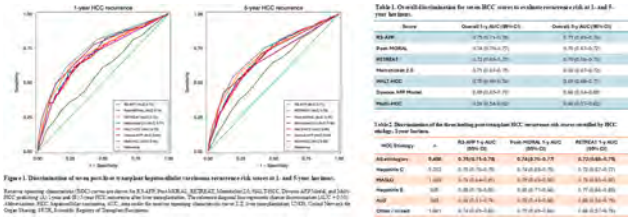
4471 | ◆ EXTERNAL VALIDATION OF POST-LIVER TRANSPLANT RISK SCORES FOR HEPATOCELLULAR CARCINOMA RECURRENCE IN LIVER TRANSPLANT RECIPIENTS



Leandro Sierra[1] Butros Fakhoury[2] Na Bo[3] Juan Pablo Arab[2] Neil Mehta[4] Amit Singal[5], [1]Cleveland Clinic Foundation, [2]Virginia Commonwealth University School of Medicine, Richmond, VA, USA, [3]Virginia Commonwealth University, Richmond, VA, USA., [4]University of California San Francisco, San Francisco, CA, USA, [5]The University of Texas Southwestern Medical Center, Dallas, TX, USA

Background: Multiple risk scores have been proposed to predict hepatocellular carcinoma (HCC) recurrence after liver transplant (LT). However, head-to-head comparisons in a national cohort are lacking. We assessed the performance of post-LT HCC recurrence risk scores stratified by median MELD at Transplant minus three points (MMaT-3 era) and HCC etiology. **Methods:** Using the United Network for Organ Sharing/Scientific Registry of Transplant Recipients (UNOS/SRTR) database, we performed an external validation of 7 prognostic scores: HALT-HCC, Multi-HCC, the Duvoux AFP Model, Metroticket 2.0, RETREAT, R3-AFP, and Post-MORAL. We included adult recipients transplanted for HCC and excluded those with prior LT, fibrolamellar HCC, mixed HCC-cholangiocarcinoma, multiorgan transplantation, and missing explant data. Scores were calculated from variables at transplant and/or explant pathology. Primary outcomes were HCC recurrence at 1 and 5 years post-LT. Discrimination was assessed by area under the ROC (AUC) curve with pairwise DeLong comparisons. Risk stratification was evaluated across score quartiles using Fine-Gray competing risk models, treating death as a competing event. Subgroup analyses were performed by allocation policy era (pre- vs post-MMaT-3) and HCC etiology. **Results:** Among 9,450 LT recipients with HCC, recurrence developed in 3.0% at 1 year and 8.1% at 5 years. Diagnostic performance of each model is detailed in **Table 1** . R3-AFP achieved the highest 1-year discrimination (AUC 0.75), which was comparable to Post-MORAL (AUC 0.74; $p = 0.10$) and significantly higher than RETREAT (AUC 0.72; head-to-head $p = 0.02$). Metroticket 2.0 (AUC 0.71), HALT-HCC (AUC 0.70), Duvoux AFP (AUC 0.69), and Multi-HCC (AUC 0.58) (global $p < 0.001$). The same pattern was observed at 5 years. From Q1 to Q4, the 5-year cumulative recurrence rate rose from 9% to 18% with R3-AFP (subhazard ratio [SHR] 5.79, 95%CI 4.77–7.02), from 9% to 20% with Post-MORAL (SHR 6.04), and from 9% to 23% with RETREAT (SHR 7.27) (all p-trend < 0.001). In subgroup analyses, 1-year discrimination improved in the post-MMaT-3 era for R3-AFP (AUC 0.85 vs 0.74; $p = 0.004$) and Post-MORAL (AUC 0.87 vs 0.72; $p = 0.001$) but not

RETREAT (p = 0.61); performance of these scores at 1 year remained consistent across most liver disease etiologies (AUC 0.74–0.85) but was attenuated in alcohol-associated liver disease (R3-AFP AUC 0.62; Post-MORAL AUC 0.55) (**Table 2**). **Conclusion:** In a representative U.S. cohort, R3-AFP and Post-MORAL achieved the highest discrimination for post-LT HCC recurrence at both 1- and 5-year horizons, including improved diagnostic performance in the MMaT-3 allocation era. These risk scores can be adopted to guide post-LT HCC surveillance and future tertiary prevention strategies.

4473 | ◆ IMPACT OF PRIOR BARIATRIC SURGERY ON MORTALITY, HOSPITAL UTILIZATION, AND GRAFT OUTCOMES AFTER LIVER TRANSPLANTATION: A TRINETX RETROSPECTIVE PROPENSITY-MATCHED COHORT STUDY

Peter Mounas[1] Mikaela Nikkola Jara-Tantoco[1] Abiodun Idowu[1] Maria Lagarde Mussa[1], [1]Jefferson Einstein Philadelphia Hospital

Background: Obesity is a major driver of metabolic dysfunction-associated steatotic liver disease (MASLD), putting patients at risk of complications including cirrhosis and hepatocellular carcinoma. Bariatric surgery has shown to improve outcomes in obese patients, which may improve transplant candidacy. There have been studies positing that bariatric surgery can lead to increased mortality and rejection due to malnutrition and malabsorption. Data is limited regarding long-term outcomes such as mortality, transplant graft rejection, and hospital utilization in patients with prior bariatric surgery. **Methods:** This retrospective cohort study used the TriNetX US Collaborative Network, encompassing 67 healthcare organizations. Adult liver transplant patients (> 18 years) were identified using CPT, ICD-10, and procedural transplant codes. Patients with a history of bariatric surgery prior to transplant were identified using CPT codes and ICD-10 codes for sleeve gastrectomy, Roux-en-Y gastric bypass, adjustable gastric banding, and biliopancreatic diversion procedures. Propensity score matching (1:1) adjusted for demographics, metabolic disease, liver disease etiology, MELD score, and immunosuppressive medication exposure (see table 1). After matching, outcomes of mortality, transplant graft rejection, and hospital utilization were compared using Kaplan-Meier survival analysis and hazard ratios. E-value was measured for each outcome to determine the effect of unmeasured confounders. **Results:** After propensity score matching, 2,006 patients remained in each cohort for analysis. There was significantly increased hazard of all-cause mortality (HR 1.156 CI 1.002-1.334), inpatient hospitalization (HR 1.288 CI 1.041-1.594), ICU admission (1.168 CI 1.002-1.361), and graft outcomes (1.300 CI 1.141-1.481) in patients with prior bariatric surgery compared to liver transplant recipients alone (all p < 0.05). Moreover, when E-values were computed for these outcomes, HR and their CI were found below their respective E values (see table 2). **Conclusion:** In this propensity-matched, multi-institutional cohort, bariatric surgery prior to liver transplant was associated with an increased hazard in mortality, hospital utilization and transplant graft rejection, highlighting its less favorable outcomes. Factors such as malnutrition can contribute to worsening outcomes in bariatric surgery patients. Some limitations of the study include TriNetX reliance on ICD coding, which may introduce coding inaccuracies and bias. Future studies can be beneficial in understanding the effects of nutritional status, bariatric surgery timing, and surgical subtypes.

4474 | ◆ BEYOND REJECTION DETECTION: PRECISION IMMUNOSUPPRESSION UTILIZING DONOR-DERIVED CELL-FREE DNA AS A DYNAMIC BIOMARKER AFTER LIVER TRANSPLANTATION

Alexander Frangenberg[1] Kinnari Modi[1] Kyle Schneider[1] Khushbu Tejani[2] Kanish Mohib[2] Parvez Mantry[1], [1]Methodist Dallas Medical Center, Dallas, Texas, USA, [2]CareDx,Inc., California, USA

Background: Immunosuppression (IS) management in liver transplant recipients requires balancing rejection prevention with risks of renal toxicity, infection, and malignancy to improve survival and morbidity. Current IS adjustment strategies rely primarily on liver enzyme monitoring, which may result in late detection of allograft rejection. This study evaluates the utility of donor-derived cell-free DNA (dd-cfDNA) as a serum marker to guide IS titration in liver transplant recipients. **Methods:** We retrospectively analyzed 154 liver transplant recipients with stable liver function tests (LFTs) who underwent dd-cfDNA testing (AlloSure, CareDx Inc) between August 2021 and January 2026 at a single medical center. Based on dd-cfDNA levels, patients were categorized into three IS management cohorts: Stable (no IS change), decreased IS (DIS), and increased IS (IIS). Statistical analyses included Kruskal Wallis, Mann Whitney U, and Wilcoxon signed rank tests. **Results:** Of 134 patients, dd-cfDNA levels guided categorization into: Stable (n = 84), DIS (n = 37), and IIS (n = 13). Age and LFTs were comparable across groups. The DIS group showed significantly lower median pre-adjustment dd-cfDNA levels compared to the IIS group (1.8%; IQR 1.0-3.4% vs. 9.8%; 5.3-15.5%, p = < 0.0001). Post-adjustment, DIS group dd-cfDNA levels remained stable (2.6%; 1.5-3.8% vs. 1.8%; 1.0-3.4%, p = 0.32). In the IIS group, dd-cfDNA levels decreased in 75% of patients, achieving levels comparable to stable patients (3.2%; 2.8-13% vs. 2.9%; 1.8-5.0%, p = 0.035). Based on dd-cfDNA results, 93% of patients underwent any class medication down titration adjustment of therapy, with 78% down titrating CNI levels. Of the patients, 95% maintained stable AST and ALT post-titration. Eight post-titration biopsies showed no rejection. **Conclusion:** Donor-derived cell-free DNA testing appears to be an effective biomarker for guiding immunosuppression management in stable liver transplant recipients. The successful medication adjustments in down titration of 93% of patients, with maintained stability post-titration, suggests dd-cfDNA monitoring enables more precise immunosuppression optimization compared to traditional liver enzyme monitoring alone. These findings support incorporating dd-cfDNA testing into post-transplant monitoring protocols for identifying candidates suitable for IS reduction thus reducing risk of systemic toxicity, though further prospective studies are needed to validate these results.

Table 1: Clinical Characteristics, Medication Adjustments, and Outcomes

Parameter	Stable (n=84)	Augmented IS (n=13)	Decreased IS (n=37)
Laboratory Values			
Prior to IS Adjustment, AST (u/L), median (IQR)	19 (19-28)	59.5 (31-102)	21 (16-25)

★ 4475 | ◆ LOW-DOSE ORAL METHYLPREDNISOLONE REVERSES INTRAHEPATIC FIBROSIS AFTER PEDIATRIC LIVER TRANSPLANTATION BY ELIMINATING CD206⁺HLA-DR⁺CD14⁺ MACROPHAGE

Yuan Liu[1] Bingran Wang[2] Qiang Xia[2], [1]Renji Hospital affiliated to Shanghai Jiao Tong University, [2]Renji Hospital affiliated to Shanghai Jiao Tong University School of Medicine

Background: Liver transplantation is the most effective treatment for pediatric patients with end-stage liver diseases, with 10-year survival rate exceeded 90%. However, intrahepatic fibrosis has emerged as a significant long-term threat to graft survival. Nearly 30% of recipients were found fibrosis within the first year after LT, and this proportion increases to over 70% at 10 years. Currently, no therapy has been established for the treatment of graft fibrosis after LT. Methylprednisolone (MP) has been widely used in the treatment of autoimmune hepatitis. However, its role in reversing graft fibrosis after LT remains largely unexplored. **Methods:** We conducted a prospective clinical study involving pediatric LT recipients who were diagnosed with intrahepatic fibrosis during protocol liver biopsy. Rcipients with LAFSc >2 were enrolled for oral MP treatment. Depending on fibrosis severity, the initial dosage of MP was 8-20 mg/day and was gradually tapered every 2 weeks, after which maintained at 4 mg/day for 6–12 months. Follow-up liver biopsies were subsequently performed to evaluate fibrosis progression or regression. In parallel, mass cytometry (CyTOF) was performed to analyze changes in the intrahepatic immune microenvironment before and after treatment. **Results:** Between June 2023 and March 2026, 705 pediatric LT recipients underwent protocol liver biopsy at Renji Hospital. Among them, 141 recipients (20.0%) were found to have intrahepatic fibrosis, with a mean follow-up duration of 48.3 months. Of these patients, 123 recipients were classified as LAFSc >2, and 95 recipients received MP treatment. The average treatment duration was 12.9 months. Among all treated participants, 65 recipients (68.4%) demonstrated fibrosis improvement or complete resolution. After treatment, the average LAFSc decreased from 3.449 to 0.849, with inflammation grade was reduced from 1.688 to 0.182. In addition, the average FibroScan decreased from 9.71 to 6.96 kPa. No significant metabolic adverse effects were observed during treatment. CyTOF analysis revealed that CD206⁺HLA-DR⁺CD14⁺ macrophages accumulated predominantly in the peripheral regions surrounding fibrotic scars, and MP treatment markedly reduced this macrophage subset. *In vitro* analyses indicated intrahepatic CD206⁺HLA-DR⁺CD14⁺ macrophages could secrete pro-inflammatory cytokines following stimulation. Interestingly, recipients who were resistant to MP treatment exhibited lower levels of CD206⁺HLA-DR⁺CD14⁺ macrophage infiltration. Instead, a distinct CD11c⁺HLA-DR⁺ DC subset was enriched within the fibrotic core regions of these recipients. The abundance of CD11c⁺HLA-DR⁺ DC increased progressively with worsening graft fibrosis, even after MP treatment. **Conclusion:** Low-dose oral MP may effectively reverse intrahepatic fibrosis after pediatric LT by inhibiting the function of CD206⁺HLA-DR⁺CD14⁺ macrophages.

4476 | ◆ MACHINE LEARNING OUTPERFORMS MELD AND IDENTIFIES SOCIAL DETERMINANTS AS KEY PREDICTORS OF POST-TRANSPLANT SURVIVAL

Chiwoo Song[1] Myna Lim[2] Jaekyoung Kim[2] Raza Malik[3], [1]Roger Williams Medical Center, [2]KAIST, South Korea, [3]Lahey Hospital & Medical Center

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: The Model for End-Stage Liver Disease (MELD) score was introduced as an organ allocation system to reduce waitlist mortality and has become the most widely used tool. However, it does not reliably predict post-transplant survival. Originally derived using linear regression, MELD may oversimplify complex, non-linear interactions among recipient, donor, and perioperative factors. Certain machine learning algorithms offer the ability to model such interactions while addressing the "black box" limitation. This study aimed to develop an improved and interpretable prediction model for post-transplant outcomes and to identify key influential factors. **Methods:** We retrospectively analyzed adult patients who underwent liver transplant at a single academic center from 2000 to 2024, collecting >200 variables across five domains: MELD score, preoperative, donor, surgical, and postoperative. Post-transplant survival predictions at 90 days, 1 year, and long-term (>1 year) were modeled using CatBoost for short-term and Random Survival Forest (RSF) for long-term, evaluated by the area under the receiver operating characteristic curve (AUROC). To assess the incremental value of clinically available data over time, sequential models were constructed using progressively added data domains: MELD-only, preoperative, donor, surgical, and postoperative variables. Shapley Additive Explanations (SHAP) values quantified each variable's contribution to model predictions. **Results:** A total of 1,655 recipients were included. Sequential CatBoost models outperformed MELD alone, with AUROC improving from 0.567 to 0.786 for 90-day and 0.587 to 0.770 for 1-year mortality (Figures 1-1, 1-2). SHAP analysis identified "primary language" as the most influential predictor at all timepoints, with non-English primary language predicting poorer outcomes independent of clinical severity. Insurance type and race were additional SDOH predictors in preoperative models. Adverse clinical predictors included MELD >30, BUN >40 mg/dL, cold ischemia time >300 minutes, and serum sodium <130 mmol/L one day prior LT. In contrast, favorable predictors included English primary language, private insurance, outpatient evaluation, and living donor grafts (Figures 2-1, 2-2). RSF analysis confirmed primary language as a significant predictor beyond 1 year, with predictor importance varying dynamically across 1-, 3-, 5-, and 10-year timepoints (Figure 3). **Conclusion:** Our models outperformed MELD alone in predicting post-transplant mortality. They consistently identified "primary language," likely reflecting underlying SDOH, as a significant prognostic factor across all prediction timepoints, highlighting the importance of incorporating SDOH into risk stratification.

[2]University of Toronto, [3]University of California, Irvine, [4]Department of Computer Science, University of Toronto, Toronto, ON, Canada., [5]Princess Margaret Cancer Centre, University Health Network, Toronto, ON, Canada, [6]Institute for Pathology, Hannover Medical School, Hannover, Germany, [7]Hannover Medical School, Hannover, Germany, [8]Toronto General Hospital

Background: Liver graft dysfunction affects more than 30% of liver transplant recipients (LTRs). Current non-invasive assays detect graft injury but have limited ability to distinguish clinically competing causes such as T cell-mediated rejection (TCMR) and post-transplant metabolic dysfunction-associated steatohepatitis (MASH-LT), often leaving biopsy as the diagnostic standard. This is critical because TCMR and MASH-LT require different immunosuppression strategies. We developed a multimodal AI biomarker integrating circulating cell-free DNA (cfDNA) methylation signatures with clinical variables to enable non-invasive, cause-specific diagnostic support. **Methods:** Plasma-derived genome-wide cfDNA methylation profiles from 125 biopsy-confirmed LTRs across 2 transplant centres, UHN and Hannover Medical School, were integrated with matched clinical variables. The cohort was partitioned into training and held-out test sets while preserving class balance. Boruta feature selection identified 201 informative methylation windows. We developed a dual-branch attention-gated neural network (dbAGNN), which learned separate methylation and clinical representations to classify TCMR, MASH-LT, and Controls. Attention-gate weights and SHAP were used to quantify modality contributions and feature importance. Model performance was assessed on the test set using 101 stratified bootstrap iterations. Tissue-of-origin deconvolution was used to localize the cfDNA injury signal. **Results:** The multimodal dbAGNN achieved a mean weighted AUROC of 0.974 (95% CI 0.969-0.978) on the held-out test set, outperforming methylation-only and clinical-only models. Bootstrap metrics confirmed robust performance: accuracy 0.883 (95% CI 0.872–0.895), macro-F1 0.872 (95% CI 0.859–0.885), and negative predictive value (NPV) 0.944 (95% CI 0.939–0.950). Attention-gate weights varied significantly across classes (Kruskal-Wallis $H = 26.42$, $p < 0.001$). TCMR predictions relied predominantly on methylation (mean weight: 0.924 ± 0.101), while MASH-LT also relied strongly on methylation (0.844 ± 0.089). CTRL-LT showed greater clinical contribution (clinical weight 0.566 ± 0.225), indicating pathology-appropriate modality prioritization. SHAP identified relevant methylation loci (RUNX1, NOTCH1, WNT5A) and clinical factors (AST, BMI). Tissue-of-origin deconvolution localized injury-associated cfDNA to immune- and hepatocyte-derived fragments. Immune-enriched cfDNA was elevated in TCMR versus CTRL-LT (AUROC 0.721), and hepatocyte-enriched cfDNA was elevated in MASH-LT versus TCMR (AUROC 0.665), concordant with liver tissue methylation ($R = 0.56$-0.71). **Conclusion:** This multimodal AI biomarker shows diagnostic potential for non-invasive transplant monitoring. The framework adds interpretability through attention-gate attribution, patient-level feature importance, and tissue-of-origin deconvolution.

4478 | ◆ LONG-TERM OUTCOMES OF BASILIXIMAB INDUCTION THERAPY IN ADULT LIVER TRANSPLANT RECIPIENTS: A PROPENSITY SCORE–MATCHED, LARGE-SCALE REAL-WORLD EVIDENCE STUDY

Mythily Rao Ponaganti[1] Moksha Prasoona Avvaru[2] Erick Phocco[1] Suresh Kumar Nayudu[1] Naga Praneeth Vakkalagadda[3], [1]SBH Health System, [2]Harnett Health, [3]University of Alabama at Birmingham

Background: Basiliximab(BSX), a renal protective interleukin-2 receptor antagonist, for induction immunosuppression in liver transplantation (LT) to delay calcineurin inhibitor (CNI) use. Though short-term benefits are well known, limited data available on long-term outcomes. We aimed to evaluate the association between BSX induction and acute kidney injury (AKI) as the primary outcome, and the cardiovascular events and mortality as secondary outcomes in adult LT recipients over a 5-year follow-up period. **Methods:** We conducted a retrospective propensity score–matched cohort study using the Global Collaborative Network. Adult ($\geq$18 years) LT recipients were divided into BSX and control cohorts who received BSX and tacrolimus respectively. Propensity score matching (1:1) was performed on characteristics including demographics, comorbidities and laboratory values. The primary outcome was AKI and secondary outcomes

included MI, stroke, CKD and all-cause mortality over a period of 5 years. Measures of association and Kaplan-Meier (KM) survival analyses with log-rank tests and hazard ratios [HR] were calculated. Patients with the outcome prior to the time window were excluded from each respective analysis. **Results:** After propensity score matching, a total of 5260 patients were included in each cohort with mean age of 55.2 years at index and 66% were male. AKI risk was significantly lower in the BSX group at 30 and 90 days, but the difference attenuated later with no difference at 5 years, though KM analysis showed a higher AKI-free survival in the BSX group (table 1). MI rates were low but did not differ significantly between groups at any time point, whereas Stroke was significantly lower in the BSX group at 30 days but not at subsequent time points. All-Cause Mortality was significantly lower in the BSX group at 5 years [table2] although benefit was not apparent at earlier time points, with a trend emerging at 3 years. Notably, CKD was significantly higher in the BSX group from 90 days onward. **Conclusion:** BSX induction in adult LT recipients resulted in lower incidence of AKI at early time points and improved 5-year survival. However, BSX induction showed higher rates of CKD, likely reflecting residual confounding by indication, as BSX is preferentially used in high-risk patients with history of CKD. These findings support the short-term renal-protective role of BSX induction with a potential long-term survival benefit, while highlighting the need for prospective studies with comprehensive adjustment for disease severity to establish the development of CKD.

Table 1: Significant Values for AKI (Basiliximab vs. Control)

Time Point	Analysis Type	Basiliximab Risk/Survival	Control Risk/Survival	Effect Estimate (95% CI)	P-value
30 days	Risk analysis	5.6%	7.7%	RR 0.736 (0.592, 0.914); OR 0.720 (0.571, 0.908)	**0.005**
30 days	Survival analysis	94.30%	92.19%	HR 0.712 (0.569, 0.891)	**0.003**
90 days	Risk analysis	9.9%	12.1%	RR 0.820 (0.697, 0.965); OR 0.801 (0.667, 0.961)	**0.017**
90 days	Survival analysis	89.89%	87.50%	HR 0.782 (0.659, 0.929)	**0.005**
5 years	Survival analysis	70.40%	66.88%	HR 0.879 (0.786, 0.983)	**0.024**

Table 2: Significant Values for Mortality (Basiliximab vs. Control)

Time Point	Analysis Type	Basiliximab Risk/Survival	Control Risk/Survival	Effect Estimate (95% CI)	P-value
5 years	Risk analysis	12.2%	14.1%	RR 0.865 (0.783, 0.956); OR 0.846 (0.754, 0.950)	**0.004**
5 years	Survival analysis	84.46%	81.13%	HR 0.851 (0.765, 0.948)	**0.003**

4479 | ◆ FIBROSIS PROGRESSION AFTER BIOPSY-CONFIRMED POST-TRANSPLANT MASH: A 35-YEAR LONGITUDINAL HISTOLOGY COHORT STUDY

Sobia Laique[1] Muhammad Ahmad Nadeem[1] Puneet Bansal[1] Chase Wehrle[1] Jacob Sweeney[1] Xuefeng Zhang[1] Mohamed El Hag[1] Pablo Bejarano[2] Rhea Abraham[1] Sapana Verma[1] Erlind Allkushi[1] Alejandro Pita[1] Mazhar Khalil[1] Masato Fujiki[1] Federico Aucejo[1] Jaekeun Kim[1] Andrea Schlegel[1] Koji Hashimoto[1] Jamak Modaresi Esfeh[3] Daniela Allende[1], [1]Cleveland Clinic, [2]Cleveland Clinic, Florida, [3]Cleveland Clinic Foundation

Background: Post-transplant metabolic dysfunction-associated steatohepatitis (MASH) is increasingly recognized, but its fibrotic trajectory remains poorly characterized. Because non-invasive fibrosis tests (NITs) are not validated after liver transplant (LT), histology remains essential. We evaluated fibrosis progression and predictors among LT recipients with biopsy-confirmed post-LT MASH and serial biopsies. **Methods:** Of 3,912 adult LT recipients at Cleveland Clinic (Ohio and Florida) between 1985-2020, 2,577 had post-transplant biopsy data. Among these, 134 patients with biopsy-confirmed post-transplant MASH comprised the analytic cohort. The longitudinal cohort included 64 patients with ≥ 1 biopsy after index MASH (19 recurrent, 45 de novo). Fibrosis was staged using NASH-CRN criteria. Progression was defined as ≥ 1-stage increase from index to last biopsy. Annualized progression rate was calculated as fibrosis stage change divided by inter-biopsy interval. Groups were compared using Fisher exact or Wilcoxon rank-sum tests. Cumulative progression was assessed using Kaplan-Meier estimates with censoring at last biopsy. Given limited events, multivariable analysis was not performed. **Results:** Median time from transplant to index MASH biopsy was 1.63 years (IQR 0.51–4.03); 3.37 years for recurrent and 1.10 years for de novo MASH ($P = 0.041$). Patients had a median of 3 biopsies (IQR 2–4) over a median index-to-last-biopsy interval of 2.66 years (IQR 0.74–5.21). At index biopsy, fibrosis was F0–F1 in 48 (75.0%), F2 in 13 (20.3%), and F3 in 3 (4.7%); none had F4. Fibrosis progression occurred in 31 patients (48.4%): 7/19 recurrent (36.8%) and 24/45 de novo (53.3%; $P = 0.228$). Progression to advanced fibrosis ($\geq$F3) occurred in 12 (18.8%) and to cirrhosis in 4 (6.3%), with no difference by MASH type. Among progressors, median annualized rate was 0.38 stages/

year (IQR 0.19–0.91), corresponding to an estimated F0-to-F4 interval of approximately 10 years. Kaplan-Meier analysis showed no significant difference in cumulative progression between recurrent and de novo MASH (log-rank P = 0.205). On univariable analysis, no baseline variable, including MASH type, age, BMI, diabetes, NAS score, or fibrosis stage, was significantly associated with progression; index ballooning grade showed a non-significant trend (P = 0.070). **Conclusion:** In this 35-year multicenter longitudinal histology cohort, nearly half of patients with post-transplant MASH experienced fibrosis progression, with an estimated decade-long trajectory from no fibrosis to cirrhosis. Progression rates were similar regardless of whether MASH was recurrent or de novo, and no baseline feature reliably predicted progression. These findings establish that post-transplant MASH carries meaningful fibrotic potential regardless of indication, and highlight the need for validation of NITs against histology to enable scalable post-LT surveillance.

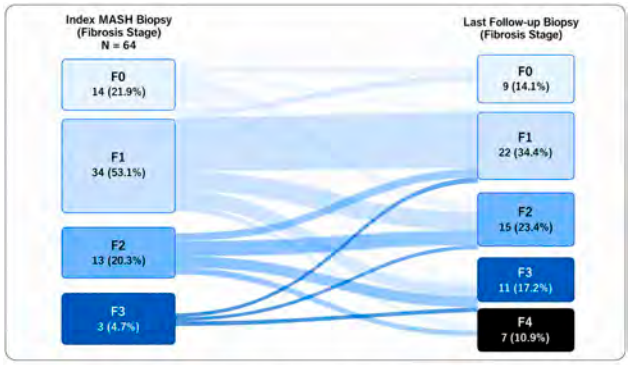

Figure 1. Fibrosis Stage Transitions From Index to Last Follow-Up Biopsy After Post-Transplant MASH

64 recipients with post-transplant MASH and ≥1 follow-up biopsy (19 recurrent, 45 de novo). Band width is proportional to patient count. Median inter-biopsy interval: 2.66 years (IQR 0.74–5.21). Trajectory was defined by change in fibrosis stage from index MASH biopsy to last follow-up biopsy. MASH, metabolic dysfunction-associated steatohepatitis; F, fibrosis stage.

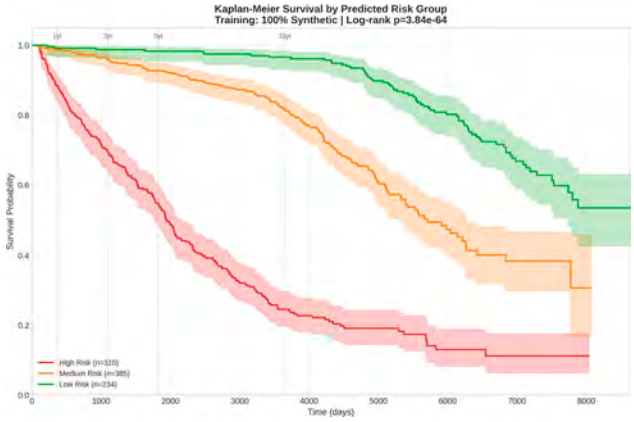
4480 | ◆ LONGITUDINAL INTELLIGENT FORECAST FOR EXPECTED OUTCOMES POST-LIVER TRANSPLANT (LIFE-LT) – AN ARTIFICIAL INTELLIGENCE PREDICTION MODEL



Omar Mousa[1] Aadarsh Barot[1] Andrew Keaveny[1] Rohan Goswami[1], [1]Mayo Clinic Florida

Background: Predicting long-term survival after liver transplantation (LT) is critical for patient counseling and organ allocation optimization. Post-LT prediction tools are lacking, and the Model for End-Stage Liver Disease (MELD) has limited post-transplant prognostic utility (C-index 0.60-0.65). A key barrier to clinical AI tools is the tension between data access and privacy. We hypothesized that training an AI model exclusively on synthetic patients could overcome this barrier while achieving clinically meaningful accuracy. **Methods:** This retrospective study included adult LT recipients at a high volume transplant center from 1/1/2002 to 12/31/2016. The original cohort (N = 1896) was randomly divided in two groups: 51% source cohort (n = 967) and 49% held-out test cohort (n = 929). A conditional tabular generative adversarial network was trained exclusively on the source cohort to learn statistical relationships among donor, recipient and transplant variables, and subsequently generated 5,138 synthetic patients without containing identifiable patient data. Statistical fidelity was confirmed through distribution matching and correlation preservation. An 18-model stacking ensemble with isotonic calibration was trained exclusively on synthetic data using 105 donor-recipient-transplant features. The model was tested on the source and held-out cohorts. Performance was assessed via C-index, time-dependent AUC, net reclassification improvement (NRI), and integrated discrimination improvement (IDI) versus MELD. **Results:** In the test cohort (929 patients, 462 events), the model achieved a C-index of 0.825 (95% CI: 0.806-0.843), compared with 0.802 in the source cohort for predicting post-LT survival up to 15 years, supporting good generalization. Time-dependent AUC was stable: 1-year 0.866, 3-year 0.884, 5-year 0.886, 10-year 0.885. The model outperformed MELD (NRI = 0.560, IDI = 0.355; $p < 0.001$), even when applied across multiple clinical subgroups. Risk stratification yielded three prognostic groups with markedly different outcomes and median survivals of 5.3, 11.5, and 17.2 years ($p < 0.001$) (Figure 1). Preliminary analysis of a MASLD subgroup (n = 81) showed promising discrimination (C-index 0.88, 95% CI: 0.83-0.92), warranting confirmation in larger cohorts. SHAP identified hepatocellular carcinoma status, recipient sodium, and donor-recipient interactions as top predictors. **Conclusion:** An AI

model trained exclusively on synthetic data achieved excellent discrimination for post-LT survival without real patient exposure during development, substantially outperforming MELD. This privacy-preserving paradigm eliminates data-sharing barriers in transplant AI, enables individualized survival counseling and may inform allocation policy. Preliminary data concerning recipients transplanted for MASLDs merit investigation in larger cohorts of this rapidly expanding transplant population.

4481 | ETIOLOGY-SPECIFIC AND INSULIN-DEPENDENCE-STRATIFIED RISK OF NEW-ONSET DIABETES POST-LIVER TRANSPLANTATION

Mishal Ali[1] Raghavendra Mirmira[2] Mary Rinella[2] Alan Hutchison[2], [1]University of Chicago -, [2]University of Chicago

Background: New-onset diabetes after transplant (NODAT) is a recognized driver of post-liver-transplant mortality, but the risk profile is widely assumed to be temporally uniform. Whether NODAT risk and its insulin-dependence phenotype vary by pre-transplant liver disease etiology, and whether these signals change across the post-transplant timeline, is not well characterized. **Methods:** We assembled all adult liver-only transplants in OPTN/SRTR 1987–2021 with complete baseline diabetes status. Of 111,783 non-diabetic recipients at transplant, 102,201 remained at risk at the 1-year landmark (declining to 82,525, 47,836, and 24,351 at 5, 10, and 15 yr, respectively, after accounting for NODAT events and competing deaths). For each of the pre-transplant etiologies, we fit Fine-Gray subdistribution hazard models with death-without-NODAT as the competing event, adjusted for age, sex, BMI, and transplant era, separately within four landmark windows (0–1, 1–5, 5–10, 10–15 yr). Insulin-dependent (IDDM) and non-insulin-dependent (NIDDM) NODAT were modeled as cause-specific subtypes within the same Fine-Gray framework, using the OPTN INSULIN_DEPENDENT field at each NODAT onset visit to define the phenotype; events with unknown insulin status were excluded from the stratified sub-analysis. **Results:** Of 39 unique pre-transplant etiologies analyzed, two showed elevated NODAT risk consistently across all four landmark windows: cystic fibrosis (combined sHRs 6.09–8.09, the strongest etiology-NODAT association in the cohort) and chronic HCV infection (sHR 1.23–1.29, modest). Acute hepatic necrosis showed near-consistent elevation (sHR 1.23, 1.30, and 1.28 at 0–1, 1–5, and 5–10 yr, respectively). Three additional etiologies came up significant as late-onset risks at 10–15 yr: hemochromatosis (sHR 3.14 [1.42–6.94]), autoimmune cirrhosis (sHR 1.62 [1.09–2.42]), and biliary atresia (sHR 10.95 [2.54–47.17], n = 2 events). Three cholestatic and biliary etiologies were associated with consistently reduced NODAT risk across windows: biliary atresia, extrahepatic (sHR 0.27–0.48), primary sclerosing cholangitis (sHR 0.62–0.71 through 10 yr), and primary biliary cholangitis (sHR 0.58–0.82). All cited associations were significant at $p < 0.05$ (most at $p < 0.001$).The insulin-stratified analysis showed etiology-specific phenotype divergence concentrated in the first post-transplant decade: cystic fibrosis and HCV showed insulin-dependent (IDDM)-predominant patterns (CF IDDM sHRs 7.74, 8.06, and 7.63 across 0–1, 1–5, and 5–10 yr). **Conclusion:** Post-liver-transplant NODAT risk varies strongly by pre-transplant etiology. Cystic fibrosis, HCV, hemochromatosis, and autoimmune cirrhosis represent high-risk subgroups; the IDDM phenotype captures most etiology-specific signal and warrants targeted glycemic surveillance.

4482 | HEPATIC IRON DEPOSITION IN LIVER EXPLANTS: PATTERNS, ETIOLOGIES, AND CLINICAL ASSOCIATIONS

Roxanna Sharifi[1] Yinan Su[1] Daanyaal Kumar[2] Paul Paik[3] Andrew John Cruz[2] Kalpana Gopalkrishnan[3] Niveda Balemurughan[3] Juan Carlos Delgado[4] Alejandro Delgado[2] Scott Jun[2] Derek Samson[5] Jeffrey Kahn[6] Norah Terrault[6] Liyun Yuan[6], [1]Keck School of Medicine, University of Southern California, Los Angeles, California, [2]The USC/Los Angeles General Medical Center Internal Medicine Residency Program, [3]Keck School of Medicine, University of Southern California, [4]Kaiser Permanente Los Angeles Medical Center, [5]Keck Medicine of USC, University of Southern California, [6]University of Southern California

Background: Hepatic iron loading is common in alcohol-associated liver disease (ALD) and metabolic dysfunction-associated steatotic liver disease (MASLD) and may worsen liver injury through ferroptosis. However, its prevalence, distribution, and clinical significance in decompensated cirrhosis are not well defined. We aimed to characterize hepatic iron deposition in liver explants and assess its associations with liver disease etiology and severity. **Methods:** We retrospectively analyzed adult liver transplant recipients at a single liver transplant center from 2013-2023. Explant pathology reports were reviewed for the presence and pattern of hepatic iron. Total and hepatocellular(HC) iron were evaluated in relation to pre-transplant MELD-Na, liver disease etiology, hepatocellular carcinoma (HCC), and metabolic risk factors using chi-square testing and multivariable logistic regression adjusted for age, sex, body mass index, and diabetes. The analyses were further assessed by exclusion of advanced chronic kidney disease (CKD stage 4-5) or simultaneous liver-kidney transplantation (SLK). **Results:** Among 1,345 liver transplant recipients, hepatic iron deposition was present in 49.9% of explants, including 30.7% hepatocellular (HC), 6.1% mixed pattern, and 12.0% reticular (RE) pattern. Total iron deposition prevalence varied by etiology (Figure 1) and was highest in viral hepatitis (64.2%) and ALD (63.3%), followed by MASLD (54.4%) and cryptogenic liver disease (53.9%). Lower prevalence was observed in autoimmune hepatitis (39.1%), PBC (31.3%), and PSC (9.8%). As HC iron is considered pathognomonic and is the most common pattern in explants, we further evaluated associations with MELD-Na severity. HC iron prevalence increased across MELD-Na categories. In adjusted analyses, MELD 25-29 (OR 1.53, 95% CI 1.10-2.13; $p = 0.011$) and MELD 30-34 (OR 2.09, 95% CI 1.42-3.08; $p < 0.001$) were associated with higher odds of HC iron (Table 1). Diabetes (OR 0.67, 95% CI 0.51-0.88; $p = 0.004$) and HCC (OR 0.71, 95% CI 0.53-0.97; $p = 0.029$) were associated with lower odds, whereas age, sex, and body mass index were not independently associated. Associations with MELD severity, diabetes, and HCC remained significant after exclusion of recipients with advanced CKD or SLK. **Conclusion:** Hepatic iron deposition in liver transplant explants is highly prevalent in ALD, MASLD, and viral hepatitis, with a predominantly HC pattern. Iron deposition was associated with higher MELD-Na scores, suggesting a link with more advanced liver dysfunction. In contrast, HCC and diabetes were associated with lower odds of HC iron deposition. Whether hepatic iron accumulation contributes to portal hypertension and clinical decompensation warrants further investigation.

4483 | CENTER-LEVEL VARIATION IN MARGINAL LIVER TRANSPLANT OUTCOMES

Billy Block[1] Amirhossein Moosavi[1] David Hutton[1] Mariel Lavieri[1] Neehar Parikh[2], [1]University of Michigan, [2]University of Michigan Medical Center

Background: With the advent of novel organ preservation strategies, transplant centers (TCs) are increasingly using livers from historically marginal donors, however center-level variation in outcomes with these donors is not well characterized. We aimed to quantify TC-level variation in marginal liver transplant outcomes and assess performance changes over time. **Methods:** We analyzed OPTN STAR data for adult deceased-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

donor liver transplants performed from 2010–2024, restricted to centers performing ≥10 transplants per year. Marginal organs were defined as those above the 75th percentile of the Donor Risk Index (DRI). The primary outcome was 1-year graft failure. Center performance was estimated using mixed-effects logistic regression with empirical Bayes random-effects centering, adjusting for donor and recipient characteristics via backward elimination. Centers were classified as Better, Expected, or Worse based on whether their 95% CI for risk-adjusted log-odds excluded or included zero. Inter-center variability was compared across two eras (2015–2019 vs. 2020–2024) using Levene's test. **Results:** The cohort included 104,201 liver transplants across 95 TCs (78,147 standard, 26,054 marginal). Marginal liver transplants were more concentrated among select TCs compared to standard organs. Risk-adjusted center performance varied widely, ranging from −1.7 to +0.9 in the relative log-odds of graft failure. Performance on standard and marginal organs was only moderately correlated ($R^2 = 0.309$), suggesting that outcomes with standard livers do not reliably predict success with marginal organs. Median graft failure rates for marginal transplants declined from 12.8% in 2015 to 7.6% in 2024 (rho = -0.76, p = 0.011), while standard rates fell from 9.1% to 7.5% (rho = -0.20, p = 0.580). Between-TC variability in marginal transplant outcomes decreased significantly in the more recent era (Levene's p < 0.001). Marginal transplants had significantly higher failure rates than standard organs overall (Wilcoxon p < 0.001), though this gap narrowed over time with weak significance (rho = -0.60, p = 0.067). **Conclusion:** TCs' outcomes vary substantially when utilizing marginal livers. Performance with standard organs is only moderately predictive of marginal organ success. While outcomes have improved and between-center variability has narrowed, a performance gap persists between standard and marginal organs. Standardized strategies are necessary to optimize marginal liver utilization and expand the effective donor pool.

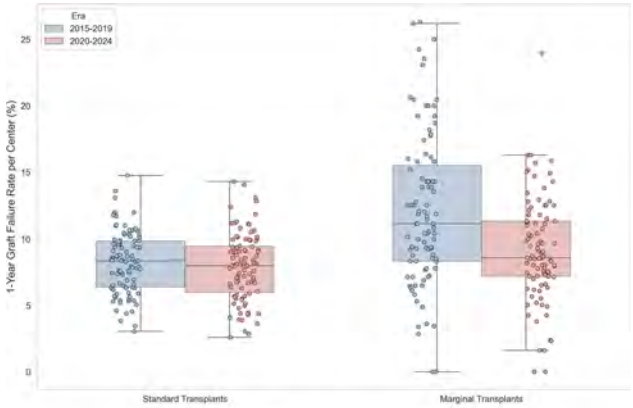

Figure 1: TC-level 1-year graft failure rates for standard (DRI ≤ 75th percentile) vs. marginal (DRI > 75th) percentile) organs, by era. Each point represents a single TC.

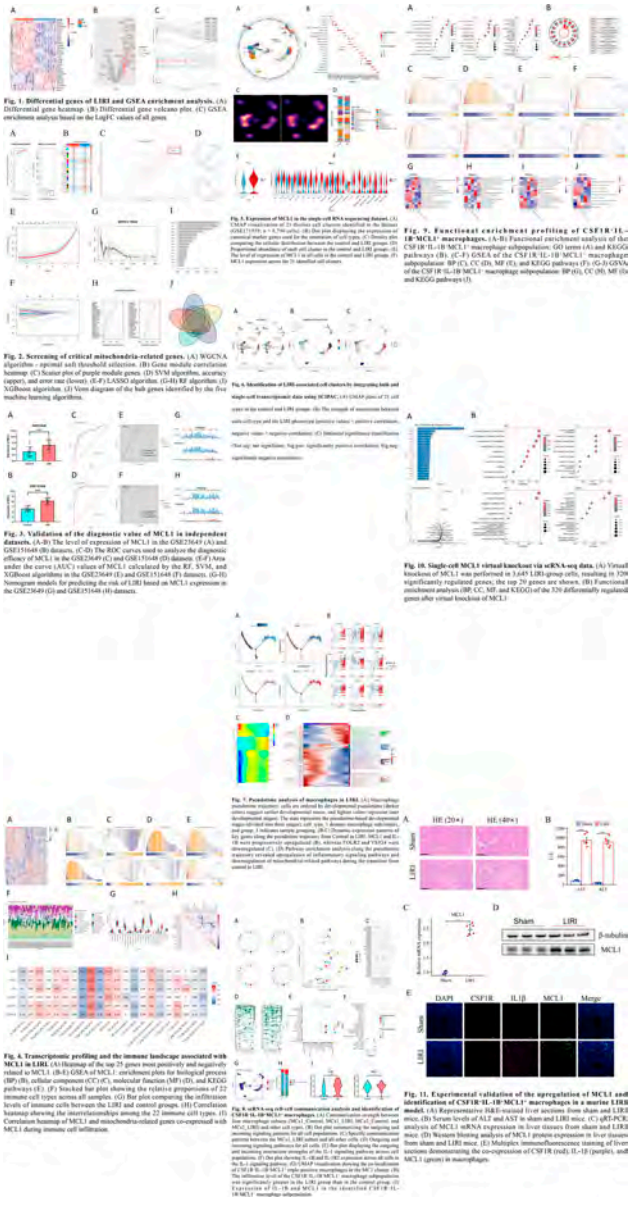
4484 | SINGLE-CELL AND BULK RNA SEQUENCING REVEAL MCL1 AS A KEY REGULATOR OF MITOCHONDRIAL FUNCTION IN LIVER ISCHEMIA-REPERFUSION INJURY



Xianxiang Chen[1], [1]The First Affiliated Hospital of Guangxi Medical University

Background: Liver ischemia-reperfusion injury (LIRI) may occur after liver transplantation or surgery, and few treatments are available to overcome this problem. The pathogenesis of LIRI is closely related to maladaptive immune responses and mitochondrial dysfunction; however, key regulators that link the above processes are still not known. **Methods:** Several microarray datasets (GSE12720, GSE112713, GSE23649, and GSE151648) were used in combination with single-cell RNA sequencing data (GSE171539). Additionally, hub genes were identified through differential analysis (WGCNA) and using four machine learning algorithms (SVM, LASSO, RF, and XGBoost). The results were validated with additional datasets using the murine LIRI model by in silico perturbation. **Results:** Our findings revealed that MCL1 is a hub gene related to mitochondria, whose expression is considerably increased in LIRI, and it has satisfactory diagnostic accuracy. Additionally, single-cell analysis revealed that MCL1 was specifically enriched in endothelial cells and macrophages. Moreover, the new macrophage subset CSF1R+IL-1B+MCL1+, which has a dual pro-inflammatory and pro-survival phenotype, was detected in

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

LIRI patients. This process results in increased intercellular crosstalk and is related to important pathways such as the NF-κB, apoptosis, and cytokine signaling pathways. Moreover, knocking out MCL1 in silico dramatically altered immune-related gene networks. MCL1 was experimentally confirmed to be upregulated, and the macrophage subset was validated to exist in the LIRI mouse model. **Conclusion:** Through bulk and single-cell RNA sequencing analysis, we identified that MCL1 is the key factor for LIRI, which links immune inflammation and mitochondrial function through a new subset of macrophages. MCL1 is a candidate diagnostic biomarker and therapeutic target for treating LIRI.

4485 | CLINICAL OUTCOMES OF GLP-1 RECEPTOR AGONIST USE IN LIVER TRANSPLANT RECIPIENTS WITH DIABETES: A MULTICENTER STUDY

Azhar Hussain[1] Avleen Kaur[2] Prerna Kherajani[2] Kalsoom Khalil[3] Ahmad Nawaz[2] Bishnu Sapkota[2] Savio John[4], [1]SUNY Upstate Medical University, NY, [2]SUNY Upstate Medical University, NY, USA, [3]Ameer-ud-Din Medical College, Lahore, Pakistan, [4]SUNY Upstate Medical University

Background: While GLP-1 receptor agonists (GLP-1 RAs) have demonstrated substantial efficacy in the general population for glycemic control and weight loss, data regarding their safety and clinical impact specifically within the liver transplant population remain limited. This study aims to compare clinical outcomes between LT recipients with T2DM who are treated with GLP-1 RAs versus standard anti-diabetic regimen. **Methods:** This was a retrospective propensity-matched cohort study using deidentified data from the U.S. population-based TriNetX Research Network. Adult patients (18-89 years) with a confirmed history of liver transplantation who had existing T2DM or developed PTDM (defined as HbA1c >6.5% or fasting glucose >126 mg/dL diagnosed >3 months post-transplant when stable on immunosuppression) were identified. Exclusion criteria included T1DM and multi-organ transplant status. After matching for demographics, comorbidities, and laboratory parameters, two cohorts were established: 983 patients initiated on GLP-1 RAs (semaglutide, liraglutide, dulaglutide, or tirzepatide), and a 983-matched non-GLP-1 RAs cohort with standard anti-diabetic regimen cohort or (all-antidiabetic agents except GLP-1 RAs). The primary outcome of the study was the all-cause mortality at 1, 3, and 5 years after the index event. Secondary outcomes included systemic complications (sepsis, septic shock), improvements in HbA1c, weight loss (mean difference in BMI), acute liver graft failure within 6 months after LT, Major Adverse Cardiovascular Events (MACE), and Major Adverse Kidney Events (MAKE). MACE is defined as a composite outcome of myocardial infarction, stroke, or death after index event. MAKE is defined as a composite outcome of initiation of new dialysis or kidney replacement therapy, decline of cGFR >50% from baseline or death after index event. **Results:** Over a mean follow-up of 25.5 ± 18.3 months, the LT recipients in the GLP-1 RA cohort had a significantly lower incidence of all-cause mortality at 1, 3, and 5 years after the index event (OR 0.266; 95% CI, 0.191-0.369 for the 5th year) compared to the non-GLP-1 RAs cohort (Figure 1). LT recipients who received GLP-1 RA had lower HbA1c and BMI at 1-year with a mean difference of 1.5 ± 0.9%, and 1.7 ± 0.9 kg/m2, (p < 0.05

for both). LT recipients in the GLP-1 RA cohort had a lower risk of sepsis, septic shock, MACE, MAKE, mechanical ventilation, need for ICU admission, acute liver graft failure/rejection, and lower ER visits/all-cause hospitalizations, compared to those in the non-GLP-1 RA cohort ($P < 0.001$ for all) at 3-years (Table 1). **Conclusion:** GLP-1 RAs use in LT recipients with preexisting T2DM or PTDM was associated with a lower risk of all-cause mortality, improved metabolic and overall clinical outcomes, and lower healthcare utilization.

Table 1: Primary and secondary outcomes among GLP-1 RA cohort vs. non-GLP-1 RAs cohort

Outcome	GLP-1 RAs cohort (n=983)	SGLT2i cohort (n=983)	Odds Ratio (95% CI)	p-value
Primary Outcome				
All-Cause Mortality at 1-Year	31 (3.1%)	69 (7.0%)	0.426 (0.283–0.678)	0.004
All-Cause Mortality at 3-Year	46 (4.8%)	132 (13.4%)	0.331 (0.235–0.466)	<0.001
All-Cause Mortality at 5-Year	51 (5.1%)	167 (16.9%)	0.266 (0.191–0.369)	<0.001
Secondary Outcomes at 3 Years				
MACE	100 (10.1%)	195 (19.8%)	0.458 (0.353–0.593)	<0.001
MAKE	98 (10.2%)	128 (12.9%)	0.911 (0.699–0.917)	0.042
Sepsis	58 (5.9%)	150 (15.2%)	0.348 (0.254–0.478)	<0.001
Septic Shock	15 (1.5%)	75 (7.6%)	0.188 (0.107–0.329)	<0.001
Mechanical Ventilation	23 (2.3%)	69 (7.0%)	0.317 (0.196–0.513)	<0.001
ICU Admission	49 (4.8%)	119 (12.0%)	0.376 (0.2669–0.533)	<0.001
ED Visit/All-Cause Hospitalization	199 (20.2%)	257 (26.1%)	0.717 (0.581–0.885)	0.001
Acute liver graft failure/rejection at 6 months	60 (6.1%)	172 (17.4%)	0.307 (0.225–0.417)	<0.001

Abbreviations: MACE: Major Adverse Cardiovascular Events, MAKE: Major Adverse Kidney Events, ICU: Intensive Care Unit, ED: Emergency Department

4486 | EXTERNAL VALIDATION OF PRE-LIVER TRANSPLANT RISK SCORES FOR WAITLIST OUTCOMES IN LIVER TRANSPLANT CANDIDATES WITH HEPATOCELLULAR CARCINOMA

Leandro Sierra[1] Butros Fakhoury[2] Na Bo[3] Juan Pablo Arab[2] Neil Mehta[4] Amit Singal[5], [1]Cleveland Clinic Foundation, [2]Virginia Commonwealth University School of Medicine, Richmond, VA, USA, [3]Virginia Commonwealth University, Richmond, VA, USA., [4]University of California San Francisco, San Francisco, CA, United States, [5]The University of Texas Southwestern Medical Center, Dallas, TX, USA

Background: Multiple risk scores have been proposed to predict adverse waitlist (WL) outcomes in liver transplant (LT) candidates with hepatocellular carcinoma (HCC), yet head-to-head comparisons in a national cohort are lacking. We aimed to assess the discrimination and risk stratification of five HCC risk scores for 1-year WL dropout and mortality. **Methods:** Using the United Network for Organ Sharing/Scientific Registry of Transplant Recipients (UNOS/SRTR) database, we performed an external validation of five prognostic scores: HALT-HCC, Multi-HCC, the Duvoux AFP Model, the Mehta Dropout Score, and Metroticket 2.0. We included adult candidates listed with HCC between 2000 and 2025 and excluded those who had prior liver transplant, incident HCC after listing, listing for multiorgan transplant, and fibrolamellar HCC. All scores were calculated from variables at listing. Primary outcomes of interest were waitlist dropout and waitlist mortality at 1 year. Discrimination was quantified by area under the receiver operating characteristic (AUC) curve with pairwise DeLong comparisons. Risk stratification was evaluated across score quartiles using Fine-Gray competing risk models treating LT as a competing event, censored at 1 year. **Results:** Among 19,285 LT candidates with HCC (median WL time 161 days), 13,820 (71.6%) underwent LT at a median of 121 days from listing. 1-year WD occurred in 2,345 (12.2%) and 1-year WM in 832 (4.3%) patients. For 1-year dropout, Multi-HCC (AUC 0.75, 95% CI 0.74–0.77) and Mehta (AUC 0.75, 95% CI 0.73–0.76) significantly outperformed HALT-HCC (AUC 0.64, 95 %CI 0.63–0.66), Metroticket 2.0 (AUC 0.60, 95% CI 0.58–0.62), and Duvoux AFP (AUC 0.58, 95% CI 0.56–0.59) (global $p < 0.001$), with no significant difference between Multi-HCC and Mehta ($p = 0.11$). For 1-year mortality, Multi-HCC achieved the highest discrimination (AUC 0.81, 95% CI 0.79–0.83), exceeding Mehta (AUC 0.79, 95% CI 0.77–0.81; head-to-head $p < 0.001$) and the remaining scores (HALT-HCC, Metroticket 2.0, Duvoux AFP; all AUC ≤ 0.62, global $p < 0.001$). Multi-HCC and Mehta had steep risk gradients across quartiles. From Q1 to Q4, 1-year WD rose from 11% to 50% (Multi-HCC HR 4.71, 95% CI 4.13–5.37; Mehta HR 4.84, 95% CI 4.15–5.65), and 1-year WM rose from 2% to 25% (Multi-HCC HR 10.8, 95% CI 8.1–14.2 ; Mehta HR 9.75, 95% CI 7.06–13.5) (all p-trend < 0.001). **Conclusion:** Multi-HCC and the Mehta Dropout Score reliably identified HCC candidates at high risk for 1-year waitlist dropout and mortality, outperforming other prognostic models. These scores may help prioritize candidates for access to LT, closer monitoring, and more aggressive bridging therapy.

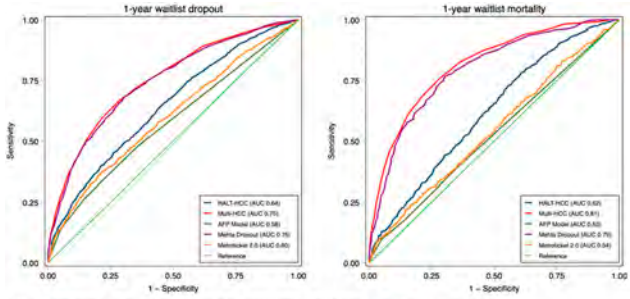

Figure 1. Discrimination of five pre-transplant risk scores for 1-year waitlist outcomes in liver transplant candidates with hepatocellular carcinoma.

Receiver operating characteristic (ROC) curves for 1-year waitlist dropout (left panel) and 1-year waitlist mortality (right panel). Areas under the curve (AUC) with 95% confidence intervals are shown for each score. Multi-HCC and the Mehta Dropout Score demonstrated the strongest discrimination for both outcomes. Multi-HCC was the single best discriminator for 1-year waitlist mortality (head-to-head DeLong $p < 0.001$ vs Mehta).

4487 | GLP-1 RECEPTOR AGONISTS VERSUS BARIATRIC SURGERY AND UNTREATED CONTROLS IN PATIENTS WITH OBESITY AND CIRRHOSIS: A PROPENSITY-MATCHED MULTICENTER COHORT STUDY

Aldanah Althwanay[1] Muhammad Haris Latif[2] Imran Khokhar[3] Maya Mahmoud[4], [1]washington university at st louis, [2]SSM Health St Mary's Hospital, [3]Reading Hospital-Tower Health, [4]Saint Louis University Hospital

Background: Obesity affects over 40% of patients with cirrhosis, accelerates hepatic decompensation, and represents a barrier to transplant listing for eligible candidates, yet optimal weight management strategies in this population remain undefined. Bariatric surgery carries elevated perioperative risk in cirrhosis, while GLP-1 receptor agonists (GLP-1 RAs) demonstrate hepatoprotective properties beyond weight loss. Real-world comparative evidence in established cirrhosis is lacking. **Methods:** Propensity score-matched (PSM) cohort study using the TriNetX multicenter network of adults with obesity and all-cause cirrhosis: (1) GLP-1 receptor agonist (GLP-1 RA) therapy vs bariatric surgery (n = 1,080/group); (2) GLP-1 RA vs untreated controls (n = 14,816/group). Post-PSM cohorts were balanced for age, sex, diabetes, and body mass index (BMI); albumin and bilirubin remained imbalanced. Outcomes assessed by Kaplan-Meier survival analysis at 1 and 5 years included all-cause mortality, ascites, paracentesis, hepatic encephalopathy (HE), hepatorenal syndrome (HRS), spontaneous bacterial peritonitis (SBP), malnutrition, hospitalization, liver transplant, and hepatocellular carcinoma (HCC). **Results:** Comparison 1 (bariatric surgery vs GLP-1 RA): Bariatric surgery was associated with higher hazards of mortality (HR 4.41 at 1yr; 2.76 at 5yr), ascites (HR 2.42; 1.48), paracentesis (HR 4.75; 2.18), HRS (HR 1.82 at 5yr), SBP (HR 2.29 at 5yr), and malnutrition (HR 5.11 at 5yr); all $p < 0.05$ vs GLP-1 RA. Liver transplant did not differ (HR 1.87 at 5yr, $p = 0.062$). Bariatric surgery achieved greater BMI reduction (32.6 vs 35.3 kg/m2 at 5yr). Estimated MELD-Na was higher in the bariatric cohort at baseline (17 vs 8), 1 year (23 vs 11), and 5 years (25 vs 12), indicating residual severity imbalance limiting causal inference. Comparison 2 (untreated controls vs GLP-1 RA): Controls had higher hazards of mortality (HR 2.73 at 1yr; 2.07 at 5yr), ascites, paracentesis, SBP, HRS, HE, and hospitalization at both time points (all $p < 0.001$ vs GLP-1 RA), and higher liver transplant rates at 1 year (HR 1.71) and 5 years (HR 1.29, $p = 0.003$). HCC did not differ in either comparison. **Conclusion:** GLP-1 RA therapy was associated with lower risks of hepatic decompensation and mortality vs both bariatric surgery and untreated controls, and with reduced liver transplant utilization vs untreated controls, suggesting a hepatoprotective effect beyond weight loss alone. HCC rates were unaffected. Residual confounding by disease severity and the observational design limit causal inference; MELD imbalance in the surgical comparison warrants particular caution. Prospective randomized trials are needed to confirm these findings and define optimal obesity management strategies in patients with established cirrhosis.

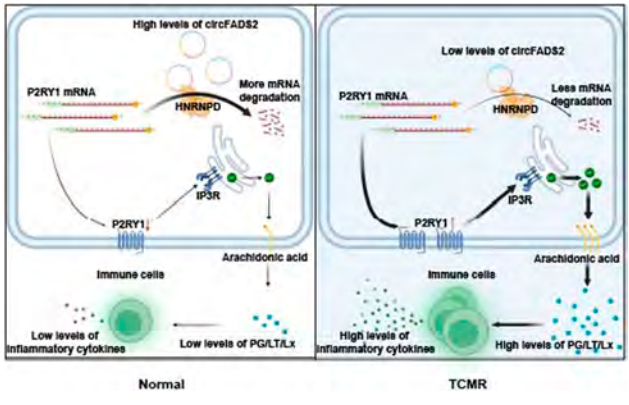
4488 | HEPATOCYTE CIRCFADS2 MODULATES TCMR IN PEDIATRIC LIVER TRANSPLANTATION



Qi Pan[1] Aiwei Zhou[1] Yuan Liu[1] Yongbo Liu[1] Qiang Xia[1], [1]Renji Hospital

Background: T cell-mediated rejection (TCMR) remains a major immune complication after pediatric liver transplantation, compromising graft function and long-term survival. Sensitive and tissue-specific early warning markers are still lacking, and graft-intrinsic susceptibility remains insufficiently understood. **Methods:** Graft biopsy specimens from pediatric liver transplant recipients were analyzed by circRNA microarray. Candidate circRNAs were validated by RT-qPCR in an independent cohort, and cellular origin was determined by fluorescence-activated cell sorting. Mechanistic studies were performed in THLE2 hepatocytes using overexpression, post-transcriptional interaction assays, and signaling analyses. A hepatocyte-conditioned medium system was used to assess effects on primary human CD4+ T cells. In vivo

relevance was examined by pharmacological targeting of P2RY1 in an allogeneic mouse liver transplantation model. **Results:** CircRNA profiling showed a distinct expression pattern between TCMR and non-rejection grafts. CircFADS2, a hepatocyte-enriched circRNA derived from exons 2-5 of FADS2, was significantly downregulated in pediatric TCMR. In an independent diagnostic cohort, circFADS2 discriminated TCMR from non-rejection with an AUC of 0.86. Mechanistically, circFADS2 promoted HNRNPD-dependent degradation of P2RY1 mRNA, reduced P2RY1 expression, and suppressed the P2RY1-related Ca2+/cPLA2 pathway, leading to decreased release of arachidonic acid and lipid mediators. Conditioned medium from circFADS2-overexpressing hepatocytes inhibited the proliferation, activation, and effector cytokine production of primary human CD4+ T cells, and these effects were reversed by arachidonic acid add-back. In the allogeneic mouse liver transplantation model, P2RY1 activation aggravated graft injury and immune responses, whereas P2RY1 antagonism alleviated graft damage and inflammation-related indices. **Conclusion:** Hepatocyte-enriched circFADS2 is closely associated with pediatric TCMR and may serve as a tissue biomarker of rejection. Mechanistically, circFADS2 restrains graft injury by promoting HNRNPD-mediated degradation of P2RY1 mRNA, suppressing P2RY1-Ca2+/cPLA2 signaling, limiting arachidonic acid release, and weakening the graft microenvironment's support for CD4+ T cell effector responses. The circFADS2-HNRNPD-P2RY1-arachidonic acid axis suggests a potential target for early diagnosis and precision intervention in pediatric liver transplant rejection.

