The Liver Meeting: 2026 Abstracts

0001 | CROSSTALK BETWEEN ONE-CARBON METABOLISM AND BILE ACID SIGNALING DRIVES THE ONSET OF METABOLIC LIVER DISEASE

Snehal Chaudhari[1] Jonathan Williams[1] Yongtao Wang[2] Raymond Chung[3], [1]University of Wisconsin - Madison, [2]Harvard/MGH, [3]Massachusetts General Hospital

Background: The onset of metabolic dysfunction-associated steatotic liver disease (MASLD) is largely asymptomatic, delaying diagnosis until irreversible damage occurs. Identifying early metabolic aberrations is critical to discover driver pathways and develop timely interventions. We previously demonstrated that alterations in the intestinal bile acid (BA) repertoire precede liver damage (***Science Advances, 2022*** , PMID: 36026454). However, the downstream hepatic pathways triggered by these shifted BAs at MASLD onset remain poorly defined. Concurrently, one-carbon metabolism (OCM) deficiencies —folates in particular—strongly correlate with MASLD and MASH severity , but their precise mechanistic roles and regulation by BA signaling remain unknown. **Methods:** We utilized a novel LC/MS metabolomics platform profiling over 150 OCM-associated metabolites to map the first tissue-specific OCM atlas in conventional and germ-free mice (***Nature Metabolism, 2026***, PMID: 41888596). Novel aspects of the platform include an extraction protocol that allows stable isolation of metabolites from all organs, and a custom LC system that leverages physicochemical properties of metabolites for MS detection. We have built an interactive website (https://chaudharilab.com/folate-atlas/) for the science community to have free access to this foundational dataset.Applying this platform to multiple rodent models (choline-deficient [CDA] and Gubra-Amylin [GAN] diets) and human MASLD/MASH biopsies, we tracked early metabolic shifts. Mechanistic validation incorporated transcriptomics, proteomics, 16S rRNA microbiome sequencing, and *in vitro/in vivo* assays. **Results:** We identified profound deficiencies in hepatic folate and its downstream metabolite, taurine, strictly preceding histological liver damage. Bioinformatic analysis across 46 rodent models and longitudinal human studies confirmed taurine depletion as a universal MASLD/MASH feature. Proteomic profiling revealed this depletion stems from the downregulation of cysteine dioxygenase 1 (CDO1), the rate-limiting enzyme in taurine synthesis. Interventional administration of taurine in drinking water significantly rescued MASLD/MASH phenotypes in CDA rats. Enterohepatic BA profiling via LC/MS revealed that the secondary bile acids lithocholic acid (LCA) and deoxycholic acid (DCA) act as potent inhibitors of hepatic OCM and taurine synthesis. Notably, LCA/DCA-mediated OCM suppression does not signal through canonical BA receptors, but rather operates through the nuclear receptor LRH-1. **Conclusion:** This study defines a novel gut microbiome–BA–OCM–MASLD axis. We demonstrate that secondary BA-mediated inhibition of hepatic CDO1 drives early taurine depletion and metabolic dysfunction via LRH-1. These early OCM alterations offer highly promising biomarkers for early detection and novel therapeutic targets to halt MASLD progression.

0002 | SINGLE-CELL SPATIAL TRANSCRIPTOMIC ANALYSIS OF THE UNFOLDED PROTEIN RESPONSE IN PRIMARY SCLEROSING CHOLANGITIS AND PRIMARY BILIARY CHOLANGITIS

Xiaoying Liu[1] Connor Lantz[1] Michael Mihalov[1] Richard Green[1], [1]Northwestern University Feinberg School of Medicine

Background: Primary sclerosing cholangitis (PSC) and primary biliary cholangitis (PBC) are chronic cholestatic liver diseases characterized by biliary injury that can progress to liver fibrosis, cirrhosis and need for liver transplantation. The etiology and pathogenesis of both diseases are complex and remain incompletely understood. The unfolded protein response (UPR) is a protective cellular response activated in response to endoplasmic reticulum stress and has been implicated in cholestatic liver disorders. In this study, we characterized UPR signaling pathway activation in PSC and PBC at a spatially resolved single-cell level to better understand their molecular pathogenesis. **Methods:** Formalin-fixed paraffin-embedded patient liver biopsy specimens were identified through Northwestern Medicine Enterprise Data Warehouse and obtained from Northwestern University Pathology Core facility. Specimens were classified into three groups: (1) control with normal liver morphology and normal liver function test (n = 2); (2) PSC (n = 5); and (3) antimitochondrial antibody positive PBC (n = 3). Single-cell spatial transcriptomic analysis was performed using the Xenium In Situ platform (10x Genomics) with the Xenium Prime 5K Human Pan Tissue & Pathways Panel supplemented by 50 custom probes targeting bile acid metabolism and UPR-related genes. Initial analyses, including cell segmentation and clustering, were performed on the Xenium instrument and visualized with Xenium Explorer. Cell types were manually annotated based on enriched expression of canonical marker genes. This study was approved by NU Institutional Review Board. **Results:** In PBC samples, clusters of plasma cells were identified in periportal regions surrounding bile ducts based on the expression of marker genes *MZB1*, *IRF4*, *CD38* and *PRDM1*. UPR pathway gene expression was significantly higher in these plasma cells compared with the other cell types, including *XBP1* ($log_2FC = 2.9$), *XBP1* spliced ($log_2FC = 3.5$), the XBP1 downstream targets *ERdj4* ($log_2FC = 2.6$) and *EDEM1* ($log_2FC = 2$), as well as *ERN1* ($log_2FC = 2$), *EIF2AK3* ($log_2FC = 3.2$), and *ATF4* ($log_2FC = 1.7$) ($P_{adj} < 0.00001$ for all genes). Across all groups, *XBP1* expression was moderate in hepatocytes, but minimal in cholangiocytes, hepatic stellate cells and Kupffer cells. In one PSC case, two distinct cholangiocyte clusters were identified: one lining bile ducts within portal tracts and another diffusely distributed in periportal regions. *TRAF2* gene expression was enriched in cholangiocytes in control and PSC samples, but not in PBC. **Conclusion:** These findings demonstrate that UPR gene expression and activation are cell-type specific and appear to differ across cholestatic liver diseases. Single-cell spatial transcriptomics provides novel insights into the molecular pathogenesis of PSC and PBC. Furthermore, the enhanced expression of UPR-related genes in plasma cells suggests potential therapeutic targets in PBC.

★ 0003 | SHARED AND ISOFORM-SPECIFIC ROLES OF PPAR-α, -δ, AND -γ SIGNALING IN MITIGATING CHOLESTATIC HEPATOCYTE INJURY IN PRIMARY BILIARY CHOLANGITIS

Garnik Arustamyan[1] Masashi Okawa[1] Yein Woo[1] Daniel Pinski[1] Meng Li[1] Takeshi Saito[2], [1]University of Southern California, Keck School of Medicine, [2]University of Southern California

Background: PBC is a chronic cholestatic liver disease in which autoimmune-mediated bile duct injury impairs bile flow, leading to intrahepatic accumulation of toxic bile acids and consequent hepatocyte stress and injury. UDCA remains the first-line therapy; however, a substantial proportion of patients have an incomplete response and remain at risk for disease progression. PPAR agonists have emerged as effective second-line PBC therapies; however, the isoform-specific mechanisms by which PPAR activation protects hepatocytes from cholestatic bile acid injury remain poorly defined. We therefore aimed to define the shared and distinct roles of PPAR-α, -δ, and -γ signaling in regulating bile acid homeostasis and mitigating cholestatic injury in primary human hepatocytes (HHs). **Methods:** HHs were benchmarked against normal human liver tissue to confirm PPAR isoform expression and intracellular localization. HHs were then treated with PPAR isoform-selective and multi-isoform agonists, including fenofibrate, seladelpar, elafibranor, and lanifibranor. Effects on bile acid homeostasis and canalicular bile secretory machinery were assessed by RNA-seq profiling, fluorescence microscopy with CDFDA and fluorescent bile acids, and LC-MS quantification of intracellular and extracellular bile acid species. PPAR isoform dependence was tested using solid-phase reverse-transfection–based siRNA knockdown of PPAR isoforms, individually and in combination. Parallel studies with

UDCA and obeticholic acid assessed additive or synergistic interactions between PPAR pathways and FXR signaling. Therapeutic efficacy of PPAR isoform-specific agonists alone or in combination with UDCA was evaluated in a CDCA-induced in vitro model of cholestatic HH injury by assessing reductions in bile acid–induced cellular stress and injury and modulation of canalicular bile secretory function. **Results:** Gain- and loss-of-function studies using PPAR agonists and siRNA-mediated silencing revealed isoform-specific regulation of bile acid homeostasis. Dual PPAR-α/δ agonism most effectively reduced the intracellular toxic bile acid pool in HHs, whereas PPAR-γ signaling had minimal effect. The anticholestatic effect of PPAR-α/δ agonist was mediated primarily through enhanced canalicular bile acid export. Dual PPAR-α/δ agonism, particularly when combined with UDCA, exhibited the strongest anticholestatic and cytoprotective effects in the CDCA-induced cholestatic hepatocyte injury model. **Conclusion:** Dual PPAR-α/δ agonism, exemplified by elafibranor, enhanced canalicular bile acid export in primary HHs, thereby reducing the intracellular toxic bile acid pool that drives CDCA-induced cholestatic stress and injury. The additional protection observed with UDCA co-treatment further supports enhanced hepatocellular bile acid disposal as a central mechanism for mitigating cholestatic injury in PBC.

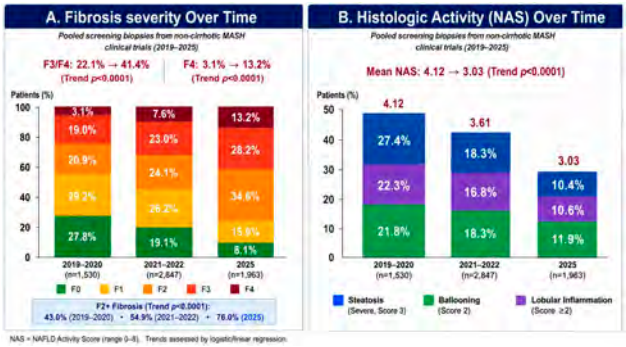
0005 | DECOUPLING OF DISEASE ACTIVITY AND FIBROSIS IN MASH: INSIGHTS FROM CONTEMPORARY BIOPSY COHORTS IN THE GLP-1 RECEPTOR AGONIST ERA



Winston Dunn[1] Gražina Binkauskiene[2] Elizabeth Brombosz[2] Rashmee Patil[3] Rohit Puskoor[4] David Huang[5] Nirupama Esther Jerome[4] John Poulos[6] Alaa Abousaif[7] Aasim Sheikh[8] Alma Laura Ladrón de Guevara[9] Marcelo Kugelmas[10] Mousab Tabbaa[11] Sam Moussa[12] Vlad Ratziu[13] Meena Bansal[14] Jörn Schattenberg[15] Mazen Noureddin[16] Naim Alkhouri[17], [1]University of Kansas Medical Center, [2]Summit Clinical Research Solutions, [3]Pinnacle at San Antonio, Summit Clinical Research Solutions, [4]Pinnacle at Austin, Summit Clinical Research Solutions, [5]Houston Research Institute – Main, [6]Coastal Research Institute, [7]Providence St. Joseph Hospital-Orange, [8]GI Specialists of Georgia, [9]Centro De Investigacion Y Gastroenterologia, [10]South Denver Gastroenterology, [11]Clinical Research Institute of Ohio, [12]Adobe Clinical Research, [13]Service D' Hepatogastroenterologie (FR), [14]Icahn School of Medicine at Mount Sinai (ISMMS), [15]Saarland University Medical Center, [16]Houston Methodist Hospital, Houston Research Institute, Summit Clinical Research Solutions, [17]Summit Clinical Research

Background: GLP-1 receptor agonists (RAs) are increasingly used in MASH, yet their association with liver histology in real-world biopsy cohorts remains incompletely characterized. We evaluated temporal trends in fibrosis severity and histologic activity among patients enrolled in contemporary MASH clinical trials and assessed the relationship between GLP-1RA use and biopsy findings. **Methods:** We analyzed pooled biopsy data from patients screened for non-cirrhotic MASH clinical trials between 2019 and 2025. Cirrhosis-focused trials were excluded to reduce selection bias. Histologic outcomes included NAS and its individual components. Temporal trends were assessed using logistic and linear regression models. GLP-1RA exposure, ongoing GLP-1RA use, diabetes, BMI, and biopsy year were evaluated in adjusted models examining associations with fibrosis and NAS. **Results:** Among 7,819 patients with available biopsy date and fibrosis staging, advanced fibrosis increased substantially over time. F4 increased from 3.1% in 2019–2020 to 13.2% in 2025, while F3/F4 increased from 22.1% to 41.4%, and F2+ from 43.0% to 76.0% (all $p < 0.0001$). In contrast, histologic activity improved over time: mean NAS decreased from 4.12 to 3.03 (estimate −0.259/year, $p < 0.0001$). Severe steatosis declined from 27.4% to 10.4%, ballooning decreased from 21.8% to 11.9%, and higher lobular inflammation scores also declined over time. GLP-1RA use increased from 7.8% in 2023 to 10.3% in 2025 (total $n = 553$). During the same period, F4 prevalence increased from 7.7% to 31.4%, while F3/F4 fibrosis increased from 28.6% to 55.2%. Logistic models confirmed increasing odds of F4 fibrosis over time (OR 2.07/year, $p < 0.0001$). GLP-1RA users had greater unadjusted fibrosis severity than non-users (F3/F4: 69.8% vs 41.6%; F4: 32.5% vs 21.0%; both $p < 0.0001$). However, after adjustment for biopsy year, BMI, and diabetes, GLP-1RA use was associated with lower NAS (estimate −0.186, $p = 0.01$), with similar findings for ongoing GLP-1RA use (estimate −0.222, $p = 0.005$). Diabetes was more common among GLP-1RA users (57.7% vs 37.3%). **Conclusion:** In contemporary MASH clinical trial populations, fibrosis severity increased markedly over time despite improvement in inflammatory and steatotic histologic features. Increasing GLP-1RA use was associated with lower adjusted NAS, suggesting improved necroinflammatory activity, but not with reduced fibrosis severity. The higher fibrosis burden observed among GLP-1RA

users likely reflects confounding by diabetes, metabolic risk, referral patterns, and insufficient duration for fibrosis regression. These findings highlight a potential divergence between short-term improvements in disease activity and longer-term fibrosis outcomes in modern MASH populations.

★ 0006 | *GLP1R* GENE VARIANTS MODIFY LONGITUDINAL OUTCOMES AND GLP1 RECEPTOR AGONIST RESPONSE IN MASLD: A WHOLE-GENOME SEQUENCING PHARMACOGENOMIC STUDY

Sarpong Boateng[1] Guy Nguefang[2] Yazan Al-ajlouni[3] Chimezirim Ezeano[4] Nkengeh Tazinkeng[5] Ihunanya Kanu[6] Basile Njei[7], [1]Yale New Haven Health, Bridgeport Hospital, [2]Guy Loic Nguefang, [3]Montefiore School of Medicine, [4]Advocate Aurora Healthcare, [5]Rutgers/Newark Beth Israel Medical Center, [6]Baptist Memorial Hospital- Golden Triangle, [7]Yale University

Background: GLP-1 receptor agonists (GLP-1RAs) improve metabolic and hepatic outcomes in MASLD, yet substantial variability in treatment response persists. Inherited variation in the GLP1R gene may contribute to heterogeneity in MASLD progression and treatment-associated outcomes, but longitudinal data are limited. We thus evaluated whether functionally characterized GLP1R variants are associated with differential longitudinal outcomes whether these variants modify therapeutic response to GLP-1RA therapy. **Methods:** We identified 3,161 adults with MASLD and whole-genome sequencing data in the All of Us Research Program (2016–2023). Four previously characterized GLP1R variants were evaluated: gain-of-function (GoF) variants rs10305492 and rs75151020, and loss-of-function (LoF) variants rs10305420 and rs2268647. Incident outcomes included cirrhosis, CKD, major adverse cardiovascular events (MACE; MI, heart failure, or stroke), any cardiovascular disease (CVD), HCC, and all-cause mortality. Baseline was defined as MASLD diagnosis; prevalent cases were excluded from each outcome analysis. GLP-1RA use was defined as post-MASLD ever-use based on EHR records. Follow-up continued until outcome, death, or censoring (October 1, 2023). Cox models adjusted for age, ancestry, BMI, diabetes, hypertension, statin, and SGLT2 inhibitor use. Interaction analyses evaluated GLP1R variant×GLP-1RA therapy effects. Prespecified analyses were performed in non-obese individuals (BMI < 30 kg/m²). **Results:** Mean age at MASLD diagnosis was 55.5 ± 13.4 years; 58.2% were White and 7.4% Black/African American. Mean BMI was 35.4 ± 8.4 kg/m², and 25.3% received GLP-1RA therapy. Median follow-up was 3.5–4.0 years.In adjusted analyses, the GoF variant rs10305492 was associated with lower risk of incident cirrhosis (HR 0.71, 95% CI 0.54–0.95; $p = 0.022$). Interaction analyses demonstrated treatment-associated heterogeneity for incident CKD by rs10305492 carrier status and GLP-1RA use (interaction HR 0.49, 95% CI 0.28–0.85; $p = 0.012$). Among non-obese individuals with MASLD, the loss-of-function variant rs2268647 was associated with higher risk of incident MACE (HR 1.87, 95% CI 1.32–2.65; $p < 0.001$) and incident CVD (HR 1.66, 95% CI 1.25–2.21; $p < 0.001$). No significant associations were observed for HCC or all-cause mortality. **Conclusion:** Functionally characterized GLP1R variants were differentially associated with longitudinal hepatic and cardiometabolic outcomes in adults with MASLD. A GoF variant was associated with lower incident cirrhosis risk and modified the association between GLP-1RA therapy and CKD risk, whereas a LoF variant identified non-obese individuals at elevated cardiovascular risk. These findings suggest that inherited GLP1R variation may contribute to MASLD heterogeneity and support further investigation of pharmacogenomic approaches to risk stratification and GLP-1RA treatment-response prediction.

Background: Bulevirtide (BLV) monotherapy yields high rates of virological and biochemical responses in chronic hepatitis delta (CHD); however, the impact of BLV treatment on hard clinical outcomes has not been established. **Methods:** Consecutive CHD patients with cirrhosis receiving BLV monotherapy for up to 3 years in a retrospective European cohort study were compared with pooled data from two BLV-untreated cohorts. The primary endpoint was the incidence of de novo liver-related events ([LREs]: decompensation and hepatocellular carcinoma [HCC]); deaths, and liver transplantation occurring over 3 years were compared for treated and untreated patients, including risk adjustment by inverse probability of treatment weighting (IPTW) and Cox regression analysis. **Results:** A total of 642 patients were included: 344 BLV-treated and 298 untreated controls. Treated patients were older (50 *vs.* 40 years, $p < 0.0001$), more frequently women (males 62% *vs.* 78%, $p = 0.001$), Caucasian (84% *vs.* 62%, $p < 0.0001$), on NUC (91% vs. 40%, $p < 0.0001$) and with higher HDV RNA (5.4 *vs.* 4.9 Log_{10}IU/mL, $p = 0.002$). By contrast, the proportion of patients with previous decompensation, HCC or CSPH was similar. The 3-year cumulative incidence of LREs was lower in BLV-treated patients *vs.* untreated: 8.9% (95%CI 4-12%) *vs.* 16.2% (95% CI 11-22%), respectively ($p = 0.03$). The corresponding figures for decompensation were 2.7% (95%CI 1-4%) *vs.* 11.3% (95%CI 7-16%) ($p = 0.001$) and for HCC 6.1% (95% CI 3-8%) *vs.* 6.6% (95% CI 3-11%) ($p = 0.49$), respectively. In IPTW-adjusted Cox regression analysis, BLV-treated *vs.* untreated controls had significantly lower risk of developing LREs (HR 0.44, 95% CI 0.27-0.72, $p = 0.001$) or decompensation (HR 0.16, 95% CI 0.07-0.36, $p < 0.0001$). These results were confirmed by IPTW-adjusted competing risks regression model (SHR 0.16, 95%CI 0.06-0.40, $p < 0.0001$). Conversely, the HCC risk was similar across all cohorts. Lower baseline albumin values independently predicted LREs, both in the BLV-treated cohort (HR 0.22, 95% CI 0.08-0.64, $p = 0.006$) and untreated controls (HR 0.38, 95% CI 0.20-0.72, $p = 0.002$). Mild pruritus (10%) and injection site reactions (3%) were the most reported adverse events during BLV treatment. **Conclusion:** In CHD patients with cirrhosis, a 3-year course of BLV monotherapy reduced the risk of LREs and decompensation, but not HCC, compared to an untreated IPTW-matched population.

★ 0008 | CRISPR-CAS12 BASED GENE EDITING THERAPY FOR PRIMARY HYPEROXALURIA TYPE 1: A PHASE 1 CLINICAL TRIAL

Taihua Yang[1], [1]Shanghai Jiao Tong University School of Medicine

Background: Primary hyperoxaluria type 1 (PH1) is a rare inherited metabolic disorder caused by hepatic oxalate overproduction, leading to recurrent kidney stones, nephrocalcinosis and progressive kidney failure. Targeting key enzymes in hepatic oxalate metabolism can reduce oxalate production and provides a therapeutic strategy for PH1. **Methods:** Here we report results from an open-label, first-in-human phase 1 clinical trial (ClinicalTrials.gov identifier: NCT06511349) of YOLT-203, a lipid nanoparticle-delivered in vivo gene-editing therapy using an engineered CRISPR–Cas12 nuclease to disrupt HAO1. Seven patients with PH1 aged 8–25 years received a single intravenous infusion of YOLT-203 at 0.3 mg kg^{-1} (n = 2) or 0.45 mg kg^{-1} (n = 5) and were followed for 52 weeks. **Results:** No serious treatment-related adverse events or dose-limiting toxic effects were observed. All adverse events were mild to moderate, with infusion-related reactions in four patients (57.1%) and transient elevations in alanine aminotransferase and aspartate aminotransferase in one patient (14.3%). Mean 24-hour urinary oxalate excretion was reduced from baseline by day 14 and remained suppressed throughout follow-up, with reductions of 45.7% in the 0.3 mg kg^{-1} group and 64.9% in the 0.45 mg kg^{-1} group at week 52. **Conclusion:** These findings support further clinical evaluation of YOLT-203 as a potential treatment for PH1.

