant year is an important distinction for counseling recipients and directing rehabilitation efforts. We aimed to characterize national employment trajectories after LT and examine the clinical determinants and long-term prognostic significance of working at 1 year. **Methods:** Retrospective cohort study of working-age adult LT recipients (18–64) using OPTN/UNOS STAR data (2014–2024). Recipients with documented 1-year employment status were included. Employment trajectories were characterized using transition matrices from listing to 1 year. Multivariable logistic regression identified predictors of working at 1 year with emphasis on first-year recovery. Landmark Cox regression from 1 year assessed associations with subsequent patient and graft survival. **Results:** Of 59,493 eligible working-age recipients, 44,959 had observed 1-year employment status; 32.5% were working for 1 year versus 31.8% at listing. Encouragingly, 64.5% (9,373/14,543) of baseline-employed recipients successfully retained employment, and 17.0% (5,094/29,978) of those not working at listing returned to work after transplant. The strongest predictors of working at 1 year were pre-transplant employment (OR 6.59, 95% CI 5.67–7.66) and functional independence at follow-up (OR 4.07, 95% CI 2.70–6.13) — both markers of robust recovery. First-year hospitalization reduced odds of employment (OR 0.72, 95% CI 0.66–0.78). Government insurance (Medicaid OR 0.34; Medicare OR 0.22 vs. private) and older age (OR 0.96/year) also predicted non-employment. In landmark analysis, working at 1 year was associated with markedly superior patient survival (HR 0.67, 95% CI 0.63–0.72) and graft survival (HR 0.67, 95% CI 0.62–0.71), both $p < 0.001$. **Conclusion:** LT restores productive life for a meaningful proportion of working-age recipients, and those who return to work by 1 year demonstrate substantially improved long-term survival. This association reflects the success of first-year recovery — functional independence and freedom from rehospitalization — rather than employment as a direct cause of survival benefit. Return to work is a powerful composite indicator of transplant success and recipient resilience. Optimizing first-year recovery through readmission reduction, functional rehabilitation, and targeted socioeconomic support represents a high-yield opportunity to expand productive recovery and improve long-term outcomes after LT.

4435 | PERFORMANCE OF ANTHROPOMETRIC STANDARD LIVER VOLUME EQUATIONS IN CONTEMPORARY MRI-BASED LIVING LIVER DONOR EVALUATION

Roger Hsieh[1] Chad Abbott[2] Anum Aslam[2] Christopher Sonnenday[3] Nikhilesh Mazumder[4], [1]University of Michigan School of Medicine, [2]University of Michigan, [3]University of Michigan Medical Center, [4]University of Michigan Hospitals and Health Centers

Background: Liver volume estimation is essential to optimize appropriate graft selection and donor safety in living donor liver transplantation (LDLT). Urata (1995), Heinemann (1999), Ichihara (PLOS 2023), and Chan (2006) formulas are anthropometric standard liver volume (SLV) equations historically used for this purpose. Despite widespread use, the external validity of these equations in a midwestern, modern cohort has not been established especially as rates of obesity and hepatic steatosis increase. **Methods:** Adult living liver donor candidates (N = 202) underwent preoperative MRI volumetry between 2017-2025 were included. Predicted liver volumes were calculated using Urata (1995), Heinemann (1999), Ichihara (PLOS 2023), and Chan (2006) equations and compared to MRI-derived liver volumes. LASSO regularized linear regression with five fold cross validation was used to train a linear model to predict SLV from clinical data. Primary outcomes included mean absolute error (MAE), root mean square error (RMSE), and correlation. Donors were quantitatively grouped by hepatic steatosis using MRI proton density fat fraction (PDFF) $\geq 5\%$ or $< 5\%$, and subgroup differences in MAE were evaluated using two-sample t-tests. Association of BMI, steatosis, and equation prediction error was determined using multivariable linear regression. **Results:** Baseline donor characteristics include mean age of 39 years, BMI 27.2 kg/m^2, with mean MRI-derived total liver volume 1606 ± 318 mL. Among published models, the Ichihara formula had the lowest bias (-68 mL) and MAE (175 mL). Urata and Chan both systemically underestimated liver volumes, with Chan demonstrating the largest overall error MAE (396 mL). Bland-Altman analysis revealed increasing disagreement at large liver volumes for both Urata and Chan formulas. On univariate and multivariate analyses PDFF $\geq 5\%$ but not BMI was associated with worsening error for both Urata (362 vs 235 mL, $p < 0.01$) and Chan (478 vs 373 mL, $p < 0.01$) but not Heinemann (216 vs 199 mL, $p = 0.85$). Our LASSO derived model (TLV (mL) = 347.3 + 10.61 × weight (kg) + 2.44 × height (cm)) had significantly lower MAE than Urata, Chan, and Heineman formulas ($p < 0.01$). Our model had a lower bias compared to the Ichihara model with lower bias (+4 vs -68, $p < 0.001$). (Figure). **Conclusion:** Among the evaluated anthropometric equations, our LASSO derived model and the Ichihara model were superior to historic SLV predictive models which demonstrated increasing error as steatosis increased. Future research should validate our findings to improve accuracy of donor selection.

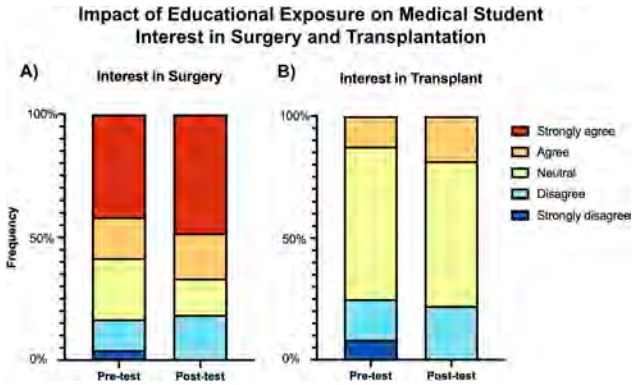
4436 | LESSONS LEARNED FROM IMPLEMENTING A STANDARDIZED CURRICULUM ON DECEASED DONOR PROCUREMENT AND TRANSPLANT SURGERY CURRICULUM FOR PRECLINICAL MEDICAL STUDENTS



Morgan Miovski[1] Darin Mak[1] Anirudh Koneru[1] Joseph Torkieh[2] Vrindda Atrii[2] Shareef Syed[2] Danielle Krinsky[2] Keri Lunsford[1] Flavio Paterno[1] Jay Graham[1] William Boyan[2] Matthew Rosenzweig[3] Matthew Hanlon[3] Valeria Ripa[3] Advaith Bongu[2] Harry Sun[3] Arpit Amin[1], [1]Rutgers New Jersey Medical School, [2]Rutgers Robert Wood Johnson Medical School, [3]Cooperman Barnabas Medical Center

Background: The current American College of Surgeons medical student preclinical curriculum strives to provide medical students with foundational surgical knowledge. One of the limitations of this curriculum is the lack of information about organ donation and transplant surgery. **Methods:** We implemented a formal standardized curriculum for preclinical medical students from October 18, 2025, to April 30, 2026, focused on deceased donor organ procurement and abdominal transplant surgery at Rutgers-affiliated medical schools. Students' baseline knowledge about organ donation and abdominal transplant surgery was

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

assessed using a 10-point questionnaire. Thereafter, students participated in a didactic session and observed deceased donor procurement and/or abdominal transplant surgery through a 24-hour call. **Results:** 119 out of 195 [61%] 24-hour call shifts were filled by students. 28 students observed either a donor procurement or an abdominal transplant surgery during their assigned shift. Pretest questionnaire revealed that 60% of the cohort were interested in surgery and 10% of the cohort were interested in transplant surgery. Post-test questionnaire revealed that 67% of the participating students were interested in surgery and 15% were interested in transplant surgery. Participating students' feedback revealed that the curriculum was awe-inspiring and simultaneously improved their knowledge on surgical technique, donor procurement process, and anatomy. Competing mandatory school sessions, increasing difficulty of course load through the academic year, and unpredictability of procurement/transplant surgery schedule were the main barriers faced by students in completing the curriculum successfully. **Conclusion:** A standardized curriculum on deceased donor procurement and abdominal transplant surgery provides an excellent opportunity for preclinical medical students to increase their knowledge on surgical anatomy and may act as a gateway to students pursuing surgery as their eventual career choice.

4437 | LIVING DONOR LIVER TRANSPLANTATION IN ALCOHOL-ASSOCIATED HEPATITIS: UNOS ANALYSIS

Chencheng Xie[1] Suvisesh Pothuraju[2] David Maundu[3] Fatima Elmustafa[4] Mangesh Pagadala[5] Nimish Thakral[6] Faris Abdulaziz[7] Steven Flamm[8] Ashwani Singal[2], [1]Univeristy of Iowa, [2]University of Louisville, [3]University of Kansas Medical Center, [4]Henry Ford Warren, [5]Methodist Dallas Medical Center, [6]University of Kentucky Medical Center, [7]Henry Ford, [8]Rush University

Background: Over the last 10-15 years, there has been a growing interest in early liver transplantation (LT) in patients with severe alcohol-associated hepatitis (AH). Since these patients are very sick with a high MELD score, living donor liver transplantation (LDLT) remains controversial and has been performed less frequently. The data on the efficacy and safety of LDLT in patients with AH are limited. We sought to assess patient and graft survival at 1 year, comparing LDLT and deceased donor liver transplantation (DDLT) in patients undergoing LT for AH using the United Network for Organ Sharing (UNOS) database. **Methods:** First-time LT (1/1/2004 to 3/31/2026) in adults at the UNOS database were analyzed. A cohort of LT performed for AH using LDLT was extracted and propensity score-matched on recipient age, sex, obesity, MELD score, and donor risk index (DRI). Outcomes were patient and graft survival rates at 1 year. Chi-square and Student t-tests were used to compare categorical and continuous variables, respectively. Kaplan-Meier survival curves were generated comparing LDLT vs. DDLT, and the log-rank test was used to analyze the statistical significance. Cox proportional hazards regression models were fitted to assess the independent effect of LDLT vs. DDLT on graft and patient survival at 1 year. **Results:** Of 163,658 total LT, there were 7,225 (4.5%) LDLT. 3,915 LTs (2.4%) were performed for AH, including only 33 by LDLT. Of the 33 LDLTs in AH, 29 were performed after 2021. Regional distribution showed 12, 6, and 4 LDLT in UNOS regions 2, 4, and 5, respectively. In LT for AH, compared to DDLT, recipients with LDLT were older, more frequently female, had poorer performance status, and were less obese. Interestingly, LDLT recipients had lower median MELD scores at listing (18 [range 7–29] vs. 36 [range 7–69]; $p < 0.001$) and transplantation (18 [range 7–29] vs. 36 [range 6–69]; $p < 0.001$), with a longer waitlist time and lower DRI than DDLT recipients (**Table**). After propensity score matching, patient and graft survival rates were similar comparing LDLT vs. DDLT: 100% vs. 99.0%, $p = 0.543$, and 100% vs. 94.7%, $p = 0.183$. Obesity, performance status 80-100 vs. 10-30, MELD score, and DRI were associated with graft and patient survival, with respective hazard ratios (95% confidence interval) of 1.39 (1.02-1.88, $p = 0.035$), 2.55 (1.46-4.47,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

p = 0.001), 1.03 (1.01-1.05, p = 0.011), and 1.39 (1.05-1.85, p = 0.022). **Conclusion:** LDLT is used in fewer than 1% of LT procedures performed in AH patients, with a high concentration in regions 2, 4, and 5. In the select population, patient and graft survival after LDLT are similar to those after DDLT. With very low MELD scores at listing and LT, longer wait times, and limited data on LDLT use, multicenter prospective studies are needed to assess the utility and optimal timing of LDLT in patients with severe AH.

Table 1 Baseline characteristics comparing unmatched and matched cohorts using living donor liver transplantation (LDLT) vs. deceased donor liver transplantation (DDLT) in patients with alcohol-associated hepatitis (AH)

	Before propensity score matching			After propensity score matching		
	DDLT (N=3882)	LDLT (N=33)	p	DDLT (N=95)	LDLT (N=32)	p
Age at listing (years, mean ± SD)	44.7 ± 10.9	50 ± 10.2	0.005	50.1 ± 10.3	49.8 ± 10.3	0.874

4438 | STRUCTURED REFERRAL PATHWAYS IMPROVE GEOGRAPHIC REPRESENTATION AND TRANSPLANT ACCESS IN A CENTRALIZED NATIONAL LIVER TRANSPLANT SYSTEM: A REAL-WORLD STUDY FROM COSTA RICA

Maria Fernanda Lynch-Mejia[1] Daniel Pérez-Muñoz[2] Francisco Vargas Navarro[1] Wagner Ramirez[1] Vanessa López-Jara[2] Pablo Coste[1], [1]Liver Lab CR / Liver Unit, Hospital R.A. Calderón Guardia, [2]Liver Unit, Hospital R.A. Calderón Guardia

Background: Geographic inequities may substantially limit access to liver transplantation (LT) in centralized healthcare systems, particularly in middle-income countries where transplant services are concentrated in metropolitan regions. This study aimed to evaluate the impact of implementing a structured referral pathway on geographic representation and transplant outcomes within the national LT waiting list in Costa Rica. **Methods:** A retrospective quasi-experimental cohort study was conducted including consecutive adults incorporated into the national liver transplant waiting list between 2020 and 2024 at a tertiary referral center in San José, Costa Rica. Eligible patients were ≥ 18 years old and formally accepted onto the LT waiting list, regardless of liver disease etiology or transplant indication. Patients were categorized according to referral pathway period: pre- versus post-algorithm implementation (March 13, 2023). Geographic burden was evaluated using rurality, travel distance, and travel time to the transplant center. Clinical severity, waitlist outcomes, Kaplan-Meier time-to-transplant analyses, and multivariable logistic regression for LT within 12 months were performed. **Results:** A total of 93 patients were included. Following pathway implementation, rural patient representation increased from 31.1% to 60.4% (p = 0.005). Median travel burden significantly increased, including travel time (p = 0.002) and distance to the transplant center (p = 0.020). Despite greater travel burden, post-algorithm patients were referred at earlier stages of liver disease severity, including fewer Child-Pugh C presentations (10.4% vs. 26.7%, p = 0.006) and lower median MELD 3.0 scores (15 vs 18 points, p = 0.034). LT within 12 months increased from 33.3% to 70.8% (p < 0.001), while mortality decreased from 40.0% to 20.8% (p = 0.044). In multivariable analysis, pathway implementation independently predicted LT within 12 months (OR 5.47, 95%CI 1.94–15.42; p = 0.001). **Conclusion:** Structured referral pathways may reduce geographic inequities in centralized LT systems by improving rural representation and access to transplantation despite greater travel burden. These findings support coordinated referral networks as scalable strategies to optimize equitable and timely access to LT in middle-income countries and other regions with centralized high-complexity care systems.