4489 | DIASTOLIC DYSFUNCTION INCREASES POST-TRANSPLANT MORTALITY IN NON-ACLF PATIENTS

Nishita Sunkara[1] Kathryn Thompson[1] Jake MacDonald[1] Naveena Murugan[1] Vignesh Jayaraman Muralidharan[1] Hima Veeramachaneni[1] Andrew Yu[1] Ram Subramanian[2] Nader Dbouk[3], [1]Emory University School of Medicine, [2]Emory University, [3]Emory Universirty School of Medicine

Background: Diastolic dysfunction is a hallmark of cirrhotic cardiomyopathy, a condition affecting up to 50% of patients with cirrhosis, particularly those with decompensated liver disease. Cardiovascular disease is a major contributor to both short- and long-term mortality after liver transplantation (LT), although the impact of diastolic dysfunction on post-LT outcomes remains controversial. We evaluated the association between diastolic dysfunction and post-LT outcomes in patients without acute-on-chronic liver failure (ACLF). **Methods:** We conducted a retrospective study of 816 liver transplant recipients between 2014 and 2025, including 572 patients without ACLF. Primary outcomes included 1-, 3-, and 5-year patient and graft survival. We evaluated the impact of diastolic dysfunction on these outcomes. ChatGPT (OpenAI) was used solely to assist with language refinement and improve readability of the abstract. **Results:** Diastolic dysfunction was a significant predictor of both patient and graft survival in the overall cohort ($p = 0.002$ and $p = 0.004$, respectively) and emerged as the strongest predictor of outcomes among non-ACLF patients (both $p < 0.0001$). In non-ACLF patients, those with diastolic dysfunction had significantly worse 1-, 3-, and 5-year patient survival compared to those without diastolic dysfunction (82.7% vs 94.0%, 80.2% vs 91.0%, and 76.4% vs 89.2%, respectively; $p < 0.0001$). Graft survival demonstrated a similar pattern, with significantly lower 1-, 3-, and 5-year graft survival in patients with diastolic dysfunction compared to those without (82.7% vs 94.5%, 80.2% vs 91.7%, and 77.1% vs 89.9%, respectively; $p < 0.0001$). A history of coronary artery disease (CAD) was associated with consistently 3–4% lower patient and graft survival across all time points; however, CAD was not a significant predictor of outcomes in the overall cohort (all $p = 0.159$). **Conclusion:** In this retrospective study, diastolic dysfunction emerged as the strongest predictor of both short- and long-term mortality among non-ACLF patients. These findings highlight the importance of careful screening for diastolic dysfunction in liver transplant candidates, including evaluation of more granular echocardiographic markers such as left ventricular longitudinal strain to better assess preoperative cardiac function.

4490 | BURDEN OF PRE-TRANSPLANT CARDIOMETABOLIC RISK FACTORS PREDICT MAJOR ADVERSE CARDIOVASCULAR EVENTS AFTER LIVER TRANSPLANT

Andrew John Cruz[1] Paul Paik[2] Juan Carlos Delgado[3] Kalpana Gopalkrishnan[4] Niveda Balemurughan[2] Yinan Su[2] Roxanna Sharifi[2] Daanyaal Kumar[5] Scott Jun[5] Alejandro Delgado[5] Derek Samson[6] Navpreet Kaur[2] Jeffrey Kahn[2] Norah Terrault[2] Liyun Yuan[2], [1]USC/ LA General Medical Center Internal Medicine Training Program, [2]University of Southern California, [3]The Kaiser Permanente Los Angeles Medical Center, [4]University of Southern Calironia, [5]USC/Los Angeles General Medical Center Internal Medicine Residency Program, [6]Transplant Institute, Keck medical center of USC

Background: Cardiometabolic risk factors (CMRFs) including diabetes, hypertension, dyslipidemia, and elevated BMI are increasingly prevalent among liver transplant (LT) candidates across all indications. Despite pre-transplant cardiovascular screening, major adverse cardiovascular events (MACE) remain a leading cause of post-LT morbidity. Whether cumulative pre-LT CMRF burden predicts MACE across all LT indications has not been evaluated. **Methods:** Adult LT recipients (2013-2023) at a single large LT center were studied at 1-year (n = 1,000), 3-year (n = 724), and 5-year (n = 481) follow-up. The number of pre-LT CMRFs (0-4) was determined using AACE metabolic syndrome criteria: diabetes, hypertension, dyslipidemia, and BMI ≥ 25 kg/m. The primary outcome was MACE (MI, CVA, unstable angina hospitalization). Cox proportional hazards regression adjusted for age, sex, MELD-Na, HCC, indication, and pre-LT CAD was used to estimate the independent effect of CMRF burden. Multivariable logistic regression with the same covariates was performed at each timepoint. Cochran-Armitage trend tests assessed the association between CMRF burden and MACE at each timepoint. Univariate logistic regression evaluated each individual CMRF as a predictor of MACE. **Results:** Among 1,172 LT recipients (59% male, 50% Latinx, median age 57 [IQR 48-63], median MELD-Na 20 [IQR 14-27], 177 [15%] LDLT), etiologies included ALD (33%), viral (23%), MASLD (22%), autoimmune/cholestatic (12%), and other (10%). Overall MACE incidence at 1, 3, and 5 years was 0.5%, 1.2%, and 4.6% (22 events at 5 years), with increasing CMRF burden associated with higher MACE at 5 years: 0.9%, 2.9%, 6.5%, 13.7%, and 10.0% for 0-4 CMRFs (trend p = 0.0002) (Figure 1, Table 1). On univariate analysis, HTN (OR 3.35, p = 0.006), DM (OR 3.24, p = 0.008), BMI ≥ 25 (OR 2.55, p = 0.10), and dyslipidemia (OR 2.18, p = 0.23) were assessed; DM and HTN were significant predictors. On Cox regression, each additional CMRF was associated with a 75% increase in the hazard of MACE (HR 1.75, 95% CI 1.16-2.66, p = 0.008). On logistic regression at 5 years, each additional CMRF had an OR of 1.84 (95% CI 1.18-2.85, p = 0.007). By etiology, 68% of 5-year MACE events occurred in non-MASLD recipients (ALD 27%, viral 18%, autoimmune/cholestatic 18%, other 5%), with MASLD accounting for 32%. **Conclusion:** Pre-LT CMRF burden shows a dose-dependent association with MACE after LT across all indications. DM and HTN are the strongest individual predictors. The majority of MACE events occurred in non-MASLD recipients. These findings support cardiometabolic risk stratification and optimization at the pre-transplant phase for all LT indications.

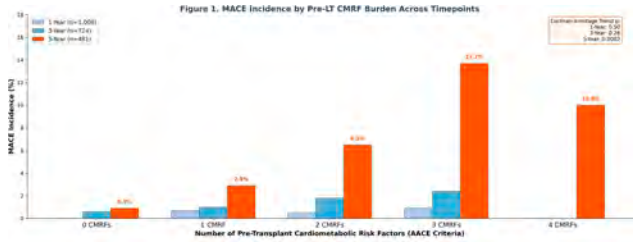

Table 1. 5-Year MACE by Pre-LT CMRF Burden (0-4), n=481

Events	0 CMRFs (n=106)	1 CMRF (n=207)	2 CMRFs (n=107)	3 CMRFs (n=51)	4 CMRFs (n=10)	p-value
MACE (any)	1/111 (0.9%)	6/207 (2.9%)	7/107 (6.5%)	7/51 (13.7%)	1/10 (10.0%)	0.0002
MI	0/106 (0%)	2/207 (1.0%)	4/107 (3.7%)	2/51 (3.9%)	1/10 (10.0%)	0.0001
CVA/stroke	0/106 (0%)	2/207 (1.0%)	2/107 (1.9%)	2/51 (3.9%)	0/10 (0%)	0.17
Unstable angina hospitalization	1/106 (0.9%)	2/207 (1.0%)	1/107 (0.9%)	3/51 (5.9%)	0/10 (0%)	0.08

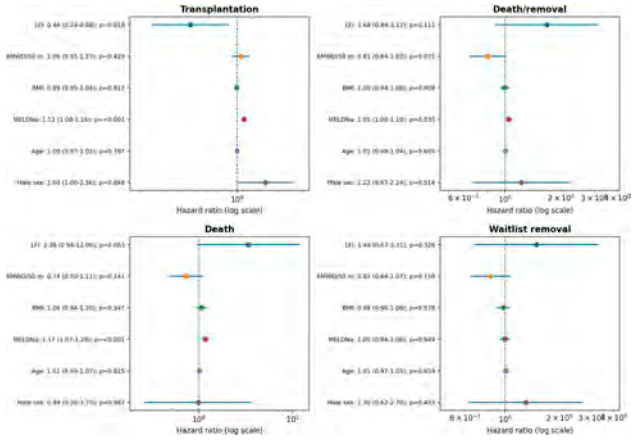
4491 | DYNAMIC LIVER FRAILTY INDEX PREDICTS ADVERSE WAITLIST OUTCOMES IN LIVER TRANSPLANT CANDIDATES: A MULTI-STATE SURVIVAL ANALYSIS



Rakan Alqahtani[1] Ibrahim Alomar[1] Erica Lo[2] Tracy Fuller[2] Kristin Morris[2] Tania Larsen[2] Anouar Teriaky[1] David Hudson[1] Karim Qumosani[1] Tamoor Afzaal[1], [1]Western University, [2]London Health Sciences Centre

Background: Frailty is a key determinant of outcomes in liver transplant candidates (LTCs). However, the prognostic significance of longitudinal changes in Liver Frailty Index (LFI) and six-minute walk distance (6MWD) while awaiting transplant remains uncertain. We evaluated whether dynamic frailty and physical function trajectories predict waitlist outcomes including transplantation, death on the waitlist, and waitlist removal. **Methods:** We conducted a retrospective cohort study of adult LTCs waitlisted in London, ON, Canada between January 2020 and December 2022, who underwent serial physiotherapy assessments. Patients were followed from waitlisting until transplantation, death on the waitlist, waitlist removal, or censoring (June 30, 2024). Baseline characteristics were compared using χ^2 or Fisher's exact tests for categorical variables, and ANOVA or Kruskal-Wallis tests for continuous variables. Missing data were addressed using multiple imputation by chained equations. Multi-state survival analyses were performed using Aalen-Johansen estimators. Cause-specific Cox proportional hazards models evaluated associations of time-varying LFI, 6MWD, BMI, age, sex, and MELDNa with transplantation and waitlist death, and removal. Secondary exploratory analyses evaluated LFI and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

6MWD cutoffs, concordant-discordant frailty / physical function phenotypes, and longitudinal changes (ΔLFI, Δ6MWD). **Results:** Among 164 LTCs, 103 (62.8%) underwent transplantation, 14 (8.5%) died on the waitlist, 43 (26.2%) were removed, and 4 (2.4%) were censored. Median baseline MELDNa and LFI differed significantly across outcome categories (MELDNa: 23.0 in deaths vs 17.6 in transplanted patients; p = 0.018; LFI: 3.9 in deaths/removals vs 3.5 in transplanted patients; p = 0.009). Baseline 6MWD was lowest among patients who died on the waitlist (336 m, p = 0.060). One-year cumulative incidences of death, waitlist removal, and transplantation were 7.9%, 21.3%, and 54.3%, respectively. In multivariable multi-state Cox models, higher time-varying LFI independently reduced transplantation likelihood (HR 0.46, 95%CI 0.24–0.88; p = 0.018), while higher MELDNa increased transplantation likelihood (HR 1.12, 95%CI 1.08–1.16; p < 0.001). Higher LFI showed a trend towards increased risk of waitlist death/removal (HR 1.68, 95%CI 0.89–3.17; p = 0.111). Each 50m increase in 6MWD trended toward lower risk of waitlist death/removal (HR 0.81, 95%CI 0.64–1.02; p = 0.071) (Figure). Worsening ΔLFI and declining Δ6MWD trajectories were associated with higher waitlist death/removal and lower transplantation probabilities. **Conclusion:** Dynamic frailty assessment via LFI provides useful prognostic information beyond static measures, predicting liver transplantation likelihood. Serial monitoring of frailty and physical function trajectories may mprove waitlist risk stratification and identify targets for prehabilitation.

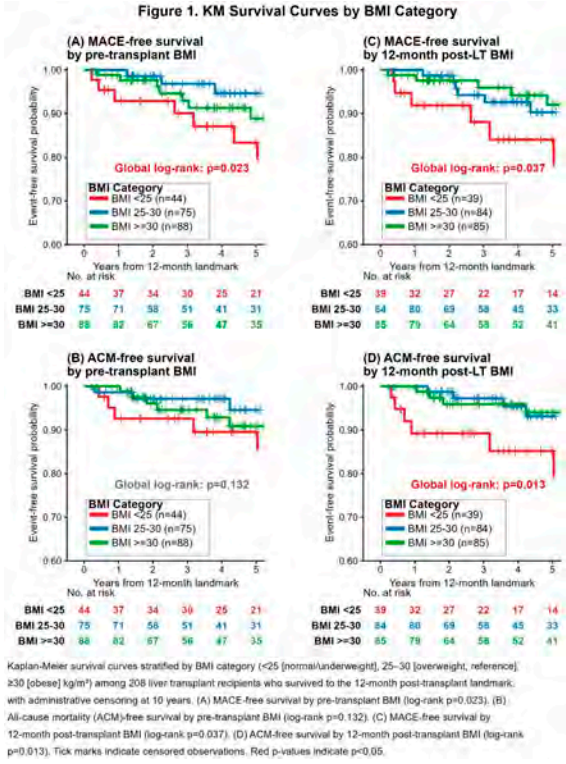
4492 | WEIGHT TRAJECTORIES AFTER LIVER TRANSPLANTATION PREDICT MORTALITY AND CARDIOVASCULAR RISK



Isra Taha[1] Khang Nguyen[2] Barbara Okeke[3] Kelly Fan[3] Rusdha Mansuri[2] Spencer Hobbs[2] Ava Delonais-Parker[2] Sneha Manikandan[2] Sahita Gandra[2] Mina Benjamin[3] Uchenna Agbim[4], [1]SSM Saint Louis University Hospital, [2]Saint Louis University School of Medicine, [3]SSM Health Saint Louis University Hospital, [4]SSM Health Saint Louis University Hosptial

Background: Weight change after liver transplantation (LT) is common and may reflect physiologic recovery, yet its relationship with outcomes remains unclear. We evaluated associations between pre-LT and 12-month post-LT BMI with major adverse cardiovascular events (MACE) and all-cause mortality (ACM) in LT recipients. **Methods:** We conducted a single-center retrospective cohort study of adult LT recipients from January 2014 to January 2024. BMI was categorized as < 25 kg/m² (normal/underweight), 25–30 kg/m² (overweight), or ≥ 30 kg/m² (obese). Mixed-effects models assessed BMI trajectories pre-LT through 12 months post-LT across BMI categories. A 12-month landmark analysis was applied to Cox proportional hazard and Kaplan-Meier (KM) models: patients who died or were lost to follow-up within 12 months were excluded and survival was measured from the 12-month post-LT landmark. Cox and KM analyses evaluated associations between pre- and post-LT BMI and MACE or ACM, and Cox model was adjusted for age, sex, diabetes, hypertension, and MELD. Outcomes were capped to 10 years post-LT. **Results:** In 208 patients, 26 MACE and 22 ACM events were recorded over 10 years. Mixed effects model showed normal/underweight patients gained BMI more rapidly during the first 12 months post-LT compared to overweight patients (2.79 vs. +1.25 kg/m²/yr; interaction β = 0.128/month, p = 0.028) but remained normal/underweight at 12 months. Obese patients remained weight stable (0.02 kg/m²/year; interaction β = −0.102/month, p = 0.035). KM analysis showed significant between-group differences in MACE-free survival by pre-LT BMI (p = 0.023) and in ACM-free survival (p = 0.013) by 12-month post-LT BMI; pairwise comparisons of KM analysis showed statistically significant worse MACE-free survival in pre-LT BMI < 25 kg/m² vs. BMI 25-30 (p = 0.006) and ACM-free survival by 12-month post-LT BMI < 25 kg/m² vs. BMI 25-30 (p = 0.014). Adjusted Cox models found pre-LT BMI < 25 kg/m² was associated with higher MACE risk compared to BMI 25-30 (HR 6.34, 95% CI 1.63–24.63; p = 0.008) and 12-month post-LT BMI < 25 kg/m² was associated with higher ACM risk (HR 9.20, 95% CI 1.86–45.51; p = 0.006) compared to BMI 25-30 kg/m². **Conclusion:** Normal/underweight BMI (< 25 kg/m²) both pre- and post-LT predicted adverse outcomes,

with pre-LT BMI < 25 kg/m² predicting post-LT MACE and 12-month post-LT BMI < 25 kg/m² predicting ACM. These findings suggest that peri-LT BMI is associated with post-LT outcomes, highlighting the importance of nutritional status in transplant recipients.

Kaplan-Meier survival curves stratified by BMI category (<25 [normal/underweight], 25–30 [overweight, reference], ≥30 [obese] kg/m²) among 208 liver transplant recipients who survived to the 12-month post-transplant landmark, with administrative censoring at 10 years. (A) MACE-free survival by pre-transplant BMI (log-rank p=0.023). (B) All-cause mortality (ACM)-free survival by pre-transplant BMI (log-rank p=0.132). (C) MACE-free survival by 12-month post-transplant BMI (log-rank p=0.037). (D) ACM-free survival by 12-month post-transplant BMI (log-rank p=0.013). Tick marks indicate censored observations. Red p-values indicate p<0.05.

4493 | ANGIOTENSIN II TYPE I RECEPTOR ANTIBODIES ARE ASSOCIATED WITH RETRANSPLANTATION IN LIVER ALLOGRAFTS

Jeyamani Ramachandran[1] Kathleen Davy[1] Sarah Mikowski[2] Adrian Fleet[3] Tim Emery[3] Kate Muller[4] John Chen[2] Alan Wigg[5] Robert Carroll[3] Alexander Rodgers[4], [1]Hepatology and liver transplant medicine unit, Flinders Medical Centre, [2]South Australian Liver Transplant Unit, Flinders Medical Centre, [3]Australian Red Cross Lifeblood, [4]Flinders Medical Center, [5]Southern Adelaide Local Health Network

Background: The clinical significance of antibodies to non-HLA targets such as Angiotensin II Type 1 Receptor (AT1R-Abs) is not well known in liver transplantation (LT) despite their association with rejection and graft loss in renal transplantation. **Aim:** To study the prevalence of AT1R-Abs and their association with LT complications including antibody mediated rejection (ABMR), hepatic artery complications and re-LT. **Methods:** This prospective study included primary LT recipients, from the South Australian Liver Transplant Unit between 2015-2023, with at least 12 months follow-up. AT1R-Abs from pre- and post-LT serum samples were tested and the clinical course was reviewed. **Results:** 105 patients (58% male) with a median age 62 years (IQR 13) were studied for a median period of 4 years. The prevalence of AT1R-Abs pre-LT was as follows: negative (< 10 U/mL) -18%, at risk (10-17 U/mL) - 44%, positive (> 17 U/mL) - 38%. There was no significant association between their prevalence and age, gender or liver disease etiology. Post-LT, the prevalence of negative AT1R-Abs increased to 45% whereas that of risk and positive AT1R-Abs decreased to 30% and 25% respectively. More women than men (61 VS 39%) were positive for AT1R-Abs post-LT. Four patients underwent re-LT– three for vascular complications and one for ABMR. They demonstrated significantly higher pre-LT AT1R-Abs than patients without re-LT. Four patients had ABMR and their post- LT AT1R-Abs were significantly higher than those without ABMR. Five patients developed de novo detection of AT1R-Abs, with one developing ABMR. One of these patients also required a third LT for ABMR. The antibody levels and their association with complications is demonstrated in Table 1. **Conclusion:** In our study cohort, high AT1R-Abs were associated with ABMR and with re-LT. Further studies are required to confirm their role as a predictive biomarker for LT complications and intervention with AT1R blocking drugs

Table 1: Comparison of ATR1-Ab levels in patients with and without post LT complications

Complication	Occurrence	Pre-LT AT1R-Ab U/mL Median (IQR)	Post-LT AT1R-Ab U/mL Median (IQR)
T-Cell mediated rejection	Yes (n=39)	14(30)	Yes–11(11)
	No (n=66)	13(12)	No--10(5)
	p value	0.248	0.663
Antibody mediated rejection	Yes (n=4)	64(284)	100(303)
	No (n=101)	13(15)	11(9)
	p value	0.231	**0.049**
Re transplantation	Yes (n=4)	29(265)	25(265)

4494 | BIOELECTRICAL IMPEDANCE PHASE ANGLE AND FLUID DISTRIBUTION DURING LIVER TRANSPLANT EVALUATION: A PROSPECTIVE OBSERVATIONAL COHORT STUD

Yichen Wang[1] Yan Yan[1] Yuting Huang[1] Lu Kang[1] Andrew Lian[1] Dana Perry[1] Burcin Taner[1] Cui Tao[2] Liu Yang[2], [1]Mayo Clinic Florida, [2]Mayo Clinic, Florida

Background: Patients with advanced liver disease often have malnutrition, extracellular volume expansion, and frailty incompletely captured by body-mass index or muscle-size metrics. Bioelectrical impedance analysis (BIA) quantifies phase angle and fluid distribution at the point of care. In this largest cohort of BIA during liver transplant evaluation to date, We evaluated whether BIA-derived measures were associated with mortality, post-transplant outcomes, and clinical benchmarks during liver transplant evaluation. **Methods:** We prospectively collected baseline BIA assessments in 816 patients undergoing liver transplant evaluation, 188 later underwent transplantation. Cox models for mortality treated transplantation after BIA as a time-varying covariate, and post-transplant outcomes were modeled among recipients (Figure 1). **Results:** During a median 315-day follow-up, 66 of 815 patients died. Higher whole-body phase angle was associated with lower mortality (hazard ratio per 1-SD [0.9-degree] increase, 0.65; 95% CI, 0.49-0.86), whereas higher whole-body extracellular water-to-total body water ratio was associated with higher mortality (hazard ratio per 1-SD [0.017] increase, 1.34; 95% CI, 1.10-1.63) (Figure 2). Appendicular skeletal muscle index was not associated with mortality. MELD and MELD-Na provided the largest incremental mortality prediction, but selected BIA measures added more prognostic value than body-mass index, appendicular skeletal muscle index, documented sarcopenia, documented reduced grip strength, and 6-minute walk distance. Whole-body BIA associations attenuated after direct MELD/MELD-Na adjustment. Post-transplant mortality was infrequent; other post-transplant analyses were exploratory. **Conclusion:** BIA-derived phase angle and extracellular water-to-total body water ratio outperform conventional size-based and functional benchmarks for prognostic vulnerability during liver transplant evaluation. BIA complements MELD-based severity assessment and warrants external validation as a scalable risk-phenotyping tool.

4495 | EARLY POSTOPERATIVE RESUSCITATION PHENOTYPES ARE ASSOCIATED WITH RENAL DYSFUNCTION AND CLINICAL OUTCOMES FOLLOWING LIVER TRANSPLANTATION

Rohit Khullar[1] Ki Jung Lee[1] Mohammad Almeqdadi[1], [1]Tufts Medical Center

Background: Optimal postoperative fluid management following liver transplantation remains poorly defined. Albumin, blood products, and isotonic fluids are frequently administered during the immediate postoperative period, yet the relationship between distinct resuscitation strategies and post-transplant outcomes remains unclear. We sought to characterize early postoperative resuscitation phenotypes and evaluate their association with graft function, renal dysfunction, and clinical outcomes following liver transplantation. **Methods:** We performed a retrospective cohort study of adult liver transplant recipients at a single academic transplant center. Patients were classified into albumin-, blood product-, or isotonic fluid-predominant phenotypes based on the largest proportion of total intravenous fluid resuscitation administered during the first 24 postoperative hours. Patients without a predominant phenotype were excluded from comparative analyses. Outcomes included early allograft dysfunction (EAD) defined by Olthoff criteria, acute kidney injury (AKI), renal replacement therapy (RRT), postoperative laboratory values, and healthcare utilization. Continuous variables were compared using analysis of variance and categorical variables using chi-square testing. **Results:** Among 287 transplant recipients, 25 (8.7%) were albumin-predominant, 175 (61.0%) blood product-predominant, and 87 (30.3%) isotonic fluid-predominant. Total resuscitation volume differed

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

significantly among phenotypes ($p < 0.001$), with blood product-predominant patients receiving the greatest fluid administration. Rates of EAD were similar across groups (36.0% vs. 32.6% vs. 24.1%, $p = 0.31$). Compared with albumin- and isotonic fluid-predominant patients, blood product-predominant patients were more likely to develop MELD ≥ 18 by postoperative day 5 (60.0% vs. 32.0% vs. 37.9%, $p < 0.001$), require RRT (25.7% vs. 12.0% vs. 13.8%, $p = 0.044$), mechanical ventilation (47.4% vs. 28.0% vs. 29.9%, $p = 0.011$), and prolonged hospitalization ≥ 10 days (79.4% vs. 60.0% vs. 51.7%, $p < 0.001$). Blood product-predominant patients also demonstrated higher bilirubin levels on postoperative days 1 and 5 ($p = 0.02$ and $p < 0.001$, respectively). AKI occurred more frequently in blood product-predominant patients, although this difference did not reach statistical significance (26.9% vs. 8.0% vs. 21.8%, $p = 0.11$). **Conclusion:** Although EAD rates were similar across phenotypes, blood product-predominant resuscitation was associated with greater postoperative morbidity, including increased RRT utilization, higher bilirubin levels, and prolonged hospitalization. Early postoperative resuscitation phenotypes may provide a practical framework for identifying liver transplant recipients at increased risk for postoperative renal dysfunction and adverse clinical outcomes.

Table 1. Baseline Characteristics and Post-Transplant Outcomes Stratified by Early Postoperative Resuscitation Phenotype

	Fluid Resuscitation Predominant Phenotype			p-value[b]
	Albumin	Blood Product	Isotonic Fluid	
n	25	175	87	-
Total IV Fluid Resuscitation, mL (Mean)	1236	3995	1847	< 0.001
Albumin	633	238	157	< 0.001

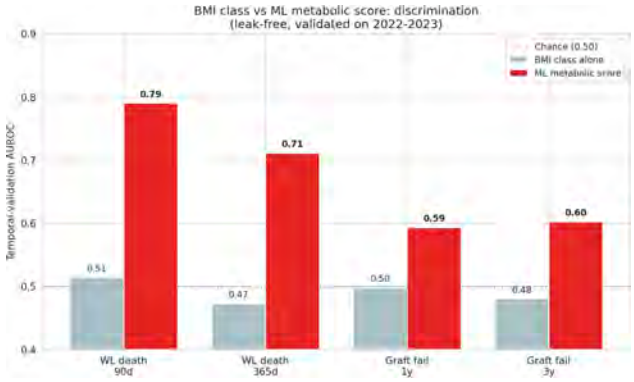
4496 | MACHINE LEARNING OUTPERFORMS BMI FOR PREDICTING WAITLIST MORTALITY IN MASH-SPECTRUM LIVER TRANSPLANT CANDIDATES



Sri Harsha Boppana[1] Subhash Gurappa[2] Sachin Sravan Kumar Komati[2] Gautam Maddineni[3] Raja Chandra Chakinala[4] Venkata Sunkesula[5] Pradeep Yarra[6] Christina Awad[6], [1]Nassau University Medical Center, [2]Florida International University, [3]Creighton university school of medicine, [4]Guthrie Robert Packer Hospital, [5]Case Western Reserve University, [6]UT health San Antonio

Background: Body mass index (BMI) remains a highly visible factor in liver transplant (LT) evaluation for metabolic dysfunction-associated steatohepatitis (MASH), yet its prognostic value relative to integrated clinical risk modeling is uncertain. We developed and temporally validated machine-learning (ML) models to determine whether listing BMI class meaningfully predicts waitlist mortality and post-LT graft failure in MASH-spectrum LT candidates. **Methods:** Adult, single-organ LT candidates listed from 2018-2023 with MASH or cryptogenic cirrhosis were identified from a national registry cohort. Candidates listed in 2018-2021 formed the training cohort and those listed in 2022-2023 formed a temporal validation cohort. Outcomes were waitlist death within 90 and 365 days and graft failure within 1 and 3 years after LT. BMI class was compared with ML models using XGBoost, random forest, and elastic net. Discrimination was assessed by validation AUROC; model improvement over BMI was quantified using AUROC gain, net reclassification improvement (NRI), and integrated discrimination improvement (IDI). SHAP values identified dominant predictors. **Results:** Among 5,063 listed candidates, 3,152 underwent LT and 1,911 were never transplanted; 994 waitlist deaths occurred, including 399 within 90 days and 718 within 365 days. The 90- and 365-day cumulative incidence of waitlist death was 8.0% and 14.9%, respectively, with 365-day transplant as a competing event in 54.6%. Waitlist death at 365 days was similar across BMI strata: non-obese 14.7%, class I 14.4%, class II 15.0%, and class III 19.2% ($p = 0.125$). BMI alone performed at chance for waitlist death (AUROC 0.514 at 90 days; 0.472 at 365 days) and graft failure (0.498 at 1 year; 0.480 at 3 years). In temporal validation, leak-free ML models improved discrimination for waitlist death (AUROC 0.771 at 90 days; 0.711 at 365 days), with AUROC gains of 0.257 and 0.239 over BMI alone. The full-feature ML model achieved AUROC 0.860 for 90-day and 0.779 for 365-day waitlist death, with NRI 1.130/0.833 and IDI 0.184/0.157. De-leaked SHAP analysis ranked age, MELD-Na, bilirubin, albumin, and

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

creatinine above BMI, which ranked sixth of 12 predictors. (Figure1) **Conclusion:** In a contemporary national MASH-spectrum LT cohort, BMI class did not meaningfully stratify waitlist mortality and BMI alone predicted death or graft failure no better than chance. Temporally validated ML models substantially improved short-term waitlist mortality prediction by integrating liver disease severity, renal function, age, and BMI. These data challenge BMI-centered listing decisions and support AI-enabled risk stratification to individualize LT evaluation in MASH.

4497 | FACTORS INFLUENCING LIVER TRANSPLANT WAITLIST REMOVAL FOR NON-CLINICAL REASONS: A NATIONAL RETROSPECTIVE COHORT ANALYSIS

Nikhilesh Kumar[1] Shayana Seneviratne[1] Kali Zhou[1],
[1]Keck School of Medicine of University of Southern California

Background: Liver transplant (LT) waitlist removal for non-clinical reasons has had limited exploration despite the high likelihood of subsequent morbidity and mortality. Unlike clinical reasons such as medical/surgical contraindications or being too early for transplant, non-clinical reasons including psychosocial barriers and loss to follow-up are potentially modifiable. This retrospective cohort analysis seeks to identify factors that influence non-clinical reasons for waitlist removal. **Methods:** We analyzed waitlist removal data from the Scientific Registry of Transplant Recipients database on adults listed for LT from 2005-2022. Reasons for waitlist removal were categorized as non-clinical, clinical, death, and transplant. Removals classified as "Other" (N = 5473) were manually re-categorized. Non-clinical reasons were grouped into (1) psychosocial barriers, (2) lost to follow-up, and (3) patient choice/refusal. The patient choice group was excluded from analysis as they represented a different population. Multivariable competing risk Cox regression analysis was used to examine factors at time of waitlisting associated with non-clinical removal, with transplant as the competing risk and other reasons censored at time of waitlist removal. **Results:** Among 82,895 waitlist removals, 54,709 (66.0%) were transplanted and 17,617 (21.3%) died. 5,324 (6.4%) were removed for non-clinical reasons and 5,245 (6.3%) were removed for clinical reasons. Of non-clinical removals, 55.5% were due to psychosocial reasons, 16.8% were lost to follow-up, and 27.6% for patient choice/transplant refusal. Among psychosocial removals, 50.3% were for alcohol/substance use and 30.1% for non-adherence, with the remaining for insufficient social support/transportation/finances. Factors associated with non-clinical waitlist removals included Hispanic race/ethnicity (vs White; SHR: 1.11 [1.01-1.21]), living in a higher median MELD at transplant (MMAT) region (vs lower MMAT; SHR: 1.42 [1.32-1.53]), non-private insurance (vs private), and alcohol etiology (vs HCV, SHR: 1.40 [1.28-1.52]) (Figure). Protective factors included older age, CTP category C, higher MELD and HCC MELD exception. There was a significant interaction between alcohol etiology and MELD at listing ($p < 0.01$): the likelihood of non-clinical removal was higher for alcohol compared to non-alcohol etiologies with MELD scores < 25 (SHR MELD < 25: 1.40 [1.28–1.52], SHR MELD ≥ 25: 0.85 [0.63–1.15]). **Conclusion:** Psychosocial concerns account for most non-clinical LT waitlist removals. Higher urgency based on clinical factors protected against removal for non-clinical reasons, while sociodemographic factors and higher organ competition heightened risk. Interventions are needed to address psychosocial barriers while on the waitlist to ensure equitable LT access for socially vulnerable individuals.

4498 | KIDNEY ALLOGRAFT OUTCOMES AFTER SIMULTANEOUS LIVER–KIDNEY VS SAFETY-NET TRANSPLANTATION

Abhijith Atkuru[1] Sidart Pradeep[2] Eugenia Tsai[2], [1]Tulane University School of Medicine, [2]Texas Liver Institute; UT Health San Antonio

Background: Following the 2017 Organ Procurement and Transplantation Network (OPTN) policy, short-term kidney allograft outcomes between simultaneous liver–kidney (SLK) and Safety-Net pathways have been described, yet longer-term graft survival, patient survival, and early graft function metrics remain uncharacterized in a national cohort. Kidney allograft outcomes were compared between SLK and Safety-Net recipients in the largest post-policy national cohort to date. **Methods:** Using OPTN/Scientific Registry of Transplant Recipients (SRTR) Standard Transplant Analysis and Research (STAR) data (2018–2024), adults who underwent SLK or received a Safety-Net kidney 60-365 days after liver-alone transplantation were identified. Outcomes included delayed graft function (DGF), kidney graft failure by follow-up graft status, creatinine at kidney transplant, 6 and 12 months, and Kaplan-Meier (KM) patient survival. Kidney graft failure was defined as failed graft status; deaths without graft-status failure and return to maintenance dialysis alone were not counted. Comparisons used chi-square, Wilcoxon rank-sum, log-rank, and linear models. **Results:** Among 4,197 recipients, 3,506 underwent SLK and 691 received a Safety-Net kidney. Safety-Net recipients had higher Model for End-Stage Liver Disease score (34 vs 28), dialysis use (66.3% vs 46.3%), and kidney-transplant creatinine (4.00 vs 3.20 mg/dL; all $p < 0.001$). DGF was more frequent after SLK (30.8% vs 18.6%, $p < 0.001$), whereas kidney graft failure by follow-up graft status was similar (4.5% vs 4.4%, $p = 0.978$). Safety-Net recipients also had higher creatinine at 6 months (1.40 vs 1.23 mg/dL) and 12 months (1.41 vs 1.25 mg/dL; both $p < 0.001$). KM patient survival was lower after SLK at 1 year (90.4% vs 95.7%), 3 years (82.8% vs 90.5%), and 5 years (75.0% vs 82.6%; all $p < 0.001$) (Table 1). **Conclusion:** Despite greater pre-transplant renal dysfunction and higher post-transplant creatinine through 12 months, Safety-Net recipients had lower DGF and superior 1-, 3-, and 5-year patient survival compared to SLK. These findings suggest that chronic kidney disease burden at liver transplantation, rather than acute renal dysfunction, is the dominant driver of long-term mortality in this population and support early Safety-Net listing planning.

Table 1. Kidney Allograft and Patient Survival Outcomes
SLK versus Safety-Net kidney transplantation, OPTN/SRTR STAR data 2018-2024

Outcome	SLK	Safety-Net	P value
Pre-Kidney Transplant Clinical Profile			
Model for End-Stage Liver Disease score, (median)	28	34	<0.001
Dialysis use at kidney transplant	46.3%	66.3%	<0.001
Kidney-transplant creatinine, median [IQR], mg/dL	3.20 [2.08-4.87]	4.00 [2.90-5.62]	<0.001
Early Kidney Allograft Events, n/N (%)			
Delayed graft function	1,043/3,390 (30.8%)	128/689 (18.6%)	<0.001
Kidney graft failure by follow-up graft status	147/3,249 (4.5%)	30/680 (4.4%)	0.978
Post-Kidney Transplant Renal Function, median [IQR], mg/dL			
At kidney transplant	3.20 [2.08-4.87]	4.00 [2.90-5.62]	<0.001
6 months	1.23 [1.00-1.53]	1.40 [1.12-1.74]	<0.001
12 months	1.25 [1.03-1.53]	1.41 [1.13-1.70]	<0.001
Kaplan-Meier Patient Survival			
1 year	90.4%	95.7%	<0.001
3 years	82.8%	90.5%	<0.001
5 years	75.0%	82.6%	<0.001
Pathway-by-Etiology Interaction for Creatinine			
At kidney transplant			0.012
6 months			0.852
12 months			0.863

Note: Kidney graft failure was defined as failed follow-up graft status, deaths without graft-status failure and return to maintenance dialysis alone were not counted. Patient survival was estimated using Kaplan-Meier analysis.

Abbreviations: DGF, delayed graft function; IQR, interquartile range; KM, Kaplan-Meier; MELD, Model for End-Stage Liver Disease; OPTN, Organ Procurement and Transplantation Network; SLK, simultaneous liver-kidney; SRTR, Scientific Registry of Transplant Recipients; STAR, Standard Transplant Analysis and Research.

4499 | BRIDGING OBESE LIVER TRANSPLANT CANDIDATES TO LISTING: SAFETY AND EFFICACY OF VLCD COMBINED WITH PHARMACOTHERAPY IN DECOMPENSATED CIRRHOSIS

Aldanah Althwanay[1] Scott McHenry[2] Megan White[3], [1]washington university at st louis, [2]Washington University in St. Louis, [3]Washington University Medical Center

Background: Liver transplant candidates with BMI > = 40 kg/m2 face a 29% lower adjusted transplant rate and decreased post-transplant survival. When rapid pre-transplant weight reduction is required, pharmacotherapy alone may take months for meaningful BMI reduction, and endoscopic bariatric procedures, while promising for sustained weight loss, have not been well studied in patients with decompensated cirrhosis. Very low-calorie diets (VLCD, < 900 kcal/day) offer a rapid bridging strategy, yet safety data in decompensated cirrhosis requiring urgent listing remain limited. **Methods:** Prospective single-center case series (09/2023-03/2025) of 13 patients whose obesity precluded transplant eligibility. Ten initiated VLCD (< 900 kcal/day) with phentermine (n = 9) and GLP-1 receptor agonists (n = 8; tirzepatide, semaglutide, liraglutide, or dulaglutide). Three received pharmacotherapy alone as a pragmatic comparison. All underwent multidisciplinary transplant evaluation with weekly electrolyte and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

acid-base monitoring. **Results:** Mean age 62 years; 54% male. Etiologies: MASH (54%), HCV (15%), AIH/PBC (15%), Met-ALD (8%), SSC (8%). 77% had decompensated cirrhosis. Mean initial BMI 46 kg/m2 (range 36-58); median initial MELD 21 (range 18-30). VLCD patients achieved mean weight loss of 45 lbs (range 13-106) over 61 days (range 32-119), reducing mean BMI to 40 kg/m2 with median listing MELD of 24 (range 16-27). No patient required discontinuation for metabolic complications; weekly monitoring showed no electrolyte derangements or metabolic acidosis, including in advanced decompensation. Nine of 10 VLCD patients (90%) achieved transplant approval; 6 were transplanted (one simultaneous liver-kidney) with 5 alive and well. Two early deaths (gastrointestinal bleed day 3, subdural hematoma day 11) were not attributed to VLCD. None of the 3 pharmacotherapy-only patients achieved eligibility. **Conclusion:** To our knowledge, this is the largest prospective case series evaluating VLCD for rapid pre-transplant weight reduction in decompensated cirrhosis. VLCD (< 900 kcal/day) was safe, metabolically well-tolerated, and achieved transplant eligibility in 90% of patients under multidisciplinary oversight. When urgency demands rapid BMI reduction, this approach should be considered as a safe and efficacious strategy. The small sample, single-center design, and limited follow-up constrain generalizability; larger multicenter studies with longer-term outcomes are warranted.

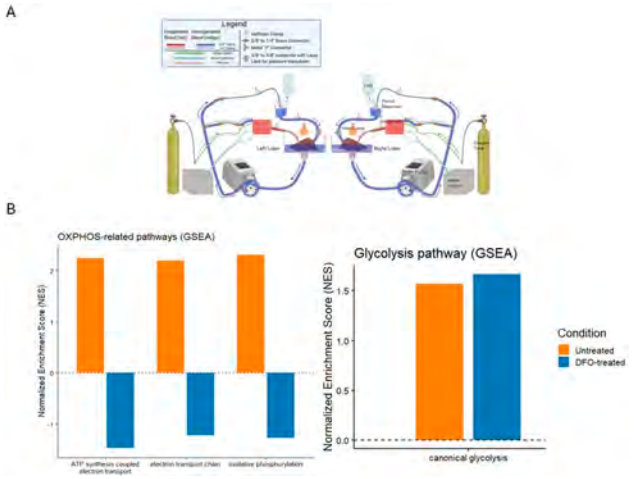
Table 1. Patient Characteristics, Interventions, and Clinical Outcomes (N=13)

Patient Characteristics	Time on VLCD (Days)	GLP-1 RA (Generic / Brand)	Oral Weight Loss Medication	Outcomes
64F MASH Ascites + HE	36	Tirzepatide (Mounjaro)	Phentermine	Transplanted BMI 41.3 → 37.5 (−9.8) No complications
73M Met-ALD Ascites + HCC	N/AT	Semaglutide (Ozempic / Wegovy)	None	Approved for transplant Removed from list 07/2025 (patient request) HCC: non-viable >12 months; viable synthetic function
65F MASH HE	97	Tirzepatide (Mounjaro) Semaglutide (Ozempic) Liraglutide (Victoza)	Phentermine	SLK transplanted 12/2025 BMI 49.0 → 38.0 (−10.0) No complications
39M MASH Ascites + HE	37	Tirzepatide (Mounjaro) Dulaglutide (Trulicity)	Phentermine	Approved; 30 lb weight loss achieved Died of presumed septic shock 2 months post-approval (prior to waitlist outcome)
42M MASH Ascites + HE Prior GIB	118	None	Phentermine	Transplanted BMI 46.3 → 44.3 (−2.0) RTCP +1 for hematoma washout Currently doing well
63F MASH Ascites + HE	47	Tirzepatide (Mounjaro)	None	Transplanted BMI 58.0 → 38.6 (−19.4) Acalculous cholitis requiring biliary stenosis (cross site) Currently doing well
65M HCV Ascites + HE Prior HTN + HCC	32	Semaglutide (Ozempic)	Phentermine	Transplanted BMI 40.7 → 36.6 (−4.1) Delayed CMV viremia Currently doing well
51M MASH Ascites + HE Prior GIB	55	Semaglutide (Ozempic)	Phentermine	Died intraoperatively BMI 52.3 → 45.3 (−7.0) Cardiac collapse after reperfusion
68F AIH / PBC Overlap	115	None	Phentermine	Died during admission Spontaneous SDH + seizures (11 days after VLCD initiation) Never listed
65F AIH / PBC Overlap Ascites + HE + HRS	33	Dulaglutide (Trulicity)	None	Admitted for UGI bleed (likely before VLCD initiation) Discharged to hospice; died shortly after Never listed
73F MASH Ascites + HCC	53	None	Phentermine	Transplanted BMI 43.8 → 34.3 (−9.5) Recurrent IV paracentesis Currently doing well
58M HCV HCC	N/AT	None	Topiramate-phentermine (Qsymia, stopped 1W)	Approved for transplant Removed from list (patient request) HCC non-viable
40F SSC	N/AT	None	None	Not listed; followed in clinic (Pharmacotherapy only comparison group)

Abbreviations: HE = hepatic encephalopathy; HCC = hepatocellular carcinoma; GIB = gastrointestinal bleeding; HRS = hepatorenal syndrome; SLK = simultaneous liver-kidney transplant; SDH = subdural hematoma; RTCP = return to operating room; SE = side effects; SAC = secondary autoimmune cholangitis; CMV = cytomegalovirus; Pulm HTN = pulmonary hypertension; AIH = autoimmune hepatitis; PBC = primary biliary cholangitis; Met-ALD = metabolic dysfunction–associated steatotic liver disease; HCV = hepatitis C virus; VLCD = very low-calorie diet (<900 kcal/day); SLP 1 RA = glucagon-like peptide-1 receptor agonist.
† Did not tolerate VLCD; managed with pharmacotherapy alone (weight loss comparison group).
‡ Early deaths not attributed to VLCD; day 3 (upper GI bleed, likely within VLCD initiation) and day 11 (unwitnessed SDH).

Disclosures: Aldanah Althwanay:Nothing to Disclose, Scott McHenry:Nothing to Disclose, Megan White: Nothing to Disclose.

4500 | IRON CHELATION MODULATES THE TRANSCRIPTOME TO ATTENUATE FERROPTOSIS IN HUMAN MARGINAL DONOR LIVERS



Shun Onishi[1] Takahiro Okura[1] Chandrashekhara Manithody[1] Mustafa Nazzal[1] Ajay Jain[1], [1]Saint Louis University

Background: Marginal donor livers (MDLs) expand the transplant pool but are vulnerable to ischemia–reperfusion injury (IRI). Ferroptosis, an iron-dependent lipid peroxidation cell death pathway, mediates IRI. Deferoxamine (DFO), an iron chelator, may attenuate ferroptosis, but its transcriptomic effects during ex vivo human liver perfusion are undefined. We tested impact of DFO in paired human MDLs using PROTECT. **Methods:** Six discarded human MDLs were split into paired lobes and perfused using our patent pending PROTECT (Perfusion Regulated Organ Therapeutics with Enhanced Controlled Testing). One lobe received DFO, with single or dual dosing, while the contralateral lobe served as control. Biopsies were obtained at baseline and 5 hours. Bulk RNA-seq was analyzed by Time × Treatment interaction modeling; significant genes, padj < 0.1, underwent GSEA, GO, and Reactome enrichment. Validation included tissue iron, ferroptosis markers, HIF-1α, TUNEL, MDA, and injury markers. **Results:** Baseline transcriptomes were concordant between paired lobes, validating PROTECT. By 5 hours, DFO induced metabolic-redox changes. GSEA showed oxidative phosphorylation and mitochondrial respiratory enrichment in controls, while DFO suppressed mitochondrial oxidative signatures. DFO downregulated electron transport chain genes across Complexes I–V while preserving glycolytic enrichment, including PFKP, PFKFB1, FOXK1, and ENO2 upregulation, and modulated iron-handling, ROS, and inflammasome pathways. Transcriptomic changes aligned with chelation and reduced injury. DFO achieved ≥ 20% tissue iron reduction and downregulated ferroptosis genes, including HIF-1α, IREB2, RPL8, FTH1, ACSF2, and ATP5G3, with multiple targets $p < 0.0001$. HIF-1α protein decreased, $p = 0.0040$. Injury was attenuated, with fewer TUNEL-positive cells, $p = 0.0283$, decreased MDA, and a trend toward lower AST, $p = 0.0727$. Non-chelated lobes showed persistent iron accumulation, ferroptosis activation, oxidative stress, and apoptosis. Iron reduction associated with ferroptosis gene suppression, $p = 0.0040$–0.0485, and lower injury markers. Dual dosing improved chelation efficacy, 2/2 dual-dose versus 2/4 single-dose;

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

protection was observed in steatotic livers. **Conclusion:** DFO induces transcriptomic programming during ex vivo perfusion of human MDLs, suppressing mitochondrial oxidative phosphorylation while preserving glycolytic metabolism and attenuating iron-, ROS-, inflammasome-, and ferroptosis-associated pathways. These changes were accompanied by reduced iron burden, lipid peroxidation, apoptosis, and early hepatocellular injury providing evidence of therapeutic optimization in donor livers.

4501 | FXR AGONIST IN POST LIVER TRANSPLANTATION PATIENTS: FINAL RESULTS FROM A RANDOMIZED OPEN-LABEL STUDY (CTRI/2021/11/038218)

Anila Kutty Narayanan[1] Saraswathy S Nair[1] Arun Valsan[1] Anandakrishnan Nandakumar[2] Sudhindran S[1], [1]Amrita Institute of Medical Sciences and Research Centre, Kochi, Amrita Vishwa Vidyapeetham, India, [2]Amrita Institute of Medical Sciences & Research Centre, Kochi, Amrita Vishwa Vidyapeetham, India

Background: Post-liver transplant cholestasis remains a common complication following living-donor liver transplantation (LDLT), contributing to delayed graft recovery, increased morbidity, and greater healthcare burden. Ursodeoxycholic acid (UDCA) is widely used in this setting; however, it does not directly target bile acid regulatory pathways. Obeticholic acid (OCA), a potent farnesoid X receptor agonist, may therefore offer a mechanism-based therapeutic alternative. This study aimed to compare the efficacy and safety of OCA versus UDCA in ameliorating cholestasis following LDLT. **Methods:** In this prospective, open-label trial, conducted between 2021 and 2025, 287 adult LDLT recipients were randomized to OCA or UDCA using a computer-generated sequence. The primary endpoint was the proportion achieving ≥15% reduction in alkaline phosphatase (ALP) and gamma-glutamyl transferase (GGT) at 3, 6, and 12 months from the 1-month post-transplant baseline. Secondary outcomes included absolute values of liver biochemistry, molecular markers (Fibroblast Growth Factor-19, cytokeratin-18, Bile Salt Export Pump serum autotaxin, and Transforming Growth Factor-β), rejection, biliary complications, survival, adverse events, and quality of life (by Chronic Liver Disease Questionnaire). Modified intention-to-treat analysis excluded patients who did not survive beyond one month(N = 44). Baseline-adjusted analyses used logistic regression, ANCOVA, and repeated-measures models. **Results:** Of 287 randomized patients, 225 were included in the primary efficacy analysis (OCA n = 109; UDCA n = 116). Baseline characteristics were broadly comparable, although early cholestatic enzyme levels were higher in the OCA group. Although in unadjusted analyses, OCA showed higher ALP responder rates at 3 months (50% vs 35%, p = 0.018) and 6 months (50% vs 33%, p = 0.010), and higher GGT response at 12 months (83% vs 69%, p = 0.022) compared to UDCA, after baseline imbalance adjustment, no clear longitudinal superiority was observed. OCA demonstrated greater early reduction in plasma bile acids [OCA 250 (133, 332) vs UDCA 326 (245, 337), p < 0.001]. CRP levels were significantly higher in the OCA group at 6 months (p = 0.019) and 12 months (p = 0.011), while LDL levels were also higher at baseline (p = 0.014), 3 months (p = 0.015), and 6 months (p < 0.001), becoming comparable by 12- months. Rates of rejection, EAD, pruritic, biliary complications, hospital stay, and mortality was similar. Quality of life was largely comparable, though abdominal symptoms and worry domains favored UDCA. There were no major adverse effects in liver function in the postoperative period attributable to OCA **Conclusion:** Although OCA demonstrated FXR-mediated biochemical activity, it was not superior to UDCA in longitudinal biochemical, molecular, or clinical outcome analyses. Its safety profile appeared comparable to that of UDCA in post-liver transplant patients.

Table 1: Number of patients with 15% reduction in Alkaline Phosphatase (ALP) & Gamma Glutamyl Transferase (GGT) - Primary Endpoints.

Biomarker/Time points	Overall, N = 225[1]	OCA, N = 109[1]	UDCA, N = 116[1]	p-value[2]
ALP (month to month)				
1 to 3	95 (42%)	55 (50%)	40 (35%)	0.018
3 to 6	68 (31%)	32 (31%)	36 (32%)	0.9
1 to 6	89 (41%)	52 (50%)	37 (33%)	0.010
6 to 12	71 (36%)	39 (39%)	32 (32%)	0.3
1 to 12	89 (45%)	51 (52%)	38 (38%)	0.063
GGT (month to month)				
1 to 3	164 (74%)	81 (75%)	83 (72%)	0.6
3 to 6	117 (54%)	61 (59%)	56 (50%)	0.3
1 to 6	154 (72%)	78 (76%)	76 (68%)	0.2
1 to 12	149 (76%)	81 (83%)	68 (69%)	0.022

4502 | POST-LIVER TRANSPLANT CARDIOVASCULAR-KIDNEY-METABOLIC SYNDROME STAGING PREVALENCE AND TEMPORAL PROGRESSION

Joseph Gunderson[1] Ludovic Saba[2] Saket Girotra[1] Sarah Lieber[1] Arjmand Mufti[1] Madhukar Patel[1] Lisa VanWagner[1], [1]University of Texas Southwestern Medical Center, [2]UT Southwestern Medical Center

Background: Cardiovascular disease (CVD) is the leading cause of non-graft-related death after liver transplantation (LT), yet risk assessment remains fragmented across metabolic, renal, and cardiovascular domains. The American Heart Association cardiovascular-kidney-metabolic (CKM) framework integrates these interrelated conditions, highlighting shared pathophysiology, overlapping risk factors, and common therapeutic approaches. The CKM staging continuum - from ideal health (stage 0), excess adiposity (Stage 1), metabolic risk factors or chronic kidney disease (CKD) (Stage 2), subclinical or high predicted CVD risk (Stage 3), to clinical CVD (Stage 4) - captures escalating risk and emphasizes prevention. However, the burden and progression of CKM disease after LT are unknown. **Methods:** We conducted a retrospective cohort study using the TriNetX Global Collaborative Network, a federated health research network that provides deidentified electronic health record data from 171 healthcare organizations. We identified living adult LT recipients (2009-2026) and excluded multi-organ transplants. CKM stage was defined using ICD-10-CM, LOINC, and CPT codes and assessed across four transplant eras (Figure). **Results:** Among 55,525 living LT recipients (mean age 60 years, 61.6% male, 61.3% White, 8.2% Hispanic), 83.9% met criteria for CKM stage $\geq$1. Stage 2 was most prevalent (36.9%), followed by stage 3 (27.3%) and stage 4 (14.3%), with 41.6% classified as stage 3-4. Stage 1 was uncommon (5.3%). CKM severity varied across transplant eras, demonstrating a gradient consistent with time-dependent progression (Figure). Stage 4 prevalence increased with longer post-transplant follow-up (11.9% for patients transplanted in 2021-26 vs 17.2% in 2009-12), while stage 0 was most common in the most recent era (19.2%). Notably, advanced CKM stages (3-4) were already prevalent in recent cohorts. **Conclusion:** CKM syndrome affects the vast majority of LT recipients, with a substantial burden of advanced disease and evidence of progressive stage advancement over time. The presence of advanced CKM even in recent cohorts suggests that cardiovascular risk emerges early after LT, representing a critical window for intervention. Stage 2 predominance highlights metabolic-renal disease as a key, modifiable target before progression to overt CVD. These findings support integration of CKM staging into routine post-transplant care and early, multidisciplinary risk management to mitigate long-term adverse cardiovascular outcomes in this high-risk population.

4503 | EVALUATION OF A BLOOD-BASED MICRORNA CLINICAL ASSAY FOR GUIDING IMMUNOSUPPRESSIVE MANAGEMENT IN LIVER TRANSPLANT RECIPIENTS

Yipeng Wang[1] Haleigh Parker[1] Chang Han[1] Byung-In Lee[1] Gordon Vansant[1] Shuguang Huang[1] Bao-Li Loza[2] Brendan Keating[3] Kim Olthoff[4] Abraham Shaked[2], [1]LuminoDx Inc., [2]University of Pennsylvania, [3]New York University, [4]Hospital of the University of Pennsylvania

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Liver transplant recipients require lifelong immunosuppression, which is associated with infection, malignancy, nephrotoxicity, metabolic complications, and reduced quality of life. Current monitoring relies on liver enzymes and biopsy, which typically detect rejection only after liver injury has occurred. HepatoTrack is a circulating microRNA assay previously shown to have strong clinical performance for detection of acute cellular rejection (ACR) in liver transplant recipients and may identify rejection-associated molecular signals before clinical injury becomes apparent. This study evaluated the utility of HepatoTrack for guiding immunosuppression minimization and identifying patients at risk for rejection during withdrawal. **Methods:** HepatoTrack uses 200 µL serum or plasma for RT-qPCR analysis of four microRNAs: miR-122, miR-885, miR-23a, and cel-miR-39. HepatoTrack prediction scores (HPS) for acute cellular rejection (ACR) were generated using a predefined proprietary algorithm. Two liver transplant cohorts undergoing immunosuppression withdrawal were analyzed. Cohort 1 included samples from the A-WISH study (ITN030ST), and Cohort 2 included samples from the OPTIMAL study (ITN056ST; NCT02533180). Biopsy-confirmed ACR served as the reference standard when available. HepatoTrack performance was assessed using ROC analysis and compared with alanine aminotransferase (ALT). **Results:** In Cohort 1, 22 samples had paired liver biopsy results, including 16 biopsy-confirmed ACR and 6 non-ACR samples. HepatoTrack demonstrated strong diagnostic performance for ACR detection with an AUC of 0.896, compared with 0.51 for ALT alone ($p < 0.05$). In Cohort 2, 404 samples from 62 patients undergoing immunosuppression withdrawal were analyzed. Positive HepatoTrack scores (HPS > 2) were infrequent in tolerant patients (6.2%) but more common in non-tolerant by biopsy (30.4%), failed after withdrawal (26.8%), and failed withdrawal (28.4%) groups. Among biopsy-confirmed non-tolerant patients, HPS became elevated 180–240 days after enrollment indicating ACR while ALT remained within normal range. Detectable baseline miR-885 was associated with subsequent withdrawal failure, suggesting potential utility for identifying patients less likely to tolerate immunosuppression minimization. **Conclusion:** HepatoTrack demonstrated strong performance for detecting acute cellular rejection and identified molecular evidence of alloimmune activation during immunosuppression withdrawal before biochemical injury or biopsy-proven rejection became apparent. These findings support HepatoTrack as a promising noninvasive tool for guiding immunosuppression minimization and personalized post-transplant management, with the potential to identify high-risk patients earlier and reduce reliance on liver biopsy.

4504 | ASSOCIATION OF PRE-TRANSPLANT FRAILTY WITH MAJOR ADVERSE CARDIOVASCULAR EVENTS AFTER LIVER TRANSPLANTATION

Isra Taha[1] Yanqing Lyu[2] Sneha Manikandan[3] Barbara Okeke[2] Kelly Fan[2] Spencer Hobbs[3] Ava Delonais-Parker[3] Sahita Gandra[3] Mina Benjamin[2] Uchenna Agbim[2], [1]SSM Saint Louis University Hospital, [2]SSM Health Saint Louis University Hospital, [3]Saint Louis University School of Medicine

Background: Frailty is an established predictor of adverse outcomes in liver transplantation (LT), including higher waitlist mortality, post-transplant mortality, healthcare utilization, and acute rejection. The relationship between frailty and post-transplant major adverse cardiovascular events (MACE) remains unclear. We evaluated whether pre-transplant frailty is associated with post-transplant MACE in LT recipients. **Methods:** We conducted a single-center retrospective cohort study of adult LT recipients from January 2014 to January 2024. Frailty was defined using Liver Function Index (LFI) score: frailty as LFI 4.5, pre-frailty as LFI 3.2 – 4.4, and non-frailty as LFI 3.1. Univariate and multivariable logistic and Cox regression analyses evaluated associations between frailty status and post-LT outcomes. Frail/pre-frail patients were grouped for multivariable analysis due to limited event numbers. **Results:** Among 126 LT recipients, cardiovascular comorbidities were largely similar across frailty groups, although diabetes mellitus and MASLD differed significantly by frailty status ($p = 0.025$ and $p = 0.030$, respectively).Overall MACE incidence was 22.2%. MACE incidence was highest in non-frail patients (37.5%) compared with pre-frail (19.7%) and frail (13.8%) patients ($p = 0.1098$). In multivariate analysis, frailty/pre-frailty was associated with lower odds of MACE (OR 0.39, 95% CI

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

0.15–0.99, p = 0.0496). Findings were consistent in time-to-event analysis (HR 0.44, 95% CI 0.20–0.96, p = 0.0397). Overall all-cause mortality incidence was 14.3%. Mortality rates were 23.3% in frail, 7.4% in pre-frail, and 21.4% in non-frail patients (p = 0.043). Frailty status was not independently associated with all-cause mortality in multivariable analysis. Kaplan-Meier analysis demonstrated significantly worse survival among frail patients (p = 0.049). **Conclusion:** Pre-LT frailty was **associated with higher all-cause mortality risk but paradoxically lower post-LT MACE risk.** This association may reflect competing mortality risk or transplant candidacy selection bias. Differences in baseline metabolic risk factors, including diabetes and MASLD prevalence across frailty groups, may have also contributed to this paradoxical association. Limited sample size and low cardiovascular event rates limit statistical power. Overall, while frailty shows associations with post-transplant mortality risk, frailty alone may not be a reliable predictor of post-transplant cardiovascular risk and warrants further evaluation in larger cohorts.

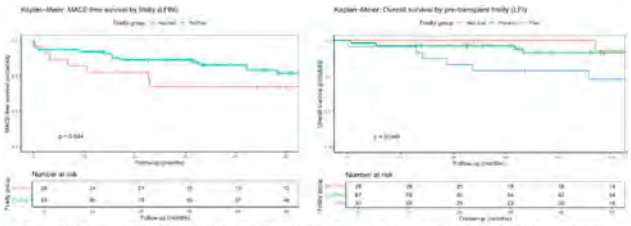

Figure 1: Kaplan Meier survival curves demonstrating worse MACE-free survival among non-frail patients compared to pre-frail/frail patients (p = 0.034) and worse all-cause mortality in frail patients compared to pre-frail or non-frail patients (p = 0.049).