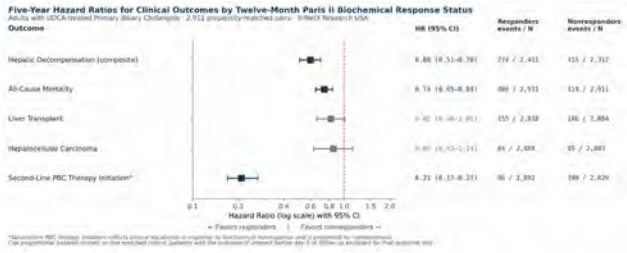
★ 0009 | TWELVE-MONTH BIOCHEMICAL RESPONSE TO UDCA PREDICTS FIVE-YEAR DECOMPENSATION AND MORTALITY IN PRIMARY BILIARY CHOLANGITIS: A PROPENSITY-MATCHED LANDMARK COHORT STUDY



EzzElDien A. Ibrahim[1] Mahmoud Majed Mansour[1] Mostafa Adel T. Mahmoud[2] Nourhan Saleh[1] Darian Fard[1] Mohammad Alabbas[3] Saranya Arumugam[4] Ahmad Alhusen[5] Khulood T Ahmed[1], [1]University of Missouri, Columbia, MO, USA, [2]Beni Suef university, Beni Suef, Egypt, [3]Cleveland Clinic Foundation, [4]University of California, Riverside school of medicine, [5]Advocate Illinois Masonic Medical Center

Background: Primary biliary cholangitis (PBC) is a chronic immune-mediated cholestatic liver disease for which ursodeoxycholic acid (UDCA) is first-line therapy. Biochemical response at 12 months, assessed by criteria such as Paris II, anchors treatment-escalation decisions in registry cohorts (UK-PBC, GLOBE), but real-world multi-center EHR validation against hard 5-year clinical endpoints remains limited. **Methods:** Retrospective propensity-matched landmark cohort using TriNetX Research USA (147M adults, 112 healthcare organizations). Adults ≥18 with PBC (≥2 ICD-10 K74.3 codes ≥30 days apart, 2013–2024) initiating UDCA were classified at a 12-month landmark using ALP and total bilirubin measured 9–15 months after the index diagnosis: responders met modified Paris II criteria (ALP ≤130 U/L and bilirubin ≤1.0 mg/dL); nonresponders failed one or both. AST was not included due to EHR data limitations; absolute thresholds were used as a proxy for ULN-based cutoffs. Pre-index HCC, liver transplant, HIV, HBV, and prior second-line PBC therapy were excluded. 1:1 propensity matching on 29 covariates (demographics, liver and behavioral comorbidities, baseline labs, encounter types) achieved all categorical SMDs <0.05. Outcomes ascertained days 1–1825 post-landmark: composite hepatic decompensation, liver transplant, HCC, all-cause mortality, and second-line PBC therapy initiation; patients with the outcome before the window were excluded for that outcome only (incident-event analysis). Cox proportional hazards models estimated hazard ratios (HR) from the landmark date forward, eliminating immortal-time bias. **Results:** 2,911 matched pairs (mean age 61, 87% female, 77% White) were analyzed. Over 5 years, biochemical responders had lower composite hepatic decompensation (HR 0.60, 95% CI 0.51–0.70; 5-year event-free survival 75.9% vs 67.7%; p<0.001) and lower all-cause mortality (HR 0.74, 95% CI 0.65–0.84; p<0.001). Liver transplant (HR 0.82, 95% CI 0.66–1.01; p=0.06) and hepatocellular carcinoma (HR 0.85, 95% CI 0.63–1.14; p=0.28) trended favorably without reaching statistical

significance, likely reflecting limited 5-year event accrual. Second-line PBC therapy initiation was substantially lower among responders (HR 0.21, 95% CI 0.17–0.27), consistent with clinical practice escalating therapy in nonresponders. Absolute 5-year differences in the responder arm: 6.6 percentage-point lower decompensation incid **Conclusion:** In a large real-world EHR cohort, modified Paris II response at 12 months was associated with lower 5-year hepatic decompensation and mortality, supporting its use as a prognostic anchor for treatment escalation.

0010 | EARLY AND WEEK 52 BIOMARKER (MRI-PDFF, ALT, MRE AND PRO-C3) RESPONSES TO RESMETIROM PREDICT IMPROVEMENTS IN MASH AND LIVER FIBROSIS

Rohit Loomba[1] Rebecca Taub[2] Krishna Padmanabhan[2] Dominic Labriola[2] Mazen Noureddin[3] Naim Alkhouri[4], [1]San Diego School of Medicine, [2]Madrigal Pharmaceuticals, [3]Houston Methodist Hospital, [4]Summit Clinical Research

Background: MAESTRO-NASH (NCT03900429) is an ongoing 54-month, randomized, double-blind, placebo (PBO)-controlled Phase 3 trial evaluating the efficacy of resmetirom (RES) in patients with MASH and F2/F3 fibrosis. The 52-week histologic endpoints demonstrated resolution of MASH (MR) and fibrosis improvement (FI) with RES 80 mg and 100 mg leading to approval. We report early non-invasive biomarkers of change and their correlation with Week (W) 52 biopsy responses, as well as the odds of achieving an early biomarker response with treatment. **Methods:** To assess relationships between early biomarker responses and W52 liver biopsy outcomes, changes in ALT, MRE, MRI-PDFF, at W12,24 52 following initiation of RES or PBO were analyzed for correlation with biopsy-defined MR and FI. Odds of achieving early improvement in these biomarkers were evaluated as a function of treatment. PRO-C3 change was a measure of response. **Results:** $\geq$20% reduction in ALT at w12, 24, 52 was associated with higher odds (OR) of W52 MR/FI. With RES, ALT response showed an OR of 2.0, 2.2, 2.6 repectively at W12, 24, 52; $p < 0.002$). RES OR of achieving an FI response at w12, 24 and 52, compared to PBO: ORs of 2.2, 2.7, 3.6 respectively. All $p < 0.001$. MR was similar. $\geq$15% reduction in MRE at W16, 52 was associated with higher OR of Week 52 FI/MR. With RES, MRE response ORs FI, 2.6 and 2.3 at W16, 52, respectively, $p \leq 0.02$, less association in PBO. MR was similar. RES compared with PBO stat sig. odds of achieving an MRE response, at W52 (OR = 1.71) but not at (W16 OR = 1.31). A $\geq$30% reduction in MRI-PDFF from baseline at W16 and 52 was strongly associated with higher odds of FI and MR. With RES, MRI-PDFF response was associated with increased odds of FI (ORs 1.9 and 2.95 at w16 and 52, respectively; $p \leq 0.02$) and MR at Week 52 (OR ~ 6.5). RES was associated with significantly higher odds of achieving an PDFF response compared with PBO at W16, 52 (ORs 12.4 and 6.7; both $p < 0.0001$). For Pro-C3, change and % change n PRO-C3 at Weeks 24 and 52 in F3 showed a relationship to FI in all treatment groups, w52: 80 mg, -7%, -23%; 100 mg, -14%, -20%; PBO, 0%, -20% FI nonresponders and responders, respectively with far more responders in RES, regression currve $p = 0.0017$ RES, $p = 0.04$ PBO. **Conclusion:** Early and W52 responses to RES, particularly reduction in PDFF at W16 and W52, correlate with FI and MR responses on liver biopsy. Reduction in ALT, MRE and PRO-C3 ($\leq$W24 and W52) showed a significant correlation with FI on biopsy with RES treatment.

0011 | DYSERYTHROPOIESIS UNDERLIES SEVERE REFRACTORY ANAEMIA IN DECOMPENSATED CIRRHOSIS THROUGH ERYTHROPOIETIN RESISTANCE, ERYTHROID DIFFERENTIATION ARREST, AND IMPAIRED CELLULAR COBALAMIN UPTAKE

Chhagan Bihari[1] Sukriti Baweja[2] Shiv Kumar Sarin[2], [1]Institute of Liver and Biliary Sciences, [2]Institute of Liver and Biliary Sciences, New Delhi

Background: Severe anemia (Hb < 8 g/dL) affects > 1/3 decompensated cirrhosis patients, more so in CTP-B/C. Standard haematological investigations fail to identify its cause in a substantial subgroup. We examined whether disordered erythroid maturation (dyserythropoiesis) in the bone-marrow (BM) underlies this refractory phenotype and its mechanistic basis. **Methods:** Cirrhosis patients (n = 475) undergoing BM examination (2010-2025) for clinical indications were enrolled alongside non-liver-disease controls (n = 196) and CKD patients (n = 170) as comparators. Dyserythropoiesis was graded (> 5% abnormal erythroid precursors; mild 5–10%, moderate 10–15%, marked > 15%). Serum erythropoietin (EPO), erythroferrone (ERFE), hepcidin, vitamin B12, iron panel, reticulocyte count, lactate dehydrogenase (LDH), and thyroid stimulating harmone (TSH) were compared between dyserythropoietic and non-dyserythropoietic patients. Erythroid cell biomarkers and RNA sequencing was performed. **Results:** Severe anaemia occurred in 36.2% of cirrhosis patients, highest in CTP-C. Dyserythropoiesis was seen in 9.4% of cirrhosis patients, 2.4% in CKD, and none in controls, clustering in CTP-B/C (p = 0.003), with grade 3 limited to CTP-C. Dyserythropoietic patients had lower haemoglobin [7.8 (6.8–8.9) vs 8.9 (7.5–10.8) g/dL; p < 0.001].Conventional markers did not distinguish dyserythropoietic patients: serum iron, transferrin saturation, ERFE, hepcidin, reticulocyte count, LDH, and TSH were similar. Serum EPO was higher in cases with dyserythropoiesis (8.3 vs 6.9 mU/mL; p = 0.052), elevated overall in cirrhosis vs controls/CKD, and inversely correlated with haemoglobin (rho = −0.37; p < 0.001), suggesting EPO resistance. Serum B12 was paradoxically higher in dyserythropoietic patients (2,000 vs 1,413 pg/mL; p = 0.006), indicating impaired cellular cobalamin uptake.Erythroid TFs: *EGR3* (log2FC−2.9) and *EGR1* (−2.4), which drive terminal differentiation, were downregulated, with reduced GATA-1 and nonnuclear HSP70 protein levels. Notch effectors *HES6* (+3.9) and *HES5* (+2.8) were upregulated, maintaining progenitors in an undifferentiated state and promoting erythroid hyperplasia with ineffective output. *TCN2* (−2.3), which mediates cobalamin uptake into erythroblasts, was downregulated, explaining elevated serum B12 despite impaired maturation. *ERFE* (+1.53) was upregulated, confirming intense but ineffective erythropoiesis. **Conclusion:** In decompensated cirrhosis, dyserythropoiesis is the BM correlate of severe treatment-refractory anaemia, concentrated in CTP-B/C and invisible to all standard laboratory parameters. Coraborative evidence points to erythroid transcription factor collapse, Notch pathway gene upregulation, and impaired cellular cobalamin transport as the mechanistic substrate. Bone marrow examination is required for identification of this entity.

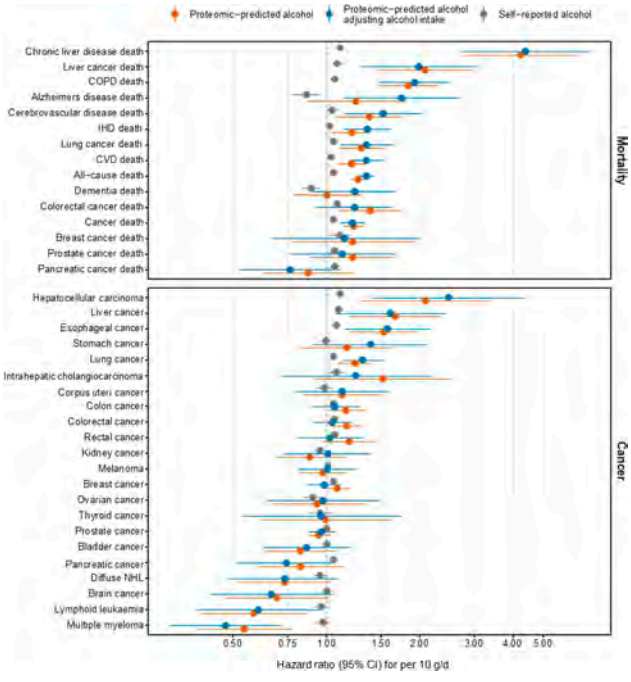
0012 | ALCOHOL-RELATED PLASMA PROTEOMIC SIGNATURE AND RISK OF CANCER AND MORTALITY: A PROSPECTIVE STUDY IN THE UK BIOBANK



Loggang Zhao[1] Xuehong Zhang[2], [1]Yale School of Nursing, [2]Yale University

Background: Alcohol intake is an established risk factor for liver disease, cancer, and mortality, but risk assessment based on self-reported intake is limited by measurement error and may not capture alcohol-related biological injury. Plasma proteomics may provide a molecular signature of alcohol exposure and its downstream effects, but its relevance to liver-related, cancer, and mortality outcomes remains unclear. We developed a proteomic signature of alcohol intake in the UK Biobank and examined its associations with cancer incidence and cause-specific mortality beyond self-reported alcohol intake. **Methods:** We conducted a prospective analysis of UK Biobank participants with baseline Olink Explore plasma proteomic data and self-reported alcohol intake, excluding participants with baseline cancer or liver disease (N = 35,519). Proteomic-predicted alcohol intake was derived using elastic net regression with 10-fold cross-validation. Incident cancers and deaths were ascertained through cancer and death registries. Cox

models estimated hazard ratios (HRs) and 95% CIs for cancer incidence and mortality per 10 g/day increment in proteomic-predicted alcohol intake, adjusting for sociodemographic, lifestyle, and clinical factors, including self-reported alcohol intake. **Results:** The elastic net model selected 74 proteins to derive the proteomic-predicted alcohol intake. Enrichment analyses suggested inflammatory, cytokine-response, immune-cell trafficking, and cell-adhesion pathways. During a median follow-up of 10.9 years, 3,270 cancers and 2,131 total deaths were documented. After adjustment for self-reported alcohol intake, higher proteomic-predicted alcohol intake was associated with increased risks of multiple cancer and mortality outcomes, with the strongest associations observed for liver-related outcomes. Each 10 g/day increment in proteomic-predicted alcohol intake was associated with higher risks of chronic liver disease mortality (HR [95% CI]: 4.36 [2.70–7.04]), hepatocellular carcinoma (2.47 [1.40–4.35]), liver cancer incidence (1.60 [1.06–2.42]) and mortality (1.98 [1.29–3.03]). Positive associations were also observed for selected cancers, respiratory and neurovascular mortality, cardiovascular mortality, all-cause mortality, and cancer mortality, with HRs ranging from 1.21 to 1.92. **Conclusion:** Alcohol-related proteomic signatures were associated with risks of cancer and mortality outcomes beyond self-reported alcohol intake, especially for liver-related outcomes. Plasma proteomics may provide molecular insight into alcohol-related biological risk and improve identification of high-risk individuals.

0013 | QEL-001, AN ENGINEERED TREG CELL THERAPY TARGETING HLA-A2, DEMONSTRATES SAFETY, PHENOTYPIC STABILITY, DURABILITY AND FACILITATES MINIMIZATION OF IMMUNOSUPPRESSION IN LIVER TRANSPLANT PATIENTS (LIBERATE)

Alberto Sanchez-Fueyo[1] Kourosh Saeb-Parsy[2] Jacques Pirenne[3] Jordi Colmenero[4] Manuel Rodriguez-Peralvarez[5] Anthony Demetris[6] Andrew Lesniak[6] Gareth Wright[7] Annie Woodburne[7] Sarah-Jayne Reilly[7] Chris Sharpe[7] Nikola Novcic[7] Rupert Kenefect[7] Anna Fettiplace[7] Laurie Baylor Curtis[8] Marc Martinez-Llordella[7] Alan Magovern[7] Nathalie Belmonte[7] Kasia Averall[7] Luke Devey[7], [1]RW Institute of Liver Studies, Kings College London, [2]University of Cambridge and NIHR Biomedical Research Centre, Cambridge, UK, [3]University Hospitals Leuven, [4]Liver Unit, Hospital Clinic Barcelona, Spain, [5]Hospital Reina Sofia, Universidad de Cordoba, Spain, [6]University of Pittsburgh, [7]Quell Therapeutics Ltd, [8]Quell Therapeutics

Background: Regulatory T cells (Tregs) are essential for maintaining immune tolerance & pre-clinical data supports their ability to promote allograft tolerance. LIBERATE (NCT05234190) was a first-in-human Phase I/II trial evaluating QEL-001, an autologous HLA-A2-specific CAR-Treg therapy, in liver transplantation. Here we report the clinical, cellular kinetic, pharmacodynamic & immunosuppression (IS) modulation data from LIBERATE. **Methods:** LIBERATE was an open-label, dose-escalation Phase I/II study in HLA-A2-negative adult recipients of HLA-A2-positive liver allografts with QEL-001 CAR-Tregs targeting HLA-A2 to promote liver allograft tolerance. The primary objective of LIBERATE was to evaluate safety & tolerability of a single dose of QEL-001. Secondary and exploratory endpoints included clinical activity, CAR-Treg cellular kinetics, pharmacodynamic effects on peripheral and graft-associated immune populations, and feasibility of immunosuppression minimisation. Patients in the expansion cohort received ATG prior to QEL-001 dosing. **Results:** A total of 9 participants were dosed with QEL-001 during the LIBERATE study (n = 3, safety cohort; n = 6, expansion cohort). Overall, QEL-001 was well-tolerated, with no acute peri-/post-infusion toxicities & no safety signals observed (up to 2.5 years follow-up). Most adverse events (AEs) were Grade 1–2 and no AEs were related to QEL-001; 2 participants experienced serious AEs (rejection AEs; resolved). No CAR-positive cellular impurities (i.e., CD8+ effector cells) were detected in blood or liver tissue in any participants, including those

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

who experienced rejection episodes. In the expansion cohort, IS weaning was evaluated in 5 participants. All 5 discontinued calcineurin inhibitors (CNI [tacrolimus]) at a median of 28 days post-infusion & remained stable on mTOR inhibitor monotherapy (everolimus [EVR]) for at least 6 months. On weaning beyond low dose EVR, 3 experienced T cell mediated rejection episodes, which resolved with re-introduction of IS. Longitudinal analysis showed that QEL-001 persists in peripheral blood for ≥12 months & maintains lineage stability and canonical Treg phenotype in blood and liver tissue. In liver biopsies, the magnitude of CAR-Treg accumulation was strongly correlated with the overall degree of T-cell infiltration. CAR-Tregs preferentially co-localized to portal regions containing other immune cell infiltrates, indicating targeted homing to sites of alloimmune activity. **Conclusion:** These results from LIBERATE demonstrate that QEL-001 is safe & well-tolerated with durable persistence & preferential enrichment in the liver, providing a foundation for CAR-Tregs to potentially facilitate weaning of long-term immunosuppression in liver transplantation.