4439 | MELD 3.0 IS ASSOCIATED WITH LOWER WAITLIST MORTALITY AND HIGHER TRANSPLANT INCIDENCE ACROSS RACE AND ETHNICITY GROUPS

Farinaz Ghodrati[1] Ashley Bo Zhang[2] Nadim Mahmud[2], [1]University of Pennsylvania, [2]Hospital of the University of Pennsylvania

Background: MELD 3.0 was implemented to address known limitations of MELD-Na, particularly sex-related disparities. While studies have since found MELD 3.0 to have narrowed sex-based disparities, less is known about how it performs across racial and ethnic groups, a critical dimension of evaluation for prediction models. Our study aimed to evaluate changes in 90-day waitlist death/dropout and transplant incidence following MELD 3.0 implementation. **Methods:** This was a retrospective cohort study using United Network for Organ Sharing registry data. We included adult liver transplant candidates listed between 2016 and the most recent available follow-up. The primary policy exposure was listing era, defined as pre-MELD 3.0 versus post-MELD 3.0 implementation, defined by listing date on or after July 13, 2023. Crude cumulative incidence functions were estimated for (1) waitlist death/dropout and (2) transplantation, accounting for the alternative event as a competing risk. Post-MELD 3.0 minus pre-MELD 3.0 differences in cumulative incidence over 90 days were calculated within racial/ethnic groups, yielding "delta cumulative incidence" curves. Adjusted analyses were performed using Fine-Gray competing-risk regression. Separate models were fit for waitlist death/dropout, treating transplantation as the competing event, and vice versa. Models included post-MELD 3.0 era, race/ethnicity, a post-MELD 3.0 × race/ethnicity interaction term, age, and sex. Subhazard ratios (sHRs) and 95% confidence intervals were reported. **Results:** Our study included 108, 044 adult liver transplant waitlist candidates, of whom 82,402 were listed in the MELD-Na era and 25,642 in the MELD 3.0 era. The MELD 3.0 era had slightly younger candidates (median age 56 vs. 58 years, $P < 0.001$) and a higher proportion of females (40.8% vs. 36.6%, $P < 0.001$). Race/ethnicity distributions also differed between eras ($P < 0.001$), with a lower proportion of White candidates and a higher proportion of Hispanic and Other candidates in the MELD 3.0 era. Delta cumulative incidence curves demonstrated lower 90-day post-MELD 3.0 waitlist death (**Figure panel A**) and higher transplant incidence (**Figure panel B**) across all for all race/ethnicity groups in the post vs. pre-MELD 3.0 era. In adjusted analyses, there was no significant interaction between era and race/ethnicity in waitlist mortality ($p = 0.77$) or transplant models (0.06). **Conclusion:** MELD 3.0 implementation was associated with lower waitlist mortality and higher transplant incidence across all racial/ethnic groups. These findings suggest MELD 3.0 improved short-term allocation outcomes without clear evidence of worsening racial/ethnic inequities. Our findings broaden the current MELD 3.0 literature beyond sex disparities and highlight the importance of post-implementation surveillance to monitor long-term equity and subgroup-specific allocation effects.

4440 | OUTCOMES OF PORTAL VEIN RECANALIZATION VARY BY INDICATION

Christopher Danford[1] Kendon Holdaway[2] James Trotter[1] Suaka Kagbo-Kue[1], [1]Intermountain Medical Center, [2]University of Utah

Background: Portal vein recanalization with/without transjugular intrahepatic portosystemic shunting (PVR-TIPS) is a relatively novel procedure with a high technical success rate of 95% and a 12-monthPV patency of 79% 1 . Despite high rates of technical success, there is limited literature on clinicaloutcomes of patients post-PVR-TIPS outside of transplant. This study aims to describe clinicaloutcomes PVR-TIPS performed for transplant and other indications and identify predictors ofsuccess to aid in future patient selection. **Methods:** We performed a retrospective chart review of electronic medical records on 69 consecutivePVR/PVR-TIPS procedures performed at Intermountain Health from 2018 to 2024. Four caseswere excluded due to procedures other than PVR/PVR-TIPS performed, and/or lack ofthrombosis found upon procedural examination. Nine cases were repeat procedures on the sameindividuals and ultimately 56 unique individuals were included. Primary outcomes includedtechnical and clinical success, with technical success determined primarily by patency onimaging at 12 months. Subjective clinical success was determined via consensus panel review ofthree hepatologists, with consideration of factors including vascular patency, resolution oforiginal symptoms/indication, and successful liver transplantation (when applicable) balancedwith adverse events such as bleeding, infection, need for repeat procedures, and mortality **Results:** Most patients were male (68.4%) and Caucasian (80.7%), with an average age of 51.7 ± 14.6years. Approximately half (52.6%) had cirrhosis, with the most common cirrhotic etiologies ofalcohol consumption (29.8%) and metabolic-dysfunction associated steatohepatitis (17.5%).Portal hypertensive bleeding (43.9%), to enable liver transplantation (26.3%), and abdominalpain (21.1%) were the most common indications.While 83% of these PVR/PVR-TIPS procedures were deemed technically successful, only 48%(n = 27) were deemed clinically successful. Most patients who underwent TIPS-PVR to enabletransplantation (92.3%) were successful whereas those whose initial indication was abdominalpain or had underlying JAK2 mutation or malignancy were unlikely to be successful, 28.6% and12.5% respectively. **Conclusion:** These findings underscore the importance of careful selection of PVR/PVR-TIPS candidates.Indications such as bridge to transplantation showed highest rates of clinical success whereasprocedural indications of abdominal pain or underlying malignancy and JAK2 mutation wereunlikely to be clinically successful.

4441 | COMPARATIVE OUTCOMES OF OPEN, LAPAROSCOPIC, AND ROBOTIC LIVER RESECTION FOR INTRAHEPATIC CHOLANGIOCARCINOMA: A NETWORK META-ANALYSIS

Muhammad Ahmad Nadeem[1] Puneet Bansal[1] Mohammed Quazi[2] Abdul Awan[3] Mohanad Baroudi[1] Beren Berber[1] Jaekeun Kim[1] Chase Wehrle[1] Federico Aucejo[1] Mazhar Khalil[1], [1]Digestive Disease and Surgery Institute, Cleveland Clinic, [2]Department of Family and Community Health, West Virginia University, [3]Nishtar Medical University

Background: Intrahepatic cholangiocarcinoma (ICC) is an aggressive hepatobiliary malignancy for which surgical resection remains the only potentially curative treatment. Minimally invasive liver resection is increasingly used in this setting, but comparative evidence across open, laparoscopic, and robotic approaches remains fragmented and largely confined to pairwise studies. We aimed to evaluate perioperative outcomes and mortality across open, laparoscopic, and robotic hepatic resection for ICC. **Methods:** Four databases were searched from inception to September 2025 for studies comparing open, laparoscopic, and robotic hepatic resections in adults with ICC. A Bayesian network meta-analysis assessed differences in mortality, complications, readmissions, and hospital stay. Surgical intensity and complexity were incorporated as covariates within MCMC-based random-effects. **Results:** Eighteen studies (10,010 patients) were included. Open surgery was associated with significantly higher 30-day mortality compared with laparoscopic resection (OR [95% CI]: 7.47 [1.07-78.37]). Clavien-Dindo $\geq$ 3 complications were significantly more frequent after open surgery than laparoscopic surgery (OR [95% CI]: 2.01 [1.16-3.71]). Open resection was also associated with significantly longer hospital stay compared with laparoscopic surgery (MD [95% CI]: 3.76 days [1.32-6.33]) and greater estimated blood loss (MD [95% CI]: 178 mL [72-301]). After adjustment for morbidity, these differences were attenuated and no longer statistically significant, although open surgery consistently ranked highest for risk. No significant differences were observed for 90-day mortality, operative time, readmission, or R0

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

resection, while robotic surgery consistently ranked most favorable across several outcomes. **Conclusion:** Minimally invasive approaches, particularly robotic surgery, demonstrated more favorable perioperative profiles than open surgery for ICC resection, while achieving comparable R0 resection rates. Although differences in mortality and major complications were attenuated after adjustment for surgical morbidity, robotic and laparoscopic techniques consistently ranked more favorably across multiple endpoints. These findings support broader adoption of minimally invasive techniques in appropriately selected patients at centers with sufficient expertise, and highlight the need for prospective comparative studies to refine modality selection across varying degrees of surgical complexity and to confirm long-term oncologic equivalence.

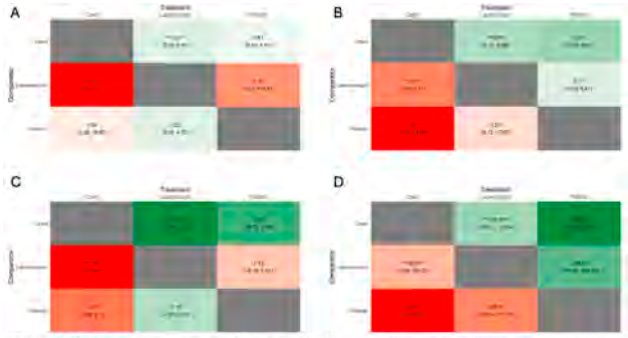

Figure 1. Pairwise Bayesian network meta-analysis comparing perioperative outcomes across open, laparoscopic, and robotic liver resection for intrahepatic cholangiocarcinoma. Heatmaps display pooled unadjusted effect estimates with 95% credible intervals for each pairwise comparison, with the column-defined treatment compared against the row-defined comparator. Effect measures are odds ratios for binary outcomes and mean differences for continuous outcomes. Double asterisks indicate statistical significance. Panels depict 30-day mortality (A), Clavien-Dindo grade ≥3 complications (B), hospital length of stay in days (C), and estimated blood loss in mL (D).

4442 | CLINICAL PHENOTYPES AND CORRELATES OF SAFETY-NET VERSUS SIMULTANEOUS LIVER–KIDNEY TRANSPLANTATION

Abhijith Atkuru[1] Sidart Pradeep[2] Eugenia Tsai[2],
[1]Tulane University School of Medicine, [2]Texas Liver Institute; UT Health San Antonio

Background: The 2017 Organ Procurement and Transplantation Network (OPTN) simultaneous liver–kidney (SLK) allocation policy introduced standardized SLK criteria and a Safety-Net pathway prioritizing kidney allocation for liver-alone recipients with persistent renal dysfunction. Yet independent correlates of kidney pathway have not been examined in a national registry analysis. This study compared recipient and donor profiles associated with Safety-Net versus SLK pathways using the largest post-policy cohort to date. **Methods:** Using OPTN/Scientific Registry of Transplant Recipients (SRTR) Standard Transplant Analysis and Research (STAR) data (2018–2024), adults who underwent SLK or received a Safety-Net kidney 60–365 days after liver-alone transplantation were identified. Recipient demographics, illness severity, functional status, diabetes, liver disease etiology, estimated glomerular filtration rate (eGFR), and Kidney Donor Profile Index (KDPI) were compared using Wilcoxon and chi-square tests. Multivariable logistic regression identified factors associated with Safety-Net kidney receipt versus SLK, adjusting for age, Model for End-Stage Liver Disease (MELD), eGFR, body mass index (BMI), functional status, dialysis, type 2 diabetes mellitus (T2DM), Kidney Donor Profile Index (KDPI), hepatocellular carcinoma (HCC), and liver disease etiology. **Results:** Among 4,197 recipients, 3,506 (83.6%) underwent SLK and 691 (16.4%) received a Safety-Net kidney. Compared with SLK, Safety-Net recipients were younger (55 vs 58 years), had higher MELD score at liver transplant (34 vs 28), higher eGFR (33.1 vs 18.1 mL/min/1.73 m²), and higher body mass index (BMI; 29.9 vs 27.5 kg/m²; all $p < 0.001$). Higher MELD among Safety-Net recipients likely reflects urgent liver transplantation before 90-day chronic kidney disease criteria for SLK eligibility could be met. Alcohol-associated liver disease and metabolic dysfunction-associated steatohepatitis were the leading etiologies in SLK (33.4% and 25.6%, respectively) and Safety-Net recipients (51.1% and 24.5%, respectively; overall $p < 0.001$). In adjusted analyses, higher MELD, eGFR, BMI, dialysis, and KDPI were associated with Safety-Net receipt (all $p < 0.001$; Figure 1). T2DM was associated with lower odds of Safety-Net receipt (aOR 0.80, 95% CI 0.65–0.99; $p = 0.037$; Figure 1), likely reflecting confounding by indication, with severe chronic kidney disease preferentially selected for upfront SLK. **Conclusion:** SLK and Safety-Net recipients represent clinically distinct populations. Despite higher eGFR at liver transplantation, Safety-Net recipients carried higher illness severity and worse functional status, suggesting eGFR alone inadequately captures renal risk trajectory at listing. These findings support early post-transplant renal surveillance in patients with high MELD, functional impairment, or elevated BMI at the time of liver transplantation.

4443 | MELD 3.0 DEMONSTRATES PRESERVED PREDICTIVE PERFORMANCE ACROSS RACIAL AND ETHNIC GROUPS WITH MODEST CALIBRATION VARIABILITY

Ashley Zhang[1] Farinaz Ghodrati[1] Nadim Mahmud[1], [1]Hospital of the University of Pennsylvania

Background: The implementation of MELD 3.0 addressed known limitations of MELD-Na, namely sex-related disparities and suboptimal calibration. MELD 3.0 has been shown to more accurately predict waitlist mortality with equity across sex; however, its predictive performance across racial and ethnic groups remains largely unexplored. Our study aimed to evaluate the predictive performance of MELD 3.0 across race and ethnicity for waitlist mortality. **Methods:** This was a retrospective cohort study using United Network for Organ Sharing registry data. Adult candidates listed for a single liver transplant between 2016 and the most recent available follow-up were identified. Listing era was defined as pre-MELD 3.0 versus post-MELD 3.0 implementation (listing date on or after 7/13/2023). Within each era, an era-specific logistic regression model was fit with 90-day waitlist death/dropout as the outcome and the corresponding score as the predictor. Predicted probabilities and linear predictors from these models were used to evaluate discrimination and calibration. Discrimination was assessed using the area under the receiver operating characteristic curve. Calibration was assessed using calibration slope, calibration intercept, and observed-to-expected ratios. Calibration plots were generated by grouping candidates into score deciles and plotting observed versus predicted event probabilities by race/ethnicity and era. **Results:** Of the total 108,044 waitlist candidates included in our study, 25,642 were listed in the MELD 3.0 era, which had younger candidates (median age 56 vs. 58 years, $P < 0.001$) and a higher percentage of females (40.8% vs. 36.6%, $P < 0.001$). The distribution of race/ethnicity also varied ($P < 0.001$) with the MELD 3.0 era have a higher proportion who self-reported as Hispanic and Other compared to White. Predictive performance metrics stratified by race/ethnicity and allocation showed that overall discrimination for 90-day waitlist mortality was similar across eras. The overall AUC was 0.699 (95% CI 0.692-0.707) in the MELD-Na era and 0.700 (95% CI 0.685-0.715) in the MELD 3.0 era. Overall calibration was preserved across eras, but there was modest subgroup heterogeneity by race/ethnicity (**Figure 1**). In the MELD 3.0 era, Black candidates demonstrated a calibration slope < 1 (0.569, 95% CI 0.262-0.877), whereas Asian candidates demonstrated a calibration slope > 1 (1.538, 85% CI 1.088-1.988) (**Figure 1**). **Conclusion:** In this national cohort, MELD 3.0 demonstrated preserved predictive performance across racial and ethnic groups, with comparable discrimination to the MELD-Na era and modest subgroup variability in calibration. Although overall performance was preserved, the observed subgroup calibration differences warrant continued evaluation of allocation equity across racial and ethnic groups.