4505 | FRAILTY IS ASSOCIATED WITH INCREASED HEPATIC DECOMPENSATION AND ADVERSE WAITLIST OUTCOMES IN LIVER TRANSPLANT CANDIDATES

Lily Johnsky[1] Amanda Van Jacobs[1] Quyen Diep[1] Sarah Peterson[1], [1]Rush University Medical Center

Background: The Liver Frailty Index (LFI) is a validated frailty tool developed for patients with cirrhosis that objectively quantifies physiologic reserve. A score ≥4.5 has been associated with increased waitlist mortality and adverse post-transplant outcomes. Although multicenter studies reinforced the prognostic value of the LFI, many included patients from the original University of California San Francisco (UCSF) FraILT cohort. The aim of this study was to independently evaluate the predictive value of the LFI in an urban setting outside of the FraILT cohort. Notably, the majority of our cohort had alcohol-associated liver disease (AUD) (45%) and metabolic dysfunction-associated steatotic liver disease (MASLD) (25%), two populations at higher risk for malnutrition and frailty. **Methods:** A retrospective cohort study of adult patients undergoing liver transplant evaluation at a single tertiary care center from January 2020-August 2024 was conducted. Frailty assessment was completed at the patient's initial outpatient transplant evaluation appointment by a registered dietitian. Patients with an LFI ≥4.5 were classified as frail. Demographic characteristics, disease severity, cirrhosis complications, and waitlist outcomes were compared between frail and non-frail patients. **Results:** A total of 428 patients were included, of whom 164 (38.3%) met criteria for frailty. Frail patients were older, more likely to be female, and more likely to have diabetes mellitus. Frail patients had significantly higher MELD scores compared with non-frail patients (18 vs 15, p < 0.001). Frailty was associated with higher rates of hepatic encephalopathy (65.9% vs 48.5%, p < 0.001), ascites (83.5% vs 64%, p < 0.001), and more frequent paracentesis requirements (p < 0.001). Frail patients also experienced longer hospital length of stay (6.8 vs 4.4 days, p = 0.045), higher waitlist mortality (4.9% vs 1.1%, p = 0.038), and higher rates of delisting due to being too high risk (21% vs 13%) or noncompliance (12% vs 7.4%). Frail patients were less likely to undergo transplantation (30.5% vs 36.4%). No significant differences were observed in BMI category or spontaneous bacterial peritonitis rates. **Conclusion:** Frailty was common at this urban transplant center and demonstrated similar predictive utility to prior FraILT studies, including increased risk of waitlist mortality. Additionally, frail patients were more likely to experience hepatic decompensation, particularly hepatic encephalopathy, potentially reflecting the impact of malnutrition and sarcopenia commonly seen in patients with AUD and MASLD. These findings further validate the prognostic utility of the LFI when evaluating patients for liver transplant and suggest that frailty assessment may provide prognostic value beyond MELD 3.0, helping guide early intervention and risk stratification.

4506 | INCIDENCE, TIMING, AND PREDICTORS OF RECURRENT AND DE NOVO MASLD AFTER LIVER TRANSPLANTATION: A 35-YEAR MULTICENTER HISTOLOGY-BASED COHORT STUDY

Sobia Laique[1] Muhammad Ahmad Nadeem[1] Puneet Bansal[1] Chase Wehrle[1] Jacob Sweeney[1] Mohamed El Hag[1] Xuefeng Zhang[1] Pablo Bejarano[2] Rhea Abraham[1] Awwab Hammad[1] Erlind Allkushi[1] Mazhar Khalil[1] Jaekeun Kim[1] Alejandro Pita[1] Federico Aucejo[1] Shilpa Junna[1] Masato Fujiki[1] Andrea Schlegel[1] Koji Hashimoto[1] Daniela Allende[1] Jamak Modaresi Esfeh[3], [1]Cleveland Clinic, [2]Cleveland Clinic, Florida, [3]Cleveland Clinic Foundation

Background: MASLD is the fastest-growing indication for liver transplantation (LT), yet the natural history of post-transplant MASLD remains poorly defined. Prior studies have been limited by small sample sizes, heterogeneous diagnostic criteria, and inconsistent distinction between recurrent and de novo disease. We aimed to characterize biopsy-confirmed post-transplant MASLD in a large LT cohort. **Methods:** We evaluated 2,577 adult LT recipients with clinically indicated post-transplant liver biopsy data from 3,912 patients transplanted at Cleveland Clinic Ohio and Florida between 1985 and 2020. All biopsies underwent centralized histologic re-review using NASH-CRN criteria. Post-transplant MASLD was classified as recurrent (MASH transplant indication; n = 445) or de novo (non-MASH transplant indication; n = 2,132). Transplant eras were defined as Era 1 (1985–1999), Era 2 (2000–2009), and Era 3 (2010–2020). Cumulative event rates were assessed at 3, 5, 10, and 20 years post-transplant using fixed denominators. Multivariable logistic regression incorporating recipient, donor, and metabolic covariates, with multiple imputation for missing data, was used to identify independent predictors of post-transplant MASH. **Results:** Post-transplant MASL occurred in 217 recipients (34 recurrent [7.6%], 183 de novo [8.6%]); MASH occurred in 134 (36 recurrent [8.1%], 98 de novo [4.6%]). De novo disease accounted for most MASL (84.3%) and MASH (73.1%) cases. Median time to disease was early: 1.42 and 1.01 years for recurrent and de novo MASL, and 3.43 and 1.81 years for recurrent and de novo MASH, respectively. Cumulative rates are shown in Figure, Panel B; notably, the majority of events accrued within the first 5 years, with 20-year rates reaching 8.4% and 7.6% for de novo and recurrent MASL, and 4.5% and 8.1% for de novo and recurrent MASH. On multivariable analysis (Figure, Panel C), BMI at 1 year post-LT was independently associated with MASH (aOR 1.08/kg/m²; 95% CI 1.04–1.13; P < 0.001), whereas BMI at transplant was not (P = 0.589). Younger age at transplant (aOR 0.98/year; P = 0.021) and Era 3 transplantation (aOR 0.64 vs Era 1/2; P = 0.036) were also significant. **Conclusion:** In this largest histology-based post-transplant MASLD cohort, MASL and MASH were common, developed early, and predominantly occurred de novo, underscoring that all LT recipients require metabolic surveillance regardless of indication. BMI at 1 year, not at transplant, was the key modifiable predictor, identifying a critical early window for weight-focused interventions. Lower Era 3 MASH odds may reflect evolving immunosuppression practices, while younger recipients warrant intensified monitoring given their longer at-risk period. These findings support integrating structured metabolic protocols into post-transplant care.

4507 | INCIDENCE, DISTRIBUTION, AND DETERMINANTS OF MAJOR ADVERSE CARDIOVASCULAR EVENTS FOLLOWING LIVER TRANSPLANTATION IN A CONTEMPORARY POPULATION-BASED COHORT

Mohammad Qasim Khan[1] Juan Pablo Arab[2] Melody Lam[3] Brooke Carter[3] Kristin Clemens[1], [1]University of Western Ontario, [2]Virginia Commonwealth University, [3]ICES Western, London Health Sciences Centre Research Institute

Background: Cardiovascular disease is a major contributor to mortality following liver transplantation (LT), yet contemporary population-based data evaluating major adverse cardiovascular events (MACE) beyond the early post-LT period remain limited. Considering the changing epidemiological landscape in liver transplantation, with older recepients and increasing burden of steatotic liver disease, we evaluated the incidence, distribution, and determinants of MACE among adult liver transplant recipients (LTRs) across Ontario, Canada. **Methods:** We conducted a population-based, retrospective cohort study using linked healthcare administrative databases housed at ICES. Adult patients undergoing primary liver-only transplantation between January 1, 2008 and December 31, 2017 were included and followed for up to 5 years post-LT. The primary outcome was MACE, defined as cardiovascular death or hospitalization for myocardial infarction (MI), atrial fibrillation (AF), heart failure (HF), revascularization, pulmonary embolism (PE), cardiac arrest, transient ischemic attack (TIA), or stroke. Kaplan-Meier analyses estimated cumulative incidence and event rates, while Cox proportional hazards models identified predictors of post-LT MACE. Era-based analyses compared pre-direct acting antiviral (DAA) (2008–2012) and post-DAA (2013–2017) periods. **Results:** Among 1,564 LTRs, median age was 57 years (IQR 50–62), 69.4% were male, and MASLD represented the most common liver disease (63.5%). Over a median follow-up of 4 years, 44.9% developed MACE (incidence rate: 15.3 events per 100 person-years). AF was the most common MACE subtype (5.7 events per 100 person-years). Development of MACE was associated with significantly reduced survival post-LT (log-rank $p < 0.001$). Although overall MACE incidence did not differ between pre- and post-DAA eras (16.1 vs. 14.6 events per 100 person-years; $p = 0.207$), the phenotype evolved, with lower MI rates (7.7 vs. 3.8 events per 100 person-years; $p < 0.0001$) and higher cerebrovascular event rates (1.7 vs. 2.5 events per 100 person-years; $p = 0.042$) in the contemporary era. A strong graded relationship was observed between cumulative baseline cardiovascular risk burden and MACE incidence (log-rank $p < 0.0001$). In adjusted analyses, older age (aHR 1.02, 95%CI 1.01–1.03), AF (aHR 1.69, 95%CI 1.34–2.12), HF (aHR 2.41, 95%CI 1.86–3.11), and prior cerebrovascular accident (aHR 1.44, 95%CI 1.05–1.97) independently predicted post-LT MACE. **Conclusion:** Nearly half of LTRs developed MACE within 5 years post-LT, highlighting a worrisome long-term cardiovascular burden in the contemporary era. MACE risk was strongly associated with pre-existing cardiovascular disease and cumulative baseline risk rather than isolated atherosclerotic risk factors alone, underscoring the need for improved risk stratification and integrated cardiometabolic care pathways post-LT.

[4]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia

Background: Steatotic liver disease (SLD) is the most common indication for liver transplantation (LT) in the United States. Metabolic-associated steatotic liver disease (MASH) cirrhosis is inherently accompanied by metabolic dysfunction (MetD), whereas alcohol-related liver disease (ALD) may present without (ALD-1) or with (ALD-2) overt metabolic dysfunction including diabetes and/or obesity. We assessed temporal trends and waitlist and post-transplant outcomes in SLD patients stratified by metabolic status. **Methods:** Adult LT candidates and recipients with SLD-related cirrhosis as primary listing diagnosis (2000–2025) were identified from the Scientific Registry of Transplant Recipients (SRTR). SLD subtypes included MASH, ALD-1 (ALD without overt metabolic dysfunction), and ALD-2 (ALD with overt metabolic dysfunction). **Results:** Among 274,868 LT candidates with chronic liver disease, SLD cirrhosis increased substantially from 27% (2000) to 69% (2025). MASH rose from 10% (2000) to peak at 28% (2019–2022), declining to 24% (2025). ALD-1 increased from 12% to 27% (2022), declining to 25% (2025). ALD-2 demonstrated the most pronounced increase: 4% (2000) → 9% (2015) → 13% (2020) → 19% (2025). Among recent candidates (2021–2025), MASH patients were significantly older (60 ± 9 years) compared to ALD-1 (52 ± 11 years) and ALD-2 (54 ± 10 years). MELD scores were higher in both ALD subtypes (22.5 ± 10.1 and 22.7 ± 9.9) than MASH (20.3 ± 9.0). Hepatocellular carcinoma (HCC) prevalence was highest in MASH (15.5%) versus ALD-1 (5.4%) and ALD-2 (12.5%).Transplant rates were similar across groups (70%). Cumulative waitlist mortality was highest in MASH (13.5%) compared to ALD-1 (8.4%) and ALD-2 (9.9%). ALD-1 demonstrated the highest clinical improvement rate (6.6% vs. 2.5% MASH, 3.9% ALD-2).In multivariable competing-risk analysis, ALD-2 (ALD-Met) was not independently associated with increased waitlist mortality versus ALD-1 (aHR = 1.03 [0.94–1.13]), whereas MASH demonstrated significantly higher risk (aHR = 1.21 [1.11–1.33]). Five-year post-transplant mortality: MASH 19.9%, ALD-1 15.2% and ALD-2 17.6%. After adjustment for other predictors, neither SLD etiology (MASH or ALD-2 vs. ALD-1) was independently associated with post-transplant mortality (all $p > 0.05$). Older age, poorer pre-LT functional status, public insurance, pre-LT diabetes, more advanced liver disease (higher MELD, decompensation, life support, HCC) were independently associated with higher waitlist and post-LT mortality in SLD. **Conclusion:** ALD with MetD has become a major indication for liver transplantation in the U.S. Despite greater metabolic burden, these patients demonstrated waitlist and post-transplant mortality comparable to ALD without MetD and MASH.

4509 | HEPATIC ARTERY DISSECTION DURING ENDOVASCULAR TREATMENT OF HEPATIC ARTERY STENOSIS AFTER LIVER TRANSPLANTATION

Ricardo Paz-Fumagalli[1] Miguel Cadenas[1] Ali Montazeri[1] Kristopher Croome[2], [1]Mayo Clinic, [2]Mayo Clinic Florida

Background: Hepatic artery stenosis (HAS) following orthotopic liver transplantation is a risk factor for hepatic artery thrombosis, graft ischemia, biliary injury, and graft loss. Endovascular therapy is the first-line treatment but can be complicated by arterial dissection. Hepatic artery dissection (HAD) remains a poorly characterized procedural complication. This study evaluates the incidence, and outcomes of HAD during endovascular treatment of HAS. **Methods:** A retrospective review was performed of 4569 liver transplants conducted between January 1999 and April 2026 that had endovascular intervention for hepatic artery stenosis. Data collected included imaging findings (CT scan, MRI, color Doppler with

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

spectral analysis), alkaline phosphatase levels, vessel tortuosity, timing of intervention relative to transplantation (< 60 vs ≥ 60 days), main versus branch hepatic artery involvement, flow-limiting versus non-flow-limiting dissection, hepatic artery thrombosis, and biliary complications. Outcomes included technical success, primary patency, assisted primary patency, secondary patency, graft survival, and retransplantation. **Results:** HAS was treated in 175/4569 grafts (3.8%). HAD occurred in 23/175 (13.1%). Features common in HAD included tortuous vessels, early post-transplant interventions, and branch artery stenoses. Flow-limiting dissections demonstrated higher rates of thrombosis, reintervention, and biliary injury than non-flow-limiting dissections. Dissection involving hepatic artery branches correlated with increased risk of arterial occlusion. Non-flow-limiting dissections frequently remained clinically stable and were successfully managed conservatively. One patient with severe biliary injury after arterial dissection received retransplantation (1/23, 4.3 %). At 6, 12 and 36 months, the primary patency rates were 61, 47, and 47%, primary-assisted 77, 73, and 73%, and secondary patency rates were 77, 73 and 73%. Biliary injury occurred in 2 patients who suffered flow limiting dissection, one required retransplantation and the other chronic biliary drain management. Despite having variable degrees of arterial flow alteration 21/23 did not develop biliary injury, often because of development of hilar and capsular hepatic artery collaterals. **Conclusion:** HAD during endovascular treatment of HAS is uncommon and can lead to biliary injury and graft loss. Tortuosity, branch vessel intervention, and early post-transplant timing appear to increase procedural risk. Non-flow-limiting dissections are well tolerated and can heal completely. Arterial occlusion from HAD is associated with inferior patency and increased graft-related morbidity. Angioplasty and stent placement, repeated as needed, can achieve long-term arterial patency in about 70% of grafts despite procedure-related arterial dissection.

4510 | A SURVEY OF TRANSPLANT CENTER EVALUATION AND MANAGEMENT OF PATENT FORAMEN OVALE

Puja Brahmbhatt[1] Burcin Ekser[2] Yucel Yankol[1] Scott Cotler[1] Eric Kallwitz[1], [1]Loyola University Health System, [2]Loyola University Chicago

Background: A patent foramen ovale (PFO) presents a potential risk for paradoxical embolism and stroke during liver transplantation. Retrospective studies have not shown a definitive benefit to prophylactic PFO closure prior to liver transplant. The theoretic risk of paradoxical embolism must be balanced against the potential risk of delaying liver transplant for PFO closure. There are no current guidelines or consensus for managing PFOs in liver transplant. The purpose of this study was to survey management of PFOs at US liver transplant centers. Methods: A survey was sent out to medical and surgical directors **Methods:** A survey was sent out to medical and surgical directors at US transplant centers to query management of PFOs. The survey contained questions regarding evaluation, diagnosis and management of PFOs in liver transplant candidates. There were additional questions regarding any potential observed complications. One response was included per center **Results:** Twenty eight centers responded with 20 centers reporting a volume greater than 100 liver transplants per year. All centers use an echocardiogram with bubble study during evaluation. Most centers use a threshold number of cardiac cycles to distinguish intra-cardiac versus intrapulmonary shunting (21 centers used cardiac cycles, 6 did not). Only 5 of the 28 centers routinely perform a transesophageal echocardiogram (TEE) for a positive bubble study. However, most centers (n = 20) routinely have anesthesia use TEE during liver transplant. Seventeen centers selectively close PFOs, while 11 centers report not closing any PFOs. For centers that selectively close PFOs, a history of prior stroke was the most common indication for closure. When a PFO is discovered, 15 of 28 centers reported rarely closing PFOs and 3 of 28 centers reported never closing PFOs. Three of 28 centers reported closing most PFOs and 2 of 28 centers reported closing all. If a PFO is closed, most centers immediately active for transplant (n = 17), while some centers wait one month (n = 9). Seven centers reported at least one patient complication attributed to a PFO, all of which consisted of stroke. Two centers reported a complication attributed to the PFO closure. Twenty-two centers thought that PFO management should be addressed formally in liver transplant guidelines. **Conclusion:** A majority of transplant centers selectively close PFOs, particularly in patients with a history of stroke. Overall, relatively few adverse events attributed to a PFO were reported. Society recommendations would be useful to provide a more uniform approach to PFOs. Finally, multi-center prospective data would be helpful in developing guidance.

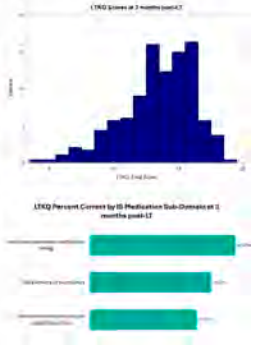
4511 | COGNITIVE IMPAIRMENT AND ALCOHOL ASSOCIATED LIVER DISEASE INDEPENDENTLY PREDICT LOWER SCORES ON THE LIVER TRANSPLANT KNOWLEDGE QUESTIONNAIRE: RESULTS FROM LIVCOG, A PROSPECTIVE COHORT STUDY



Abbie Jin[1] Douglas Schaubel[1] Ann Tierney[1] Nianfu Song[1] Serena Sohmen[1] Anna Gurian[2] Julia Benavente[3] Sumeet Asrani[4] Michael Wolf[3] Marina Serper[5], [1]University of Pennsylvania Perelman School of Medicine, [2]University of Colorado Anschutz School of Medicine, [3]Northwestern University Feinberg School of Medicine, [4]Liver Consultants of Texas, [5]University of Pennsylvania Health System

Background: Cognitive impairment is prevalent among liver transplant recipients (LTRs) and may negatively affect self-management skills and health behaviors following liver transplantation (LT). Our study aim was to evaluate associations between post-LT cognition and transplant-related knowledge using the novel Liver Transplant Knowledge Questionnaire (LTKQ). **Methods:** LivCog is an NIDDK-funded prospective, multicenter cohort study which longitudinally follows LTRs to study cognition, health behaviors, and health outcomes. At 1-, 3-, 12-, and 24-months post-LT, cognition was assessed using the Animal Naming Test (ANT) and Montreal Cognitive Assessment (MoCA). Transplant knowledge was assessed using the LTKQ, a performance-based instrument measuring knowledge and skills required for post-LT self-management that includes immunosuppression timing, drug interactions, medication safety, and health behaviors. The LTKQ items which pertained to immunosuppression (IS) medication knowledge were categorized into three subdomains: medication timing, side effects of tacrolimus, and medications that may cause drug interactions. Using the GEE version of linear regression, we fitted (separate) models for total LTKQ score and each of the afore-listed LTKQ subdomains. **Results:** Among 447 LTRs, the median age is 56 (IQR 48-64); 82% are white; 63% are male; 42% have < = high school education. At 3-months post-LT, 186 participants (50.7%) had a MoCA score < 26 consistent with mild cognitive impairment; 32 (8.7%) had ANT < 15. The median LTKQ score was 14/19 (74% correct). As shown in **Figure 1**, participants scored highest on the IS medication timing subdomain (84.6%), followed by tacrolimus side effects (70.1%) and lowest on drug interactions (61.9%).Adjusted for demographic and baseline clinical characteristics, longer time post-LT ($\beta = 0.04$; $p < 0.001$) was associated with higher LTKQ scores. Older age ($\beta = -0.10$; $p = 0.025$), education level at high school or less ($\beta = -1.23$; $p < 0.001$), and alcohol-associated liver disease ($\beta = -0.62$; $p = 0.038$) were associated with significantly lower LTKQ scores, as were low MoCA ($\beta = -0.69$; $p = 0.007$) and ANT ($\beta = -0.86$; $p = 0.048$) scores. Pre-LT hepatic encephalopathy ($\beta = -0.21$) was associated with lower LTKQ only in univariable analysis.In adjusted models for IS medication subdomains (medication timing, tacrolimus side effects, and drug interactions), lower scores were independently associated with worse cognitive performance on the MoCA ($\beta = -0.03$, $\beta = -0.01$, and $\beta = -0.04$, respectively). Medication timing and drug interactions scores were also independently associated with lower ANT scores ($\beta = -0.04$ and $\beta = -0.05$). **Conclusion:** LTRs demonstrate gaps in post-LT knowledge that are significantly associated with cognitive impairment, age, and alcohol-associated liver disease. The LTKQ questionnaire can help identify knowledge deficits post-LT, tailor interventions, and improve health outcomes.

Figure 1. Predictors of LTKQ Score and Distribution at 3 months post-LT

Table 1. Predictors of Liver Transplant Knowledge Questionnaire (LTKQ) Score: covariate-adjusted

Predictor	β	p value
Month	0.044	<0.001
Age (per 5 yrs)	-0.105	0.025
Female	0.261	0.299
Education: shigh school	-1.226	<0.001
Pre-LT hepatic encephalopathy	-0.206	0.416
Liver disease: Alcohol-related	-0.619	0.038
Liver disease: HCC	1.058	0.006

4512 | VALIDATION OF A NATURAL LANGUAGE PROCESSING ALGORITHM FOR IDENTIFYING KERATINOCYTE CARCINOMA IN SOLID ORGAN TRANSPLANT RECIPIENTS

Danelle Antelo[1] Carolina Carvajalino[1] David Goldberg[1] David Kaplan[2] Cindy Delgado[1] Therese Bittermann[3] Catherine Blandon[1], [1]University of Miami, [2]University of Pennsylvania, [3]Royal Brisbane & Women's Hospital

Background: Keratinocyte carcinoma (KC), encompassing squamous cell carcinoma (SCC) and basal cell

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

carcinoma (BCC), is the most common malignancy following solid organ transplantation. Administrative coding algorithms for identifying clinical diagnoses have known limitations, underscoring the need for validated approaches using electronic health records. We developed and validated a natural language processing (NLP) algorithm to identify KC in Veterans Health Administration (VHA) transplant recipients. **Methods:** We conducted a cross-sectional study using linked VHA and Organ Procurement and Transplantation Network (OPTN) data including kidney and liver transplant recipients (January 2005–December 2021) with pre- and post-transplant VHA engagement. Potential KC cases required either an ICD-O-3 code or a combination of ICD-9/10 and CPT code (Mohs, destruction, or excision) plus an NLP-confirmed pathology report within 7 days. The NLP algorithm, developed with transplant physicians, dermatologists, and a dermato-pathologist, classified pathology reports as KC-positive based on: (1) KC-related keywords; (2) active diagnosis language; and (3) skin-relevant anatomical site. We evaluated positive predictive value (PPV) via independent review of 100 randomly selected NLP-positive pathology reports, calculating a point estimate and 95% binomial confidence interval. We also reviewed medical charts for 100 patients with KC-related administrative codes who lacked a corresponding NLP-identified pathology report. **Results:** Among 176 reviewed patients, median age at transplant was 62.0 years (IQR 58.0–66.0); 98.3% were male, 86.9% were White, and 42.0% were liver-transplant recipients. Of 100 pathology reports classified as KC-positive by the NLP algorithm, 95 (95%) were validated as true KC diagnoses by human reviewers, yielding a PPV of 95% (95% CI 88.7%–98.4%). The 5 unconfirmed reports reflected patients with a known prior history of KC, suggesting the algorithm captured historical cases. Among patients with KC-related administrative codes but no supporting pathology report or NLP-identified case, KC was confirmed via chart review in 95 of 100 cases (95%). **Conclusion:** A combined administrative code and NLP algorithm demonstrated high accuracy (PPV 95%) for identifying KC among VHA solid organ transplant recipients. Among patients with KC-related administrative codes but no NLP-captured pathology report, KC was confirmed via chart review in 95% of cases, further strengthening confidence in the overall algorithm performance. Given the elevated KC burden in this high-risk population, this validated tool addresses a critical methodological gap and enables future large-scale studies examining risk factors, treatment patterns, and outcomes of post-transplant KC. Accurate identification of KC can inform post-transplant skin cancer surveillance guidelines for transplant recipients.

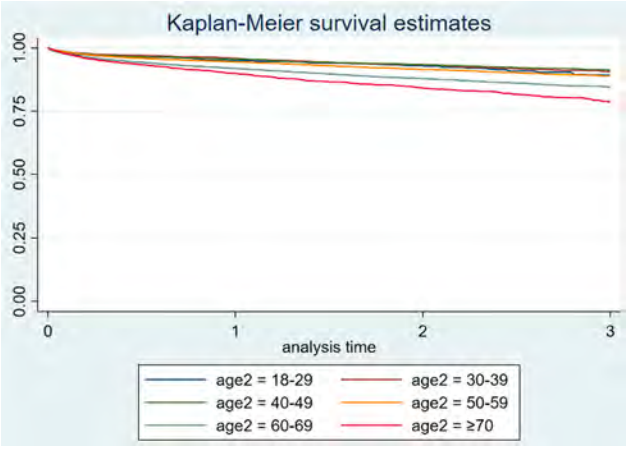
4513 | POST TRANSPLANT SURVIVAL BY AGE GROUP AND DONOR TYPE (DCD VS DBD) IN DECEASED DONOR LIVER TRANSPLANT OVER THE PAST 5 YEARS: A NATIONAL ANALYSIS



Maria Diaz Soto[1] Behnam Saberi[2] Alan Bonder[1] Sebastian Niezen[1], [1]Beth Israel Deaconess Medical Center, [2]BIDMC Harvard Medical School

Background: Both the proportion of elderly liver transplant recipients as well as the use of DCD grafts (donation after circulatory death) have been increasing over the past decade. In the United States there were 207 liver transplant recipients 70 years or older in 2015 and over 700 in 2025. There is mixed data in terms of survival outcomes for the elderly population . Similarly the use of DCD grafts has significantly increased specially over the last 5 years after the widespread adoption of normothermic machine perfusion (NMP). 11.6% of the total transplants were DCD in 2020 vs 42.7% in 2025. We examined post transplant survival across recipient age groups and compared survival between DCD and DBD donor types. **Methods:** Using the UNOS database we identified adults (³ 18yrs) deceased donor liver transplant recipients from January 2021 to December 2025 (N = 41,346). Simultaneous liver kidney, other multiorgan, living donors, partial liver/split grafts and prior liver transplants were excluded. Recipients were classified into 6 age groups (18-29, 30-39, 40-49, 50-59, 60-69 and ³ 70 years). Patient survival was estimated by Kaplan Meier and compared across age groups with log rank test. Multivariable Cox proportional hazard regression was used to identify independent factors associated with mortality. Candidate variables included age category, race, sex, etiology of disease, dialysis, MELD, donor type, age, BMI. Figures were generated with Claude AI, data

analysis was done with STATA. **Results:** Among 41,346 recipients there were 3,706 deaths (9%). In the Kaplan Meier curve survival declined with increasing age group (log-rank $\chi^2 = 315.4$, df = 5, $p < 0.001$). The age group effect remained independently significant in the multivariate analysis with higher risk of mortality for age group ³ 70 years HR 2.42 (95% CI 2.12–2.77), age group 60–69 = HR of 1.86 and for age group HR 50–59 = 1.29: all $p < 0.001$. Other Independent predictors of mortality included pre transplant dialysis HR 1.6, black race HR 1.2 $p < 0.001$. 1 year mortality was comparable between DCD and DBD recipients HR 1.04 (0.93–1.16) $p = 0.53$. **Conclusion:** In a contemporary US cohort, increasing recipient age was independently associated with worse post transplant survival with the highest mortality risk for patients ³ 70 years. Despite rapid expansion of DCD grafts use over the past 5 years, 1 year mortality was comparable between the DCD and DBD recipients which can support the continued use of DCDs.

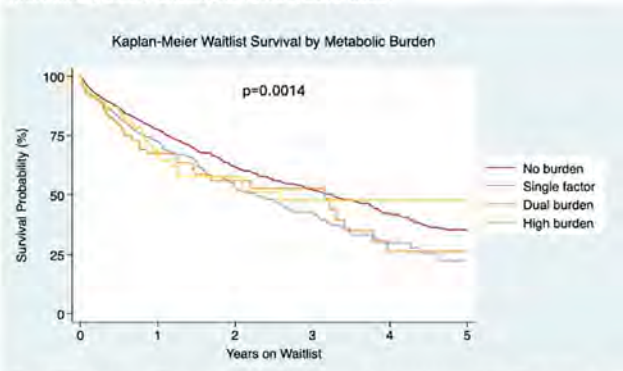
4514 | METABOLIC BURDEN AND WAITLIST OUTCOMES IN PATIENTS WITH PRIMARY BILIARY CHOLANGITIS: A NATIONAL REGISTRY ANALYSIS



Giuliana Arevalo[1] Ana Marenco-Flores[2] Romelia Barba[3] Victoria Abadi-Ron[2] Natalia Rojas-Amaris[2] Fernando Munguia[2] Alan Bonder[2], [1]University Of Miami Miller School of Medicine, [2]Beth Israel Deaconess Medical center, [3]Texas Tech University

Background: Metabolic comorbidities are increasingly prevalent in patients with primary biliary cholangitis (PBC), yet their combined impact on transplant outcomes remains undefined. We evaluated the effect of a composite metabolic burden score on waitlist and post-transplant survival in PBC using a national registry. **Methods:** We analyzed adults with PBC listed for liver transplantation in the UNOS database (2013–2025). Multi-organ transplants were excluded. A metabolic burden score was constructed: 0 = no diabetes and BMI < 30; 1 = diabetes alone or BMI 30–34.9; 2 = diabetes + BMI 30–34.9; 3 = diabetes + BMI ≥ 35 kg/m². The primary waitlist outcome was a composite of death or removal for clinical deterioration. Kaplan-Meier methods, log-rank tests, and multivariable Cox regression adjusted for age, sex, and MELD were used. Statistical significance was defined as $p < 0.05$. **Results:** Among 4,240 adults with PBC, 60.3% had no metabolic burden, 24.3% had single-factor burden (score 1), 4.0% had dual burden (score 2), and 2.9% had high burden (score 3). Higher metabolic burden was associated with older recipient age ($p = 0.002$), higher MELD ($p = 0.024$), and significant differences in racial/ethnic distribution ($p = 0.007$). A composite waitlist event occurred in 22.1% of patients overall, with rates of 20.9%, 23.4%, 29.8%, and 25.8% across burden groups ($p = 0.019$). Kaplan-Meier analysis demonstrated significantly worse waitlist survival with increasing metabolic burden (log-rank $p = 0.0014$). On multivariable Cox regression adjusted for age, sex, and MELD score, single-factor burden (HR 1.22, 95% CI 1.05–1.43, $p = 0.010$) and dual burden (HR 1.73, 95% CI 1.29–2.30, $p < 0.001$) were independently associated with waitlist mortality. Post-transplant survival analyses demonstrated persistently lower long-term survival among metabolically burdened recipients, with disparities most pronounced among White and Hispanic patients. **Conclusion:** In a contemporary national cohort of PBC patients, a composite metabolic burden score independently predicted waitlist mortality. These findings highlight the growing impact of metabolic dysfunction on liver transplant outcomes in a traditionally non-metabolic indication and support the integration of metabolic risk stratification into PBC listing and management decisions. This composite metabolic burden score represents a hypothesis-generating risk stratification framework and requires prospective validation in independent cohorts.

4515 | NOT ALL EXCEPTIONS ARE EQUAL: DISEASE-SPECIFIC CAUSE OF DEATH PATTERNS AFTER MELD-EXCEPTION LIVER TRANSPLANTATION IN MASH AND ALCOHOL-ASSOCIATED LIVER DISEASE

Jonathan Smith[1] Shiv Patel[1] Brian Wentworth[1] Zachary Henry[1] Curtis Argo[1] Nicolas Intagliata[1] Neeral Shah[1] Stephen Caldwell[1] Anya Mezina[1] Yazan Al-Adwan[1] Shawn Pelletier[1] Stephanie Silpe[1] Juan Guerra[1] Mohammad Siddiqui[1] Anh Bui[1], [1]University of Virginia

Background: MELD-based allocation prioritizes waitlist candidates by mortality risk; however, over one-third of liver transplants (LT) in the US now occur through MELD-exception (eMELD) pathways that bypass conventional MELD (cMELD) scoring for select disease states. Whether eMELD allocation translates into durable post-LT survival, and how outcomes differ by exception indication and cause of death, remains poorly characterized. This study addresses this critical gap using the UNOS/SRTR database. **Methods:** This SRTR/UNOS analysis, focused on adults undergoing deceased donor LT between 2003-2023, classified as eMELD or cMELD based on approved exception status. Kaplan-Meier analyses estimated survival by pathway and exception indication. Cause-specific mortality was compared across disease etiology (MASH vs. ALD) by allocation pathway. Multivariable Cox regression evaluated pathway-associated post-LT mortality. **Results:** Among 113,334 adult LT recipients, 37,263 (32.9%) were transplanted via eMELD. eMELD recipients demonstrated superior 1-year survival; however, this advantage attenuated over time **(Panel A)** . Survival trajectories diverged strikingly by exception indication: recipients transplanted for hepatic cancers (HCC or cholangiocarcinoma) experienced profound early post-LT attrition followed by stabilization, while non-oncologic eMELD recipients followed a distinct survival pattern **(Panel B)** . Disease-specific cause-of-death profiling revealed that HCC/cholangiocarcinoma was absent in both cMELD groups yet accounted for 15.1% and 18.0% of deaths in MASH-eMELD and ALD-eMELD respectively **(Panel C)** . Within eMELD, non-hepatic malignancy mortality was lower in MASH (4.0%) than ALD (6.2%), while both remained below their cMELD counterparts (~8%), suggesting reduced de novo oncologic risk in MASH-eMELD. Conversely, renal/multiorgan failure was substantially higher in MASH-cMELD (9.7%) versus ALD-cMELD (5.1%), whereas cardiovascular mortality was consistent across all four groups (~13%). eMELD was independently associated with increased post-LT mortality overall (aHR 1.11, 95% CI 1.08–1.14), in MASH (aHR 1.15), and ALD (aHR 1.16; all $P < 0.001$). **Conclusion:** eMELD pathways confer early survival advantages, but long-term benefit is eroded by hepatic cancer recurrence. Disease-specific profiling reveals divergent oncologic and renal mortality patterns across allocation pathways, supporting individualized post-LT surveillance and reappraisal of exception criteria.

4516 | MACHINE LEARNING PREDICTION OF RENAL FAILURE AT ONE YEAR AFTER LIVER TRANSPLANTATION IN HIGH-MELD RECIPIENTS USING NATIONAL OPTN/UNOS DATA

Sri Harsha Boppana[1] Subhash Gurappa[2] Sachin Sravan Kumar Komati[2] Gautam Maddineni[3] Raja Chandra Chakinala[4] Venkata Sunkesula[5] Pradeep Yarra[6] Kamran Qureshi[7], [1]Nassau University Medical Center, [2]Florida International University, [3]Creighton university, [4]Guthrie Robert Packer Hospital, [5]Case Western Reserve University, [6]UT Health San Antonio, [7]Saint Louis University

Background: High-MELD liver transplant (LT) recipients are vulnerable to post-LT renal failure, yet national-scale prediction using pre-LT renal trajectory and machine learning remains limited. Many established risk factors for persistent renal failure after LT have been identified. We aimed to identify predictors of severe renal impairment (SRI) at 1 year after LT, compare conventional and machine-learning prediction models, and evaluate machine learning models for the prediction of safety-net renal transplantation (SNRT) after LT. **Methods:** We performed a retrospective OPTN/UNOS STAR cohort study of adult primary single-organ LT recipients transplanted from 2014–2024 with MELD $\geq$25 who survived $\geq$30 days. The primary outcome was SRI at 1 year, defined as creatinine $\geq$2.5 mg/dL using the closest follow-up value within 9–18 months post-LT. Multivariable logistic regression estimated adjusted odds ratios (ORs). Logistic regression, gradient boosting, XGBoost, and neural network models were compared using 5-fold cross-validated area under the receiver operating characteristic curve (AUC) and additionally evaluated for SNRT prediction. Post–1-year mortality was assessed using landmark Cox regression. **Results:** Among 33,864 recipients, median MELD was 33 and median transplant creatinine was 1.4 mg/dL; 2,058 (6.1%) received donation-after-circulatory-death (DCD) grafts. One-year creatinine follow-up was available in 30,904 (91.3%): 21,224 (68.7%) recovered (creatinine $<$1.5 mg/dL), 7,910 (25.6%) had persistent CKD (creatinine 1.5–2.5 mg/dL), and 1,770 (5.7%) had SRI (creatinine $\geq$2.5 mg/dL). DCD was not independently associated with SRI after adjustment (OR 0.84, 95% CI 0.64–1.09; p = 0.19). Independent SRI predictors included Black race vs. White race (OR 1.71, 95% CI 1.45–2.02), male sex (OR 1.52, 95% CI 1.36–1.70), alcohol-related disease vs. HCV (OR 1.30, 95% CI 1.11–1.53), age (OR 1.025/year), cold ischemia time (OR 1.04/hour), pre-LT dialysis days (OR 1.05/day), initial creatinine (OR 1.17/mg/dL), and waitlist dialysis (OR 2.64; all p $\leq$ 0.049). Gradient boosting performed best (AUC 0.771), followed by XGBoost (0.769), logistic regression (0.746), and neural network (0.740). XGBoost identified pre-LT dialysis days as the dominant feature (importance 0.22, $>$3-fold the next feature). One-year renal status strongly predicted mortality: persistent CKD HR 1.22 (95% CI 1.14–1.31) and SRI HR 2.67 (95% CI 2.41–2.96). (Figure 1) **Conclusion:** SRI at 1 year is uncommon but prognostically powerful in high-MELD LT. Pre-LT dialysis burden outperformed donor type as a risk signal. Tree-based machine learning modestly improved discrimination over logistic regression; neural networks added no benefit, supporting interpretable renal-trajectory models for SLK evaluation, post-LT nephroprotection, and SNRT risk stratification.

4517 | RULING OUT CAD: DIAGNOSTIC UTILITY OF CCTA IN LIVER TRANSPLANT CANDIDATES

Lauren Callans[1] Sandeep Sikerwar[2] Jacky Choi[1] Himel Mallick[1] Elizabeth Verna[2] Danielle Brandman[1], [1]Weill Cornell Medicine, [2]Columbia University Medical Center

Background: Major Adverse Cardiac Events (MACE) are a significant cause of post-liver transplant (LT) morbidity, underscoring the need for preoperative cardiac risk stratification. Coronary computed tomography angiography (cCTA) has emerged as a noninvasive alternative to coronary angiography in this setting, yet its diagnostic performance and prognostic value in LT candidates remain undefined. This study evaluated 1) the diagnostic performance of cCTA in detecting coronary artery disease (CAD) and 2) the association between CAD identified on cCTA and post-LT MACE. **Methods:** Adult patients who underwent LT evaluation at Weill Cornell and Columbia University (2021-2024) were included. cCTA findings were categorized as no CAD, non-obstructive CAD, or obstructive CAD, and dichotomized (any CAD vs. none) for diagnostic performance analyses. Sensitivity, specificity, Cohen's kappa, and AUC were calculated, using left heart catheterization (LHC) as the reference standard. MACE events were classified as a composite of acute coronary syndrome, new heart failure, tachyarrhythmia, cardiac arrest, cardiac death, and revascularization. MACE-free survival was estimated using Kaplan-Meier with log-rank tests, and hazard ratios were obtained from univariate unadjusted Cox proportional hazards regression. **Results:** Of 548 patients evaluated for LT, 133 (24%) underwent cCTA; these patients were older and had higher rates of diabetes, hypertension, hyperlipidemia, and smoking history compared with patients who underwent alternative imaging modalities ($p < 0.01$ for all comparisons). On cCTA, 60% of patients had non-obstructive CAD, 21% had obstructive CAD, and 19% showed no CAD.Among 42 patients who underwent both cCTA and LHC, cCTA demonstrated 100% sensitivity for detecting both any CAD and obstructive CAD, with specificity of 40 and 60%, respectively. Cohen's kappa demonstrated moderate agreement between cCTA and LHC, with the strongest agreement for identifying any CAD (κ = 0.54), and ROC analysis demonstrated good discriminative ability for obstructive CAD (AUC 0.80, 95% CI 0.71-0.89) (Figure 1).Among 80 patients with cCTA who underwent LT, 14 MACE occurred. Post-LT MACE-free survival did not differ across CAD categories, and no clear predictive relationship between cCTA findings and MACE was identified. **Conclusion:** cCTA demonstrated excellent sensitivity for detecting CAD. However, the modest specificity of cCTA may have resulted in overestimation of obstructive CAD, and cCTA findings did not predict post-LT MACE, likely reflecting limited event rates and false-positive disease classification. These findings support the utility of cCTA for ruling out obstructive CAD in LT candidates, potentially reducing the need for invasive angiography among patients with no or non-obstructive CAD on cCTA. Larger prospective studies are needed to clarify the role of cCTA in post-LT cardiac outcomes.

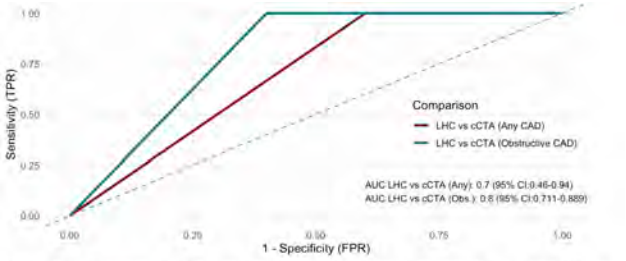

Figure 1. ROC curves for cCTA in detecting any CAD and obstructive CAD, with LHC as the reference gold standard.

4518 | IMPACT OF PRE-TRANSPLANT PORTAL VEIN THROMBOSIS ON LIVER TRANSPLANTATION OUTCOMES: A RETROSPECTIVE COHORT STUDY FROM A TERTIARY CARE CENTER IN MEXICO CITY

Paola Cáceres-Moreno[1] Sergio Escalante Gutiérrez[1] Berenice Monserrat Román Calleja[1] Nayelli Cointa Flores García[1] José González-Regueiro[1], [1]Instituto Nacional de Ciencias Médicas y Nutrición "Salvador Zubirán"

Background: Portal vein thrombosis (PVT) affects up to 26% of candidates awaiting liver transplantation (LT). Extensive PVT was considered a contraindication for LT and nowadays remains as a major technical challenge for LT, contributing to increased morbidity and mortality despite surgical advancements. We aimed to evaluate the impact of pre-transplant PVT on clinical outcomes during and after LT. **Methods:** A retrospective cohort study was conducted at the Instituto de Nutrición y Ciencias Médicas "Salvador Zubirán" in Mexico City. We included all adult LT recipients from 2018 to 2024. Patients were stratified by presence or absence of pre-LT PVT diagnosis on imaging studies. Data was recorded from electronic medical records. Perioperative

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

and postoperative clinical outcomes were compared between both groups. Normality was assessed using Kolmogorov-Smirnov test. Continuous variables were compared using Student's t test or Mann-Whitney U test, and categorical variables using Chi-square or Fisher's exact test. Multivariable logistic regression was performed to identify independent predictors of vascular complications. **Results:** A total of 275 patients were analyzed and included 222 patients (80.72%) without PVT and 53 patients (19.28%) with PVT who underwent LT. There were no significant differences between groups regarding demographic characteristics, LT indication, comorbidities, cirrhosis etiology and severity of liver disease. Perioperatively clinical outcomes: PVT was associated with significant higher anhepatic time (61 vs. 56 min; p = 0.033), intraoperative bleeding (3500 vs. 2000 mL; p < 0.001), increased blood units requirements (5 vs. 3 units; p < 0.001), and peak lactate value (5.9 vs 4.9 mmol/L; p = 0.018). Postoperatively clinical outcomes: PVT was associated with longer hospital stay (12 vs. 8 days; p = 0.002), and more frequent vascular complications (17% vs 9.5%; p = 0.039). Mortality (11.8% vs. 12.2%; p = 0.886) was not significantly different between groups. Multivariate analysis identified pretransplant PVT as an independent predictor factor of postoperative vascular complications (OR 2.65; CI 95% 1.07-6.55; p = 0.035). **Conclusion:** Pre-transplant PVT significantly increases perioperative blood loss and surgical complexity and is an independent predictor factor for postoperative vascular complications. Despite this, long-term patient survival remains comparable to recipients without PVT, supporting the feasibility of LT for this population in specialized centers.

Table 1. Perioperative and postoperative clinical outcomes of liver transplantation stratified by presence or absence or portal vein thrombosis.

Table 1A. Perioperative clinical outcomes of liver transplantation stratified by presence or absence of portal vein thrombosis.

	Total (n=275)	PVT (n=53)	Non-PVT (n=222)	P Value
Surgical time (min)	386 (330-450)	405 (349-480)	385 (327-439)	0.050

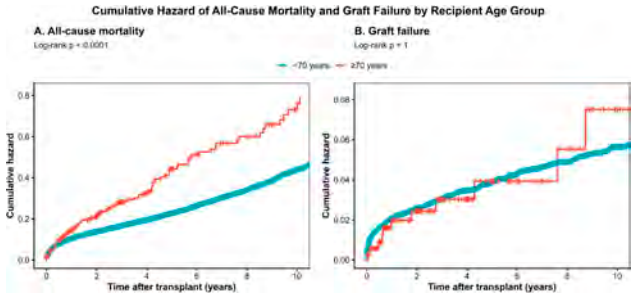
4519 | CARDIOVASCULAR DEATH DRIVES INCREASED MORTALITY IN OLDER PATIENTS UNDERGOING LIVER TRANSPLANTATION FOR MASH CIRRHOSIS



Wyatt Nice[1] David Lee[1] Neha Jakhete[1], [1]University of Maryland School of Medicine

Background: It is well established that older patients undergoing liver transplantation (LT) for metabolic dysfunction-associated steatohepatitis (MASH) have increased post-transplant mortality. However, it remains unclear whether the increased mortality observed in older recipients is driven by specific causes of death or by increased graft failure. We aimed to evaluate age-stratified post-transplant outcomes in patients undergoing LT for MASH cirrhosis, with a focus on cause-specific mortality and graft survival. **Methods:** We performed a retrospective cohort study using the United Network for Organ Sharing Standard Transplant Analysis and Research (UNOS-STAR) registry from 2005 to 2019 of adult patients undergoing primary LT for MASH cirrhosis. Recipients were stratified by age < 70 versus ≥ 70 years at the time of transplantation. The primary outcomes were all-cause mortality and graft failure following LT. Secondary outcomes included cause-specific mortality. Prognostic survival curves were generated and compared using the log-rank test. Multivariable Cox proportional hazards models adjusted for recipient demographic and clinical covariates were used to evaluate post-transplant outcomes. **Results:** A total of 9,797 recipients age < 70 years and 366 recipients age ≥ 70 years underwent LT for MASH cirrhosis and were included in the analysis. Recipients ≥ 70 years had a significantly increased risk of all-cause mortality compared to recipients < 70 years (HR 1.60, 95% CI 1.33–1.93; p < 0.001). In contrast, there was no significant difference in graft failure between the groups (HR 0.98, 95% CI 0.54–1.80; p = 0.95). The increased mortality observed among recipients ≥ 70 years was primarily driven by a higher risk of cardiac mortality (HR 1.67, 95% CI 1.08–2.57; p = 0.020). Older recipients also demonstrated a significantly increased risk of mortality related to renal causes (HR 2.83, 95% CI 1.51–5.31; p < 0.001). **Conclusion:** Older recipients undergoing LT for MASH cirrhosis experience significantly increased post-transplant mortality despite similar graft survival compared to younger recipients. This increased mortality appears to be driven primarily by cardiovascular death and, to a lesser extent, renal mortality. These findings highlight the importance of

cardiovascular risk stratification prior to LT and aggressive management of cardiometabolic risk factors in older patients with MASH cirrhosis.

4520 | DEVELOPMENT AND INTERNAL VALIDATION OF A NOVEL MACHINE LEARNING-BASED CLINICAL DECISION SUPPORT SYSTEM FOR PREDICTING T-CELL MEDIATED REJECTION AFTER LIVING DONOR LIVER TRANSPLANTATION

Neeraj Saraf[1] Swapnil Dhampalwar[1] Narendra Choudhary[1] Kunwar Singh[1] Nischal Modak[1] Prashant Bhangui[2] Arvinder Soin[1], [1]Medanta The Medicity, [2]Medanta - The Medicty

Background: T-cell mediated rejection (TCMR) may occur in 20-30% of living donor liver transplantation (LDLT) recipients in the early post-operative period which requires an invasive liver biopsy to rule out other causes of graft dysfunction. However, a liver biopsy may get delayed and often difficult to perform because of ascites and/or coagulopathy. Early risk stratification for likelihood of TCMR may allow pre-emptive immunosuppressive optimization, but validated bedside prediction tools for TCMR after LDLT are unavailable. We aimed to analyze performance of different Machine Learning (ML) models and develop a simple, interpretable clinical scorecard for TCMR prediction using machine learning. **Methods:** We have a prospectively maintained database of 4703 LT recipients from August 2004. LT recipients with graft dysfunction underwent liver biopsy after ruling out biliovascular complications by imaging. 249 such patients who underwent liver biopsy within 1st month of LT from January 2015 to August 2023 were included in this study to see the performance of 12 different ML models. Each patient's data instance consisted of demographic parameters, perioperative variables (i.e. operative time, GRWR), and biochemical parameters at the time of biopsy including trends in LFTs. Data were split 80/20 with stratification. Performance was evaluated using AUROC with 95% CI, calibration, and decision curve analysis. TRIPOD guidelines were followed. **Results:** Two hundred and forty-nine patients were included for analysis. TCMR occurred in 113/249 patients (45.4%). Amongst, the comprehensive 12-model comparison, Linear SVM achieved the highest test AUROC of 0.798 (95% CI 0.691-0.905). Forward selection identified a simple 3-feature logistic regression scorecard (test AUROC 0.753, 95% CI 0.638-0.868) using: Neutrophil-to-Lymphocyte Ratio at biopsy (NLR), Day-3 pre-biopsy bilirubin (Bili D-3), and recipient age (*Figure 1*). The formula is: logit(P) = 3.575 + (−0.057 × NLR) + (−0.150 × Bili D-3) + (−0.046 × Age). All coefficients were negative, reflecting biologically coherent protective mechanisms: elevated NLR indicates neutrophilic rather than T-cell inflammation, high bilirubin reflects cholestasis/ischemia-reperfusion injury, and older age confers immune-senescence. This risk stratification model classified patients into Low (n = 50, TCMR 20%), Intermediate (n = 160, TCMR 49%), and High risk (n = 39, TCMR 80%) categories. **Conclusion:** Among 12 ML models, Linear SVM had best performance (AUROC 0.798) for likelihood of TCMR. A simple 3-feature bedside scorecard using routinely available peri-biopsy parameters can serve as Clinical Decision Support tool by stratifying risk of TCMR risk after LDLT. External multi-center validation is warranted for optimal use of these ML models in improving graft and patient survival.

4521 | GLP1RA USE AND CLINICAL OUTCOMES AMONGST LIVER TRANSPLANT CANDIDATES

Sara Naimimohasses[1] Tomohiro Tanaka[1], [1]University of Iowa Hospitals and Clinics

Background: Obesity in liver transplant (LT) candidates often prompts the need for weight loss pre LT. The safety and clinical utility of glucagon-like peptide 1 receptor agonists (GLP1RA) amongst individuals on the LT waitlist remains understudied. This study aimed to evaluate the clinical impact of GLP1RA initiation amongst patients with decompensated liver disease awaiting LT. **Methods:** A retrospective cohort design based on a linked dataset comprising the Scientific Registry of Transplant Recipients (SRTR) and Medicare administrative claims were used to compare outcomes between LT candidates initiated on GLP1RA therapy during their waitlist tenure and a matched cohort of non-users. Adults, newly listed for LT between 1/ 2021 and 12/ 2022 were included. A 1:3 propensity score matching without replacement was implemented. The propensity score was estimated via logistic regression using a prespecified set of covariates including age, sex, race, BMI, initial MELD score, MELD exception status, and metabolic dysfunction associated steatotic liver disease (MASLD) diagnosis, DM, KPS at listing, and transplant center volume tercile. Matching incorporated exact matching on index date (GLP1RA initiation date for treated patients). The primary outcomes for this study were the cumulative incidence of LT and waitlist mortality (defined as death or removal due to clinical deterioration), which were treated as competing risks to each other. **Results:** Following propensity score matching, data was analyzed from 540 patients listed for LT; 135 were treated with GLP1RA and 405 were non-users on the index date. MASLD was listed as the indication for LT in (n = 189, 46.7%) vs. (n = 59 43.7%), p = 0.62. Mean initial MELD was 12.7 vs. 12.5, p = 0.76. Mean BMI was 32.4 vs 32.7, p = 0.94, most patients had a diagnosis of DM (n = 352, 86.9%) vs. (n = 118, 87.4%), p = 1.00. At 120 days, patients treated with GLP1RA demonstrated a significantly lower risk of death compared with those who were untreated (risk difference -7.6%, 95% CI -14.6 to -0.6, p = 0.034). [TT1] However, no significant difference in mortality was observed beyond 120 days. There was no significant difference in the probability of LT between the two groups at any evaluated time interval. **Conclusion:** Amongst patients listed for LT, GLP1RA use was associated with increased shot-term survival at 120 days following listing, suggesting potential benefit in this population, although this effect was not consistently observed over time, nor for LT access.

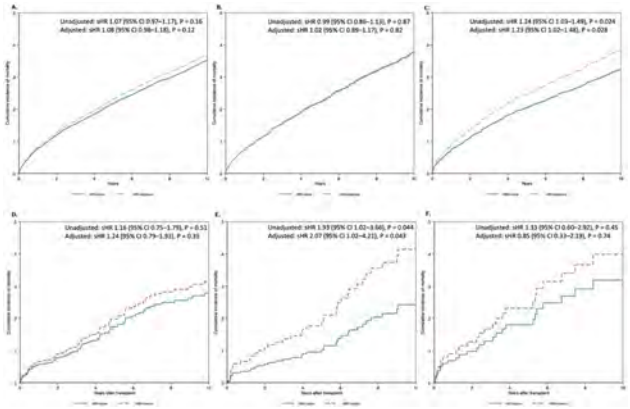
4522 | DONOR-RECIPIENT SEX PAIRING MODIFIES THE ASSOCIATION BETWEEN DONOR HEPATITIS B VIRUS STATUS AND POST–LIVER TRANSPLANT MORTALITY



Katherine Cooper[1] Leandro Sierra[2] Rachael Mahle[3] Deepika Devuni[4] Emily Bethea[3] Karin Andersson[3], [1]Massachusetts General Hospital, Harvard Medical School, [2]Cleveland Clinic Foundation, [3]Massachusetts General Hospital, [4]UMass Chan Medical School

Background: Donor hepatitis B virus (HBV) exposure and infection are increasingly relevant in liver transplant (LT) as donor organ availability expands. Whether the association between donor HBV status and recipient outcomes differs by donor–recipient sex pairing remains unclear. We evaluated post-LT mortality associated with donor HBV category, stratified by donor-recipient sex pairing. **Methods:** We performed a retrospective cohort study of adult liver transplant recipients using propensity score-matched donor HBV cohorts. Recipients of HBV-naïve donor grafts were compared with recipients of HBV-exposed donor grafts and, separately, HBV-infected donor grafts. Donor-recipient sex pairing was categorized as sex-matched, female donor to male recipient, or male donor to female recipient. The primary outcome was all-cause mortality within 10 years after LT. Cumulative incidence functions were estimated using Fine–Gray competing risks models, with retransplantation before death treated as a competing event. Subdistribution hazard ratios (sHR) were estimated before and after adjustment for recipient, donor, and transplant-specific characteristics. **Results:** In the HBV-naïve versus HBV-exposed donor cohort, 6,087 recipients were matched in each group. Among sex-matched donor–recipient pairs, HBV-exposed donor grafts were not associated with increased mortality after adjustment compared with HBV-naïve grafts (adjusted sHR 1.08, 95% CI 0.98–1.18). No mortality difference was observed among female donor to male recipient pairs (adjusted sHR 1.02, 95% CI 0.89–1.17). In contrast, among male donor to female recipient pairs, HBV-exposed donor grafts were associated with higher mortality (adjusted sHR 1.23, 95% CI 1.02–1.48). In the HBV-naïve versus HBV-infected donor cohort, 377 recipients were matched in each group. HBV-infected donor grafts were not significantly associated with mortality among sex-matched pairs (adjusted sHR 1.24, 95% CI 0.79–1.93) or male donor to female recipient pairs (adjusted sHR 1.95, 95% CI 0.33–2.19). However, HBV-infected donor grafts were associated with higher mortality among female donor to male recipient pairs (adjusted sHR 2.07, 95% CI 1.02–4.21). **Conclusion:** The association between donor HBV status and post-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

LT mortality may vary by donor-recipient sex pairing. HBV-exposed donor grafts were associated with higher mortality specifically among male donor to female recipient pairs, while HBV-infected donor grafts showed a signal for increased mortality among female donor to male recipient pairs. These findings suggest that donor-recipient sex pairing may modify risk associated with HBV-positive LT grafts, although results should be interpreted cautiously due to low sample size. Further studies are needed to validate these findings and clarify whether sex-specific immunologic or graft-related mechanisms contribute to differential post-LT outcomes.

4523 | PERIOPERATIVE RENAL DYSFUNCTION, NOT METABOLIC BURDEN, DRIVES LONG-TERM MORTALITY AFTER MASLD/MASH LIVER TRANSPLANTATION

Patricia Almeida[1] Giovana Fernandes[2] Maria Pilz[2] Andre Souza[2] Lilian Curvelo[1] Celso Matielo[1], [1]Einstein Hospital Israelita, [2]Faculdade Israelita de Ciencias Medicas Einstein

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD/MASH) is a rapidly growing indication for liver transplantation. Although MASLD/MASH recipients frequently carry substantial metabolic burden, the relative contribution of obesity versus perioperative renal dysfunction to long-term survival remains unclear. We evaluated predictors of long-term mortality after liver transplantation for MASLD/MASH, focusing on early post-transplant hemodialysis and body mass index. **Methods:** We retrospectively analyzed 100 consecutive adult recipients undergoing liver transplantation for MASLD/MASH between 2008 and 2025 at a tertiary transplant center. Overall survival was assessed using Kaplan-Meier analysis and Cox proportional hazards models. To mitigate immortal time bias, a predefined 30-day landmark analysis evaluated the impact of early post-transplant hemodialysis (HD-30d) on subsequent mortality. **Results:** Median follow-up was 4.9 years (IQR 2.6–8.8). Overall survival at 1, 3, 5, and 10 years was 92.9%, 89.4%, 80.4%, and 75.0%, respectively. HD-30d occurred in 20% of recipients and was associated with markedly inferior long-term survival (10-year survival: 47.9% vs 83.6%; log-rank $p = 0.004$). In landmark multivariable Cox analysis excluding deaths within 30 days, HD-30d was the strongest independent predictor of mortality (HR 5.07, 95%CI 1.63–15.74, $p = 0.005$), independent of age, MELD-Na, and baseline creatinine.In contrast, obesity was not associated with worse survival. Recipients with BMI ≥ 30 had numerically higher survival than those with BMI < 30 at both 5 years (87.3% vs 72.3%) and 10 years (84.3% vs 57.8%), suggesting that BMI alone may poorly capture biological vulnerability in cirrhotic MASLD/MASH candidates. **Conclusion:** In MASLD/MASH liver transplantation, early renal dysfunction requiring hemodialysis, rather than obesity or baseline metabolic burden, is the dominant predictor of long-term mortality. The unexpectedly poorer outcomes among non-obese recipients may reflect hidden sarcopenia or reduced physiologic reserve, supporting integrated assessment of renal vulnerability and body composition in this population.