0014 | EXTRACORPOREAL LIVER SUPPORT USING A BIOENGINEERED LIVER FOR THE TREATMENT OF ACUTE LIVER FAILURE, ALCOHOL ASSOCIATED HEPATITIS OR ACUTE-ON-CHRONIC LIVER FAILURE: RESULTS FOR A FIRST-OF-ITS-KIND PHASE I CLINICAL TRIAL

Christopher Danford[1] Aanchal Kapoor[2] Sander Florman[3] Jody Olson[4] John Lake[5] M Mason Macenski[6] Christopher Fecteau[6] Joshua Carlson[6] Jeff Ross[6],

[1]Intermountain Health, [2]Cleveland Clinic, [3]Mount Sinai Medical, [4]Mayo Clinic Rochester, [5]University of Minnesota, [6]Miromatrix Medical

Background: Currently, there is no effective treatment for acute liver failure other than liver transplantation. We performed a Phase 1 study of extracorporeal Liver Support (miroliver*ELAP*®) using a bioengineered liver (MIRO-001) to treat acute liver failure. Herein, we report the safety profile of treatment and identified early effectiveness signals. **Methods:** The miroliver*ELAP* system consists of a MIRO-001 inserted into an extracorporeal blood circuit. MIRO-001 is manufactured using a decellularized porcine liver matrix seeded with human umbilical vein endothelial cells and primary human liver cells. Seven critically ill patients (mean MELD = 39; see Table 1) presenting with acute liver failure, acute-on-chronic liver failure or alcohol associated hepatitis were recruited from 4 study sites. Inclusion criteria included MELD ≥ 20, INR ≥ 2.0, and West Haven HE grade I – III. Subjects were liver transplantation ineligible. Subjects or legal representative granted informed consent and the study conformed to the ethical guidelines of the 1975 Declaration of Helsinki. Subjects were monitored every 4 hours during treatment and followed on days 3, 4, 14, 21, and 32 post-treatment. All adverse events (AE) were recorded and assessed for severity and relatedness. **Results:** Seven subjects received from 9 to 60 hours of continuous miroliver*ELAP* therapy. Across all subjects, with alcohol associated hepatitis or acute-on-chronic liver failure, there were 42 total AEs. Of these, 29% were possibly or probably related to the miroliver*ELAP* treatment or system. No subjects experienced a serious AE while on treatment. Clinically insignificant thrombocytopenia occurred in 4 of 7 treated subjects. Three deaths occurred in 5 subjects that completed treatment (≥44 hrs) and none were related to the miroliver*ELAP* treatment. Two of 3 deaths were due to multi-organ failure, secondary to the underlying disease and occurred well after treatment completion. The third death was attributed to aspiration. Four of 5 subjects who completed treatment experienced improved HE grade. Of the 3 patients on vasopressors at baseline who completed treatment, vasopressors were discontinued in 2 and the dose markedly reduced in the other. **Conclusion:** Extracorporeal liver support using miroliver*ELAP* with a MIRO-001 was associated with a very favorable safety profile. There were no deaths or unanticipated serious AEs attributed to miroliver*ELAP* treatment. Promising efficacy signals (improved HE grade and lower vasopressor requirements) were observed. The very favorable Phase 1

0015 | ADDING NORMOTHERMIC REGIONAL PERFUSION BEFORE NORMOTHERMIC MACHINE PERFUSION ENHANCES EARLY LACTATE REDUCTION AND INDIRECTLY REDUCES EARLY ALLOGRAFT DYSFUNCTION IN DCD LIVER TRANSPLANTATION

Atsushi Nishimagi[1] Almokdad Mohammad[1] Jack Avedikian[1] Adhnan Mohamed[1] Ahmed Nassar[1] Abbas Al-Kurd[1] Atsushi Yoshida[1] Marwan Abouljoud[1] Shunji Nagai[1],
[1]Henry Ford Hospital

Background: Normothermic machine perfusion (NMP) and normothermic regional perfusion (NRP) are increasingly used in liver transplantation (LT) from DCD donors. However, the clinical benefit of adding NRP before NMP remains unclear. The aim of this study was to investigate the effects of adding NRP on early metabolic recovery. **Methods:** This retrospective single-center study included adult recipients who underwent isolated DCD LT with NMP between January 2022 and February 2026. Patients were divided into NMP alone and NMP with NRP groups according to NRP use. Lactate levels during NMP were assessed at 60, 120, and 180 minutes using the closest available measurement to each target time point. Lactate reduction was calculated for each interval using the actual elapsed time between measurements. The primary clinical outcome was early allograft dysfunction (EAD). Multivariable logistic regression adjusted for donor BMI and donor sex, along with mediation analysis, was used to evaluate the association among NRP use, early lactate reduction, and EAD. **Results:** A total of 215 DCD LT recipients were included, of whom 145 underwent NMP alone and 70 underwent NMP with NRP. Donor age was significantly higher in the NMP with NRP group than in the NMP alone group (61 vs. 53 years, $p < 0.001$). EAD incidence did not differ between groups (16.0% vs. 18.6%, $p = 0.63$). There was no significant difference in lactate levels at the start of NMP. The 0–60 minute lactate reduction was greater in the NMP with NRP group than in the NMP alone group (47.8% vs. 30.5%, $p < 0.001$), while no significant differences were observed during 60–120 or 120–180 minutes. Lactate reduction during the first 60 minutes of NMP was categorized as < 0%, 0–40%, or > 40%, with the 40% cutoff selected based on the median value of early lactate reduction. A lactate reduction > 40% within 60 minutes occurred more frequently in the NMP with NRP group than in the NMP alone group (71.6% vs. 37.5%, $p < 0.001$). EAD incidence decreased across lactate reduction categories, from 33.3% in patients with < 0% reduction to 22.6% in those with 0–40% reduction and 9.4% in those with > 40% reduction ($p = 0.01$). In multivariable logistic regression adjusted for donor BMI and donor sex, lactate reduction > 40% during the first 60 minutes of NMP was an independent protective factor against EAD (OR 0.30, 95% CI 0.12–0.75, $p = 0.01$), whereas NRP use itself was not directly associated with EAD. Mediation analysis demonstrated a significant indirect effect of NRP on EAD through lactate reduction > 40% during the first 60 minutes of NMP (ACME −0.05, 95% CI −0.11 to −0.01, $p = 0.004$), whereas the direct effect was not significant (ADE 0.10, 95% CI −0.02 to 0.22, $p = 0.10$). **Conclusion:** Although NRP was used in older donors, adding NRP before NMP was associated with improved early lactate reduction during the first 60 minutes of NMP. Mediation analysis further suggested that NRP may indirectly reduce the risk of EAD through enhanced early lactate reduction.

Effect	Estimate	95% CI	*p-value*
ACME average	-0.05	-0.11, -0.01	0.004
ADE average	0.10	-0.02, 0.22	0.10
Total effect	0.05	-0.07, 0.17	0.49

Adjusted: Donor BMI, Donor Sex Values in parentheses indicate 95% CIs.

0016 | WAITLIST RECOMPENSATION ACROSS STEATOTIC LIVER DISEASE PHENOTYPES: ALD, METALD, AND MASLD IN 43,410 UNOS CANDIDATES (2017–2023)

Islam Mohamed[1] Mohamed Nadeem[2] Basil Jalamneh[2] Mohamad Ali Ibrahim[3] Prasun Jalal[3], [1]The Cleveland Clinic Foundation-Fairview hospital, [2]Cleveland Clinic Foundation, [3]Baylor College of Medicine

Background: The 2023 Delphi consensus established MetALD metabolic dysfunction superimposed on intermediate alcohol use as a distinct steatotic liver disease (SLD) phenotype. Whether MetALD confers a recompensation trajectory on the liver transplant waitlist distinct from ALD or MASLD is unknown. We conducted the first national competing-risk analysis of waitlist recompensation stratified by 2023 SLD nomenclature. **Methods:** Using OPTN/UNOS STAR data (2017–2023), we classified 43,410 adult waitlist candidates across 120 centers as ALD, MetALD, or MASLD via the validated UNOS algorithm (MELD-Na ≥ 10; first-time liver-only listing). The primary outcome was waitlist recompensation. Fine-Gray subdistribution hazard models estimated adjusted subdistribution hazard ratios (aSHR; transplant + death as competing events), adjusted for age, sex, race, MELD-Na, BMI, diabetes, ascites, encephalopathy, HCC, calendar year, insurance, and UNOS region. Durability among 1,590 recompensated patients was assessed by Kaplan-Meier and Cox proportional hazards for time-to-re-listing. Recompensation defined as >5 points decrease in MELD score since lisitng or removal from the waitlist due to improvement. **Results:** At 24 months, cumulative recompensation incidence was 8.4% (ALD), 5.1% (MetALD), and 2.1% (MASLD). In adjusted Fine-Gray models (reference: ALD), MetALD carried equivalent recompensation hazard (aSHR 1.00, $p = 0.98$), while MASLD was associated with 57% lower recompensation hazard (aSHR 0.43, $p < 0.001$). Among recompensated patients, 24-month freedom from re-listing was 98.0% (ALD), 93.4% (MetALD), and 89.4% (MASLD), $p < 0.001$. Cox regression confirmed MetALD (HR 3.00, $p = 0.001$) and MASLD (HR 4.41, $p < 0.001$) carried significantly higher re-listing hazard than ALD. Phenotype-stratified analyses identified albumin as the dominant recompensation predictor in ALD and BMI with diabetes in MASLD (Figures 1&2). In phenotype-stratified multivariate analyses, albumin and lack of encephalopathy were the dominant predictors of recompensation in ALD and MetALD, whereas lower BMI and absence of diabetes predicted recompensation in MASLD. Notably, metabolic risk factors explicitly drove the higher re-listing hazard observed in the MetALD cohort. **Conclusion:** We identify a phenotype-specific dissociation: the alcoholic component drives recompensation equally in ALD and MetALD, while the metabolic substrate predicts recompensation failure in both MetALD and MASLD (3–4× higher re-listing hazard). These data support phenotype-specific listing observation periods and post-recompensation surveillance protocols across SLD.

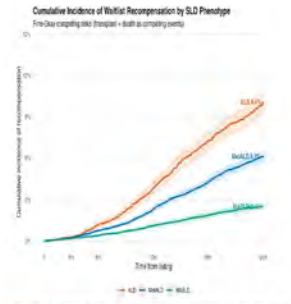

Figure 1. Cumulative incidence of recompensation by SLD phenotype. ALD 8.4%, MetALD 5.1%, MASLD 2.1% at 24 months.

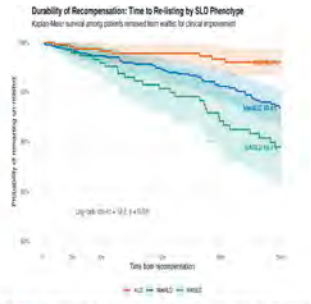

Figure 2. Durability of recompensation: freedom from re-listing at 24 months. ALD 98.0%, MetALD 93.4%, MASLD 89.4%.

0017 | LOW-DOSE CONTINUOUS TERLIPRESSIN: COMPARABLE EFFICACY, LOWER TOXICITY IN ACLF VARICEAL BLEEDING

Khushboo Yadav[1] Vinod Arora[2] Chitranshu Vashishtha[2] Manoj Sharma[2] Rakhi Maiwall[2] Ashok Kumar Choudhury[2] Rajan Vijayaraghavan[2] Ankur Jindal[2] Harsh Tevethia[3] Kavitha Jonnalagadda[2] Shiv Kumar Sarin[2], [1]institute of liver and biliary science, [2]Institute of Liver and Biliary Sciences, [3]Institute of Liver and Biliary Sciences(ILBS), New Delhi

Background: Acute oesophageal variceal bleeding (AVB) in patients with acute-on-chronic liver failure (ACLF) carries a high 28-day mortality. Recent data in cirrhosis suggest that continuous infusion (CI) of terlipressin is as effective as bolus injections (BOL)

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

and is preferred owing to fewer adverse events; however, data in ACLF patients with AVB are lacking. We compared efficacy and safety of CI versus BOL terlipressin in ACLF patients presenting with AVB. **Methods:** This single-centre, prospective, open-label, randomized controlled trial (NCT06815770) was conducted at ILBS, New Delhi. ACLF patients (18–70 years), with esophageal variceal bleed were randomized to CI terlipressin (2 mg/24 h IV; escalated to 4 mg/24 h if required) or BOL terlipressin (1 mg IV every 4 h for 48 h, followed by every 6 h for 72 h). All patients underwent endoscopic variceal ligation and standard medical therapy. Primary endpoint was 28-day all-cause mortality. Secondary endpoints included rebleeding, transfusion requirement, renal outcomes, hemodynamic response, and terlipressin-related adverse events at 24 hours, Day 5, and Day 28 **Results:** Of 104 ACLF patients present with AVB, 60 were randomized (n = 30 per arm). Exclusions were due to gastric/non-variceal bleed, severe hyponatremia, cardiac contraindications, and lack of consent. Baseline characteristics were comparable [MELD score: 30.8 ± 7.2 vs 31.7 ± 7.2, p = 0.618; AARC Grade III: 53.3% vs 63.3%, p = 0.60].28-day survival was comparable (CI 46.7% vs BOL 43.3%; p = 0.79). There was no significant difference in 5-day rebleeding (16.7% vs 13.3%; p = 0.45) or PRBC transfusion requirements (3.7 vs 3.6 units; p = 0.54). Mean daily terlipressin dose was approximately half in the CI arm (1.84 vs 3.70 mg/day; p < 0.001). CI group showed significantly fewer adverse events (23.3% vs 73.3%; p < 0.001) and fewer drug discontinuations (10.0% vs 30.0%).Although HVPG could not be assessed in all patients due to the critically ill nature of the cohort, in the evaluable subset (HVPG subset, n = 4 per arm), CI demonstrated a trend towards superior portal pressure reduction — relative HVPG reduction at 48 hours: 12.1 ± 5.4% (CI) vs 9.6 ± 6.1% (BOL); p = 0.080; absolute reduction: 2.8 ± 1.2 vs 2.2 ± 1.5 mmHg; p = 0.070. The CI was associated with a 66% reduction in the odds of post-bleed AKI within 5 days (16.7% vs 36.7%; OR 0.34; 95% CI 0.10–1.16) and a reduced need for RRT (3.3% vs 13.3% p = 0.36). **Conclusion:** In ACLF-AVB subset, continuous terlipressin infusion achieves equivalent hemostatic efficacy to standard bolus dosing with half the cumulative drug exposure, a three-fold reduction in adverse events, renal-protective effects, and a trend towards better portal pressure control. Continuous terlipressin infusion should be recommended in ACLF patients presenting with acute variceal bleed.

0018 | EARLY DEEP SEDATION IS ASSOCIATED WITH INCREASED MORTALITY IN MECHANICALLY VENTILATED PATIENTS WITH CIRRHOSIS

Benjamin Rosenthal[1] Douglas Schaubel[1] Marina Serper[1], [1]University of Pennsylvania

Background: Patients with cirrhosis who require mechanical ventilation (MV) experience high mortality, yet optimal sedation strategies are poorly defined. Cirrhosis alters sedative and analgesic pharmacokinetics and increases vulnerability to prolonged coma, hepatic encephalopathy (HE), delirium and organ failure. We evaluated whether early deep sedation was associated with mortality among mechanically ventilated adults with cirrhosis. **Methods:** This was a retrospective cohort study of adults with cirrhosis who underwent mechanical ventilation across 6 hospitals in the University of Pennsylvania Health System between 2017-2025 using the Complete Inpatient Record Using Comprehensive Electronic Data. Sedation depth was quantified using the observed Richmond Agitation-Sedation Scale (RASS). Deep sedation was defined as RASS -5 to -3 ("unarousable" to "moderate sedation") within the first 48 hours after MV initiation. We evaluated time-weighted deep sedation as the proportion spent in deep sedation, modeled per 10% increase. The primary outcome was time to 14-day in hospital mortality after the first 48-hours. Large language models identified HE and other patient characteristics. Cox proportional hazards models were adjusted for age, PaO_2/FiO_2, laboratory values, vasopressor use, renal replacement therapy, HE and hospital. **Results:** Among n = 859 MV patients with cirrhosis, the median percentage of time in deep sedation was 52% (IQR 19-83%). 82% and 74% of patients were deeply sedated $\geq$ 10% and $\geq$ 20% of the time. Patients with sedation $\geq$ 10% had higher median MELD-Na score (26 vs 23, p < 0.001), bilirubin (3.6 vs 2.0 mg/dL, p < 0.001), INR (1.8 vs 1.6, p < 0.001), lactate (3.6 vs 2.4 mmol/L, p < 0.001), were more likely to be located at a non-transplant center (67% vs 53%, p = 0.001), and more likely to be on vasopressors (84% vs 71%, p < 0.001). Deeply sedated patients received more midazolam (57% vs 36%, p < 0.001) and less dexmedetomidine (18% vs 26%, p = 0.021). Fourteen-day mortality was 30%. In a multivariable model, time in deep sedation was independently associated with mortality (adjusted hazard ratio 1.07 per 10% increase of time, 95% CI 1.02-1.12, p = 0.004). Older age, bilirubin, INR, creatinine, lactate, and history of HE were also associated with mortality. Kaplan-Meier analyses demonstrated lower survival probability among patients with $\geq$ 10% deep sedation (Figure). **Conclusion:** In this multi-hospital cohort of

mechanically ventilated patients with cirrhosis, greater time spent in deep sedation was associated with increased 14-day mortality. Early sedation depth is an important and potentially modifiable risk factor in critically ill patients with cirrhosis and support future studies evaluating liver-specific sedation strategies.

Covariate	Adjusted Hazard Ratio (95% CI)	p-value
Primary exposure		
Time-weighted deep sedation, per 10% increase	1.07 (1.02–1.12)	0.004
Demographics		
Age, per year	1.04 (1.03–1.05)	<0.001
PF ratio category		
200–300 vs >300	0.64 (0.38–1.06)	0.086
<200 vs >300	0.86 (0.60–1.24)	0.419
Laboratory values, first 48 hours		
Sodium minimum	0.98 (0.96–1.01)	0.067
Bilirubin maximum	1.02 (1.01–1.04)	0.005
INR maximum	1.19 (1.06–1.34)	0.005
Creatinine maximum	1.11 (1.04–1.18)	0.001
Albumin minimum	1.03 (0.80–1.33)	0.807
Lactate maximum	1.08 (1.05–1.11)	<0.001
WBC maximum	1.01 0.99–1.02)	0.353
Clinical severity markers		
Any vasopressor: Yes vs No	1.39 (0.79–2.43)	0.250
RRT exposure: Yes vs No	0.89 (0.66–1.21)	0.473
Hepatic Encephalopathy History	1.39 (1.00–1.92)	0.049
Transplant Center vs Non-Transplant Center	0.81 (0.56–1.19)	0.294

Description: Multivariable Cox proportional hazards model evaluating factors associated with hazards of 14-day landmark mortality after the 48-hour mechanical ventilation exposure period among mechanically ventilated patients with cirrhosis. The primary exposure was time-weighted deep sedation during the first 48 hours after mechanical ventilation initiation, modeled per 10% increase in time spent deeply sedated. The model included 689 patients and 211 mortality events. Hazard ratios greater than 1 indicate a higher hazard of mortality, while hazard ratios less than 1 indicate a lower hazard.

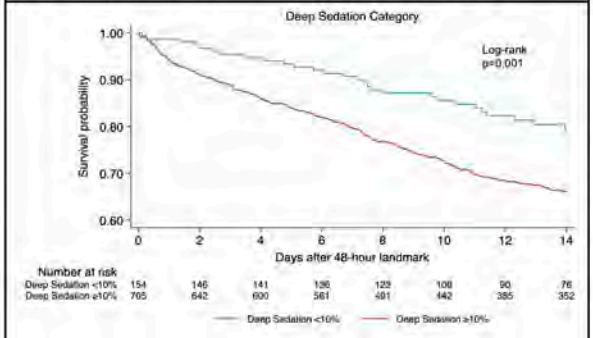

Figure: Kaplan–Meier survival after the 48-hour landmark by early deep sedation exposure.
Kaplan–Meier curves show lower 14-day survival among patients who spent ≥10% of the first 48 hours of mechanical ventilation in deep sedation compared with those who spent <10% of time in deep sedation. The number at risk is shown below the plot.

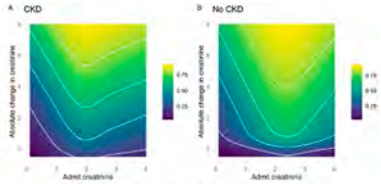
0019 | CHRONIC KIDNEY DISEASE AND MORTALITY IN CRITICALLY ILL PATIENTS WITH DECOMPENSATED CIRRHOSIS

Rahul Thakkar[1] Sumeet Asrani[2] Gerald Ogola[1] Lauren Hall[1] Kavish Patidar[3], [1]Baylor University Medical Center, [2]Liver Consultants of Texas, [3]Houston Methodist Hospital



Background: Background: Kidney dysfunction is a major driver of mortality in critically ill patients with acute-on-chronic liver failure. International Club of Ascites (ICA) and global liver societies (including AASLD) use serum creatinine (sCr)-based definitions to classify AKI stages irrespective of baseline chronic kidney disease (CKD) status. We aimed to determine whether current definitions adequately capture the impact of kidney dysfunction given the evolving population of critically ill patients with decompensated cirrhosis. **Methods:** Methods: We examined critically ill adult patients with decompensated cirrhosis admitted to intensive care units across a large integrated healthcare system comprising 20 hospitals between 2019–2022. The primary outcome was 30-day all-cause mortality. Key exposures included admission sCr and maximum absolute change in sCr during hospitalization (ΔsCr). Mortality contour mapping was performed to identify admission sCr and ΔsCr thresholds associated with predefined mortality probabilities of 20%, 30%, 40%, and 50% by presence of CKD. **Results:** Results: Among 3,913 critically ill patients, 14% had CKD. Across CKD and non-CKD, higher admission sCr and greater ΔsCr were associated with progressively higher 30-day mortality; however, equivalent sCr trajectories carried markedly **different** prognostic effects according to baseline CKD status. The greatest divergence was observed at admission sCr levels between 2–3 mg/dL, where relatively small increases in sCr among non-CKD patients were associated with sharp increases in mortality. For example, a ΔCr of 1.0 mg/dL (2.5–3.5mg/dL) carried a predicted 30-day mortality of 62% in non-CKD patients compared to 40.2% in CKD patients. A lower KDIGO stage thus carried **higher** mortality than a higher stage when admission sCr was elevated. (**Figure 1A**) Mortality contour mapping further demonstrated that non-CKD patients crossed predefined 20%, 30%, 40%, and 50% mortality thresholds at substantially smaller ΔsCr values than CKD patients (**Figure 1B**). **Conclusion:** In critically ill patients with decompensated cirrhosis, the prognostic significance of kidney dysfunction differs substantially according to baseline CKD status. We propose that mortality-based creatinine thresholds may better characterize clinically meaningful renal dysfunction than current creatinine staging systems (e.g. KDIGO or AKIN) and have important implications for organ failure definitions for renal failure, endpoint selection in ACLF clinical trials and organ transplantation.