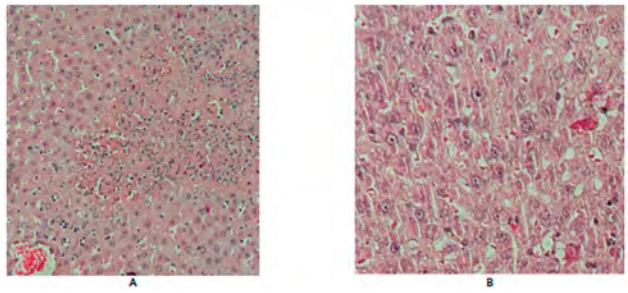
4444 | NOVEL PERFUSION SOLUTION ADDRESSING REVERSE ELECTRON TRANSPORT, FERROPTOSIS, AND MITOCHONDRIAL DYSFUNCTION IMPROVES HEPATIC VIABILITY DURING HYPOTHERMIC OXYGENATED MACHINE PERFUSION



Boris Yaremin[1] Bakhtiyar Kazymov[2] Catherine Anosova[3] Aslan Balkarov[4] Murad Novruzbekov[2], [1]NV Sklifosovsky Research Institute of Emergency Medicine, [2]Sklifosovsky Institute Of Emergency

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Medicine, [3]Sklifosovsky Emergency Medicine Institute, [4]Sklifosovsky Institute Of Emergency Moscow

Background: Available preservation solutions were developed for static cold storage and fail to address reperfusion-specific mechanisms operative during HOPE. Mitochondrial reverse electron transport (RET) driven by succinate reoxidation and ferroptosis-mediated lipid peroxidation are major drivers of hepatocellular and cholangiocellular injury after donation after circulatory death (DCD). We developed an 18-component extracellular-type solution with simultaneous pharmacologic action on RET, ferroptosis, mPTP opening, endothelial dysfunction, and ATP depletion. **Methods:** 18 male Wistar rats underwent 30-min warm ischemia (DCD), 2-hr HOPE at 8–10°C with HTK/Custodiol (control) or experimental solution, then 60-min normothermic reperfusion. Endpoints: ALT, AST, LDH, lactate, ATP recovery, bile production, 4-HNE, MDA, GPX4 activity, mitochondrial swelling, sinusoidal endothelial detachment, Suzuki score, zonal necrosis area, apoptotic index (TUNEL). Stability confirmed 7 days at 4°C. Statistics: ANOVA, Tukey, Holm-Bonferroni. **Results:** Hepatocellular injury markers were markedly reduced: ALT −76% (169 ± 91 vs. 694 ± 247 U/L; $p < 0.05$), AST −71% (243 ± 118 vs. 836 ± 301 U/L; $p < 0.05$), LDH −68% (412 ± 154 vs. 1289 ± 436 U/L; $p < 0.05$). Lactate after reperfusion fell from 5.8 ± 1.7 to 2.1 ± 0.9 mmol/L ($p < 0.05$); tissue ATP recovered to 81 ± 14% of baseline vs. 43 ± 16% in controls, confirming effective metabolic rescue. Bile production increased 2.4-fold (0.74 ± 0.24 vs. 0.31 ± 0.15 µL/min/g; $p < 0.05$), directly reflecting cholangiocyte viability. Ferroptosis was effectively suppressed: 4-HNE −58%, MDA −49%, GPX4 activity +1.9-fold. Mitochondrial swelling score improved from 2.8 ± 0.6 to 1.1 ± 0.5. Sinusoidal endothelial detachment was observed in 67% of control specimens vs. 17% in the experimental group. Histologically, controls demonstrated confluent centrilobular necrosis involving 34 ± 11% of lobular area with severe sinusoidal congestion and ballooning extending into zone II; the experimental group showed only focal pericentral degeneration affecting 8 ± 4% of tissue ($p < 0.05$). Suzuki score: 1[1–2] vs. 3[2–4]. Apoptotic index decreased from 18.6 ± 5.2% to 6.1 ± 2.7% ($p < 0.05$). **Conclusion:** Simultaneous targeting of RET, ferroptosis, mPTP opening, energy depletion, and endothelial dysfunction during HOPE produced substantial, mechanistically verified hepatoprotection in a model. Marked reduction of centrilobular necrosis combined with 2.4-fold improvement in bile production directly addresses the 20–30% ischemic cholangiopathy burden — the principal unresolved complication of DCD liver transplantation. These findings establish that HOPE requires pharmacologic strategies fundamentally distinct from static cold storage solutions. Patent application pending (2025). A prospective clinical study at a high-volume DCD transplant center is in preparation, with biliary complication rate as primary endpoint.

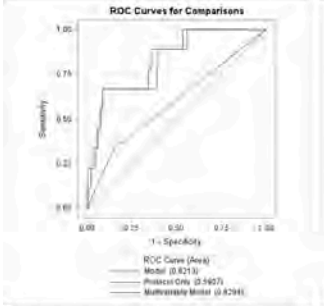
4445 | PERFORMANCE OF A STRATIFIED CARDIAC SCREENING PROTOCOL FOR CORONARY ARTERY DISEASE IN LIVER TRANSPLANT CANDIDATES

Sanjaya Satapathy[1] David Stern[1] Tapan Buch[2] Fariha Ilyas[2] Sohil Khurana[2] Reanay Berezovskiy[2] Shahidul Islam[2] Cristina Sison[2] Nabil Dagher[2] James Park[2], [1]Northshore University Hospital/Northwell Health, [2]Northwell Health



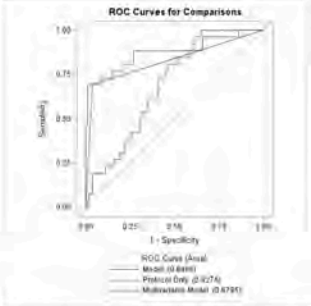
Background: Cardiovascular disease—particularly coronary artery disease (CAD)—is a leading cause of morbidity and mortality among liver transplant candidates. To improve pre-transplant cardiac evaluation, we implemented a stratified screening protocol based on the presence of high-risk features and the total number of cardiovascular risk factors. This study evaluates the diagnostic performance of the protocol in detecting asymptomatic CAD, including both clinically significant and obstructive disease. **Methods:** We retrospectively evaluated liver transplant candidates categorized into high-risk (≥ 1 high-risk feature or ≥ 3 total risk factors) and low-risk groups. The protocol directed patients to dobutamine stress echocardiography (DSE), coronary CT angiography (CCTA), or invasive coronary angiography based on their risk stratification and noninvasive test results. We assessed protocol performance in predicting three outcomes: any CAD, clinically significant CAD, and obstructive CAD. Diagnostic accuracy was evaluated using sensitivity, specificity, positive and negative predictive values (PPV and NPV). Discrimination was assessed using the area under the receiver operating characteristic curve (AUC) derived from both standard logistic and Firth-penalized logistic regression as appropriate. **Results:** Among 254 patients, the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

protocol demonstrated strong discrimination for clinically significant CAD (AUC: 0.83 overall; 0.80 in high-risk vs. 0.59 in low-risk patients). In the high-risk group, the protocol alone outperformed multivariable models. For obstructive CAD, Firth-penalized regression showed modest discrimination (AUC: 0.59–0.83), with higher performance in high-risk patients. Sensitivity and NPV were highest in the low-risk group, supporting its utility for ruling out disease. PPV remained limited, particularly in the low-risk strata, reflecting the low prevalence of CAD in this population. **Conclusion:** A stratified cardiac screening protocol demonstrates robust performance for detecting clinically significant CAD in high-risk liver transplant candidates, outperforming traditional risk models. Its high negative predictive value in low-risk patients supports its role in guiding safe transplant listing decisions and reducing unnecessary testing.

Figure 1. ROC Curves Comparing Predictive Models for Obstructive CAD in High-Risk Liver Transplant Candidates.



Receiver operating characteristic (ROC) curves comparing the diagnostic performance of three Firth logistic regression models for predicting obstructive coronary artery disease (CAD) in the high-risk group:

- **Protocol Only Model** (AUC = 0.591, 95% CI: 0.424–0.757)
- **Multivariable Model** (AUC = 0.828, 95% CI: 0.698–0.959), adjusted for age, BMI, diabetes, MASH, hypertension, dyslipidemia, and family history of CAD.
- **Full Model** including protocol status and covariates (AUC = 0.821, 95% CI: 0.679–0.963).

The multivariable model outperformed the protocol-only model, indicating improved discrimination when clinical variables were incorporated.

Figure 2. ROC Curves Comparing Predictive Models for Clinically Significant CAD in High-Risk Liver Transplant Candidates.

Receiver operating characteristic (ROC) curves comparing the diagnostic performance of three logistic regression models for predicting clinically significant coronary artery disease (CAD) in the high-risk group:

- **Protocol Only Model** (AUC = 0.828, 95% CI: 0.735–0.920)
- **Multivariable Model** (AUC = 0.680, 95% CI: 0.576–0.783), adjusted for age, BMI, diabetes, MASH, hypertension, dyslipidemia, and family history of CAD
- **Full Model including protocol status and covariates** (AUC = 0.889, 95% CI: 0.807–0.970)

The cardiac protocol demonstrated strong discrimination for clinically significant CAD, which was further improved when combined with clinical risk factors. The multivariable model without protocol status showed substantially lower discriminatory performance.

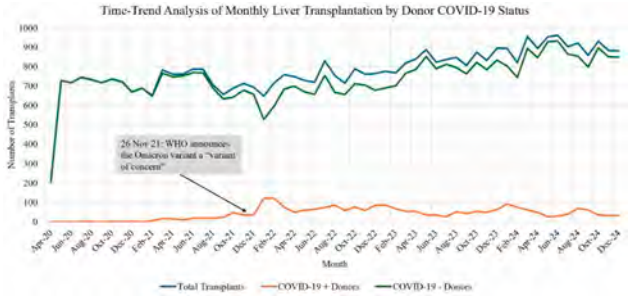
4446 | TEMPORAL TRENDS AND POST-TRANSPLANT OUTCOMES OF COVID-POSITIVE LIVER DONORS: A UNOS ANALYSIS



Oliver Liu[1] Nandini Sriram[1] Jewel Ng[1] Arthi Venkatesan[1] Daisuke Imai[1], [1]Virginia Commonwealth University School of Medicine

Background: The COVID-19 pandemic introduced unprecedented volatility into the organ donor pool, raising concerns regarding transplantation of COVID positive organs. No prior study has evaluated liver transplant outcomes across the full COVID-era UNOS dataset. Here, we aimed to characterize temporal trends in donor utilization and the impact of donor COVID status on post-transplant outcomes. **Methods:** We analyzed all COVID positive (n = 2,381) and COVID negative (n = 42,038) liver donors recorded in UNOS from 2020–2024 to characterize temporal trends in COVID positive donor usage. Transplant outcomes were assessed using a 1:3 propensity-matched cohort of COVID-positive (n = 1,026) and COVID negative (n = 3,068) donors based on donor BMI, DCD status, cold ischemia time, diabetes/steatosis/HCV status, and recipient MELD, age, primary diagnosis, sodium, and first vs. re-transplant. Kaplan-Meier analyses were used to assess effects on patient mortality/graft failure. A Cox proportional hazards model with fixed, baseline covariates (COVID status, Age, MELD, cold ischemia time, and DCD status) was used to assess the associated HRs. Logistic regression was used to assess effects on biliary complications, primary rejection, and diffuse cholangiopathy. **Results:** Time-trend analysis revealed a breakpoint at Dec 2021-Jan 2022, where COVID positive donor utilization rates increased from 5.06% to 18.7%. The Kaplan-Meier curves indicated that COVID status did not impact graft failure ($p = 0.0608$) or mortality ($p = 0.0698$). Cox modeling confirmed no association (mortality $p = 0.8453$, graft failure $p = 0.0948$). Among covariates, mortality risk was increased by age (HR 1.0110 per year, 95%, $p = 0.0009$), MELD score (HR 1.0126 per point, $p = 0.0137$), and cold ischemia time (HR 1.0215 per hour, $p = 0.0437$), but decreased by DCD status (HR 0.5492, $p = 0.0036$). Graft failure risk was increased by age (HR 1.0120 per year, $p < 0.0001$), MELD score (HR 1.0093 per point, $p = 0.0490$), and cold ischemia time (HR 1.0189 per hour, $p = 0.0473$). DCD status did not impact graft outcomes ($p = 0.1135$). Logistic regression showed that COVID status was not

associated with acute rejection (p = 0.662) or primary non-function (p = 0.804), though a trend toward diffuse cholangiopathy (p = 0.0674) was observed. **Conclusion:** The breakpoint of COVID positive donor utilization in Dec 2021 coincides with the emergence of Omicron. Additionally, we found that carefully selected COVID positive donors did not have worse outcomes than COVID negative donors. However, COVID status may still impact biliary complications, though lack of reliable UNOS data regarding anastomotic strictures and non-anastomotic biliary strictures limits further biliary outcome analysis. Notably, given the highly selective use of COVID positive grafts early in the pandemic, residual selection bias remains a concern.