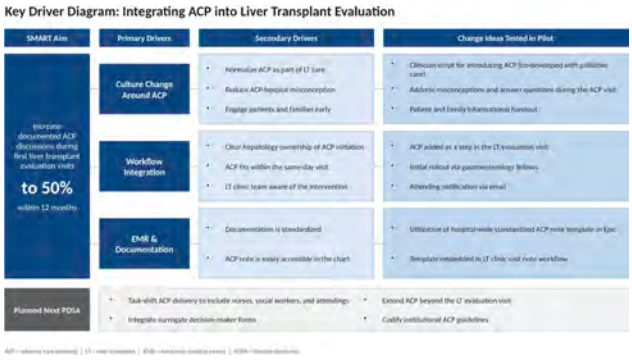
4524 | CLOSING THE ADVANCE CARE PLANNING GAP IN LIVER TRANSPLANT EVALUATION: A QUALITY IMPROVEMENT PILOT



Mayowa Adefuye[1] Swathi Krishnan[2] Michelle Hughes[2] Vandana Khungar[2], [1]Yale New Haven Health System, CT, USA, [2]Section of Digestive Diseases, Yale School of Medicine, New Haven, CT, USA

Background: Patients with end-stage liver disease face high mortality and risk of delisting from the transplant waitlist due to serious illness or death, yet advance care planning (ACP) is poorly integrated into liver transplant (LT) evaluation. Nationally, fewer than half of LT centers require advance directive discussions during evaluation, and only 9% of LT candidates complete ACP beforehand, despite most reporting

readiness. We piloted a quality improvement (QI) intervention as proof of concept to embed a structured ACP into the initial LT evaluation visit. **Methods:** This single-center QI pilot was conducted at Yale New Haven Hospital between Jan 23 and May 15, 2026, per SQUIRE 2.0. Our SMART aim was to increase documented ACP during first LT evaluation visits to 50% within 12 months. We mapped the clinic workflow and built a key driver diagram targeting culture change, workflow, and EMR optimization. Core change ideas included a clinician script co-developed with palliative care, a patient handout, and a structured ACP note template embedded in the LT visit note, implemented by gastroenterology fellows. We compared documentation between the pilot and an equal 16-week pre-intervention period via chart review. Co-primary outcomes: overall ACP documentation rate and capture rate among patients without prior ACP. Acceptability was assessed via post-visit patient survey. **Results:** Pre-intervention, 6 of 31 patients (19%) had documented ACP. During the pilot, documentation rose to 27 of 37 (73%), exceeding the SMART aim. Among 32 patients without prior ACP, the intervention captured 22 (69%). Median age was 58 years (IQR 46–66), 64% were male; 68% White (non-Hispanic), 14% Hispanic, 5% Black; median MELD 3.0: 14 (IQR 9–19); Child-Pugh B in 59%. Leading etiologies were alcohol-related liver disease (59%), MASH (18%), hepatitis C-related (14%). All ACP discussions (100%) were documented on the same-day, and a healthcare proxy was identified in every encounter; a support person was present at 77% of visits. All patients completed the survey, 100% found it helpful, 92% felt the topic was important, and 83% reported no anxiety or discomfort **Conclusion:** A structured, workflow-integrated ACP intervention is feasible, highly acceptable to patients and providers, and produced a near-fourfold increase in documentation (19% → 73%) in a 16-week pilot. Coordinated change across culture, workflow, and EMR enabled rapid measurable improvement without added visit burden. Next steps include integrating other healthcare professionals into ACP delivery and codifying institutional ACP guidelines to support scale.

4525 | BEYOND LIVER TRANSPLANTATION: LONG-TERM SURVIVAL AND CAUSES OF MORTALITY IN HEPATIC SARCOIDOSIS

Alexis Kim[1] Anh Bui[2] Siddhant Nair[1] Shilpa Jasti[3] Aamer Syed[1] Thomas Iden[1] Jessica McLaughlin[1] Dana Alderson[1] Jordana Kron[1] Huzaefah Syed[1] Neha Gupta[1] Ryan Canissario[1] Duaa AbdelHameid[1] Mohammad Siddiqui[4] Vaishali Patel[2], [1]Virginia Commonwealth University Health System, [2]Virginia Commonwealth University, [3]Virginia Commonwealth University Medical School, [4]University of Virginia

Background: Hepatic sarcoidosis (HS) is a rare indication for liver transplantation (LT), and its long-term outcomes remain poorly characterized compared to other immune-mediated liver diseases. This study aimed to evaluate post-LT survival and cause-specific mortality in patients with HS compared to those with primary sclerosing cholangitis (PSC), primary biliary cholangitis (PBC), and autoimmune hepatitis (AIH). **Methods:** Using the OPTN/UNOS database (2002-2022), we identified 872 adult deceased-donor LT recipients with HS and compared their outcomes to those with PSC (n = 4705), PBC (n = 3166), and AIH (n = 2960). Patients with prior LT or concurrent hepatocellular carcinoma were excluded. Survival was analyzed using Kaplan-Meier (KM) curves and Cox proportional hazards regression, while Fine-Gray subdistribution hazards models were applied to assess cardiovascular disease (CVD)-specific mortality. **Results:** HS LT recipients demonstrated significantly lower 5- and 10-year survival (75.8%, 62.7%) compared to PSC (85.8%, 75.2%, $p < 0.0001$), PBC (83.5%, 71.0%, $p < 0.0001$), and AIH (80.2%, 67.2%, $p = 0.0063$) (Figure 1A). On multivariate analysis adjusting for age, sex, race, MELD score, transplant year, obesity, and pre-existing diabetes, HS remained an independent predictor of worse 10-year survival compared to PSC (HR 1.47, $p < 0.001$) and PBC (HR 1.22, $p = 0.03$), though survival differences compared to AIH were not statistically significant (HR 1.06, $p = 0.51$). CVD (23.5%) was the leading cause of death in HS (23.5%), followed by infection (15.2%) and malignancy (11.3%). Cumulative incidence analysis further revealed significantly higher CVD-specific mortality in HS patients, with a three-fold increased risk compared to PSC (HR 3.33, $p < 0.001$) and approximately two-fold increased risk compared to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

both PBC (HR 1.85, p = 0.013) and AIH (HR 1.86, p = 0.004) (Figure 1B). **Conclusion:** Patients receiving an LT for HS demonstrate worse long-term survival when compared to PSC and PBC patients. CVD-related mortality accounts for this increase in mortality in HS compared to other cholestatic and autoimmune liver diseases, underscoring the need for targeted strategies to mitigate cardiovascular risk following LT in HS.

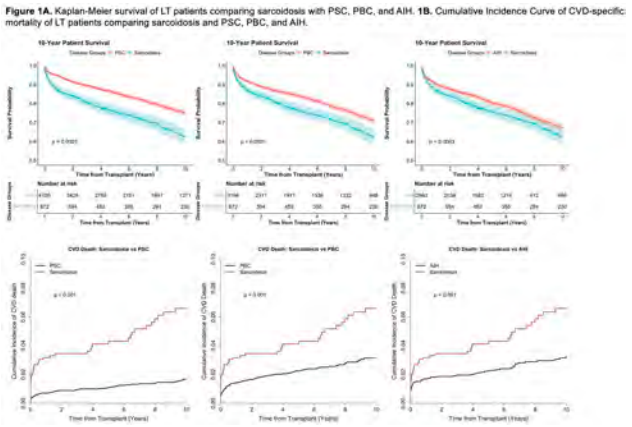

Figure 1A. Kaplan-Meier survival of LT patients comparing sarcoidosis with PSC, PBC, and AIH. 1B. Cumulative Incidence Curve of CVD-specific mortality of LT patients comparing sarcoidosis and PSC, PBC, and AIH.

4526 | INCIDENCE AND RISK FACTORS FOR ANASTOMOTIC BILIARY STRICTURES FOLLOWING LIVER TRANSPLANTATION USING MACHINE PERFUSION

Caroline Olson[1] Andrew Keaveny[1] Nicole Loo[1] Liu Yang[1] Surakit Pungpapong[1] Kristopher Croome[1] Omar Mousa[1], [1]Mayo Clinic Florida

Background: Biliary strictures are the most common complication following donation-after-circulatory-death (DCD) liver transplantation (LT), occurring in 5-30% of cases. Machine perfusion (MP) technologies including in situ normothermic regional perfusion (NRP) and ex situ normothermic machine perfusion (NMP) perfuse donor organs with oxygenated blood at body temperature, prolong viability and expand the DCD donor pool. Their impact on biliary strictures is not well studied. The aim of our study was to determine the incidence of biliary strictures by MP modality and identify factors associated with stricture development after DCD-LT. **Methods:** This was a retrospective review of 437 DCD-LT recipients at a single center between 2/2017 - 10/2025. Patients were included if they had an endoscopic retrograde cholangiopancreatography procedure (ERCP) post-LT. Donor/recipient demographics, NMP time, anastomosis type, transplant year, bile leak, and vascular complications were compared by χ^2 and Kruskal–Wallis tests. Univariate and multivariable logistic regression identified factors associated with the presence of stricture. **Results:** Recipients were grouped by perfusion modality: NMP (n = 166), NRP (n = 75), combined NRP+NMP (n = 29) and no MP (n = 167). Anastomotic biliary strictures occurred in 22.8% recipients. The overall incidence was highest in NMP (56/166, 33.7%) vs NRP (14/75, 18.7%) vs NRP/NMP (4/29, 13.8%) and no MP (26/167, 15.6%; p < 0.001). Anastomotic stricture rates improved year-over-year in the NMP group (46% in 2023, 35% in 2024, 24.5% in 2025). NMP recipients had longer NMP time (median 16.2 vs 6.2 vs 6.3 h; p < 0.001), older donor age (59.5 vs 57.0 vs 39.0 y; p < 0.001), and higher donor BMI (p < 0.001). On univariate analysis, NMP (OR 2.30, p < 0.001), and biliary leak (OR ~8.0, p < 0.001) were associated with increased odds of biliary stricture. Recipient age, recipient BMI, donor age, and donor BMI were not significantly associated with stricture risk. On multivariate analysis adjusting for recipient and donor factors as well as perioperative variables, biliary leak remained the only independent predictor of biliary stricture (OR ~8.0, p < 0.001), and NMP was not significantly associated with stricture development. The use of perfusion modality did not impact survival (log-rank p $\asymp$ 0.18). **Conclusion:** Anastomotic biliary stricture rates were higher in NMP-preserved DCD-LT recipients but improved over the years likely due to refinements in surgical and organ perfusion techniques. The unadjusted NMP-stricture association attenuated after adjustment for era, donor characteristics, and NMP time, suggesting that donor selection and perioperative complexity, rather than perfusion modality alone, may drive risk. Bile leak was the strongest independent predictor of ABS. These findings inform donor allocation, peri- and post-operative management, and risk stratification in DCD-LT programs using machine perfusion.

4528 | MTOR INHIBITOR-BASED IMMUNOSUPPRESSION IS ASSOCIATED WITH INCREASED MORTALITY IN LIVER TRANSPLANT RECIPIENTS WITH MEDICARE

Therese Bittermann[1] Douglas Schaubel[2] Charles Leonard[2] Qufei Wu[2] David Goldberg[3] David Kaplan[4], [1]University of Pennsylvania Perelman School of Medicine, [2]Department of Biostatistics, Epidemiology and informatics; University of Pennsylvania, [3]University of Miami, [4]University of Pennsylvania

Background: Mechanistic target of rapamycin inhibitors (mTORi) are used off-label in liver transplantation (LT) based on clinical trial and single center data suggesting benefits in selected recipients. Using a large retrospective cohort of Medicare LT beneficiaries, we previously demonstrated that mTORi use is highly variable among centers and most often occurs in patients with high comorbidity burden. To date, U.S. population-based studies on the association of mTORi with outcomes using real-world data are lacking. **Methods:** This study used an existing data linkage of Medicare claims and data from the Organ Procurement and Transplantation Network. The study population (n = 17,239) included adult recipients of first-LT-alone between 1/1/2007-12/31/2019. For each patient a risk score for mTORi initiation was derived using a stratified Cox model based on a large number baseline and time-updating demographic, clinical and socio-economic covariates. Each mTOR inhibitor treated patient was matched at the time of mTORi initiation to 1-3 comparators within the same transplant center, +/- 5 years of age and +/- 0.05 of prognostic score. The association of mTORi initiation on survival was then evaluated using the sequential stratification version of Cox regression. Sub-analyses included examining interactions between mTORi and each of pre and/or post-LT cancer and post-LT end-stage renal disease (ESRD) or chronic kidney disease (CKD). Models were also fit allowing for non-proportional hazards. **Results:** Median follow-up time was 3.8 (IQR: 1.2-7.1) years. A total of 3,537 (20.5%) unique patients ever initiated mTORi. From this group, 2,944 (83.2%) were matched to 1-3 comparators (64.2% to 3 comparators), resulting in 7,204 matched comparators. mTORi initiation occurred at a median 5.0 months (IQR: 2.0-14.6) from LT and median follow-up time post-matching was 4.11 years (IQR: 1.74-7.58). In total, 3,043 (30.0%) deaths were observed. mTORi initiation was associated with an increased risk of mortality: HR = 1.92 (95% CI 1.78-2.07; p < 0.001) averaged across follow-up. The magnitude of this effect persisted for at least 4 years after mTORi-initiation and was still present, albeit considerably diminished, for up to 10 years (Figure). Significant interactions by cancer status and renal function were detected. Mortality risk with mTORi initiation was higher for patients with cancer (HR = 2.02; p < 0.001) vs without (HR = 1.47; p < 0.001). However, for patients the mTORi hazard ratio was decreased for patients with ESRD (HR = 1.45; p = 0.001) or CKD (HR = 1.50; p < 0.001) relative to patients with neither (HR = 2.53; p < 0.001). **Conclusion:** We previously found that post-transplant comorbidity incidence is associated with increased mTORi initiation rates. Despite employing methodology that matches on time-dependent risk factors, mortality risk remains significantly elevated after mTORi initiation.

4529 | TACROLIMUS VARIABILITY AND DAY 7 LABORATORY TRAJECTORIES PREDICT GRAFT FAILURE AFTER LIVER TRANSPLANTATION

Kevin Korenblat[1], [1]Washington University School of Medicine

Background: Post-liver transplant graft failure occurs in 5-10% of recipients within the first year. While risk scores such as L-GrAFT and EASE incorporate perioperative laboratory data to predict post-transplant outcomes, these models have not achieved widespread clinical adoption. A model for early risk stratification using accessible electronic health record data could enable targeted interventions during index hospitalization when most patients remain admitted. Gradient boosting models using 528,000 laboratory measurements across 28 unique analytes were developed to predict 90-day graft failure, comparing models using complete hospitalization data versus data restricted to postoperative day 7, when 70% of patients remain hospitalized and accessible to interventions. **Methods:** This retrospective analysis included 922 adult liver transplant recipients at a single center (August 2019-August 2025). Graft failure was defined as retransplantation or death within 90 days. Laboratory data were aggregated into time windows with calculation of trajectory features (mean, maximum, variability, peak timing). Derived features included MELD scores, tacrolimus coefficient of variation (CV), and interaction terms. Gradient-boosted decision trees were trained using 5-fold stratified cross-validation. **Results:** Among 922 transplant recipients, 50 (5.4%) experienced graft failure within 90 days. The complete model achieved mean cross-validation AUC 0.803 (SD 0.131, 95% CI 0.640-0.965). The day 7 restricted model achieved AUC 0.801 (SD 0.035, 95% CI 0.757-0.844), representing only 0.2% performance loss. Feature importance analysis identified AST peak timing (12.3%), lactate trajectory (7.1%), and tacrolimus CV × creatinine interaction (6.2%) as dominant predictors in the day 7 restricted model. Calibration analysis demonstrated good agreement between predicted and observed outcomes (Brier score 0.161 in the day 7 restricted model). **Conclusion:** Machine learning models using day 7 laboratory trajectories predict 90-day graft failure after liver transplantation with excellent discrimination (AUC 0.81). The tacrolimus variability × creatinine interaction emerged as a novel predictor, identifying modifiable risk factors for early intervention. Minimal performance loss with day 7 implementation enables early risk stratification while most patients remain hospitalized, establishing targets for intensive monitoring to reduce graft failure risk.

Disclosures: Kevin Korenblat:Nothing to Disclose.

4530 | COMBINED HEART–LIVER TRANSPLANTATION: CURRENT EVIDENCE AND EVOLVING PRACTICES

Fatima Elmustafa,[1] Shahzad Ashraf[2] Faris Abdulaziz[1] Sajid Jalil[3] Mangesh Pagadala[4] Akash Shukla[5] Binu John[6] Patrizia Burra[7] Winston Dunn[8] Ashwani Singal[9], [1]Henry Ford Warren, [2]Eastridge PrimeCare Hospital, [3]Stanford University, [4]Methodist Transplant Specialists, [5]Seth GS Medical College & KEM Hospital, [6]University of Miami and Miami VA, [7]University of Padova, [8]University of Kansas Medical Center, [9]University of Louisville

Background: Data on combined heart–liver transplantation (CHLT) are limited. We aimed to examine trends, indications, and outcomes of CHLT. **Methods:** Adult (≥18 years) CHLT recipients in the United Network for Organ Sharing (UNOS) database (1987-2025) were included. Prior LT recipients were excluded. Survival was analyzed using Kaplan–Meier and Cox regression methods. **Results:** Among 805 CHLT recipients, simultaneous heart–liver transplants (sHLT) accounted for most cases (n = 660, 82.0%), followed by heart-before-liver (HBL) transplants (HBL; n = 116, 14.4%),

and heart-after-liver (HAL) transplants (n = 29, 3.6%). Trends (1987-1995 to 2016-2025) varied: HBL 93.4% to 4.4%, sHLT 3.9% to 95.3%, (P < 0.001). HAL remained relatively stable, 2.5% to 7.1%. Diabetes mellitus, MELD-XI score, ventilator support, and dialysis use differed (Table). Congenital heart disease and cardiomyopathy accounted for 39% and 32% for sHLT, whereas cardiomyopathy was the commonest cardiac cause in HAL (79%) and HBL (35%) transplants. Coronary artery disease and valvular heart disease accounted for 2.1%, 0%, 4.3% and 0.9%, 6.9%, 2.6% in sHLT, HAL, HBL respectively. MASH or cryptogenic was the liver diagnosis in 75%, 55%, 32% in sHLT, HAL, HBL transplants respectively. Alcohol-associated liver disease and hepatocellular carcinoma were other common causes, with respective figures of 4.5%, 10.3%, 2.6% and 3.6%, 24.1%, 6.9%. Over a median (25th – 75th percentile) follow-up of 3 (1-7.3) yrs., 224 (30.6%) recipients lost cardiac graft, with only four rejection episodes, one ACR in HAL, and three chronic rejection (1 SLH and 2 HBL). Patient survival at 1 yr. was 96.7%, 84.6%, and 75.9% in HBL, sHLT, and HAL, respectively. However, this was similar at 3 yrs. P = 0.495 and at 5 yrs. P = 0.403. Adjusted Cox regression models showed that compared to HBL, recipients with HAL had an over 11-fold hazard of dying within a year. (HR 11.59, 95% CI 1.36–98.97, P = 0.025). The survival was like that of sHLT. Being on dialysis was associated with a hazard ratio of over 2, and recipient age with a 2% mortality reduction for every unit increase in age. There was no effect of year of transplant (Table). **Conclusion:** sHLT has become the predominant CHLT approach over time, reflecting evolving transplant practices. In this UNOS cohort selected for CHLT, HBL demonstrated the best 1-yr. survival, with similar long-term survival highlights the need for diligent candidate selection for CHLT.

Table: Baseline Characteristics of Adult Combined Heart–Liver Transplant Recipients by Transplant Sequence

Parameter	SLH (n=660)	HAL (n=29)	HBL (n=116)	P	HR (95% CI)
sHLT as CHLT type					6.92 (0.92-52.0), p=0.060
HAL as CHLT type					11.59 (1.36-99.0), p=0.025
HBL as CHLT type					Ref.
Calendar yr					1.02 (0.98-1.06), p=0.314
Age, years	46 (33–57)	57 (46–63)	50 (37–58)	0.399	0.98 (0.96-0.99), p=0.002

4531 | ALLOGRAFT STEATOSIS REFLECTS PRE-TRANSPLANT METABOLIC RISK RATHER THAN AN INDEPENDENT DRIVER OF OUTCOMES IN ADULT LIVER TRANSPLANT RECIPIENTS

Yinan Su[1] Roxanna Sharifi[1] Daanyaal Kumar[2] Paul Paik[3] Andrew John Cruz[2] Kalpana Gopalkrishnan[4] Niveda Balemurughan[4] Juan Carlos Delgado[5] Alejandro Delgado[2] Scott Jun[2] Derek Samson[6] Jeffrey Kahn[7] Norah Terrault[8] Liyun Yuan[8], [1]Keck Medicine of USC, University of Southern California, [2]USC/Los Angeles General Medical Center Internal Medicine Residency Program, [3]Keck School of Medicine, University of Southern California. Los Angeles, California, [4]Keck School of Medicine, University of Southern California, [5]The Kaiser Permanente Los Angeles Medical Center, [6]Transplant Institute, Keck Medicine of USC, University of Southern California,, [7]Keck School of Medicine, University of Southern Cal, [8]University of Southern California

Background: Allograft steatosis is commonly identified on liver biopsy among liver transplant (LT) recipients. The natural history of allograft steatosis and associated fibrosis has been reported with a wide range of outcomes, ranging from slow indolent courses to rapid progression. These discrepancies may derive from heterogeneity in patient populations, metabolic risk burden, and differences in fibrosis assessment methodology. In this study, we investigated i) the prevalence and the associated risk factors for allograft steatosis and ii) evaluate graft fibrosis and post-transplant mortality in patients with allograft steatosis. **Methods:** We conducted a retrospective,

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

single-center study of adult liver transplant recipients transplanted 2015-2023 who underwent post-transplant liver biopsy for abnormal liver tests at any point from 3 months to 5 years post-LT. Hepatic steatosis was defined as ≥5% macrovesicular steatosis. Fibrosis was assessed histologically and graded as F1, F2/F3, F4, or indeterminate. Multivariable logistic regression adjusted for age and sex assessed factors associated with allograft steatosis. **Results:** Among the subgroup of 489 patients who underwent post-LT biopsy (median age 57, 45.4% female), 158 (32.3%) had allograft steatosis at any point between 3 months and 5 years post-LT. The cumulative number of patients identified with allograft steatosis increased over time post-LT. Pre-LT metabolic syndrome (aOR 2.59, 95% CI 1.59-4.21; p < 0.001), diabetes (aOR 1.62, 95% CI 1.06-2.47; p = 0.02), and obesity (aOR 1.59, 95% CI 1.04-2.41; p = 0.03) were associated with allograft steatosis, while post-LT development of de novo metabolic risk factors was not after adjustment for age and sex. Hepatic fibrosis was uncommon and predominantly mild in patients with allograft steatosis. Among patients with allograft steatosis biopsied up to 5 years post-LT, 3.8% (n = 6) had F1 fibrosis, 1.3% (n = 2) had F2 or F3, and no patients had F4 or allograft cirrhosis. **Conclusion:** Allograft steatosis is a common finding among individuals receiving post-LT biopsy. It is linked to pre-transplant metabolic risk factors including metabolic syndrome, type 2 diabetes and obesity, whereas de novo post-LT diabetes and obesity were not independently associated. Yet, the progression to advanced fibrosis was rare within 5 years, and no patients developed allograft cirrhosis at up to 5 years post-LT. However, longer-term follow-up may identify additional patients with advanced fibrosis. Additionally, patients with allograft steatosis did not present with worse outcomes in comparison to those without allograft steatosis. These findings suggest that allograft steatosis may primarily reflect pre-transplant metabolic risk rather than serving as an independent driver of adverse outcomes.

Table1. Outcomes counted at each time interval among individuals with allograft steatosis

	3 month	6 month	1year	3 year	5 year
Cumulative allograft steatosis(n)	55	77	108	143	157
Fibrosis at this visit	5 (9.1%)	5 (6.5%)	13 (12%)	19 (13.3%)	9 (5.7%)
F1	4 (7.3%)	4 (5.2%)	11(10.2%)	13 (9.1%)	6 (3.8%)
F2/F3	1 (1.8%)	0 (0.0%)	1 (0.9%)	1 (0.7%)	2 (1.3%)
F4	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)	0 (0.0%)
Indeterminate score	0 (0.0%)	1 (1.3%)	1 (0.9%)	5 (3.5%)	1 (0.6%)

Table 2. Associated risk factors with the presence of allograft steatosis.

	aOR (95% CI)	P
Pre-LT metabolic syndrome	2.59 (1.59-4.21)	<.001
Pre-LT diabetes	1.62 (1.06-2.47)	.02
Pre-LT obesity	1.59 (1.04-2.41)	.03
Post-LT new diabetes	1.51 (0.92-2.50)	.11
Post-LT obesity	1.68 (0.88-3.21)	.12

Multivariable logistic regression, with presence of allograft steatosis found on biopsy at any point from 3 months to 5 years post-LT as the outcome, adjusted for age and sex.

4532 | A SIMPLIFIED STRATEGY TO STRATIFY HEPATOCELLULAR CARCINOMA RECURRENCE RISK AFTER LIVER TRANSPLANTATION

Akarshi Brar[1] Michele Barnhill[1] Fares Jamal[1] Abdullah Alsulaiman[1] W. Ray Kim[2] Bashar Aqel[1] Channa Jayasekera[2], [1]Mayo Clinic, [2]Mayo Clinic Arizona

Background: Hepatocellular carcinoma (HCC) recurrence risk after liver transplantation (LT) necessitates imaging-based surveillance in most patients. Among several risk-prediction models, the Risk Estimation of Tumor REcurrence After Transplant (RETREAT) score is a well-validated 0-8 scale derived from the alfa-fetoprotein level at LT, and number of viable tumors, largest viable tumor size and microvascular invasion status in the explant, to direct the frequency and duration of surveillance. Our institution utilizes an alternative, consensus-derived, low (LR), intermediate (IR), and high risk (HR) classification based on tumor burden, vascular invasion, and grade of differentiation that obviates the need to compute a discrete score. Whereas a RETREAT of 5-8 proposes 12-14 chest and abdomen scans over 5 years, our HR category requires 6 chest and abdomen scans over 3 years. We investigated how our institutional scale performs against the RETREAT score in predicting HCC recurrence. **Methods:** We conducted a survival analysis, stratified by RETREAT and Mayo Clinic risk scores, of all patients who underwent LT for HCC or were incidentally found to have HCC at LT at Mayo Clinic Arizona between 1/2015-12/2023, followed through May 2026. We categorized RETREAT 0-3, 4-5, and 6-8 as risk groups that may correspond to LR, IR, and HR, respectively. **Results:** In 401 LT recipients, median follow up was 4.3 years (IQR 2.8-7.3) and overall HCC recurrence rate was 6.4%, with only 1.2% recurring beyond 3 years. Recurrence rate was 4.2%, 5.8% and 27.1% in LR, IR, and HR groups respectively, and 4.9%, 19.3%, and 40% by RETREAT scores 0-3, 4-5, and 6-8 respectively. LR and IR recurrence rates were comparable to RETREAT 0-3, allowing LR+IR to be collapsed into a single New Low Risk category ($p = 0.44$) (Fig. 1A). HR outcomes were comparable to RETREAT 4-5 and 6-8, allowing RETREAT 4-8 to be collapsed as a single high-risk category ($p = 0.88$) (Fig. 1B). C-index for predicting recurrence with RETREAT was 0.631 and 0.691 with the Mayo score. **Conclusion:** In this retrospective single-center analysis, a simplified risk stratification based on tumor burden differentiated patients at lower and higher HCC recurrence risk, comparable to the four-variable, 9-point RETREAT score. HCC recurrence rate beyond 3 years was low. If further validated, this simplified paradigm may adequately identify patients who need more intensive post-LT HCC recurrence surveillance, and necessitate fewer scans and shorter surveillance duration than proposed in the RETREAT guidelines.

4533 | COMPUTED TOMOGRAPHY–DEFINED SARCOPENIA AND VISCERAL OBESITY PHENOTYPES ARE NOT INDEPENDENTLY ASSOCIATED WITH POST-LIVER TRANSPLANT MAJOR ADVERSE CARDIOVASCULAR EVENTS

Poojitha Pai[1] Tamoor Afzaal[2] Sangmin Lee[1] Lujain Alrabghi[1] Saleh Alobaid[1] Carly Burow[1] Anya Sarma[3] Daniel Picard[4] Milad Hamwi[4] Harry Marshall[5], [1]Department of Medicine, Western University, [2]Department of Medicine, Division of Gastroenterology, Western University, [3]Western University, [4]Department of Radiology, London Health Sciences Centre, [5]Department of Radiology, Vanderbilt University Medical Center

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading indication for liver transplantation (LT) and is closely linked to sarcopenia and visceral obesity (VO). Sarcopenic visceral obesity (SVO) is associated with poor post-LT outcomes, however, its relationship with post-LT major adverse cardiovascular events (MACE) is ill-defined. We evaluated the association between CT-defined sarcopenia/VO phenotypes and post-LT MACE. **Methods:** We performed a retrospective cohort study of adult LT recipients (LTR) in London, Canada (2005-2019) with available pre-LT abdominal CT imaging and longitudinal follow-up. Patients with multi-organ transplantation, previous transplant, severe allograft dysfunction, re-transplantation within 1 year, and living donors, were excluded. Cross-sectional body composition analysis at the L3 vertebral level quantified skeletal muscle index (SMI) and visceral-to-subcutaneous adipose tissue ratio (VSR). Sarcopenia was defined as SMI < 50 cm²/m² in men and < 39 cm²/m² in women. VO was defined using sex-specific VSR thresholds. LTRs were categorized into 4 phenotypes: no sarcopenia/no VO, sarcopenia only, VO only, and combined SVO. Primary outcome was post-LT MACE, defined as cardiovascular death or hospitalization for myocardial infarction, revascularization, heart failure, atrial fibrillation, stroke/TIA, pulmonary embolism, or cardiac arrest. Cox proportional hazards (PH) models identified risk factors for post-LT MACE. **Results:** Among 566 LTRs, 419 met exclusion criteria. In the analyzed 147 LTRs (mean age 61.0 ± 16.4 years; 82.3% male), sarcopenia only, VO only, and SVO phenotypes were present in 17.7%, 10.9%, and 5.4%, respectively. Post-LT MACE incidence was 26.7%. MACE rates differed across phenotypes but not statistically significant (no sarcopenia/no VO 26.0% vs sarcopenia only 14.3% vs VO only 55.6% vs SVO 20.0%; $p = 0.168$). In multivariable Cox PH analysis, sarcopenia only (aHR 1.39, 95%CI 0.28–6.87), VO only (aHR 1.32, 95%CI 0.33–5.27), and SVO (aHR 3.37, 95%CI 0.36–31.2) were not associated with post-LT MACE. Older age (aHR 1.05/year, 95%CI 1.02–1.09; $p = 0.004$) and hypertension (aHR 4.36, 95%CI 1.34–14.1; $p = 0.014$) were significantly associated with post-LT MACE. Longitudinal analyses revealed concerning metabolic trajectories among VO phenotypes, persistently higher HbA1c levels 5 years post-LT (7.0% in VO only vs 6.2% in no sarcopenia/no VO; $p = 0.055$), while sarcopenic phenotypes trended towards worsening renal function. **Conclusion:** Sarcopenia and VO phenotypes were not independently associated with post-LT MACE after adjusting for traditional cardiovascular risk factors. However, VO demonstrated higher MACE rates and concerning metabolic trajectories, suggesting a potential signal warranting larger, adequately-powered studies. Older age and hypertension, remain significantly associated with post-LT MACE

4534 | OLDER LIVING DONORS: NOT THE BEST, BUT DEFINITELY WORTH WAITING FOR

Lauren Callans[1] Russell Rosenblatt[1], [1]Weill Cornell Medicine

Background: Living donor liver transplantation (LDLT) is associated with improved post-transplant survival, but a recent study suggested that older LDLT grafts have worse outcomes. This study aims to evaluate the survival differences in patients on the waitlist by graft type, with a focus on older LDLT donors. **Methods:** Adults listed for LT in the UNOS STAR file from 2015-2025 were included. Patients were excluded if they were listed for multiple organs, had prior liver transplants, had exception points, or had acute liver failure. Graft types were classified as LDLT old (donor age ≥ 45), LDLT young (donor age < 45), donation after brain death (DBD), donation after circulatory death (DCD), DCD with machine perfusion (DCD+M), and not transplanted. The primary outcomes were graft and overall survival. We performed two analyses: 1. As-treated (AT), starting at time of LT and 2. Intention-to-treat (ITT), starting at time of waitlisting. Survival analysis was performed and, to counteract immortal time bias, time-varying covariates were utilized. A flexible parametric survival model was fitted using the Royston-Parmar approach and predicted survival curves were generated. The multivariable model included liver disease etiology, age, MELD, and sex. Finally, LDLT old were compared to all patients awaiting deceased donor to evaluate whether this was superior to waiting. **Results:** 82,216 were included in the AT analysis – 3.9% LDLT young, 1.5% LDLT old, 82% DBD, 8.7% DCD, and 4.2% DCD+M. An additional 129,769 were included in the ITT analysis who were not transplanted. LDLT recipients were younger with lower MELD scores than deceased donor LT recipients.In the AT analysis, survival was excellent across all donor types. LDLT young had the best, while DCD had the worst graft/overall survival (Figure 1A). In multivariable models, compared to LDLT old, only LDLT young was significantly different, showing improved survival (HR 0.79, 95% CI 0.66–0.95). Time-varying analyses demonstrated these differences remained stable over time.In the ITT analysis, compared to LDLT old, LDLT young maintained a survival advantage across all timepoints, DBD and DCD+M showed an early survival advantage that attenuated over time, and DCD showed no difference compared with LDLT old. Remaining on the waitlist was associated with significantly higher mortality that increased over time.Finally, LDLT old was compared to all patients awaiting deceased donor. LDLT old showed improved survival across all time points (HR 0.45, 95% CI 0.39-0.52) (Figure 1B). **Conclusion:** LDLT old achieved survival rates that were comparable to patients receiving deceased donor transplants but worse than LDLT young. However, LDLT old maintained significantly better survival compared to those awaiting deceased donor transplant on the waitlist, demonstrating its overall benefit on survival.

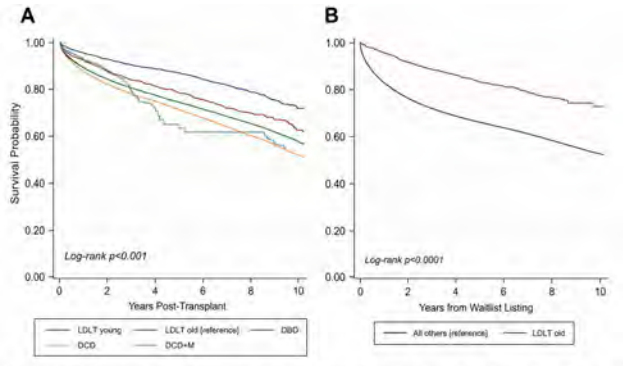

Figure 1A. Observed overall survival post-transplant grouped by transplant donor type in AT analysis starting at time of transplant. **B.** Observed overall survival post-listing comparing LDLT old vs. All others (excluding LDLT young) in ITT analysis starting at time of waitlisting.

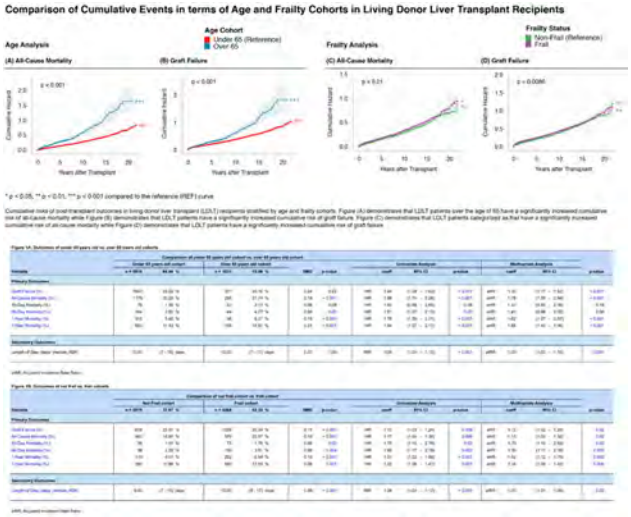
Disclosures: Lauren Callans:Nothing to Disclose, Russell Rosenblatt:Gilead: Grant/Research Support.

4535 | AGE ABOVE 65 YEARS OLD AND FRAILTY ARE ADVERSE PREDICTORS OF LIVING-DONOR LIVER TRANSPLANT RECIPIENTS' GRAFT FAILURE, MORTALITY, AND LENGTH OF HOSPITALIZATION



Christina Lee[1] Gregory Fan[1] Ki Jung Lee[1] Raffi Karagozian[1], [1]Tufts medical center

Background: Frailty is a well-known predictor of adverse outcomes in liver transplant recipients and living-donor liver transplantation (LDLT) is widely known to provide excellent post-transplant outcomes. However, there exists a knowledge gap for predictors of LDLT outcomes. Our study is aimed to understand the survival outcomes of elderly and frail patients undergoing LDLT. **Methods:** A total of 6,847 LDLT patients were selected from the 2002-2024 UNOS-STAR database and stratified by age (1031 over 65 years old and 5816 under 65 years old) and by frailty (4268 frail and 2579 non-frail). Demographics were the following in the cohort for the elderly patients: race (white, 81%), mean age 68 years old, sex (male, 50%), BMI (27 kg/m2). Demographics were the following in the cohort for the frail patients: race (white, 79%), mean age 56 years old, sex (male, 51%), BMI (26 kg/m2). Elderly age was defined as > 65 years old and non-elderly age was defined between 18-64 years old. Frailty was defined using the following clinical findings: presence of dialysis, Karnofsky's functional status < 70%, BMI < 18 kg/m2,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

presence of hepatic encephalopathy, albumin < 2.5 g/L. A cumulative total score of 3 or greater defined frailty. Primary outcomes were the following: graft failure, all-cause mortality, 30-day, 90-day mortality, 1-year, 5-year mortality. Length of hospital stay was investigated as our secondary outcome. For both graft failure and all-cause mortality, follow-up time was 8 years. All outcomes were analyzed using cause-specific Cox regression while accounting for competing risks. **Results:** After LDLT, elderly patients overall had significantly higher graft failure and all-cause mortality within 8-years ($p < 0.001$). Elderly patients demonstrated higher mortality at 90 days ($p = 0.02$) in the univariate analysis, higher mortality at both 1-year and 5-year status-post LDLT ($p = < 0.001$). Secondarily, length of hospital stay was longer in the elderly patients ($p = 0.001$). **Figure 1A.** Frail patients exhibited significantly higher rates of the following after LDLT: graft failure ($p = 0.02$), all-cause mortality ($p = 0.02$), 30-day mortality ($p = 0.02$), 90-day mortality ($p = 0.010$), 1-year mortality ($p = 0.003$), 5-year mortality ($p = 0.006$), and length of hospital stay ($p = 0.02$). **Figure 1B. Conclusion:** Both elderly age and frailty served as strong adverse predictors of higher graft failure, all-cause mortality, as well as increased length of hospitalization status post LDLT. Our results help guide future liver transplant recipient selection processes, as well as heightens awareness about the potential higher complications which can occur in this specific population of patients undergoing a LDLT.

4536 | ANALYSIS OF CIRCADIAN DYSFUNCTION IN NON-DIABETIC INDIVIDUALS WITH CIRRHOSIS

Sofia Alikhan[1], [1]University of Chicago

Background: Circadian rhythms are the internal clocks which regulate sleep, eating patterns, physical activity, and metabolism. The liver plays a central role in maintaining metabolic stability, and many of its functions are synchronized with these circadian rhythms. In cirrhosis, this metabolic stability is disrupted, which impacts these rhythms. We aim to determine how these disruptions occur across sleep and eating patterns in non-diabetic individuals with cirrhosis. **Methods:** This study used activity monitoring and continuous glucose monitoring (CGM) to characterize sleep and eating patterns in non-diabetic individuals with cirrhosis undergoing liver transplant evaluation. Fifty-one subjects with cirrhosis without diabetes completed sleep monitoring using a Fitbit Inspire 3 and 34 subjects completed glucose monitoring using blinded Abbott Libre Pro CGMs, which were then compared against surveys completed by each of the patients including the Morningness-Eveningness Questionnaire (MEQ), Pittsburgh Sleep Quality Index (PSQI), and PRAPARE socioeconomic questionnaire. **Results:** Overall, the subjects objectively woke consistently between 3 - 4 AM regardless of preferred wake timing on the MEQ ($p = 0.94$, Fig. A). Subjects went to bed significantly later than their self-reported ideal bedtime by an average of 1.54 hours ($p < 0.0005$, Fig. B). Objective sleep duration averaged approximately 5 - 7 hours nightly and did not significantly differ across PSQI self-reported sleep-duration categories ($p = 0.35$, Fig. C), indicating a disconnect between perceived and objective sleep. Sleep, wake, and sleep duration misalignment were not significantly associated with socioeconomic factors, sleep quality, glucose spikes, MELD 3.0 score, or CTP score ($p > 0.05$ for all confounders). Average CGM eating analyses showed that timing of glucose-spike events and low-glucose events did not significantly predict altered sleep timing, wake timing, or sleep-duration discrepancy ($p > 0.05$ for all). Time of first eating and eating schedules differed significantly between individuals ($p < 0.0001$). However, meal timing remained stable across days of the week for each individual ($p = 0.34$, Fig. D), indicating individuals had distinct patterns of eating and CGM spikes. **Conclusion:** These findings demonstrate circadian disruption in non-diabetic individuals with cirrhosis undergoing transplant evaluation that is not explained by common social, or disease-severity confounders. In the future, we will continue to research the underlying mechanisms of these irregularities, as well as possible interventions to restore circadian

4537 | CONTEMPORARY OUTCOMES FOLLOWING KIDNEY TRANSPLANTATION FROM HCV-POSITIVE DONORS: A NATIONAL UNOS REGISTRY ANALYSIS

Ki Jung Lee[1] Gregory Fan[1], [1]Tufts Medicine

Background: The utilization of hepatitis C virus (HCV)-positive donor kidneys has increased substantially in the direct-acting antiviral era to expand the donor pool and reduce waitlist times. However, concerns remain regarding graft survival and post-transplant outcomes among recipients of HCV-positive donor organs. **Methods:** We performed a retrospective cohort study using the United Network for Organ Sharing (UNOS) registry from 2016-2024 evaluating adult kidney transplant recipients stratified by donor HCV status. Baseline recipient and donor characteristics were compared between groups. Multivariable logistic regression and Cox proportional hazards models were used to evaluate delayed graft function (DGF), graft failure, mortality, and post-transplant complications after adjustment for recipient demographics, comorbidities, dialysis duration, donor characteristics, HLA mismatch, and ischemic time. **Results:** A total of 202,798 kidney transplant recipients were included, of whom 13,244 (6.5%) received kidneys from HCV-positive donors. Recipients of HCV-positive donor kidneys exhibited a greater comorbidity burden and longer cold ischemic times, while HCV-positive donors were more frequently male and had higher rates of cocaine exposure. In unadjusted analyses, transplantation from HCV-positive donors was associated with increased delayed graft function (OR 1.27, 95% CI 1.22-1.32), 5-year graft failure (HR 1.22, 95% CI 1.16-1.27), 1-year mortality (HR 1.49, 95% CI 1.36-1.64), and overall mortality (HR 1.47, 95% CI 1.39-1.55). However, these associations were largely attenuated after multivariable adjustment. HCV-positive donor status was not independently associated with increased 5-year graft failure (aHR 0.99, 95% CI 0.94-1.05), overall mortality (aHR 1.05, 95% CI 0.99-1.11), cardiovascular complications (aHR 1.01, 95% CI 0.88-1.16), or infectious complications (aHR 1.01, 95% CI 0.91-1.13). Adjusted analyses demonstrated lower odds of delayed graft function among recipients of HCV-positive donor kidneys (aOR 0.93, 95% CI 0.89-0.97). Although most associations were attenuated after adjustment, increased risks of malignancy complications (aHR 1.24, 95% CI 1.02-1.52) and multisystem organ failure complications (aHR 1.37, 95% CI 1.03-1.82) persisted. **Conclusion:** Recipients of HCV-positive donor kidneys demonstrated worse unadjusted graft and mortality outcomes, reflecting substantial baseline differences in recipient and donor risk profiles. However, these associations were largely attenuated after multivariable adjustment, with no independent increase in long-term graft failure or overall mortality observed. These findings suggest that HCV-positive donor kidneys can be utilized without compromising long-term graft or patient survival and support continued use of these organs to expand the donor pool.

4538 | TIMING OF LIVER RETRANSPLANTATION FOR EARLY GRAFT FAILURE: A NATIONAL REGISTRY ANALYSIS

Eytan Palte[1] Elizabeth Verna[2] Jason Hawksworth[1] Tomoaki Kato[3] Giuseppe Cullaro[1], [1]Columbia University Irving Medical Center, [2]Columbia University Medical Center, [3]Columbia University

Background: Early graft failure within 30 days of liver transplantation (LT) is a rare but devastating complication requiring urgent decisions about retransplantation (re-LT). The optimal timing of re-LT in this setting is poorly characterized. **Methods:** We conducted a retrospective cohort study using the Scientific Registry of Transplant Recipients (SRTR) including all adult (≥ 18 years) liver transplant recipients who underwent re-LT within 30 days of their index transplant during the MELD era (2002-2025). The primary outcome was post-re-LT survival censored at 5 years. An optimal timing threshold was identified using maximally selected rank statistics with bootstrap validation. Multivariable Cox proportional hazards models assessed associations between re-LT timing and survival, adjusting for recipient, donor, and transplant-level covariates. **Results:** Among 2,161 patients who underwent re-LT within 30 days, median time to re-LT was 8 days (IQR 4-15). Overall 1-year survival after re-LT was 82.5%. 7 days was the optimal timing threshold (bootstrap stability 78%, 95% CI 2-8 days). In the multivariable analysis, patients retransplanted > 7 days after index LT had 47% lower hazard of death compared to those retransplanted within 7 days (adjusted HR 0.53, 95% CI 0.43-0.65). Hepatic artery thrombosis (HAT) as the cause of graft failure was independently associated with improved post-re-LT survival (adjusted HR 0.47, 95% CI 0.31-0.72). These findings persisted in a contemporary cohort (2016-2025) isolated to account for decreases in HCV recurrence (n = 785; adjusted HR 0.54, 95% CI 0.36-0.81). Among those who underwent re-LT within 7 days, each one-point increase in donor risk index (DRI) was associated with a 20% increased hazard of death (HR 1.20, 95% CI 1.00-1.44, p = 0.045). There was no statistically significant interaction between cause of graft failure and time to retransplant. **Conclusion:** Among patients undergoing re-LT for early graft failure, survival beyond 7 days from the index transplant identifies a subgroup with substantially better post-re-LT outcomes, likely reflecting survivor selection rather than a causal benefit of delay. Within 7 days, donor quality (DRI) is a key determinant of survival. These findings cannot guide allocation policy but can inform clinician–patient discussions of risk in early re-LT.

Overall survival of the entire cohort and stratified by time from index transplant to retransplant p<0.0001 between Re-LT ≤7d and Re-LT >7d groups

4539 | IMPACT OF DONOR AND RECIPIENT DIABETES STATUS ON CAUSE-SPECIFIC POST-TRANSPLANT MORTALITY IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS

Kai-Lou Yue[1] Katherine Cooper[2] Ami Patel[1] Deepika Devuni[3], [1]UMass Chan Medical School, Worcester, MA, [2]Massachusetts General Hospital, Boston, MA, [3]UMass Memorial Medical Center, Worcester, MA

Background: Pre-transplant type 2 diabetes mellitus (T2DM) in liver transplant (LT) recipients is associated with increased post-LT mortality, particularly in those transplanted for metabolic dysfunction-associated steatotic liver disease (MASLD). However, the impact of donor diabetes on mortality remains unclear. **Methods:** This study used United Network for Organ Sharing (UNOS) Standard Transplant Analysis and Research (STAR) data from 1/1/05-12/31/25. Adult deceased donor LT recipients transplanted for metabolic dysfunction-associated steatohepatitis (MASH) with known donor and recipient diabetes status were included, excluding those listed for status 1A or multi-organ transplant. Diabetes status was categorized as: no diabetes, recipient-only (RO) diabetes, donor-only (DO) diabetes, and combined donor and recipient (D+R) diabetes. All-cause mortality rates were compared across diabetes groups using chi-squared analyses. Causes of death were grouped per UNOS categorizations. Cox regression models adjusted by sex, MELD score, age, BMI, and donor hypertension were used to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

evaluate cause-specific mortality in combined D+R diabetes vs RO diabetes. Secondary analyses examined the impact of DO diabetes on cause-specific mortality in recipients without pre-transplant diabetes. **Results:** A total of 4319 individuals were included, of whom 1931 died within the study period. All-cause mortality differed across diabetes groups ($p < 0.01$): 40.9% no diabetes (722/1767), 48.3% RO (943/1952), 39.6% DO (108/273), and 48.3% R+D (158/327). Among those with recipient diabetes, use of a donor with diabetes was not associated with increased mortality ($p = 1.00$). Similarly, among those without recipient diabetes, donor diabetes did not increase mortality ($p = 0.68$). The three most common reported causes of death across diabetes groups were infection (n = 276, 14.3%), cardiovascular disease (CVD; n = 263, 13.6%), and malignancy (n = 211, 10.9%). There were no significant differences in cause-specific mortality between R+D and RO; however, there was a trend toward increased CVD-related (HR 1.29, 95% CI 0.81-2.06) and decreased malignancy-related (HR 0.67, 95% CI 0.35-1.30) mortality in the R+D group. Similarly, there were no significant associations between DO and cause-specific mortality compared to no diabetes. **Conclusion:** In this cohort of LT recipients transplanted for MASH, D+R diabetes did not confer significant additional cause-specific mortality risk beyond that of RO diabetes across the three leading identified causes of post-transplant death. DO diabetes also did not increase mortality risk in those without T2DM. These findings suggest that donor diabetes status alone should not preclude utilization of an otherwise suitable organ in this population, which may have implications for organ allocation.

Table 1: Association between diabetes status and cause-specific post-transplant mortality in MASH

Cause of death	Comparison diabetes group	Reference diabetes group	Hazard Ratio (95% confidence interval)
Infection	Donor + recipient	Recipient only	0.99 (0.61-1.61)
	Donor-only	No diabetes	1.08 (0.65-1.78)
Cardiovascular disease	Donor + recipient	Recipient only	1.29 (0.81-2.06)
	Donor-only	No diabetes	1.21 (0.68-2.17)
Malignancy	Donor + recipient	Recipient only	0.67 (0.35-1.30)
	Donor-only	No diabetes	0.56 (0.27-1.17)

4540 | NEW SUBMISSIONWAITLIST OUTCOMES AND LIVER TRANSPLANT ACCESS IN THE MELD 3.0 ERA: A UNOS ANALYSIS

Mangesh Pagadala[1] Jamil Abdo[2] David Maundu[3] Chencheng Xie[4] Sajid Jalil[5] Winston Dunn[6] Yong-Fang Kuo[7] Ashwani Singal[2], [1]Liver Institute Methodist Dallas, [2]University of Louisville, [3]KUMC, [4]University of Iowa, [5]Stanford University, [6]University of Kansas Medical Center, [7]UTMB

Background: MELD 3.0 was implemented on July 13, 2023, to reduce inequity in liver transplant (LT) allocation among women by incorporating sex into the algorithm. We evaluated the impact of MELD 3.0 on access to LT and waitlist (WL) mortality. **Methods:** A retrospective cohort (01/01/21 to 12/31/25) using the UNOS database of adult candidates listed for first deceased-donor LT was stratified into pre- (01/01/21 to 07/12/23) and post- (07/13/23 to 12/31/25) MELD 3.0 eras. We excluded status 1A/1B listings, pediatric candidates, living donor recipients, and multi-organ transplants. The primary outcome was the 90-day cumulative probability of WL mortality comparing males and females in the two MELD eras, with LT as the competing event. Fine and Gray regression models in the two eras were fitted to examine the sex-based impact on 90-day WL mortality after adjusting for other variables. **Results:** 52,208 adult LT listings (19,439 females), with 25,102 in the post–MELD 3.0 era (9578 females), were analyzed. Comparing pre- and post- MELD 3.0 eras, there was an increase in females (38 to 41.2%), alcohol-associated liver disease etiology (50 to 62%), and alcohol-associated hepatitis (16.1 to 34.7%), and a decrease in MASH (25 to 13%) < $P < 0.001$ for all. The crude rate of LT within 90 days increased for women (44.3% to 52.2%) and men (45.3% to 52.8%). WL mortality at 90 days declined, with a greater absolute reduction in women (6.6% to 5.5%) than men (5.4% to 4.9%). The unadjusted sub-hazard ratio (sHR) with 95% CI comparing 90-day WL mortality in women vs. men declined from 1.23 (1.11-1.36) in the pre- MELD 3.0 era to 1.12 (1.00-1.25) in the post- MELD 3.0 era. Similar figures, after adjusting for demographics, comorbidities, MELD score at listing, blood group, insurance, and performance status, were 0.97 (0.86–1.10, $P = 0.661$) and 0.97 (0.84–1.12, $P = 0.655$), respectively. In the post-MELD 3.0 era, a higher MELD score, poorer functional status, and older age predicted WL mortality, whereas ALD etiology was associated with lower WL mortality. **Conclusion:** MELD 3.0 implementation is associated with a greater reduction in waitlist mortality in women. Studies are needed to assess the role of factors beyond those in MELD 3.0, such as liver disease etiology, in determining the optimal use of liver transplantation

4541 | CLINICAL UTILITY OF DONOR-RECIPIENT INTERACTION METRICS IN LIVER TRANSPLANTATION: A UNOS REGISTRY ANALYSIS

Shashank Varma Nadimpalli[1] Zyannah Malick[1] Tanisha Roy[1] Jacob Hallesy[1] Yuzuru Sambommatsu[1] David Bruno[1] Seung Duk Lee[1] Amit Sharma[1] Aamir Khan[1] Muhammad Saeed[1] Vinay Kumaran[1] Adrian Cotterell[1] Daisuke Imai[1], [1]Virginia Commonwealth University

Background: The Model for End-Stage Liver Disease (MELD) is widely used for liver transplant allocation but does not incorporate donor–recipient interaction effects or capture heterogeneity in donor age and recipient age relationships that may influence post-transplant outcomes. We evaluated whether interaction-based metrics, DMELD (donor age × MELD) and DRMELD (donor age × recipient age × MELD), provide incremental prognostic value over MELD alone across clinical eras and recipient subgroups. **Methods:** We performed a retrospective cohort study of adult liver transplant recipients from a national registry, assessing time to graft failure (graft loss or death). Exclusion criteria included age < 18 years, retransplantation, acute liver failure, HIV positivity, combined or split organ transplantation, in-vivo or non-heart-beating donation, metastatic disease, and incomplete records. Separate multivariable Cox proportional hazards models were constructed for MELD, DMELD, and DRMELD, adjusting for recipient age, BMI, creatinine, INR, donor characteristics, and ischemia times. Analyses were stratified by transplant era (2002–2014 vs 2015–present) and HCV serostatus. Model performance was assessed using Akaike Information Criterion (AIC) and Harrell's C-index. **Results:** Overall, all three models demonstrated similar discrimination. DMELD showed the lowest AIC (22,606) and highest C-index (0.561), compared with MELD (22,626; 0.554) and DRMELD (22,608; 0.560), although absolute differences were small. In multivariable analysis, recipient age (HR 1.011, $p < 0.001$), cold ischemia time (HR 1.029, $p < 0.001$), and warm ischemia time (HR 1.007, $p = 0.003$) were consistent independent predictors across models. Serum creatinine was significant only in the MELD model. Both DMELD (HR 1.0003, $p < 0.001$) and DRMELD (HR 1.000005, $p < 0.001$) were statistically significant but had minimal effect size per unit increase. Stratified analyses showed modest variation across subgroups. In the historical era (2002–2014), interaction-based metrics modestly outperformed MELD (DMELD C-index 0.566 vs 0.557), while in the modern era MELD performed similarly or slightly better (0.561 vs 0.554). In HCV-stratified analyses, patterns were comparable. DRMELD showed slightly improved visual separation in higher-risk strata despite near-identical global discrimination metrics. **Conclusion:** Interaction-based donor–recipient metrics are associated with graft survival and demonstrate statistically significant but small improvements in model performance compared with MELD. DMELD showed the most consistent incremental improvement; however, differences in discrimination were minimal across eras and subgroups. Overall, donor–recipient interaction effects appear biologically relevant but provide limited additional prognostic value beyond MELD in contemporary liver transplantation.

4542 | RISK FACTORS FOR DEATH OR WAITLIST REMOVAL FOR DETERIORATION AMONG LIVER TRANSPLANT CANDIDATES AGED 70–74 YEARS: A COMPETING-RISK ANALYSIS

Kush Patel[1] Eyad Abdulrazzak[1] Irena Helenowski[1] Eric Kallwitz[1] Scott Cotler[1], [1]Loyola University Health System

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Liver transplantation is increasingly considered for carefully selected older patients, but waitlist outcomes in candidates aged 70–74 are not well defined. We compared waitlist outcomes in candidates aged 70–74 with those of younger candidates and identified factors associated with death or waitlist removal for deterioration within the 70–74 cohort. **Methods:** The study population consisted of liver transplant candidates younger than 75 years placed on the UNOS liver transplant waiting list from 2/2020 to 12/2024. The primary endpoint was death or removal from the waitlist for deterioration. Fine-Gray competing-risk models were performed, with candidates aged 40–59 serving as the reference group. A full-cohort multivariable model adjusted for race/ethnicity, sex, diagnosis, ABO blood type, BMI < 25, diabetes, MELD, TIPS, bacterial peritonitis, hepatic encephalopathy grade 3–4, and Karnofsky score < 40% at registration. A separate multivariable model was performed within the 70–74 cohort. **Results:** The study population included 59,000 liver transplant candidates, of whom 3,448 were aged 70–74. Compared with younger candidates, those aged 70–74 more frequently had MASH, HCC, and diabetes, and had lower frequencies of hepatic encephalopathy grade 3–4, Karnofsky score < 40%, dialysis, bacterial peritonitis, and high MELD categories (all $p < 0.05$). In univariable Fine-Gray analysis, candidates aged 70–74 had increased risk of death or removal for deterioration compared with candidates aged 40–59 (sHR 2.09, 95% CI 1.86–2.34). In the full-cohort multivariable model, age 70–74 remained associated with increased risk (sHR 2.13, 95% CI 1.87–2.42). In the 70–74 cohort, factors independently associated with death or waitlist removal for deterioration included higher MELD categories, including MELD 30–34 (sHR 1.88, 95% CI 1.13–3.15) and MELD 35–40 (sHR 4.26, 95% CI 2.33–7.79), non-HCC cancer (sHR 1.98, 95% CI 1.06–3.69), BMI < 25 (sHR 1.53, 95% CI 1.19–1.96), and diabetes (sHR 1.44, 95% CI 1.12–1.85) (Figure). Female sex was associated with lower risk (sHR 0.73, 95% CI 0.56–0.95). **Conclusion:** During the acuity-circle allocation era, liver transplant candidates aged 70–74 had increased risk of death or waitlist removal for deterioration compared with younger candidates. Within the 70–74 cohort, adverse waitlist outcomes were associated with higher MELD, non-HCC cancer, BMI < 25, and diabetes, while female sex was associated with lower risk. These findings may help refine risk stratification among older liver transplant candidates.

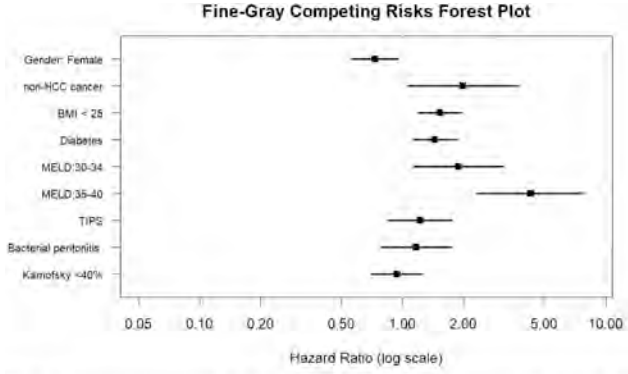

Figure. Factors associated with death or waitlist removal for deterioration in the aged 70-74 cohort.

4543 | INCIDENCE OF CHYLOUS COMPLICATIONS AFTER PEDIATRIC LIVER TRANSPLANTATION: A SINGLE-CENTER RETROSPECTIVE ANALYSIS

Richa Gupta[1] Rachel Smith[1], [1]UPMC Children's Hospital of Pittsburgh

Background: Chyle leaks are a recognized and relatively common complication following liver transplantation (LT); however, data specific to post-operative chylous effusion (CE) in the pediatric population is scarce. We aimed to evaluate the incidence of CE among recent liver recipients at our institution, and to identify potential medical risk factors for development of CE after transplant. **Methods:** This retrospective pilot study examined the frequency of chylous effusion and chylous ascites (CA) in a large, single-center pediatric LT cohort. The study comprised 81 patients undergoing first time isolated liver transplant between January 2023 and April 2026, with a median age at transplant of 2.5 years. Data including diagnosis, graft type, abdominal wall closure, initiation of enteral nutrition or TPN/lipids within 72 hours of transplant, and length of stay were collected and stratified based on the presence of CE and/or CA, with a focus on CE given the scarcity of data on this complication. **Results:** The incidence of CE in our study population (16%) was higher than values of chylous leak that have been reported in other mixed pediatric and adult

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

studies. Almost a third (32%) of our cohort were transplanted for a diagnosis of maple syrup urine disease (MSUD) which is much higher than national averages. Patients with MSUD had a lower incidence of CE compared to other diagnoses, as did patients with biliary atresia, despite an increased risk of chylous leak due to extensive perihepatic dissection during transplant. 61.5% of patients who developed CE did have full abdominal wall closure at the time of transplant, compared to 51.5% of patients who did not develop CE. The average length of stay for patients with CE was 8.8 days longer compared to those without CE. A binomial logistical regression analysis was performed for patients with any chylous complication (effusion or ascites), chylous effusion alone, and chylous ascites alone. For any chylous complication, there was a statistically significant association with graft type, with an odds ratio of 0.064 (CI 0.003-0.675, p = 0.041) for whole organ vs LLS. For chylous effusion alone, there was a statistically significant association with those who had TPN initiation within 72 hours, with an odds ratio of 0.172 (CI 0.027 – 0.941, p = 0.047). There were no statistically significant findings for the group with chylous ascites alone. **Conclusion:** This study highlights that chylous leaks continue to be a challenging post-transplant complication, occuring with relative frequency and associated with suboptimal outcomes including length of stay. Larger, multicenter studies are needed to better define patient- and procedure-specific risk factors for CE, clarify the role of perioperative nutritional management, and evaluate strategies for prevention and early intervention aimed at reducing morbidity and length of stay after pediatric liver transplantation.