0020 | PRAGMATIC DEFINITION OF ACLF USING GLOBAL HARMONIZATION PREDICTS MORTALITY WITH INCREASING GRADES ACROSS THREE LARGE PATIENT COHORTS

Jasmohan Bajaj[1] Scott Silvey[2] Ohm Patel[2] Florence Wong[3] Jacob George[4] Wai-Kay Seto[5] Qing Xie[6] Mário Alvares-da-Silva[7] Peter Hayes[8] Mark Topazian[9] Brian Bush[2] Ramazan Idilman[10] Aldo Torre[11] Patrick Kamath[12] Nilang Patel[2], [1]Virginia Commonwealth University, [2]VCU, [3]University of Toronto, [4]The University of Sydney, [5]The University of Hong Kong, [6]Ruijin Hospital, [7]Porto Alegre, [8]U Edinburgh, [9]St Paul Millennium College Addis Ababa, [10]Ankara University School of Medicine, [11]Gastroenterology Department Centro Médico ABC, [12]Mayo Clinic

Background: Acute on Chronic Liver failure is associated with higher death and need for transplant but definitions vary. A consensus is building towards getting an equitable, data-driven definition that has worldwide representation and is benchmarked to mortality. The definition, created using a harmonization process, focuses on ensuring that the definition is easy to remember and apply in the hands of all clinicians and not just liver or ICU specialists. This defintion involves pragmatic combinations of liver and extrahepatic organ dysfunction (EHOD) and failures (EHOFs) but needs validation. **Methods:** Three large datasets were evaluated for the diagnosis and grading of ACLF based on consensus EHOD/F definitions. The definition (Fig A) includes user-friendly definitions of liver failure (bilirubin 5mg/dl+INR > 1.5) , EHOD (HE grade 2, AKI stage 1 per KDIGO criteria, MAP < 70, respiratory compromise per ARDS criteria) & EHOF (HE 3-4 or mechanical ventilation (MV) for that , AKI ≥ stage 2, vasopressor use (per SOFA-2) or severe respiratory compromise/ MV for ARDS) with ACLF grading (Fig B). The datasets used were: (a) **CLEARED**, a global consortium of inpatients with cirrhosis , (b) **Veterans Corporate Data Warehouse** (US Veterans with cirrhosis with MELD3.0 > 15 on admission between 2020-24), and (c) **TriNetX database** (US-based insured patients with cirrhosis admitted between 2020-24). In each cohort, definitions and grades of ACLF were extracted and their impact on 30D mortality was evaluated. We also did a sensitivity analysis using bilirubin 7.5mg/dl+INR > 1.5 for all liver failure variables. **Results: CLEARED** : 6206 patients from 125 centers from 37countries (36% high, 44% upper-middle & 20% low-income) were included. 50% of the patients were from Asia, 20% from North America, 9% Africa, 8% Oceania, S America & Europe each. Median age was 57 yrs, 64% men, with MELD-Na 21. 18% died at 1 month. Prevalence of Grade 1ACLF was 6.7%, Grade 2, 9.3%, & Grade 3 was 6.6%. **TriNetX:** 117,437 patients were included. The median age was 61 yrs, 59% were men, and median MELD-Na was 22. Prevalence of ACLF-1: 7.2%, Grade 2:4.7% and Grade 3 was 6.5% . 14.5% died at 1 month. Death rate increased with higher ACLF grades **.VA-CDW:** 18,781 patients, median age 69 yrs, 97% men as expected due to military service, with a median of MELD-Na 20. 17.8% died at 1 month. ACLF-1 was seen in 2.9%, Grade 2:1.5%, and Grade 3 : 1%. For all 3 cohorts, the death rate significantly increased with increasing ACLF grades (Fig C-E). Similar patterns but relatively lower prevalence was seen for the 7.5mg/dl bilirubin threshold. **Conclusion:** The new pragmatic definition of ACLF and grading shows higher 30-day mortality with increasing grades in three large unrelated cohorts of inpatients with cirrhosis, despite differences in demographics. These have global and North American representation and could improve harmonization of ACLF diagnosis worldwide.

0021 | SOLUBLE PROGRAMMED DEATH LIGAND 1 OUTPERFORMS INTERLEUKIN 6, URINARY NEUTROPHIL GELATINASE-ASSOCIATED LIPOCALIN, AND NEUTROPHIL-TO-LYMPHOCYTE RATIO FOR ACLF PREDICTION IN PATIENTS WITH CIRRHOSIS: THE LIVERHOPE BIOMARKER STUDY

María Moreta[1] Adrià Juanola[1], [1]Liver Unit, Hospital Clínic of Barcelona, Barcelona, Catalunya, Spain

Background: Acute-on-chronic liver failure (ACLF) is the most severe form of decompensated cirrhosis, characterized by systemic inflammation and immune dysfunction. Identification of patients at high risk of ACLF remains challenging. Previous studies identified Interleukin-6 (IL-6), urinary Neutrophil Gelatinase-Associated Lipocalin (uNGAL) and Neutrophil-to-Lymphocyte ratio (NLR) as promising prognostic biomarkers in cirrhosis. However, their ability to predict ACLF remains inconsistent. Soluble programmed death ligand-1 (sPD-L1) has recently emerged as a marker of immune dysregulation and bacterial infection development in cirrhosis. The current study aimed to evaluate the prognostic value of sPD-L1, IL-6, uNGAL, and NLR for ACLF development in patients with decompensated cirrhosis. **Methods:** Prospective multicohort study including 562 patients with decompensated cirrhosis from two European cohorts. The derivation cohort included 222 patients from the LiverHope Efficacy Trial, while the validation cohort included 340 patients from two European University Hospitals. Patients were followed for 1 year. Time-to-event analyses were performed using Cox and Fine-Gray competing risk models. **Results:** In the Liverhope Trial cohort, patients were predominantly male (74%) with alcohol-related liver disease as the main etiology (71%). During follow-up, 28 patients (12%) in the derivation cohort developed ACLF. Among all biomarkers, only sPD-L1 was associated with ACLF development. Baseline sPD-L1 levels were higher in patients developing ACLF (116 vs 92 pg/mL; $p = 0.017$), and each 10 pg/mL increase was associated with increased ACLF risk (HR 1.045; 95%CI 1.008–1.084). In multivariable analyses, sPD-L1 and MELD-Na remained independent predictors of ACLF. Patients with sPD-L1 ≥ 147 pg/mL showed higher cumulative ACLF incidence ($p = 0.0075$) compared to those with sPD-L1 < 147 pg/mL. There was a relationship between sPD-L1, bacterial infection, and ACLF. Among 35 patients who developed bacterial infection during follow-up, 11 (31%) progressed to ACLF. These patients had higher baseline sPD-L1 and MELD-Na values. In the validation cohort, 47 (14%) patients developed ACLF during follow-up. Soluble PD-L1 levels were higher in patients developing ACLF (155 vs 119 pg/mL; $p < 0.001$), and multivariate analysis confirmed sPD-L1, MELD-Na, and previous bacterial infection as independent predictors, whereas NLR showed no prognostic value. **Conclusion:** The sPD-L1 is a reproducible and independent predictor of ACLF in decompensated cirrhosis. It outperformed IL-6, uNGAL, and NLR across two international cohorts and provided prognostic information beyond MELD-Na. Its association with bacterial infection and ACLF highlights the central role of immune dysfunction in cirrhosis progression and supports sPD-L1 as a biomarker for risk stratification of ACLF.

Pennsylvania, [2]University of Pennsylvania, [3]University of Pennsylvania Health System

Background: Acute-on-chronic liver failure (ACLF) is a syndrome of acute decompensation in patients with chronic liver disease (CLD) characterized by organ failure and high short-term mortality. Patients with CLD are at elevated risk for infections, which are common precipitants of acute decompensations and hospitalizations. Given growing concern for multidrug-resistant organisms, we aimed to better characterize bloodstream infection organisms among patients hospitalized with ACLF. **Methods:** We conducted a retrospective cross-sectional study of patients with cirrhosis in the VOCAL cohort (Veterans Health Administration, 128 centers, 2008-2025). ACLF hospitalizations were graded using EASL-CLIF criteria and evaluated for associated positive blood cultures. Bloodstream organisms were grouped into categories and resistance phenotypes. Patient characteristics and organism distributions were compared using chi-square and Wilcoxon rank-sum tests. **Results:** The analytic cohort comprised 7,888 ACLF hospitalizations; the most common CLD etiologies were MASLD (35.1%), HCV (28.6%), and ALD (12.1%). ACLF grades 1, 2, and 3 comprised 54.3%, 28.1%, and 17.6% of hospitalizations, respectively. ACLF-3 patients were younger, more likely to have ALD, and had higher rates of organ failures ($p < 0.001$). Across ACLF grades, bloodstream organism distribution varied significantly ($p < 0.001$). *Candida*/fungal organisms were identified in 0.5% of ACLF-1 hospitalizations versus 1.4% in ACLF-3 hospitalizations (**Figure 1A**). VRE phenotypes were identified in 0.8% of ACLF-1 hospitalizations versus 2.8% of ACLF-3 hospitalizations (**Figure 1B**). Conversely, MRSA bloodstream infections were less likely in ACLF-3 hospitalizations (6.3%) compared to ACLF-1 hospitalizations (9.5%) (**Figure 1B**). *Proteus/Morganella/Providencia* organisms were less common in ACLF-3 hospitalizations (1.6%) compared to ACLF-1 hospitalizations (2.9%) (**Figure 1A**). *Candida*/fungal organisms and VRE phenotypes showed a greater concentration of higher ACLF grades compared with other infection categories (**Figure 1C/D**). **Conclusion:** Greater ACLF severity was associated with distinct bloodstream infection and resistance phenotypes, including higher frequencies of Candida/fungal organisms, VRE, and polymicrobial infections. These findings improve understanding of infectious precipitants of ACLF and may inform diagnostic evaluation, empiric antibiotic selection, and future management for patients with ACLF. Additionally, resistant and fungal bloodstream infection phenotypes were associated with greater ACLF severity distributions, suggesting potential relationships between organism profile and severity of critical illness in ACLF.

0023 | USING INTERPRETABLE MACHINE LEARNING MODEL TO PREDICT HEALTH-RELATED QUALITY OF LIFE IN PATIENTS WITH MASLD

Wen Li[1] Sufang Lu[1] Fajuan Rui[1] Jie Li[1], [1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD) is a common chronic liver condition that can impair health-related quality of life (HRQoL). Identifying patients at risk of low HRQoL is challenging due to multifactorial influences. Interpretable machine learning (ML) can predict risk and clarify key contributors. **Methods:** HRQoL was assessed in 821 MASLD patients using the Chronic Liver Disease Questionnaire (CLDQ). Six predictors—alcohol use, exercise habits, smoking history, age, education, and arthritis—were selected via combined univariate, random forest, and LASSO feature selection. Six ML algorithms were trained and evaluated using ROC, calibration, and decision curve analyses; SHapley Additive exPlanations (SHAP) provided interpretability. **Results:** Among 821 patients, 205 (25%) were classified as having low HRQoL (CLDQ < 25th

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

percentile). Gradient Boosting achieved the highest performance with AUC = 0.942, accuracy = 84.5%, sensitivity = 76.4%, specificity = 91.5%, and F1-score = 0.82. SHAP analysis identified alcohol use (mean |SHAP| = 0.91) and exercise habits (mean |SHAP| = 0.89) as the dominant predictors, followed by smoking history (0.70), age (0.45), education (0.32), and arthritis (0.28). Age modified the effects of lifestyle behaviors, while other predictors contributed consistently across subgroups. **Conclusion:** Interpretable ML models accurately identify MASLD patients at risk of low HRQoL using six routinely obtainable variables. Lifestyle behaviors—especially alcohol consumption and exercise—are the primary drivers, supporting targeted risk screening and actionable interventions in clinical practice.

★ 0024 | LITEMEDSAM AND MEDNET: A SEGMENTATION-ASSISTED, ATTENTION-GUIDED LIGHTWEIGHT FRAMEWORK FOR EDGE-DEPLOYABLE SONOGRAPHIC CLASSIFICATION OF HEPATOCELLULAR CARCINOMA

Jansi Sethuraj[1] Elangovan Krishnan[2] Kavin Elangovan[3] Nayanika Tummala[4] Ramya Elangovan[5], [1]The University of Texas Health Science Center at Houston, [2]Indian Institute of Technology Bombay, [3]AIM, [4]NYMC St Marys St Clares, [5]Johns Hopkins University

Background: Accurate sonographic differentiation of hepatocellular carcinoma (HCC) from benign hepatic hemangioma, critical given HCC's global burden exceeding 800,000 deaths annually, remains one of the most consequential unresolved challenges in liver imaging. B-mode ultrasound, the dominant surveillance modality across most health systems, yields diagnostically equivocal findings in a substantial proportion of cases. Existing deep learning solutions achieve high benchmark accuracy through architecturally complex, GPU-dependent models that are structurally ill-suited for resource-limited or point-of-care deployment. **Methods:** We developed LiteMedSAM-MedNet: LiteMedSAM, operating from bounding-box prompts, segmented focal liver lesions and extracted perilesional crops (10–20% margin), which were then classified by MedNet — a purpose-designed lightweight architecture integrating depthwise separable convolutions, residual connections, and convolutional block attention module (CBAM) spatial-channel attention. Training and internal validation used SMC-LUD — 5,385 B-mode images from 1,021 patients, all HCC cases histopathologically confirmed and hemangioma cases independently verified by two board-certified abdominal radiologists, patient-level split 70:20:10. External validation used the TCIA liver dataset; prespecified outcomes included AUROC, sensitivity, specificity, F1-score, F2-score, and Dice Similarity Coefficient (DSC). **Results:** LiteMedSAM yielded a DSC of 0·85 (zero-shot) and 0·86 (fine-tuned). MedNet on standard lesion crops achieved 92·0% accuracy and F1-score; perilesional-margin cropping improved performance to 93·0%. AUROC was 0·97, HCC sensitivity 97%, and hemangioma specificity 98%. Full pipeline inference completed under 1 second on consumer-grade CPU hardware without GPU acceleration. **Conclusion:** LiteMedSAM-MedNet demonstrates that domain-adapted, attention-guided lightweight architectures can approach the diagnostic accuracy of computationally intensive classifiers in liver lesion characterisation. The convergence of CBAM-based attention with efficient convolutional design offers a translatable blueprint for edge-deployable hepatology AI. Validation across heterogeneous ultrasound platforms and geographically diverse patient cohorts is required before clinical implementation.

0025 | MENOPAUSE IN WOMEN WITH LIVER DISEASE: SYMPTOM BURDEN, METABOLIC CHANGES, AND HORMONAL REPLACEMENT THERAPY USE

Lorrinda Gray-Davis[1] Mustafa Behan[2] Jutta Kurz[2] Karen Hoyt[1] Tresha Elaine Ramonal[2] Rachma

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Purnama[3] Michael Tunkelrott[3] Emmanuel Gorospe[4] Tarek Hassanein[5], [1]None, [2]Amsety, [3]Amsety LLC, [4]Burrell College of Osteopathic Medicine, [5]Southern California Liver Centers

Background: Menopause is a key physiological transition in women associated with hormonal changes that can have wide-ranging effects on metabolic and systemic health. In the context of liver disease, these changes may influence liver fat accumulation, cholesterol, and inflammation. There is a need to better understand the relationship between menopause and liver disease in clinical practice. Aim: to examine differences in symptom burden, metabolic and clinical changes, and real-world use of hormonal and non-hormonal therapies across menopausal stages in women with liver disease. **Methods:** We conducted an exploratory survey of 71 women with liver disease across menopausal stages, drawn from the Amsety database of 650,000 Americans living with liver disease. It examined menopause status, symptoms, perceived changes in metabolic and clinical markers, and the use of hormone replacement therapy (HRT) and non-hormonal treatments. **Results:** Average age of respondents was 48 years and an average BMI of 30. 49% were pre- and peri-menopausal, while 51% were post-menopausal and surgical menopausal. The majority had MASLD (69%) as the etiology for liver disease. 8% had cirrhosis. Liver disease diagnosis varied by menopausal stage: MASLD was higher in the post-menopausal stage (72%) compared with the pre- and peri-menopausal stages (66%), while MASH was also higher in the post-menopausal stage (11%) compared with the pre- and peri-menopausal stages (8%). Early-stage disease was more common among pre- and peri-menopausal patients (74%) than post-menopausal patients (42%). Common symptoms for pre- and peri-menopausal patients include hot flashes (76%), fatigue (74%), and joint pain (68%), while for post-menopausal patients, fatigue is highest (89%), followed by joint pain (86%) and mood changes (72%). For HRT use, 54% have never used it, 21% are currently using it, and 14% have previously used it. Reported benefits after HRT use include improved hot flashes (39%), mood (19%), and fatigue (13%). 50% experience side effects after HRT use such as elevated liver enzymes. Respondents also use alternatives to HRT, including dietary changes/supplements (18%), SSRIs/SNRIs (15%), and gabapentin/pregabalin (15%). **Conclusion:** Menopause is an important but often under-recognized factor in women with liver disease, with differences observed across stages in disease presentation, symptom burden, and metabolic changes. Hormonal and non-hormonal treatments are used across groups with varying perceived effects. This analysis highlights the importance of considering menopausal stage in assessment and management to support more individualized care in liver patients. There's a need for further research and clearer guidance on the use of HRT in women with liver disease, including its potential benefits and risks.

0026 | SERUM IGM AS A PROGNOSTIC BIOMARKER LINKED TO INTRAHEPATIC IMMUNE ACTIVATION IN PRIMARY BILIARY CHOLANGITIS: INSIGHTS FROM HISTOPATHOLOGY

Taiki Okumura[1] Kaede Fujita[1] Yuma Kamijo[1] Shun-Ichi Wakabayashi[2] Hiroyuki Kobayashi[1] Tomoo Yamazaki[1] Takefumi Kimura[1], [1]Shinshu University Hospital, [2]Shinshu University School of Medicine

Background: Elevated serum immunoglobulin M (IgM) is a hallmark of primary biliary cholangitis (PBC), yet its prognostic significance and biological basis remain incompletely understood. We investigated whether serum IgM normalized to the upper limit of normal (IgM/ULN) predicts liver-related events (LREs) in PBC and explored the pathological and molecular mechanisms underlying IgM elevation. **Methods:** A total of 427 treatment-naïve patients with PBC from four Japanese centers were retrospectively analyzed. Associations between baseline IgM/ULN and LREs were evaluated using Cox proportional hazards models. LREs were defined as ascites, gastroesophageal varices, hepatic encephalopathy, or hepatocellular carcinoma. Additional integrative analyses, including histopathology, immunohistochemistry, bulk mRNA expression profiling, single-cell transcriptomics, and network analyses, were performed to investigate intrahepatic sources and mechanistic pathways associated with IgM elevation. **Results:** The median age at diagnosis was 58 years, and the cohort included 70 males and 357 females, with a median follow-up of 9.0 years. During follow-up, 39 LREs occurred, and the cumulative incidence of LREs at 20 years was 22.7%. In multivariate Cox analysis, low serum albumin (hazard ratio [HR] 0.18, $P < 0.001$) and elevated IgM/ULN (HR 1.53, $P < 0.001$) were independently associated with LREs. An optimal cutoff of IgM/ULN ≥ 1.6 identified patients with significantly higher cumulative incidence of LREs compared with IgM/ULN < 1.6 ($P < 0.001$), and this prognostic significance was retained in clinically and pathologically early-stage disease. Higher IgM/ULN levels were associated with histological progression, particularly bile duct loss. Hepatic IGHM expression correlated with both serum IgM/ULN levels and bile duct injury. Immunohistochemistry demonstrated intrahepatic IgM-producing plasma cells and mature B cells, while single-cell transcriptomic analysis identified plasma cells, mature B cells, and plasmacytoid dendritic cells as potential contributors to local IgM production. Network analyses implicated NF-κB– and cytokine-related inflammatory pathways associated with cholangiocyte injury and IgM elevation. **Conclusion:** Serum IgM/ULN is a simple, standardized, and widely available biomarker that independently predicts liver-related events in PBC, including in early-stage disease. Integrative molecular analyses suggest that elevated IgM reflects intrahepatic immune activation and bile duct injury, supporting its utility as both a prognostic and pathobiological biomarker in PBC.