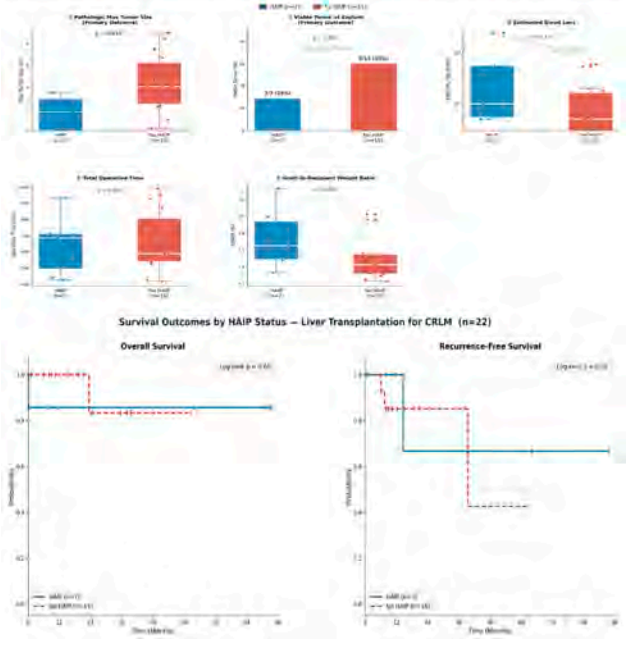
4447 | HEPATIC ARTERIAL INFUSION PUMP THERAPY BEFORE LIVER TRANSPLANTATION FOR COLORECTAL LIVER METASTASES IS ASSOCIATED WITH SUPERIOR PATHOLOGIC DOWNSTAGING



Ahmed Sayed Ahmed[1] Chase Wehrle[1] Sami Shoucair[1] Muhammad Ahmad Nadeem[1] Kyungran Justina Cho[2] Kim Jaekeun[1] Federico Aucejo[1] Koji Hashimoto[1] Mazhar Khalil[1], [1]Department of Surgery Transplantation Center, The Cleveland Clinic Foundation, OH, USA, [2]Department of Gastroenterology, The Cleveland Clinic Foundation, OH, USA

Background: Liver transplantation (LT) for unresectable colorectal liver metastases (CRLM) has gained traction as a treatment strategy in carefully selected patients. Hepatic arterial infusion pump (HAIP) therapy delivers high-dose regional chemotherapy directly to the liver and may achieve deeper locoregional tumor response than systemic chemotherapy alone. Whether pre-LT HAIP therapy translates into superior pathologic response at explant remains unknown. **Methods:** We reviewed 22 patients who underwent LT for CRLM at a single center. Patients were grouped by pre-LT HAIP therapy (n = 7) vs. systemic chemotherapy and locoregional therapy (LRT) (n = 15). Primary outcomes were viable tumor at explant and maximum pathologic tumor size. Secondary outcomes included recurrence-free survival (RFS), overall survival (OS), portal hilar lymph node yield and status, estimated blood loss (EBL), Roux-en-Y biliary reconstruction rate, and operative time. **Results:** Baseline characteristics were comparable. Mean age was 43.1 ± 4.2 vs. 50.4 ± 9.6 years (p = 0.072). Bilobar disease was present in 5/7 (71.4%) vs. 13/15 (86.7%) (p = 0.57), synchronous CRLM in 2/7 (28.6%) vs. 6/15 (40.0%) (p = 1.00), and median CEA was 3.3 (IQR 1.4–4.1) vs. 3.6 (IQR 1.9–5.5) ng/mL (p = 0.53). HAIP patients received more chemotherapy cycles [median 27.5 vs. 15.0, p = 0.41] and had a significantly longer interval from CRLM diagnosis to transplantation [mean 60.9 ± 20.8 vs. 34.5 ± 14.1 months, p = 0.002]. Portal hilar lymph nodes were sampled in 15/22 patients (68%); zero had nodal involvement. Operative outcomes were similar: operative time 637 ± 178 vs. 671 ± 189 min (p = 0.70) and median EBL 1,000 vs. 501 mL (p = 0.18). Of 22 patients, 12 (54.5%) received Y-90 radioembolization pre-LT. Viable tumor was present in 5/12 (41.7%) Y-90-treated vs. 6/10 (60.0%) untreated patients (p = 0.67). Patients receiving both HAIP and Y-90 (n = 2) had 0% viable tumor vs. 80.0% (4/5) receiving neither (p = 0.17), suggesting a potential additive downstaging effect. On explant analysis, HAIP patients had a significantly smaller mean maximum pathologic tumor size [1.6 ± 1.6 vs. 4.4 ± 2.7 cm, p = 0.019]. Viable tumor was present in 2/7 (28.6%) vs. 9/15 (60.0%) explants (p = 0.36).Recurrence occurred in 1/7 (14.3%) vs. 3/15 (20.0%) (p = 1.00). Median OS was 11.4 (IQR 4.1–77.9) vs. 19.1 (IQR 9.6–30.0) months (log-rank p = 0.60) and median RFS 11.4 (IQR 4.1–39.2) vs. 12.2 (IQR 7.7–22.7) months (log-rank p = 0.70). Shorter OS in the HAIP group reflects one intraoperative death and shorter follow-up. **Conclusion:** Pre-LT HAIP was associated with significantly smaller residual tumor at explant and a trend toward viable tumor elimination, supporting superior locoregional downstaging vs. systemic chemotherapy and LRT. Universal portal lymph node negativity across all 22 patients supports oncologic safety of LT for CRLM. Larger prospective studies are needed to validate findings and optimize patient selection.

4448 | EARLY POST-OPERATIVE OUTCOMES IN PEDIATRIC LIVER RECIPIENTS OF WHOLE, REDUCED AND SPLIT LIVER GRAFTS FOLLOWING NORMOTHERMIC MACHINE PERFUSION

Varvara Kirchner[1] Tyler York[1] Sidra Yang Xu[1] Sue Fu[1] Jacquelyn Yu[1] Kamil Hanna[1] Noelle Ebel[2] Leina Alrabadi[3] Carlos Esquivel[4] Kliment Bozhilov[1] Stephan Busque[1] Kazunari Sasaki[1] Marc Melcher[1] Thomas Pham[1] Gregory Tiao[1], [1]Stanford University, [2]Stanford, [3]Stanford/Lucile Packard Childrens Hospital, [4]Stanford University Medical Center

Background: Limited availability of size-matched organs and higher complication risk remain major challenges in pediatric liver transplantation (LT). Normothermic machine perfusion (NMP) may expand access to life-saving organs for children by enabling prolonged preservation during transport, graft assessment/rehabilitation, and ex vivo graft reduction/splitting prior to implantation. Although NMP is widely used in adult LT, early outcomes in pediatric LT using whole and technical-variant grafts are not well defined. We report early outcomes of NMP for grafts intended for pediatric recipients. **Methods:** We retrospectively evaluated outcomes of liver grafts initially allocated to pediatric recipients that were preserved with NMP and transplanted as whole or technical-variant grafts, with a minimum follow-up of 30 days. Livers were transported on NMP and transplanted either as whole grafts or after ex vivo reduction/splitting at the recipient center. Donor/recipient characteristics, 30-day graft survival, and early allograft function were assessed. **Results:** Twenty-three livers underwent NMP. Eleven were transplanted as whole grafts into pediatric recipients, including one simultaneous heart–liver and one lung–liver transplant. Seven grafts were reduced after NMP and transplanted as left or extended-left segments into pediatric recipients. Five grafts were split into extended-right segments (ERS) and left-lateral segments (LLS); 4 ERS were transplanted into adults and 1 into a teenage recipient (simultaneous liver–kidney), and all 5 LLS were transplanted into infants. Pediatric recipient age ranged from 6 months to 17 years for whole grafts and 6 months to14 years for technical variant grafts. All grafts were from donors following donation after brain death with age range 2–53 years old. NMP duration was 8–31 hours and transport distance to recipient hospital was 250–2,300 nautical miles. Thirty-day graft survival was 91% for whole grafts, 100% for reduced grafts, 80% for LLS, and 80% for ERS. Causes of graft loss within 30 days: primary nonfunction (1 whole graft from a pediatric donor; 1 ERS in an adult recipient) and 1 portal vein

thrombosis (LLS). Postoperative laboratory trajectories for grafts surviving ≥30 days are summarized in Table 1. **Conclusion:** NMP for pediatric recipients increases access to high quality livers by enabling extended-distance transport and optimizing transplant logistics with acceptable short-term graft survival for whole and reduced grafts. The outcomes after split/reduced graft transplantation following NMP warrant further evaluation and technical optimization, particularly for small-volume grafts that demonstrate pronounced early transaminitis.

4449 | GDF-15 AT 4 MONTHS POST-LIVER TRANSPLANTATION PREDICTS KIDNEY FAILURE AND ENHANCES RISK STRATIFICATION IN PATIENTS WITH SEVERELY REDUCED EGFR

Kai-Philipp Seeger[1] Zhihao Li[2] Julie Heimbach[1], [1]Mayo Clinic Rochester, [2]Mayo Clinic

Background: 5-year-incidence of post-transplant kidney failure in liver transplant (LTx) patients is 29%, carrying significant morbidity and mortality. Growth differentiation factor 15 (GDF-15), a stress-responsive cytokine released under tissue injury and metabolic stress, correlates with chronic kidney disease (CKD) progression in both diabetic and non-diabetic populations. We assessed GDF-15 as a novel biomarker for post-transplant kidney failure. **Methods:** Adults undergoing orthotopic LTx for metabolic dysfunction-associated liver disease at Mayo Clinic Rochester (2010–2024), who had frozen plasma samples drawn pre-transplant (t0) and at 4 months post-transplant (t4) stored in the institutional biobank, were included. GDF-15 was assessed using enzyme-linked immunosorbent assay. Kidney failure was defined as sustained estimated glomerular filtration rate (eGFR) <15 mL/min/1.73m² or dialysis dependency over 30 days. GDF-15 was log-transformed prior to regression analyses. Time-to-event analyses used Fine-Gray models for competing risks regression, with death as a competing event. **Results:** 213 patients with a median age of 59.4 years [IQR: 54.4–64.6] were included. 26 (12%) patients developed kidney failure and 65 (31%) died over a median follow-up of 7.3 years. The median model for end-stage liver disease (MELD) score at LTx was 23 [IQR:15-32] and 59% of patients were diabetic. Median GDF-15 declined significantly from 3,834 pg/mL at t0 [IQR: 2,591–5,742] to 2,161 pg/mL at t4 [IQR: 1,411–3,546] (paired t-test, $p = 0.013$). Pre-transplant GDF-15 correlated with MELD score ($R^2 = 0.40$, $p = 0.013$) and was independently associated with diabetes (OR: 2.06, 95% CI 1.22–3.64, $p = 0.008$). GDF-15 at t4 independently predicted kidney failure (HR: 2.59, 95% CI 1.03–6.55, $p = 0.04$), with the strongest effect in the first post-transplant year (HR: 11.6, 95% CI 1.4–94.68, $p = 0.028$). Competing risks regression confirmed this association accounting for the high competing risk of death (sub-distribution HR: 1.66, 95% CI 1.06–2.58, $p = 0.025$, *figure 1.a*). Discrimination tended to be superior to concurrent eGFR (C-statistic 0.760 vs. 0.733), failing to reach significant superiority. In the subgroup of patients with severely reduced eGFR at 4 months (<30 mL/min/1.73m², n = 23), GDF-15 significantly discriminated between progressors to kidney failure and non-progressors (median 4,387 vs 2,961 pg/mL, $p = 0.033$, *figure 1.b*). This suggests additive value in the highest-risk stratum, although these findings should be interpreted cautiously given the small subgroup size. **Conclusion:** GDF-15 at 4 months post-LTx independently predicts kidney failure across multiple analytical frameworks and adds risk stratification beyond eGFR in the highest-risk patients, with implications for early identification of candidates who may benefit from calcineurin inhibitor minimization or subsequent kidney transplantation referral.

4450 | IMPACT OF DONOR-LIVER ENZYMES FLUCTUATIONS ON LIVER TRANSPLANTATION OUTCOME

Héloïse Giudicelli[1] Yann de Rycke[2] Olivier Scatton[2] Filomena Conti[2] Eric Savier[2], [1]Université de Montréal, Sorbonne Université, [2]Sorbonne université

Background: Organ shortage remains a critical issue in liver transplantation (LT). While multiple strategies aim to expand the donor pool, the impact of pre-procurement fluctuations in donor liver enzymes on post-LT outcomes is unclear. We evaluated whether LTs from donors with marked variations in donor alanine aminotransferase (ALT) were associated with poorer outcomes and should influence graft acceptance. **Methods:** Donor ALT variation within 7 days before procurement was quantified using a linear regression coefficient. Patients were classified as "Stable ALT" (patients whose donor had stable ALT, eg. regression coefficient [-10, 10) IU/day) or "Disturbed ALT (D-ALT)" (patients whose donor had either ascending or declining ALT, eg. regression coefficient < -10 or ≥ 10 IU/day). The primary endpoint was arterial and biliary complication (ABC)-free interval. Secondary endpoints included 60-month ABC-free survival (ABCFS), 60-month transplant survival, early allograft dysfunction and acute kidney injury. First analysis included LTs performed at our center (2012–2020); Second analysis included all eligible adult LTs performed in all other French LT centers (2008–2020). Survival analyses were adjusted using propensity scores. **Results:** In the derivation cohort (n = 565), 361 patients were in the « Stable ALT » group and 204 in the « D-ALT » group. « Stable ALT » donors were older (p < 0,001), more frequently hypertensive (p < 0,001) and less likely to have experienced cardiac arrest prior organ procurement (p < 0,001). Graft-to-recipient weight ratio was lower (p < 0,01) and Euro-Transplant Donor Risk Index higher (p < 0,01) in the « Stable ALT » group. Recipient variables were comparable between the two groups. Following compensation with the propensity score, at 60 months, at least one ABC event occurred more often in « Stable ALT » group (31.4% vs. 21.1%; p = 0.02). At multivariate analysis « D-ALT » was associated with longer ABC-free interval (0.80 vs 0.65; p < 0.01) and higher ABCFS (0.65 vs 0.51; p < 0.01). At univariate analysis, 60-month post LT survival was also better in « D-ALT » group (p = 0.02). Other post operative complications were comparable. The French cohort (n = 7621) confirmed similar donor and recipient characteristics. A trend toward improved transplant survival was observed in « D-ALT » group (p = 0.21). **Conclusion:** Fluctuations in donor ALT-whether increasing or decreasing- within 7 days before procurement were not associated with worse post-LT outcomes and were even linked to improved ABC-free interval which could lead to a beneficial effect on transplant survival. These findings suggest that marked fluctuations in donor ALT levels alone should not justify discarding liver grafts.

4451 | SEX DISPARITIES IN LIVER TRANSPLANT PRIORITIZATION ACROSS SCORING SYSTEMS: A KOREAN MULTICENTER COHORT STUDY

Jeayeon Park[1], [1]Ajou University Hospital

Background: Given the scarcity of donor organs, equitable allocation in deceased donor liver

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

transplantation (DDLT) is crucial. The Model for End-Stage Liver Disease (MELD) score was developed to prioritize patients with the highest mortality risk. Although it has significantly improved organ allocation, the MELD score has been associated with sex disparities, leading to the introduction of MELD 3.0. However, validation of these revised models in Asian populations remains limited. Thus, using a Korean multicenter cohort, this study aims to validate whether these improved scoring systems mitigate sex disparities in liver transplant allocation within an Asian population. **Methods:** We retrospectively analyzed consecutive patients aged ≥19 years listed for DDLT between 2010 and 2024 using multicenter cohorts from Seoul National University Hospital (SNUH) and the Catholic Medical Center (CMC). To account for the transition in South Korea's organ allocation system from the Child-Pugh Score (CPS) to the MELD score during the study period, analyses were stratified into the CPS era and the MELD era. The primary outcome was DDLT within 90 days. Death without transplantation was treated as a competing event, and the outcomes were assessed using cumulative incidence functions and Fine–Gray subdistribution hazard models. The secondary outcomes were transplantation-free survival (TFS) and 90-day waitlist mortality. **Results:** A total of 1,390 patients were included (1,034 from SNUH and 356 from CMC). During the Child-Pugh Score (CPS) era, the cumulative incidence of DDLT within 90 days was significantly higher in females (subdistribution hazard ratio 1.37, 95% CI 1.06–1.78, P = 0.02, Figure 1). However, this sex disparity was resolved in the MELD era (P = 0.36). Waitlist mortality showed no significant sex differences in either the CPS (P = 0.95) or MELD (P = 0.38) eras. Transplantation-free survival (TFS) was significantly reduced in females during the CPS era (hazard ratio 1.32, 95% CI 1.07–1.63, P = 0.01), likely driven by their higher transplantation rate, whereas no significant difference was observed in the MELD era (P = 0.85) (Figure 2). Furthermore, in the CPS era, the sex-based difference in 90-day waitlist mortality risk increased sharply within the high-risk group. In the MELD era, the Gender-Equity Model for Liver Allocation corrected by serum sodium (GEMA-Na) model demonstrated the lowest and most stable sex disparity (Figure 3). **Conclusion:** While the transition of DDLT allocation criteria from CPS to the MELD score has partially alleviated sex disparities, our findings suggest that GEMA-Na could serve as a more optimal scoring system for the Asian population.