Table 1: Patient Characteristics With and Without Postoperative Chylous Leak

	Postoperative CE (n = 13)	No postoperative CE (n = 68)	Postoperative CA (n = 27)	No postoperative CA (n = 54)
Age at LT, years	2.50	2.55	2.29	2.70

4544 | PSYCHOSOCIAL BURDENS IN LIVER TRANSPLANT SURVIVORSHIP: PREVALENCE OF LONELINESS AND SOCIAL ISOLATION

Nicole Lulkin[1] Shilpa Jasti[1] Alexis Kim[2] Amon Asgharpour[2] Anh Bui[2] Zachary Henry[3] Nicolas Intagliata[4] Juan Guerra[3] Stephanie Silpe[3] Vaishali Patel[2] Idris Yakubu[2] Mohammad Siddiqui[3], [1]Virginia Commonwealth University School of Medicine, [2]Virginia Commonwealth University, [3]UVA Health, [4]University of Virginia

Background: Social isolation and lack of social support have been linked to poorer clinical outcomes across various organ transplant populations. Loneliness, in particular, has been associated with delayed recovery and increased complications in both chronic disease and post-transplant settings. Despite its growing recognition as a factor of health, the prevalence and clinical relevance of loneliness in liver transplant (LT) recipients remain understudied. This study investigates the frequency of loneliness among LT recipients and examines its relationship to health-related quality of life (HRQoL), symptom burden, and self-perceived health. **Methods:** We completed a cross-sectional study of adult LT recipients at a large academic medical center. Patients completed the De Jong Gierveld Loneliness Scale, Lubben Social Network Scale, and Patient-Reported Outcomes Measurement Information System (PROMIS) scale to assess physical, emotional, and social elements of HRQoL. Clinical and demographic data were used from the electronic health record. Associations between loneliness and quality of life domains were analyzed using multivariable linear and logistic regression analyses adjusted for age, sex, time since transplant, and comorbidities. **Results:** Seventeen participants (16.5%) were at risk for loneliness, and 19 (18.4%) were at risk for social isolation. Only four participants met the criteria for both conditions, suggesting limited overlap between loneliness and social isolation. Loneliness prevalence was highest among patients transplanted for metabolic dysfunction-associated steatotic liver disease. Patients at risk for social isolation were more likely to be unemployed or disabled (63.2% vs 35.7%, p = 0.039). No other significant demographic or clinical differences were identified, and no independent predictors remained significant on multivariable analysis. **Conclusion:** Approximately one in six LT recipients were at risk for loneliness or social isolation despite many reporting established social support systems. Loneliness and social isolation demonstrated limited overlap, suggesting they represent distinct psychosocial constructs. These findings highlight the need for targeted psychosocial screening and interventions in LT survivorship care.

4545 | RADIATION EXPOSURE FROM CT AND FLUOROSCOPICALLY-GUIDED PROCEDURES IN LIVER TRANSPLANT PATIENTS

Pavel Trunecka[1] Denisa Kyselova[1] Irena Mikova[2] Tomas Hucl[1] Lucie Sukupova[3], [1]Institute for Clinical and Experimental Medicine, [2]Institute for Clinical and Experimetal Medicine, [3]Institute for Clinical and Experimebtal Medicine

Background: Liver transplant (LT) candidates typically undergo long-term medical management requiring imaging that utilizes ionizing radiation. Numerous examinations are required both prior to waitlisting and post-TX follow-up. With the prolonged survival of LT recipients, concerns have arisen regarding the stochastic effects of radiation from repeated imaging, specifically computed tomography (CT) scans and fluoroscopically guided interventions. We aimed to evaluate the cumulative radiation dose accrued from medical imaging in a cohort of 1,000 consecutive LT pts treated at our institution between December 2017 and June 2025. **Methods:** Data on radiation doses were collected for each patient for every high-exposure procedure (CT scans and fluoroscopy) using the institutional dose monitoring system and converted to cumulative effective dose (CED) using standard protocols. The study cohort comprised 383 females and 617 males, with a median age at LT of 59 years (IQR: 47–67). We analyzed the CED incurred by the type of examination and evaluated the impact of the LT indication on the CED. Pts with a CED exceeding 100 mSv were identified, and relative rates for each diagnostic entity were calculated. Differences between groups were assessed using non-parametric methods (the Kruskal-Wallis test). **Results:** Abdominal CT was the most frequently performed examination (2,754 exams), followed by fluoroscopically guided abdominal procedures (1,974 procedures); together, these contributed substantially to cumulative radiation exposure. The mean number of examinations and radiation dose per exam were as follows: brain CT: 0.6 exams (1.1 mSv); chest CT: 0.9 exams (8.5 mSv); abdominal CT: 2.8 exams (20.3 mSv); cardiac CT: 0.1 exams (20.3 mSv); fluoroscopically guided abdominal procedures: 2.0 procedures (8.4 mSv); and fluoroscopically guided cardiac procedures: 0.4 procedures (6.6 mSv). Overall, 278 pts received a CED > 100 mSv. Among these, 184 patients received 100–200 mSv, 65 received 200–300 mSv, 20 received 300–400 mSv, 8 received 400–500 mSv, and 1 patient received > 500 mSv. The maximum CED was 601 mSv. On average, pts accumulated a mean total effective dose of 85 mSv, with a median cumulative dose of 58 mSv. The highest CED was received by pts transplanted for cholangiocarcinoma and hepatocellular carcinoma, whereas the lowest exposures were noted in pts with acute conditions and liver cirrhosis without carcinoma (Table 1). **Conclusion:** A substantial proportion of patients received cumulative effective doses well above 100 mSv—a level generally considered to increase long-term radiation risks—with major differences observed between diagnostic groups. Especially in patients with a long post-transplantation life expectancy, strict clinical justification and a preference for alternative imaging modalities with limited or no ionizing radiation must be prioritized.

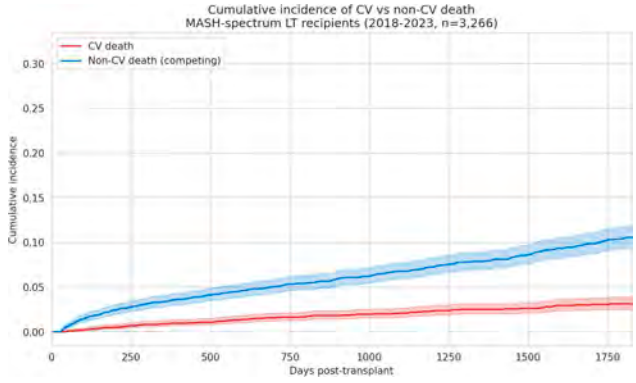
Table 1. Cumulative effective doses accrued during the management of liver transplant patients and differences between major diagnostic groups.

Diagnostic group	N	CED Median (IQR) (mSv)	Proportion of subjects with CED >100 mSv (%)
Alcoholic liver disease	189	49 (32–76)	16.9
ACLF	21	39 (13–66)	4.8
Acute liver failure	40	28 (12–53)	5.0
Autoimmune cirrhosis	23	39 (23–87)	13.0
Cholangiocarcinoma	12	123 (65–178)	58.0
Hepatocellular carcinoma	233	103 (64–179)	57.9
Viral hepatitis B	15	53 (33–75)	6.7
Viral hepatitis C	21	61 (29–92)	9.5
MASLD	71	50 (37–117)	29.6
Cryptogenic cirrhosis	42	49 (23–74)	11.9
Polycystic disease	48	47 (25–82)	22.9
Primary sclerosing cholangitis	78	37 (19–55)	9.0
Primary biliary cholangitis	37	36 (33–164)	5.4
Retransplanted recipients	82	78 (47–147)	31.0



Footnote & Legend:
CED, cumulative effective dose; ACLF, acute-on-chronic liver failure; MASLD, metabolic dysfunction-associated steatotic liver disease; IQR, interquartile range. Differences between groups were assessed using the Kruskal-Wallis test and were significant ($p < 0.0001$).

4546 | COMPETING-RISKS PREDICTION OF CARDIOVASCULAR DEATH AFTER LIVER TRANSPLANTATION FOR MASH-SPECTRUM DISEASE

Sri Harsha Boppana[1] Subhash Gurappa[2] Sachin Sravan Kumar Komati[2] Gautam Maddineni[3] Raja Chandra Chakinala[4] Meghana Kakarla[5] Venkata Sunkesula[6] Christina Awad[7] Pradeep Yarra[7], [1]Nassau University Medical Center, [2]Florida International University, [3]Creighton university, [4]Guthrie Robert Packer Hospital, [5]infirmary health, [6]Case Western Reserve University, [7]UT Health San Antonio

Background: Cardiovascular (CV) death is often presumed to be a dominant post-transplant threat in metabolic dysfunction-associated steatohepatitis (MASH), yet conventional binary models may obscure competing non-CV mortality. We aimed to define the incidence and predictors of CV death after liver transplantation (LT) for MASH-spectrum disease using a competing-risks predictive framework. **Methods:** We performed a retrospective cohort study of adult, primary, single-organ LT recipients in the OPTN/UNOS STAR file with MASH-spectrum diagnoses (MASH, cryptogenic cirrhosis, or unspecified MASH-spectrum codes), transplanted from 2018-2023 and alive at 30 days. CV death was defined by cause-of-death codes 4800-4899; non-CV death was modeled as the competing event. Cumulative incidence functions were estimated by Aalen-Johansen methods and compared across body mass index (BMI) classes. Cause-specific Cox models evaluated recipient, donor, metabolic, liver disease, and functional predictors. A 1-year landmark model tested post-LT mean creatinine and new-onset diabetes as longitudinal predictors of subsequent CV death. **Results:** Among 3,266 recipients, median age was 58 years and 1,528 (46.8%) were male. Diagnoses included MASH (n = 1,551), cryptogenic cirrhosis (n = 1,120), and unspecified MASH-spectrum disease (n = 595). During follow-up, 424 deaths occurred: 95 CV and 329 non-CV. CV death cumulative incidence was 0.9% at 1 year, 2.1% at 3 years, and 3.1% at 5 years, versus 3.4%, 6.8%, and 10.6% for non-CV death. BMI class did not discriminate CV death risk (3-year incidence: non-obese 2.0%, class I 2.5%, class II 2.7%, class III 0.9%; Gray/cause-specific $p = 0.41$). In CV death models, age was the only significant predictor (HR 1.013/year, 95% CI 1.002-1.024; $p = 0.025$), whereas diabetes (HR 0.93, 95% CI 0.70-1.24; $p = 0.62$), BMI (HR 1.00, 95% CI 0.98-1.02; $p = 0.91$), and MELD ($p = 0.72$) were not predictive; concordance was 0.637. In contrast, diabetes predicted non-CV death (HR 1.44, 95% CI 1.18-1.76; $p < 0.001$). Among 3,051 1-year survivors, post-LT mean creatinine (HR 1.02, 95% CI 0.86-1.21; $p = 0.82$) and new-onset diabetes (HR 0.93, 95% CI 0.62-1.39; $p = 0.72$) did not improve CV death prediction. **Conclusion:** In contemporary MASH-spectrum liver transplant recipients, CV death was uncommon and substantially outnumbered by competing non-CV mortality. BMI, diabetes, MELD score, renal trajectory, and new-onset post-transplant diabetes did not independently predict cardiovascular death, though the study was likely underpowered to detect clinically meaningful predictors. Competing-risks modeling materially reframes post-transplant risk stratification: metabolic risk factors - diabetes in particular - mapped more strongly to non-CV than CV mortality, underscoring the importance of accounting for competing causes when interpreting outcomes in this population.

4547 | PREVALENCE AND EVALUATION OF CORONARY ARTERY DISEASE IN LIVER TRANSPLANT CANDIDATES

Tasmia Promi[1] Shirley Eng[1] Anwesha Satapathy[1] James Park[1] Nabil Dagher[1] Tapan Buch[1] David Stern[1] Amgad Makaryus[1] Sanjaya Satapathy[2], [1]Northwell Health, [2]Northshore University Hospital/ Northwell Health

Background: Coronary artery disease (CAD) is a major determinant of perioperative morbidity and mortality in liver transplant candidates and remains a critical component of pre-transplant cardiovascular risk assessment. The increasing prevalence of diabetes, obesity, and metabolic dysfunction-associated steatotic liver disease has heightened concern for underlying coronary atherosclerosis in this population. However, reported CAD prevalence varies widely across studies, reflecting differences in patient characteristics, disease definitions, and diagnostic modalities used for detection. **Methods:** We conducted a systematic review and meta-analysis of studies reporting CAD prevalence in adult liver transplant candidates. Databases were searched through 2025. Random-effects models were used to pool prevalence of any CAD and obstructive CAD, with subgroup analyses by diagnostic modality. **Results:** Twenty-one studies (n = 37–17,482 participants) published between 1995 and 2024 were included. Reported prevalence of any CAD varied widely (approximately 9% to >80%), with consistently higher estimates in CT-based imaging cohorts. Obstructive CAD prevalence was lower, generally ranging from 2% to 18%. Pooled analyses demonstrated substantial heterogeneity (I^2 >75%). CT-based strategies identified significantly higher prevalence of any CAD, driven primarily by nonobstructive atherosclerosis, whereas estimates of obstructive CAD were more consistent across modalities. Sensitivity analyses confirmed that modality-driven differences accounted for most heterogeneity. **Conclusion:** CAD is highly prevalent among liver transplant candidates, but estimates are strongly influenced by diagnostic modality. CT-based imaging reveals a substantial burden of nonobstructive coronary atherosclerosis that is not captured by invasive angiography alone. These findings demonstrate the need to distinguish total atherosclerotic burden from obstructive disease in pre-transplant cardiovascular risk assessment.

4548 | LIVER TRANSPLANT INTRAOPERATIVE TRANSFUSION VOLUME AND HEPATOCELLULAR CARCINOMA RECURRENCE

William Vroom[1] Devi Veeramgari[1] Yonatan Kaplan[1] Keri Zhou[1] Sami Ali[1] Daisuke Imai[1] Yuzuru Sambommatsu[1] Vinay Kumaran[1] Muhammad Saeed[1] Aamir Khan[1] Amit Sharma[1] Adrian Cotterell[1] Hannah Lee[1] David Bruno[1] Seung Duk Lee[1], [1]VCU School of Medicine

Background: Intraoperative PRBC transfusion has been associated with increased and earlier recurrence in a variety of cancers, including in hepatocellular carcinoma (HCC) following liver resection. However, there is limited evidence regarding transfusion in liver transplants. This study will analyze whether intraoperative PRBC transfusion affects HCC recurrence following transplant and if it does so in a dose dependent manner. **Methods:** A total of 75 patients with HCC who underwent liver transplantation were analyzed. Intraoperative PRBC transfusion was standardized to units (1 unit = 300 mL) and modeled continuously and categorically (0, 1–2, ≥3 units). Cox proportional hazards regression evaluated associations with time to recurrence; binary logistic regression assessed early recurrence (<24 months). Preoperative neutrophil-to-

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

lymphocyte ratio (NLR) was evaluated as an independent predictor in both models. **Results:** Seventy five recurrence events were available for analysis. When modeled continuously, intraoperative PRBC units did not significantly predict time to recurrence ((HR 1.047, 95% CI 0.991–1.106, p = 0.103)) or early recurrence (OR 1.058, 95% CI 0.967–1.159, p = 0.218). However, categorical analysis showed that transfusion of 3+ units was associated with significantly increased risk of recurrence compared to no transfusion (HR 2.339, 95% CI 1.008–5.429, p = 0.048) and of early recurrence (OR 3.141, 95% CI 1.049–9.401, p = 0.041). The 1-2 unit category was not significant in either model. Preoperative NLR was independently associated with both time to recurrence (HR 1.129, p = 0.009) and early recurrence. (OR 1.185, p = 0.010). The Cox model demonstrated significant overall fit (LLR p = 0.0036), and the logistic model showed no evidence of poor calibration (Hosmer-Lemeshow p = 0.451). **Conclusion:** Intraoperative PRBC transfusion of 3+ units was associated with earlier and increased risk of HCC recurrence following liver transplant, though it did not predict faster time to recurrence or early recurrence in a dose-dependent manner. These findings likely reflect a variety of factors related to PRBC transfusion which worsen liver transplant outcomes, such as immunosuppressive effects and greater operative difficulty, and indicate the value of minimizing intraoperative blood loss and transfusion volume. However, missing registry data limited analysis on certain covariates, namely cell-saver use, underscoring the need for larger studies to fully understand the effects of intraoperative PRBC transfusion.

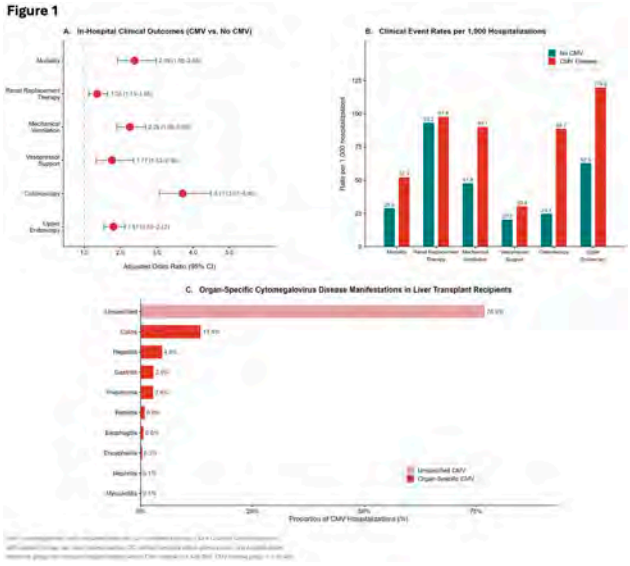
4549 | IMPACT OF CYTOMEGALOVIRUS DISEASE ON INPATIENT OUTCOMES AND RESOURCE UTILIZATION AFTER LIVER TRANSPLANTATION

Serena Brosten[1] Spencer Goble[2] Timothy Davie[1] Jesse Fletcher[1] Kartik Dapke[3] Anna Strauss[1] Giovanni Roldan[2] Supavit Chesdachai[4] Prowpanga Udompap[5],



[1]Department of Medicine, University of Minnesota, [2]Division of Gastroenterology, Hepatology and Nutrition, [3]Department of Medicine, Saint Vincent Hospital, Worcester, MA, [4]Division of Public Health, Infectious Diseases, and Occupational Medicine, Mayo Clinic, Rochester,MN, [5]Division of Gastroenterology, Minneapolis VA Medical Center

Background: Cytomegalovirus (CMV) is the most common opportunistic viral infection after liver transplantation, with the highest disease risk occurring in donor-seropositive and recipient-seronegative pairs. CMV disease negatively impacts liver transplant outcomes through direct organ involvement and indirect immune dysregulation. Nationally representative data on inpatient outcomes and resource utilization attributed to CMV disease in liver transplantation remains limited. **Methods:** A retrospective analysis was conducted on data from the National Inpatient Sample (NIS). Hospitalizations for liver transplant recipients with concurrent CMV diseasea between 2016 and 2023 were identified using ICD-10 codes. The clinical and economic outcomes were evaluated and compared between recipients admitted with and without CMV disease. Primary outcomes of interest included mortality, length of stay, and total hospitalization costs. Secondary outcomes assessed included mechanical ventilation, renal replacement therapy, vasopressor support, and endoscopic evaluation. Weighted multivariable analyses were performed to identify independent predictors of the specified outcomes. **Results:** Among 437,190 liver transplant hospitalizations, 10,430 presented with CMV disease. Compared to liver transplant receipients without CMV disease, recipients with CMV were slightly younger (median: 58 vs. 62 years; p < 0.01) and had a lower comorbidity burden (median Charlson Comorbidity Index: 3 vs. 4; p < 0.01). While sex was not associated with CMV disease (p = 0.46), significant differences were observed across race/ethnicity, hospital region, and primary payer strata (all p < 0.01). Regarding organ manifestation, most CMV cases (76.9%) had no organ-specific codes, followed by CMV colitis at 13.4%, with the remaining manifestations detailed in Figure 1C. The presence of CMV disease significantly increased the adjusted risk for severe clinical outcomes, including in-hospital mortality (52.3 vs. 28.9 per 1,000 hospitalizations; adjusted odd ratio (aOR) 2.39, p < 0.01), requirement for mechanical ventilation (90.1 vs. 47.8 per 1,000 hospitalizations; aOR 2.26, p < 0.01), and need for vasopressor support (30.4 vs. 20.3 per 1,000 hospitalizations; aOR 1.77, p < 0.01) (Figures 1A and 1B). Furthermore, CMV hospitalizations incurred a significantly longer median length of stay (7 vs. 4 days; aRR 2.21, p < 0.01) and higher median healthcare costs ($19,846 vs. $11,820; aRR 2.40, P < 0.01). **Conclusion:** In this retrospective study, CMV disease following

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

liver transplantation was associated with significantly worse inpatient outcomes and greater healthcare resource utilization despite having a slightly younger demographic with fewer comorbidities. These findings reinforce the importance of early detection and intervention of CMV disease.

4550 | PATIENT SELECTION, SURVIVAL, AND REJECTION OUTCOMES IN DUAL LIVER–LUNG TRANSPLANT RECIPIENTS

Piotr Babinski[1] Janae Gonzales[1] Amanda Kamar[1] Mrinalini Venkata Subramani[1] Krishnan Warrior[1] Alan Betensley[1] Anthony Joudi[1] Bradford Bemiss[1] Catherine Myers[1] Andres Duarte-Rojo[1] Ambalavanan Arunachalam[1], [1]Northwestern University

Background: Liver transplantation is a life-saving procedure that can often be performed simultaneously with another organ, most commonly seen with the kidney because of the high prevalence of renal insufficiency in patients with end-stage liver disease. As a result, there is more robust data regarding general outcomes, organ dysfunction, and rejection with kidney's compared to simultaneous liver-lung transplantations. We report our experience with 14 simultaneous lung-liver organ transplants at our institution and general associated outcomes. **Methods:** All patients consented to our IRB approved general lung transplant biorepository. Data was collected as a retrospective analysis using data from the biorepository and chart review. **Results:** From 8/1/2022 - 5/1/2026, our institution performed 14 simultaneous lung-liver transplants on adult patients, with the indications for lung and liver transplantation listed below (Table 1). Most of the transplants performed were bilateral lung transplants (11/14) and were completed on cardiopulmonary bypass or ECMO (10/14). Patients on average had a MELD-NA score of 11 and a CAS score of 29.795. Two patients were considered highly sensitized (PRAs of 88/0 and 85/46) with a positive T/B cell crossmatch and received our institution's lung transplant desensitization protocol. All patients had uneventful immediate post-operative hospital courses and had an average 18-day post-operative length of stay. None of our 14 patients required treatment for AMR following dual organ transplant and or had persistent DSA on outpatient follow-up. Two of our highly sensitized patients had positive DSAs post-transplant that were no longer detected on follow-up without targeted treatments. There was one case of pulmonary grade A1 acute cellular rejection that was treated within the first year. Literature suggests that following lung transplantation patients typically have an 88% 1-year survival: Our cohort showed a 90.91% 1-year survival (10/11, 3 patients have not reached one year). One patient passed away less than a year from transplant during a hospitalization for hepatic ACR, hemorrhagic shock, and possible hemophagocytic lymphohistiocytosis. **Conclusion:** Our simultaneous lung-liver transplant data showed 1-year survival rates comparable to overall national lung transplant data with minimal signs of rejection following transplant, despite being an overall sicker cohort of patients. This suggests that simultaneous liver-lung transplant is feasible in this carefully selected patient population.

4551 | LONGITUDINAL WAITLIST TRAJECTORY IMPROVES LIVER TRANSPLANTATION DISCRIMINATION OVER STATIC MELD: A NATIONAL REGISTRY PROOF-OF-CONCEPT

Sri Harsha Boppana[1] Pradeep Yarra[2] Eugenia Tsai[3], [1]Nassau University Medical Center, NY, USA., [2]UT Health San Antonio, TX, USA., [3]UT Health San Antonio, TX, USA. / Texas Liver Institute, TX, USA.

Background: The Model for End Stage Liver Disease score predicts 90-day waitlist mortality but performs poorly for transplant access, an outcome shaped not only by biological severity, but by blood type, geographic organ availability, and transplant center behavior. Among patients with equivalent MELD scores, those whose laboratory values are actively worsening face meaningfully different prognoses than those who are stable, yet current allocation treats them identically. The DELTA Score was developed to address this limitation by integrating serial laboratory trajectories and exception data to predict 12-month transplant probability across the US national waitlist. **Methods:** In this retrospective cohort study using UNOS/OPTN STAR data of all (n = 223,941) newly listed adult liver transplant patients between 2002–2024, trajectory features (laboratory slopes, variability, recency) and exception variables (exception MELD, HCC burden, locoregional therapy, AFP) were derived exclusively from pre-landmark data at six timepoints (1, 2, 3, 6, 9, 12 months post-listing). Of 206,422 patients reaching at least one landmark timepoint, a gradient boosting ensemble (XGBoost, LightGBM, CatBoost) was trained on pre-2020 listings (n = 166,424) and temporally validated on 2020–2024 listings (n = 39,998). Comparators were era-appropriate MELD and a trajectory-naïve snapshot model using identical features without trajectory or exception data. **Results:** DELTA achieved AUROC 0.771 (95% CI 0.762–0.780) in temporal validation versus 0.704 (95% CI 0.694–0.714) for the snapshot model and 0.524 (95% CI 0.513–0.535) for era-appropriate MELD. The 0.067 AUROC gain represents the isolated contribution of trajectory and exception data. Discrimination increased with follow-up: 0.712 (95% CI 0.706–0.718) at 1 month to 0.833 (95% CI 0.826–0.840) at 12 months. High-risk patients had three-fold higher 1-year transplant cumulative incidence (56.2% vs. 18.8%, , $p < 0.001$), with equivalent waitlist death and deterioration across strata, confirming DELTA captures transplant access rather than biological urgency. Performance was consistent across cirrhosis etiologies (AUROC > 0.75 in all groups) and lower in HCC (0.716–0.654), which was expected given tumor-driven allocation policy. **Conclusion:** Integrating serial laboratory trajectories and exception data improves discrimination of liver transplantation over static MELD across the national waitlist, with consistent performance across all cirrhosis etiologies. These findings establish proof of concept for trajectory-aware modeling as a complement to static MELD for waitlist risk stratification in the US. Whether trajectory-based prediction identifies patients who would benefit from earlier intervention, beyond what serial MELD monitoring already informs requires further prospective validation.

4552 | INCREASED RISK OF ACUTE CORONARY SYNDROME AFTER LIVER TRANSPLANT IN MASLD VS ALCOHOL-ASSOCIATED CIRRHOSIS: A PROPENSITY-MATCHED ANALYSIS

Nadera Altork[1] Omar Abureesh[2] Ismail Elkhattib[3] Nathalie Khoury[1] Marco Olivera-Martinez[1], [1]University of Nebraska Medical Center, Omaha, NE, [2]Staten Island University Hospital, Staten Island, NY, [3]University of Nebarska Medical Center, Omaha, NE

Background: Liver transplantation (LT) is an established treatment for end-stage liver disease, with metabolic dysfunction-associated steatotic liver disease (MASLD) and alcohol-associated liver disease (ALD) serving as leading indications. Post-transplant cardiovascular complications represent a significant cause of morbidity. This study utilizes a large-scale federated health research network to compare the three-year risk of acute coronary syndrome (ACS) and all-cause mortality between LT recipients with ALD and those with MASLD. **Methods:** A retrospective cohort study was conducted using the TriNetX platform, which provided access to electronic medical records across 107 healthcare organizations. Two

cohorts were identified: patients with ALD who underwent a liver transplant (n = 7,966) and patients with MASLD cirrhosis who underwent a liver transplant (n = 3,776). Propensity score matching (PSM) was performed to balance 23 baseline characteristics, including demographics, cardiometabolic risk factors and comorbidities (e.g., hypertension, chronic kidney disease), medications, and laboratory values. Outcomes were evaluated within 3 years after transplant. **Results:** Following PSM, 2,817 patients were included in each cohort. The analysis revealed a significantly higher risk of ACS in the MASLD cohort compared to the ALD cohort (4.9% vs. 3.5%; risk ratio 1.39, 95% CI 1.07–1.80, p = 0.013). There was no statistically significant difference in 3-year all-cause mortality between the two groups (MASLD 13.5%, vs. ALD 13.6%; Risk Ratio 0.988, 95% CI 0.865–1.127, p = 0.855). **Conclusion:** Liver transplant recipients with MASLD face a significantly higher risk of developing acute coronary syndrome within the first three years post-transplant compared to those transplanted for ALD, even after matching for traditional cardiovascular risk factors. Despite this increased cardiovascular risk, three-year all-cause mortality remained comparable between the two etiologies. These findings support early, structured cardiovascular risk assessment and aggressive risk factor modification in MASLD transplant candidates and recipients, even when traditional risk factors appear balanced.

Outcome	MASLD + Transplant	ALD + Transplant	Risk Ratio (95% CI)*	P-value
Acute Coronary Syndrome	4.9%	3.5%	1.389 (1.070, 1.802)	0.013
All-Cause Mortality	13.5%	13.6%	0.988 (0.865, 1.127)	0.855

4553 | ISCHEMIC CHOLANGIOPATHY AFTER DCD LIVER TRANSPLANTATION IN THE NMP ERA: A SINGLE-CENTER CASE SERIES

Saleh Al-Juburi[1] Almokdad Mohammad[1] Jack Avedikian[1] Adhnan Mohamed[1] Ahmed Nassar[1] Atsushi Yoshida[1] Marwan Abouljoud[1] Shunji Nagai[1], [1]Henry Ford Hospital

Background: Ischemic cholangiopathy (IC) is a serious complication after liver transplantation (LT) and may lead to graft loss or retransplantation. Although normothermic machine perfusion (NMP) may reduce ischemia-reperfusion injury, IC still occurs. Therefore, this study aimed to describe the clinical characteristics and outcomes of IC cases after DCD liver transplantation at our center. **Methods:** A single-center retrospective analysis was conducted of all recipients who underwent LT from DCD donors between January 2018 and December 2025. LT from DBD donors, living donor liver transplantation, simultaneous multi-organ liver transplantation, and retransplantation were excluded. Among 268 DCD LTs, NMP was used in 191 cases. **Results:** IC developed in 11 of 268 DCD LT recipients (4.1%): 5 cases occurred in the NMP group and 6 occurred in the non-NMP group (2.6% vs. 7.8%, p = 0.08). Among recipients who developed IC, donor BMI was significantly higher in the NMP group than in the non-NMP group (35.8 vs. 23.8 kg/m², p = 0.02). In the NMP group, patients who developed IC had a higher donor BMI than those without IC (35.8 vs. 27.6, p = 0.04) and a longer agonal phase time (31 vs. 18 min, p = 0.03). Ten cases were diagnosed by ERCP at a median of 90 days after LT [51–177], and one case was diagnosed by MRCP. IC was classified as confluence-dominant in 5 cases, multifocal progressive in 4 cases, and minor in 2 cases. Most patients were managed with ERCP stenting, while one patient was successfully treated with percutaneous transhepatic cholangiography catheter placement. Two patients underwent retransplantation due to IC: one with the multifocal progressive type at 160 days after LT and the other with the confluence-dominant type at 181 days after LT. Both patients were in the NMP group. The median follow-up duration was 1.7 years [0.8–5.7]. At the last follow-up, 7 patients were alive, including the 2 patients who underwent retransplantation, whereas 4 patients had died. Among the 4 patients who died, the median patient survival was 3.8 years (range, 1.7–5.9 years), and the causes of death were cerebral hemorrhage, infection, respiratory failure, and unknown; none of the deaths were attributed to IC. **Conclusion:** IC tended to be less frequent in the NMP group than in the non-NMP group, although the difference was not statistically significant. IC remained clinically relevant, with two patients requiring retransplantation; however, both were alive at the last follow-up, and no deaths were directly attributed to IC.

4554 | FULLY COVERED METAL STENTS REDUCE ERCP BURDEN AND ACCELERATE RESOLUTION OF ANASTOMOTIC BILIARY STRICTURES AFTER MACHINE PERFUSION-PRESERVED DCD LIVER TRANSPLANTATION

Caroline Olson[1] Andrew Keaveny[1] Nicole Loo[1] Frank Lukens[1] Liu Yang[1] Kristopher Croome[1] Omar Mousa[1], [1]Mayo Clinic Florida

Background: Anastomotic biliary strictures (ABS) are a major cause of morbidity after donation-after-circulatory-death (DCD) liver transplantation (LT). Machine perfusion (MP), including ex-situ normothermic oxygenated perfusion via normothermic machine perfusion (NMP) and in-situ normothermic regional perfusion (NRP), mitigates biliary ischemic injury and has expanded safe use of DCD grafts, but its impact on ABS incidence, endoscopic burden, and stent-specific outcomes in DCD-LT is less well defined. We characterized ABS rates, ERCP burden, stent type, and time to resolution across perfusion modalities. **Methods:** Retrospective cohort of 414 adult DCD-LT recipients at a single center (2/2017–10/2025), stratified by modality: no MP/static cold storage (SCS, n = 157), NMP alone (n = 154), NRP alone (n = 74), and NRP+NMP (n = 29). ABS was defined as ERCP confirmed anastomotic stricture. ERCP count, initial stent (plastic vs fully covered self-expandable metal stent [FCSEMS]), stent strategy, time to resolution, and complications were assessed. Logistic regression adjusted for transplant year, recipient age/sex/BMI, MELD, donor age, and cold ischemia plus perfusion time. Time-to-resolution was modeled with Kaplan-Meier and Cox regression; ERCP count with Poisson regression. **Results:** The rates of ABS and biliary leaks were 22.9% and 7.0% in this cohort, respectively. ABS incidence differed by modality: NMP alone 33.1% (95% CI 26.2–40.9), NRP alone 18.9%, NRP+NMP 13.8%, SCS 16.6% (p = 0.002). Among 95 ABS cases, the initial stent was plastic in 78.9%, FCSEMS in 12.6%, and no stent placed in 8.5%. Cases using plastic stents had a complication rate of 10.9% (pancreatitis, cholangitis, stent migration, bleeding) compared with 28.6% in FCSEMS. The observed resolution rate was similar (plastic 84.0% vs FCSEMS 83.3%; p = 1.000), but FCSEMS required fewer ERCPs (median 2 vs 3, p = 0.014) and achieved faster resolution (KM median 3.0 vs 6.2 months; log-rank p = 0.018) (Figure). In adjusted models, FCSEMS independently predicted faster resolution (HR 2.10, 95% CI 1.06–4.18, p = 0.034) and 27% fewer ERCPs (IRR 0.73, 95% CI 0.56–0.93, p = 0.013). These results were similar across the perfusion modalities; within the NMP subgroup, KM median time to resolution was 2.7 months for FCSEMS vs 5.8 months for plastic. **Conclusion:** In this large DCD-LT cohort spanning the contemporary machine perfusion era, ABS incidence varied across preservation modalities. Among recipients who developed ABS, FCSEMS when used initially achieved equivalent resolution with significantly fewer ERCPs and faster time to resolution than plastic stents. This benefit was observed consistently across perfusion strategies, including NMP-preserved grafts. These data support FCSEMS as the preferred first-line endoscopic strategy to promote stricture resolution, reduce procedural burden and accelerate recovery in DCD-LT recipients with ABS, regardless of preservation modality.

Figure: Kaplan-Meier cumulative stricture resolution by initial stent type.

Initial stent comparison: Plastic vs Metal/FCSEMS had similar observed resolution proportions (84.0% vs 83.3%; Fisher p=1.000), but Metal/FCSEMS required fewer ERCPs (median 2.0 vs 3.0; Wilcoxon p=0.014) and had faster time to resolution/censor (p=0.013).

4555 | SIX-MINUTE WALK TEST AND THE LIVER FRAILTY INDEX ARE COMPARABLE IN PREDICTION OF PRE- AND POST-TRANSPLANT OUTCOMES IN LIVER TRANSPLANT CANDIDATES

Amani Elshaer[1] Elizabeth Carey[1] Fares Jamal[1], [1]Mayo Clinic Arizona

Background: Assessing functional status in liver transplant candidates is an integral part of any liver transplant evaluation given its prognostic value. Although multiple assessment tools exist, comparative studies are lacking, leaving uncertainty about the optimal method to use in clinical practice. The AASLD guidance does not specify a preferred frailty tool, allowing centers to choose based on practice. Our institution utilizes both the Six Minute Walk Distance (6MWD) and Liver Frailty Index (LFI) to evaluate candidates, enabling a direct comparison of their prognostic value in predicting pre- and post-transplant

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

outcomes among liver transplant candidates. **Methods:** This was a single center retrospective cohort study including 287 adults who underwent liver transplant evaluation. LFI and 6MWD were obtained in each patient as part of the evaluation. Pre-transplant outcomes including transplant denial, transplant approval/waitlist and clinical deterioration or death while waitlisted. Post transplant outcomes were also explored including re-admission rates within 6 months of transplant, intensive care unit duration and hospital length of stay. Logistic regression models with categorical and continuous frailty measures were developed for each outcome with and without adjustment for MELD 3.0. Discrimination was assessed using the area under the receiver operating characteristic curve. **Results:** For transplant denial, LFI-defined frailty was associated with higher odds compared to 6MWD (adjusted OR 10.89 vs. 4.53). For transplant approval, frailty by LFI was strongly associated with lower likelihood of approval (adjusted OR 0.19, $p < 0.001$). 6MWD-defined frailty was also significantly associated with reduced odds after adjustment (adjusted OR 0.33, $p = 0.002$). Nine patients experienced waitlist mortality or clinical deterioration; given the limited sample size, neither tool reached statistical significance (AUC 0.531–0.571 for both). In post-transplant outcomes, 6MWD frailty categories significantly predicted longer hospital stays (Kruskal-Wallis $p = 0.044$; frail median 8.0 vs.5.0–6.0 days for robust and pre-frail respectively), while LFI did not ($p = 0.786$). **Conclusion:** Frailty is a crucial factor to consider when evaluating patients for liver transplantation. Our study aimed to compare the 6MWD and the LFI to determine which tool is more predictive of complications before and after transplantation. Based on our results, either tool may be used interchangeably in pretransplant evaluation, depending on availability and patient tolerance. In post-transplant outcomes, pretransplant 6MWD was shown to be more predictive of hospital length of stay in comparison to LFI; however, larger prospective studies are required to validate these findings.

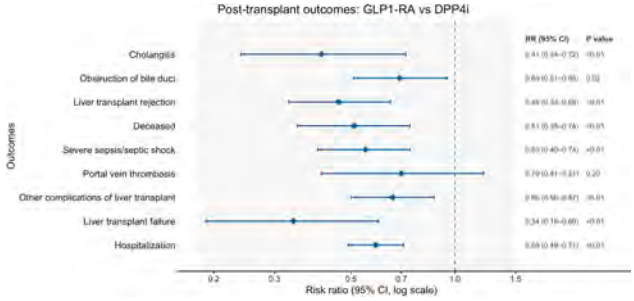
4556 | GLP-1 RECEPTOR AGONISTS ARE ASSOCIATED WITH LOWER RATES OF REJECTION, GRAFT FAILURE, AND MORTALITY AFTER LIVER TRANSPLANTATION COMPARED TO DPP-4 INHIBITORS: A PROPENSITY-MATCHED ANALYSIS

Ethan Chivi[1] Blesscamal Nadeak[1] Ishan Antony[2] Ashali Jain[2] Mary Beth Hodge[2] Jagriti Upadhyay[2] Ming Lin[2],



[1]UMass Chan Medical School, [2]Lahey Hospital and Medical Center

Background: GLP-1 receptor agonists (GLP-1 RAs) have demonstrated anti-inflammatory properties, including reductions in IL-6, IL-17 and TNF-a which may provide benefits in immunocompromised populations. In solid organ transplant recipients, GLP-1 RAs are associated with low rejection rates and reduced cardiovascular mortality. However, comparative data on broader post-liver transplant (LT) complications between GLP-1 RAs and DPP4-inhibitors (DPP-4i) is limited. This study aims to compare rates of these post-LT complications in adults with type 2 diabetes mellitus (T2DM) receiving GLP-1 RAs vs DPP-4is using an active comparator new-user design. **Methods:** Data were derived from the TriNetX Global Collaborative Network (55 healthcare organizations, 2007 – 2025). Adults ≥ 18 years with T2DM and a history of LT were identified. New users of GLP-1 RAs without prior DPP-4i exposure were compared with new users of DPP-4is without prior GLP-1 RA exposure, both initiated 3–24 months post-LT. Propensity score matching (1:1) was performed to balance demographics, immunosuppression and comorbidities. We identified nine commonly encountered post-LT complications/outcomes and these include cholangitis, bile duct obstruction, liver graft rejection, sepsis, portal vein thrombosis (PVT), other LT complications, LT failure, all-cause mortality, and unplanned inpatient/observation admission. These outcomes were compared over a five-year time window after initiation of incretin-based therapy. Risk ratios (RR), risk differences (RD), 95% confidence intervals, and p-values were obtained for each outcome. **Results:** After matching, 545 patients remained in each group with no significant differences in baseline characteristics. GLP-1 RAs were associated with significantly lower risk of cholangitis (3.2% vs 7.8%; RR 0.41 [95% CI 0.24 – 0.72]), bile duct obstruction (10.8% vs 15.6%; RR 0.71 [95% CI 0.51 – 0.95]), graft rejection (7.8% vs 16.9%; RR 0.46 [95% CI 0.32 – 0.65]), graft failure (2.9% vs 8.4%; RR 0.34, [95% CI 0.19 – 0.61]), all-cause mortality (6.8% vs 13.5%; RR 0.51 [95% CI 0.35 – 0.74]), severe infection (10.3% vs 18.8%; RR 0.55 [95% CI 0.40 – 0.74]), rate of hospitalization (23.8% vs 40.1%; RR 0.59 [95% CI 0.49 – 0.71]), and other complications of LT (13.7% vs 20.7%; RR 0.66 [95% CI 0.50 – 0.87]). PVT rates were comparable (4.0% vs 5.7%; RR 0.70 [95% CI 0.41 – 1.21]). **Conclusion:** This study demonstrated the use of GLP-1 RAs were associated with significant reduction in mortality, graft rejection, graft failure, cholangitis, bile duct obstruction, severe infections and hospitalization when compared to DPP-4is, with portal vein thrombosis being the only outcome without a significant difference. These findings suggest that GLP-1 RAs anti-inflammatory properties may confer a favorable safety profile in liver transplant recipients and warrants further

4557 | BETA-BLOCKER MANAGEMENT GAPS AND SUBMAXIMAL DOBUTAMINE STRESS ECHOCARDIOGRAPHY IN LIVER TRANSPLANT CANDIDATES: BASELINE FINDINGS FOR A QUALITY IMPROVEMENT INITIATIVE

Yusuf Yalcin[1] Carmi Punzalan[2] Amir Qamar[2] Ming Lin[3] Raza Malik[1] Sarah Meade[3], [1]Lahey Hospital & Medical Center, [2]Lahey Clinic Medical Center, [3]Lahey Hospital and Medical Center

Background: Submaximal dobutamine stress echocardiography (DSE) can lead to additional cardiac testing and delays during liver transplant evaluation. Inconsistent pre-test beta-blocker instructions and documentation may contribute to potentially avoidable nondiagnostic studies. **Methods:** We performed a retrospective quality review of liver transplant candidates undergoing DSE at a tertiary transplant center from March 2015 through July 2025. Outside studies were excluded. Submaximal DSE was defined as failure to achieve adequate target heart rate; symptom-limited studies were excluded from the primary outpatient comparison. The primary analysis compared outpatient submaximal versus adequate DSEs after excluding inpatient evaluations. Chart review assessed prescribed beta-blocker use and documentation of medication-hold status. **Results:** Among 1,321 DSEs performed at the center, the primary outpatient cohort included 205 submaximal and 942 adequate studies. Excluded from the primary comparison were 34 symptom-limited submaximal studies, 39 inpatient submaximal studies, and 101 inpatient adequate studies. Prescribed beta-blocker use was more common among submaximal than adequate outpatient DSEs: 72.2% versus 42.9%, respectively. Beta-blocker use was associated with higher odds of submaximal DSE, with an OR of 3.46, 95% CI 2.51–4.78; $p < 0.001$. Among submaximal outpatients prescribed beta-blockers, $n = 148$, only 2 patients, 1.4%, had documented appropriate medication holding; 55, 37.2%, did not hold medications appropriately; and 91, 61.5%, lacked documentation of hold status. **Conclusion:** In liver transplant candidates undergoing outpatient DSE, prescribed beta-blocker use was strongly associated with submaximal studies. Medication holding was rarely documented as appropriate and was often either not performed or not documented, identifying a modifiable systems gap. These baseline findings support a targeted quality improvement intervention using standardized medication-hold instructions, pre-test reminders, and routine documentation of beta-blocker hold status, with planned reassessment of submaximal DSE rates and documentation compliance after implementation.

Figure 2. Association Between Beta-Blocker Use and DSE Adequacy in Outpatient Liver Transplant Candidates

DSE outcome	On beta-blocker	Not on beta-blocker	Total
Submaximal DSE	148 (72.2%)	57 (27.8%)	205
Adequate DSE	404 (42.9%)	538 (57.1%)	942
Odds ratio	OR 3.46 (95% CI 2.51–4.78), p < 0.001		

Key result
Beta-blocker use was significantly more common in submaximal than adequate outpatient DSEs.

4558 | TRANSITIONS BETWEEN MELD SUBTYPES PREDICT WAITLIST MORTALITY IN LOW-MELD LIVER TRANSPLANT CANDIDATES

Nicholas Kosinski[1] Russell Rosenblatt[2] Giuseppe Cullaro[3], [1]NewYork-Presbyterian / Weill Cornell Medical Center, [2]Division of Gastroenterology and Hepatology, Weill Cornell Medicine, New York, NY, [3]Center for Liver Disease and Transplantation, Vagelos College of Physicians & Surgeons

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Despite changes in MELD score calculation, mortality risk remains underestimated in certain liver transplant (LT) candidates, especially those with low MELD scores. Prior studies demonstrated that MELD subtyping by creatinine (MELD-Cr), bilirubin (MELD-Br), and INR (MELD-INR) dominance may improve mortality risk stratification. We investigated whether transitions between MELD subtypes further predicted waitlist (WL) mortality among low-MELD liver transplant candidates. **Methods:** Adult LT candidates from the UNOS STAR file from 2020–2025 were analyzed. Patients with acute liver failure, MELD exception points, hepatocellular carcinoma, or multi-organ transplantation were excluded. To isolate patients listed by lab MELD and allow time for subtype transitions, analysis was limited to patients at or below median MELD (≤ 23) of the cohort. MELD subtypes were defined using K-means clustering. Multi-state models were used to evaluate transitions between MELD subtypes, stratified by rising versus stable/falling MELD trajectories. The primary outcome was WL mortality, analyzed using time-dependent competing risk regression adjusted for age, race/ethnicity, disease etiology, height, and BMI and accounting for LT. Patients without subtype transition and with stable/falling MELD were the reference. **Results:** A total of 28,265 patients were included after applying all exclusion criteria. Patients were grouped into three MELD subtypes at baseline: MELD-Cr (n = 2,055, 7.3%), MELD-Br (n = 17,416, 61.6%), and MELD-INR (n = 8,794, 31.1%). Of the 28,265 patients at listing, 3,037 (10.7%) died on the waitlist, 16,265 (57.5%) underwent liver transplantation, 5,236 (18.5%) were delisted, and 3,727 (13.2%) remained waiting at censoring. Transitions into a new MELD-dominant state with rising MELD score were associated with increased waitlist mortality – most prominently in transition to MELD-Cr (SHR 4.41, 95% CI [3.66-5.31]), MELD-INR (SHR 3.65, 95% CI [3.12-4.26]) and MELD-Br (SHR 2.50, 95% CI [2.03-3.07]). Transitions occurring with falling MELD scores were associated with comparatively lower risk, but still increased WL mortality (SHR 1.77 for MELD-Cr, 1.74 for MELD-Br, and 1.22 for MELD-INR; all $p < 0.001$). A rising MELD score without subtype transition was independently associated with increased waitlist mortality (SHR 2.34). **Conclusion:** Dynamic transitions into different MELD subtypes are associated with differential WL mortality risks compared with MELD score changes alone. Even when MELD is static or falling, transitions into different subtypes still increase the risk of mortality. This study supports the concept that changes in the physiologic drivers of MELD score provide prognostic information that is missing from a static MELD score.

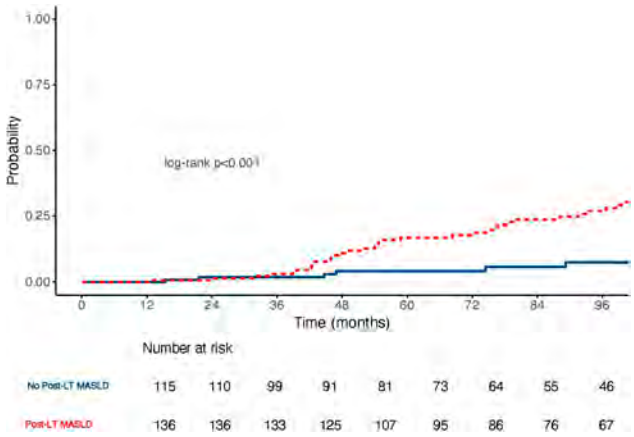
4559 | POST-LIVER TRANSPLANT MASLD PREVALENCE INCREASES OVER TIME AND IS ASSOCIATED WITH HIGHER MACE BUT SIMILAR SURVIVAL



Gupse Adali[1] Osman Karatas[1] Baver Ordu[1],
[1]University of Health Sciences Istanbul Umraniye Training and Research Hospital

Background: Post-liver transplant metabolic dysfunction-associated steatotic liver disease (MASLD) is increasingly recognized after liver transplantation (LT); however, its long-term clinical impact remains unclear. We aimed to evaluate the prevalence, predictors, and clinical outcomes of post-LT MASLD in a longitudinal LT cohort. **Methods:** This retrospective cohort study included 251 adult LT recipients. Baseline demographic, metabolic, and laboratory characteristics were analyzed. Post-LT steatosis was assessed using either transient elastography or MRI. Logistic regression analyses were performed to identify the predictors of post-LT MASLD, and survival analyses were conducted using Kaplan–Meier and Cox regression analyses. **Results:** The mean age was 56.8 ± 12.5 years, and 64.1% of the patients were male. Living donor liver transplantation accounted for 82.5% of the cases, with a median follow-up duration of 88.1 months (IQR 48.2–125.5). Viral liver disease was the most common indication for transplantation (53.8%), whereas MASLD-related liver disease accounted for 16.3% of cases. Pre-LT MASLD was present in 24.7% of the patients. Overall, post-LT MASLD was identified in 54.2% of recipients, with a median time to diagnosis of 52.3 months (IQR, 28.4–84.6). The cumulative prevalence of post-LT

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

MASLD increased over time, from 3.2% at 1 year, 19.9% at 3 years, 30.9% at 5 years, and 54.0% beyond 5 years after LT (Figure 1). In the multivariable analysis, post-LT diabetes (aOR 4.7, 95% confidence interval [CI] 2.42–9.13, p < 0.001), hypertension (aOR 3.6, 95% CI 1.92–6.73, p < 0.001), and post-LT BMI (aOR 1.16, 95% CI 1.07–1.26, p < 0.001) were independently associated with post-LT MASLD. Overall survival was similar between patients with and without post-LT MASLD (HR 1.12, 95% CI 0.61–2.06, p = 0.713) (Figure 2). However, post-LT MASLD was associated with a significantly higher risk of major adverse cardiovascular events (MACE) (HR 3.47, 95% CI 1.85–6.51, p < 0.001)(Figure 3). No significant difference in post-LT malignancy rates was observed between patients with and without post-LT MASLD (p = 0.141). **Conclusion:** Post-LT MASLD increases over time and affects more than half of liver transplant recipients during long-term follow-up. Post-LT diabetes, hypertension, and increased BMI were independent predictors of post-LT MASLD development. Although the overall survival was comparable between patients with and without post-LT MASLD, it was associated with a significantly higher risk of MACE. These findings highlight the importance of long-term metabolic surveillance and cardiovascular risk management following LT.

4560 | PROTOCOLED CA 19-9 TESTING FOR LIVER TRANSPLANT EVALUATION IN A SOUTHWEST COHORT

Diwanshu Soni[1] Bianca Arellano[2] Abdullah Niyas[2] Kevin Mesinas[3] Pooja Rangan[3] Rohit Nathan[4],

[1]University of Arizona College of Medicine- Phoenix, [2]University of Arizona College of Medicine - Phoenix, [3]University of Arizona College of Medicine, [4]Einstein Medical Center

Background: Carbohydrate antigen 19-9 (CA 19-9) is commonly used as a tumor marker for cholangiocarcinoma (CCA) but may also be elevated in cholestasis and chronic liver disease. Although CA 19-9 is incorporated into liver transplant (LT) evaluation at many centers, this practice is not universal, and its utility in this setting remains unclear. We aim to determine the prevalence of elevated CA 19-9 among patients undergoing LT evaluation and identify clinical factors associated with these elevations. **Methods:** This single-center, retrospective cohort study included patients undergoing LT evaluation from January 1, 2020, to April 1, 2025. Inclusion criteria included age ≥ 18 and ICD-10 codes consistent with liver transplant status. Only patients with electronically available CA 19-9 values were included. Patients were stratified into elevated (> 37 U/ml) and normal CA 19-9 groups. The primary outcome was the frequency of elevated CA 19-9 levels during LT evaluation and identifying clinical associations, including CCA, liver disease etiology, and total bilirubin elevation. Univariate and multivariable logistic regression analyses were performed to identify predictors of CA 19-9 elevations. **Results:** In this cohort, among all patients who underwent LT evaluation, 373 had electronically available CA 19-9 values; 180 had elevated values. No association was observed between CA 19-9 levels and CCA on explant (p = 0.68). Total bilirubin was strongly associated with CA 19-9 status (p < 0.001). Alcohol-associated liver disease (ALD) was most associated with elevated CA 19-9 (p = 0.01). Patients with hepatocellular carcinoma had reduced odds of elevated CA 19-9 compared to ALD (p = 0.002). Primary sclerosing cholangitis showed no association with CA 19-9 (p = 0.35). Comorbidities such as diabetes (DM) (p = 0.007), hyperlipidemia (HLD) (p = 0.03), and hypertension (HTN) (p = 0.003) were inversely associated with elevated CA 19-9. In univariable logistic regression analysis, ethnicity, total bilirubin, liver disease etiology, DM, HLD, and HTN were all significant predictors of elevated CA 19-9. In multivariable analysis, only ethnicity and total bilirubin remained significant predictors: Non-Hispanic/Latino patients (OR 1.85, 95% CI 1.16–2.95; p = 0.01) and elevated total bilirubin (OR 2.05, 95% CI 1.24–3.43; p = 0.005). **Conclusion:** While several clinical factors were associated with elevated CA 19-9 in univariable analysis, only ethnicity and total bilirubin remained independent predictors after multivariable adjustment. CA 19-9 elevation was not associated with CCA on explant, suggesting that CA 19-9 elevations in this population may primarily reflect underlying cholestasis and liver dysfunction rather than malignancy. These

findings question the utility of routine CA 19-9 screening during pre-transplant evaluation and warrant further prospective multicenter studies to better define its role in the transplant process.

Table 1: Multivariable Logistic Regression Predicting Elevated CA 19-9

Characteristic	No. (%) Normal (N=193)	Elevated (N=180)	multivariable OR(CI95)†	
Ethnicity—no. (%)				
Hispanic/Latino	82 (42.49)	53 (29.44)	Ref

4561 | A RARE CASE OF PERSISTENT HEPATOPULMONARY SYNDROME POST LIVER TRANSPLANT

Bipneet Singh Vivek Jasti[1] Nimish Thakral[2], [1]University of Kentucky, [2]University of Kentucky Medical Center

Background: Congenital extrahepatic portosystemic shunts are rare and responsible for complications like hyperammonemia, encephalopathy, pulmonary arterial hypertension, and hepatopulmonary syndrome even in the absence of liver cirrhosis. Generally, these occur in conjunction with other anomalies like polysplenia or biliary atresia, but isolated instances have been reported.Hepatopulmonary syndrome is caused by intrapulmonary right-to-left shunting, which leads to insufficient oxygenation. It is diagnosed with the contrast echocardiogram. It occurs due to portocaval shunting, with or without portal hypertension, bypassing hepatic metabolism of vasoactive ET-1, a potent vasodilator. **Methods:** A 42-year-old male with alcohol-associated cirrhosis and hepatopulmonary syndrome (HPS) underwent orthotopic liver transplantation, but his post-transplant course was complicated by persistent hypoxemic respiratory failure. CT imaging demonstrated a large right colic vein to IVC shunt, leading to portosystemic shunting even in the absence of portal hypertension, possibly leading to persistent HPS. The patient underwent an echocardiogram, which demonstrated a co-existing intracardiac and hepatopulmonary shunt. The patient subsequently underwent portosystemic shunt embolization with improvement in oxygen requirement from 15L/min of intranasal oxygen to 3L/min which was noticable within the first few weeks post procedure. Patient continued to show improvement with towards the end of 3 months with concomitant pulmonary rehabilitation. **Results:** At least 20% people have persistent hepatopulmonary syndrome post liver transplant, but the presence of a portosystemic shunt allowed for persistent hepatopulmonary physiology in the patient. The right colic vein is a tributary of the superior mesenteric vein, and its connection to the inferior vena cava allows for portosystemic shunting even in the absence of portal hypertension. Interestingly, the patient did not have features of portal hypertension. However, the presence of a persistnet portosystemic shunt post transplant allowed for the continuation of the disease physiology **Conclusion:** HPS is a persistent complication from cirrhosis and takes months after transplant to improve. Persistent or worsening HPS should warrant factors that might lead to persistent symptoms.

4562 | IMPACT OF PRE-TRANSPLANT WAITLIST DURATION ON WAITLIST AND POST-TRANSPLANT OUTCOMES IN ALCOHOL-RELATED LIVER DISEASE: A NATIONAL UNOS ANALYSIS

Sanjaya Satapathy[1] Nazia Qazi[2] Jiten Kothadia[3] Nabil Dagher[2], [1]Northshore University Hospital/Northwell Health, [2]Northwell Health, [3]University of Tennessee

Background: Alcohol-related liver disease (ALD) remains a leading indication for liver transplantation (LT), yet the impact of pre-transplant waitlist duration on waitlist outcomes and long-term post-transplant survival remains poorly characterized. We aimed to evaluate the association between waitlist duration and both waitlist and post-transplant outcomes among LT candidates with ALD using a national United Network for Organ Sharing (UNOS) cohort. **Methods:** Adult LT candidates with ALD listed in the UNOS database were identified and categorized according to pre-transplant waitlist duration: <30 days, 30–89 days, 90–179 days, and ≥ 180 days. Competing-risk regression models were used to evaluate waitlist mortality or removal for being too sick, accounting for transplantation as a competing event. Kaplan-Meier and multivariable Cox proportional hazards models were used to assess post-transplant patient and graft survival. Analyses were adjusted for demographic, clinical, and transplant-related variables. **Results:** Among 49,613 ALD waitlist candidates, 6,451 experienced waitlist death or removal for clinical deterioration. In competing-risk

analysis, prolonged waitlist duration was associated with increased adverse waitlist outcomes. In adjusted post-transplant analyses of 31,887 LT recipients, recipients transplanted after prolonged waitlist duration ($\geq$180 days) demonstrated significantly worse patient survival (adjusted hazard ratio [aHR] 1.11, 95% confidence interval [CI] 1.02–1.22) and graft survival (aHR 1.11, 95% CI 1.02–1.22) compared with recipients transplanted within <30 days. Alcohol-associated liver disease with concomitant hepatitis C virus infection was independently associated with inferior patient survival (aHR 1.27, 95% CI 1.16–1.39) and graft survival (aHR 1.21, 95% CI 1.11–1.33). Kaplan-Meier analyses demonstrated significantly lower long-term patient and graft survival among recipients with prolonged waitlist duration (log-rank $p < 0.0001$ for both). **Conclusion:** Among LT candidates with ALD, prolonged pre-transplant waitlist duration was associated with worse waitlist outcomes and inferior long-term post-transplant patient and graft survival. These findings highlight the importance of timely transplantation and may inform future strategies for risk stratification and allocation in ALD transplantation.

Table 1. Competing-Risk Regression Analysis for Waitlist Dropout Among Adult Patients With Alcohol-Related Liver Disease.

Variable	Subdistribution Hazard Ratio (SHR)	95% CI	p-value
Age at listing (per year)	1.041	1.038–1.044	<0.001
Female sex	1.090	1.032–1.151	0.002
MELD at listing (per point)	1.026	1.023–1.029	<0.001
HCC absent (vs HCC present)	0.798	0.742–0.859	<0.001
ALD subtype			
Alcohol cirrhosis	Reference	—	—
Acute alcohol hepatitis	0.884	0.784–0.997	0.045
Alcohol + HCV	1.120	1.025–1.223	0.012
MetALD	0.431	0.262–0.709	0.001
Waitlist registration era			
Pre-2014	Reference	—	—
2014–2019	10.44	8.01–13.61	<0.001
2020–2022	7.42	5.68–9.69	<0.001
2023–present	4.95	3.77–6.49	<0.001

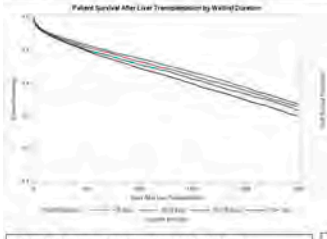

Figure 2. Kaplan-Meier patient survival after liver transplantation stratified by pre-transplant waitlist duration. Kaplan-Meier analysis demonstrating post-transplant patient survival among adult liver transplant recipients with alcohol-related liver disease according to duration of waitlist time prior to transplantation. Recipients transplanted after prolonged waitlist duration (≥180 days) demonstrated the lowest long-term survival, whereas recipients transplanted within <30 days had the most favorable post-transplant survival. Differences between groups were statistically significant by log-rank testing (p<0.0001). Waitlist duration categories were defined as <30 days, 30–89 days, 90–179 days, and ≥180 days prior to transplantation.

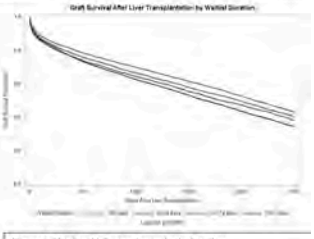

Figure 3. Kaplan-Meier graft survival after liver transplantation stratified by pre-transplant waitlist duration. Kaplan-Meier curves demonstrating post-transplant graft survival among adult liver transplant recipients with alcohol-related liver disease according to pre-transplant waitlist duration. Recipients transplanted after prolonged waitlist duration (≥180 days) demonstrated the lowest long-term graft survival, whereas recipients transplanted within <30 days had the most favorable graft survival outcomes. Intermediate graft survival patterns were observed among recipients waiting 30–89 days and 90–179 days prior to transplantation. Differences between groups were statistically significant by log-rank testing (p<0.0001). Waitlist duration categories were defined as <30 days, 30–89 days, 90–179 days, and ≥180 days prior to liver transplantation.