[2]GSK, Durham, NC, USA, [3]GSK, Collegeville, PA, USA, [4]GSK, London, UK, [5]GSK, Munich, Germany, [6]GSK, Collegeville, PA, US (at time of study conduct), [7]University of California Davis, Sacramento, CA, USA, [8]University of Zurich, Zurich, Switzerland

Background: Bile acid binding resins (BABRs) and fibrates/peroxisome proliferator-activated receptor (PPAR) agonists have been recommended in treatment guidelines for cholestatic pruritus in primary biliary cholangitis (PBC). Linerixibat (ileal bile acid transporter inhibitor) was approved in the US for the treatment of cholestatic pruritus in PBC, following positive results from the GLISTEN study (NCT04950127). This post hoc analysis assessed the effect of linerixibat on mediators of pruritus (total serum bile acids [TSBA]; autotaxin [ATX]; a surrogate for lysophosphatidic acid; interleukin-31 [IL-31]) and pharmacodynamic markers of bile acid synthesis/reabsorption (7-alpha-hydroxy-4-cholesten-3-one [C4]; fibroblast growth factor-19 [FGF-19]) in a subset of patients (pts) receiving a stable dose of BABRs and/or PPAR agonists. **Methods:** GLISTEN was a Phase 3, randomized, double-blind, placebo-controlled study of adults with PBC and moderate-to-severe pruritus. In Part A, patients received linerixibat 40 mg twice daily or placebo for 24 weeks; this was followed by Part B, an 8-week crossover period where patients either switched or maintained treatment. Biomarker concentrations were measured at baseline and every 4 weeks through Week 32; change from baseline was assessed in pts on a stable background (no initiation/discontinuation/dose changes 8 weeks before screening through treatment end) of BABRs and/or PPAR agonists. **Results:** Of 238 randomized pts, 8% were receiving concomitant BABRs at baseline (linerixibat n = 10; placebo n = 10) and 22% were receiving PPAR agonists (linerixibat n = 23; placebo n = 30). Overall, linerixibat produced greater (generally sustained) reductions in TSBA, ATX, and IL-31 than placebo when added to stable BABR or PPAR agonist therapy over 24 weeks (Part A). At Week 32, after switching between linerixibat and placebo pts had rapid, directional biomarker changes across cohorts. Decreases in TSBA, ATX, and IL-31 were greater with linerixibat plus stable PPAR agonists than with placebo plus PPAR agonists in Part A; switching treatments led to corresponding increases or decreases despite stable PPAR agonist therapy (**Figure, bottom**). Similar trends were observed for IL-31 with linerixibat added to BABR regimens compared to placebo with BABR regimens; TSBA and ATX showed greater variability across cohorts in Part A. However, following treatment switch, biomarker reductions were rapid in pts switching to linerixibat, while concentrations increased in pts switching to placebo despite stable BABR therapy (**Figure, top**). C4 increased and FGF-19 decreased when adding linerixibat to stable concomitant BABR or PPAR agonist therapy. **Conclusion:** Reduction of systemic markers of cholestatic pruritus are detectable following addition of linerixibat in patients entering GLISTEN on stable guideline therapies for itch. **Funding:** GSK (212620)

Figure: Mean change from baseline in pruritus mediators by treatment group in GLISTEN participants entering the study and remaining on stable background BABR (top row) or PPAR agonist (bottom row) therapy

0028 | FIRST-IN-DISEASE OBJECTIVE ASSESSMENT OF SCRATCH AND SLEEP PATTERNS USING A WEARABLE DIGITAL HEALTH TOOL IN PRIMARY BILIARY CHOLANGITIS: THE LUMINARIA STUDY

Cynthia Levy[1] Anita Kohli[2] Marlyn Mayo[3] Andreas Kremer[4] Mark Swain[5] Seema Meloni[6] Christelle Pommie[7] Marwan Sleiman[7] Joanna Harton[8] Yu Hong[8] Marlene Smurzynski[8] David Jones[9], [1]Schiff Center for Liver Diseases, University of Miami, Miami, FL, USA, [2]Arizona Liver Health, Chandler, AZ, USA, [3]University of Texas Southwestern Medical Center, Dallas, TX, USA, [4]Department of Gastroenterology and Hepatology, University Hospital Zürich, Zürich, Switzerland, [5]Department of Medicine, Cumming School of Medicine, University of Calgary, Calgary, AB, Canada, [6]Ipsen, Cambridge, MA, USA, [7]Ipsen, Paris, France, [8]Genesis Research Group, Hoboken, NJ, USA, [9]NIHR Newcastle Biomedical Research Centre, Newcastle University, Newcastle Upon Tyne, UK

Background: While patient-reported outcome (PRO) instruments are valuable for assessing symptoms in primary biliary cholangitis (PBC), their subjective nature introduces potential bias and measurement variability. LUMINARIA (NCT07049887) is the first study to utilize a wearable sensor to objectively measure nocturnal scratch and sleep patterns in patients (pts) with PBC. **Methods:** In LUMINARIA, a multicenter, non-interventional, prospective, longitudinal US study, pts with PBC received standard clinical care and wore the ADvanced Acousto Mechanic (ADAM) sensor on the dominant hand during sleep across four 7-day wear periods (Weeks 0, 4, 8, and 12). Pts also completed validated PRO measures of pruritus, sleep disturbance, and fatigue at baseline (BL) and during each wear period. Analyses are descriptive; pts were stratified by BL pruritus severity using Worst-Itch Numeric Rating Scale (WI NRS), with no formal hypothesis testing. **Results:** Of 30 pts enrolled, 28 met inclusion criteria for analysis. Of these, 26 (93%) were female, mean age was 59.7 (SD: 11.7) years, and median time since diagnosis was 3.8 (IQR: 1.7−13.8) years. For 17 pts with BL data, median ALP was 150 (IQR: 109−184) U/L. At BL, 10 (36%) pts had mild/no pruritus (WI NRS < 4, “low itch”) and 18 (64%) had moderate-to-severe pruritus (WI NRS ≥ 4, “high itch”). Most ($n = 24$; 86%) pts wore the sensor for all wear periods. Median total wear duration during the study was 27 days. At Weeks 4, 8, and 12, median hourly nocturnal scratch events ranged from 0.1–0.4 in pts with low itch and 0.4–0.6 with high itch (**Table**). Median hourly scratch duration appeared slightly higher in pts with high versus low itch; there was no difference in scratch duration per night or scratch intensity. While total sleep time per night as well as proportions of wakefulness time during either overall sleep or scratch periods were consistent for all pts, median duration of sleep between scratch periods ranged from 110−200 mins in pts with low itch and 82 −115 mins with high itch. Median scores across WI NRS, PBC-40 Itch domain, and 5-D Itch were generally consistent within each group over 12 weeks (**Table**). For other PBC-40 domains (General Symptoms, Fatigue, Cognitive Function, Social Function, Emotional Function); PROMIS Fatigue SF-7a; and Sleep Disturbance NRS, IQRs were broad and overlapping with no differences between the low and high itch groups. All 19 pts who completed a usability survey rated their experience using the sensor as “good” or “excellent.” **Conclusion:** The integration of wearable sensor technology provides unprecedented, objective insights into novel dimensions of itch in PBC, including the interplay between nocturnal scratching behavior and

sleep disturbance. This innovative approach generates clinically meaningful new evidence and advances understanding of symptom burden in this population.

0029 | REAL-WORLD EFFICACY OF ELAFIBRANOR IN PATIENTS WITH PRIMARY BILIARY CHOLANGITIS: EXPERIENCE FROM A COMMUNITY-BASED HEPATOLOGY PRACTICE

Rida Nadeem[1] Anita Kohli[1] Richard Manch[1] Justin Reynolds[1] Cody Chen[1] Jessica Omana Castaneda[1] Ann Moore[1] Erfan Asadipour[1] Rayan Ahmed[1] Phuong Nguyen[1], [1]Arizona Liver Health

Background: Primary biliary cholangitis (PBC) is a chronic cholestatic liver disease associated with progressive fibrosis, cirrhosis, and liver-related morbidity. Despite standard therapy with ursodeoxycholic acid (UDCA), a substantial proportion of patients fail to achieve adequate biochemical response. Elafibranor, a dual peroxisome proliferator-activated receptor (PPAR)-α/δ agonist, has emerged as a novel therapeutic option for patients with inadequate response or intolerance to UDCA. Real-world data evaluating the effectiveness of elafibranor in routine clinical practice remain limited. **Methods:** We conducted a retrospective real-world analysis of adult patients with PBC treated with elafibranor at a single outpatient hepatology center for at least 12 months. Patients with available baseline and follow-up laboratory data were included. Primary efficacy outcomes included changes in alkaline phosphatase (ALP), total bilirubin normalization, improvement in liver transaminases, and patient reported outcomes following initiation of therapy. **Results:** A total of 10 patients with PBC were included in the final analysis (mean age 66 years; 83.3% females; mean BMI 28.9). Average time on ursodiol before starting a second-line agent was about 4.3 years. Following initiation of elafibranor therapy, patients demonstrated clinically meaningful reductions in ALP levels compared with baseline (mean reduction of 84 IU/L). Mean reduction in total bilirubin of 0.16 mg/dL. Improvements were also observed in cholestatic and hepatic biochemical parameters, including reductions in AST and GGT of 2.9 IU/L and 96.1 IU/L respectively. 17% reported improvement in pruritis. Elafibranor was generally well tolerated in this real-world cohort, with a 26.67% discontinuation rate overall. **Conclusion:** In this real-world community hepatology cohort, elafibranor treatment was associated with improvements in cholestatic liver biochemistries and fibrosis-related markers among patients with PBC. These findings support the effectiveness of elafibranor in routine clinical practice and reinforce its role as a promising therapeutic option for patients with inadequate biochemical response to standard therapy. Larger longitudinal studies are warranted to further evaluate long-term clinical outcomes and treatment durability.

0030 | ELAFIBRANOR VERSUS SELADELPAR IN UDCA-TREATED PRIMARY BILIARY CHOLANGITIS: A 111-HEALTH-SYSTEM PROPENSITY-MATCHED COMPARATIVE EFFECTIVENESS STUDY

Mohammad Alabbas[1] Barish Eren[1] Omar Sims[1] Dian Chiang[2], [1]Cleveland Clinic Foundation, [2]Cleveland Clinic

Background: Elafibranor and seladelpar have expanded second-line options for primary biliary cholangitis (PBC) with inadequate response to ursodeoxycholic acid (UDCA), but head-to-head real-world comparative data are limited. Because both agents received accelerated approval based on alkaline phosphatase (ALP) reduction rather than proven prevention of liver decompensation, comparative effectiveness and safety data are clinically important. **Methods:** We used the TriNetX Research Network (111 healthcare organizations) to emulate an active-comparator cohort study

of adults with PBC receiving UDCA who initiated elafibranor or seladelpar. Index date was first qualifying drug exposure after documented UDCA plus PBC. Patients with competing liver diseases, including PSC, autoimmune hepatitis, alcohol-related liver disease, viral hepatitis, hemochromatosis, Wilson disease, or alpha-1-antitrypsin deficiency, were excluded. Outcomes were assessed from day 1 through 365 days after index. Cohorts were 1:1 propensity-score matched on available demographics, diagnoses, medications, and laboratory values. The primary outcome was a major adverse liver outcome (MALO) composite including hepatic encephalopathy, variceal bleeding, ascites, portal hypertension, hepatorenal syndrome, cirrhosis codes, hepatocellular carcinoma, or death. Secondary outcomes included all-cause hospitalization, MACE, ALP distribution, albumin ≤ 3.5 g/dL, and spontaneous bacterial peritonitis. **Results:** After matching, 238 elafibranor and 238 seladelpar users were analyzed. At 1 year, MALO occurred in 12.6% versus 15.5% (RR 0.81, 95% CI 0.52–1.27; HR 0.82, 95% CI 0.51–1.33; log-rank $p = 0.417$). All-cause hospitalization was similar (5.5% vs 5.0%; RR 1.08, 95% CI 0.51–2.33; HR 1.11, 95% CI 0.50–2.42; $p = 0.803$). MACE was numerically lower with elafibranor but not significant (6.3% vs 8.0%; RR 0.79, 95% CI 0.41–1.52; HR 0.81, 95% CI 0.41–1.59; $p = 0.538$). Among patients with available follow-up ALP, mean ALP was 162.7 ± 110.6 U/L with elafibranor versus 175.1 ± 103.8 U/L with seladelpar (median 135 vs 142 U/L; $p = 0.324$). Albumin ≤ 3.5 g/dL occurred in 8.4% versus 9.2% (RR 0.91, 95% CI 0.51–1.62; HR 0.92, 95% CI 0.50–1.68; $p = 0.784$). No spontaneous bacterial peritonitis events occurred in either group. **Conclusion:** In this propensity-matched real-world cohort of UDCA-treated PBC patients, elafibranor and seladelpar showed comparable 1-year liver, hospitalization, cardiovascular, ALP, albumin, and SBP outcomes. Although event rates were numerically favorable for elafibranor for MALO, MACE, ALP, and hypoalbuminemia, confidence intervals crossed the null. These early data support clinical equipoise and underscore the need for larger comparative studies with longer follow-up and validated biochemical-response definitions.

0031 | EFFICACY AND MECHANISM OF VITAMIN E COMBINED WITH URSODEOXYCHOLIC ACID (UDCA) IN THE TREATMENT OF CHOLESTATIC LIVER DISEASE VIA MODULATING LIPID-ASSOCIATED MACROPHAGES

Yunke Peng[1] Li Yang[2], [1]West China hospital, sichuan university, [2]West china hospital

Background: Ursodeoxycholic acid (UDCA) serves as the primary first-line clinical treatment for cholestatic liver diseases, such as primary biliary cholangitis (PBC); however, a subset of patients exhibits an insufficient response, presenting a significant clinical challenge. This study aims to investigate the therapeutic efficacy of vitamin E (VitE) combined with UDCA in the treatment of cholestatic liver disease and to elucidate the underlying mechanisms from the interactive perspective of macrophage lipid metabolism. Ultimately, this research seeks to provide a novel combination therapy strategy for patients with an insufficient response to UDCA. **Methods:** Plasma samples were collected from PBC patients with sufficient and insufficient responses to UDCA treatment. Untargeted metabolomics analyses were performed to evaluate the association between metabolite abundance and clinical parameters. Two murine models of cholestatic liver disease were established using 0.1% DDC diet induction and ANIT induction. Mice were subsequently treated with UDCA or VitE monotherapy, as well as their combination. Single-cell RNA sequencing (scRNA-seq) was utilized to analyze alterations in the hepatic immune microenvironment. Finally, in vivo flow cytometry was applied for the phenotypic validation of critical cell subpopulations, notably lipid-associated macrophages (LAMs). **Results:** Metabolomic analysis revealed that the relative abundance of α-tocopherol (the active form of vitamin E) in the plasma of patients with a sufficient response to UDCA was significantly higher than that in the insufficient response group. Furthermore, the abundance of α-tocopherol was significantly and negatively correlated with multiple clinical indicators of liver function and lipid metabolism. In both DDC and ANIT murine models, UDCA and VitE, either alone or in combination, effectively ameliorated liver injury. scRNA-seq data indicated a substantial increase in the proportion of lipid-associated macrophages (LAMs) exhibiting a pro-inflammatory phenotype in the livers of DDC model mice. Following VitE treatment, the proportion of these pro-inflammatory LAMs decreased significantly. Transcriptomic results demonstrated that VitE primarily enriched and modulated lipidmetabolism-related pathways **Conclusion:** During the treatment of cholestatic liver disease, UDCA functions primarily by targeting hepatocytes to regulate bile acid metabolism, whereas vitamin E specifically acts on the lipid metabolism pathways of macrophages, improving the hepatic immune microenvironment by suppressing the expansion of pro-inflammatory LAMs. The combined application of these two agents establishes a synergistic complementarity in metabolic mechanisms, providing a robust theoretical foundation and translational prospect for enhancing the clinical response rate of PBC patients to UDCA.

0032 | UTILITY OF NONINVASIVE CRITERIA IN IDENTIFYING PATIENTS WITH MASH CIRRHOSIS FOR CLINICAL TRIALS

Naim Alkhouri[1] Gražina Binkauskiene[2] Winston Dunn[3] Elizabeth Brombosz[2] Rohit Puskoor[4] Rashmee Patil[3] John Poulos[5] Alma Laura Ladrón de Guevara[6] Marcelo Kugelmas[7] Sudha Kodali[8] Meena Bansal[9] Jörn Schattenberg[10] Mazen Noureddin[11], [1]Summit Clinical Research Solutions, Clinical Research Institute of Ohio, [2]Summit Clinical Research Solutions, [3]Pinnacle at San Antonio, Summit Clinical Research Solutions, [4]Pinnacle at Austin, Summit Clinical Research Solutions, [5]Coastal Research Institute, [6]Centro De Investigacion Y Gastroenterologia, [7]South Denver Gastroenterology, [8]Houston Methodist Hospital, [9]Icahn School of Medicine at Mount Sinai (ISMMS), [10]Saarland University Medical Center, [11]Houston Methodist Hospital, Houston Research Institute, Summit Clinical Research Solutions

Background: New criteria based on noninvasive tests (NITs) have been recently approved by regulatory authorities to enroll patients in MASH cirrhosis trials without the need for liver biopsy. These criteria are based on meeting certain thresholds based on VCTE liver stiffness measurement (LSM), enhanced liver fibrosis (ELF) test, and platelet count. However, given the known limitations of NITs, there is an inherent risk of enrolling patients with lower fibrosis stages which will impact the expected number of clinical outcomes. This study aimed to evaluate the efficacy of these criteria in identifying subjects with MASH cirrhosis in a multicenter database using fibrosis stage on biopsy as the gold standard. **Methods:** Patients with LSM, ELF, platelet count, and available biopsy data were identified from a multicenter database of screening and baseline data from 12 MASH clinical trials. Performance of the following NIT criteria for MASH cirrhosis were evaluated: Criterion 1: VCTE $\geq$20 kPa, Criterion 2: VCTE $\geq$20 kPa plus ELF $\geq$10.25 or platelets $\leq$150, Criterion 3: VCTE $\geq$15 and $<$20 kPa plus ELF $\geq$10.25 or platelets $\leq$150, Criterion 4: VCTE $\geq$10 and $<$15 kPa plus ELF $\geq$10.25 and platelets $\leq$110, and Criterion 5: VCTE $\geq$10 and $<$15 kPa plus ELF $\geq$10.25 and platelets $\leq$150. **Results:** Our cohort consisted of 10,386 patients with biopsy proven MASLD including 1,880 patients with cirrhosis (F4) (18.1%). The mean age was 55.4 years, 43.8% were male, median BMI of 36.5 kg/m2, and 38.3% with type 2 diabetes. The mean LSM for the entire cohort was 13.9 8.3 kPa and the mean LSM for the cirrhosis group was 20.3 $\pm$ 10.8. The mean ELF for the entire cohort was 9.82 and for the cirrhosis group was 10.52. The percentage of patients with cirrhosis on biopsy that met each criterion was as follows: Criterion 1: 55.3%, Criterion 2: 75.6%, Criterion 3: 60.4%, Criterion 4: 57.1%, and Criterion 5: 47.7%. The breakdown of other fibrosis stages on biopsy in patients meeting different criteria is shown in the figure. **Conclusion:** Using different NIT-based criteria to diagnose MASH cirrhosis may overestimate the likelihood of MALO in patients with no evidence of significant fibrosis on liver biopsy. More strict criteria based on combination NITs are needed.

Background: Efficient identification of cirrhosis is critical for MASLD clinical trial enrollment. Current prescreening strategies rely on VCTE LSM and ELF testing, but VCTE has limited accessibility and ELF is costly with prolonged turnaround time. We aimed to develop an adaptive machine learning (ML) strategy integrating point-of-care laboratory parameters, selective VCTE, and selective ELF testing to improve cirrhosis prescreening. **Methods:** A total of 2,909 patients with MASLD from a multi-center cohort, including 743 with cirrhosis, were used for model training, with external validation in 2,383 patients (455 with cirrhosis) from network sites. XGBoost ML models predicted cirrhosis probability. A sequential strategy was used in which point-of-care laboratories (AST, ALT, platelets, HbA1c, GGT, globulin) were first used to impute LSM. Patients with imputed LSM $\geq$11 kPa underwent measured VCTE. ELF was then imputed using laboratories and LSM, unless the imputed ELF was $\geq$9.8; in these cases, ELF was measured directly. The final prediction used hybrid measured and imputed LSM and ELF values. **Results:** SHAP analysis identified the top-performing variables used to create the SMART-MASH model (Panel A). SMART-MASH achieved AUC 0.90 without imputation. Imputed LSM and ELF correlated with measured values (r = 0.42 and r = 0.60). SMART-MASH using imputed LSM >11 kPa and imputed ELF >9.8 to trigger measured VCTE and ELF achieved AUC 0.885, outperforming Agile 3 (0.865, p = 0.0075) and Agile 4 (0.870, p = 0.0195) (Panel B). Measured VCTE and ELF were required in 72.4% and 36.6% of patients, respectively. Performance remained superior to Agile 4, particularly in female and diabetic patients (Panel C). At a fixed 33% biopsy screen failure rate, 18 of 100 screened patients would proceed to confirmatory biopsy, 12 of whom would have biopsy-confirmed cirrhosis, representing >36% improvement over Agile 4 (Panel D). **Conclusion:** SMART-MASH, a novel adaptive sequential ML strategy integrating POC laboratory parameters, selective VCTE, and selective ELF testing, substantially improved cirrhosis prescreening efficiency compared with Agile 3 and Agile 4. By dynamically escalating testing intensity only in higher-risk patients, the strategy reduced reliance on universal VCTE and ELF testing while maintaining high discrimination and improving clinical trial enrollment efficiency. The web-based calculator is publicly available at https://aihepatology.shinyapps.io/SMART-MASH/

0034 | BEYOND ALCOHOL SELF-REPORT: PHOSPHATIDYLETHANOL (PETH) ASSESSMENT UNCOVERS CLINICALLY SIGNIFICANT ALCOHOL EXPOSURE IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD)

Zobair Younossi[1] Nikolaj Torp[2] Fatema Nader[3] Mads Israelsen[2] Camilla Dalby Hansen[4] Markos Kalligeros[1] Johanne Hansen[2] Linda Henry[1] Helle Schnefeld[4] Andrei Racila[1] Katrine Bech[4] Shira Zelber-Sagi[5] Marianne Bergmann[6] Maria Stepanova[1] Aleksander Krag[7], [1]The Global NASH/MASH Council, [2]Odense University Hospital, [3]Center for Outcomes Research in Liver Diseases, CORLD, [4]Liver Research Centre, Department of Gastroenterology and Hepatology, Odense University Hospital, Od, [5]Global NASH/MASH Council, [6]Department of Biochemistry and Immunology, Lillebaelt Hospital - University Hospital of Southern De, [7]University of Southern Denmark

Background: MASLD is defined by the absence or minimal alcohol use; however, self-reported alcohol intake underestimates actual exposure. PEth, a direct metabolite of ethanol, is an objective biomarker of alcohol consumption. We evaluated PEth in two MASLD cohorts. **Methods:** MASLD subjects (hepatic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

steatosis and at least one cardiometabolic risk) with available PEth were included. The cases comprised 1,065 MASLD patients enrolled from US hepatology setting (age 48.0 ± 12.9 years, 38.3% male, BMI 41.1 ± 10.6 kg/m²; 32.3% type 2 diabetes [T2D], 55.6% hypertension, 54.2% hyperlipidemia, 18.3% current smokers). Controls consisted of 1,152 MASLD subjects from Denmark hepatology setting (age 55.3 ± 9.1 years, BMI 34.9 ± 5.6 kg/m²; 62.6% T2D, 84.9% hypertension, 70.1% dyslipidemia, 9.1% smokers). Alcohol use was assessed by self-report, and PEth was measured in stored blood. PEth cutoffs were ≥ 20 ng/mL (any alcohol exposure), < 20 ng/Md (MASLD), 20– < 200 ng/mL (MetALD), and ≥ 200 ng/mL (ALD). Clinical characteristics were stratified by PEth status within each group. **Results:** Combined analysis of 2,217 subjects revealed substantial discordance between self-report and objective assessment. In the U.S., 89.8% reported no alcohol use and only 0.4% reported ≥ 15 drinks/week; however, PEth ≥ 20 ng/mL was detected in 13.4% (n = 143), with 11.3% meeting MetALD and 2.2% ALD criteria. The control group from Denmark showed PEth ≥ 20 ng/mL in 33.9% (n = 391), with 28.9% MetALD and 5.0% ALD. Across both groups, patients with elevated PEth were predominantly male (U.S.: 56.6% vs. 35.5%; controls: 54.0% vs. 28.8%; both $p < 0.001$) and had lower BMI (U.S.: 36.1 ± 9.2 vs. 41.9 ± 10.6; controls: 33.1 ± 4.5 vs. 35.8 ± 5.9; both $p < 0.001$). U.S. patients with PEth ≥ 20 ng/mL were more likely smokers (41.0% vs. 14.5%, $p < 0.0001$) but had lower T2D prevalence (19.5% vs. 34.2%, $p = 0.0007$), while controls with PEth ≥ 20 ng/mL showed the opposite pattern: T2D 67.8% vs. 59.9%, $p = 0.009$; smoking 10.2% vs. 8.5%, $p = 0.35$. Self-report concordance with PEth differed substantially between cohorts. In the U.S., among patients with PEth ≥ 20 ng/mL, 59.4% reported no alcohol use and only 6.3% reported ≥ 15 drinks/week, demonstrating weak correlation and concordance (Spearman's $r = 0.28$, Cohen's $\kappa = 0.24$, $p < 0.0001$). Controls exhibited better correlation and concordance: 84.8% with PEth ≥ 20 ng/mL reported any alcohol use and 14.4% reported ≥ 15 drinks/week, with Spearman's $r = 0.66$, $p < 0.005$, Cohen's $\kappa = 0.42$. **Conclusion:** Self-reported alcohol assessment underestimates actual alcohol exposure among MASLD patients. Our findings demonstrate that objective PEth testing reclassified over 13% of U.S. cases initially attributed to MASLD as MetALD or ALD, highlighting a critical diagnostic gap. Objective biomarker assessment via PEth is essential for accurately distinguishing true MASLD from occult alcohol-related disease and enabling appropriate patient stratification and treatment.