transplantation (SLK) in the United States are a significant concern. MELD 3.0 was designed to address gender disparity in LT; its real-world impact on SLK has not been studied. We analyzed Scientific Registry of Transplant Recipients data from January 2018 to June 2023 (T1-pre-MELD 3.0) and July 2023 to March 2026 (T2-post-MELD 3.0) to assess these effects. **Methods:** We analyzed primary outcomes including days to transplant, waitlist mortality, delisting due to clinical deterioration and delisting due to improvement. Bivariate analysis by gender were done for each era. Cause specific cumulative incidence functions for each outcome stratified by gender and era were built. Differences between groups were evaluated with Gray's test. **Results:** A total of 6,102 candidates in T1 and 2,123 candidates in T2 were listed for SLK. Age at listing was higher for women in both eras. The ethnic distribution was similar between genders in both eras. The etiology of cirrhosis was different, predominantly alcohol related in men and metabolic dysfunction associated steatotic liver disease in women, in both eras. Women had lower serum creatinine levels (at listing) in both eras (T1- 2.67 [IQR 1.79-4.09] vs 3.41 [IQR 2.21-5.41], $p < 0.001$ and T2- 2.61 [1.83-4.10] vs 3.50 [2.30-5.39], $p < 0.001$). The median MELD at listing was higher for women in T2 (24 [20-30] vs 23 [20-29], $p = 0.035$), but the same in T1 (24 for both), $p = 0.27$. The distribution of SLK listings across UNOS regions did not reveal gender disparity in either era. The median waiting time for SLK was similar for both genders in both eras, however it was lower for both genders in T2. Most importantly, persistence on the wait list was lower for women in T2 (11.3% vs 14.3%, $p = 0.043$). During the follow-up period, the number of patients receiving SLK was comparable in both genders in both eras (M/F 62.1%/61.2% in T1 and 62.2%/60.6% in T2), Fig.1A. Similarly, the rates of delisting for improvement on the waitlist were comparable between both genders in both eras, Fig.1B. There were more deaths on the waitlist in both genders in T2 (Fig.1C) and more delisting due to deterioration in both genders in Group T2 (Fig.1D). **Conclusion:** Following the implementation of MELD 3.0, the median MELD at listing for SLK became higher for women, and a lower percentage of women remained on the waitlist for SLK. No significant gender disparity was observed in SLK rates or delisting due to clinical improvement or deterioration before or after implementation of MELD 3.0. Long-term follow-up is required to understand further the impact of MELD 3.0 on addressing gender disparity in the receipt of SLK.

4453 | WAITLIST OUTCOMES ARE BETTER, AND POST-TRANSPLANT OUTCOMES ARE SIMILAR IN ALCOHOL ASSOCIATED HEPATITIS VS. ALCOHOL ASSOCIATED CIRRHOSIS: A UNOS ANALYSIS

Bipneet Singh[1] Mangesh Pagadala[2] Yong-Fang Kuo[3] Umang Arora[4] Anil Arora[5] Robert Wong[6] Winston Dunn[7] Brian Lee[8] Norah Terrault[9] Ashwani Singal[10], [1]University of Kentucky, [2]Liver Institute Methodist Dallas, Irving, United States,, [3]University of Texas Medical Branch, Galveston, United States, [4]Mayo Clinic, Rochester, [5]Sir Ganga Ram Hospital, [6]Stanford/ VA Palo Alto Healthcare System, [7]University of Kansas Medical Center, [8]Keck School of Medicine, University of South California, United States, [9]University of Southern California, [10]University of Louisville

Background: Alcohol-associated liver disease, which includes alcohol-associated cirrhosis (AC) and alcohol-associated hepatitis (AH) forms the leading indication of liver transplantation. Post-LT results in AH were similar to those of LT recipients for AC in our earlier study (UNOS database). However, information regarding waiting outcomes and long-term post-transplant outcomes comparing AH and AC is scarce. **Methods:** UNOS codes were used to stratify adult LT listings for ALD in the UNOS database (01/2004-03/2025) to AH and AC as indications. Living donor LT was not

included. AH and AC were compared in the following analyses: a) trends on listings and LT; b) 90-day cumulative waitlist (WL) mortality and receipt of LT using competing risk analysis; and c) 10-yr. post-LT graft and patient survival. Propensity score matching (PSM) was performed to balance baseline demographic, clinical, and disease severity variables at listing. Sub-hazard ratios (SHR) and 95% confidence intervals (95% CI) were reported for WL outcomes using Fine and Gray models, and HR (95% CI) reported outcomes using Cox proportional models. **Results:** Of 63,025 listings [4168 (6.6%) AH], listings for AH increased from 3.1% in 2004 to 16.1% in 2025. Candidates from AH were younger (45 vs. 53 years) and more female (35 vs. 29%), $P < 0.001$. Further, AH candidates were more likely to be obese, on life support, and, despite a higher MELD score, have a better functional status. 90-day cumulative waitlist mortality was lower in AH (13.9 vs. 24.5%) with HR (95% CI) of 0.88 (0.78-0.98), $P = 0.019$. Concurrently, 90-d LT probability was higher in AH (76.9% vs 60.3%), 2.53 (2.43–2.63), $P < 0.001$. In the PSM cohort after matching for demographics and MELD score, 90-d WL mortality was similar comparing AH vs. AC, 0.916 (0.801–1.046), $P = 0.195$. However, AH candidates had a slightly higher probability of 90-d LT, 1.050 (1.003–1.100), $P = 0.037$. Age, MELD score, hepatic encephalopathy, and being on life support were other predictors of WL mortality. Between 2004 and 2025, LT for AH rose from 2.3% to 16.1% of 40,902 LT [3233 (7.9%) AH]. AH and AC on graft had comparable 10-year post-LT results in the PSM cohort [88 vs. 82%, Log Rank $P = 0.329$, 1.09 (0.96-1.24), $P = 0.177$] and patient survival [90 vs. 84%, $P = 0.988$, 1.01 (0.88-1.16), $P = 0.873$] **Conclusion:** Compared to AC, AH had a higher probability of LT, with similar adjusted 90-day waitlist mortality and long-term post-LT graft and patient survival as AC. These results underline the need to assess organ access equity for a wider range of patients with alcohol-related liver disease, while also supporting the continued LT for AH.

4454 | TWO-DECADE TRENDS AND OUTCOMES OF LIVER TRANSPLANTATION FOR AUTOIMMUNE HEPATITIS IN THE UNITED STATES AND EUROPE

Maria Stepanova[1] Giacomo Germani[1] Ana Lleo[1] Vincent Karam[1] René Adam[1] Saleh Alqahtani[1] Linda Henry[1] Patrizia Burra[1] Zobair Younossi[1], [1]The Global NASH/MASH Council

Background: Autoimmune hepatitis (AIH) is an immune-mediated liver disease that may progress to liver failure requiring liver transplantation (LT). We assessed demographics, clinical features, and outcomes of LT recipients with AIH in the US and Europe. **Methods:** Adult (≥18) LT recipients with AIH were identified from the European Liver Transplant Registry (ELTR) and U.S. Scientific Registry of Transplant Recipients (SRTR) (2000–2022) using their primary listing diagnoses. **Results:** Over 22 years, a total of 6,925 LT recipients with AIH were included (ELTR n = 3,069; SRTR n = 3,856). The AIH recipients in SRTR were older (mean ± SD : 48 ± 15 vs. 46 ± 15 years, p < 0.0001), had higher BMI (28.2 ± 6.4 vs. 25.6 ± 5.0, p < 0.0001), and were more likely to have ascites (82% vs. 60%) and hepatic encephalopathy (66% vs. 32%) than those from ELTR (all p < 0.0001). MELD scores were also higher in SRTR (24 ± 10 vs. 18 ± 8, p < 0.0001). Overall, 29% of recipients were male, more common in ELTR (31% vs. 28%, p = 0.01). HCC was present in 6.8% of LT recipients with AIH (increased from 2-4% in 2000-2006 to 11% in 2022, p < 0.0001), while cholangiocarcinoma was rare (< 0.1%). AIH as a proportion of all LTs for a chronic liver disease increased in ELTR from 2.8% (2000) to 3.8% (2022) (p < 0.0001), while remaining stable in SRTR (pooled 3.2%, p > 0.05). Post-transplant mortality was 11% at 1 year, 17% at 3 years, 22% at 5 years, and 35% at 10 years. In multivariable survival analyses of patients with AIH, higher post-transplant mortality was independently associated with earlier calendar year (aHR (95% CI) = 0.982 (0.972-0.992) per year), older age (1.014 (1.010-1.018) per year), higher MELD score (1.013 (1.007-1.019) per point), severe hepatic encephalopathy (1.44 (1.21-1.72)), transplantation in a small transplant center (< 15/year; aHR = 1.56 (1.13-2.16)), and older donor age (1.007 (1.004-1.010) per year) (all p < 0.05). There was no significant difference in post-transplant mortality between ELTR and SRTR (aHR = 1.05 (0.92-1.20), p = 0.51), and recipient-donor sex matching was also not associated with post-transplant survival (aHR = 1.00 (0.90-1.11), p = 0.97). **Conclusion:** Liver transplantations for AIH remained stable in the US but increased in Europe over time. Despite regional differences in recipient characteristics, post-transplant survival was similar between ELTR and SRTR cohorts. Post-transplant survival exceeded 75% at 5 years in both registries and continued to improve over time.

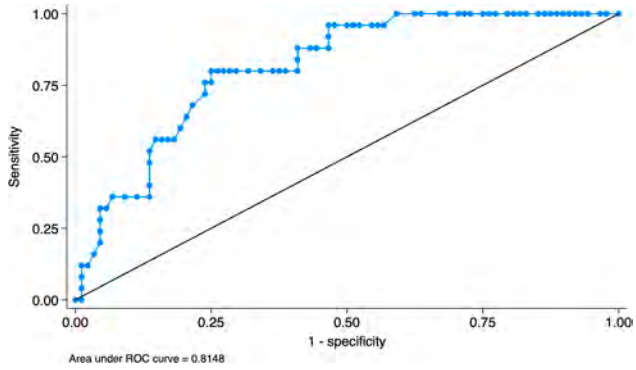
4455 | CONTROLLED ATTENUATED PARAMETER (CAP) IS AN ACCURATE METHOD TO SCREEN LIVING LIVER DONOR (LLD) CANDIDATES IRRESPECTIVE OF OBESITY



Lane Herbert[1] Jacob Liskh[1] Daniel Borja-Cacho[2] Justin Boike[3] Juan Carlos Caicedo[1] Daniel Ganger[4] Zachary Dietch[1] Daniela Ladner[5] Amir Borhani[1] Sarang Thaker[2]

Christopher Moore[1] Andres Duarte-Rojo[1], [1]Northwestern Medicine, [2]Northwestern, [3]Northwestern Memorial Hospital/Northwestern University, [4]Northwestern Memorial Hospital, [5]Northwestern University

Background: Steatosis assessment with CAP from vibration-controlled transient elastography (VCTE) has been proposed as an alternative to proton density fat fraction (PDFF) from magnetic resonance in LLD. In November 2025, we incorporated VCTE (Fibroscan 430, Echosens, Paris) to the standard of care of our LLD evaluations. Herein, we report our comparative experience against PDFF and liver biopsy. **Methods:** This was a prospective quality improvement project. Apart from baseline characteristics and steatosis metrics, transplant outcomes were collected. We used the following PDFF thresholds for steatosis grading: < 6.4%, 6.4 to < 17.4%, 17.4 to < 22.1%, and 22.1% for grades 0-3, respectively. ROC curves were constructed to assess CAP accuracy to identify any degree of steatosis. When available, steatosis grading was compared against biopsy. **Results:** A total of 124 donors were evaluated (71 [57%] female; 39 ± 10 years; White 77%; obese 30%). VCTE was done in 123, and PDFF in 115. Forty-eight LLD candidates were approved for donation and 27 ultimately donated. Main reasons for decline were surgical 30%, consent withdrawn 13%, having a deceased donor offer 10%, medical and alternate LLD candidate 8% for either. Both CAP (248 dB/m [212-305] vs 223 [192-256]; p < 0.002) and PDFF (4.1% [2.7-6.5] vs 2.8 [2.1-4.8]; p = 0.034) were higher among nonapproved vs approved donors, and there was a trend for BMI (28.4 ± 4.5 kg/m^2 vs 26.9 ± 3.5; p = 0.051). However, there were no differences in liver stiffness (4.8 [4.2-6.7] vs 5.0 [4.1-5.9]; p = 0.68). Steatosis (any degree) by PDFF was found in 22%. The CAP AUROC showed excellent accuracy to identify any degree of steatosis (**Figure**) and 255 dB/m was the threshold with best sensitivity (80%), specificity (75%), and positive/negative predictive values (93% and 48%); the AUROC for moderate-to-severe steatosis was 0.808. Using the recommended threshold of 300 dB/m for moderate-to-severe steatosis, CAP overestimated steatosis in 19 LLD who had no or mild steatosis per PDFF. Sensitivity analysis limiting donors to those with BMI ≤ 30 or ≤ 35 kg/m^2 did not change results. Among 17 donors with liver biopsy, 3 had mild steatosis and there was similar agreement with either CAP (82.4%, kappa = 0.564, p = 0.004) or PDFF (82.3%, kappa = 0.463, p = 0.02). **Conclusion:** Our results support the use of CAP in LLD given its excellent accuracy. CAP offers a practical alternative to rule out steatosis with a high negative predictive value. This strategy can be particularly applied to rapidly screen for LLD in outreach or peripheral clinics where PDFF is not available.

4456 | OUTCOMES OF LIVER RETRANSPLANTATION IN THE UNITED STATES: A 25-YEAR ANALYSIS OF THE UNOS STAR REGISTRY (2000–2024)

Kevin Nhieu[1] Oliver Liu[1] Megan Castle[1] Anjelica Alfonso[1] Sonal Rajpal[1] Jacob Hallesy[1] Shashank Nadimpalli[1] Daisuke Imai[1], [1]Virginia Commonwealth University School of Medicine

Background: Liver retransplantation remains the only curative option for organ/graft failure (GF) following primary liver transplant. However, the risk factors for poor outcomes after liver retransplantation remain incompletely defined. In this study, we aimed to identify predictors of post-retransplant GF and produce an associated risk stratification model. **Methods:** We analyzed adult deceased-donor liver transplants in the UNOS STAR registry from 2000 through 2024, identifying a group of retransplants (n = 9,615) and primary transplants (n = 150,320). Survival analyses

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

were applied to a propensity-matched group of subjects (using BMI, sex, age, Karnofsky performance status (KPS), transplant era, center volume, MELD, deceased donor status) with known 1-year mortality outcomes (n = 16,330). Using a multivariable Cox model, we identified predictors of both overall and death-censored GF. **Results:** Kaplan-Meier analysis indicated that retransplantation had significantly worse survival outcomes than primary transplantation, both for graft failure ($p < 0.001$) and patient mortality ($p < 0.001$). On logistic regression, prior graft failure due to biliary complication (OR 4.42; $p < 0.001$), infection (OR 4.99; $p < 0.001$), and hepatic arterial thrombosis (OR 2.52; $p = 0.004$) were the strongest graft-loss predictors. Later transplant era markedly reduced risk (2016–2020 vs 2000–2005: OR 0.50; $p < 0.001$). Cox modeling identified recipient age, MELD, donor age, KPS, cause of prior failure, and transplant era as significant predictors of GF. **Conclusion:** Retransplant recipients face substantially lower graft survival than primary recipients, even after propensity adjustment. Prior graft failure due to biliary complication or infection confers the greatest graft-loss risk, while era-level improvements reflect advances in perioperative care. Recipient age, MELD, donor age, KPS, cause of prior failure, and transplant era are significant predictors of post-retransplant GF and should inform patient selection and risk counseling.