4563 | POINT-OF-CARE MUSCLE ULTRASOUND REFLECTS FUNCTIONAL IMPAIRMENT AFTER LIVER TRANSPLANTATION

Patricia Almeida[1] Thiago Carvalho[1] Samia Sousa[1] Angelica Cruz[1] Fernanda Rezende[1] Fernanda Oliveira[1], [1]Einstein Hospital Israelita

Background: Frailty and sarcopenia are increasingly recognized as major determinants of outcomes in liver transplantation. Although the Liver Frailty Index (LFI) is a validated tool for functional assessment in patients with advanced liver disease, data correlating functional frailty with objective muscle ultrasound parameters in the immediate post-transplant setting remain scarce. This study aimed to evaluate the association between LFI and quadriceps muscle cross-sectional area measured by point-of-care ultrasonography in hospitalized patients after liver transplantation. **Methods:** This cross-sectional observational study included adult patients admitted to the solid organ transplant ward of a tertiary hospital in Brazil after discharge from the intensive care unit following liver transplantation. Data from the first physiotherapy assessment after ward admission were analyzed, including LFI and quadriceps muscle cross-sectional area assessed by bedside ultrasonography. Patients with severe cognitive impairment, permanent motor limitations, or death before evaluation were excluded. Quantitative variables were expressed as mean ± standard deviation. Normality was assessed using the Ryan-Joiner test, and correlations were analyzed using Pearson's correlation coefficient, with a significance level of 5%. **Results:** Fifteen patients were included. Mean LFI was 5.17 ± 1.31, while mean quadriceps muscle cross-sectional area was 3.63 ± 0.53 cm². A significant moderate negative correlation was observed between LFI and muscle cross-sectional area ($r = -0.591$; $p = 0.020$), demonstrating that greater frailty was associated with lower muscle mass in the early post-transplant period. **Conclusion:** Functional frailty was significantly associated with lower quadriceps muscle cross-sectional area in the early post-transplant period. These findings support point-of-care peripheral muscle ultrasonography as a promising bedside biomarker of frailty in liver transplant recipients, providing an objective and readily applicable tool for early risk stratification and individualized rehabilitation planning after transplantation.

4564 | TOWARDS PATIENT-LED ACUTE REJECTION SURVEILLANCE IN LIVER TRANSPLANTATION: EXPLORING ACCEPTABILITY AND ATTITUDINAL DOMAINS IN A NATIONAL CROSS-SECTIONAL STUDY

Omar Quidwai[1] Linda Kelly[1] Grace Buckley[2] Stephanie Bollard[1] Audrey Dillon[1] Zita Galvin[1] Masood Iqbal[1] Fiona Hand[1] Emir Hoti[1] John Hammond[1] Andrew Malone[1] Aurelie Fabre[1] Helen Heneghan[3] Henk Giele[4] Omar Elsherif[1] Roisin Dolan[1], [1]St Vincent's University Hospital, [2]UCD School of Medicine & Medical Sciences, [3]University College Dublin, [4]Oxford University Hospitals NHS Foundation Trust

Background: Invasive protocol biopsy remains the diagnostic gold standard for rejection surveillance after liver transplantation, despite procedural risks and the absence of reliable early predictive biomarkers. Co-transplanted sentinel skin flaps (SSF) have been proposed as a visible, minimally invasive adjunct to conventional monitoring; however, patient acceptability data in liver transplant populations are lacking. Exploratory data in simultaneous pancreas-kidney (SPK) recipients, in whom the SSF concept has existing clinical precedent, are similarly absent. **Methods:** We conducted a cross-sectional acceptability study of 100 liver transplant candidates and recipients at a national transplant centre, with a convenience sample of 22 SPK candidates and recipients enrolled for exploratory comparison. Following a standardised explanation of the SSF concept, participants rated willingness to adopt, perceived benefits, concerns, and confidence in self-monitoring using five-point Likert scales. Exploratory factor analysis (EFA) identified underlying attitudinal domains and free-text responses underwent inductive thematic analysis. **Results:** Acceptability was high among liver participants, with 89% reporting definite or likely willingness to adopt an SSF. Perceived reassurance (93%), patient empowerment (84%), and confidence in self-monitoring (91%) were the principal drivers of acceptability. Cosmetic (29%) and social stigma (19%) concerns were common but did not substantially reduce willingness, with 76-93% of concerned participants remaining willing to proceed. EFA identified three domains: perceived benefit and reassurance, acceptance and willingness to adopt, and confidence in self-monitoring. Cosmetic concern was the only independent predictor of reduced willingness on multivariate analysis ($\beta = -0.65$, $p = 0.004$). Thematic analysis confirmed reassurance and early rejection detection as dominant themes, with visibility and body image as the principal concerns. In the exploratory SPK cohort, comparable acceptability was observed, with candidates awaiting transplantation reporting greater anticipated benefit than established recipients. **Conclusion:** Liver transplant candidates and recipients demonstrate high acceptability of forearm SSF monitoring, with three attitudinal domains identified and cosmetic concern representing the primary modifiable barrier. Exploratory findings in SPK recipients support comparable acceptability and warrant dedicated evaluation in larger cohorts. These findings support progression to early-phase feasibility evaluation, with structured pre-operative counselling addressing cosmetic and visibility concerns during implementation.

4565 | ENDOSCOPIC ULTRASOUND-GUIDED VERSUS STANDARD LIVER BIOPSY IN LIVER TRANSPLANT RECIPIENTS: A PROPENSITY SCORE MATCHED STUDY

Pauline Bozon-Rivière[1] Philippe Willems[1] Eya Hamdani[2] Meziane Silhadi[2] Catherine Vincent[3] Julien Bissonnette[4] Julian Hercun[5], [1]CHUM, Montréal, Québec, Canada, [2]Université de Montréal, Québec, Canada, [3]University of Montreal, Canada, [4]University of Montreal Hospital Center, [5]Centre hospitalier de l'Universite de Montreal

Background: Liver biopsy (LB) remains the gold standard for diagnosing graft-related complications after liver transplantation (LT). However, percutaneous biopsy (PC-LB) may be limited by ascites, split LT or antiplatelet therapy, whereas transjugular biopsy (TJ-LB) can be challenging in cases of difficult venous access. Endoscopic ultrasound-guided liver biopsy (EUS-LB) has emerged as an alternative that also allows direct presinusoidal portal pressure assessment, but data in liver transplant recipients remain limited. Our study aimed to assess the diagnostic adequacy and safety of EUS-LB and to compare it with standard biopsy approaches in LT recipients. **Methods:** We conducted a retrospective single-center study including all consecutive LT recipients who underwent EUS-guided LB between January 2023 and December 2025. To reduce the risk of selection bias related to the choice of biopsy technique, we compared EUS-LB to a cohort of LT patients who underwent LB between January 2021 and December 2022, before the introduction of EUS-LB at our institution. Propensity score matching including age, sex, BMI, presence of ascites, anticoagulation, antiplatelet therapy, platelet count, international normalized ratio, creatinine level, and type of caval anastomosis was performed in a 1:1 ratio. Primary endpoints were diagnostic adequacy and safety. Secondary endpoints included specimen quality and recovery time. **Results:** A total of 19 EUS-LB were included. The majority were male (78.9%), with a median age of 54 ± 18 years. At the time of biopsy, 31.6% of patients were on anticoagulation, 42.1% on antiplatelet therapy and 10.5% had ascites. EUS-LB was preferred over conventional techniques because of either the need for concomitant EGD or biliary assessment (68.4%), prior difficult transjugular access or anatomical constraints (21.1%), or patient preference (10.5%).The historical cohort included 62 consecutive patients. Propensity score matching was performed, resulting in 19 matched biopsies. Diagnostic adequacy was high in both groups, with a numerically higher rate in the EUS-LB group (100% vs. 89.5%; p = 0.486). Overall histological quality was comparable between groups (p = 0.31). The number of biopsy passes was significantly lower in the EUS-LB group compared with the standard biopsy group (SBG) (1.26 ± 0.56 vs. 2.42 ± 1.17; p < 0.001). Two inadvertent renal tissue samples were obtained in the SBG, without clinical consequence. Post-procedural pain occurred in 15.8% of patients in both groups. One case of bleeding (subcapsular hematoma) occurred in the SBG while one case of biliary infection requiring hospitalization occurred in both groups. Recovery time was significantly shorter after EUS-LB (120 vs. 240 minutes; p < 0.001). **Conclusion:** In liver transplant recipients, EUS-guided LB appears to be a feasible and safe alternative to standard biopsy techniques.

4566 | ASSOCIATION OF ACUITY CIRCLES IMPLEMENTATION WITH TIME TO LIVER TRANSPLANTATION IN PATIENTS WITH MASLD

Navin Prasad[1] David Twitchell[2], [1]Presbyterian Hospital, [2]Banner University Medical Group

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the fastest growing indication for liver transplantation in the United States. With an aim to minimize geographic disparities in liver transplant,, the Organ Procurement and Transplantation Network (OPTN) implemented the acuity circles allocation policy in February 2020. This model prioritizes the highest acuity patients per MELD score and expands the donor pool region to concentric circles in miles from the donor center, opposed to allocating only within rigid regions. The association between this policy change and transplantation patterns among patients with MASLD remains incompletely understood. **Methods:** We performed a retrospective analysis of adult liver transplant recipients with a primary diagnosis of MASLD (NASH/MASH) identified within the OPTN database from 2016–2023. Adult liver transplant recipients with a primary diagnosis of MASLD (NASH/MASH) were stratified into pre–acuity circles (before February 4, 2020) and post–acuity circles cohorts. The primary outcome was time from listing to transplantation. Secondary outcomes included demographic and clinical characteristics, including MELD scores at listing and transplantation. **Results:** A total of 10,519 MASLD transplant recipients were included (pre-acuity cohort: 5,186; post-acuity cohort: 5,333). Median time to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

transplantation decreased significantly from 86 days (IQR 21–286) in the pre-policy era to 56 days (IQR 10–159) following implementation of acuity circles ($p < 0.001$).Baseline characteristics were largely similar between groups. Median age (61 vs 61 years, $p = 0.165$), diabetes prevalence (44.1% vs 43.5%, $p = 0.563$), and MELD at listing (20 vs 20, $p = 0.341$) were unchanged. The proportion of female recipients increased modestly following policy implementation (47.5% vs 49.5%, $p = 0.041$). BMI was slightly lower in the post-policy cohort (31.6 vs 32.0 kg/m², $p = 0.004$). Median MELD at transplantation was similar between groups (24 vs 24), although a small statistically significant distributional difference was observed ($p = 0.003$). **Conclusion:** Implementation of acuity circles in liver transplant allocation is associated with significantly shorter time from listing to transplantation among patients with MASLD, without meaningful differences in disease severity at listing. These findings suggest that the acuity circle model improves efficiency of liver transplant in the MASLD cirrhosis population.

4567 | COMPARATIVE WAITLIST AND EARLY POST-TRANSPLANT OUTCOMES IN ASIAN VS. NON-ASIAN LIVER TRANSPLANT CANDIDATES: A PROPENSITY-MATCHED UNOS STUDY (2002-2025)

Amukta Palakurthi[1] Mangesh Pagadala[2] Suvisesh Pothuraju[3] Sajid Jalil[4] Chencheng Xie[5] Nimish Thakral[6] Yong-Fang Kuo[7] Winston Dunn[8] Robert Wong[9] Paul Kwo[10] Ashwani Singal[11], [1]Appalachian Regional Healthcare, [2]Liver Institute, Methodist Dallas Medical Center, [3]University of Louisville School of Medicine, [4]Stanford University School of Medicine, [5]University of Iowa, [6]University of Kentucky Medical Center, [7]University of Texas Medical Branch, [8]University of Kansas Medical Center, [9]Stanford/VA Palo Alto Healthcare System, [10]Stanford University Medical Center, [11]University of Louisville

Background: Data on waitlist and post-transplant outcomes after liver transplant (LT) in Asians compared to other racial/ethnic groups in the US are limited. **Methods:** Using the United Network for Organ Sharing (UNOS) database (2002 to 2025), we identified adult LT candidates and recipients, excluding pediatric and multi-organ transplants except for liver and kidney. Propensity score matching was conducted to compare Asians with Non-Hispanic Whites (NHW), African Americans (AA), Hispanics (HW), and Native Americans (NA) based on demographics, comorbidities, liver disease etiology, and MELD score. Primary outcomes were 90-day waitlist mortality and post-transplant patient/ liver graft survival at 1 year. **Results:** Among 194,535 listings, 7,568 (3.9%) were for Asians. In unadjusted analyses, Asians had lower waitlist mortality than AA (HR 0.80; 95% CI 0.71–0.89), HW (HR 0.81; 95% CI 0.73–0.90), and NA (HR 0.78; 95% CI 0.64–0.94). After PSM, waitlist mortality in Asians remained lower than in NA (HR 0.74; 95% CI 0.56–0.97), but was like NHW (0.90; 0.76–1.05), AA (0.89; 0.76–1.05), and HW (0.85; 0.73–1.00). A total of 4533 LTs were performed in Asians, with better graft and patient survival rates than AA: 90.1 vs. 86.7%, 0.84 (0.71–0.98, $p < 0.001$) and 92.7 vs. 89.4%, 0.80 (0.67–0.97) respectively, $p < 0.001$ for both. These rates were similar for Asians compared with NHW, HW, or NA ($p > 0.20$ for all). HBV accounted for 40% of listings and LT in Asians, compared with approximately 1–8% in other groups. Within the HBV subgroup, compared to Asians, NA had a higher hazard of 90-day waitlist mortality, 1.91 (1.11-3.31, $p = 0.020$), and NHW had a higher hazard of graft/patient loss: 1.340 (1.05-1.85, $p = 0.021$) and 1.55 (1.10-2.16, $p = 0.01$), respectively. **Conclusion:** These findings highlight population-specific ethnic differences in waitlist and post-transplant outcomes among liver transplant candidates and recipients, which require further investigation.

4568 | CAD-LT AND THE BURDEN OF FUTILE CORONARY ANGIOGRAPHY

Bandar Aljudaibi[1] Saleh Alqahtani[2] Khalid Bzeizi[3] Manhal Izzy[4] Saad Alghamdi[5] Ehab Abufarhaneh[3] Fuat Saner[6] Maryam Abdulla[7], [1]King Faisal Specialist Hospital and Research Centre, [2]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [3]King Faisal Specialists Hospital and Research Centre, [4]Vanderbilt University Medical Center, [5]King Faisal Specialist Hospital and Research Center, [6]King Faisal Specilaists Hospital and Research Centre, [7]Alfaisal Univeristy

Background: Cardiovascular disease remains a major source of morbidity after liver transplantation (LT). The CAD-LT score was developed to identify LT candidates at increased risk for coronary artery disease (CAD), but its performance in Middle Eastern populations in living-donor LT programs is uncertain. This study evaluated the association between CAD-LT risk stratification, invasive coronary angiography findings, preoperative coronary intervention, and post-transplant cardiovascular outcomes in a Middle Eastern LT cohort. **Methods:** This retrospective single-center study included 353 adult LT recipients who underwent preoperative cardiac catheterization between 2020 and 2024. Patients were stratified into low–intermediate and high-risk groups according to the CAD-LT score. Baseline characteristics, angiographic findings, coronary interventions, and post-transplant cardiovascular outcomes were analyzed. **Results:** Of the 353 patients, 244 (69.1%) were classified as high risk and 109 (30.9%) as low–intermediate risk. High-risk patients were older and had significantly higher rates of diabetes mellitus, hypertension, hypercholesterolemia, and prior CAD. Obstructive CAD ($\geq$50% stenosis) was identified in 37 patients (10.48%) overall and was more common in the high-risk group (12.30% vs. 6.42%, p = 0.096). Percutaneous coronary intervention (PCI) was performed in 10.06% of patients, predominantly in the high-risk group (11.93% vs. 5.71%, p = 0.077). Despite a higher cardiovascular risk profile and more frequent invasive interventions, post-transplant cardiac outcomes were comparable between groups. Cardiac-related mortality was low (2.04%) and did not differ significantly between low–intermediate and high-risk patients (1.87% vs. 2.12%, p = 0.89). Rates of cardiac arrest, atrial arrhythmias, acute coronary syndrome, and post-transplant dialysis were also similar between groups. **Conclusion:** In this Middle Eastern LT cohort, the CAD-LT score identified patients with a higher cardiovascular risk profile and greater likelihood of coronary intervention. However, the prevalence of obstructive CAD requiring PCI remained low, with nearly 90% of invasive coronary angiograms demonstrating non-obstructive disease. CAD-LT ability to predict clinically significant obstructive CAD requiring intervention is modest in this population.

4569 | POST-TRANSPLANT CARDIAC OUTCOMES AND SURVIVAL ACCORDING TO CAD-LT RISK CLASSIFICATION

Bandar Aljudaibi[1] Maryam Abdulla[2] Saad Alghamdi[3] Manhal Izzy[4] Saleh Alqahtani[5] Ehab Abu-Farhaneh[6] Khalid Bzeizi[7] Fuat Saner[7], [1]King Faisal Specialist Hospital and Research Centre, [2]Alfaisal Univeristy, [3]King Faisal Specialist Hospital and Research Center, [4]Vanderbilt University Medical Center, [5]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [6]University of Toronto, [7]KFSH

Background: Cardiac complication post liver transplantation (LT) are a leading cause of morbidity and mortality. CAD-LT score was designed to stratify the risk of obstructive coronary artery disease (CAD) in LT candidates; however, its association with post-transplant cardiac outcomes and survival in Saudi and Arabian Gulf population LT recipients has not been well described. We evaluated whether CAD-LT risk classification predicts post-LT cardiac events, patient survival, and graft survival in our cohort. **Methods:** We conducted a retrospective single-center analysis 353 LT candidates evaluated at King Faisal Specialist Hospital and Research Centre (KFSHRC), Riyadh, Saudi Arabia, between 2020 -2024**.** All patients underwent coronary angiography as part of pre-transplant workup and were stratified by CAD-LT risk classification into low/intermediate-risk and high-risk groups. Post-LT cardiac outcomes included cardiac death, cardiac arrest, atrial fibrillation/flutter, ventricular arrhythmia, myocardial infarction, and need of post-transplant dialysis. Patient and graft survival were compared between CAD-LT risk groups using Kaplan-Meier analysis with log-rank testing. Multivariable Cox proportional hazards regression was performed to assess predictors of patient survival. **Results:** Of 353 patients, 109 were classified as low/intermediate risk and 244 as high risk. Overall, post-LT cardiac events occurred in 35 patients (9.9%). Cardiac events were more frequent in the high-risk group compared with the low/intermediate-risk group (12.3% vs 4.6%). Cardiac death occurred in 7 patients, cardiac arrest in 17, atrial fibrillation in 5, atrial flutter in 2, ventricular arrhythmia in 1, and myocardial infarction in 12. Dialysis after transplant occurred in 25 patients overall and was more common in the high-risk group (8.6% vs 3.7%). Despite the higher burden of post-LT cardiac events in the high-risk group, patient survival did not differ significantly between CAD-LT risk categories. Death occurred in 42 patients overall, with similar rates in low/intermediate-risk and high-risk groups (11.9% vs 11.9%). Graft failure also occurred in 42 patients, with identical rates between groups. Kaplan-Meier curves demonstrated no significant difference in patient or graft survival between risk categories (log-rank $p = 0.937$ for both endpoints). On multivariable Cox regression, CAD-related variables were not independently associated with patient survival. **Conclusion:** In this large LT cohort, CAD-LT high-risk classification was associated with a higher observed rate of post-transplant cardiac events, but not with inferior patient or graft survival. These findings suggest that while CAD-LT may help identify patients requiring closer perioperative cardiac monitoring, its prognostic value for long-term survival appears limited in this population

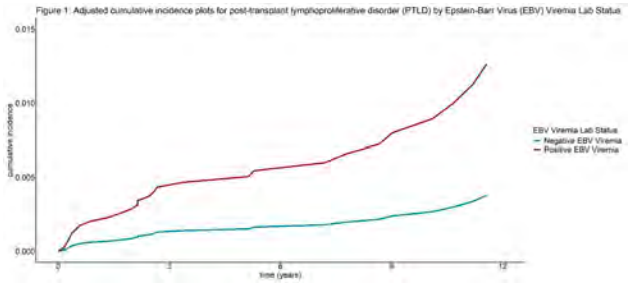
4570 | EPSTEIN BARR VIRUS VIREMIA ASSOCIATED WITH INCREASED POST TRANSPLANT LYMPHOPROLIFERATIVE DISORDERS AND OVERALL MORTALITY IN ADULT LIVER TRANSPLANT RECIPIENTS



Carter Chapman[1] Deena Brosi[2] Jesse Schold[2] Michael Kriss[3] Jon Rice[3] Cassandra Duarte[4] Bradley Haverkos[5], [1]University of Colorado Anschutz Internal Medicine Residency, [2]University of Colorado School of Medicine, Division of Transplant Surgery, [3]University of Colorado School of Medicine, Division of Gastroenterology and Hepatology, [4]University of Colorado School of Medicine, Division of Hematology and Oncology, [5]Unviersity of Colorado School of Medicine, Division of Hematology and Oncology

Background: Post-Transplant Lymphoproliferative Disorders (PTLD) represent a spectrum of lymphoid neoplasms that occur following solid-organ and hematopoietic stem cell transplant and are strongly associated with the Epstein-Barr Virus (EBV). Although uncommon, they are the leading cause of cancer-related mortality in solid-organ transplant recipients. Despite this, there is limited adult liver transplant recipient specific data confirming the relationship between EBV viral load and future risk of PTLD development. Therefore, this study seeks to further investigate the relationship between EBV viremia and the development of PTLD in adult liver transplant recipients. **Methods:** We used our internal organ transplant registry at the University of Colorado Health Transplant Center to identify first-time adult

liver transplant (LT) recipients from 1/1/2012 – 9/8/2025. Our sample includes 1,237 LT recipients, 27.6% (n = 342) of which had a detectable EBV PCR (either whole blood or plasma) taken after LT. The remaining patients – those with either negative EBV testing or those that had never been tested – formed the negative EBV viremia group. Our primary outcomes of interest were diagnosis of PTLD and all-cause mortality. We estimated sub-distribution hazard ratios (sHRs) using Fine & Gray's competing risks analysis, which considered retransplant and loss-to follow up as competing events for both outcomes and all-cause mortality as an additional competing event for risk of PTLD. Sub-distribution hazard ratios were adjusted for primary liver diagnosis prior to transplant, immunosuppressive regimens, treatment of rejection, baseline demographics, EBV serostatus, and history of cytomegalovirus viremia. **Results:** The unadjusted sHR of PTLD was 4.17 (95% confidence interval [CI]: 1.92 – 8.05; p-value < 0.001) higher among LT recipients in the positive EBV viremia group compared with those in the negative EBV viremia group. The adjusted sHR of PTLD was 3.61 (95% confidence interval [CI]: 1.55 – 8.41; p-value = 0.003) higher among LT recipients in the positive EBV viremia group. Adjusted cumulative incidence of PTLD was also found to be higher in the positive EBV viremia group compared to the negative EBV viremia group (Figure 1). LT recipients in the positive EBV viremia group had significantly higher risk of mortality with an adjusted sHR of 2.35 (95% CI: 1.62 – 3.40; p-value < 0.001). **Conclusion:** Our study demonstrates a significant association between a history of detected EBV viremia and the development of PTLD in adult liver transplant recipients, as well as a significant association between EBV viremia and all-cause mortality in this population. Future directions of our study involve evaluating the relationship between quantitative EBV viral load and immune suppression and the development of PTLD in order to establish viral load cutoffs that identify high risk patients.

4571 | OPHTHALMIC MANIFESTATIONS FOLLOWING LIVER TRANSPLANTATION IN THE EPIC COSMOS DATABASE

Miles Richman[1] Reagan McGinley[1] Sidart Pradeep[2] Jan Petrasek[3] Masih Ahmed[4], [1]School of Medicine, Baylor College of Medicine, Houston, Texas, USA, [2]UT Health San Antonio, [3]Texas Liver Institute, San Antonio, TX, USA, [4]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, Texas, USA

Background: The purpose of this study was to report the incidence of ophthalmic manifestations in liver transplant recipients. **Methods:** This is a retrospective cohort study of the Epic Cosmos database where we looked at patients who received a liver transplant between October 01, 2017, to September 30, 2023. Patients were only included if they had a baseline eye exam in the year preceding liver transplant. We then searched for predefined ophthalmic conditions using ICD-10 codes in the two years following transplant, recorded the average time to diagnosis, and identified incident manifestations by comparison with the baseline eye exam. We categorized the pathologies into eyelid, corneal, conjunctival, lens, retina, optic disc, and ocular surface conditions, as well as viral infections. **Results:** We retrieved 5,051 liver transplant recipients from the database. The mean age of patients was 55.7 ± 11.5. Overall, 516 (10.22%) had any incident ocular pathology. The most common categories of incident pathologies were retina (4.59%), lens (2.87%), conjunctival (2.65%), and ocular surface (1.76%). The most common manifestations were diabetic retinopathy (2.79%), nuclear sclerosis (2.55%), dry eye (1.76%), conjunctivitis (1.90%), and age-related macular degeneration (1.41%). The average time to diagnosis following transplant ranged from 22 to 433 days. **Conclusion:** Ophthalmic manifestations were seen in a substantial portion of liver transplant recipients. It is important for providers to understand the incidence of these conditions following liver transplants and to recommend that patients undergo ocular exams to diagnose early and avoid treatment delays.

4572 | METABOLIC, CARDIOVASCULAR, AND HEPATIC OUTCOMES ASSOCIATED WITH GLP-1 RECEPTOR AGONIST USE IN LIVER TRANSPLANT RECIPIENTS WITH TYPE 2 DIABETES MELLITUS: A PROPENSITY-MATCHED COHORT STUDY

Allan Zhang[1] Mohamad Ali Ibrahim[2] Kimberly Taing[1] Prasun Jalal[2], [1]University of Texas Southwestern Medical Center, [2]Baylor College of Medicine

Background: As survival after liver transplantation improves, long-term metabolic and cardiovascular complications have emerged as important determinants of post-transplant outcomes. While GLP-1 receptor agonists (GLP-1RAs) grant cardiometabolic benefits in the general population, evidence supporting their use after liver transplantation remains limited. As such, this study evaluated the association of GLP-1RA use with metabolic, hepatic, and cardiovascular outcomes among liver transplant recipients with type 2 diabetes mellitus (T2DM). **Methods:** Using the TriNetX Research Network, we identified adult liver transplant recipients with T2DM who initiated a GLP-1RA (semaglutide, exenatide, liraglutide, dulaglutide, or tirzepatide) within 3 months of transplant. These patients were compared against non-GLP-1RA controls in a retrospective cohort design. Patients with kidney, lung, or heart transplantation were excluded. Outcomes assessed as 5-year cumulative incidence beginning 90 days after index (date of transplant) included mortality, major adverse cardiovascular events (MACE), liver transplant complications, metabolic dysfunction-associated steatotic liver disease (MASLD), decompensated cirrhosis events (DCE), and hepatocellular carcinoma (HCC). Transplant complications were defined as a composite of liver transplant rejection, liver transplant failure, and other complications of liver transplant. Cohorts were propensity score matched 1:1 for demographics, metabolic and cardiovascular comorbidities, liver disease etiologies, immunosuppressive therapy, and laboratory markers. **Results:** Among 16,593 eligible liver transplant recipients, 1,558 patients receiving GLP-1RAs and 15,035 controls were identified. After matching, 1,536 patients remained in each cohort. GLP-1RA use was associated with significantly reduced risk of mortality (RR 0.19, 95% CI 0.13-0.29; $p < 0.0001$) and MACE (RR 0.56, 95% CI 0.44-0.71; $p < 0.0001$). No significant differences were observed in HCC or DCE. Interestingly, GLP-1RA exposure was associated with increased 5-year cumulative rates of MASLD (RR 1.78, 95% CI 1.31-2.40; $p = 0.0001$) and transplant complications (RR 1.6, 95% CI 1.30-1.98; $p < 0.0001$). **Conclusion:** In liver transplant recipients with T2DM, GLP-1RA use was linked to lower mortality and cardiovascular risk. Higher MASLD rates could reflect confounding by indication, as GLP-1RAs may be initiated in patients who are more likely to develop de novo graft steatosis. Furthermore, observed elevations in transplant complications may reflect claims-data limitations and surveillance bias. As such, prospective studies with graft biopsies and drug monitoring are needed to clarify post-transplant GLP-1RA safety.

4573 | ANTI-CD25 ANTIBODY INDUCTION COMBINED WITH REDUCED-DOSE CORTICOSTEROIDS IN LIVER TRANSPLANTATION: A REAL-WORLD COMPARISON OF SHORT- AND LONG-INTERVAL DOSING REGIMENS

Xuguang Hu[1] Zhidan Xu[2] Laibang Luo[2] Zehong Fang[2] Xuyang Wang[2] Gang Liu[2], [1]Jiangxi Provincial People's Hospital, [2]Jiangxi Provincial People's Hospital, Nanchang, China

Background: Humanized anti-CD25 monoclonal antibodies (mAbs) are commonly used for induction therapy in liver transplantation (LT) to prevent early acute cellular rejection (ACR). Nevertheless, real-world data regarding their clinical efficacy and optimal dosing interval remain limited. This study assessed clinical outcomes of anti-CD25 mAb induction paired with a reduced-dose corticosteroid protocol, and compared short- and long-interval dosing strategies. **Methods:** This single-center retrospective cohort study enrolled 140 LT recipients treated between September 2022 and December 2024. All patients received anti-CD25 mAb (two 50-mg doses) and a 50% reduced corticosteroid protocol (initial daily dose < 120 mg). Patients were stratified according to the timing of the second dose: short-interval group (7–10d, n = 98) and long-interval group (14d, n = 42). Baseline characteristics were well balanced between groups. The primary endpoint was clinically confirmed ACR. Secondary endpoints comprised infection rates, and both graft and patient survival.Continuous and categorical variables were compared using t-test/Mann-Whitney U test and χ^2/Fisher's exact test, respectively; survival was analyzed via Kaplan-Meier method. **Results:** Clinically confirmed ACR developed in 13.6%. All episodes responded to corticosteroid, and no steroid-resistant rejection occurred. Six- and 12-month graft survival rates were 100% and 99.3%; patient survival rates were 95.9% and 90.1%. Median IV steroid discontinuation was 6 days (87.0% success rate), and 85% of patients achieved target TAC troughs by month 1.Pre-second-dose immune monitoring revealed a trend toward lower absolute T-cell counts (356 ± 259 vs. 501 ± 329, P = 0.109) and CD4+ T-cell counts (212 ± 160 vs. 309 ± 213, P = 0.108) in the short-interval group, suggesting more sustained perioperative T-cell suppression. Consistently, TAC trough levels were lower in the short-interval group on postoperative day7 (7.3 ± 3.6 vs. 9.4 ± 18.3 ng/mL, P = 0.019) and on day14 (8.5 ± 8.3 vs. 11.1 ± 30.3 ng/mL, P = 0.060). The short-interval group also had a trend toward a lower ACR rate (10.2% vs. 21.4%, P = 0.075), while overall infection rates were similar between the two groups (22.2% vs. 26.2%, P = 0.45). Cohort infection rate was 22.1% , including 3.6% requiring ICU admission. AKI occurred in 12.9% ; none required renal replacement. No drug-related adverse events were observed. **Conclusion:** Induction therapy with humanized anti-CD25 mAb plus reduced-dose corticosteroids yields favorable anti-rejection efficacy and safety among LT recipients. The 7–10 day short-interval dosing schedule optimizes perioperative immune control, with a trend toward reduced ACR without elevating infection risk. These real-world data provide valuable evidence for timing optimization of induction regimens, and support the adoption of individualized, precision immunosuppression in clinical liver transplantation.

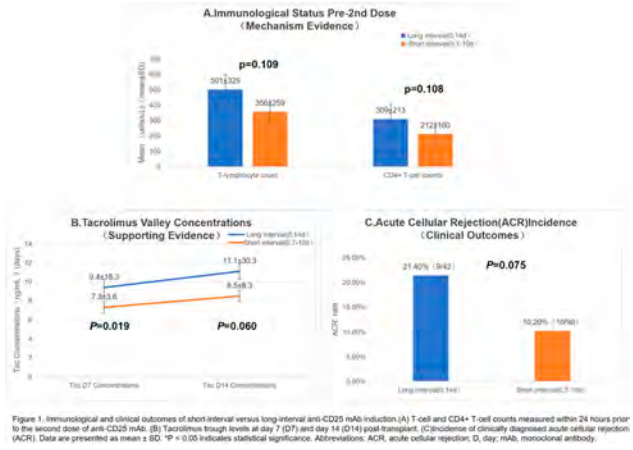

Figure 1. Immunological and clinical outcomes of short-interval versus long-interval anti-CD25 mAb induction.(A) T-cell and CD4+ T-cell counts measured within 24 hours prior to the second dose of anti-CD25 mAb. (B) Tacrolimus trough levels at day 7 (D7) and day 14 (D14) post-transplant. (C)Incidence of clinically diagnosed acute cellular rejection (ACR). Data are presented as mean ± SD. *P < 0.05 indicates statistical significance. Abbreviations: ACR, acute cellular rejection; D, day; mAb, monoclonal antibody.

4574 | TUMOR BIOLOGY MODIFIES THE ASSOCIATION BETWEEN SURGICAL MARGIN WIDTH AND RECURRENCE FOLLOWING CURATIVE-INTENT RESECTION FOR HEPATOCELLULAR CARCINOMA

Matthew Kim[1] Devi Veeramgari[1] Yonatan Kaplan[1] Adina Shrestha[1] Aashrith Madagiri[1] Daisuke Imai[1] Yuzuru Sambommatsu[1] Vinay Kumaran[1] Muhammad Saeed[1] Aamir Khan[1] Amit Sharma[1] Adrian Cotterell[1] Hannah Lee[1] David Bruno[1] Seung Lee[1], [1]Virginia Commonwealth University School of Medicine

Background: For patients with hepatocellular carcinoma (HCC), recurrence following liver resection remains high. While surgical margin width and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

biological factors have been shown to independently predict recurrence, whether these adverse risk factors modify the relationship between surgical margin width and recurrence is poorly understood. We aimed to determine if margin width modified recurrence risk differently based on tumor biology (tumor grade, alpha fetoprotein [AFP], and microvascular invasion [MVI]) for curative-intent HCC resection. **Methods:** A retrospective analysis of patients from an institutional HCC registry from 2010 to 2020 was performed. Patients were categorized into a no risk (0 risk factors), intermediate risk (1 risk factor), or high risk group (2+ risk factors) based on AFP levels (<20 vs ≥ 20 ng/mL), tumor grade (low grade = G1/G2, high grade = G3/G4), and MVI (negative or positive), with an AFP $\geq$ 20 ng/mL, high grade, or positive MVI being considered a risk factor. Stratified multivariable cox proportional hazards model analyzed independent predictors of recurrence free survival (RFS), and fine gray analysis accounted for death without recurrence. A pooled cox model was used to assess effect modification. Sensitivity analysis on AFP thresholds was conducted. Models were adjusted for age, sex, tumor number, resection type, and cirrhosis. **Results:** 49 patients were included in this analysis (margin $<$1cm: n = 23, margin $\geq$ 1cm: n = 16, positive margin: n = 10). In multivariable cox analysis, intermediate and high risk group were independent predictors of RFS in the margin $<$1cm ($p = .04$ and $p < .001$, respectively) and positive margin group ($p = .03$ and $p < .001$, respectively). Pooled interaction analysis found a significant interaction between margin width and risk status ($p = .03$), with the interaction remaining significant across all tested AFP cutoffs (AFP $\geq$ 20 ng/mL, AFP $\geq$ 200 ng/mL, AFP $\geq$ 400 ng/mL) in the high risk margin width $<$1cm group (HR 5.12, $p = .03$; HR 4.88, $p = .03$; HR 4.72, $p = .04$, respectively). Fine gray analysis found worse RFS in the high risk group compared to no/intermediate risk in the margin $<$1cm group (sHR 3.84, 95% CI 1.92 - 7.68, $p < .001$) and positive margin group (sHR 5.62, 95% CI 2.41 - 13.09, $p < .001$). **Conclusion:** These findings suggest that achieving a surgical margin width $\geq$ 1cm may be crucial to improve survival, and for individuals with a surgical margin width $<$1cm or with positive margins, poor tumor characteristics may significantly worsen prognosis.

4575 | POST LIVER TRANSPLANT OUTCOMES IN CONTEMPORARY RECIPIENTS AGED 70–74 YEARS: A NATIONAL COHORT ANALYSIS

Iyiad Alabdul Razzak[1] Kush Patel[1] Irena Helenowski[2] Eric Kallwitz[3] Scott Cotler[3], [1]Loyola University Medical Center, [2]Loyola University, [3]Loyola University Health System

Background: Liver transplantation (LT) has increased in older patients. While age is not a contraindication to LT, it is associated with comorbidities and reduced functional status. We aimed to compare post-LT patient and graft survival between contemporary recipients aged 70–74 years and younger recipients and to identify factors associated with post-transplant outcomes in the age 70-74 cohort. **Methods:** This retrospective cohort study used United Network for Organ Sharing (UNOS) data from adult LT recipients aged $<$75 years transplanted between Feb 2020 and Dec 2024. Recipients aged 70–74 years were compared with younger age cohorts (see Fig 1 for cohorts) with the 40-59 age cohort serving as the reference group. Primary outcomes included post-LT patient and graft survival. Kaplan Meier curves were compared by log-rank tests and Cox proportional hazards models were adjusted for recipient, donor, and transplant related characteristics. **Results:** Among 33,889 adult LT recipients, 2,164 (6.4%) were aged 70–74. Compared with younger recipients, recipients aged 70-74 more frequently had HCC (34.1% vs 13.8%), MASH (29.2% vs 18.8%), diabetes (44.4% vs 28.5%), received donors aged $\geq$70 years (10.9% vs 3.9%) and had lower rates of Karnofsky score $<$40% at transplant (30.7% vs 41.1%) and ICU hospitalization at transplant (22.5% vs 38.0%) (all $p < 0.05$). In unadjusted Cox analysis, age 70–74 was associated with worse patient survival (HR 2.33, 95% CI 2.08–2.61, $p < 0.001$) and graft survival (HR 1.85, 95% CI 1.66–2.07, $p < 0.001$) compared with recipients aged 40–59 (Figures 1A, B). In adjusted models, recipient age 70–74 remained associated with worse patient survival (HR 3.22, 95% CI 2.00–5.17) and graft survival (HR 3.00, 95% CI 1.90–4.74). Within the 70–74 cohort, factors associated with reduced patient survival included non-HCC malignancy (HR 2.41, 95% CI 1.33–4.39), diabetes (HR 1.57, 95% CI 1.24–1.97), BMI $<$25 (HR 1.55, 95% CI 1.22–1.98), ICU hospitalization at transplant (HR 1.51, 95% CI 1.09–2.08) and portal vein thrombosis (HR 1.31, 95% CI 1.00–1.72). Similarly, within the 70–74 cohort, worse graft survival was associated with non-HCC malignancy (HR 2.24, 95% CI 1.22–4.13), diabetes (HR 1.59, 95% CI 1.26–1.99), BMI $<$25 (HR 1.46, 95% CI 1.15–1.85), and ICU hospitalization at transplant (HR 1.56, 95% CI 1.14–2.14). **Conclusion:** Contemporary LT recipients

aged 70–74 years had reduced patient and graft survival compared with younger recipients. In the age 70-74 cohort, adverse outcomes were associated with comorbidities, low BMI, perioperative acuity, and portal vein thrombosis, supporting individualized candidate selection and development of risk stratification tools to better identify older LT candidates most likely to achieve favorable outcomes.

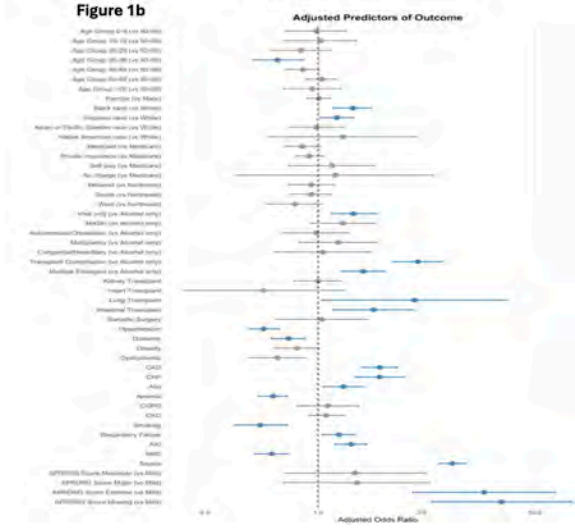
4576 | LIVER DISEASE ETIOLOGY CO-OCCURRENCE, DUAL-ORGAN TRANSPLANTATION, AND PERSISTENT RACIAL/ETHNIC DISPARITIES IN OUTCOMES: A 25-YEAR NATIONAL ANALYSIS OF U.S. LIVER TRANSPLANTATION



Monica Tincopa[1] Mohammed Abu Rumaileh[2] Bisher Sawaf[2] Hamzeh Abugharbieh[2] Marwan Joma[2] Umberto Battistin[2] Yusuf Hallak[2] Mohannad Qwaider[2] Kyrillos Gerges[3] Leena Alnsour[4] Naser Gharaibeh[5] Abdallah Kheshman[6], [1]University of California, San Diego, [2]University of Toledo, [3]Sohag University,, [4]South Tyneside and Sunderland NHS Foundation Trust,, [5]Icahn School of Medicine at Mount Sinai, [6]Wayne State University

Background: Long-term national trends in liver transplantation (LT) integrating etiology co-occurrence, recipient complexity, and outcomes across distinct epidemiologic eras remain incompletely characterized. This study aimed to: 1) characterize shifts in LT indications including co-occurring liver disease across three epidemiologic eras; 2) describe changes in recipient complexity, length of stay (LOS), and hospital charges; and 3) identify predictors of in-hospital mortality including racial/ethnic disparities. **Methods:** We conducted an analysis of LT hospitalizations in the National Inpatient Sample (NIS) over 25 years (1998–2022). LT hospitalizations were identified using procedure codes. Liver disease etiologies were classified as non-mutually exclusive to characterize co-occurring etiologies. Temporal trends in recipient complexity, comorbidities, dual-organ transplantation, LOS, hospital charges, and in-hospital mortality were assessed. Multivariable logistic regression identified independent predictors of mortality. **Results:** Among 31,454 LT hospitalizations, ALD (29.2% to 43.8%) and MASH (1.8% to 24.7%) increased while viral hepatitis declined (47.7% to 12.6%) across three epidemiologic eras. Etiology co-occurrence was common: viral hepatitis with malignancy (14.3%), viral hepatitis with ALD (9.1%), and ALD with malignancy (5.6%) (**Figure 1a**). Recipient complexity increased including older age (47.1 to 52.0 years), rising metabolic comorbidities, and liver-kidney transplantation (2% to 8%). Despite this, in-hospital mortality declined from 8.0% to 2.5%, with the most rapid declines in viral hepatitis and ALD recipients; malignancy showed no significant decline in mortality. Longer LOS and highest costs were observed with transplant related complications, Medicaid insurance and Hispanic ethnicity ($638,555 vs. $470,560 for White recipients). Independent predictors of higher mortality included transplant complications (OR 2.89), co-occurring etiologies (OR 1.61), viral hepatitis (OR 1.46), lung-liver (OR 2.79) and liver-intestinal transplantation (OR 1.80), Black race (OR 1.45) and Hispanic ethnicity (OR 1.22)(**Figure 1b**). **Conclusion:** Despite increasing complexity including rising age, dual liver disease etiology, increased comorbidity burden and multiorgan transplant, early post-LT mortality improved substantially over 25 years. Systematic characterization of etiology co-occurrence reveals the multifactorial nature of modern LT indications with direct clinical implications. Persistent racial/ethnic disparities in mortality, cost and LOS, including a hypothesis-generating signal among Hispanic recipients, underscore the need for targeted interventions and dedicated disparities research.

4577 | INADEQUATE EMPIRICAL ANTIBIOTICS IN POST-TRANSPLANT PNEUMONIA ARE ASSOCIATED WITH LONGER TREATMENT AND HIGHER TREATMENT FAILURE RATES

Zehra Karabal[1] Muhammad Ebrahim Ferozie[2] Nihad Jamalli[2] Narmin Dadashova[2] Laman Karimli[2] Elshad Yagubzade[2] Irem Yasa[2] Tonguc Utku Yilmaz[3] Iftihar Koksal[3], [1]Acibadem University, [2]Acibadem University Medicine Faculty, [3]Acibadem Atakent Hospital

Background: Pneumonia following liver transplantation represents a life threatening infectious complication in an already immunocompromised host. When a liver transplant recipient develops pneumonia, the treating clinician must choose empirical antibiotics before cultures return, a high stakes decision with guidance extrapolated from non-transplant populations. Causative pathogens include multidrug-resistant and opportunistic organisms more prevalent than in the general population, and immunosuppression blunts the clinical deterioration that normally signals treatment failure. Despite this complexity, the clinical consequences of empirical regimen inadequacy have never been quantified specifically in liver transplant recipients. **Methods:** All 118 liver transplant recipients with pneumonia were identified retrospectively from a single-center cohort (2015-2025). Regimen change was defined as any modification to the initial empirical regimen made in response to culture results demonstrating resistance to the prescribed antibiotics or lack of clinical improvement within 72 hours as assessed by the treating physician. Patients with missing antibiotic regimen data (n = 7) were excluded from the primary analysis. The primary endpoints were treatment duration (days) and treatment failure, defined as no clinical response at the end of the full treatment course. Pneumonia specific hospital LOS was a secondary outcome. Mann-Whitney U and Fisher's exact tests were used. **Results:** Regimen change occurred in 45 of 111 analyzable patients (40.5%); 66 (59.5%) completed treatment without modification. Regimen-change patients had significantly longer treatment duration (median 14 days, IQR 9-29 vs. 8 days, IQR 6-12; p = 0.0002) and longer hospital LOS (median 1 day, IQR 0-7 vs. 0 days, IQR 0-0; the vast majority of patients in the unchanged group required no additional inpatient days; p < 0.001). Treatment failure occurred in 17 of 44 evaluable patients (38.6%) in the regimen-change group vs. 8 of 65 (12.3%) in the unchanged group (one missing outcome per group); OR 4.49 (95% CI 1.72-11.68; p = 0.002). **Conclusion:** Empirical regimen change occurred in 40.5% of evaluable cases and was associated with a 75% longer treatment course and a significantly higher treatment failure rate (OR 4.49; p = 0.002). When the initial regimen proved adequate, 87.7% of patients achieved resolution without modification. To our knowledge, this is the first such quantification in liver transplant recipients. These findings support transplant-specific empirical protocols informed by local resistance surveillance rather than general community-acquired or hospital-acquired pneumonia guidelines, and early microbiological sampling to enable prompt culture-guided therapy.

4578 | DE NOVO MALIGNANCY AFTER ISOLATED INTESTINAL TRANSPLANTATION: HIGHER THAN THE GENERAL POPULATION BUT COMPARABLE TO LIVER TRANSPLANTATION IN A PROPENSITY-MATCHED COHORT

Akram Alnounou[1] Mohammad Alabbas[2] Ezzeldien Ibrahim[3] Syed-Mohammed Jafri[4] Faruq Pradhan[5], [1]Western Michigan University Homer Stryker MD SOM, [2]Cleveland Clinic Foundation, [3]University of Missouri-Columbia, [4]Henry Ford Health System, [5]University of Nebraska Medical Center

Background: De novo malignancy is a recognized complication of solid-organ transplantation, but its risk after isolated intestinal transplantation, and relative to other transplant populations, is poorly defined in multicenter data. We compared de novo malignancy among adults with isolated intestinal transplant status, matched non-transplant adults, and matched isolated liver transplant recipients. **Methods:** Using the TriNetX Research Network (111 health care organizations), we identified adults aged ≥18 years with intestinal transplant status (ICD-10-CM Z94.82); isolated status required no other transplant-status code before or within 1 month after index. Patients with malignancy before the outcome window were excluded. The primary outcome was de novo malignancy (malignant neoplasm or neuroendocrine tumor codes) from day 31 after index; post-transplant lymphoproliferative disorder (PTLD) and skin cancer were also assessed against liver transplant. Recipients were separately 1:1 propensity-score matched, on demographics and comorbidities, to non-transplant controls and to isolated liver transplant recipients (Z94.4). Kaplan–Meier hazard ratios (HRs) with 95% CIs were estimated and groups compared by log-rank test. **Results:** Of 486 identified isolated intestinal transplant recipients, 460 were matched to non-transplant adults and 473 to liver transplant recipients. Versus non-transplant adults, intestinal transplant status was associated with higher de novo malignancy (38/449 [8.5%] vs 17/458 [3.7%]; HR 2.217, 95% CI 1.251–3.930; risk difference 4.8%, 95% CI 1.6–7.9; P = .005). Versus liver transplant recipients, risk did not differ for de novo malignancy (38/462 [8.2%] vs 43/457 [9.4%]; HR 0.923, 95% CI 0.597–1.429; P = .720), PTLD (12/446 [2.7%] vs 13/461 [2.8%]; HR 0.989, 95% CI 0.451–2.168; P = .978), or skin cancer (14/473 [3.0%] vs 11/473 [2.3%]; HR 1.375, 95% CI 0.624–3.029; P = .428). **Conclusion:** In this matched EHR cohort, isolated intestinal transplant status was associated with more than twofold higher de novo malignancy risk than non-transplant adults but comparable to liver transplant recipients across malignancy, PTLD, and skin cancer. Because cohorts were matched on demographics and comorbidities but not on immunosuppression, time since transplant, or transplant indication, and outcomes were code-based, prospective studies incorporating these measures are warranted.

4579 | SYSTEMIC IMMUNE-INFLAMMATION INDEX (SII) AND TUMOR DIFFERENTIATION GRADE

William Vroom[1] Devi Veeramgari[1] Yonatan Kaplan[1] Sophia Cury[1] Matthew Kim[1] Daisuke Imai[1] Yuzuru Sambommatsu[1] Vinay Kumaran[1] Muhammad Saeed[1] Aamir Khan[1] Amit Sharma[1] Adrian Cotterell[1] Hannah Lee[1] David Bruno[1] Seung Duk Lee[1], [1]VCU School of Medicine

Background: Validated models have been developed to predict post-transplant recurrence in hepatocellular carcinoma (HCC) patients and included markers such as neutrophil-lymphocyte ratio (NLR) and alpha-fetoprotein (AFP). The systemic immune-inflammation Index (SII) is an additional composite biomarker that may serve as a useful tool to identify recurrence. We aimed to determine if a higher SII correlated with poorly differentiated HCC could predict recurrence. **Methods:** 58 patients with HCC who underwent curative resection or liver transplantation between 2005-2011 were included. Preoperative SII was calculated as neutrophil count × platelet count / lymphocyte count. Log-transformed SII and AFP were evaluated for associations with tumor grade (n = 39 with complete pathologic data), time to first recurrence, and early recurrence (≤24 months) using ordinal logistic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

regression, Cox proportional hazards, and binary logistic regression, respectively. Covariates included surgery type, microvessel invasion, and maximum tumor diameter. **Results:** 58 patients were reviewed, of which 19 had recurrence events and 39 had tumor grade data available for analysis. SII predicted increased tumor grade on ordinal logistic regression (β = 1.428, SE = 0.612, p = 0.020), reduced time to recurrence on Cox proportional hazards (HR = 2.65, 95% CI 1.38 - 5.09, p = 0.003), and increased early recurrence on binary logistic regression (OR = 3.12, 95% CI 1.45 - 6.71, p = 0.004). AFP did not display significant predictive value on tumor grade (β = 0.115, SE = 0.185, p = 0.534), time to recurrence (HR = 1.08, 95% CI 0.88 - 1.33, p = 0.451), or early recurrence (OR = 1.12, 95% CI 0.75 - 1.68, p = 0.582). The predictive values of surgery type (OTL vs resection), microvascular invasion, and max tumor diameter were also assessed, with the latter being associated with reduced time to recurrence (HR = 1.14, 95% CI 1.06 - 1.22, p < 0.001) and increased early recurrence (OR = 1.18, 95% CI 1.07 - 1.31, p = 0.001). **Conclusion:** Elevated SII was independently associated with worse tumor differentiation, shorter time to recurrence, and increased odds of early recurrence in HCC, even after adjustment for AFP and key clinical factors. AFP was not a significant predictor in our models, suggesting that SII provides additional prognostic value beyond traditional biomarkers. Overall, our results support SII as an effective biomarker that may inform post-operative surveillance strategies in HCC.

4580 | ONE-YEAR PATIENT AND GRAFT SURVIVAL AFTER LIVER TRANSPLANTATION FOR ACUTE-ON-CHRONIC LIVER FAILURE: A COMPARATIVE ANALYSIS OF MASH AND NON-MASH RECIPIENTS

Sanjaya Satapathy[1] Jiten Kothadia[2] Fariha Ilyas[3],
[1]Northshore University Hospital/Northwell Health,
[2]University of Tennessee, [3]Northwell Health

Background: Metabolic dysfunction–associated steatohepatitis (MASH) has become one of the leading indications for liver transplantation (LT). However, post-transplant outcomes among recipients transplanted for acute-on-chronic liver failure (ACLF) remain incompletely characterized. We evaluated 1-year patient and graft survival, organ failure patterns, and causes of death following LT for ACLF in recipients with MASH compared with non-MASH etiologies. **Methods:** We performed a retrospective cohort study of 29,820 adult LT recipients with ACLF, including 3,907 (13.1%) with MASH and 25,913 (86.9%) with non-MASH liver disease. Recipient demographics, organ failure profiles, post-transplant outcomes, and causes of death were compared. Kaplan–Meier methods and Cox proportional hazards models were used to assess patient and graft survival. **Results:** Compared with non-MASH recipients, patients with MASH were older (56 ± 10 vs. 48 ± 12 years) and had higher body mass index (32.6 ± 6.8 vs. 28.2 ± 6.1 kg/m²), with a substantially higher prevalence of diabetes mellitus (47.0% vs. 12.3%; all p < 0.001). Organ failure profiles differed significantly between groups; kidney failure was more common among MASH recipients (56.6% vs. 43.0%, p < 0.001), whereas liver and circulatory failure occurred more frequently in non-MASH recipients (both p < 0.001).At 1 year after LT, overall mortality was 8.3% (n = 2,488) and graft loss occurred in 10.3% (n = 3,081). Kaplan–Meier analysis demonstrated comparable 1-year patient survival (log-rank p = 0.21) and graft survival (log-rank p = 0.57) between MASH and non-MASH recipients. In unadjusted analysis, MASH was not associated with graft loss (HR 0.97, 95% CI 0.87–1.08; p = 0.58). After adjustment for recipient, donor, and transplant characteristics, MASH was independently associated with a reduced risk of 1-year graft loss (adjusted HR 0.84, 95% CI 0.75–0.95; p = 0.004).Among recipients who died within 1 year, infection was the leading cause of death (48.6%), followed by malignancy (22.2%) and cardiovascular events (6.0%). The distribution of causes of death did not differ significantly between MASH and non-MASH recipients (p = 0.23). **Conclusion:** Among LT recipients transplanted for ACLF, 1-year patient and graft survival were similar between MASH and non-MASH etiologies. Despite a distinct metabolic phenotype and higher burden of kidney failure, MASH was independently associated with improved adjusted graft survival. Infection remains the predominant cause of early post-transplant mortality irrespective of underlying liver disease. These findings support equitable transplant access for patients with MASH-related ACLF and underscore the importance of tailored peri-transplant management strategies in this rapidly growing population.

4581 | NEW SUBMISSION BEYOND BIOPSY: NON-INVASIVE AND MOLECULAR DIAGNOSTICS FOR ACUTE REJECTION IN LIVER TRANSPLANTATION - A SYSTEMATIC REVIEW

Helena Paran[1] Omar Quidwai[2] Sinead Sullivan[3] Fiona Hand[2] John Hammond[2] Emir Hoti[4] Stephanie Bollard[4] Zita Galvin[4] Audrey Dillon[4] Masood Iqbal[4] Omar El Sherif[4] Roisin Dolan[4], [1]University College Dublin School of Medicine, [2]St. Vincent's University Hospital, Dublin, Ireland, [3]University of Limerick, [4]St. Vincent's University Hospital, Dublin, Ireland.

Background: Timely detection of acute rejection remains central to preserving graft function after liver transplantation. Although liver biopsy is considered the diagnostic reference standard, it is invasive, carries procedural risk, and is limited by sampling error and inter-observer variability. In response, a new generation of minimally invasive and non-invasive diagnostic approaches has emerged, including donor-derived cell-free DNA assays, gene expression profiling, immune monitoring platforms, and advanced imaging modalities. These technologies offer the potential to detect early alloimmune activity before overt graft dysfunction, reducing reliance on invasive biopsy. However, the diagnostic performance of these emerging modalities relative to biopsy-proven acute cellular rejection has not been comprehensively synthesised. This systematic review aimed to evaluate the diagnostic accuracy of minimally invasive and non-invasive diagnostic modalities for detecting biopsy-proven acute cellular rejection following liver transplantation. **Methods:** A systematic review was conducted in accordance with PRISMA-DTA guidelines and registered with PROSPERO. MEDLINE (Ovid), Embase, and CENTRAL were searched using controlled-vocabulary and free-text terms without restrictions. Of 2,266 records identified, 478 duplicates were removed, leaving 1,788 for screening. Studies evaluating minimally-invasive or non-invasive tests for detecting biopsy-proven acute rejection in LT were included. Screening, data extraction, and risk-of-bias assessment (QUADAS-2) were performed independently by two reviewers, with conflicts resolved by a third reviewer. **Results:** Twenty studies (2,612 recipients) were included. Diagnostic approaches included donor-derived cell-free DNA, gene-expression profiling, immune-monitoring platforms, and imaging. Molecular biomarkers demonstrated the most consistent performance, with some studies identifying subclinical alloimmune activity preceding graft-dysfunction. However, heterogeneity in study design, sampling, thresholds, and definitions of rejection was substantial. Bias (QUADAS-2) related to patient selection and index-test interpretation. **Conclusion:** Minimally invasive and non-invasive modalities, particularly molecular biomarkers, show promise for detecting ACR and may reduce reliance on biopsy. However, heterogeneity and methodological limitations necessitate standardisation and further validation before routine clinical use.

Paola Francalanci[2] Luca Della Volpe[2] Daniela Liccardo[2] Diego Martinelli[2] Barbara Siri[2] Carlo Dionisi Vici[2] Rosanna Pariante[2] Marco Spada[2], [1]Bambino Gesù Children Hospital, IRCCS, Rome, Italy, [2]Bambino Gesù Children's Hospital, IRCCS, Rome, Italy

Background: Metabolic diseases (MD) represent the second most common indication for liver transplantation (LT) in children. Indications include prevention of metabolic decompensation, treatment of the liver disease and improvement of neurological outcomes and organ damage. **Methods:** We retrospectively reviewed the clinical records of patients who underwent LT for MD at the Bambino Gesù Children's Hospital from January 2008 to December 2025. **Results:** 92 out of 422 (21.8 %) (age: 90.5 months, IQR: 72) children underwent a LT for MD. Weight and height z-scorewere -0.855 (IQR: 2.2) and -0.887 (IQR: 2.45). 18 had a MD with structural liver disease (ALF, HCC or ESLD) with amedian MELD/PELD of 28 (IQR: 15): tyrosinemia type 1 [n:8, 8.7%], Wilson's disease [n: 5, 5.4%], bile acid synthesis disorders [n: 3, 3.3%], DGUOK deficiency and cholesteryl ester storage disease [n: 1 (1%) for each]. 74 underwent LT without structural severe liver disease: organic acidemias [n: 24, 26%], urea cycle disorders [n: 16, 17.4%], maple syrupurine disease [n: 13, 14%], primary hyperoxaluria type 1 [n: 13, 14%], glycogen storage disease type Ia [n: 4, 4.3%], others [n: 4 (4.3%)] (Fig. 1). Heterozygous living donor LTs were performed in 16 (17.4%); deceased donor whole and split livers transplantation in 25 (27.2%) and 47 (51%). 8 had a combined or sequential liver-kidney transplant. A patient with MSUD who underwent LT provided a whole liver for a child with biliary cirrhosis. After 63.9 months (IQR: 72)(median follow-up) patient and survivals were 96.7% and 94.6%: 2 died because of perioperative complications, 1 of cardiorespiratory failure with normal liver function. 2 pts were retx because of EGD. In the 1-year after LT, 8 (9%) required relaparotomy; 12 (13%) and 13 (14%) developed vascular and biliary complications successfully treated with interventional radiology and/or endoscopy. 27 had an acute liver rejection (29%). CMV viremia was seen in 41 (44.5%) with pre-emptive treatment needed in 21 (22.8%). EBV viremia was reported in 60 (65.2%) with 45 already positive before LT. Throughout the follow-up period, 4 patients (4.4%) were diagnosed with PTLD/lymphoma. 14 (15.2%) experienced either acute or chronic neurological complications (i.e.PRESS, seizures, or tremors) with 4 attributed to CNI toxicity. With the exception of one patient (propionic acidemia), no metabolic decompensation was observed after LT. All children resumed a normal protein intake within 4 weeks. 1-yearafter LT, patients presented a median increase in height and weight z-scores of 0.389 (IQR: 2.15) and 0.181 (IQR:1.74). **Conclusion:** LT in MD had excellent outcomes with a significant regression of the risk of metabolic decompensation and an improvement in QoL. Long-term data are needed to evaluate the role on neurological and organ damage. Multidisciplinary follow-up and timely transplantation are key factors in the management of these patients.