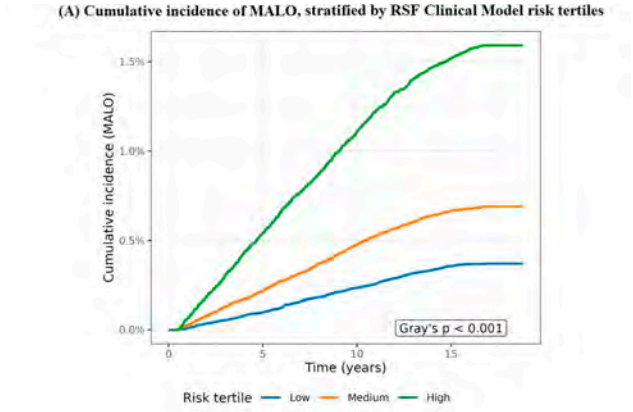
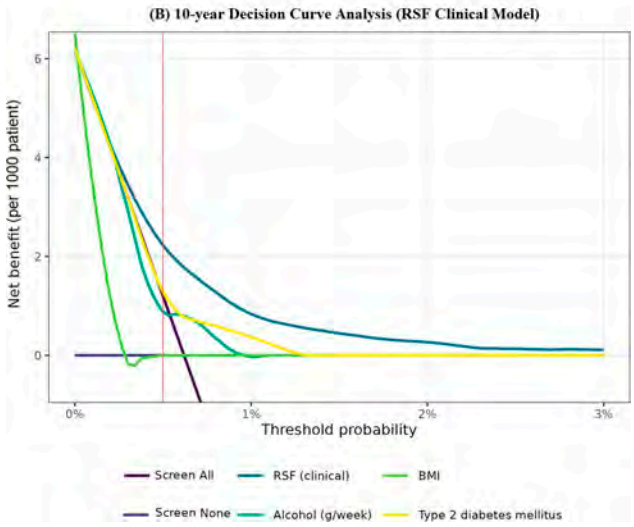
★ 0035 | IDENTIFYING SILENT PROGRESSORS: MACHINE LEARNING PREDICTION OF MAJOR ADVERSE LIVER OUTCOMES IN AN EARLY AT-RISK SLD POPULATION



Butros Fakhoury[1] Ronnie Li[1] Vinay Jahagirdar[1] Leandro Sierra[2] Krishan Patel[1] Stephen Hoang[1] Richard Sterling[1] Luis Díaz[3] Juan Pablo Arab[1],
[1]Virginia Commonwealth University, [2]Cleveland Clinic Foundation, [3]Pontificia Universidad Católica de Chile



Background: Among early at-risk steatotic liver disease (SLD) patients with low FIB-4, current guidelines assign surveillance intervals based on the presence of type 2 diabetes or ≥ 2 cardiometabolic risk factors. These categorical rules do not integrate alcohol dose-response, adiposity thresholds, or risk factor interactions. We developed a Random Survival Forest (RSF) model to predict major adverse liver outcomes (MALOs) and individualize surveillance intensity in this population. **Methods:** We included 205,541 UK Biobank participants meeting early at-risk SLD criteria: type 2 diabetes, medically complicated obesity, metabolic syndrome, or alcohol intake exceeding MASLD thresholds (> 140 g/week for women, > 210 g/week for men). We excluded prevalent advanced liver disease (baseline FIB-4 > 2.67 or prior MALO). The primary outcome was incident MALO (cirrhosis, decompensation, HCC, transplant, or liver-related mortality), with non-liver death modeled as a competing event within a cause-specific hazard framework. After validating non-linear risk trajectories via natural cubic splines, we trained an RSF Clinical Model (age, sex, BMI, diabetes, smoking, alcohol intake) and a Precision Model (adding waist circumference, PNPLA3, TM6SF2, and HSD17B13 variants). Global feature importance was extracted via Monte Carlo-approximated SHAP values. Performance was validated across 5 cross-validation folds using time-dependent AUC, Harrell's C-index, and Decision Curve Analysis (utilizing inverse-probability-of-censoring weighting) against Fine-Gray regression, CLivD, and FIB-4. **Results:** Over a median 16.9-year follow-up, 1,807 MALOs occurred (0.88%). Alcohol consumption was the dominant prognostic

driver, exhibiting a non-linear risk trajectory captured by the RSF framework. The RSF Clinical Model achieved a 5-year td-AUC of 0.706 and 10-year td-AUC of 0.700, with C-index of 0.692; the Precision Model achieved 0.721, 0.714, and 0.706, respectively. Both models outperformed the laboratory-based CLivD score (C-index 0.678) and FIB-4 (0.613). Risk tertiles derived from the Clinical Model revealed a greater than four-fold gradient in 10-year MALO incidence (0.25% vs. 0.5% vs. 1.1%). Decision Curve Analysis confirmed superior net clinical benefit across relevant thresholds compared to individual risk factor-based strategies at both 5- and 10-year horizons. **Conclusion:** An RSF model using routine primary care variables identifies silent progressors within the early at-risk SLD population, enabling individualized fibrosis surveillance within the existing guideline framework. Patients with predicted 10-year MALO incidence $\geq$0.5% may warrant intensified FIB-4 reassessment (every 1–2 years), while lower-risk individuals may be appropriately managed with standard surveillance. External validation in diverse cohorts is warranted.

0036 | ELEVATED LIPOPROTEIN (A) LEVELS CHARACTERIZE A DISCORDANT MASLD PHENOTYPE

Álvaro Raya Marín[1] Alain Ibañez de Opakua[1] Rubén Gil-Redondo[1] Maider Bizkarguenaga[1] Ángela de Diego[1] Mikel Azkargorta[1] Nieves Embade[1] David Fernández Ramos[2] Fernando Lopitz-Otsoa[1] Ángela Domínguez-Gil[1] Felix Elortza[1] Serena Pelusi[3] Sara Margarita[3] Francesco Malvestiti[3] Massimiliano Ruscica[4] Shelly Lu[5] Urko Marigorta[1] Luca Valenti[3] Óscar Millet[1] José Mato[1], [1]CIC bioGUNE, BRTA, [2]CIBERehd, ISCIII, [3]Fondazione Ca' Granda OMP Milano, [4]Università degli Studi di Milano, [5]Cedars-Sinai Medical Center

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD) is a heterogeneous condition with variable lipid and cardiovascular risk profiles. We investigated whether lipoprotein(a) [Lp(a)] identifies biologically distinct MASLD subtypes with divergent metabolic, genetic, and cardiovascular characteristics. **Methods:** Lipoproteins, metabolites, and clinical parameters were analyzed in 337 individuals at high risk of MASLD (Liver Bible cohort). Findings were validated in 5,068 participants with metabolic syndrome and/or MASLD from the UK Biobank (UKBB), integrating lipoprotein profiling, metabolomics, clinical outcomes, and polygenic scores (PGSs). **Results:** Two MASLD phenotypes were identified. A concordant phenotype exhibited more pronounced liver involvement, a triglyceride-rich, pro-atherogenic lipoprotein profile, and was associated with low Lp(a). In contrast, a discordant phenotype displayed reduced triglyceride-rich lipoproteins, higher HDL-cholesterol, and elevated Lp(a), together with a distinct metabolic signature.In UKBB, MASLD was associated with lower circulating Lp(a) levels compared with controls despite similar *LPA* PGS. Within MASLD, higher Lp(a) levels were associated with higher *LPA* PGS, lower triglyceride content in VLDL and chylomicrons, and increased prevalence of atherosclerotic heart disease, whereas lower Lp(a) was linked to a dysmetabolic phenotype, including higher

glucose, branched-chain amino acids, and type 2 diabetes prevalence. MASLD PGS did not differ across Lp(a) strata. **Conclusion:** These findings support a two-axis model of MASLD heterogeneity: hepatic steatosis is primarily driven by genetic susceptibility and metabolic factors, whereas genetically determined Lp(a) modulates cardiovascular risk. Thus, once MASLD is established, individuals may diverge into distinct cardiometabolic trajectories –one dominated by dysmetabolic, triglyceride-rich lipoproteins, and another characterized by elevated Lp(a) and atherothrombotic risk– despite similar overall polygenic burden for MASLD, potentially reflecting distinct underlying genetic and metabolic architectures.

★ 0037 | LEAN PHENOTYPE IDENTIFIES A HIGH-RISK GROUP FOR MAJOR LIVER-RELATED OUTCOMES ACROSS STEATOTIC LIVER DISEASE SUBTYPES

Takao Miwa[1] Shun-Ichi Wakabayashi[2] Takefumi Kimura[2] Nobuharu Tamaki[3] Luis Antonio Díaz[1] Burcin Özdirik[4] Xinyi Wang[1] Hongzhong Zhou[1] Xinlian Zhang[1] Naoki Tanaka[5] Masayuki Kurosaki[3] Rohit Loomba[6] Bernd Schnabl[6], [1]University of California San Diego, [2]Shinshu University School of Medicine, [3]Musashino Red Cross Hospital, [4]UCSD, [5]Shinshu University Graduate School of Medicine, [6]University of California, San Diego

Background: The clinical implications of the lean phenotype across steatotic liver disease (SLD) subtypes, including metabolic dysfunction-associated SLD (MASLD), metabolic dysfunction and alcohol-associated liver disease (MetALD), and alcohol-associated liver disease (ALD), remain incompletely understood, particularly in MetALD and ALD. We aimed to evaluate the impact of the lean phenotype on the incidence of clinical endpoints across SLD subtypes. **Methods:** This population-based cohort study included participants with SLD from the UK Biobank and Japan Medical Data Center (JMDC) cohorts. We evaluated the associations of lean phenotype with major adverse liver outcomes (MALOs), major adverse cardiovascular events (MACEs), and all-cause mortality across SLD subtypes. **Results:** A total of 79,709 participants from the UK Biobank and 720,951 from the JMDC cohort were included. Lean phenotype was consistently associated with increased risk of MALOs in MASLD, MetALD, and ALD in both UK Biobank **(Figure 1A–1C)** and JMDC cohort **(Figure 1D–1F)** . Adjusted hazard ratios (95% confidence intervals) for MALOs in MASLD, MetALD, and ALD were 1.64 (1.22–2.22), 1.45 (1.01–2.10), and 1.99 (1.50–2.64), respectively, in the UK Biobank and 3.98 (2.90–5.44), 4.13 (2.89–5.89), and 3.12 (1.99–4.90), respectively, in the JMDC cohort. In contrast, lean phenotype was associated with lower MACE risk in MASLD, whereas MetALD and ALD showed no significant association. For all-cause mortality, lean phenotype was associated with increased risk in MetALD, whereas no significant association was observed in MASLD. These findings remained consistent across sensitivity analyses. **Conclusion:** The lean phenotype was associated with increased risk of MALOs across all SLD subtypes and mortality in MetALD, while MACE risk was lower in MASLD. In particular, lean individuals with MetALD may constitute a particularly high-risk group requiring clinical attention.

0038 | AIM-AH: A MINISTRY SUPPORTED MULTICENTRE INDIAN EXPLAINABLE AI DECISION SUPPORT TOOL FOR RISK STRATIFICATION, REFERRAL, AND EARLY MORTALITY PREDICTION IN ALCOHOL-ASSOCIATED HEPATITIS

Nipun Verma[1] Pratibha Garg[2] Anmol Ojha[3] Tarana Gupta[4] C Eapen[5] Ashish Goel[5] Joy Varghese[6] Sandeep Nijhawan[7] Dinesh Jyotimani[8] Neeraj Saraf[9] Narendra Choudhary[10] Shalimar .[11] Shiv Kumar Sarin[12] Manoj Kumar[12] Rohit Gupta[13] Arun Valsan[14] Gajanan Rodge[15] Sunil Dadhich[16] PN Rao[17] Anand Kulkarni[17] Biman Saikia[18] Amit Agarwal[18] Naveen Bhagat[18] Babu Lal Meena[18] Arka De[18] Madhumita Premkumar[2] Sunil Taneja[18] Srinivas Rana[19] Rakhi Maiwall[20] Anand Sharma[21] Santhosh Kumar[22] Sahaj Rathi[23] Manas Kumar Panigrahi[24] Akash Roy[25] Mahesh Goenka[26] Ajay Duseja[2], [1]PGIMER, Chandigarh, [2]Postgraduate Institute of Medical Education & Research, [3]Wadhwani Institute for Artifical Intelligence, [4]PGIMS Rohtak, [5]CMC VELLORE, [6]Apollo Chennai, [7]SMS Jaipur, [8]Rela Institute Hyderabad, [9]Medanta, New Delhi, [10]Medanta New Delhi, [11]AIIMS New Delhi, [12]ILBS New Delhi, [13]AIIMS Rihsikesh, [14]Amrita Institute of Medical Sciences, Kochi, [15]Bombay Hospital, [16]SNMC Jodhpur, [17]AIG Hyderabad, [18]PGIMER Chandigarh, [19]Wadhwani Institute for Artificial Intelligence, [20]Institute of Liver and Biliary Sciences, [21]AIIMS Rishikesh India, [22]CMC Vellore India, [23]Virginia Commonwealth University, [24]AIIMS Bhubaneshwar India, [25]Apollo Hospital Kollatta India, [26]Apollo Hospital, Kolkatta India

Background: Alcohol-associated hepatitis (AH) is associated with high short-term mortality, yet early bedside risk stratification remains suboptimal. Conventional prognostic scores were not designed as real-time clinical decision support systems for triage, referral, ICU escalation, or transplant-related decision-making across heterogeneous and resource-variable healthcare settings. We developed and externally validated AIM-AH, a Ministry-supported multicentre Indian explainable artificial intelligence (AI)-based clinical decision support tool for early mortality prediction and clinically actionable risk stratification in AH **Methods:** Data from 2,396 patients with AH across 15 tertiary care centres in India were analysed. Following quality control and missingness filtering, 2,227 patients constituted the derivation cohort, while 169 patients from PGI Chandigarh served as the external validation cohort. Multiple machine learning and survival-analysis approaches, including logistic regression (LR), random forest, XGBoost, Cox proportional hazards, and XGBoost survival-embedding models, were systematically evaluated. Feature selection was performed using RFECV and Boruta algorithms. Model performance was assessed using AUROC, calibration, decision-curve analysis (DCA), and clinically actionable operating thresholds. The final model was developed as a web-based decision support tool enabling low-, intermediate-, and high-risk stratification to facilitate referral from primary and secondary care settings and escalation decisions at tertiary centres. **Results:** The most generalizable model was an interpretable six-variable LR model incorporating hepatic encephalopathy (HE),

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

infection status, oxygen saturation, bilirubin, INR, and creatinine. On external validation, AIM-AH achieved an AUROC of 0.884 (95% CI, 0.832–0.932), outperforming MELD (0.769), MDF (0.748), and ABIC (0.727). At a low-risk threshold of <0.40, AIM-AH demonstrated 80.0% sensitivity, while at a high-risk threshold of >0.50, the specificity was 92%, significantly better than MELD ($p<0.001$). DCA demonstrated superior net clinical benefit over conventional prognostic scores. A compact and interpretable web tool with a guideline-grounded decision support application was developed and successfully tested in a TRL-5 clinical environment **Conclusion:** AIM-AH represents the first multicentre Indian explainable AI-based decision support tool for AH. Using six routinely available bedside variables, AIM-AH improves early mortality prediction beyond conventional prognostic scores and enables clinically actionable low-, intermediate-, and high-risk stratification to support referral pathways, treatment-intensity decisions, ICU escalation, and early transplant evaluation across resource-variable healthcare systems

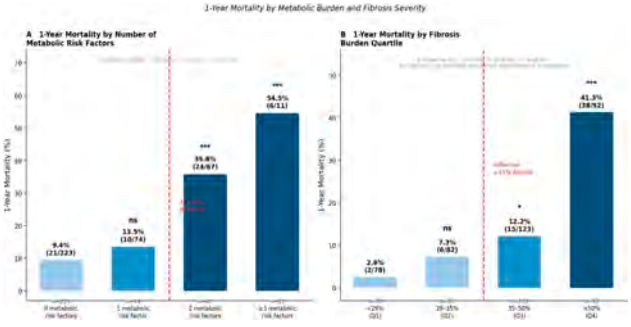
0039 | BEYOND MELD: METABOLIC RISK FACTOR BURDEN AND QUANTITATIVE FIBROSIS IDENTIFY DISTINCT HISTOPHENOTYPES AND PREDICT DOSE-RESPONSE MORTALITY IN ALCOHOL-ASSOCIATED LIVER CIRRHOSIS (QFM-ALD STUDY)



Mohit Kumar Varshney[1] Chhagan Bihari[1] Ravi Nishad[1] Zeenat Naz[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary sciences

Background: The 2023 SLD nomenclature classifies alcohol-associated liver disease into MetALD (alcohol 210–420 g/week [men] or 140–350 g/week [women] with ≥ 1 metabolic risk factor [MRF]) and ALD (>420/>350 g/week men/women), stratified by MRF count. How MRF burden shapes histology and outcomes across subtypes remains undefined. We aimed to characterise their histophenotypic features and identify predictors of short-term mortality. **Methods:** We prospectively enrolled adults with biopsy-proven alcohol-associated SLD cirrhosis; categorized them into MetALD and ALD with varying number of MRFs (ALD-0, ALD-1, or ALD-hm (≥ 2 MRFs)). All biopsies were reviewed by two blinded hepatopathologists; quantitative fibrosis burden was measured as collagen proportionate area (CPA) by digital morphometry. Immunohistochemistry for p21 and CDK2 characterised hepatic cell senescence. The primary outcome was death or liver transplantation at one year. Dose-response relationships between MRF count, histological parameters, and one-year outcome were assessed by Fisher's exact test; independent predictors were identified by multivariable logistic regression **Results:** Of 409 patients enrolled (375/409, 91.7% follow-up), 249 (60.9%) were ALD-0, 27 (6.6%) ALD-1, 106 (25.9%) MetALD, and 27 (6.6%) ALD-hm. Fibrosis rose stepwise: ALD-0 33.8% (IQR 28.9–46.0%), ALD-1 35.0% (IQR 29.6–41.3%), MetALD 45.0% (IQR 32.4–53.7%), ALD-hm 60.0% (IQR 49.0–63.5%); all inter-subtype $p<0.001$; ALD-0 vs ALD-1 $p=0.955$. Conventional injury markers were comparable (all $p>0.05$). A p21-high/CDK2-low senescence signature was present in MetALD and ALD-hm vs ALD ($p<0.001$). One-year mortality showed a clear MRF dose-response: 9.4% (0 MRF, $n=223$), 13.5% (1 MRF, $n=74$; ns), 35.8% (2 MRF, $n=67$; OR 4.56, 95% CI 2.18–9.55; $p<0.001$), and 54.5% (≥ 3 MRF, $n=11$; OR 8.71, 95% CI 1.75–43.30; $p<0.001$). Mortality at 0 vs 1 MRF was equivalent ($p=0.379$), rising steeply at ≥ 2 MRFs, confirming the ALD-hm designation. By subtype: 9.4% (ALD), 23.3% (MetALD), 51.9% (ALD-hm; $p<0.001$); a five-fold gradient. On multivariable analysis, fibrosis burden (aOR 1.08/1%, 95% CI 1.05–1.11; $p<0.001$) and MRF count (aOR 1.77, 95% CI 1.29–2.42;

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

$p < 0.001$) independently predicted mortality; MELD was non-significant ($p = 0.219$). A five-variable score achieved AUROC 0.824 vs 0.492 for MELD ($p < 0.001$). ALD-hm had selectively higher jaundice (62.1% vs 33.8–34.1%; $p = 0.012$) and AKI (27.6% vs 8.8–22.8%; $p = 0.016$); portal hypertensive complications did not differ. **Conclusion:** Our data document for the first time that MetALD, ALD (0–1 MRF), and ALD-hm (≥ 2 MRF) are histologically and prognostically distinct phenotypes. Quantitative fibrosis burden is the strongest short-term mortality predictor across all subtypes and warrants incorporation into prognostic algorithms. A p21/CDK2 senescence signature implicates regenerative exhaustion as a mechanistic substrate for the fibrosis-mortality gradient.