Table 3. *Multivariable logistic regression for 1-year graft loss: overall graft survival (death = event) and death-censored graft survival (death = censored).*

Covariate	Overall Graft Survival OR (95% CI)	p	Death-Censored Graft Survival OR (95% CI)	p
Recipient Factors				
Recipient age (per year)	1.02 (1.02–1.03)	<0.001	1.01 (1.00–1.02)	0.011
MELD at retransplant (per point)	1.01 (1.01–1.02)	0.001	1.01 (1.00–1.02)	0.204
Karnofsky performance status (per point)	0.99 (0.99–1.00)	<0.001	0.99 (0.98–1.00)	0.003
Hospitalized (floor/ward) vs outpatient at transplant	0.81 (0.66–0.99)	0.037	0.90 (0.64–1.26)	0.537
ICU vs outpatient at transplant	0.92 (0.70–1.21)	0.559	1.27 (0.81–1.99)	0.304
Donor Factors				
Donor age (per year)	1.01 (1.00–1.01)	0.033	1.00 (0.99–1.01)	0.712
DCD donor	1.08 (0.51–2.30)	0.846	1.74 (0.51–6.00)	0.379
Cause of Prior Graft Failure				
Biliary complication	4.42 (2.37–8.25)	<0.001	4.97 (2.63–9.37)	<0.001
Hepatic artery thrombosis	2.52 (1.34–4.75)	0.004	2.70 (1.39–5.26)	0.004
Infection	4.99 (2.95–8.44)	<0.001	5.16 (3.03–8.79)	<0.001
Era and Center Effects				
Era 2011–2015 vs 2000–2005	0.61 (0.48–0.77)	<0.001	0.50 (0.33–0.74)	<0.001
Era 2016–2020 vs 2000–2005	0.50 (0.39–0.65)	<0.001	0.32 (0.20–0.52)	<0.001
Center volume Q4 vs Q1	1.07 (0.86–1.33)	0.530	0.92 (0.64–1.34)	0.669

Note: *ORs > 1 indicate higher odds of graft loss within 1 year. Overall graft survival (OGS) counts patient death as a graft failure; death-censored graft survival (DCGS) censors patients who die with a functioning graft, isolating allograft-specific failure. Reference categories: cause of prior failure = Acute Rejection; medical condition at transplant = not hospitalized/outpatient; era = 2000–05; center-volume quartile: Q1 = lowest-volume centers, Q4 = highest-volume centers.*

4457 | OUTCOMES OF DIFFERING SUTURING TECHNIQUES ON BILIARY ANASTOMOTIC COMPLICATIONS AFTER LIVER TRANSPLANT

Adina Shrestha[1] Sophia Cury[1] Megan Lee[1] Ritika Kanapareddy[1] Hannah Alex[1] Daisuke Imai[1] Yuzuru Sambommatsu[1] Vinay Kumaran[1] Muhammad Saeed[1] Amit Sharma[1] Adrian Cotterell[1] David Bruno[1] Seung Lee[1] Aamir Khan[1], [1]Virginia Commonwealth University School of Medicine

Background: Biliary anastomotic complications, including strictures, leaks, and post-transplant cholangitis, remain common after liver transplantation and may impact graft and patient survival. Anastomosis technique is a potentially modifiable factor, but comparative evidence between continuous and mixed (continuous-posterior/interrupted-anterior) techniques is limited. **Methods:** The retrospective study cohort included 373 adult liver transplant recipients between July 2022 to December 2024 (continuous n = 295; mixed n = 55; interrupted n = 23). Primary outcomes were anastomotic biliary stricture, bile leak, and post-transplant cholangitis. Propensity score matching (PSM, 1:1, n = 96) was performed on 8 clinically selected covariates (recipient age, sex, BMI, MELD, warm and cold ischemia times, NMP use, biliary duct size mismatch) with priority weighting for key confounders. Outcomes were compared using chi-square/Fisher's exact tests, Mann-Whitney U test, logistic regression (adjusted for residual imbalance), and time-to-event analyses with Kaplan-Meier curves and Cox proportional hazards models. **Results:** Baseline characteristics were well balanced after PSM (⅞ covariates with |SMD| < 0.10; biliary mismatch slightly imbalanced, |SMD| ~ 0.12, adjusted in regression). Unadjusted and adjusted analysis showed no statistically significant differences in primary outcomes between continuous and mixed techniques: anastomotic stricture (18.4% vs. 20.0%; adjusted OR 0.98, 95% CI 0.44-2.18), bile leak (7.1% vs. 5.5%; adjusted OR 0.90, 95% CI 0.23-3.49), post-transplant cholangitis (16.3% vs. 20.0%; adjusted OR 1.25, 95% CI 0.55-2.80). Time-to-event analysis confirmed these findings, with 1-year stricture-free survival rates of 83.1% (continuous) vs. 84.3% (mixed, log-rank p = 0.946) and bile leak-free survival rates of 93.3% vs. 96.2% (log-rank p = 0.393). Similarly, patient and graft survival showed no significant differences (adjusted HR range 0.67-0.90). **Conclusion:** Continuous and mixed sutures techniques demonstrated comparable rates of biliary

anastomotic complications and survival outcomes after liver transplantation. Limitations included modest sample size, organ specific factors, and potential surgeon-specific technical confounders. Despite these constraints, the findings suggest similar safety profiles for continuous and mixed biliary anastomotic techniques. Prospective studies are needed to confirm these results and guide optimal surgical practice.

4458 | TRACKING LIVING DONOR-CANDIDATE DYADS: EHR INFRASTRUCTURE CHALLENGES

Ursula Rogers[1] Tyler Schappe[1] Anthony Dreher[2] Jacqueline Henson[1] Elisa Gordon[2] Neehar Parikh[3] Peter Reese[2], [1]Duke University, [2]Vanderbilt University Medical Center, [3]University of Michigan Medical Center

Background: Living donor liver transplantation (LDLT) offers superior outcomes compared to deceased donor transplantation, including improved survival and reduced waitlist time. Yet over the past decade, growth in living donation has stagnated. An underexplored barrier to LDLT access is the health system–level data infrastructure to support the study and improvement of the living donor pipeline. **Methods:** We assembled a retrospective cohort of adults (age $\geq$18) referred for LT evaluation or living liver donation between November 1, 2016, and December 31, 2022, at Duke University Medical Center and Vanderbilt University Medical Center. Investigators extracted data directly from the EHRs of each institution. We linked potential living donors with their intended recipients to examine interactions between the donor and candidate experiences. Potential living donors with a linked potential liver transpalnt recipient were considered dyads. **Results:** Among 603 donor referrals during the study period, 20 linked dyads were ultimately deemed implausible: 19 because the donor referral date occurred prior to the candidate referral date and 1 because the donor was linked to the wrong referral episode in a candidate with 3 referrals during the study period. In addition, 25 unique donor study IDs were present in the donor cohort file but did not appear in the dyad file. Of these, 15 were referred after the recipient's administrative censor date or prior to the recipient referral date, 2 were incorrectly labeled as donating an organ not needed by their intended recipient, 1 was linked to a recipient who was incorrectly listed, and 6 donors were excluded due to the donor referral date occurring prior to the recipient referral date. **Conclusion:** The current EHR data infrastructure lacks the capability to allow reliable donor-recipient dyad linkages for patients with multiple transplant referrals. This shortcoming risks implausible dyads in analytic datasets, ultimately reducing the ability to identify where in the pipeline potential donors are lost or evaluate the impact of interventions aimed at converting potential donors to actual donors. These limitations have direct consequences for health system–based research and quality improvement, as the current data environment reduces the living donor process to an incomplete and potentially misleading narrative. Addressing these challenges requires a coordinated approach that spans EHR design, data capture at the point of care, and alignment with national data systems.

4459 | PUMPING UP THE VOLUME: NORMOTHERMIC MACHINE PERFUSION DRIVES PROGRAM EXPANSION WITHOUT SACRIFICING PATIENT OUTCOMES

Resham Ramkissoon[1] Julie Gartland[1] Samir Barazi[1] Sara Ali[1] Japhet Amoah[1] Naemat Sandhu[2] Stanley Cohen[3] Seth Sclair[2], [1]Case Western Reserve University/University Hospitals, [2]University Hospitals Cleveland Medical Center, [3]Case Western Reserve University

Background: The growing demand for liver transplantation (LT) has driven the adoption of advanced preservation techniques such as normothermic machine perfusion (NMP), enabling expanded utilization of donation after circulatory death (DCD) grafts. DCD donors were associated with higher rates of ischemic cholangiopathy and inferior outcomes compared with donation after brain death (DBD). Recent data suggests that outcomes and survival between DCD and DBD donors are comparable, likely due to improved donor and recipient selection, rapid procurement techniques, and the implementation of machine perfusion technologies. We aim to compare the donor and recipient characteristics, LT outcomes, and discuss real-world experience using NMP at an urban liver transplant center. **Methods:** A retrospective analysis of 165 liver transplant, including simultaneous liver-kidney transplants, preformed from 1/1/2023 to 12/31/2025. Outcomes between NMP and standard static cold storage (SCS) were compared using standard two-sided t-test and chi squared analysis and fisher's exact test for subgroups. **Results:** 165 liver transplants occured during the study period; 97 NMP and 68 SCS LTs (Table 1). Donor characteristics were compared between NMP and SCS groups with significant differences in miles to hospital (202.6 vs 294.3), DCD donors (89 vs 5) and CIT (1011.8 vs 409.3). No difference was found in donor age, BMI, donor risk criteria, or HCV. Recipients' characteristics were compared, showing significant differences in age (55.9 vs 52.4), MELD (22.8 vs 27.9), hospitalized at transplant (23.7% vs 41.2%) and portal vein thrombosis (21.6% vs 8.8%). No difference found in recipient BMI, gender, alcohol associated liver disease, simultaneous liver-kidney transplant or retransplant status. Transplant outcomes were compared among NMP and SCS groups with significant differences in nighttime OR (16.5% vs 52.9%), PRBC transfusion intraoperatively (4.7 vs 7.3), use of cell saver (71.1% vs 50%), and hospital length of stay (11.0 vs 14.2). No differences were found for early allograft dysfunction, allograft rejection, AKI, severe postop thrombocytopenia, washout for bleeding, or hospital readmission. **Conclusion:** Our program has grown from 26 LTs in 2023 to 74 LTs in 2025. This was largely due to the use of NMP and extended donor criteria. The use of NMP has facilitated transplantation for patients with lower MELD scores, older age, not hospitalized at transplant, without compromising quality of care including rejection and early allograft dysfunction. Additionally, the use of NMP has allowed us to have non-urgent OR start times when ancillary staff and resources are abundant. There is a decreased need for blood transfusions and shorter hospital length of stay with use of NMP. As transplant rates and NMP use increase across the world, continued data and understanding of risks and benefits of NMP need to be collected and published.

4460 | CT BODY COMPOSITION CONTRIBUTES TO RISK ASSESSMENT IN LIVING LIVER DONOR EVALUATION

Saurav Panda[1] Tyler Zemla[1] Sara Daleiden[1] Timucin Taner[2] Kymberly Watt[1], [1]Mayo Clinic Rochester, MN, [2]Mayo Clinic Rochester

Background: Body Mass Index (BMI) is a suboptimal metric for evaluation of living donor candidacy as it fails to accurately reflect visceral adiposity distribution and is affected by muscle and bone mass. Computed Tomography (CT) imaging obtained at the time of live donor evaluations can provide a solution to quantify fat distribution, which can aid in identifying donors at risk of complications. **Methods:** This single center study included 219 living liver donors between 2010-2025, with anthropometric, pre-operative radiological, and procedural data collected during donation and follow-up data for complications and clinical course. The routine pre-operative CT scan for assessment of living donors, was processed through a validated fully automated deep learning body composition analysis pipeline selecting the slice with maximum visceral adipose tissue (VAT) area, subcutaneous adipose tissue (SAT) area and intermuscular adipose tissue (IMAT) area. Visceral-to-subcutaneous adipose tissue area ratio (VSR) was derived by dividing VAT by SAT. Waist circumference was estimated from the same slice, by calculating the contour around the segmented subcutaneous adipose tissue. Cox regression models were designed around these body composition variables to determine predictive potential for post-operative complications following donation. **Results:** Of these 219 donors, mean age was 39.3 years (SD 10.2), with 49% male, a mean BMI of 25.5 (SD 2.9), mean VAT of 84.2 cm^2 (SD 68.8), mean SAT of 187.6 cm^2 (SD 81.2), and mean VSR of 0.46 (SD 0.38). 50 donors had post-operative complications noted in the follow up period. The most common postoperative complications were incisional hernias (n = 18) and bile leaks (n = 9). Unadjusted probabilities for post-operative complications, incisional hernia, and bile leak were reported at 1 month, 3 months, 1 year, and 5 years in figure. Univariate cox regression model fitted to potential predictors of a first post-operative complication of any type showed VSR (per 0.25 increase) as the sole significant association [HR: 1.17 (1.01, 1.37), p = 0.006] (table). A univariate cox regression model and multivariable logistic regression model for the most common post-operative complication i.e. incisional hernia, are shown in table. The multivariable model for incisional hernia indicated BMI [HR 2.67 (1.09, 6.56), P = 0.03] and VSR [HR 1.40 (1.10, 1.78), P = 0.006] as significant predictors. **Conclusion:** CT-derived body composition markers can add to risk evaluation for post-operative complications, particularly post-operative incisional hernia for living liver donors.

Outcome	Factor	Univariate HR (95% CI)	Univariate P-value	Multivariable HR (95% CI)	Multivariable P-value

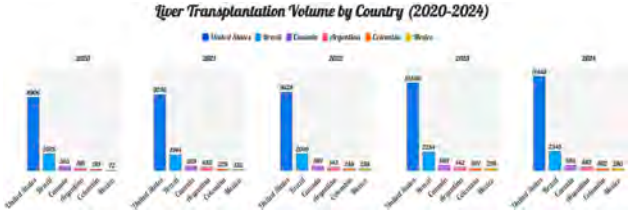
4461 | LIVER TRANSPLANTATION TRENDS AND DONOR UTILIZATION IN THE AMERICAS: A COMPARATIVE ANALYSIS OF USA, BRAZIL, CANADA, ARGENTINA, COLOMBIA, AND MEXICO (2020–2024)



Luis Bogran Perdomo[1] Karla Carias Martinez[2] Pablo Garcia[3] Juan Pineda Paz[4], [1]National Autonomous University of Honduras, [2]Renal Medicine Associates, [3]University Of New Mexico, [4]Centro Endoscopico Hondureno, Honduras

Background: Liver transplantation (LT) is the definitive treatment for end-stage liver disease, yet

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

infrastructure varies across the Americas. While high-income nations expand donor pools via advanced protocols, many Latin American countries face persistent procurement challenges. Understanding regional disparities in donor types: Donation after Brain Death (DBD) versus Donation after Circulatory Death (DCD), is critical for hemispheric health equity. This study analyzes the post-pandemic recovery of the six highest-volume transplant nations in the Americas to identify systemic barriers and opportunities for collaboration. **Methods:** A retrospective analysis was conducted using annual transplant activity data (2020–2024) from the Global Observatory on Donation and Transplantation (GODT). Total LT volumes (deceased/living donors) were evaluated for the USA, Brazil, Canada, Argentina, Colombia, and Mexico. Primary metrics included annual absolute volumes and growth rates. We analyzed DBD and DCD utilization to assess the impact of procurement protocols on regional output. **Results:** The six nations demonstrated a resilient upward trend, with a 49% average volume increase since 2021. The USA achieved a record 11,458 procedures in 2024, driven by aggressive DCD expansion. Brazil leads Latin America in absolute volume (2,345), followed by Canada (655) and Argentina (483). Colombia (302) and Mexico (280) reported steady growth but maintain lower transplant rates per million population relative to disease burdens. **Conclusion:** Regional LT activity has recovered robustly, yet a structural "protocol gap" persists. North American growth is increasingly fueled by DCD and machine perfusion, while Latin American programs remain dependent on DBD. To enhance equity, Mexico and Colombia require legal and technical frameworks supporting DCD expansion. A Pan-American framework is advocated to standardize donor management and share procurement technologies.