4583 | PRE-LIVER TRANSPLANT USE OF IMMUNE CHECKPOINT INHIBITORS FOR HEPATOCELLULAR CARCINOMA: A SINGLE CENTER EXPERIENCE

Kaitlyn Legg[1] Ian Booth[1] Neha Jakhete[2] Kenneth Saunders[1] Christine Wolesensky[1], [1]University of Maryland Medical Center, [2]University of Maryland

Background: Immune checkpoint inhibitors (ICIs) are increasingly used in patients with hepatocellular carcinoma (HCC). ICI's have changed the landscape of HCC treatment in recent years but are associated with rejection post-transplant; optimal timing for discontinuation prior to liver transplantation (LT) has not been standardized. Little information is known regarding optimal immunosuppression (IS) management in this population. We aimed to characterize patient survival, rejection outcomes, and describe IS practices post-LT in the ICI treatment population at our center. **Methods:** We reviewed all LT recipients, including multi-organ transplants, with a pretransplant diagnosis of HCC transplanted at our center from 1/1/2019 through 12/31/2025. Those identified as receiving an ICI prior to LT were followed for 2 years post-LT as this period is the highest risk for HCC recurrence. The primary endpoint was patient survival at 2 years. Secondary endpoints included biopsy proven acute rejection (BPAR), infectious complications, IS management, renal function, and HCC recurrence. **Results:** Six patients were identified as receiving ICI prior to transplant, with a median age of 66 years. One patient received simultaneous liver kidney; the remaining 5 were liver only. Pre-LT imaging showed 4 patients (66%) had a single tumor and 3 patients (50%) with a tumor larger than 5 cm. Three patients

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

received durvalumab/tremelimumab, 2 received atezolizumab/bevacizumab, and 1 received durvalumab alone with a median of 10.5 doses (IQR 7.3-13) prior to LT. Median duration of ICI pre-LT was 271 days (IQR 169.5-331.3) with the last dose prior to LT being 120.5 days (range 72-164 days). At time of abstract submission, 3 patients (50%) have reached 2 years post-LT with 100% survival. BPAR occurred in 1 patient, 23 months post-LT. Four infections occurred in 2 patients, with bacteremia accounting for 75%. Median eGFR at day 7 was 74 mL/min/1.73 m2 (IQR 72-113) and by 2 years was 53 mL/min/1.73 m2 (IQR 46-79.5). At 2 years, one patient remained on tacrolimus, while two patients had been converted to mTOR inhibitors. At 2 years, all three patients remained on mycophenolate with a median total daily dose of 500 mg (IQR 250-500, n = 3), and prednisone use was 33% (n = 1). No recurrence of HCC was seen at 2 years, though 2 patients had recurrence after 2 years. **Conclusion:** All patients who received an ICI pre-LT survived until 2 years post-LT or until last follow up with a functioning graft. No patients had rejection early post-LT, which is consistent with current literature that suggests holding ICI dose at least 50 days prior to LT. One incidence of rejection was seen at almost 2 years post-transplant, which was unlikely to be related to ICI use pre-LT. Future studies should focus on identifying the optimal time to perform a LT after the last dose of an ICI and finding the optimal IS balance to mitigate the increased risk of rejection with ICIs and long-term risk of HCC recurrence.

4584 | ◆ CLINICAL VALIDATION OF A NOVEL CELL-FREE DNA-BASED ASSAY FOR DETECTION OF REJECTION IN LIVER TRANSPLANT

Phil Gauthier[1] Mamatha Bhat[2] Ali Zarrinpar[3] Daniel Maluf[4] D. Giovanni Biagini[1] Nina Verstraete[1] Andrew Doud[1] Yen-An Chen[1] Navchetan Kaur[1] Felipe Acosta[1] Ebad Ahmed[1] Amy Baer[1] Mita Banik[1] Naoshin Haque[1] Sarah McCormick[1] Kate Woodruff[1] Jing Xie[1] Nour Al Haj Baddar[1] Niraja suresh[1] Zachary Demko[1] Adam Prewett[1] Hossein Tabriziani[1] Sangeeta Bhorade[1] Juliet Emamaullee[5], [1]Natera, Inc., [2]University Health Network / University of Toronto, [3]University of Florida, [4]University of Maryland School of Medicine, [5]Keck School of Medicine of USC

Background: Liver transplantation (LTx) is the definitive treatment for end-stage liver disease. Donor-derived cell-free DNA (dd-cfDNA) is a noninvasive biomarker for allograft rejection. We present a clinical validation study to evaluate dd-cfDNA performance characteristics for detecting active rejection (AR) in LTx recipients and assess clinical factors associated with dd-cfDNA elevation. **Methods:** Adult LTx patients with blood samples collected ≥ 14 days post LTx were included. Rejection was defined as a treated clinical rejection or biopsy-proven acute rejection. dd-cfDNA performance metrics (sensitivity, specificity, negative predictive value [NPV], positive predictive value [PPV], and area under curve [AUC]) were calculated. Random forest classifiers were applied to identify association between several clinical variables (liver function tests [LFTs; aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase], graft type (whole or partial), rejection diagnosis, donor-recipient sex mismatch, donor type (living or deceased), donor relatedness)- and positivity of dd-cfDNA (dd-cfDNA% ≥10.0%). **Results:** A total of 199 LTx patients with 209 dd-cfDNA samples were included. Among the cohort, 32 patients experienced a total of 33 rejection episodes, including 29 episodes of acute cellular mediated rejection (ACMR) and 4 episodes of treated clinical rejections; the remaining 167 patients had no rejection (NR). Median dd-cfDNA levels were significantly higher in AR (21.1%) vs NR (3.6%; p < 0.001; **Fig 1A**). Median dd-cfDNA levels were significantly higher in mild (grade 3-4) or moderate (grade 6-7) rejection activity index scores compared to none (20.8% and 25.0%, vs. 3.7%, respectively; p < 0.001 for both). A 10.0% dd-cfDNA threshold showed a sensitivity of 87.9%, specificity of 87.5%, PPV of 56.9%, and NPV of 97.5%. ROC yielded an AUC of 0.90; **Fig 1B**). Elevated LFTs, rejection, and donor-recipient sex mismatch were associated with elevated dd-cfDNA; **Fig 1C**). **Conclusion:** This validation established that dd-cfDNA ≥10.0% is associated with increased risk of allograft rejection and that it accurately distinguishes AR from NR with high sensitivity and

specificity and correlates with liver allograft histological rejection activity. dd-cfDNA elevation association with the immune related clinical factors supports its utility as a noninvasive biomarker for liver allograft injury.

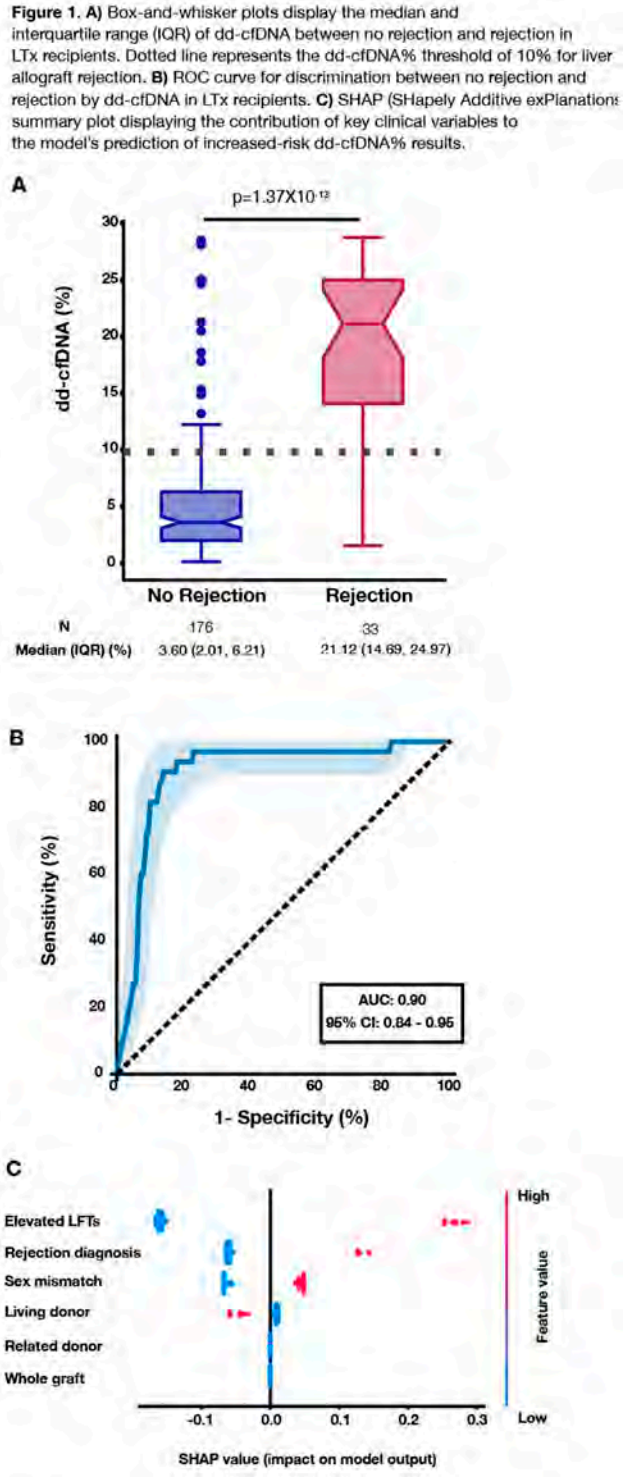

Figure 1. A) Box-and-whisker plots display the median and interquartile range (IQR) of dd-cfDNA between no rejection and rejection in LTx recipients. Dotted line represents the dd-cfDNA% threshold of 10% for liver allograft rejection. **B)** ROC curve for discrimination between no rejection and rejection by dd-cfDNA in LTx recipients. **C)** SHAP (SHapely Additive exPlanations summary plot displaying the contribution of key clinical variables to the model's prediction of increased-risk dd-cfDNA% results.

4585 | EXCELLENT LONG-LERM GRAFT SURVIVAL USING 3RD GENERATION NUCLEOS(T)IDE ANALOGS WITHOUT HEPATITIS B IMMUNE-GLOBULIN AFTER LIVER TRANSPLANTATION FOR CHRONIC HEPATITIS B

James Fung[1] Tiffany Wong[2] Kevin Ng[2] Wing Chiu Dai[1] Kin Pan Au[1] Sui-Ling Sin[1] Miu Yee Chan[1] Kwan-Lung Ko[1] Loey Mak[2] Man-Fung Yuen[2] Albert Chan[2], [1]Queen Mary Hospital, [2]The University of Hong Kong

Background: Despite efficacy of 3rd-generation nucleos(t)ide analogs (NUCs) as prophylaxis after liver transplantation (LT) for chronic hepatitis B (CHB), hepatitis B immune globulin (HBIG) continues to be routinely used despite incurring high costs. **Methods:** This is a large retrospective cohort study of consecutive CHB patients positive for hepatitis B surface antigen (HBsAg) undergoing LT from October 2005 to December 2024, using 3rd-generation NUCs including entecavir (ETV), tenofovir disoproxil fumarate (TDF), or tenofovir alafenamide (TAF) as initial antiviral prophylaxis after LT. No HBIG was administered at any stage, representing a completely HBIG-free regimen. The primary outcome was graft survival. **Results:** A total of 546 patients was included. After exclusion of those with less than 1 year follow-up, 499 were included in final analysis with a median follow up

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

of 123 months. The median age at LT was 54 years, of which 82% were male, and 22%, 33% and 45% were transplanted for decompensated cirrhosis (DC), severe flares, and hepatocellular carcinoma (HCC) respectively. After LT, 85%, 9%, 3% and 3% were treated with ETV, TDF, TAF, and ETV + TDF respectively. At the last follow-up, 68%, 1%, 30% and 1% were on ETV, TDF, TAF, and ETV + TDF respectively, with increasing use of TAF. The cumulative graft survival at 5, 10, 15, and 20 years was 93%, 86%, 78%, and 76% respectively for those who survived beyond the first year. Importantly, no patients had graft loss secondary to HBV reactivation. Over half (52%) had detectable HBV DNA at the time of LT, with a median level of 5320 IU/mL for those with quantifiable HBV DNA. HBsAg loss was observed in 95%, and was maintained in 86% at time of last follow up. There was no survival difference observed between those that was HBsAg-negative vs. positive at last follow-up ($p = 0.116$). Of the 71 patients with positive HBsAg at last follow-up, 68 (96%) had undetectable or unquantifiable HBV DNA. The remaining 3 patients achieved undetectable HBV DNA, and HBV DNA became detectable only after HCC recurrence. The cumulative incidence of HCC in the entire cohort at 5, 10 and 15 years after LT was 4%, 6%, and 6% respectively, without any de novo HCC observed. The HCC recurrence rate for those with HCC at time of LT was 10%, 13%, and 14% at 5, 10 and 15 years respectively. Patients transplanted for severe flares had better long-term survival compared to those for DC or HCC (88% vs. 76% vs. 71% respectively at 15 years, $p = 0.01$). **Conclusion:** These long-term results demonstrate definitively that completely HBIG-free regimens using 3rd generation NUCs alone are safe and effective in preventing hepatitis B reactivation, with excellent long-term survival, and should become the standard of care in CHB patients undergoing LT in the era of highly effective NUCs.

4586 | NALTREXONE USE IN EARLY POST-LIVER TRANSPLANT CARE FOR ALCOHOL-ASSOCIATED LIVER DISEASE

Fayez Jabboure[1] FNU Baimaji[1] Bill Zhang[1] Adeline Vo[2] Mayan Teles[3] Lauren Boyer[1] Daniel Warren[1] James Hamilton[2] Andrew Cameron[1] Po-Hung (Victor) Chen[2], [1]Johns Hopkins Medicine, [2]Johns Hopkins University, [3]Johns Hopkins University School of Medicine

Background: Alcohol-associated liver disease (ALD) is the leading indication for liver transplant (LT) in the US. Alcohol use disorder (AUD) is a chronically relapsing condition. Post-LT alcohol relapse is common and can adversely affect graft function and survival. Although naltrexone and other medications for AUD (MAUD) have demonstrated benefit in patients with ALD, their use in LT recipients remains poorly studied. We evaluated naltrexone use, hepatic safety, and alcohol relapse during the first post-LT year. **Methods:** We conducted a single-center study of adults who underwent LT for severe ALD between January 2021 and May 2024. For all patients who received naltrexone after LT, hepatic safety was assessed using alanine aminotransferase (ALT), alkaline phosphatase (ALP), and total bilirubin (Tbili) values from 1 month before through 2 months after naltrexone initiation. Clinically significant elevations were defined as ALT > 40 U/L in males and > 30 U/L

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

in females with a ≥1.5-fold increase, ALP >120 U/L with a ≥2-fold increase, and Tbili >1.2 mg/dL with a ≥1.5-fold increase from baseline. A separate landmark analysis evaluated alcohol relapse among patients who survived 100 alcohol-free days post-LT hospital discharge. Patients with early naltrexone start within 100 days of discharge were designated as the treatment group and analyzed using an intention-to-treat approach. Age, sex, other MAUD use, incretin therapy, and psychosocial interventions (PSI) were included as fixed covariates. Fine-Gray competing-risk regression evaluated time to first alcohol relapse (PEth >20 ng/mL), with death treated as a competing event. **Results:** We identified 186 participants. Among them, 83 (45%) received naltrexone after LT, including 37 (20%) within 100 days of discharge. Clinically significant laboratory elevations occurred in 5 patients (6%) (Figure 1). Chart review identified alternative explanations in all cases, including graft rejection in 3 (2 biopsy-proven) and obstructive biliary pathology in 2 patients. Compared to the control group, those with early naltrexone start were younger (47.6 vs. 53.7 years, p = 0.035) and had fewer days of pre-LT abstinence (105 vs. 274.5 days, p = 0.002). Early naltrexone start was associated with higher PSI engagement (57% vs. 35%, p = 0.025) and transplant clinic follow-up rates (75% vs. 70%, p = 0.039). Early naltrexone start was associated with an adjusted subhazard ratio of 0.97 (95% CI 0.37-2.56) for alcohol relapse. One-year post-LT survival was non-significantly higher among patients who started naltrexone early (100% vs. 96%, p = 0.58). **Conclusion:** Naltrexone use after LT was not associated with hepatotoxicity. Early initiation of naltrexone was associated with higher PSI engagement and clinic follow-up rates. These findings support the hepatic safety and potential benefit of naltrexone in early post-LT AUD care.

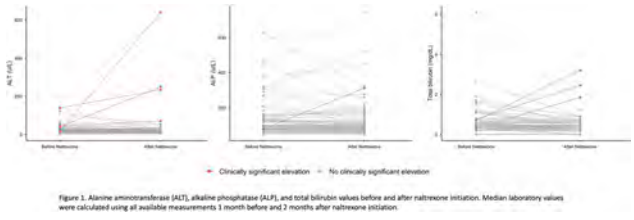

Figure 1. Alanine aminotransferase (ALT), alkaline phosphatase (ALP), and total bilirubin values before and after naltrexone initiation. Median laboratory values were calculated using all available measurements 1 month before and 2 months after naltrexone initiation.

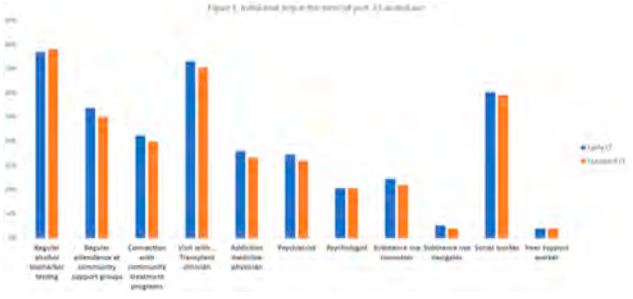
4587 | NATIONAL SURVEY ON MANAGEMENT OF ALCOHOL USE DISORDER POST-LIVER TRANSPLANT FOR PATIENTS WITH ALCOHOL-ASSOCIATED LIVER DISEASE



Debra Yen[1] Po-Hung (Victor) Chen[2] Nicholas Lim[3] Alexander Yang[4] Holly Huang[5] Chelsea Pan[6] Allison Kwong[7] Neil Mehta[6] Gene Im[8] Courtney Sherman[9], [1]California Pacific Medical Center, [2]Johns Hopkins University, [3]University of Rochester, [4]University of California San Diego, [5]University of California, San Francisco (UCSF), [6]University of California, San Francisco, [7]Stanford University Medical Center, [8]Center for Liver Disease and Transplantation, Division of Digestive and Liver Diseases Columbia Univ, [9]University of California San Francisco

Background: Alcohol-associated liver disease (ALD) is the leading indication for liver transplantation (LT) in the United States (US). However, post-LT alcohol use increases risks of graft failure and mortality. Therefore, policies to mitigate alcohol use after transplant are paramount but can vary widely between centers. We sought to examine the spectrum of post-LT strategies employed nationally to manage alcohol use disorder (AUD) in patients transplanted for ALD. **Methods:** We disseminated a web-based survey to one hepatologist at each active adult LT center in the US from November 2025 to April 2026. Medical directors or transplant hepatologists knowledgable of their center practices were selected, and only one response was accepted per center. Early liver transplant (ELT) was defined as LT for individuals with ALD with less than 6 months of alcohol abstinence. Standard LT (SLT) referred to those transplanted after at least 6 months of abstinence. **Results:** Out of 117 LT centers in the US, we received 80 responses (68.4%) representing all 11 UNOS regions. All responding centers perform ELT. Most centers (79%) require psychosocial AUD interventions after ELT, compared with 33% for SLT. Only 29% have a post-LT AUD pharmacotherapy protocol. After ELT, 96% require regular alcohol biomarker testing, and 61% require support group attendance. For routine post-ELT care, 62% require follow-up with addiction providers, 54% with mental health providers, and 47% with social workers. Over half (54%) had different follow-up requirements for ELT compared to SLT, mostly related to increased

frequency of alcohol biomarker testing and visits with addiction providers and/or social work.Nearly all centers routinely test for alcohol biomarkers: 27% for all transplant recipients regardless of indication, 51% for all ALD recipients, and 15% for ELT recipients only. All centers use serum phosphatidylethanol (PEth) for alcohol biomarker testing. In the event of post-LT alcohol use, 76% recommend visits with at least 2 provider specialties that can include the transplant clinician, addiction providers, mental health providers, or social worker (Figure 1). Respondents perceived that center AUD resources are more often utilized than community resources. **Conclusion:** After LT for ALD, routine alcohol biomarker testing is heavily relied upon, with near universal adoption for ELT. Psychosocial intervention requirements are more common in ELT than in SLT, and most centers lack an AUD pharmacotherapy protocol. Similar care plans are utilized for ELT and SLT in the event of post-LT alcohol use, which typically involve a multimodal approach including visits with different team members and connection with community AUD resources. Future work determining the impact of post-LT AUD policies on clinical outcomes can guide recommendations for optimal AUD management and resource allocation priorities in this unique population.

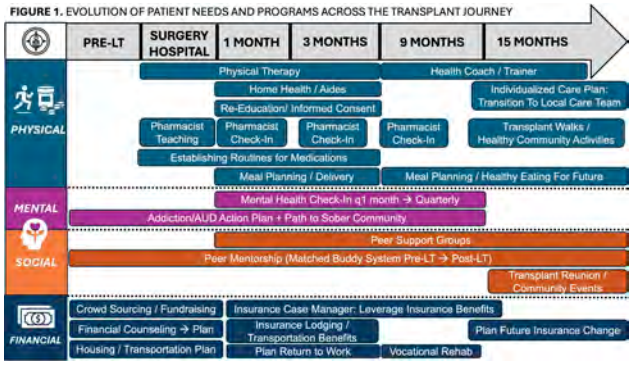
4588 | THE IDEAL POST-TRANSPLANT PROGRAM: PATIENT AND CAREGIVER PERSPECTIVES FROM A LARGE LONGITUDINAL LIVER TRANSPLANT SURVIVORSHIP COHORT



Sarah Lieber[1] Gi Giamarqo[2] Alvaro Noriega Ramirez[2] Dyanna Gregory[2] Arjmand Mufti[2] Madhukar Patel[2] Jeremy Louissaint[2] Shannan Tujios[2] Cheri Goldstein[2] Samantha Kimbrough[2] Brandy Brasfield[2] Melissa Fogg[2] Derek Bartlett[2] Lisa VanWagner[2] Amit Singal[2] Simon Craddock Lee[3] Donna Evon[4], [1]UT Southwestern Division of Digestive and Liver Diseases, [2]University of Texas Southwestern Medical Center, [3]The University of Kansas Medical Center, [4]University of North Carolina

Background: Liver transplantation (LT) is lifesaving but can pose major challenges to patients and caregivers. How their needs evolve over time remains poorly understood. LT programs differ in structure, available resources, and approaches to long-term support. We characterized longitudinal needs of LT recipients (LTRs) and their caregivers, to identify the programs and resources considered most effective in promoting successful post-LT recovery. **Methods:** This longitudinal mixed-methods study enrolled adult LTRs and their caregivers at a large transplant center. Participants completed 3 interviews at ~3, 9, and 15 months post-LT, alongside surveys assessing clinical and patient-reported outcomes (PROs). Interviews focused on post-LT physical, emotional, psychological, social, and financial challenges, as well as resources/programmatic needs to optimize LT care. De-identified transcripts were analyzed using deductive thematic content analysis (NVivo). Sequential analyses examined theme evolution over time. PRO measures evaluated health literacy (Newest Vital Sign), financial toxicity (COST-FACIT), physical and psychological symptoms, support, and quality of life (PROMIS). **Results:** Among 178 LTRs enrolled (40% female; mean age 52 years [SD 12]), 121 completed 6-month post-LT surveys. LT indication included ALD (50%) and MASLD (29%); 16% had HCC. A total of 108 qualitative interviews were analyzed—31% included caregivers and 30 LTRs completed the 3 interviews at ~3, 9, and 15-months post-LT. LTRs and caregivers emphasized the need for “proactive” not “reactive” post-LT care. Key elements included 24/7 access to the transplant team, strong coordination with local providers, and efficient communication. Suggested interventions included case managers, in-home phlebotomy, transplant “advocates”, visual care plans, and integrated clinics. Desired programs included: 1) re-orientation/ongoing education (28% had limited health literacy), 2) physical and medication support, 3) psychological and social support

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(mean PROMIS anxiety 48 [SD 10]; depression 47 [SD 9]), 4) financial counseling (21% reported high financial toxicity and 9% had transportation challenges), and 5) caregiver training. **Figure 1** highlights shifting temporal needs: early physical and financial support, later mental health, social, and community support. Programmatic needs also varied by acuity and indication: LTRs with ALD wanted destigmatizing support beyond structured sobriety programs to build sober communities. Those undergoing inpatient LT evaluation requested substantial post-LT re-orientation due to inability to fully engage in the pre-transplant process. **Conclusion:** In a large prospective survivorship cohort, we identified key features of the ideal post-transplant program. Evolving LTR and caregiver needs demand a shift from reactive to proactive, longitudinal care models in post-LT program design.

4589 | INVESTIGATING HEPATITIS B VIRUS RECURRENCE IN LIVER TRANSPLANT RECIPIENTS: A SINGLE-CENTER RETROSPECTIVE COHORT STUDY

Tonguç Utku Yılmaz[1] Iftihar Koksal[1] Alara Apa[2] Serhat Özfıstıkçı[2] Ece Cılli[2] İman Cihan[2] Zehra Karabal[2] Ömer Şaka[2] Dença Silahlı[2] Ufuk Canözer[2] Sevan Dağlıyan[2], [1]Acıbadem Atakent Hospital, [2]Acıbadem Mehmet Ali Aydınlar University School of Medicine

Background: Hepatitis B virus (HBV) infection is a primary indication for liver transplantation globally and in Türkiye. Despite effective post-transplant prophylaxis (Hepatitis B immunoglobulin and nucleos(t)ide analogues), HBV recurrence still affects approximately 10% of recipients. High pre-transplant viral load, HBeAg positivity, and poor adherence to immunosuppression are known recurrence determinants. A comprehensive assessment of recurrence risk factors is essential to optimize post-transplant prophylaxis and improve long-term outcomes in high-risk patients. The present study aims to investigate the incidence and associated risk factors of HBV recurrence among Turkish patients who underwent living donor liver transplantation (LDLT) for HBV-related disease at Acıbadem Atakent Hospital in Türkiye, a large transplant center at a university hospital. **Methods:** This retrospective, single-center cohort study included records of 150 adult Turkish patients who underwent LDLT for HBV-related disease at our center between 2014 and 2025. Collected data consist of demographic, clinical, biochemical, virological, and pre-transplant tumor parameters, alongside specific HBV prophylactic and immunosuppressive protocols. Patient characteristics and HBV recurrence incidence were summarized using descriptive statistics. Continuous variables were presented as mean ± standard deviation or median (interquartile range (IQR)), and categorical variables as n (%). Patients with and without HBV recurrence were compared using Mann Whitney U and Fisher's exact test. The distribution of HBV recurrence after LDLT over time was assessed with Kaplan-Meier survival analysis, groups were compared with the log-rank test. A p-value of <0.05 was considered statistically significant. **Results:** Among 150 patients (76.0% male, mean age 54.17 ± 9.65) included in the study, HBV recurrence was observed in 2.7% (n = 4). Median follow-up time was 42.7 months (IQR 17.1-69.9), and median time to HBV recurrence was 12 months (IQR

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

9.3-15.0). Only one of the 53 patients with hepatocellular carcinoma (HCC) had HCC recurrence. Death occurred in 21 patients (14%), and 1 patient (0.7%) required retransplantation. Hepatitis D virus coinfection was present in 23.3% of the patients, while 4.0% had Hepatitis C virus (HCV) coinfection. Positive HBV DNA and HCC presence at the time of LDLT were not significant for HBV recurrence ($p = 1.000$ and $p = 0.614$, respectively). Sex differed significantly between two groups ($p = 0.043$). Kaplan-Meier analysis showed a significant difference in HBV recurrence-free survival according to HCV coinfection (log-rank $p = 0.022$). **Conclusion:** The results of this study support the effectiveness of a structured post-LDLT prophylaxis and follow-up protocol in prevention of the recurrence of HBV infection. HCV coinfection was associated with a poorer HBV recurrence-free survival, suggesting a potential prognostic relevance.

4590 | INCREMENTAL INCREASE IN DONOR-DERIVED CELL-FREE DNA AND RISK OF REJECTION IN LIVER TRANSPLANT RECIPIENTS

Phil Gauthier[1] Mamatha Bhat[2] Ali Zarrinpar[3] Daniel Maluf[4] D. Giovanni Biagini[1] Nina Verstraete[1] Andrew Doud[1] Yen-An Chen[1] Navchetan Kaur[1] Felipe Acosta[1] Ebad Ahmed[1] Amy Baer[1] Mita Banik[1] Naoshin Haque[1] Sarah McCormick[1] Kate Woodruff[1] Jing Xie[1] Nour Al Haj Baddar[1] Niraja suresh[1] Zachary Demko[1] Adam Prewett[1] Hossein Tabriziani[1] Sangeeta Bhorade[1] Juliet Emamaullee[5], [1]Natera, Inc., [2]University Health Network / University of Toronto, [3]University of Florida, [4]University of Maryland School of Medicine, [5]Keck School of Medicine of USC

Background: Donor-derived cell-free DNA (dd-cfDNA) is a validated biomarker that is often used as a binary discriminator for rejection in patients with solid organ transplants. Whether there is a more nuanced application to dd-cfDNA utility as a continuous biomarker to assess allograft status is not well-known. Here, we utilized a cross-sectional study of liver transplant (LTx) patients to investigate the effect of time post transplant on dd-cfDNA levels and test if incremental increases in dd-cfDNA correlate with higher probability of rejection. **Methods:** Adult LTx patients were included in this study. Blood samples (drawn ≥ 14 days post LTx) were collected. dd-cfDNA fraction (%) levels were measured using the Prospera™ test. Linear generalized additive model (GAM) was fit to understand the effect of time since transplant on dd-cfDNA in stable patients (defined by lack of rejection and normal liver function tests [LFTs]). A univariate logistic regression was performed to assess the risk of each doubling of dd-cfDNA% with rejection diagnosis, defined as either biopsy-proven rejection activity index ≥ 3) or treated clinical rejection. Statistical differences were assessed using a log-likelihood ratio test. **Results:** 199 LTx patients with 209 dd-cfDNA samples were included; 32 experienced a total of 33 rejection episodes; the remaining 167 had no rejection. Out of the 199 patients, 135 (67.8%) were identified as stable. The GAM model showed no effect of time since transplant on dd-cfDNA% in stable LTx patients; **Fig 1A**). Logistic regression modelling revealed that each two-fold increase in dd-cfDNA% conferred a 4.75x higher odds of rejection (95% CI: 2.89-7.82; $p = 6.82 \times 10^{-18}$; **Fig 1B**). **Conclusion:** While standard clinical practice uses dd-cfDNA% as a binary discriminator for rejection, we found that when used as a continuous variable, the rejection risk increases monotonically with higher dd-cfDNA% levels in LTx patients. As no effect of time since transplant was observed on dd-cfDNA% levels, the increase in dd-cfDNA% is more likely associated with rejection rather than post-transplant temporal changes.

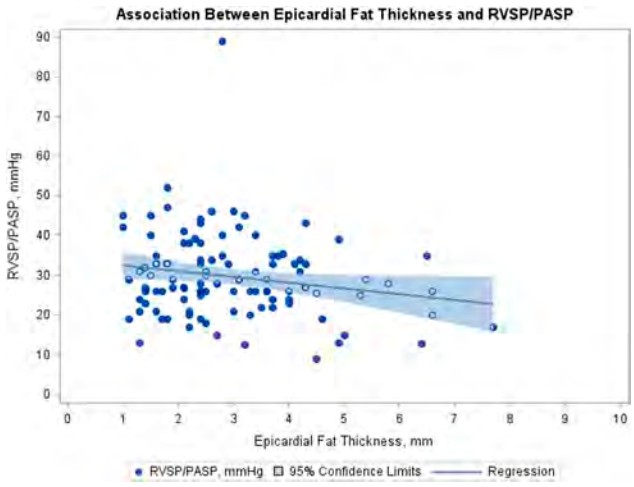
4591 | LOWER EPICARDIAL FAT THICKNESS IS ASSOCIATED WITH DIASTOLIC DYSFUNCTION AND PULMONARY HEMODYNAMIC ABNORMALITIES IN CIRRHOSIS



Anwesha Satapathy[1] Benjamin Seifer[2] Tasmia Promi[2] Manahil Muneeb[2] James Park[2] Amgad Makaryus[2] Sanjaya Satapathy[1], [1]Northshore University Hospital/ Northwell Health, [2]Northwell Health

Background: Cirrhotic cardiomyopathy (CCM) is characterized by impaired cardiac reserve, diastolic dysfunction, and pulmonary hemodynamic abnormalities in patients with advanced liver disease. Epicardial adipose tissue is a metabolically active cardiac fat depot implicated in myocardial remodeling and cardiovascular dysfunction; however, its role in CCM remains poorly understood. We aimed to evaluate the association between epicardial fat thickness (EFT) and the presence of diastolic dysfunction, as well as its individual echocardiographic components, in liver transplant candidates with cirrhosis. **Methods:** We conducted a retrospective study of adult patients with cirrhosis undergoing liver transplant evaluation at a tertiary transplant center who underwent pre-transplant transthoracic echocardiography. EFT was measured on echocardiography and analyzed both continuously and by quartile distribution. The primary outcome was the presence or absence of diastolic dysfunction on echocardiography. Individual echocardiographic components of diastolic dysfunction including medial E/e' and left atrial volume index (LAVI), as well as other parameters of right ventricular systolic pressure/pulmonary artery systolic pressure (RVSP/PASP) were also evaluated separately. Multivariable logistic and linear regression analyses were performed adjusting for age, body mass index (BMI), diabetes mellitus, and sex. **Results:** A total of 202 patients with available EFT measurements were included. Patients with higher EFT were older and had higher BMI, while MELD score and liver frailty index were similar across EFT quartiles. Lower EFT was independently associated with the presence of diastolic dysfunction on multivariable logistic regression analysis (odds ratio [OR] 0.59, 95% confidence

interval [CI] 0.38–0.91, p = 0.017). Among individual components, lower EFT was independently associated with higher pulmonary pressures, with an inverse relationship observed between EFT and RVSP/PASP on adjusted linear regression analysis (β = −2.09, 95% CI −3.93 to −0.26, p = 0.026). Although continuous associations between EFT and medial E/e' were modest, patients with lower EFT demonstrated broader distributions and clustering of elevated filling-pressure abnormalities. No independent association was observed between EFT and elevated LAVI after adjustment. **Conclusion:** Lower epicardial fat thickness was independently associated with diastolic dysfunction and elevated pulmonary pressures in cirrhosis. These findings suggest that reduced EFT may identify a distinct frailty-associated cardiocirculatory phenotype in advanced liver disease rather than a traditional obesity-mediated cardiometabolic process. EFT may serve as a novel non-invasive imaging biomarker of advanced cirrhotic cardiomyopathy in liver transplant candidates.

4592 | PULMONARY HEMODYNAMIC ABNORMALITIES AND FRAILTY IN LIVER TRANSPLANT CANDIDATES: ASSOCIATION BETWEEN ECHOCARDIOGRAPHIC MARKERS OF CIRRHOTIC CARDIOMYOPATHY AND FRAILTY

Manahil Muneeb[1] Tasmia Promi[1] Anwesha Satapathy[1] Benjamin Seifer[1] James Park[1] Amgad Makaryus[1] Nabil Dagher[1] Sanjaya Satapathy[1], [1]Northwell Health

Background: Frailty is an important predictor of adverse outcomes in patients with cirrhosis awaiting liver transplantation. Cirrhotic cardiomyopathy (CCM), characterized by structural and functional cardiac abnormalities, may contribute to impaired physiologic reserve and frailty; however, the relationship between echocardiographic manifestations of CCM and frailty remains poorly defined. We aimed to evaluate the association between echocardiographic markers of CCM and frailty among liver transplant candidates. **Methods:** We performed a retrospective cohort study of adult liver transplant candidates who underwent pre-transplant transthoracic echocardiography and frailty assessment at a tertiary transplant center between 2014 and 2023. Echocardiographic markers of CCM included medial E/e', left atrial volume index (LAVI), right ventricular systolic pressure/pulmonary artery systolic pressure (RVSP/PASP), and right atrial (RA) pressure. A composite CCM burden score was constructed based on abnormal echocardiographic parameters. Frailty was assessed using the Liver Frailty Index (LFI), Karnofsky Performance Status (KPS), and binary frailty definitions including LFI ≥ 4.5. Multivariable linear and logistic regression models adjusted for age, sex, body mass index, diabetes mellitus, and MELD score. **Results:** Among 288 liver transplant candidates with available echocardiographic data, 267 had sufficient data for CCM burden assessment and 227 had available frailty assessment. Elevated RVSP/PASP (≥ 35 mmHg) demonstrated the strongest association with frailty outcomes. In adjusted logistic regression analysis, elevated RVSP/PASP was independently associated with increased odds of LFI-defined frailty (OR 6.07, 95% CI 1.73–21.27, p = 0.0048). Continuous RVSP/PASP demonstrated a borderline association with frailty risk (OR 1.05 per mmHg increase, 95% CI 0.997–1.114, p = 0.0657). In contrast, composite CCM burden score was not independently associated with continuous LFI, KPS at listing, KPS at transplant, or frailty status after multivariable adjustment. Correlation analyses demonstrated

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

moderate inter-correlation among echocardiographic CCM markers but weak correlations between most markers and frailty measures. **Conclusion:** Pulmonary hemodynamic abnormalities, particularly elevated RVSP/PASP, were independently associated with frailty in liver transplant candidates, whereas composite echocardiographic CCM burden was not. These findings suggest that pulmonary vascular and hemodynamic dysfunction may contribute more substantially to impaired physiologic reserve than traditional structural echocardiographic markers of CCM. Further prospective studies are needed to determine whether targeted cardiopulmonary assessment may improve frailty risk stratification in patients with advanced liver disease.

4593 | REAL-WORLD USE, TOLERABILITY, AND MORTALITY ASSOCIATIONS OF PHARMACOTHERAPY FOR ALCOHOL USE DISORDER AFTER LIVER TRANSPLANTATION IN THE UNITED STATES

Wei Zhang[1] Luis Díaz[2] Kelly Hsu[3] Cassidy Sun[1] Stephanie Mrowczynski[4] Peng-Sheng Ting[4] Ami Patel[5] Deepika Devuni[6] Christina Leyson[7] Ellen Green[8] Sasha Deutsch-Link[9] Giuseppe Joseph Morelli[4] Ana Ivkovic[1] Russell Goodman[1] Esperance Schaefer[10] Jay Luther[1] Heidi Yeh[1] Emily Bethea[1], [1]Massachusetts General Hospital, [2]University of California San Diego, [3]Tuft University School of Medicine, [4]Tulane University School of Medicine, [5]Univeristy of Massachusetts, [6]University of Massachusetts, [7]University of Kentucky, [8]University of North Carolina, Chapel Hill, NC, USA, [9]UNC Chapel Hill, [10]Brigham and Women's Hospital

Background: Liver transplantation (LT) is increasingly performed for alcohol-associated liver disease (ALD), including in patients with active alcohol use, making ongoing management of alcohol use disorder (AUD) after LT a growing priority. Several pharmacotherapies reduce drinking in the general AUD population, but their uptake, tolerability, and clinical associations after LT are poorly characterized. We examined real-world prescribing patterns and outcomes across a multinational transplant consortium. **Methods:** We conducted a multicenter (5 centers) retrospective cohort study of adults who underwent LT (2016–2025) with documented AUD/alcohol-associated liver disease in the United States. We characterized pre- and post-LT AUD pharmacotherapy and non-pharmacological management, reasons for discontinuation, and modeled all-cause mortality using Cox proportional-hazards regression adjusted for age, sex, race/ethnicity, Model for End-Stage Liver Disease (MELD) at LT, post-LT AUD pharmacotherapy, and post-LT alcohol use. **Results:** We included 445 recipients with a mean age of 55.4 years, 70.2% male, and 89.4% White; 39.8% had active alcohol use at baseline. Before LT, only 15.1% had received any AUD pharmacotherapy (naltrexone 7.4%, acamprosate 6.5%), while approximately half (49.9%) had received non-pharmacological treatment. After LT, 25.5% received at least one AUD medication, most commonly naltrexone (20.0%), followed by acamprosate (6.3%), gabapentin (4.4%), and topiramate (1.2%); disulfiram and varenicline were rarely used. Over 1,713 person-years (62 deaths; maximum follow-up 9.4 years), discontinuation attributable to side effects was uncommon—patient choice and perceived lack of efficacy were the leading reasons—supporting overall tolerability. In adjusted models, post-LT AUD pharmacotherapy was associated with a numerically lower but non-significant hazard of all-cause mortality (HR 0.64, 95% CI 0.28–1.47; p = 0.295). Black and Hispanic race/ethnicity were associated with higher mortality, though small subgroup sizes warrant caution (**Figure**). **Conclusion:** In this multinational cohort, AUD pharmacotherapy remained underutilized after LT—used in only about one in four recipients and dominated by naltrexone—yet appeared well tolerated, with side effects rarely prompting discontinuation. A consistent but statistically non-significant signal toward lower mortality supports the safety and feasibility of post-LT AUD pharmacotherapy and underscores the need for adequately powered prospective studies, which the expanding LICOP-AUD consortium aims to address.

4594 | WAITLIST AND POST-TRANSPLANT OUTCOMES OF ACUTE ALCOHOL-ASSOCIATED HEPATITIS COMPARED WITH NON-AH ALCOHOL-ASSOCIATED LIVER DISEASE: A CONTEMPORARY NATIONAL ANALYSIS

Sanjaya Satapathy[1] James Park[2] Nabil Dagher[2] Nishi Joshi[2], [1]Northshore University Hospital/Northwell Health, [2]Northwell Health

Background: Liver transplantation (LT) for acute alcohol-associated hepatitis (AH) has increased substantially in recent years; however, concerns regarding waitlist prioritization and long-term post-transplant outcomes persist. We aimed to compare waitlist and post-transplant outcomes between patients with AH and non-AH alcohol-associated liver disease (ALD) using a contemporary national cohort. **Methods:** Adult ALD candidates listed for LT in the United States were identified from the United Network for Organ Sharing (UNOS) database. Patients were categorized as AH or non-AH ALD. Waitlist outcomes included waitlist death, removal for clinical deterioration, and transplantation. Post-transplant outcomes included patient survival and graft survival. Kaplan–Meier analyses and multivariable Cox proportional hazards models adjusted for demographic, clinical, and donor characteristics were performed. Sensitivity analyses included granular ALD subgroup comparisons and interaction analyses by transplant era and MELD strata. **Results:** Among 96,372 waitlisted ALD candidates, 4,098 (4.3%) had AH. The proportion of AH listings increased markedly across transplant eras, rising from < 1% before 2014 to approximately 15% in the contemporary era. AH candidates were more likely to undergo transplantation (75.3% vs 54.9%) and less likely to experience waitlist death (6.2% vs 13.1%) or removal for clinical deterioration (3.4% vs 7.6%) compared with non-AH ALD candidates.In adjusted competing-risk analyses, AH was not independently associated with waitlist death (HR 0.98, 95% CI 0.84–1.14, p = 0.79). However, patients with combined alcohol-associated liver disease and HCV demonstrated significantly higher waitlist dropout risk compared with alcohol-associated cirrhosis without AH (HR 1.36, 95% CI 1.24–1.48, p < 0.001).Among 53,245 LT recipients, unadjusted Kaplan–Meier analyses demonstrated superior patient and graft survival in AH recipients (log-rank p < 0.001 for both). However, after multivariable adjustment, AH was not independently associated with post-transplant mortality (adjusted HR 1.08, 95% CI 0.94–1.24, p = 0.26) or graft failure (adjusted HR 1.11, 95% CI 0.99–1.26, p = 0.09). Findings remained consistent in donor-adjusted sensitivity analyses and across MELD strata. A borderline interaction between AH and transplant era was observed for patient survival (interaction p = 0.051), suggesting potential temporal variation in outcomes. **Conclusion:** Liver transplantation for AH has expanded rapidly in the United States. Despite favorable unadjusted waitlist and post-transplant outcomes, adjusted analyses demonstrated post-transplant patient and graft survival comparable to traditional ALD recipients. These findings support the continued use of LT in carefully selected patients with AH.

Table 1. Adjusted Cox Proportional Hazards Models, Interaction Analyses, and Sensitivity Analyses for Post-Transplant Outcomes

Analysis Category	Comparison / Model	Adjusted Hazard Ratio (95% CI)	p-value
Primary adjusted models			
	Primary patient survival model	1.09 (0.95–1.25)	0.214
	Primary graft survival model	1.11 (0.99–1.26)	0.086
	Donor-adjusted graft survival sensitivity model	1.11 (0.98–1.26)	0.094
Interaction analyses			
	AH × MELD group interaction	—	0.863
	AH × transplant era interaction	—	0.051
Granular ALD phenotype sensitivity analyses			
	AH vs alcohol-associated cirrhosis without AH	1.09 (0.95–1.25)	0.214
	Alcohol + HCV vs alcohol-associated cirrhosis without AH	1.25 (1.14–1.37)	<0.001

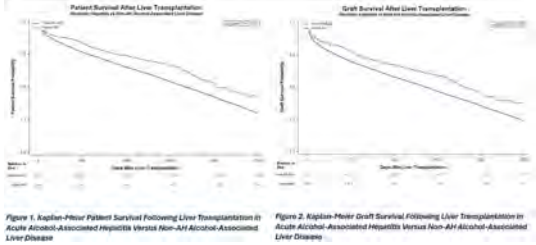

Figure 1. Kaplan–Meier Patient Survival Following Liver Transplantation in Acute Alcohol-Associated Hepatitis Versus Non-AH Alcohol-Associated Liver Disease

4595 | AFP KINETICS AS A BIOLOGY GATEKEEPER DURING DOWNSTAGING BEYOND T2: AN INTENTION-TO-TREAT ANALYSIS

Nishtha Singh[1] Erin Duggan[2] Dustin Carpenter[3] Rebecca Craig-Schapiro[3] Benjamin Samstein[3] Juan Rocca[4], [1]NewYork-Presbyterian/Weill Cornell Medical College, [2]Columbia University Medical Center, [3]Weill Cornell Medicine, [4]NewYork-Presbyterian/Weill Cornell Medical Center

Background: In HCC treated beyond OPTN T2, the real clinical question is often not "who can be transplanted," but "who can stay stable long enough to reach the waitlist." We tested whether temporal AFP kinetics capture this biologic bottleneck across the downstaging timeline. **Methods:** We analyzed 167 consecutive HCC patients treated outside OPTN T2 criteria (2015–2025), grouped as UNOS downstaging-eligible (DS, n = 65) versus all-comers beyond DS (AC, n = 102). AFP was recorded at routine clinical anchors (diagnosis and subsequent treatment/listing milestones). Biology was summarized by diagnostic AFP strata (0–20, 21–200, 201–1000, > 1000 ng/mL) and a dynamic peak-to-last pre-decision AFP response metric (peak AFP prior to the decision window vs last available pre-decision anchor AFP; response ≥ 50% decline). Primary endpoint was intention-to-treat (ITT) pathway failure (progression and/or waitlist dropout) from diagnosis, censoring at transplant. Secondary endpoints were listing and transplant rates. **Results:** AC entered with substantially higher-risk AFP biology than DS (median AFP 58.7 vs 12.8 ng/mL; AFP > 1000: 24.5% vs 7.7%) and retained a larger high-risk tail at the last anchor (AFP > 1000: 15.7% vs 3.1%). Clinically, this translated into early ITT attrition: pathway failure occurred in 50.0% of AC (51/102) versus 18.5% of DS (12/65). Failure-free survival declined in a graded, clinically intuitive manner by AFP at diagnosis: AFP 0–20, 84.3%/78.4% vs AFP > 1000, 50.4%/50.4% at 12/24 months (KM N = 166; 51 events). Listing was achieved in 43.1% of DS vs 23.5% of AC; among listed patients, transplant rates were similar (85.7% vs 79.2%). **Conclusion:** AFP kinetics operationalize tumor biology during downstaging beyond T2. High diagnostic AFP—particularly > 1000—marks early pathway attrition before listing, while access after listing appears comparable. Integrating dynamic AFP response with tumor burden may improve counseling, triage, and timing of downstaging escalation.

4596 | POST LIVER TRANSPLANT ALCOHOL RELAPSE RATE – A SINGLE CENTER EXPERIENCE

Jordan Holliday[1] Lydia Aye[1] Vikrant Rachakonda[1], [1]University of California Davis

Background: Alcohol associated liver disease (ALD) is the most common indication for liver transplant in the United States. Relapse rates for alcohol use post liver transplant (LT) have been reported to be 8-20%. We defined relapse in our patients as any patient that had a positive PETH result. Our aim is to characterize patients who relapsed with alcohol use post-LT and to identify potential risk factors and interventions to help decrease the risk of relapse in post liver transplant patients. **Methods:** Method: Retrospective chart review of post-LT patients from July 15, 2023 to July 31, 2025 at a single liver transplant center in the United States. **Results:** Results: Ninety-four patients underwent liver transplant, 79 patients were transplanted for ALD (n = 67) or alcohol associated hepatitis (AH) (n = 12).

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Eleven (13.9%) patients relapsed post-LT, 9 (13.4%) ALD and 2 (16.7%) AH. There was no difference in rate of relapse between ALD and AH patients (p = 0.528). Time to relapse from last alcohol use for ALD (333 days) and AH (267) was not significantly different (p = 0.727). SIPAT score pre-LT for ALD (25) and AH (25) was not significantly different (p = 0.781). MELD at time of LT was significantly higher for those who relapsed (35) compared to those who did not (25), p = 0.009. **Conclusion:** Conclusions: Our single center experience in post-LT alcohol relapse rate is consistent with prior studies. There have been several studies that have examined factors that influence post-LT relapse. Most of these studies examine risk factors pre-LT. There was no difference in relapse rates and time to relapse from last alcohol use between those transplanted for ALD and for AH. Time of sobriety should not be used alone in determining transplant candidacy. Our patients were found to be minimally acceptable candidates by the SIPAT score and there was no significant difference in SIPAT scores between patients who did or did not relapse post-LT. Future studies should focus on early prediction for relapse in our post-LT patients and developing early interventions for these patients.

4597 | COMPARISON OF TRANSARTERIAL RADIOEMBOLIZATION VERSUS TRANSARTERIAL CHEMOEMBOLIZATION AS BRIDGING THERAPY TO LIVER TRANSPLANTATION IN PATIENTS WITH HEPATOCELLULAR CARCINOMA

Arpit Amin[1] Lucia Romero Socorro[1] Paul Gaglio[2] Abhishek Kumar[1] Pratik Shukla[1] Keri Lunsford[3] Mumtaz Niazi[1] Vivek Lingiah[1] Zaid Tafesh[1] Flavio Paterno[3], [1]Rutgers New Jersey Medical School, [2]Rutgers NJ Medical School, [3]Rutgers University - New Jersey Medical School

Background: There is scant data in the literature about the optimal bridging locoregional treatment (LRT) option for hepatocellular carcinoma (HCC) in patients on the liver transplant (LT) waitlist. LRT resulting in complete pathologic necrosis of HCC on liver explant has been shown to improve HCC recurrence free survival in LT recipients. The main objective of this study is to evaluate the effectiveness of trans-arterial radioembolization (TARE) based LRT protocol versus trans-arterial chemoembolization (TACE) based LRT protocol in achieving complete pathologic necrosis of HCC on liver explant specimens of patients, who underwent LT. **Methods:** This is a single-center retrospective study of 80 consecutive HCC patients, who underwent LT between January 1, 2010, and August 31, 2025. Patients with HCC were primarily treated with TACE based LRT protocol between January 1, 2010, till December 31, 2019. Subsequently, patients with HCC were primarily treated with TARE based LRT protocol between January 1, 2020 till August 31, 2025. Patients were excluded if there was any crossover between TACE and TARE treatment arms. We compared pathologic necrosis, microvascular invasion, recurrence rate, and overall survival between two study groups. **Results:** Out of 80 HCC LT recipients, 64 patients (with total of 97 HCC lesions) underwent TACE based LRT and 16 patients (with total of 23 HCC lesions) underwent TARE based LRT. There was a longer interval between last TARE based LRT to LT compared to last TACE based LRT to LT (456 days vs 238 days, p 0.003) suggestive of more durable radiologic treatment response with TARE on LT waitlist. Mean number of LRT sessions were similar between TACE based LRT and TARE based LRT (1.28 vs 1.39, p 0.387). Complete pathologic necrosis was identified in 19/23 (83%) TARE treated HCC lesions compared to 51/97 (53%) TACE treated HCC lesions (p 0.01). Microvascular invasion was identified in 1/16 (6%) of TARE treated HCC patients compared to 8/97 (8%) of TACE treated HCC patients (p 0.479). There was no statistically significant difference in 2-year HCC recurrence rates between two groups (0% in TARE group vs 11% in TACE group, p 0.334). There was no statistically significant difference in overall 2-year survival rates between two groups (88% in TARE group vs 92% in TACE group, p 0.281). **Conclusion:** TARE based LRT is more effective in achieving complete pathologic necrosis of HCC lesions compared to TACE based LRT.

Table 1 – Clinical and HCC tumor characteristics

	TACE group (n=97)	TARE (Y-90) group (n=23)	p-value
Age (years)	60 ± 8	64 ± 7	0.04
MELD 3.0 score at LT	15 ± 8	13 ± 6	0.29
Time on waitlist	304 ± 408	371 ± 164	0.52
Time from last LRT to LT	238 ± 242	456 ± 286	0.003
Tumor size	2.2 ± 0.9	2.5 ± 1.5	0.21
AFP at diagnosis	37 ± 62	25 ± 61	0.50
AFP prior to LT	15 ± 28	22 ± 50	0.45
Pathologic response			0.01

4598 | SIX-MINUTE WALK DISTANCE VERSUS LIVER FRAILTY INDEX IN PREDICTING POST-TRANSPLANT OUTCOMES IN HEPATOPULMONARY SYNDROME

Amani Elshaer[1] Fares Jamal[2] Elizabeth Carey[1], [1]Mayo Clinic Arizona, [2]Mayo Clinic

Background: In patients with hepatopulmonary syndrome (HPS), impaired oxygenation and exercise intolerance may limit the reliability of walk-based assessments such as the 6-minute walk distance (6MWD), raising concern about its use in this population. Alternatively, the Liver Frailty Index (LFI) is less dependent on cardiopulmonary reserve may be preferred as the initial frailty assessment; however, the comparative superiority of either test remains uncertain. Our aim was to compare the predictive validity of pretransplant 6MWD and LFI analyzed as continuous variables for post-transplant ICU length of stay (LOS), hospital LOS, and 30-day readmission in patients with HPS undergoing LT. **Methods:** This is a retrospective single-center case series of all HPS patients undergoing LT at our institution. Pretransplant 6MWD (meters) and LFI were entered as unmodified continuous predictors. Post-transplant outcomes, ICU LOS, hospital LOS, and 30-day readmission, were analyzed as continuous variables. Pearson correlation coefficients and simple linear regression were used between each frailty measure and each outcome. **Results:** Nine HPS patients (67% female; mean age 54.9 ± 15.3 years; mean BMI 30.8 kg/m²; mean MELD 3.0 = 12.2) underwent LT; no patients were denied or died on the waitlist. Mean 6MWD was 337.9 ± 170.7 m (range: 40–495 m) and mean LFI was 3.64 ± 1.07 (range: 2.25–5.50). Mean ICU LOS was 2.7 ± 3.1 days and mean hospital LOS was 19.7 ± 27.4 days; 30-day readmission occurred in 6 of 9 patients (67%). As continuous predictors, 6MWD demonstrated statistically significant correlations with all three post-transplant outcomes: ICU LOS ($r = -0.78$, $p = 0.014$, $R^2 = 0.604$), hospital LOS ($r = -0.83$, $p = 0.005$, $R^2 = 0.694$), and 30-day readmission ($r = 0.69$, $p = 0.038$). On linear regression, each 100-meter reduction in 6MWD corresponded to approximately 1.4 additional ICU days ($\beta = -0.014$/m) and 13.4 additional hospital days ($\beta = -0.134$/m). Results remained significant when adjusted for MELD 3.0. In contrast, LFI did not reach statistical significance for any post-transplant outcome: ICU LOS ($r = 0.54$, $R^2 = 0.291$, $p = 0.134$), hospital LOS ($r = 0.65$, $R^2 = 0.428$, $p = 0.056$), and 30-day readmission ($r = -0.46$, $p = 0.219$). Neither 6MWD nor LFI significantly predicted waitlist duration. **Conclusion:** Pretransplant 6MWD was statistically significant predictor of all measured post-transplants substantially outperforming LFI, which did not reach significance for any outcome. These findings are likely reflective of the underlying physiology of HPS. The oxygen-dependent impairment of ambulation makes 6MWD more predictive of the cardiopulmonary reserve, unlike the LFI which reflects the musculoskeletal frailty with the grip strength and chair-stand components. The linear regression estimates, approximately 13 additional hospital days per 100-meter decrement in 6MWD, offer a clinically actionable threshold for risk counseling and resource planning.

4599 | INTERACTION BETWEEN LIPOPROTEINS AND BODY COMPARTMENTS IN LIVER TRANSPLANT RECIPIENTS

Tsola Efejuku[1] Olivia Reszczynski[1] Alexis Kim[2] Mohammad Siddiqui[1], [1]University of Virginia, [2]Virginia Commonwealth University

Background: Cardiovascular disease (CVD) is a leading cause of morbidity and mortality following liver transplantation (LT), with atherosclerotic cardiovascular disease (ASCVD) representing a major contributor to adverse long-term outcomes. Sarcopenic obesity and altered lipoprotein metabolism are increasingly recognized as important drivers of cardiometabolic risk in LT recipients; however, the relationship between body composition and advanced lipoprotein profiles remains poorly defined. Our goal was to evaluate the associations between MRI-derived body composition parameters, metabolomic markers, and NMR-derived lipoprotein subclasses in LT recipients. **Methods:** Adult LT recipients followed at a tertiary transplant center from 03/2013–10/2023 underwent MRI-based body composition analysis and nuclear magnetic resonance (NMR)-based metabolomic and lipoprotein profiling. Body composition variables included fat-free muscle volume (FFMV), muscle fat infiltration (MFI), and visceral adipose tissue index (VATi). Lipoprotein outcomes included LDL particle concentration (LDL-P), small LDL-P, HDL particle concentration (HDL-P), and HDL subclasses. Additional analyses evaluated inflammatory markers (GlycA), gut metabolites, and branched-chain amino acids (BCAA). Linear regression models were performed in unadjusted analyses and adjusted for age, sex, and BMI. Independent-samples t-tests compared normal versus abnormal body

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

composition groups. Statistical significance was defined as $p < 0.05$. **Results:** A total of 48 LT recipients were included. Higher MFI was independently associated with lower LDL-P (β −40.64, $p = 0.008$) and higher HDL-P (β 2.28, $p < 0.001$). Greater VATi was associated with increased HDL-P (β 3.29, $p = 0.008$) and large HDL-P (β 3.16, $p = 0.003$). Inflammatory profiling demonstrated inverse associations between GlycA and HDL subclasses, including small HDL-P (β −0.018, $p = 0.002$). BCAA metabolites were strongly associated with atherogenic lipoprotein phenotypes, including higher LDL-P (β 0.36, $p < 0.001$) and small LDL-P (β 0.38, $p < 0.001$). Patients with abnormal MFI demonstrated significantly lower LDL-P and higher large HDL-P concentrations compared to patients with normal MFI ($p = 0.008$). **Conclusion:** Skeletal muscle composition, visceral adiposity, inflammatory markers, and amino acid metabolism are strongly associated with lipoprotein remodeling following LT. MFI and BCAA metabolism demonstrated the strongest relationships with atherogenic lipoprotein subclasses, supporting the role of the muscle–liver metabolic axis in post-transplant cardiovascular risk. Integration of MRI-derived body composition analysis with advanced lipoprotein profiling may improve cardiometabolic risk stratification in LT recipients.

Table — Muscle Fat Infiltration and Lipoproteins

Outcome	β unadjusted	p-value	β adjusted	p-value
LDL-P	-54.81	<0.001	-40.64	0.008
Small LDL-P	-25.90	0.005	-20.99	0.067
HDL-P	2.64	<0.001	2.28	<0.001
Large HDL-P	2.68	<0.001	2.09	<0.001

4600 | THE EFFECT OF WEIGHT LOSS ON INSULIN RESISTANCE AND INFLAMMATION IN LIVER TRANSPLANT RECIPIENTS

Danielle Kirkman[1] Maksim Piazza[1] Domenico Chavez[1] Geneva Roache[1] Margery Connelly[2] Susan Wolver[1] Mohammad Siddiqui[3], [1]Virginia Commonwealth University, [2]Labcorp, [3]University of Virginia

Background: Clinically meaningful weight gain following a liver transplant (LT) is highly prevalent, increasing the risk of developing *de novo* steatotic liver disease and cardiovascular disease. The biological mechanisms linking post-transplant weight gain to metabolic dysfunction, however, are under-researched and complex. The purpose was to investigate whether weight loss improves key metabolic biomarkers implicated in metabolic disease development and progression, specifically insulin resistance and systemic inflammation, in LT recipients. **Methods:** This was a retrospective analysis of a randomized controlled clinical trial investigating dietary strategies for weight loss in obese LT recipients. Thirty participants (mean ± SD; Age, 56.4 ± 11.8 years; 17 female; 7 Black) were grouped based on weight change over six months into a weight-loss group (WL; ≥ 4 kg loss) and a non–weight-loss group (NWL; < 4 kg loss or weight gain). Metabolic outcomes were assessed at baseline and at six months. Venous blood samples were analyzed by nuclear magnetic resonance (NMR) spectroscopy for branched chain amino acids, lipoprotein particle concentrations and subclass sizes, and GlycA, a composite NMR-derived marker of systemic inflammation. Laboratory derived indices of insulain rsistance and inflammation were calculated including the Lipoprotein Insulin Resistance Score (LP-IR), which quantifies insulin resistance based on lipoprotein particle characteristics, and an inflammation index derived from the GlycA signal. A mixed model repeated-measures ANOVA was used to analyze changes over time and between groups, with significant interactions followed up by simple effects analyses. **Results:** By design, weight loss was significantly greater in the WL group compared to the NWL group (D –14.7 ± 20.9 *vs*. +1.6 ± 4.4 kg; interaction $p < 0.01$). Nutrition-induced weight loss resulted in significant reductions in insulin resistance as measured by LP-IR (*WL vs NWL;* D –23.5 ± 14.2 *vs*. –1.0 ± 11.2 %; interaction $p = 0.01$), and significant decreases in systemic inflammation, reflected by reductions in GlycA (D –42.0 ± 42 *vs*. –10.9 ± 33.2 mmol/L; interaction $p = 0.04$) and the inflammation index (D –7.3 ± 7.6 *vs*. + 0.3 ± 5.9 AU; interaction $p = 0.02$). **Conclusion:** These findings suggest that weight loss directly improves physiological mechanisms that contribute to the risk *de novo* steatotic liver disease and the post-transplant cardiovascular burden. This reinforces the need for effective weight management strategies after transplant.