0040 | SEX DIFFERENCES IN ALCOHOL CONSUMPTION: A GLOBAL ANALYSIS OF PREVALENCE ESTIMATES AND DRINK DEFINITION HETEROGENEITY

Ximena Parraga[1] Denisse Rubio Cruz[2] Kriti Soni[1] Tulio Correa[3] Hyundam (Dami) Gu[1] S. Fisher Rhoads[1] Vinay Jahagirdar[1] Kavin Parmar[1] Krishan Patel[1] Stephen Hoang[1] Luis Díaz[4] Juan Pablo Arab[1], [1]Virginia Commonwealth University, [2]Lahey Hospital, Virginia Commonwealth University, [3]University of Pittsburgh, [4]Pontificia Universidad Católica de Chile

Background: Alcohol is a major global health burden with marked sex differences in harm and consumption. How the differences vary by region and relate to national alcohol metrics remains unclear. Despite the WHO 10 g ethanol standard, global adherence is inconsistent. We examined global variation in standard drink definitions and their relationship with sex-specific alcohol consumption and heavy drinking patterns. **Methods:** We analyzed policy and epidemiologic data from 185 countries (WHO 2024, World Bank, national guidelines) to assess variation in standard drink definitions and their relation with alcohol per capita consumption (APC). Sex-specific studies for heavy episodic drinking (HED) and heavy continuous drinking (HCD) were also evaluated. Regional summaries and sex-stratified violin plots were performed to visualize data. **Results:** Across all regions, males demonstrated higher alcohol exposure than females. These disparities were most marked in the European, Americas, and Western Pacific Regions, where alcohol consumption among male drinkers was approximately 2–3-fold higher than among females and exceeded the WHO-recommended benchmark of 10 g/day. Regional differences in alcohol consumption were statistically significant for both sexes (males: Kruskal–Wallis $\chi^2 = 78.73$, $p < 0.001$; females: $\chi^2 = 85.78$, $p < 0.001$). Global sex-specific HED and HCD distributions differed significantly (Kruskal–Wallis $\chi^2 = 283.15$, $p < 0.001$), with greater density and variability observed in HED compared with HCD for both sexes, particularly among males. Among females, consumption patterns showed greater regional variability, potentially reflecting the differential influence of sociocultural and policy factors across settings. **Conclusion:** Global alcohol use shows marked regional and sex-specific variation, driven largely by male-female differences in consumption. These disparities coincide with wide variation in standard drink definitions, with misalignment from WHO recommendations in high-exposure regions. Given evidence that females experience greater harm per unit of alcohol consumed and that sex-specific consumption gaps are narrowing in several regions, sex-disaggregated metrics and risk thresholds warrant particular attention in future guidelines. Aligning standard drink definitions with regional and sex-specific risk profiles could strengthen global approaches to alcohol risk assessment and public health policy.

0041 | EARLY LIVER TRANSPLANTATION IS UNIVERSALLY ADOPTED BUT PRE-TRANSPLANT PSYCHOSOCIAL PROTOCOLS REMAIN HETEROGENEOUS IN THE UNITED STATES

Holly Huang[1] Debra Yen[2] Po-Hung (Victor) Chen[3] FNU Baimaji[3] Nicholas Lim[4] Allison Kwong[5] Alexander Yang[6] Neil Mehta[1] Gene Im[7] Courtney Sherman[1], [1]University of California, San Francisco, [2]California Pacific Medical Center, [3]Johns Hopkins University, [4]University of Rochester, [5]Stanford University Medical Center, [6]University of California San Diego, [7]Center for Liver Disease and Transplantation, Division of Digestive and Liver Diseases Columbia Univ

Background: Alcohol-related liver disease (ALD) remains the top indication for liver transplantation (LT) in the United States. Early liver transplantation (ELT) improves survival of vulnerable patients with severe ALD and less than 6 months of alcohol abstinence. However, pre-transplant psychosocial practices vary across U.S. LT centers. We conducted a national survey to characterize psychosocial resources, practices, and protocols in AUD and ALD management before ELT. **Methods:** We developed and disseminated a web-based survey via email from November 13, 2025 to April 20, 2026 to one hepatologist per adult LT center in the United States, selecting medical directors or transplant hepatologists knowledgeable in their center's practices. We stratified centers by ELT adoption (High ELT: ≥ 5 years and ≥ 20 patients/year [n = 15]; Low ELT: ≤ 5 years and ≤ 5 patients/year [n = 10]) and assessed differences with Fisher's exact test. **Results:** Eighty of 117 centers (68%) completed the survey. All (100%) had adopted ELT, and nearly all (99%) required no minimum abstinence period. Half (51%) had performed ELT for 5+ years, and 58% transplanted 11+ ELT patients annually. Although psychosocial resources were broadly accessible, with social workers (99%), mental health providers (95%), and substance use specialists (84%) available across all centers, only 40% felt resources were fully adequate. Three-quarters (76%) had a formal psychosocial AUD protocol. Most (73%) individualized interventions per patient and over half (53%) waived requirements for patients too ill to participate, suggesting a trend towards medical necessity superseding psychosocial risk in candidate selection (Figure 1). Minimum psychosocial intervention duration was rarely fixed, depending instead on clinical status (51%) or psychosocial risk (19%). Key drivers of intervention intensity included transplant social work assessment (77%) and post-transplant alcohol use risk tool scores (62%). Most centers accepted partial adherence to interventions assessed by the treating team (38%) or selection committee (32%). For patients needing LT during their index admission, 35% of centers imposed no psychosocial requirements, while 29% required virtual support group initiation and 24% in-person addiction counseling. ELT adoption level was not associated with resource adequacy, protocol use, inpatient requirements, or adherence expectations. **Conclusion:** ELT has been universally adopted across U.S. LT centers, but heterogeneity persists in psychosocial resource adequacy, formal protocol structure, and inpatient requirements. AUD management remains largely individualized, reflecting the complexity of balancing transplant urgency with variable psychosocial risk and intervention options. These findings provide a national baseline and underscore the need for studies linking these practices to post-transplant outcomes to optimize future ELT protocols.

0042 | DECOMPENSATION BURDEN, MORTALITY, AND RECOMPENSATION IN ALCOHOL-ASSOCIATED HEPATITIS

Kavish Patidar[1] Wanzhu Tu[2] Douglas Simonetto[3] Yunpeng Yu[2] Juan Pablo Arab[4] Amon Asgharpour[4] Vatsalya Vatsalya[5] Ashwani Singal[5] Jacqueline O'Leary[6] Patrick Kamath[3] Craig McClain[5] Vijay Shah[3] Mack Mitchell[6] Arun Sanyal[4] Naga Chalasani[7] K Rajender Reddy[8] Samer Gawrieh[7], [1]Houston Methodist Hospital, [2]Indiana University, [3]Mayo Clinic Rochester, [4]Virginia Commonwealth University, [5]University of Louisville, [6]University of Texas Southwestern Medical Center, [7]Indiana University Medical Center, [8]University of Pennsylvania

Background: Alcohol-associated hepatitis (AH) presents with hepatic decompensation and high short-term mortality. The distribution of decompensating events, incidence of recompensation, and mortality in this population are poorly defined. **Methods:** We analyzed data from 287 hospitalized patients with AH enrolled in the AlcHepNet prospective observational cohort. Baseline decompensating events, including ascites, hepatic encephalopathy (HE), and variceal bleeding (VB), were characterized individually and by combination. Mortality at 90, 180, and 360 days was compared across one, two, or three concurrent baseline features. Recompensation, defined per Baveno VII criteria as sustained resolution of decompensating events and off medical therapy, was assessed at 3, 6, and 12 months using cumulative incidence functions with death as the competing event. Factors associated with recompensation were examined by Fine-Gray subdistribution hazards regression. **Results:** Mean age was 45 years, 42% female, 84% severe AH, mean MELD 28.3 (SD 8.9) and Maddrey's discriminant function 63.3 (SD 35.0). Ascites was present in 268/287 patients (93.4%); HE in 161 (56.5%), and VB in 38 (13.6%) (**Figure 1A**). Baseline decompensation burden was associated with mortality 90, 180, and 360 days. Among patients with one, two, and three concurrent features at enrollment, mortality was 12.1%, 26.2%, and 32.0% at 90 days ($p = 0.006$); 15.9%, 28.5%, and 36.0% at 180 days ($p = 0.016$); and 20.5%, 30.8%, and 52.0% at 360 days ($p = 0.003$) (**Figure 1B**). Recompensation was uncommon: 28 patients (9.8%) at 3 months, 45 (15.7%) at 6 months, and 52 (18.1%) at 12 months. However, among patients alive at 3 months with available alcohol intake data, those who remained abstinent from alcohol (94/121) had increasing rates of recompensation over time: 19.1% at 3 months, 34.0% at 6 months, and 37.2% at 12 months. **None of the 80 patients who died within a year had recompensated** . On Fine-Gray regression, lower baseline MELD (sHR = 0.95, 95% CI [0.91, 0.99]; $p = 0.009$) and higher educational attainment (sHR = 2.62, 95% CI: [1.12, 6.12]; $p = 0.026$) were independently associated with recompensation. **Conclusion:** In AH, the baseline decompensation phenotype is dominated by ascites, and the number of concurrent decompensating features at admission predicts mortality at 90, 180, and 360 days. Recompensation is uncommon, occurring in 18.1% of patients at 12 months, but is more frequent among patients who are abstinent from alcohol at 3 months, reaching 37.2% by 12 months. Recompensation was not observed among patients who died within the first year. Enumerating decompensating events helps identify patients at the highest risk and least likely to recover.

★ 0043 | GENETIC ANCESTRY, *PNPLA3*, AND PER-DRINKER SUSCEPTIBILITY TO ALCOHOL-ASSOCIATED CIRRHOSIS: A MULTI-ANCESTRY ANALYSIS OF 414,830 ALL OF US PARTICIPANTS

Hyunseok Kim[1] Walid Ayoub[1] Alexander Kuo[2] Paul Martin[2] Aarshi Vipani[2] Yun Wang[2] Stephen Pandol[2] Yee Hui Yeo[2] Debiao Li[2] Suthat Liangpunsakul[3] Shelly Lu[2] Juan Pablo Arab[4] JuDong Yang[2], [1]Cedars-Sinai Medical Center, [2]Cedars Sinai Medical Center, [3]Indiana University Medical Center, [4]Virginia Commonwealth University Medical Center

Background: Alcohol-associated liver disease (ALD) shows U.S. racial/ethnic disparities, with lower prevalence in Black and higher prevalence in Hispanic populations. The contribution of genetic ancestry to per-drinker susceptibility, independent of alcohol exposure, metabolic comorbidities, and *PNPLA3* rs738409, has not been jointly quantified in a contemporary U.S. cohort using whole-genome sequencing (WGS). We estimated ancestry-stratified per-drinker cirrhosis risk and assessed *PNPLA3* mediation. **Methods:** We analyzed 414,830 All of Us participants with WGS (median age 60, 60.9% female; 52.4% Non-Hispanic White, 19.2% Hispanic/Latino, 17.7% Non-Hispanic Black), assigned to gnomAD ancestry groups: European (EUR; n = 234,353; reference), African (AFR; n = 84,148), Admixed American (AMR; n = 79,106; 89.8% self-reported Hispanic/Latino). Heavy alcohol exposure required AUDIT-C $\geq$ 4 (women)/$\geq$ 5 (men) or ICD-coded AUD. Alcohol-associated cirrhosis (n = 1,941) required ICD cirrhosis, heavy exposure without viral hepatitis. *PNPLA3* rs738409 dosage was extracted from short-read WGS. Logistic regression compared AMR and AFR to EUR with progressive adjustment: M1 age+sex; M2 +AUDIT-C; M3 +diabetes; M4 +BMI; M5 +*PNPLA3*, plus ancestry×alcohol and ancestry×PNPLA3 interactions. Sensitivity analyses included strict (ICD+FIB-4) and decompensated cirrhosis, AUDIT-C-tier-stratified, and AUD-diagnosed subsets. **Results:** Among heavy drinkers, alcohol-associated cirrhosis per 100,000 was 1,543 (EUR), 3,019 (AMR), 1,242 (AFR). *PNPLA3* G allele frequency was 0.23 (EUR), 0.14 (AFR), 0.45 (AMR). AMR ancestry remained strongly associated with cirrhosis versus EUR after alcohol adjustment (M2 OR 2.65), attenuating after diabetes and BMI adjustment (M4 OR 1.96, 95% CI 1.67-2.29). *PNPLA3* adjustment attenuated AMR risk by ~42% but a substantial association remained (M5 OR 1.56, 1.32-1.84, p < 0.001); the AMR effect strengthened for decompensated cirrhosis (OR 3.01, 2.43-3.74). Compared to EUR, alcohol's impact on cirrhosis was attenuated in AFR: risk did not increase proportionally with exposure intensity (M4 OR 0.69 overall; OR 0.42 in AUDIT-C $\geq$ 8 and ICD-AUD subsets; ancestry×alcohol p < 0.001), and this was *PNPLA3*-independent (M5 OR 0.74). Ancestry×*PNPLA3* interactions were null (p > 0.2), indicating conserved per-allele effects (OR 1.49 AFR, 1.59 AMR; both p < 0.001). **Conclusion:** In the largest WGS-based multi-ancestry ALD analysis to date, AMR ancestry conferred substantially higher per-drinker cirrhosis risk versus EUR, only partially explained by *PNPLA3*. In contrast, the effect of alcohol exposure on cirrhosis risk was substantially weaker in AFR ancestry independent of *PNPLA3*, suggesting that additional ancestry-linked modifiers beyond established risk variants influence alcohol susceptibility. These findings indicate that *PNPLA3* alone does not explain ancestry-related disparities in ALD susceptibility.

★ 0044 | SPATIALLY RESOLVED LINEAGE PROGRAMS DEFINE PROGNOSIS, THERAPEUTIC VULNERABILITIES, AND STROMAL CROSSTALK IN INTRAHEPATIC CHOLANGIOCARCINOMA

Kenta Makino[1] Peter Richieri[1] Vindhya Vijay[1] Lei Zhao[2] Deepa Patil[2] Sahar Hosseini[3] Richard Dunne[4] Maria McGreevy[4] Diana Agostini-Vulaj[4] Haley Ellis[1] Brandon Huffman[3] Joy Awosika[3] Alison Hannigan[3] Elizabeth Andrews[3] Linda Nieman[1] Katherine Xu[1] Yuhui Song[1] Andrew Aguirre[3] William Lotter[3] Jonathan Nowak[2] Brian Wolpin[3] Cristina Ferrone[5] Vikram Deshpande[6] Srivatsan Raghavan[3] Bidish Patel[1] Nabeel Bardeesy[1] James Cleary[3] David Ting[1], [1]Massachusetts General Hospital, [2]Brigham and Women's Hospital, [3]Dana-Farber Cancer Institute, [4]University of Rochester Medical Center, [5]Cedars-Sinai Medical Center, [6]Beth Israel Deaconess Medical Center

Background: Intrahepatic cholangiocarcinoma (iCCA) is a heterogeneous malignancy with variable outcomes, underscoring the need for biology-based molecular classification. Multi-omics profiling and CRISPR screening of cell lines previously identified two transcriptional states—Bi-lineage (BL) and Ductal—with distinct genetic dependencies. We applied spatial transcriptomics on human iCCA tumors to characterize these transcriptional states in the context of the microenvironment. **Methods:** 124 primary, treatment-naïve iCCAs were profiled on tissue microarrays by GeoMx Digital Spatial Profiler (~19,000 genes). PanCK, α-SMA, and CD45 staining segmented tumor epithelium, cancer-associated fibroblast (CAF), and immune compartments (Fig. 1A). After quality control and Q3 normalization, 703 areas of interest were analyzed, encompassing 162,546 epithelial, 13,008 fibroblast, and 31,957 immune cells. **Results:** Unsupervised clustering of highly variable genes in tumor epithelium resolved two primary transcriptional states that recapitulated the BL and Ductal subtypes defined in cell lines (Fig. 1B). ssGSEA metascores confirmed lineage distinctions: Ductal AOIs exhibited a bile duct-restricted program, whereas BL AOIs co-expressed hepatocyte and biliary markers. Differential expression nominated subtype-specific targets: FGFR genes in BL; CLDN18/MSLN in Ductal (Fig. 1C). Consistently, ligand-receptor analysis revealed FGF–FGFR signaling enrichment in BL, with FGF ligands from fibroblasts engaging FGFRs on tumor cells (Fig. 1D). Transcription factor inference identified elevated HNF1A/1B activity in BL tumors and MYC-driven programs in Ductal tumors. Ductal tumors conferred significantly poorer 5-year overall survival (22.4% vs 49.3%; log-rank $P < 0.01$) (Fig. 1E). Although immune and CAF compositions were broadly similar, BL tumors exhibited selective coupling of tumor-derived IL32 with M2 macrophage abundance (Fig. 1F) and myCAFs, cooperatively forming an immunosuppressive niche. **Conclusion:** Spatial transcriptomics has refined our understanding of lineage-encoded subtypes of iCCA linked with different clinical outcomes. Their conservation in cell line models suggests that these states are hard-wired, supporting further exploration of the regulation of these lineage programs and their links to iCCA behavior. Subtype-specific differences, notably IL32–M2 macrophage–myCAF crosstalk in BL-iCCA, suggest potential therapeutic opportunities and provide a framework for patient selection.

0045 | HUMAN LIVER STEM CELL-DERIVED EXOSOMAL MIR-4492 PROTECTS FROM ACUTE LIVER FAILURE BY INHIBITING IQGAP1-MEDIATED DISULFIDPTOSIS

Qi Yang[1] Xiaoxuan Liu[2] yu chen[2] Li Bai[2], [1]Beijing You'an Hospital ,Capital Medical University, [2]Beijing You'an Hospital, Capital Medical University

Background: Acute liver failure (ALF) is a life-threatening clinical syndrome, unfortunately, its pathogenesis remains to be elucidated and novel effective therapy is urgently needed. Our previous work confirmed that human liver stem cell line HYX1 protects mice from ALF. However, the underlying mechanism still needs to be explored. Herein, we attempted to dissect the molecular basics of hepatoprotection conferred by HYX1-derived exosomes (HYX1-Exos), and focused on disulfidptosis, a newly identified mode of programmed cell death. **Methods:** Disulfidptosis levels were assessed in vitro and in vivo ALF models. The protective role of HYX1-Exos against ALF was evaluated, and disulfidptosis signaling was analyzed. miRNA sequencing was performed, and specific miRNAs which can inhibit disulfidptosis signaling were screened. LDH and disulfidptosis levels were assessed in ALF cells treated with selected miRNA mimics. Then, the crucial disulfidptosis molecules in ALF were screened by bioinformatics analysis. Next, the target relationship between target molecule and specific miRNA was verified. Subsequently, the gain-of-function (recombinant protein) and loss-of-function (siRNA) experiments of target molecule were conducted, and LDH and disulfidptosis levels were assessed. Finally, ALF cells were treated with mimics plus recombinant protein, and hepatocyte damage and disulfidptosis levels were analyzed. **Results:** Disulfidptosis signaling was significantly activated in ALF cells, as manifested by elevated LDH and NADP+/NADPH, reduced levels of cysteine and NAPDH, increased mRNA expression of disulfidptosis molecules, and contracted F-actin. The administration of TCEP, a specific disulfidptosis inhibitor, reversed these changes. In parallel, disulfidptosis critically involved in the pathogenesis of ALF mice, as shown by reduced survival rate and ALT/AST levels as well as improved pathology upon TCEP treatment. Similarly, disulfidptosis levels were remarkably inhibited in TCEP-treated ALF mice. Hepatic damage assessed by H&E staining and ALT/AST levels was obviously mitigated in ALF mice upon Exos treatment. Correspondingly, disulfidptosis levels were evidently suppressed. miR-4492 and miR-4508 were screened out as the protective cargoes carried by HYX1-Exos. The

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

administration of miR-4492 mimics resulted in reduced LDH and disulfidptosis levels in ALF cells. IQGAP1 could be targeted and inhibited by miR-4492. Recombinant IQGAP1 aggravated hepatocyte damage and disulfidptosis levels in ALF cells, conversely, IQGAP1 knockdown brought about the decreased LDH and disulfidptosis levels. Recombinant IQGAP1 destroyed the protective effects of miR-4492 mimics on ALF cells. **Conclusion:** HYX1-derived exosomal miR-4492 protects from ALF by inhibiting IQGAP1-mediated disulfidptosis. Our work provides novel insights into the pathogenesis and therapy of ALF.

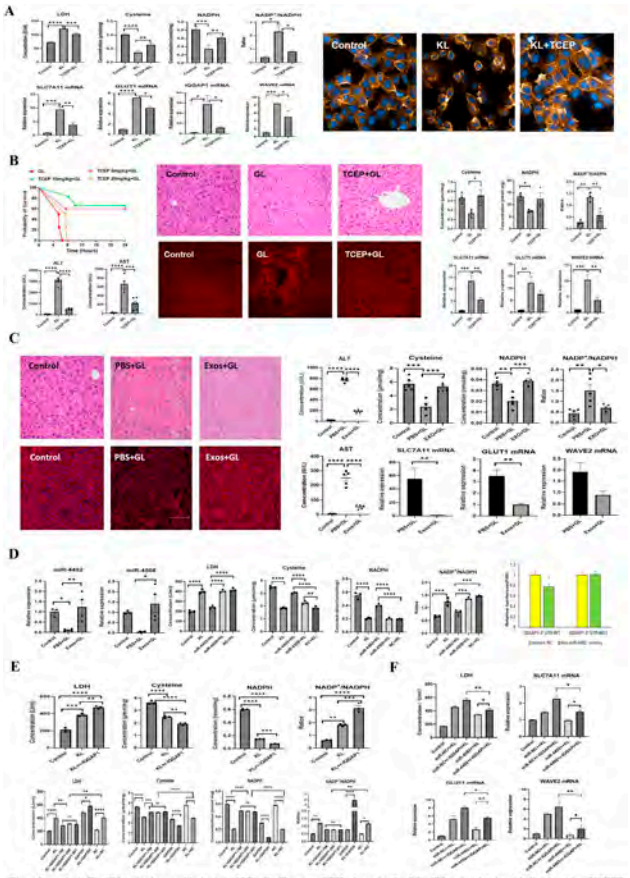

Figure Legend: **A**. Disulfidptosis plays a critical role in ALF cells. Shown are LDH release, levels of disulfidptosis-related metabolites (cysteine, NADPH, NADP+/NADPH), expression of disulfidptosis-related genes, and immunofluorescence staining of F-actin, along with changes in these parameters upon TCEP treatment; **B**. Disulfidptosis plays a critical role in ALF mice. Shown are survival rate, serum ALT/AST levels, liver H&E staining, F-actin staining, disulfidptosis-related metabolites, and expression of disulfidptosis-related genes, along with changes in these parameters upon TCEP treatment; **C**. Therapeutic effect of HYX1-Exos on ALF mice. Shown are serum ALT/AST levels, liver H&E staining, F-actin staining, disulfidptosis-related metabolites, and expression of disulfidptosis-related genes; **D**. Therapeutic effects of miR-4492 and validation of its target; **E**. Functional investigation of IQGAP1 in ALF; **F**. miR-4492 alleviates ALF by targeting IQGAP1 and inhibiting disulfidptosis.