4462 | THE INFLUENCE OF DONOR BMI ON POST-TRANSPLANT OUTCOMES IN OLDER VERSUS YOUNGER MARGINAL LIVER RECIPIENTS

Natalie Rosseau[1] Yasmeen Saker[1] Andreas Zori[1],
[1]University of Florida College of Medicine

Background: Increasing liver transplant waitlist registrations have prompted greater utilization of marginal liver donors. As obesity prevalence rises, high-BMI donors will be encountered with increasing frequency, yet the interaction between donor BMI and recipient age on post-transplant outcomes remains poorly characterized. We sought to examine whether donor BMI impacts graft and patient survival differently in older versus younger marginal liver recipients. **Methods:** A retrospective cohort study was conducted of adult marginal liver transplant recipients at the University of Florida between January 2019 and September 2024. Donors were classified as marginal if they met at least one of the following criteria: age >65 years, BMI >30 kg/m², ICU stay >4 days, serum sodium >160 mmol/L, ALT >105 U/L, AST >90 U/L, bilirubin >3 mg/dL, substance use history, extrahepatic malignancy, donation after circulatory death, cold ischemic time >12 hours, or viral hepatitis seropositivity. Recipients were stratified by age at transplant (<60 vs. ≥ 60 years) and donor BMI (<30 vs. ≥ 30 kg/m²). Primary outcome was all-cause mortality; secondary outcomes included 1- and 3-year graft survival. Survival was estimated using the Kaplan-Meier method and compared between groups using the log-rank test, with $p<0.05$ considered statistically significant. **Results:** Of 542 marginal liver transplant recipients, 352 (64.9%) were younger than 60 years and 190 (35.1%) were 60 years or older. Donor BMI was less than 30 kg/m² in 351 recipients (64.8%) and 30 kg/m² or greater in 191 (35.2%). Forty-five deaths occurred over the follow-up period. Donor BMI did not significantly impact all-cause survival overall (log-rank $p=0.279$) or within either age stratum (younger: $p=0.752$; older: $p=0.176$), though older recipients receiving livers from BMI ≥ 30 donors had numerically lower survival than those receiving BMI <30 donors (77.3% vs. 88.6%). One-year graft survival did not differ by donor BMI in younger recipients (97.3% vs. 97.5%, $p=0.909$); however, among older recipients, donor BMI ≥ 30 was associated with significantly lower 1-year graft survival compared to BMI <30 (95.4% vs. 100%, $p=0.017$), but this finding should be interpreted with caution given the small number of events. Three-year graft survival did not differ significantly by donor BMI in either age group (younger: $p=0.788$; older:

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

p = 0.355). **Conclusion:** Donor BMI ≥ 30 kg/m² was significantly associated with lower 1-year graft survival in marginal liver recipients aged 60 years or older (95.4% vs. 100%, p = 0.017), with no significant effect observed in younger recipients. While overall survival and 3-year graft survival did not differ significantly by donor BMI in either age group, older recipients receiving high-BMI donor livers demonstrated consistently lower survival estimates across all outcomes. This difference suggests further study with multi-center data is warranted.

Table 1: Log Rank Summary - donor BMI <30 vs ≥30

Outcome	Stratum	n	Events	Final surv BMI <30	Final surv BMI ≥30	χ^2	p-value
All-cause mortality	Overall	542	45	88.0%	83.3%	1.17	0.279
	Younger (< 60 years)	352	28	87.6%	86.3%	0.10	0.752
	Older (≥60 years)	190	17	88.6%	77.3%	1.83	0.176
1-yr graft survival	Overall	541	12	98.2%	96.8%	1.20	0.274
	Younger (< 60 years)	352	9	97.3%	97.5%	0.01	0.909
	Older (≥60 years)	189	3	100%	95.4%	5.69	0.017
3-yr graft survival	Overall	288	46	84.0%	81.4%	0.53	0.466
	Younger (< 60 years)	195	30	84.0%	83.0%	0.07	0.788

4463 | INTERVENTIONS TO PREVENT RELAPSE IN PATIENTS WITH ALCOHOL ASSOCIATED LIVER DISEASE UNDERGOING LIVER TRANSPLANT ASSESSMENT: A SYSTEMATIC REVIEW AND META-ANALYSES

Dorota Borovsky[1] Simon Oczkowksi[1] Muhammad Usman Ali[1] Susan Abbey[2] Jennifer Chandler[3] Vanessa Gruben[3] Vladimir Marquez[4] Marie Chantal Fortin[5] Sylvia Carbert[6] Theodore Christou[7] Susan Gilmour[8] Fatima Dharsee[9] Marilyn Swinton[1] Prosanto Chaudhury[10] Nazia Selzner[2] Joanna Dionne[1], [1]McMaster University, [2]University Health Network, [3]University of Ottawa, [4]University of British Columbia, [5]Universite de Montreal, [6]Alberta Health Services, [7]Queen's University, [8]University of Alberta, [9]Canadian Blood Services, [10]McGill University

Background: Alcohol associated liver disease (ALD) is one of the leading indications for liver transplantation in Canada. How to best assess and support these patients to prevent relapse pre and post transplant remains a top research priority. The aim of this review was to determine what interventions or programs should be offered to transplant recipients with ALD to help prevent alcohol relapse in the pre and post transplant period. **Methods:** We performed a systematic review and meta-analysis. Medline, Embase and Cochrane databases were searched from inception to October 2025 to identify prospective cohort studies and randomized controlled trials (RCTs). Title/abstract, full-text, risk of bias (ROB) assessment and data extraction were performed in duplicate. A meta-analysis with fixed and random effects models were performed using RevMan version 5.3. Certainty of evidence was assessed using GRADE. **Results:** A total of 9765 citations were identified, and 16 studies were included in the meta-analysis. The majority of studies were of high ROB. Multidisciplinary team approach and addictions counselling did result in a reduced rate of harmful drinking relapse (RR 0.55, 95% CI 0.32, 0.94) and improved all-cause mortality (RR 0.28, 95%CI0.13, 0.64). Harm reduction strategies and pharmacotherapy had an uncertain effect on rate of relapse (RR 0.95, 95%CI 0.48-1.87). The overall certainty of evidence was low. **Conclusion:** The use of multidisciplinary teams and addiction counsellings can be beneficial to prevent relapse in patients with ALD and improve overall mortality.

4464 | PERSISTENT SEX-BASED INEQUITIES IN LIVER TRANSPLANTATION FOR HEPATOCELLULAR CARCINOMA DESPITE MEDIAN MELD AT TRANSPLANT MINUS THREE (MMAT-3) EXCEPTION POLICY REFORM

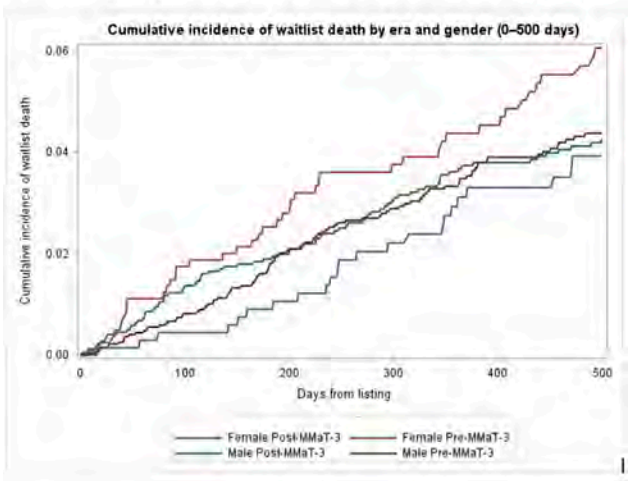
Shirley Eng[1] Ahmed Aboseria[1] Sanjaya Satapathy[2], [1]Zucker School of Medicine/Northwell Health, [2]North Shore University Hospital/Northwell Health

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: The median MELD at transplant minus 3 (MMaT-3) policy was implemented to reduce geographic inequities in liver allocation among hepatocellular carcinoma (HCC) candidates however whether this policy change differentially affects candidates by sex remains unclear. **Methods:** We performed a retrospective cohort study using UNOS/OPTN data including adult HCC exception candidates listed in the pre–MMaT-3 (August 2017–November 2018) and post–MMaT-3 (June 2019–August 2020) eras. The primary outcome was waitlist mortality, analyzed using cause-specific Cox proportional hazards models with transplantation treated as a competing event. Fine–Gray models evaluated transplant probability and waitlist dropout. Models adjusted for age, MELD score, serum sodium, and diabetes. Sex-by-era interaction analyses assessed differential policy effects. **Results:** Among 6,467 candidates (23.2% female), post-MMaT-3 era was associated with lower waitlist mortality (HR 0.87, 95% CI 0.77–0.98, p = 0.028) and female sex with reduced mortality (HR 0.83, 95% CI 0.71–1.00, p = 0.038) (Figure 1). However, no significant sex-by-era interaction was observed (p = 0.54), indicating that MMaT-3 did not differentially affect outcomes by sex. Stratified analyses demonstrated lower female mortality in the pre-policy era (HR 0.84, p = 0.048), which attenuated after MMaT-3 implementation (HR 0.91, p = 0.32). Post–MMaT-3 mortality reduction was significant among males only. No significant differences were observed in transplant probability or waitlist dropout by sex or sex-by-era interaction, and non-death dropout consistently exceeded waitlist mortality across all subgroups. **Conclusion:** MMaT-3 implementation was associated with modest improvement in overall waitlist mortality among HCC candidates, but this improvement appeared to be primarily driven by male candidates, whereas outcomes among females remained largely unchanged. Despite this, there was no significant interaction between era and sex on transplant dropout or mortality. Transplant probability remained largely unchanged across eras and between sexes, as demonstrated in cumulative incidence curves (Figure 2). This indicates that the observed reduction in mortality was not driven by increased transplant access but may instead reflect more nuanced changes in allocation timing, prioritization, or candidate selection. Thus, while allocation reforms may improve overall outcomes, additional targeted strategies may be needed to address persistent sex-related inequities in liver transplantation.

Figure 1. Cumulative incidence of waitlist death among HCC candidates stratified by gender and MMaT-3 era
Cumulative incidence functions were estimated using Fine-Gray competing risks methodology with liver transplantation treated as a competing event. Prior to MMaT-3, female candidates demonstrated a higher cumulative incidence of waitlist death compared to males. Following MMaT-3, this pattern reversed, with females exhibiting lower mortality than males, suggesting a shift in gender disparities under the revised allocation policy.



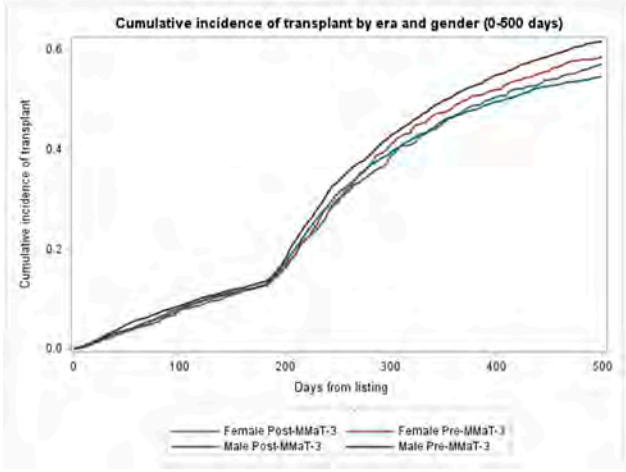


Figure 2. Cumulative incidence of transplant among hepatocellular carcinoma candidates by gender and MMaT-3 era
Cumulative incidence functions were estimated with waitlist dropout treated as a competing event. Curves were broadly similar across gender and era groups, consistent with adjusted Fine-Gray analyses showing no significant interaction between gender and MMaT-3 era for transplant probability.

4465 | COMPARISON OF EARLY VERSUS LATE COMPLICATIONS AFTER LIVING DONOR LIVER TRANSPLANTATION

James Mo[1] Nemie Beltran[1] Maria Zanini[1] Deepak Venkat[1] Syed-Mohammed Jafri[1], [1]Henry Ford Health System

Background: Due to the limited availability of deceased donor livers, living donor liver transplantation (LDLT) has emerged as an important alternative. However, post-operative outcomes after LDLT remain incompletely characterized. We aimed to compare the complications occurring within 3 months versus beyond 3 months of receiving an LDLT. **Methods:** We retrospectively reviewed all adult LDLT recipients at a single tertiary center from 2015 to 2025. Patient characteristics and post-transplant outcomes were collected through manual chart review. **Results:** A total of 76 patients received an LDLT. Of these, 57.9% were male and 90.8% were Caucasian, with a mean age of transplantation of 56 years (range 18 to 75). Etiologies of cirrhosis included alcohol (17.1%), MASH (40.8%), PSC (23.7%), PBC (7.9%), hepatitis C (5.3%), and other causes (5.3%); 7.9% of patients also had hepatocellular carcinoma. Regarding vascular complications, portal vein thrombosis/stenosis was diagnosed in 9 patients (11.8%) within 3 months of LDLT and in 5 (6.6%) beyond 3 months. None developed hepatic vein stenosis within 3 months, whereas 4 (5.3%) were beyond 3 months. Hepatic artery thrombosis/stenosis occurred in 5 patients (6.6%) within 3 months and in 3 (3.9%) beyond 3 months. Among biliary complications, bile leaks occurred in 18 patients (23.7%) within 3 months compared to 8 (10.5%) beyond 3 months. Biliary strictures were diagnosed in 18 patients (23.7%) within 3 months versus 22 (28.9%) beyond 3 months. Incisional hernias were seen in 2 patients (2.6%) within 3 months and in 10 (13.2%) beyond 3 months. Re-operative interventions were required in 13 patients (17.1%) within 3 months, including exploratory surgeries, re-do transplantations, and hepaticojejunostomies. Six patients (7.9%) required additional surgical intervention beyond 3 months. Only 1 patient required dialysis, which occurred within 3 months post-transplant. No patients experienced primary nonfunction or underwent re-transplantation. Four patients (5.3%) died within 3 months of LDLT. **Conclusion:** In this single-center cohort of LDLT recipients, complication patterns differed by timing after transplantation. Early complications within 3 months were predominantly vascular, bile leaks, and the need for re-operative interventions, whereas later complications were more frequently related to biliary strictures and incisional hernias. Understanding the timing of complications after LDLT may help inform post-transplant management strategies and patient counseling.