4601 | THE IMPACT OF AREA DEPRIVATION ON EARLY CLINICAL OUTCOMES IN LIVER TRANSPLANTATION FOR ALCOHOL-RELATED LIVER DISEASE

Jordan Holliday[1] Samuel Ji[1] Vikrant Rachakonda[1] Sophoclis Alexopoulos[1] Lea Matsuoka[1] Yvonne Kelly[1] Lydia Aye[1], [1]University of California Davis

Background: Social determinants of health are associated with poorer outcomes in liver disease and liver transplantation. Patients with alcohol-related liver disease (ALD) routinely experience psychosocial barriers to care. Therefore, the aim of this study was to determine whether socioeconomic disadvantage measured by area deprivation index (ADI) impacts clinical outcomes in liver transplantation for alcohol-related liver disease. **Methods:** This was a single-center, retrospective chart review of patients of 79 patients with alcohol-related liver diseases including cirrhosis due to ALD (N = 58), metabolic and alcohol-related steatotic liver disease (Met-ALD, N = 9), and alcohol-associated hepatitis (N = 12) transplanted between June 2023 and July 2025. National ADI scores were obtained using the University of Wisconsin Neighborhood Atlas based on patient addresses to identify census blocks. **Results:** The median ADI was 30 (IQR 19 – 42), and patients were stratified into low risk (ADI $\leq$ 30, N = 40) and high risk (ADI > 30, N = 39) cohorts. The median age was 46.0 (IQR 39.8 – 54.5 years, and there was no difference between low and high ADI groups. There were no differences in liver disease etiology across ADI cohorts, and more women (34.2%) had lower ADI. Overall, pre-transplant substance use navigation (SUN) services were provided to 32.9% of patients, but no differences were noted between ADI cohorts. However, low ADI patients had higher rates of pre-transplant addiction medicine consultation (22.5% vs 7.7% p = 0.065) and psychiatric services (52.5% vs 33.3%, p = 0.013) than high ADI groups. SIPAT scores did not differ between groups, but there was a trend towards lower median MELD 3.0 in high ADI patients [25 (IQR 20 – 31) vs 31 (23 – 39), p = 0.060], and there was negative correlation between MELD and ADI (Spearman rho -0.2019, p = 0.0745). After transplant, eleven patients (13.9%) experienced relapse, and all cases were detected by positive blood phosphatidylethanol (PETH) tests. Post transplant addiction medicine consultation was provided to 41.8% of patients, and 12.7% received medications for alcohol use disorder (MAUD) after transplant. There were no differences between rates of relapse, addiction medicine consults, acute cellular rejection (ACR), or MAUD between high and low-risk ADI cohorts. **Conclusion:** Among patients transplanted for alcohol-related liver disease, patients with high ADI received few pre-transplant addiction medicine and psychiatric services, but this did not result in increased return to drinking or ACR after liver transplant. Future studies are planned to study targeted pre-transplant AUD treatment in high-risk cohorts.

4602 | SECULAR TRENDS OF PHOSPHATIDYLETHANOL (PETH) TESTING IN THE PERI-LIVER TRANSPLANT PERIOD: A US REGISTRY-BASED ANALYSIS

Remco Kersten[1] Tami Daugherty[1] Aparna Goel[1] Allison Kwong[1] Daniela Sanchez Gil[2] Jananee Muralidharan[2] Honor Magon[2] Paul Kwo[1], [1]Stanford University Medical Center, [2]Atropos Health

Background: Phosphatidylethanol (PEth) is a sensitive and specific biomarker of alcohol use with growing clinical utility in liver transplantation (LT). Real-world data on temporal trends in post-LT PEth surveillance and clinical outcomes stratified by alcohol use disorder (AUD) history remain scarce. We evaluated post-transplant PEth patterns, graft rejection, and mortality among adult LT recipients stratified by AUD history. **Methods:** Using the Apollo Atropos Health real-world database, adult LT recipients (January 2015–October 2025) were stratified by AUD history: No AUD, Prior AUD (pre-LT diagnosis), and post-transplant AUD (post-LT diagnosis only). AUD was defined using Elixhauser ICD-10 criteria. Positive PEth was defined as $\geq$ 20 ng/mL. Outcomes included PEth testing rates, time to first positive test, graft rejection, and all-cause mortality. **Results:** Among 21,536 LT recipients (no AUD n = 14,591; prior AUD n = 5,492; post-transplant AUD n = 1,453), post-LT PEth testing occurred in 0.19%, 3.46%, and 0.62%, respectively. Testing frequency increased markedly over time in the prior AUD group, rising from 0% in 2015–2016 to 8.3% within 1 year post-LT in 2025. Positive PEth values occurred exclusively in the prior AUD cohort (0.95% anytime post-LT; mean 32.0 ng/mL vs. 2.96 ng/mL, 1.11 ng/mL in no AUD and post-transplant AUD, respectively), with a median time to first positive test of 587 days post-LT (IQR: 203–1,030 days; max 2,194 days). Graft rejection rates were approximately double in prior AUD (14.4%) and post-transplant AUD (14.2%) vs. no AUD (7.1%). The post-transplant AUD cohort had a low PEth testing rate (0.62%) with zero positive tests identified, yet

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

carried the highest all-cause mortality, 24.2% (post-transplant AUD) vs. 16.8% (no AUD) vs. 14.1% (prior AUD). **Conclusion:** Post-transplant PEth testing is increasing, reflecting growing clinical awareness, yet overall uptake remains low across all groups. The wide variability in time to first positive PEth among prior AUD patients supports the need for long-term PEth surveillance in this group. Graft rejection risk doubled with any AUD history, highlighting the clinical importance of adequate post-transplant monitoring. The post-transplant AUD group had the highest mortality, yet a low PEth testing rate with no positive tests detected. The post-transplant AUD cohort may represent individuals diagnosed purely via clinical/behavioral presentation or billing codes after a severe relapse event, and thus missing the window of PEth biomarker detection. The lack of routine surveillance raises concern for underdiagnosis of harmful alcohol use post-transplant and underscores the need for targeted, longitudinal PEth protocols in this high-risk population.

Figure 1: Post-transplant PEth testing frequency increased over time

4603 | CARDIOMETABOLIC VS NON-CARDIOMETABOLIC CIRRHOSIS PHENOTYPES AND THEIR ASSOCIATION WITH CIRRHOTIC CARDIOMYOPATHY IN LIVER TRANSPLANT RECIPIENTS

Jade Pace[1] Manahil Muneeb[1] Tasmia Promi[1] Ahmed Aboseria[1] Michael Attanasi[1] Anwesha Satapathy[2] Andrew Park[2] Benjamin Seifer[1] Justin Lin[1] Nabil Dagher[1] David Stern[1] Amgad Makaryus[1] Sanjaya Satapathy[1], [1]Northshore University Hospital/Northwell Health, [2]Zucker School of Medicine at Hofstra/Northwell

Background: Cirrhotic cardiomyopathy (CCM) is a subclinical cardiac dysfunction that arises during physiologic stress, such as liver transplantation, and may be associated with worse transplant outcomes. However, the influence of underlying cirrhosis phenotype on CCM is not well-studied. One area of increasing interest is the impact of cardiometabolic factors in the interplay between hepatic and cardiac disease processes. Our study aimed to assess whether cardiometabolic cirrhosis (CMC) is associated with higher prevalence and severity of CCM compared to non-alcoholic non-cardiometabolic cirrhosis (non-CMC). **Methods:** This retrospective cohort included 115 adult liver transplant recipients with complete pre-transplant echocardiographic data. CMC (n = 95) included cirrhosis of any etiology with cardiometabolic factors (BMI $\geq$ 30, type 2 diabetes, or metabolic syndrome). Non-CMC (n = 20) included non-alcoholic cirrhosis without any cardiometabolic factors. CCM was defined as the presence of $\geq$ 2 abnormal echocardiographic markers per the 2020 Cirrhotic Cardiomyopathy Consortium guidelines: left ventricular ejection fraction $\leq$ 50%, global longitudinal strain > -18%, left atrial volume index > 34 mL/m^2, septal e' < 7 cm/s, tricuspid regurgitation velocity > 2.8 m/s, and E/e' > 15. Logistic regression was used to assess associations, adjusting for age, MELD score, and sex. **Results:** CCM was present in 34.8% of patients, with similar prevalence in CMC (34.7%) and non-CMC (35.0%; p = 0.98). The mean number of abnormal criteria was also comparable (1.18 vs. 1.25). Individual echocardiographic parameters, as described by the 2020 guidelines, did not differ significantly between phenotypes (Table 1). In adjusted models, CMC was not independently associated with CCM (Odds Ratio 0.89, 95% Confidence Interval 0.31 – 2.53; p = 0.82). **Conclusion:** Our study shows that the cardiometabolic cirrhosis phenotype is not associated with CCM. This finding underscores the importance of routine pre-transplant cardiac evaluation across all etiologies of cirrhosis because no specific phenotype has been disproportionately linked to CCM. Future studies are warranted to

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

identify alternative drivers of CCM to better evaluate transplant candidates.

Table 1. CCM Component Comparison by Phenotype

CCM Component	CMC (n=95)	Non-CMC (n=20)	p-value
Left Ventricular Ejection Fraction ≤ 50%	4.2%	5%	0.89
Global Longitudinal Strain > -18%	29.5%	25%	0.67
Left Atrial Volume Index >34 mL/m²	60%	55%	0.72
Septal e' <7 cm/s	52.6%	50%	0.84
Tricuspid Regurgitation velocity >2.8 m/s	18.9%	15%	0.77
E/e' >15	20%	10%	0.21

4604 | NEW SUBMISSION

Diana Coman[1] Aaron Hass[1] Chaimaa Ouizzane[1] Jeanne-Marie Giard[1] Philippe Willems[1] Julian Hercun[1], [1]Montreal University Health Center

Background: Screening for obstructive coronary artery disease (CAD) prior to liver transplantation is crucial in improving post-transplant survival. However, cardiovascular risk assessment lacks standardization across centers. Coronary computed tomography angiography (CCTA) is a non-invasive modality commonly incorporated into screening algorithms, with a high negative predictive value for excluding obstructive CAD. However, it lacks functional assessment of coronary blood flow and myocardial ischemia, which may overestimate cardiovascular risk and lead to potentially unnecessary invasive angiography. Its optimal role in pre-transplant screening remains uncertain. **Methods:** We conducted a retrospective study on patients who underwent liver transplantation between 2023 and 2025 at a quaternary center. The primary endpoint was the rate of major adverse cardiovascular events (MACE) within 30 days of liver transplantation. High-risk CAD lesions on CCTA were evaluated as a secondary endpoint, including rates of downstream invasive coronary angiography, PCI yield, and perioperative MACE. **Results:** A total of 149 patients who underwent liver transplantation were included in the analysis; 68 underwent CCTA and 81 did not. One 30-day post-transplant MACE occurred in the CCTA group and none in the non-CCTA group. In the CCTA group, 32 (47%) patients had subsequent invasive coronary angiography. The cohort was predominantly male (75%), with a mean age of 60 ± 4.83 years, and 46% had a component of metabolic-related cirrhosis. Cardiovascular risk factors were common, including diabetes (50%), hypertension (59%), hyperlipidemia (46%), obesity (35%), and active smoking (26%). 9% had known CAD. In the CCTA group, 14 patients (21%) were reported to have high-risk coronary stenosis, prompting invasive coronary angiography. Of these, 3 patients (4%) had significant stenosis confirmed and underwent percutaneous coronary intervention (PCI), while 11/14 (79%) lesions were reclassified as non-severe on coronary angiography and did not require coronary intervention before transplantation. Seven (11%) patients underwent coronary angiography despite no significant stenosis on CCTA, and none required PCI. Four CCTA studies were inconclusive, of which one patient had significant coronary stenosis on angiography and benefited from a PCI. No false-negative CCTA results were observed. For detecting severe stenosis ($\geq$70% obstruction), CCTA demonstrated 100% sensitivity and negative predictive value, 56% specificity, and 21.4% positive predictive value. **Conclusion:** In this cohort of liver transplant candidates, the rate of MACE was low irrespective of CCTA screening. High-risk CAD lesions identified on CCTA were associated with a high rate of invasive coronary angiography without subsequent PCI, suggesting that CCTA may yield false-positive results in this population and that its role warrants further evaluation.

4605 | AFP, TUMOR NECROSIS, PATHOLOGIC GRADE, VASCULAR INVASION, AND TUMOR SIZE AS PREDICTORS OF INTRAHEPATIC, OLIGOMETASTATIC, AND POLYMETASTATIC RECURRENCE PATTERNS IN HEPATOCELLULAR CARCINOMA

Aashrith Madagiri[1] Devi Veeramgiri[1] Yonatan Kaplan[1] Matthew Kim[1] Sami Ali[1] Adina Shrestha[1] Seung Duk Lee[2], [1]Virginia Commonwealth University School of Medicine, [2]Virginia Commonwealth University

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Recurrence site of hepatocellular carcinoma (HCC) affects prognosis. Existing models for predicting HCC recurrence do not account for recurrence patterns of spread. This study assesses whether pre-treatment AFP, tumor necrosis, pathologic grade, vascular invasion, and tumor size are associated with intrahepatic-only, oligometastatic, or polymetastatic recurrence patterns. **Methods:** This retrospective study included 55 patients with HCC who underwent resection or liver transplantation and developed recurrence. Patients were stratified into three groups: Intrahepatic-only (n = 31) was defined as recurrence confined to the liver. Oligometastatic (n = 12) was defined as a single extrahepatic organ site only or one intrahepatic plus one extrahepatic site. Polymetastatic (n = 12) was defined as multiple extrahepatic sites and/or intrahepatic recurrence with multiple extrahepatic sites. Baseline characteristics were compared using Kruskal-Wallis and Fisher's exact tests. Ordinal logistic regression was used with recurrence pattern modeled as an ordinal outcome (intrahepatic-only < oligometastatic < polymetastatic). Log-transformed AFP and microvascular invasion were selected a priori for multivariable analysis. Tumor size, tumor necrosis, and pathologic grade were assessed in exploratory univariable analyses. **Results:** Mean pre-treatment AFP increased across groups (12.4, 65.4, 184.6 ng/mL; $p < 0.001$), as did tumor size (2.5, 4.6, 6.2 cm; $p = 0.004$). Microvascular invasion (39%, 42%, 50%; $p = 0.007$) and high-grade pathology (23%, 42%, 67%; $p = 0.015$) also increased across groups. Tumor necrosis and multifocal disease were not significantly different. In multivariable ordinal logistic regression, log10 AFP (OR 2.41, 95% CI 1.38–4.22, $p = 0.002$) and microvascular invasion (OR 3.85, 95% CI 1.21–12.35, $p = 0.023$) were independently associated with advanced recurrence patterns. Treatment type and multifocal disease were not significant. In exploratory univariable analyses, tumor size (OR 1.18, 95% CI 1.05–1.34, $p = 0.007$) and pathologic grade (OR 4.12, 95% CI 1.55–11.02, $p = 0.004$) were significant. Tumor necrosis was not significant. **Conclusion:** Pretreatment log-transformed AFP and microvascular invasion were independently associated with advanced recurrence patterns. In exploratory analyses, larger tumor size and higher pathologic grade were also associated with advanced recurrence patterns. Tumor necrosis, multifocal disease, and treatment type were not significant predictors.

4606 | A POST-LIVER TRANSPLANT PSYCHOLOGICAL CLINIC FOR MODERATE- AND HIGH-RISK PATIENTS FOR RELAPSE ON ALCOHOL: A NOVEL INTEGRATED APPROACH

Antu Segal[1] Tia Turner[2] Samantha Killian[2] Christopher Cannon[2] Kayla Rinna[2] Elise Pearl[2] Humberto Gonzalez[2] Lisa Miller-Matero[2], [1]Henry Ford Hospital Transplant Institute, [2]Henry Ford Health

Background: Routine follow-up of post-LT patients can help identify and mitigate risk factors that influence surgical outcomes such as alcohol relapses, psychiatric variables and non-adherence to treatment plans. Prior work has identified characteristics of individuals at risk for post-LT alcohol relapse, including a psychiatric diagnosis, abstinence of less than 1.5 years at time of transplant and history of alcohol relapse prior to LT. Moderate-risk patients were considered to have two of these variables and high-risk patients were considered to have all three. Psychologists are uniquely equipped to address the multitude of factors that impact patients' risk for poor surgical outcomes. The objective of the study was to investigate outcomes following the implementation of a post-LT psychological clinic to assess patients at moderate- and high-risk for alcohol relapse. **Methods:** Retrospective chart reviews were conducted for all patients who underwent LT from January 2022 to December 2023 (N = 223). Data were extracted from the evaluations conducted by transplant psychology staff pre-LT and the recommended one-and six-month post-LT visits. **Results:** Of the 223 patients, 29.1% fell into the moderate/high-risk category and were recommended for post-LT follow-up. Of the patients who were recommended to have follow-up, 96.9% completed the one-month visit and 93.8% completed the six-month visit. At the one-month visit, 86.1% had an alcohol-related etiology and at the six-month visit, 92.8%. At the one-month visit, 9% of patients had elevated depression and anxiety scores, and at the six-month visit, 11.6% had elevated depression scores and 8.6% had elevated anxiety scores. At the one- and six-month follow-ups, patients were given a variety of recommendations to optimize post-LT outcomes including continuing with prescribed psychotropic medications, establishing care with a behavioral health providers, completing relapse prevention, utilizing cognitive behavioral skills (i.e., relaxation), and quitting tobacco and cannabis use. **Conclusion:** Finding suggests it is feasible for moderate- and high-risk patients to attend a post-LT psychological clinic and may be an appropriate

method for identifying individuals who develop post-LT psychiatric symptoms. Imbedding the post-LT psychological clinic within the post-transplant hepatology clinic is imperative for success while optimizing interdisciplinary teamwork. This information could be used by other behavioral health professionals who are considering expanding the breath of psychosocial care provided to post-LT patients for individualized treatment. Future work will examine long-term benefits of this integrated clinic.

4607 | GUT MICROBIAL DYSBIOSIS IN LIVER TRANSPLANT CANDIDATES: AN EXPLORATORY METAGENOMIC ANALYSIS

Rosa Ragozzino[1], [1]Sapienza Università di Roma

Background: Gut microbiota dysbiosis has been increasingly implicated in the progression of advanced liver disease and cirrhosis-related complications. Alterations in microbial diversity and expansion of opportunistic taxa may contribute to systemic inflammation, immune dysfunction, and worsening hepatic status. This study aimed to explore gut microbial composition patterns in liver transplant candidates using publicly available metagenomic sequencing data **Methods:** Ten paired-end fecal metagenomic samples from liver transplant candidates included in the PRJNA1039781 dataset were analyzed. Raw sequencing reads underwent quality control and taxonomic classification through a standardized metagenomic workflow. Relative microbial abundance profiles were generated, and dominant taxa across samples were evaluated to identify microbial patterns associated with advanced liver disease. **Results:** The microbial landscape demonstrated marked inter-individual heterogeneity, consistent with variable degrees of gut dysbiosis in end-stage liver disease. Several samples showed relative preservation of beneficial commensal taxa, including Faecalibacterium prausnitzii, whereas others demonstrated enrichment of opportunistic microorganisms and dysbiosis-associated taxa. Oscillospiraceae-related species and Blautia wexlerae represented dominant components of the microbial ecosystem, while the presence of potentially pathogenic and inflammation-associated taxa suggested disruption of intestinal microbial homeostasis. These findings are consistent with previously reported microbiome alterations in cirrhosis and advanced hepatic disease. **Conclusion:** This exploratory metagenomic analysis supports the emerging role of gut microbial dysbiosis in liver transplant candidates. The observed microbial composition patterns reinforce the potential relevance of microbiome profiling in advanced liver disease and highlight the need for further studies investigating microbiota-derived biomarkers for disease stratification and prognostic assessment in liver transplantation.

4608 | REAL-WORLD TESTING OF MULTI-AGENT AI FOR LIVER TRANSPLANT SELECTION REVEALS GAPS IN CLINICAL REASONING

Junayd Lateef[1] Jin Ge[2] Irene Chen[3] Mamatha Bhat[4] Ghazal Azarfar[4] Peter Maksymowsky[4] Yingji Sun[4], [1]University of California, Berkeley, [2]University of California, San Francisco, [3]University of California, Berkeley and University of California, San Francisco, [4]University Health Network

Background: Multi-agentic AI systems have been proposed to simulate liver transplant selection committees, potentially mitigating biases. Prior work, however, relied on SRTR-derived synthetic cases, leaving real-world performance unknown. Building on work by collaborators at the University Health Network (UHN), we developed a novel institution-specific system incorporating local policies via retrieval-augmented generation (RAG). We then conducted the first large-scale retrospective validation of a multi-agentic AI selection committee using actual clinical and psychosocial documentation to test whether these systems can replicate real-world transplant decision-making. **Methods:** We identified 3,458 patients evaluated for liver transplantation at University of California, San Francisco (UCSF) between 2003-2024, extracting case presentation and psychosocial evaluation notes. We modified the multi-agentic

system pioneered by UHN to better reflect UCSF's committee composition by adding a nurse transplant coordinator agent to the existing transplant hepatologists, transplant surgeon, and social worker agents. In this system: 1. The surgeon, hepatologist, and social worker agents independently analyze data. 2. The transplant coordinator agent then generates questions informed by institutional policies implemented as a RAG database. 3. Committee agents engage in up to five deliberation rounds before rendering a consensus list/defer/decline decision. For comparison, we also replicated the previously published UHN multi-agentic AI architecture, which uses a binary list/decline framework. **Results:** The UCSF system achieved 61.1% accuracy, 34.4% sensitivity, 91.9% specificity, 82.3% PPV, and 56.1% NPV. The replicated UHN system performed similarly, with 63.5% accuracy and 49.7% sensitivity. The UCSF system generated more defer decisions (N = 2,313 vs. actual N = 1,323), suggesting the AI recognized clinical complexity but could not resolve it, defaulting to indecision. When the UCSF system committed to listing, it was correct 82.3% of the time. Neither system achieved sensitivity acceptable for clinical decision support, with both missing 50-66% of historically listed candidates. **Conclusion:** In the first real-world test of multi-agentic AI for liver transplant selection, we demonstrate that current multi-agentic AI cannot reliably replicate committee judgment, even with institution-specific calibration. While high PPV (82.3%) suggests potential as a confirmatory tool for clear-cut listing candidates, the systems failed to navigate the nuanced, often implicit reasoning that drives real committee decisions. These findings establish that transplant selection involves dimensions of reasoning beyond current AI models, and that substantially more work is needed before such tools can be incorporated into clinical decision-making.

4609 | INTEGRATED MITOCHONDRIAL STRESS AND DYNAMIC HEPATOBILIARY FUNCTION DURING NORMOTHERMIC PERFUSION PREDICT POST-TRANSPLANTATION ANASTOMOTIC BILIARY COMPLICATIONS: A PROSPECTIVE COHORT STUDY

Xiaojun Cai[1] Sori Lundin[1] Dana Perry[1] Isabel Yang[1] Cemal Taner[1] Omar Mousa[1] Kristopher Croome[1] Liu Yang[1], [1]Mayo Clinic Florida

Background: Anastomotic biliary complications (ABCs), including bile leak and anastomotic stricture, remain a major source of morbidity after liver transplantation. The pathogenesis of ABCs is thought to involve surgical technical factors, microcirculatory impairment at the anastomotic site, and graft dysfunction, and is mechanistically distinct from ischemic cholangiopathy (IC). Despite the widespread adoption of normothermic machine perfusion (NMP), which has significantly reduced the incidence of IC, the risk of ABCs persists. Currently, there is no reliable method to predict ABC risk. We hypothesized that integrating mitochondrial injury biomarkers with dynamic hepatobiliary functional assessment during perfusion would identify grafts at risk for post-transplant ABCs. **Methods:** In this prospective cohort study of 132 donor livers undergoing NMP, normothermic regional perfusion (NRP), or sequential NRP+NMP, we quantified perfusate and biliary flavin mononucleotide (FMN), bile production, perfusate indocyanine green (ICG) clearance, and biliary ICG excretion. The primary endpoint was post-transplant ABC. Logistic regression and receiver operating characteristic (ROC) analyses were used to evaluate predictive performance. **Results:** ABCs occurred in 22%–30% of transplanted grafts across perfusion strategies. Early hepatocellular function, as assessed by perfusate ICG clearance, was not associated with ABC. In contrast, grafts that developed ABC demonstrated: (1) elevated perfusate FMN during NMP ($p = 0.028$), (2) reduced bile output at 60 and 120 minutes ($p = 0.005$ and $p = 0.011$, respectively), (3) impaired late-phase biliary ICG excretion at 120 minutes ($p = 0.044$), and (4) shorter transport distance, which was independently associated with ABC. A composite model integrating mitochondrial stress (FMN), biliary function (bile output and ICG excretion), and transport distance showed better discrimination than any individual biomarker alone (AUC 0.7834). **Conclusion:** A biologically integrated signature linking mitochondrial

injury with impaired hepatobiliary excretory and transport function during normothermic perfusion predicts post-transplant ABCs. These findings provide new mechanistic insight into the development of ABCs and may help clinicians identify high-risk grafts earlier. **Disclosures:** Xiaojun Cai:Nothing to Disclose, Sori Lundin:Nothing to Disclose, Dana Perry:Nothing to Disclose, Isabel Yang:Nothing to Disclose, Cemal Taner:Nothing to Disclose, Omar Mousa:Nothing to Disclose, Nothing to Disclose, Kristopher Croome:Nothing to Disclose, Liu Yang:Nothing to Disclose.

★ 4610 | KINETIC BREAKPOINT ANALYSIS IDENTIFIES IMMUNE REMODELING DURING QHBSAG DECLINE IN CHRONIC HEPATITIS B

Sung Won Chung[1] Hyunjae Shin[2] Hyejung Lee[3] Changyeon Kim[2] Moon Haeng Hur[2] Yun Bin Lee[4] Eun Ju Cho[5] Su Jong Yu[2] Yoon Jun Kim[2] Jung-Hwan Yoon[2] Joo-Young Park[3] Jeong-Hoon Lee[5], [1]Department of Gastroenterology, Liver Center, Asan Medical C, [2]Seoul National University College of Medicine, [3]Seoul National University School of Dentistry, Seoul National University Dental Hospital, [4]Seoul National University, [5]Seoul National University Hospital

Background: Hepatitis B surface antigen (HBsAg) seroclearance represents functional cure in chronic hepatitis B (CHB). The immunological mechanisms underlying quantitative HBsAg (qHBsAg) decline remain incompletely understood, as prior studies have largely contrasted persistent and resolved states rather than the transitional decline phase. This study aimed to characterize longitudinal qHBsAg kinetic patterns and identify immune cell phenotypes associated with qHBsAg decline. **Methods:** This ambidirectional cohort study enrolled 71 prospectively consented CHB patients (n = 67 in final analysis). Patients were stratified as maintained (n = 27) or declining (n = 40) qHBsAg groups according to the annualized $\log_{10}$ qHBsAg slope over the preceding year (threshold: −0.25 $\log_{10}$ IU/mL/year). Candidate qHBsAg kinetic breakpoints were algorithmically detected and validated via bootstrap resempling (B = 2,000). Flow cytometry was performed to characterize 84 immune cell markers across T, B, NK, and myeloid cell populations. Single-cell RNA sequencing combined with T cell receptor V(D)J profiling was conducted to define clonal immune architecture associated with qHBsAg decline in a subset (n = 12;6 per group). **Results:** Bootstrap validation confirmed 37 of 67 (55%) candidate qHBsAg kinetic breakpoints at $P \leq 0.05$. Unsupported candidates were characterized by gradual kinetic patterns (73%) or high-noise trajectories (70%) and exhibited a smaller dynamic range (median $\log_{10}$ range 1.12 versus 3.38). Compared to patients with maintaned qHBsAg levels, patients with declining demonstrated significantly reduced innate-like effector populations, including perforin$^+$ CD4/CD8 double-negative (DN) T cells (7.6% versus 32.5%, P = 0.009), MAIT cells (0.34% versus 1.30%, P = 0.02), CD3$^+$ DN T cells (4.0% versus 6.9%, P = 0.03), and NKG2A$^+$ cells (22% versus 30%, P = 0.04). Single-cell transcriptomic and V(D)J profiling demonstrated enrichment of NK cells and clonal expansion of CD8$^+$ effector-memory T cells in patients with qHBsAg decline, without evidence of generalized cytotoxic activation. Among patients with validated kinetic breakpoints (n = 38; median interval 1.84 years), PD-1$^+$ memory T cell markers positively correlated with time since breakpoint transition (PD-1$^+$ memory CD8$^+$ T cell: $\rho = 0.54$, P = 0.03), suggesting progressive accumulation of exhaustion associated immune phenotypes following the onset of qHBsAg decline. **Conclusion:** Algorithmically defined qHBsAg kinetic breakpoints were validated in a substantial subset of patients with CHB, providing a structured framework for analyzing dynamics for antigen decline. Within this framework, qHBsAg decline was associated with reduced innate-like effector populations and subsequent PD-1$^+$ memory T-cell phenotypes. These findings support the presence of coordinated immune remodeling during the transition toward functional cure in CHB.

Hospital of Soochow University, [6]Huai'an No. 4 People's Hospital

Background: Antiviral treatment is generally not recommended for non-cirrhotic chronic hepatitis B (CHB) patients with low-level viremia and no significant ALT elevation according to the AASLD 2025 hepatitis B guidelines. The clinical benefit of antiviral therapy in CHB patients with low-level viremia and without significant alanine aminotransferase (ALT) elevation remains unclear. To address this gap, we compared the long-term risk of liver-related events (LREs) between treated and untreated HBeAg-negative, non-cirrhotic CHB patients with low HBV DNA levels and no significant ALT elevation. **Methods:** This was a muli-center cohort study which included HBeAg-negative patients without liver cirrhosis but with low HBV DNA (20-2000 IU/mL) and non-significant elevated ALT (< 80 U/L) from five medical centers in China. Inverse probability of treatment weighting (IPTW) and propensity score matching (PSM) were used to balance the baseline characteristics between groups. The development of LREs which included hepatocellular carcinoma and cirrhosis was compared between the treated and untreated patients. **Results:** A total of 2,129 CHB patients were enrolled, of whom 43.0% were treated with nucleos(t)ide analogues (NAs). During a median follow-up of 2.9 years, 41 patients (1.9%) developed LREs, including 33 patients in the untreated group and 8 patients in the treated group. In the IPTW cohort, the untreated group had a significantly higher 6-year cumulative incidence of LRE than the treated group (5.8% vs. 1.6%, $P = 0.004$). In the multivariate Cox regression, NA treatment was associated with a reduced risk of LRE development (adjusted hazard ratio[aHR]: 0.27, 95% confidence interval [CI]: 0.12-0.61, P=0.002). These findings remained consistent in the sensitivity analyses by excluding patients with significant liver fibrosis at baseline. Consistent results were also obtained in the PSM cohort. **Conclusion:** Antiviral therapy was associated with a significant reduction in the risk of LREs among HBeAg-negative, non-cirrhotic CHB patients with low-level viremia and without significantly elevated ALT, supporting expanded treatment indications for these patients.

4612 | GENETICALLY PREDICTED HEPATIC STEATOSIS INCREASES HEPATOCELLULAR CARCINOMA RISK IN PATIENTS WITH CHRONIC HEPATITIS B: A MENDELIAN RANDOMIZATION STUDY STRATIFIED BY DIABETES MELLITUS

Jia-Ying Su[1] Chien-Ling Lin[1] Jia-Ling Wu[2] Cheng-Hao Tseng[3] Mindie Nguyen[4] Yen Tsung Huang[1] Yao-Chun Hsu[5], [1]Academia Sinica, [2]E-Da Hospital, [3]E-Da Cancer Hospital, [4]Stanford University Medical Center, [5]I-Shou University

Background: Whether hepatic steatosis causally increases hepatocellular carcinoma (HCC) risk among patients with chronic hepatitis B (CHB) remains contested, with existing literature frequently confounded by shared metabolic risk factors. We applied Mendelian Randomization (MR) to estimate the effect of genetically predicted hepatic steatosis on HCC risk in CHB patients and examined effect modification by diabetes mellitus (DM). **Methods:** From the Taiwan Precision Medicine Initiative (TPMI), we identified 17,857 adults with CHB defined by HBsAg positivity, excluding individuals with hepatitis C, alcohol-related liver disease, or drug-induced hepatitis (54.9% male; median age 51.6 years at entry of TPMI). The presence of liver steatosis was ascertained by ultrasound reports and HCC was defined by ICD-10 C22.0/C22.9 with confirmatory imaging or pathology. Candidate steatosis-associated single nucleotide polymorphisms (SNPs) in GCKR, TM6SF2, MBOAT7, and PNPLA3 were evaluated as instruments. In the primary MR analysis, 3,688 patients with liver steatosis were matched 1:3 to controls by age at diagnosis using incidence density sampling, and causal hazard differences were estimated by additive hazards G-estimation under dominant and recessive models. Effect modification by DM was examined in the full unmatched cohort using semiparametric additive hazards regression stratified by DM, with follow-up from first TPMI visit to HCC diagnosis or administrative censoring. **Results:** Among SNPs in the four candidate genes, only PNPLA3 p.Ile148Met met instrument strength criteria, with F statistics of 10.14 under the dominant model and 23.01 under the recessive model. MR G-estimation showed a significantly increased hazard of liver steatosis on HCC under the recessive model (hazard difference [HD] = 0.066, 95% CI 0.012–0.120, p = 0.017). Sensitivity analysis using additional PNPLA3-region SNPs confirmed directionally consistent estimates, with 57 of 60 strong-instrument SNPs reaching nominal statistical significance (p < 0.05). In DM-stratified analysis, PNPLA3 p.Ile148Met was significantly associated with HCC in individuals with DM (HD =

0.0059, 95% CI 0.0006–0.0113, p = 0.030) but not among those without DM (HD = 0.0009, p = 0.108). Among PNPLA3-region variants, 56 of 60 SNPs were significant in the DM stratum versus 1 of 60 in the non-DM stratum. **Conclusion:** Genetically predicted hepatic steatosis was associated with an increased HCC risk in patients with CHB, with the association markedly enriched in individuals with concurrent DM. These findings support a causal role of hepatic steatosis in HCC development and suggest that diabetes-associated metabolic dysfunction may potentiate PNPLA3-driven hepatocarcinogenesis, supporting DM-stratified HCC risk surveillance among CHB patients.

INDEX

The Liver Meeting: 2026 Subject Categories

ACUTE LIVER FAILURE AND ARTIFICIAL LIVER SUPPORT

Acute Liver Failure and Artificial Liver Support

Acute Liver Failure in India, 1986–2025: Etiological Trends, Clinical Profile, and Outcomes — A Systematic Analysis of 6,382 Patients from 85 Studies 2011

Clinical Characteristics of Hepatitis E and Risk Factors for Progression to Liver Failure in Northwest China 2014

Cuproptosis Promotes Acute Liver Failure Through cGAS-STING-Associated Pyroptosis 2012

DDX3X-GSK3β Interaction Regulates Liver Regeneration and Recovery from Acetaminophen-Induced Liver Injury in Mice 2009

Development of a Volumetric 3D-Bioprinted Vascularized Artificial Liver for Transplantable Support in Liver Failure 0047

Does Continuous Renal Replacement Therapy Improve Survival in Acute Liver Failure and Acute-on-Chronic Liver Failure: A Time-Varying Analysis of 8,734 ICU Patients 0048

Endoplasmic Reticulum Stress Orchestrates the DDX3X-TFEB Axis in Drug-Induced Liver Injury 2006

Extracorporeal Liver Support using a Bioengineered Liver for the Treatment of Acute Liver Failure, Alcohol Associated Hepatitis or Acute-On-Chronic Liver Failure: Results for a First-of-its-Kind Phase I Clinical Trial 0014

HIF-1α Inhibition in Macrophages Protects Against Acute Liver Failure 2003

Hemodynamic Instability and Severe Liver Disease Synergistically Predict ICU Mortality in GI Bleeding: A Time-Series Analysis 2007

Hepatocyte p53–LIF axis drives inflammatory cell recruitment and exacerbates acute liver failure. 2002

Human Liver Stem Cell-derived Exosomal miR-4492 Protects from Acute Liver Failure by Inhibiting IQGAP1-mediated Disulfidptosis 0045

ISRIB as a promising savior for acute liver failure: modulating the gut microbiota-tryptophan metabolism-immune axis 0263

Influence of Xenogeneic Mismatch on Hepatocyte Cell Therapy Efficacy 2010

Larsucosterol decreases mortality in LPS endotoxemia by reversing promoter hypermethylation 2008

Machine learning model accurately predicts spontaneous survival of phosphorus related hepatotoxicity patients treated with plasma exchange. 0264

Mortality Benefit of Therapeutic Plasma Exchange in Acute and Acute-on-Chronic Liver Failure: A Systematic Review and Updated Meta-Analysis 2013

Recombinant ADAMTS13 ameliorates liver injury and improves hepatic microcirculation in a murine acute-on-chronic liver failure model 2004

Wide Practice Variation in Plasma Exchange for Acute Liver Failure Highlights Need for Evidence-Based Guidance 0046

ACUTE ON CHRONIC LIVER FAILURE

Acute on Chronic Liver Failure

Acute Hemodynamic Response to Carvedilol Predicts 28-Day Transplant-Free Survival in Acute-on-Chronic Liver Failure: The ACT-C ACLF Study. 2027

Acute-on-Chronic Liver Failure in Sepsis: National Trends, Predictors, and Outcomes in the United States 2074

Angiopoetin-1/WNT axis protects from sepsis-induced acute-on-chronic liver failure by preserving hepatocyte differentiation 2020

Bloodstream Infection Phenotypes and Resistance Patterns among Patients with Cirrhosis Hospitalized with Acute-on-Chronic Liver Failure 0022

Candidate biomarkers identified by multimodal artificial intelligent inform liver transplantation decisions in acute-on-chronic liver failure (ACLF) 2032

Chronic kidney disease and mortality in critically ill patients with decompensated cirrhosis 0019

Cirrhotic Cardiomyopathy Increases the Risk for Acute-on-Chronic Liver Failure, Particularly Circulatory Failure, in Waitlisted Patients. 2023

Clinical Profile, Organ Failure Pattern, and Prognostic Utility of Serial Scoring Systems in Acute-on-Chronic Liver Failure 2076

Comparison of Alcoholic Liver Disease vs Metabolic Dysfunction Associated Steatotic Liver Disease related ACLF in AARC database: A retrospective analysis 2038

Current utilisation and Impact of Plasma Exchange to treat Acute-on-Chronic Liver Failure Patients in USA: A National Inpatient Sample Analysis 2057

Daily Step Count as a Prognostic Indicator of Survival in Adults With Liver Cirrhosis 2075

Defining the Golden Window for Liver Transplantation in Acute-on-Chronic Liver Failure: A Systematic Review 2030

Defining the liver failure cut-off for serum total bilirubin and PT-INR and impact of prior decompensation in a cohort of 10,058 patients with cirrhosis requiring non-elective hospitalisation. 2054

Determinants of Persistent Early Acute Kidney Injury After Liver Transplantation: Distinct Roles of Frailty, Renal Reserve, and Perioperative Injury 2063

Development and external validation of the RE-AD score: a Machine Learning tool for acute decompensation prediction in compensated Advanced Chronic Liver Disease. 2017

Development of a PBMC Transcriptomic Machine-Learning Model for 90-Day Adverse Outcome Prediction in HBV-Related Acutely Decompensated Cirrhosis 2018

Dual Versus Single Antiviral Therapy in HBV-Related Acute-on-Chronic Liver Failure PatientsShreya Singh, Vinod , Ankit, Varsha, Satender, Harsh, Chitranshu, Ashok, Ankur, Rakhi, Manoj Kumar Sahu, S.K. Sarin 2065

Dynamic Immune Cell Interactions in Liver Failure: Multi-Omics Analyses Uncover a Hyperinflammatory CD40+ Monocyte Subset Associated with Disease Progression 2068

Early Deep Sedation Is Associated with Increased Mortality in Mechanically Ventilated Patients with Cirrhosis 0018

Early Plasma Exchange Reduces 7-Day Mortality, Improves Renal Recovery, and Creates a Bridge-to-Transplant Window in Very Severe Alcohol-Associated Hepatitis 2028

Ex vivo blood assays demonstrate systemic anti-inflammatory activity of G1090N, a novel formulation of nitazoxanide; and support further clinical evaluation in acute-on-chronic liver failure (ACLF) 2034

External Validation of the SALT-M Score in Living Donor Liver Transplantation for Acute-on-Chronic Liver Failure 2059

Female Gender and ALD Predict Superior Patient Survival After Liver Transplantation in ACLF 2072

Flux-centric coarse-graining of hepatic metabolism captures acute-on-chronic dynamics in alcohol-associated liver disease 2044

GLP-1 Receptor Agonist Initiation and Risk of Acute-on-Chronic Liver Failure in Patients with Cirrhosis 2029

Hepatic Decompensation as a Mortality Multiplier in Inflammatory Bowel Disease Hospitalizations: Transfer Burden, Severe Inpatient Outcomes, and Resource Use in a Contemporary National Analysis 2045

Hepatocyte-derived liver progenitor-like cells suppress $CCL4^{+}$ inflammatory neutrophils in acute-on-chronic liver failure 2022

Histopathological heterogeneity and its clinical relevance in acute-on-chronic liver failure 2067

Improving risk stratification in alcohol-associated ACLF through TNF-α-augmented prognostic models 2015

Incidence and predictors of recompensation in acute-on-chronic liver failure 2070

Intensity of baseline maladaptive emergency myelopoiesis is a determinant of short-term death in patients admitted for acutely decompensated cirrhosis (ADC) 2031

Investigating the Association of Statin Intensity with Reduction in Risk for Hepatocellular Carcinoma in Patients with Chronic Liver Disease 2077

Is Prioritizing ACLF-3 for Liver Transplantation Cost-Effective? A Cost-Effectiveness Analysis 2047

Ischemic Hepatitis Carries a 9-Fold Increased ICU Mortality Risk: A Population-Level Analysis of 5,473 Cases 2046

Lipoprotein Z is a biomarker of liver decompensation associated with high mortality 2025

Liver Transplant Outcomes in ACLF Patients Managed in a Dedicated Liver ICU 2039

Liver transplantation for Type A Acute-on-Chronic Liver Failure : An Unmet Need 2078

Low-Dose Continuous Terlipressin: Comparable Efficacy, Lower Toxicity in ACLF Variceal Bleeding 0017

Lumican is progressively activated during ACLF-associated fibrogenic remodeling and promotes hepatic fibrosis through H3K18 lactylation 2073

MAM-Localized SEC62 Drives APAP-Induced Hepatotoxicity Through Integrated Stress Response and Macrophage Recruitment 2050

Myeloid 5-Lipoxygenase Activation Drives Systemic Inflammation and Liver Injury in Acute-on-Chronic Liver Failure 2051

Omentin-1 derived from M2-like macrophages in the fibrotic liver mediates the hepatoprotection against acute insult in acute-on-chronic liver failure by inhibiting ferroptosis signaling 2043

PBMC transcriptomics reveals risk-stratified myeloid activation and IL1R2-associated inflammation in HBV-ACLF 2052

Palliative Care Consultation Modifies Mortality in Patients with Renal Replacement Therapy Undergoing Inpatient Liver Transplant Evaluation 2064

Plasma Proteomics Stratifies Hidden Mortality Risk in the MELD High-Risk Grey Zone of HBV-Related Acute-on-Chronic Liver Failure 2033

Pragmatic definition of ACLF using global harmonization predicts mortality with increasing grades across three large patient cohorts. 0020

Pre-Transplant ICU Length of Stay is a Strong Predictor of Mortality After Liver Transplant in ACLF Patients 2056

Prediction Of ACLF Development In A Multi-Center Outpatient Cirrhosis Cohort Across North America 2058

Prior Decompensation Shapes the Clinical Phenotype and the Prognostic Performance of Biochemical Liver-Failure Criteria in Hospitalised Cirrhosis: A Multicentre Study 2069

Prognostic Analysis of Artificial Liver Support System Therapy Guided by the Systemic Inflammation Response Index for Acute-on-Chronic Liver Failure 2021

Prognostic value of immunity, inflammation and nutrition-related biomarkers for 28-day mortality in sepsis patients with cirrhosis: A retrospective study from MIMIC IV and eICU 2048

Proton Pump Inhibitor Promotes Gut–Liver Axis Disruption and Impair Liver Regeneration During Acute-on-Chronic Liver Failure 2060

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Racial Disparities in Outcomes of Acute on Chronic Liver Failure in the United States. 2062

Risk Stratification and Mortality of Acute-on-Chronic Liver Failure Across Different Diagnostic Criteria: A Multicenter Cohort Study 2016

Role of Plasma Exchange in Acute-on-Chronic Liver Failure Due to Hepatitis B Reactivation 2055

Senescent hepatocytes hinder UCMSCs proliferation by upregulating SSBP1 through the IL-17 pathway 2061

Serum Galectin-3 is associated with organ failure burden and improves mortality risk stratification in Acute-on-Chronic Liver Failure 2041

Single-cell mapping reveals CXCR2^{+} neutrophil–NETs axis driving hepatocyte necroptosis across ACLF etiologies 2053

Soluble Programmed Death Ligand 1 Outperforms Interleukin 6, Urinary Neutrophil Gelatinase-Associated Lipocalin, and Neutrophil-to-Lymphocyte Ratio for ACLF Prediction in Patients with Cirrhosis: The LiverHope Biomarker Study. 0021

TIGIT exacerbates acute-on-chronic liver failure infection and mortality through CD8+ T cell exhaustion 2036

The ACLF Rescue Gap: High-Intensity Death Without Palliative Care and Disparities Among Hospitalizations With Acute-on-Chronic Liver Failure 2071

Therapeutic Plasma Exchange (TPE) as an Adjunct to Standard Medical Therapy in Acute-on-Chronic Liver Failure: A prospective cohort study from India 2066

Three Data-Driven Immunological Dimensions Improve ACLF Prediction Beyond MELD in Acutely Decompensated Cirrhosis: An Ambispective Cohort Study 2040

Type A and Type B ACLF by Kyoto classification clearly charters natural disease course at baseline and guides therapeutic interventions -A cohort study 2037

VISTA deficiency exacerbates the development of acute-on-chronic liver failure by promoting Tc1 Differentiation 2049

Validation of the 2025 Global Expert Panel Consensus on Acute-on-Chronic Liver Failure in an Asian Population 2019

Visco-elastic testing guided restrictive transfusion reduces blood product utilization without increasing procedure-related complications in patients of ACLF-interim results of a randomized controlled trial.(NCT06831565) 2024

Vital signs outperform MELD 3.0 and CLIF-C AD in dynamically predicting deterioration amongst inpatients with decompensated cirrhosis 2026

ADVANCED PRACTICE PROVIDERS (NP, PA, RN, PHARMD, ETC.)

Behavioral and Quality Issues

Using Interpretable Machine Learning Model to Predict Health-Related Quality of Life in Patients with MASLD 0023

PRACTICE ISSUES

Assessing the Effect of Semaglutide in Patients With MASLD: Real-World Experience From a Pharmacist-LED Sub-Clinic 2082

Advanced-practice-nurse-led lifestyle intervention after automated MASLD case-finding in primary care: 24-week outcomes from LiverSeek 2079

Implementation of a Nurse Practitioner–Led FibroScan Referral Pathway Improves Hepatology Linkage to Care in a MASLD Screening Program 2081

LiteMedSAM and MedNet: A Segmentation-Assisted, Attention-Guided Lightweight Framework for Edge-Deployable Sonographic Classification of Hepatocellular Carcinoma 0024

Menopause in Women with Liver Disease: Symptom Burden, Metabolic Changes, and Hormonal Replacement Therapy use 0025

Pharmacist-Led Implementation of AASLD Resmetirom Practice Guidance: A Real-World Experience at a Hepatology Clinic in Academic Medical Center 2080

Practice challenges facing advanced practice providers in managing MASLD patients on resmetirom: Experience of a single non-academic, community-based liver center 0281

Rebuilding Resilience: Addressing Provider Burnout to Enhance Professional Fulfillment 2084

ALCOHOL-ASSOCIATED LIVER DISEASES: CLINICAL AND EXPERIMENTAL

Alcohol-Associated Liver Diseases: Clinical and Experimental

A Deep-Learning Model Distinguishes Alcohol-Associated steatohepatitis from metabolic dysfunction-associated steatohepatitis on Routine H&E Liver Biopsy 3040

A Liver-Specific Lipidomic Prism: Particle-Normalized VLDL Signatures Distinguish Alcohol-Associated Hepatitis from Alcohol-Associated Cirrhosis 3014

A Novel Perspective on the Role of Cholinergic Anti-inflammation in Alcoholic Steatohepatitis: The Spleen–Liver Axis 3194

A Novel circRNA Regulatory Axis Driving Sphingolipid Dysregulation in Alcohol-Associated Liver Disease 0225

A Refined SLD Classification Improves Fibrosis Risk Stratification in MetALD 3112

A circulating proteomic signature predicts disease progression in alcohol-associated liver disease 3133

Adverse Childhood Experience Score is Elevated in Alcohol-associated But Not Non-alcohol-associated Cirrhosis: Evidence for an ACE→AUD→ALD Cascade From a Prospective Registry 3027

AI-driven Histopathology and Machine Learning for Morphological Analysis of Ductular Reaction and Predicting Hepatic Venous Pressure Gradient in Alcohol-associated Hepatitis 3048

AIM-AH: A Ministry supported multicentre Indian explainable AI decision support tool for risk stratification, referral, and early mortality prediction in alcohol-associated hepatitis 0038

Alcohol Exposure Impairs Kupffer Cell–Mediated Antibacterial Defense Through Zonal Remodeling Rather Than Suppression of Antimicrobial Gene Program 3122

AUDIT-C Outperforms Self-Reported Alcohol Consumption for Steatotic Liver Disease Classification: Validation Against Phosphatidyl Ethanolamine (PEth) 3127

Addiction Medicine Consultation Significantly Improves Prescription of Medications for Alcohol Use Disorder in Patients Hospitalized with Alcohol-Associated Hepatitis 3153

Admission Neutrophil-to-Lymphocyte Ratio Is Associated With 90-Day Mortality in Alcohol-Associated Hepatitis: An International Multicenter Cohort Study 3099

AlcHepNet Digital Twins Enable High-Fidelity Synthetic Control Arms for In-Silico Trials in Alcohol-Associated Hepatitis 3057

Alcohol Exposure Identifies Individuals at High-Risk of Increased Liver Stiffness Missed by FIB-4 in Alcohol Use Disorder 3114

Alcohol Potentiates PANoptosis in HIV-Infected Hepatocytes Through ZBP1-Associated Signaling Pathways 3135

Alcohol Suppresses KC Maturation in a Model of Steatotic Liver Disease. 3158

Alcohol cessation after development of ALD induces rapid emergence of new monocyte derived Kupffer cells within hepatic crown-like structures 3126

Alcohol-Associated Hepatitis Does Not Independently Affect Response or Mortality in Terlipressin-Treated Patients with Hepatorenal Syndrome-Acute Kidney Injury: Results From the HRS-HARMONY Consortium 0088

Alcohol-Associated Liver Disease Mortality Rates Peaked in 2021 and are Now Declining 3596

Alcohol-Induced Metabolic Stress Activates an Acetate–ACSS2 Epigenetic Axis in Liver Sinusoidal Endothelial Cells 3094

Alcohol-Related Plasma Proteomic Signature and Risk of Cancer and Mortality: A Prospective Study in the UK Biobank 0012

Alcohol-driven microbiome metabolism elevates hippurate, triggering TLR-mediated neutrophil hyper-inflammation and septic shock in alcohol-associated cirrhosis 3006

Alignment Between Phosphatidylethanol (Peth) and Alcohol-Associated Liver Disease (ALD) ICD Coding in a US-Based Steatotic Liver Disease Cohort 3062

An Electronic Health Record-Based Honest Broker Strategy to Identify and Engage Patients At Risk for Alcohol-Associated Liver Disease for AUD Treatment 3042

An Integrated FIB-4 and Metabolic Model Optimizes Fibrosis Screening in Severe Alcohol Use Disorder 3016

An alcohol-induced bile acid intermediate regulates intestinal FXR-FGF15/19 signaling 0226

Analysis of baseline traits, disease spectrum, and severity determinants in a multicenter cohort with alcohol-related liver disease 3084

Anti-inflammatory action of 18:2 cardiolipin treatment in an ex vivo model of alcohol-associated liver disease 3166

An Inpatient EMR-based Intervention Increases Medications for Alcohol Use Disorder Utilization 3005

Real-World Evaluation of a Multimodal Symptom-Directed Care Strategy for Muscle Cramps in Ambulatory Patients With Cirrhosis 1587

Ultrasound Localization Microscopy for Diagnosis of Clinically Significant Portal Hypertension: A Prospective Multicenter Study 1468

Utility of spleen elastography in adult patients with Fontan physiology: A pilot study 1621

VARICES AND BLEEDING

Much Ado About Heart Rate: Reassessing Beta-Blocker Tolerability in Patients with Cirrhosis 1476

A blood-test-free LSM–SSM fusion score for point-of-care diagnosis of clinically significant portal hypertension (CSPH): a multicentre study 0188

A cluster analysis of coagulation dysfunction in decompensated liver cirrhosis patients 1666

A multicenter, randomized controlled trial comparing endoscopic ultrasound-guided coil and glue embolization with balloon-occluded retrograde transvenous obliteration for prevention of rebleeding from gastric varices 0254

ANTICIPATE-NASH Risk Stratification Predicts Variceal Development in Compensated MASH Cirrhosis: Results from the NAVIGATE Trial 0253

Acute-on-chronic liver failure (ACLF) and shock at presentation predict 6-week mortality in acute variceal bleeding. 1659

Balloon-occluded retrograde transveneous obliteration following partial splenic artery embolization for gastric varices. 1642

Beta Beats Bleeds: Improving Discharge Prescribing of Nonselective Beta-Blockers in Decompensated Cirrhosis—A PDSA Quality Improvement Initiative 1661

Beta-Blocker Prescribing Trends in Cirrhosis from 2013–2025: Increasing Carvedilol Use and Residual Metoprolol Exposure in Patients with Potential CSPH 1538

Beta-Blocker Utilization in U.S. Veterans with Cirrhosis and Clinically Significant Portal Hypertension 1581

Cap-Assisted Endoscopic Polidocanol Sclerotherapy for Bleeding Internal Hemorrhoids in Cirrhosis: Long-Term Results of a Randomized Trial of Liquid versus Foam 1582

Carvedilol Is Associated With Lower Hepatic Decompensation Compared With Propranolol/Nadolol and Selective Beta-Blockers in Compensated Cirrhosis: A Population-Based Target Trial Emulation 1486

Combining Liver Stiffness with FIB-4 Categories to Stratify Risk of Major Adverse Liver Outcomes Across MASLD, MetALD, ALD and Cured HCV 0185

Comparative Effectiveness of Splenic-Probe Versus Standard Liver-Probe Transient Elastography for the Prediction of Clinical Decompensation in Patients with Cirrhosis 1552

Comparison of Pharmacological, Endoscopic, and Interventional Strategies for Primary and Secondary Prophylaxis of Variceal Bleeding: A Systematic Review and Network Meta-Analysis of Randomized Controlled Trials 1488

Correlation of Baveno VII and ANTICIPATE-NASH Noninvasive Models with HVPG in Patients with MASH Cirrhosis: Findings from a Phase 2b Belapectin Trial 1592

Diagnostic Performance of Artificial Intelligence Models for Predicting Esophageal Varices and Variceal Bleeding Risk in Cirrhosis: A Systematic Review and Meta-Analysis 1626

EUS-guided coil and glue injection in addition to ß-blockers leads to lower rates of gastric variceal bleeding compared to ß-blockers alone for primary prophylaxis of gastric varices in cirrhosis – a multicentre propensity matched analysis from India 1460

Early TIPS vs Extended-Interval Preemptive TIPS for Esophageal Variceal Bleeding: A Multi-Institutional Propensity-Matched Analysis from the TriNetX Research Network 1550

Endoscopic Ultrasound-Guided Portal Pressure Gradient Measurement (EUS-PPG) in Patients with Non-Cirrhotic Portal Fibrosis (NCPF): Safety, Feasibility, and Correlation with Histological Subtype — The EU-PORTAL Study 1547

Endoscopic esophageal varices commonly represent venovenous collaterals in patients with Fontan circulation 1511

Evaluating Predictive Models of Clinical Outcomes Following Transjugular Intrahepatic Portosystemic Shunt Placement for Acute Variceal Hemorrhage 1628

Evaluation of the Baveno VIII criteria for clinically significant portal hypertension in compensated advanced chronic liver disease: a contemporary multicenter cohort study 0234

Guideline Adoption After Baveno VII: Trends in Endoscopic Surveillance Among Compensated Advanced Chronic Liver Disease Patients on Non-Selective Beta Blocker 1594

Hemostatic Blood Product Use in Cirrhotic Patients With Acute Gastrointestinal Hemorrhage: A Propensity-Matched Analysis of Real-World Outcomes 1657

Implication of multiple first decompensation events on the definition of further decompensation 1466

Lisinopril versus Non-Selective Beta Blocker for Prevention of Decompensation in Compensated Liver Cirrhosis: A Retrospective Cohort Study 1560

Non-invasive Diagnosis of Clinically Significant Portal Hypertension Using Machine Learning Model Based on Vasomics Platform: A Development and Validation Study 0235

Optimal biochemical criteria for hepatic recompensation in hepatitis B virus-related cirrhosis 1597

Quantitative Assessment of Hemostatic Function Using a Novel Microfluidic Device in Patients with Cirrhosis. 1637

Remimazolam Versus Propofol for Procedural Sedation During Upper Endoscopy in Patients with Cirrhosis: A Systematic Narrative Review of Safety Evidence Across Child-Pugh Subgroups 1461

Selective Serotonin Reuptake Inhibitor Use and Risk of Gastrointestinal Bleeding in Patients With Cirrhosis: A Propensity Score–Matched Cohort Study 1660

Sequential 100-Hz spleen stiffness and ANTICIPATE-NASH improve the real-world detection of esophageal varices: A Thai advanced chronic liver disease cohort 1638

Serial Spleen and Liver stiffness measurement predicts haemodynamic response to carvedilol after acute variceal bleed : The “ STOP BLEED STUDY” - A prospective derivation study 0238

Short-Course Terlipressin Is as Effective and Safe as Standard Therapy for Acute Variceal Bleeding: A Meta-Analysis of Randomized Trial 1556

Towards a digital-twin-inspired framework for personalized 5-year liver disease risk prediction and prevention in individuals with elevated FIB-4 0184

Upper Endoscopy, NSBB Use, and Variceal Hemorrhage Across Baveno Eras in Alberta: A Population-based Study 0236

Using Non-Invasive Liver Fibrosis Indices to Predict Variceal Bleeding in Cirrhotic Patients Presenting with Upper Gastrointestinal Bleeding: A Retrospective Cohort Study 1655

VASCULAR LIVER DISEASE, HEMOSTASIS AND THROMBOSIS

Hemostasis and Thrombosis

Between Clot and Bleed: Low-Molecular-Weight Versus Unfractionated Heparin and 2-, 7-, and 28-Day Safety Outcomes in ICU-Level Cirrhosis 1689

Circulating fibronectin reflects disease severity and predicts variceal bleeding in advanced chronic liver disease 1683

Endothelial dysfunction rather than procoagulant state is independently associated with fibrogenesis and disease progression in advanced chronic liver disease 1690

Establishment and Validation of a Risk Prediction Model for Portal Vein Thrombosis in Patients with Hepatic Cirrhosis 1684

Incident Portal Vein Thrombosis in Cirrhosis: A Large Competing-Risk Analysis Identifying Reduced Portal Vein Velocity as the Strongest Predictor 1671

Not Just DVT: A Rare Case of Portal Vein Thrombosis Associated with Hormone Therapy 1692

Rare but Rising: Two Decades of U.S. Hospitalizations for Budd–Chiari Syndrome 1693

TPO Receptor Agonists Versus Platelet Transfusion for Procedural Thrombocytopenia in Cirrhosis: A Propensity-Matched Cohort Study 1691

LIVER SINUSOIDAL ENDOTHELIAL CELLS

Constitutive c-Maf expression via adenoviral delivery enables three-dimensional culture of LSEC like cells in vitro. 0054

VASCULAR LIVER DISEASE

A vascular MRI signature outperforms conventional scores for predicting liver-related outcomes in non-cirrhotic portal hypertension 1677

CT-based Radiomics Model for Differentiating Porto-Sinusoidal Vascular Disorder from Cirrhosis in Portal Hypertension 1685

Diagnostic Accuracy of Non-Invasive Testings (NITs) for Fontan-Associated Liver Disease (FALD): A Systematic Review and Network Meta-Analysis 1686

Efficacy and safety of direct oral anticoagulants in Budd–Chiari syndrome after endovascular intervention: a propensity score-matched analysis 1688

Extensive Portal-Mesenteric Venous Thrombosis from Occult JAK2-Positive Myeloproliferative Neoplasm Presenting as Small Bowel Obstruction with Bowel Necrosis 1694

Histologic features and markers of portal hypertension in porto-sinusoidal vascular disease across serial biopsies 1678

Incidence and management of ischemic hepatitis (“shock liver”) and patterns of N-Acetylcysteine utilization in critically ill adults: a retrospective study 1682

Inverse Association between Metabolic Dysfunction-Associated Fatty Liver Disease Activity and Porto-sinusoidal vascular disease Occurrence: A Cohort Study of 381 Liver Biopsies 1679

Liver disease manifestations in STAT1 GOF Disease 1674

Long-Term Outcomes in Patients with Budd–Chiari Syndrome (BCS) : A Retrospective Cohort Study of 989 Patients 1672

Long-term anticoagulation reduces bleeding and thrombotic outcomes in non-cirrhotic chronic portal vein thrombosis 1670

Microvessel Density Defines Immunosuppressive Spatial Niches in Hepatocellular Carcinoma 1673

Molecular profiling of liver tumors in vascular liver disorders reveals distinct genomic features and reduces diagnostic uncertainty 1669

Natural History, Clinical Spectrum, and Long-Term Outcomes of Portal Biliopathy in Extrahepatic Portal Vein Obstruction: A 34-Year Tertiary-Center Experience. 1676

Stage-Dependent Natural History, Progression, and Predictors of Adverse Outcomes in Non-Cirrhotic Portal Fibrosis: Validation of the APASL 2024 Staging System 1681

The oral cholate challenge test (HepQuant DuO®) may predict transplant-free survival in Fontan-associated liver disease 1675

Tranexamic Acid-Associated Hepatic Veno-Occlusive Disease/Sinusoidal Obstruction Syndrome: A FAERS Disproportionality Analysis (1987-2025) 1687

Whole-Exome sequence Profiling of patients with Budd Chiari syndrome to identify the pathogenic germ line variants, Mutational Signatures, and possible therapeutic targets. 1680