4466 | MAPPING THE GLOBAL LIVER TRANSPLANT LANDSCAPE

Rym Yousfi[1] Hanna Blaney[2] Juan Pablo Arab[2], [1]Virginia Commonwealth University School of Medicine, [2]Virginia Commonwealth University

Background: Liver transplantation (LT) is life-saving for select patients with advanced chronic liver disease and acute liver failure, but global access depends on transplant infrastructure, donor availability, and health system capacity. Alcohol-associated liver disease (ALD) is a major indication for LT worldwide, and severe alcohol-associated hepatitis (AH) carries high short-term mortality. This study aimed to characterize global and regional variation in LT availability and reported transplant activity, with attention to the availability of LT for AH. **Methods:** We performed a descriptive country-level analysis of LT availability and activity across 193 countries using publicly available transplant registry and country-level sources. Variables included LT availability, donor type distribution, and annual LT volume from 2011–2024. Transplant indications across regions were also examined, with particular attention to AH. Countries were grouped by geographic region to compare access and reported transplant activity. **Results:** LT availability data were available for 188 countries; 89 offered LT (47.3%). Availability varied substantially by region: Europe 34/42 (81.0%), North America 8/23 (34.8%), South America 8/10 (80.0%), Asia 33/48 (68.8%), Australia/Oceania 2/14 (14.3%), and Africa 5/54 (9.3%). Within the North America region, availability was concentrated in Canada, the United States and Mexico, with more limited availability across Central America and the Caribbean. (Figure 1A). Among the 62 total countries with donor-type data, deceased donor LT (DDLT) predominated, with a median of 93% of LTs DDLT versus 7% living donor LT (LDLT), with marked country and regional variation (Figure 1B). In 2024, 64 countries reported 43,310 LTs globally. Reported volume was highest in Asia (18,103), North America (12,113), and Europe (10,238), and lowest in Africa (65). Reported annual LT volume generally increased over time in regions with available longitudinal data, though interpretation is limited by variable reporting. Etiology-specific reporting was limited, with no publicly available country-level data identifying LTs performed for AH. **Conclusion:** LT availability varies markedly globally, with limited access across many countries in Africa,

Oceania, and the Caribbean. Access for AH is likely even more limited, but remains difficult to assess with publicly available data due to sparse etiology-specific reporting. These findings support expanded transplant infrastructure, standardized reporting, and international collaboration to improve access for patients with all forms of liver disease, including AH.

4467 | POLYCYSTIC DISEASE ACROSS ORGANS: ERA-LINKED SHIFTS IN ACCESS, TIMING, AND OUTCOMES IN SINGLE-CENTER KIDNEY(PKD) AND LIVER (PLD) TRANSPLANTATION

Nishtha Singh[1] Emily Schonfeld[2] Russell Rosenblatt[3] Rebecca Craig-Schapiro[3] Juan Rocca[2] Danielle Brandman[3] Benjamin Samstein[3] Sandip Kapur[3] Dustin Carpenter[3], [1]NewYork-Presbyterian/Weill Cornell Medical College, [2]NewYork-Presbyterian/Weill Cornell Medical Center, [3]Weill Cornell Medicine

Background: Polycystic disease spans kidney and liver failure pathways yet faces distinct allocation challenges:PKD timing is often framed by dialysis exposure,while PLD symptom burden may be underestimated by laboratory MELD.We evaluated how major U.S.allocation-era transitions aligned with access,logistics,and outcomes in PKD kidney and PLD liver transplantation at a high-volume center. **Methods:** Retrospective OPTN/UNOS donor–recipient export(1990–present).PKD kidney transplants were identified by primary diagnosis at transplant and/or listing;PLD liver transplants by primary diagnosis at transplant("Benign tumor:polycystic liver disease").Eras by transplant date:Pre-MELD(< 2/27/2002),MELD(2/27/2002–1/10/2016),MELD-Na(1/11/2016–2/3/2020), MMaT/Acuity Circles(≥ 2/4/2020).Era comparisons used Kruskal–Wallis/chi-square. PKD graft survival was Kaplan–Meier;multivariable logistic regression modeled dialysis at transplant(yes/no).PLD survival was summarized as crude survival among recipients with ≥ 1-,3-,5-year follow-up. **Results:** PKD:591 kidney transplants(Pre-MELD81;MELD269;MELD-Na102; MMaT/Acuity142).Recipient age increased (50.0→57.0y;$p < 0.001$) while dialysis at transplant declined(85.2%Pre-MELD vs44–56%later;$p < 0.001$). Living donation increased($p < 0.001$) and DCD use rose to18.3% in MMaT/Acuity($p < 0.001$);LOS decreased (6→4d;$p < 0.001$).Kaplan–Meier graft survival was95.5%(1y),93.7%(3y),90.8%(5y).Adjusted odds of dialysis were lower vs Pre-MELD:MELD aOR0.23, MELD-Na0.17,MMaT/Acuity0.09(all $p < 0.001$);living donation was protective(aOR0.23;$p < 0.001$) and longer wait increased odds(aOR1.27 per log-day;$p < 0.001$). PLD:25 liver transplants(MMaT/Acuity18;MELD-Na6; MELD1) with low lab MELD overall(median12.0 [9.0–20.0]).Waitlist time was shorter in MMaT/Acuity (32.5[20.5–113.0]d) vs MELD-Na(247.0[127.5–327.5]d; $p = 0.034$) with greater national sharing in MMaT/Acuity (77.8% vs83.3% local in MELD-Na;$p = 0.014$).Crude survival was84.2%(1y),80.0%(3y),85.7%(5y). **Conclusion:** Across allocation eras,polycystic disease transplantation demonstrated measurable gains in timely access—reduced dialysis dependence for PKD and shorter wait time with broader sharing for PLD—while maintaining strong medium-term outcomes;PLD findings are hypothesis-generating given small numbers.

4468 | A NON-INFLAMMATORY DIET-INDUCED MODEL OF DONOR HEPATIC STEATOSIS

Mobin Ibne Mokbul[1] Jack R. Cahill[2] Hidemi Nishi[2] Usman Yaqoob[2] Caixin Qiu[2] Jayla T. Millender[2] Purnima Tyagi[2] Meng Yin[1] Nidhi Jalan-Sakrikar[2] Timucin Taner[2] Robert Huebert[2], [1]Mayo Clinic, [2]Mayo Clinic Rochester

Background: Bland hepatic steatosis without accompanying inflammation or fibrosis in donor livers represents a common but important clinical challenge in transplantation, given the high discard rate of steatotic donor livers. However, robust and reproducible preclinical models that accurately represent this phenotype remain limited. We aimed to establish a diet-induced rat model of isolated hepatic steatosis to resemble discarded human donor livers. **Methods:** Forty Wistar rats (20 male, 20 female) were assigned to control or high-fat diet groups and studied across 4-week and 8-week feeding cohorts. The high-fat and high-fructose diet (HFHFrD) consisted of 45% kcal from fat (predominantly oleic acid to reduce hepatic inflammation) with 10% fructose supplementation in drinking water. Ultrasound and magnetic resonance imaging–proton density fat fraction (MRI-PDFF) was performed prior to tissue collection. Animals were further evaluated using serum liver injury markers and histology (oil red O, H&E, picrosirius red, and Mason's trichome). **Results:** Ultrasound and MRI-PDFF confirmed progressive hepatic fat accumulation in the high-fat diet group (4 weeks: 3.08 vs. 7.53, $p = 0.002$, 8 weeks: 4.57 vs. 9.47, $p = 0.008$), with significantly greater and more rapid steatosis observed in male rats compared to females. Serum ALT ($p = 0.48$) and AST ($p = 0.11$) levels did not differ significantly between high-fat and control groups, indicating the absence of hepatocellular injury. Histological analysis with hematoxylin and eosin staining demonstrated prominent micro- and macrovesicular steatosis in the HFHFrD group, without evidence of steatohepatitis or fibrosis. Oil Red O staining on liver tissues revealed significant effects of diet, sex, and time on lipid accumulation across groups. In line with the MRI data, at 4 weeks, the HFHFrD markedly increased lipid deposition in males (0.95 vs. 16.02, $p = 0.02$), but not in females (0.03 vs. 0.07, $p = 0.99$). However, at 8 weeks, both male and female groups showed significant steatosis. Interestingly, there was no further increase in steatosis between males at 4 or 8 weeks after the HFHFrD ($p = 0.98$). The absence of fibrosis in all rats was further confirmed by both picrosirius red and Mason's trichome staining. Therefore, we propose that male rats fed for 4 weeks with the HFHFrD represents the most rapid non-inflammatory steatosis model for transplant research applications. **Conclusion:** We report a rapid and reproducible dietary model of bland hepatic steatosis in rodents. The model is characterized by significant lipid accumulation in the absence of steatohepatitis or fibrosis. This model closely resembles human donor liver steatosis and may serve as a valuable platform for transplantation research and the development of therapeutics for deployment during normothermic machine perfusion.

4469 | ◆ ASSOCIATION BETWEEN MICROBIAL METABOLITES AND TACROLIMUS PHARMACOKINETICS AFTER LIVER TRANSPLANT

Yael Nobel[1] Rebecca Yeh[1] Serge Cremers[1] Anne-Catrin Uhlemann[1] Elizabeth Verna[1], [1]Columbia University Irving Medical Center

Background: Tacrolimus (TAC) is the cornerstone of immunosuppression after liver transplant (LT). Individual dose-response (drug levels following a given dose of TAC) varies widely between patients, which can lead to under- or over-dosing and risk of allograft rejection or drug toxicity. Microbial metabolites, including bile acids (BA) and short-chain fatty acids (SCFA), are plausible modifiers of TAC pharmacokinetics via effects on host enzymatic (CYP3A) and efflux pump (P-glycoprotein) activity. **Methods:** LT recipients receiving TAC underwent two timed whole blood collections at one month post-LT: approximately 1.5 hours (peak) and 12 hours (trough) after TAC dose. A pharmacokinetic modeling approach was applied to calculate true simulated peak and trough TAC concentration accounting for sample timing variation. Plasma microbial metabolites, including BA and SCFA, were measured. Dietary questionnaires, clinical data, and use of CYP inhibiting- or inducing-drugs at time of sample were collected. Correlations were assessed between microbial metabolite concentrations and dose-normalized TAC trough level, peak level, and peak-to-trough ratio. **Results:** In this pilot study, 17 participants have been analyzed. 53% were male and median age was 49 years (IQR 45-62). CYP inhibitors were used by 41% of patients and median dietary fat intake was 33% of calories (IQR 31-38%). Median peak and trough TAC levels were 9.3 (7.0-15.3) and 5.1 (3.9-6.1) ng/mL, respectively. Glycochenodeoxycholic acid (GCDCA) was the most abundant BA (median 1,841 [IQR 734-2,310] ng/mL). GCDCA was positively correlated with dose normalized TAC trough level (Spearman $r = 0.60$, $p = 0.01$) and negatively correlated with peak-to-trough ratio ($r = -0.55$, $p = 0.02$) (Figure). Ursodeoxycholic acid (UDCA) ($r = 0.60$, $p = 0.01$) and its taurine-conjugated metabolite (TUDCA) ($r = 0.48$, $p = 0.05$) were also positively correlated with trough level. In multivariable linear regression adjusting for age, sex, and use of CYP inhibitors or inducers, GCDCA remained positively associated with TAC trough level ($p = 0.05$) and inversely associated with peak-to-trough ratio ($p = 0.02$). No significant associations were identified between SCFA and TAC parameters. **Conclusion:** Plasma concentration of GCDCA was associated with increased TAC trough levels and, correspondingly, inversely associated with peak-to-trough ratio. This finding is consistent with preclinical models in which GCDCA competitively inhibits CYP3A activity and inhibits P-glycoprotein efflux pump. The microbiome may contribute to inter-patient variability in TAC dose-response after LT via BAs, and BA levels could offer a future target to help guide personalized dose selection.

Figure. Spearman correlations of plasma GCDCA concentration (ng/mL) with **(A)** dose-normalized peak tacrolimus concentration (ng/mL), **(B)** dose-normalized trough tacrolimus concentration (ng/mL), and **(C)** ratio of tacrolimus peak level to tacrolimus trough level.

Hospital, [2]Division of Gastroenterology, Beth Israel Deaconess Medical Center, Harvard Medical School, [3]Houston Methodist

Background: Early bacterial infections (BI) following liver transplantation (LT) remain a major cause of morbidity and mortality; however, the epidemiology and determinants of multidrug-resistant bacterial infections (MDRBIs) in the immediate post-LT period remain poorly characterized. We aimed to define the incidence, microbiologic spectrum, and risk factors associated with MBRBIs within 90 days after LT. **Methods:** This was a single-center retrospective cohort study of adult LT recipients (1/2016–4/2025). Patients with at least one culture-positive BI within 90 days were included. MDRBI was defined as resistance to ≥3 antimicrobial classes. Culture sources included blood, urine, respiratory tract specimens, cerebrospinal fluid, fluid from organized collections or abscesses, and bile. The primary outcome was incidence of MDRBI. Multivariable logistic regression was performed to identify independent risk factors associated with MDRBI, with candidate variables selected based on clinical relevance and significance in univariable analyses. **Results:** Of 1,787 LT recipients, 524 (29%) developed at least one culture-positive BI within 90 days; 392 met MDRBI criteria, yielding an overall incidence of 22%. There were no significant differences in age, race, MELD 3.0 scores or cirrhosis etiology between patients who developed MDRBI and those who did not. However, patients with MDRBI were more likely exposed to ciprofloxacin within 3 months pre-LT (13% vs 4%, p = 0.007). Among 515 MDRBI episodes (576 pathogens, 45 polymicrobial), the most common infection sites were urinary tract (n = 176), pulmonary (n = 161), blood (n = 104), skin/soft tissue (n = 98), and intra-abdominal (n = 34). Gram-negative organisms predominated: *Klebsiella pneumoniae* (n = 148), *Escherichia coli* (n = 83), and *Pseudomonas aeruginosa* (n = 40). Key gram-positive organisms included *Enterococcus faecium* (n = 84), coagulase-negative Staphylococci (n = 30), and *Staphylococcus aureus* (n = 23). On multivariable analysis, pre-LT ciprofloxacin exposure (OR 3.48, 95% CI 1.31–9.23, p = 0.01) and MELD-3.0 score (OR 1.03/point increase, 95% CI 1.00–1.06, p = 0.03) were independently associated with MDRBI development (**Table 1**). **Conclusion:** MDBRIs occur frequently within the first 90 days after LT and are predominantly driven by gram-negative pathogens from pulmonary and urinary sources. Pre-LT ciprofloxacin exposure was independently associated with subsequent MDRBI development, highlighting a potentially modifiable risk factor. These findings support reassessment of current spontaneous bacterial peritonitis prophylaxis strategies and highlight the importance of antimicrobial stewardship approaches among high-risk LT candidates and recipients.