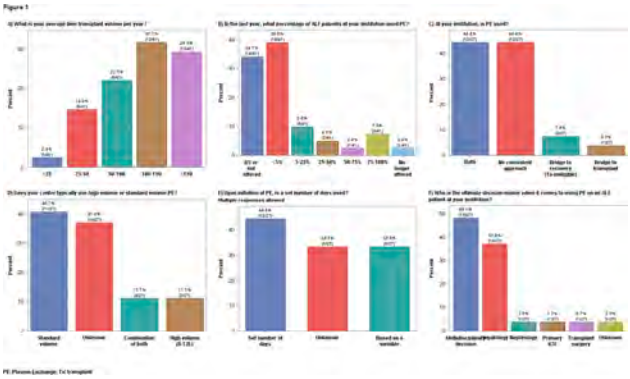
0046 | WIDE PRACTICE VARIATION IN PLASMA EXCHANGE FOR ACUTE LIVER FAILURE HIGHLIGHTS NEED FOR EVIDENCE-BASED GUIDANCE



Paige Hammis[1] Whitney Jackson[2] Rocio Lopez Moscoso[1] Jesse Schold[1] Susana Arrigain[1] Deena Brosi[1] Ryan Lavanchy[1] JP Norvell[3], [1]University of Colorado, [2]University of Colorado Denver, [3]University of Colorado School of Medicine

Background: Acute liver failure (ALF) is associated with high mortality requiring prompt management. Plasma exchange (PE) has emerged as a potential treatment to address the underlying inflammatory response seen in ALF and has been associated with increased transplant-free survival. Currently, the American societies do not provide guidance on the role of PE in ALF, while European societies provide limited direction regarding patient selection and protocol. The primary objective of this study was to obtain data from liver transplant (LT) centers across the United States to better understand how PE is used in ALF and to examine the extent of variation in clinical practice. **Methods:** We conducted a national cross-sectional survey of United States LT centers. An electronic questionnaire assessing PE utilization in ALF was emailed to transplant hepatology medical directors of all LT programs (n = 117). Responses were summarized using frequencies and percentages. **Results:** A total of 41 survey responses were received, yielding a 35% response rate. All but one were academic centers. One center reported that it did not have PE capabilities. Approximately 60% (n = 25) of respondents reported performing more than 100 LTs annually (Figure 1A). Only 24% (n = 10) reported utilizing PE in more than 5% of ALF cases during the preceding year (Figure 1B). Among centers utilizing PE for ALF (n = 27), 44.4% (n = 12) reported using PE both as a bridge to transplantation and for transplant-ineligible patients, while an equal proportion reported no consistent approach to patient selection (Figure 1C). Standard-volume PE was the most reported modality (40.7%, n = 11), compared with exclusive use of high-volume PE (11.1%, n = 3). An additional 11.1% (n = 3) reported utilizing both approaches, while 37.0% (n = 10) were unaware of the volume strategy used at their institution (Figure 1D). Upon initiation of PE, 44.4% (n = 12) of centers reported using a predetermined treatment duration, whereas 33.3% (n = 9) based treatment duration on clinical variables and 33.3%

(n = 9) were unaware of their institution's approach (Figure 1E). Decisions regarding PE use were most commonly made by a multidisciplinary team (48.1%, n = 13), followed by hepatology alone (37.0%, n = 10) (Figure 1F). **Conclusion:** These survey results demonstrate wide variation in the practice patterns of PE use among large volume academic LT programs nationally. PE is generally decided on a case-by-case basis instead of as part of a standardized protocol. Many institutions utilize PE sparingly or not at all, which may be a result of the lack of published guidelines surrounding candidate selection for PE in ALF. Most notably there is discordance in use of PE for transplant ineligible patients or as a bridge to transplant. Lack of institutional protocols and perceived limitations highlight the need for high volume centers to pool data to help facilitate evidence-based guidance.

0047 | DEVELOPMENT OF A VOLUMETRIC 3D-BIOPRINTED VASCULARIZED ARTIFICIAL LIVER FOR TRANSPLANTABLE SUPPORT IN LIVER FAILURE

Liwei Du[1] Huayu Yang[1] Yilei Mao[1], [1]Peking Union Medical College Hospital

Background: Liver failure remains a lethal condition for which transplantation is limited by donor shortage and immune rejection. Existing bioartificial liver systems provide transient detoxification but lack implantable vascular and biliary architecture. We developed a volumetric 3D-bioprinting strategy to fabricate a perfusable multicellular artificial liver for transplantable support in liver failure. **Methods:** Human iPSCs were differentiated into hepatic, vascular and bile duct organoids and assessed by morphology, lineage staining and functional assays. An ECM-mimetic bioink was optimized for printability and compatibility. Volumetric bioprinting was combined with extrusion patterning, suspended printing, acoustic assembly and sacrificial templating to fabricate 7×5×5-mm constructs with hepatocyte-rich, vascular and biliary-like compartments. Constructs were evaluated by viability, ALB/HNF4A, CD31/PDGFRβ, CK19/CK7 staining, hepatic function, biliary transport and perfusion. **Results:** We established three hiPSC-derived organoid modules. Hepatic organoids formed ALB/HNF4A-positive structures. Vascular organoids generated sprouting CD31-positive networks with mural support. Bile duct organoids acquired CK19/CK7-positive biliary epithelial features and early polarization. These modules were incorporated into 7×5×5-mm volumetric bioprinted artificial liver constructs. Our prior 3D-bioprinted liver platform showed > 99% viability at day 5 in 3–5% decellularized liver scaffold gel and 23.3 ± 2.4% Ki67-positive cells in 5% gel. Expanded hepatocytes retained ALBUMIN positivity in 96.9 ± 1.5% of cells. A 3DP-liver containing 2.7×10^7 functional hepatocytes, about 18% of mouse liver hepatocyte mass, improved liver function and survival in Fah-deficient tyrosinemia and 90% hepatectomy models. Neovascularization appeared within 1 day after transplantation, with functional GFP-positive networks by day 7. Embedded HEAL constructs with venous structures maintained > 90% viability at day 10 and > 80% at day 21; endothelialized veins increased vascular density by about 10% and total vessel length by 1.6-fold. Acoustic holography enabled patterned hepatocyte spheroid assembly within 3–6 days and improved hepatic readouts versus conventional culture. **Conclusion:** We developed a modular volumetric 3D-bioprinting strategy that integrates hiPSC-derived hepatic, vascular and biliary organoids into a multicellular artificial liver construct. This platform provides a scalable framework for generating vascularized and biliary-patterned artificial liver tissue and supports further optimization toward perfusable graft maturation, large-animal transplantation and regenerative therapy for liver failure.

0048 | DOES CONTINUOUS RENAL REPLACEMENT THERAPY IMPROVE SURVIVAL IN ACUTE LIVER FAILURE AND ACUTE-ON-CHRONIC LIVER FAILURE: A TIME-VARYING ANALYSIS OF 8,734 ICU PATIENTS

Mohamed Nadeem[1] Jingyi Huang[2] John McMichael[2] Shilpa Junna[2], [1]Cleveland Clinic Foundation, [2]Cleveland Clinic

Background: Acute liver failure (ALF) and ACLF (Acute-on-Chronic Liver Failure) are frequently complicated by acute kidney injury and hyperammonemia, and continuous renal replacement therapy (CRRT) is increasingly used in these settings. Although prior data suggest a short-term transplant-free survival (TFS) benefit, the association of CRRT with overall survival (OS) and TFS in routine practice is not well characterized, and CRRT is preferentially initiated in the most critically ill patients. **Methods:** Adults with ALF and ACLF admitted to the ICU within a single health system (2014–2024; N=8,734) were identified using ICD-10 codes, and required a new diagnosis of renal failure at the time of ICU admission to be included in the cohort. CRRT was modeled as a time-varying exposure, with follow-up split at initiation so that patients were defined as having unexposed person-time before CRRT and exposed person-time after initiation of CRRT. The CRRT hazard ratio compares event risk during follow-up after CRRT has started against event risk during follow-up when patients are not on CRRT (including pre-CRRT time and never-CRRT patients). Baseline characteristics are reported by ever-CRRT status (Table 1) to illustrate confounding by indication; these groups are descriptive and are not the units of analysis. From ICU admission and liver failure onset we assessed OS and TFS at 21 and 370 days. Cox proportional-hazards models were adjusted for age, sex, race, BMI, baseline chronic kidney disease, and MELD at ALF/ACLF diagnosis. Missing covariates (MELD missing in 24.8%) were handled with multiple imputation by chained equations; a complete-case analysis served as a sensitivity check. **Results:** Of 8,734 patients, 7,573 (86.7%) received CRRT. Baseline groups were balanced for MELD (standardized mean difference [SMD] 0.28) and race (SMD 0.40). By day 21, there were 1,337 deaths and 1,696 death-or-transplant events; by day 370, 2,928 and 3,763 events, respectively. The post-CRRT state was associated with higher adjusted hazards across all endpoints: OS-21 hazard ratio (HR) 5.34 (95% CI 4.48–6.38), TFS-21 HR 3.70 (3.21–4.26), OS-370 HR 4.36 (3.85–4.93), and TFS-370 HR 3.44 (3.12–3.81); all $p < 0.001$. Complete-case estimates were consistent and similar or larger (e.g., OS-21 HR 7.15, (5.65–9.05)). **Conclusion:** In this large ALF and ACLF mixed cohort, CRRT was associated with substantially higher short- and long-term mortality and death-or-transplant hazard rates. These findings likely reflect the severity of illness among patients requiring CRRT rather than a harmful effect of CRRT itself. Modeling CRRT as a time-varying exposure improves temporal validity, but residual confounding by dynamic clinical deterioration remains likely. Prospective studies incorporating time-updated markers of renal failure, ammonia burden, and timing of CRRT initiation are needed to identify ALF and ACLF patients most likely to benefit from CRRT.

Table 1. Baseline characteristics of the ALF/ACLF cohort by ever-CRRT status

Variable	Ever CRRT	No CRRT	SMD	Missing (%)
N	7,573	1,161		
MELD at ALF, mean (SD)	19.06 (5.80)	17.49 (5.26)	**0.283**	24.8
Age, mean (SD)	59.02 (14.45)	59.89 (15.34)	0.058	0.0
Sex, n (%)			0.026	0.0
Female	3,314 (43.8)	520 (44.8)		
Male	4,258 (56.2)	641 (55.2)		
Missing	1 (0.0)	0 (0.0)		
Race, n (%)			**0.402**	3.6
Asian	64 (0.8)	11 (0.9)		
Black	1,088 (14.4)	79 (6.8)		
Other	335 (4.4)	38 (3.3)		
White	5,891 (77.8)	910 (78.4)		
Missing	195 (2.6)	123 (10.6)		
BMI, mean (SD)	29.06 (7.32)	28.80 (6.79)	0.036	0.6
Baseline CKD, n (%)	1,480 (19.5)	159 (13.7)	**0.158**	0.0

SMD: standardized mean difference. [SRSI 2.0.1] (see) compared, non-zero imbalance. MELD missing in 24.8% was handled with m-type imputation by chained equations in the primary analysis. Groups are descriptive (confounding by indication) and are not the units of analysis.

Table 2. Adjusted hazard ratios for CRRT across survival endpoints (time-varying Cox models)

Endpoint	Events	Primary HR (MICE) 95% CI	Sensitivity HR (complete case), 95% CI
Death ≤ 21 d (OS-21)	1,337	5.34 (4.48–6.38)	7.15 (5.65–9.05)
Death or transplant ≤ 21 d (TFS-21)	1,696	3.70 (3.21–4.26)	4.30 (3.61–5.13)
Death ≤ 370 d (OS-370)	2,928	4.36 (3.85–4.93)	4.94 (4.25–5.75)
Death or transplant ≤ 370 d (TFS-370)	3,763	3.44 (3.12–3.81)	3.65 (3.24–4.10)

HR > 1 indicates higher hazard in the post-CRRT state. All p < 0.001. Cox proportional-hazards models with CRRT as a time-varying exposure, adjusted for age, sex, race, BMI, baseline CKD, and MELD at ALF. MICE, multiple imputation by chained equations.

0049 | FXR AND PPAR LIGANDS REVEAL POTENTIAL PHARMACOLOGICAL CROSSTALK WITH MRGPRX4 IN HEPATOBILIARY PRURITUS

Silvia Pickering[1] Giulia Pontarollo[1] Dominik Thimm[2] Christa Müller[2] Andreas Kremer[3], [1]University Zurich, University Hospital Zurich, [2]Pharmaceutical Institute, Pharmaceutical & Medicinal Chemistry, University of Bonn, Bonn, Germany, [3]University of Zurich, University Hospital Zurich

Background: The MAS-related G protein-coupled receptor X4 (MRGPRX4) is a bile acid and heme metabolite-sensing receptor predominantly expressed in small-diameter non-peptidergic sensory neurons of dorsal root and trigeminal ganglia. MRGPRX4 has emerged as a key mediator of hepatobiliary pruritus. Despite its pathophysiological relevance, the receptor

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

remains insufficiently characterized, and selective pharmacological antagonists are lacking, hindering biological investigation and therapeutic advancement. As nuclear receptor ligands have been widely explored in the context of hepatobiliary liver disease, potential crosstalk with MRGPRX4 may represent a clinically relevant interface between metabolic signalling, sensory neuron activation and pruritus. **Methods:** Pharmacological compounds (n = 4,356) were screened for activity at hMRGPRX4 using β-arrestin recruitment assays at a final concentration of 10 μM (PathHunter, DiscoverX). Selected ligands were further characterised by concentration–response curves to determine their EC_{50} or IC_{50} values. Calcium mobilisation assays (Flexstation 3, Molecular Devices) were used as an orthogonal functional readout. **Results:** FXR agonists activated hMRGPRX4 in β-arrestin recruitment assays, including obeticholic acid (EC_{50}: 23.1 μM), cilofexor (EC_{50}: 52.1 μM) and tropifexor (EC_{50}: 19.4 μM). Conversely, selected PPAR agonists inhibited agonist-induced hMRGPRX4 activation, including seladelpar (IC_{50}: 2.25 μM), fenofibrate (IC_{50}: 2.89 μM), elafibranor (IC_{50}: 3.26 μM) and, with lower potency, bezafibrate (IC_{50}: 83.2 μM). Calcium mobilisation assays revealed comparable activity profiles for these selected FXR and PPAR ligands. Specificity profiling further demonstrated that FXR agonist-mediated activation was not recapitulated at hMRGPRX2, an itch-relevant MRGPR family member, or at hGPR35, supporting selective hMRGPRX4 engagement. Among the PPAR agonists, seladelpar displayed the most favourable hMRGPRX4-selective inhibitory profile, while the broader activity of additional PPAR ligands suggests a wider pharmacological interaction landscape relevant to itch modulation. **Conclusion:** This study identified clinically relevant nuclear receptor ligands as modulators of MRGPRX4. FXR agonist engagement of MRGPRX4 may contribute to hepatobiliary itch, while PPAR agonist-mediated MRGPRX4 inhibition could explain antipruritic effects and suggest repurposing opportunities for other itch-entities. Functional interplay between MRGPRX4, FXR and PPAR pathways in hepatobiliary pruritus warrants further investigation. The identified compounds may serve as lead structures for developing targeted antipruritic therapies.

0050 | APALUTAMIDE AND ENZALUTAMIDE PROMOTE LIVER REGENERATION AND ATTENUATE CHOLESTATIC INJURY THROUGH CAR/PXR ACTIVATION

Meina Cai[1] Markus Ammann[1] Caixin Qiu[1] Rory Smoot[1] Danielle Carlson[1] Hidemi Nishi[1], [1]Mayo Clinic

Background: Liver failure remains major causes of mortality after liver resection and partial liver transplantation, yet no pharmacologic therapy is widely used to enhance hepatic regenerative capacity. We identified the FDA-approved androgen receptor antagonists apalutamide (APAL) and enzalutamide (ENZA) as unexpected inducers of liver growth in mice. Preliminary data suggest this effect is mediated by off-target activation of constitutive androstane

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

receptor/pregnane X receptor (CAR/PXR), rather than androgen receptor blockade. Since CAR/PXR signaling also regulates bile acid homeostasis, we further examined whether APAL may benefit cholestatic liver disease. **Methods:** Mice were treated with APAL, ENZA, or darolutamide (DARO) and evaluated for liver-to-body weight ratio, hepatocyte Ki67 labeling, plasma ALT, qPCR, and bulk RNA-seq. Regenerative efficacy was assessed in a 70% partial hepatectomy (PHx) model using perioperative ENZA treatment, followed by serial analysis of liver mass recovery and hepatocyte proliferation. To assess therapeutic potential in cholestatic liver disease, Mdr2 knockout mice were treated with APAL for 2 weeks, followed by measurement of bile acid levels and bulk RNA sequencing. **Results:** Short-course APAL or ENZA increased liver-to-body weight ratio and hepatocyte Ki67 positivity without biochemical evidence of hepatotoxicity, whereas DARO had no effect. Bulk RNA-seq of APAL-treated livers demonstrated enrichment of xenobiotic metabolism and cell-cycle programs, including E2F targets and G2/M checkpoint signatures. APAL-induced transcriptional changes showed strong overlap with a published TCPOBOP-induced CAR gene program, supporting CAR/PXR pathway activation. qPCR confirmed induction of proliferation-associated genes and canonical CAR/PXR targets. In the 70% PHx model, perioperative ENZA accelerated liver mass recovery and increased early hepatocyte proliferation after surgery. Notably, in Mdr2 knockout mice, 2-week APAL treatment reduced blood bile acid levels and decreased expression of biliary fibrosis-related genes, supporting a beneficial effect in cholestatic liver injury. **Conclusion:** APAL and ENZA induce a regenerative liver program characterized by CAR/PXR-associated transcriptional activation and hepatocyte cell-cycle entry, with perioperative benefit in experimental hepatectomy. In addition, longer-term APAL treatment ameliorates cholestatic disease features in Mdr2-deficient mice. These findings support APAL/ENZA as a promising repurposing candidate for both liver regeneration and cholestatic liver disease.

0051 | GEOMETRY-TUNED PRIMARY HUMAN HEPATOCYTE CULTURE DEFINES A MECHANOTRANSDUCTION SET POINT FOR HEPATOCYTE IDENTITY LOSS

Takeshi Saito[1] Masashi Okawa[2] Yein Woo[2] Garnik Arustamyan[2] Daniel Pinski[2] Meng Li[1] Hans I-Chen Harn[2], [1]University of Southern California, [2]Keck School of Medicine, University of Southern California

Background: Maintenance of mature human hepatocyte (HH) identity depends in part on preservation of native cellular architecture. In normal human liver, hepatocytes display constrained lateral dimensions (20–25 μm), whereas cirrhotic hepatocytes show marked geometric heterogeneity (18–40 μm), with enlargement associated with identity loss. Primary HH culture models this geometry–identity relationship, in which loss of tissue-imposed constraints renders hepatocytes susceptible to seeding density–dependent distortion and lateral spreading. This study aimed to define the cellular geometry–mechanotransduction set point that preserves hepatocyte identity by integrating liver tissue benchmarking with density-tuned primary HH culture. **Methods:** HHs were seeded as 2D monolayers at graded densities on substrates of varying stiffness to modulate lateral cell geometry and cell–matrix tension. Low-density culture permitted aberrant lateral spreading, whereas high-density culture imposed spatial confinement approximating normal liver dimensions. Cell geometry was quantified by projected area, equivalent circular diameter, and major/minor lateral axes, while cellular mechanics were measured by atomic force microscopy. Hepatocyte architecture and polarity were assessed by confocal microscopy, including bile canaliculi formation. These readouts were integrated with single-cell RNA sequencing to link geometric and mechanical states with mature hepatocyte identity and YAP/TAZ-associated mechanotransduction. In vitro geometry–identity states were benchmarked against normal and cirrhotic human liver tissue. **Results:** Density- and stiffness-tuned HH cultures generated distinct geometry states ranging from spatially confined cells within the normal liver size range to laterally enlarged cells resembling cirrhosis-associated geometric heterogeneity. Lateral enlargement >28 μm correlated with altered mechanics, disrupted canalicular architecture, YAP/TAZ-associated mechanotransduction, and loss of mature hepatocyte identity. Single-cell RNA sequencing identified a 16-gene identity-loss signature enriched in enlarged HHs and upregulated in cirrhotic hepatocytes. Signature-positive cells segregated into four subpopulations: residual mature hepatocyte, cholangiocyte-like, hepatic progenitor-like, and mesenchymal-like states. **Conclusion:** Expansion beyond an equivalent lateral diameter of 28 μm marked the emergence of hepatocyte identity-loss programs, with maladaptive mechanotransduction and canalicular disorganization mirroring cirrhosis. These findings refine cirrhosis as a hepatocyte identity-loss state, not solely hepatocyte loss, and support geometry-tuned primary HH culture as an in vitro platform to model cirrhosis-associated hepatocyte failure and identify therapeutic targets.

0052 | HEPATIC X-BOX BINDING PROTEIN 1 (XBP1) REGULATES THE BILE ACID SYNTHETIC ENZYME CHOLESTEROL 7 ALPHA-HYDROXYLASE (CYP7A1) IN THE LIVER

Xiaoying Liu[1] Moloud Aflaki Sooreshjani[1] Mahmoud Khalafalla[1] Andrew Benintende[1] Richard Green[1], [1]Northwestern University Feinberg School of Medicine

Background: The unfolded protein response (UPR) is an adaptive cellular response to endoplasmic reticulum (ER) stress that occurs in multiple liver disorders including cholestatic liver diseases. X-box binding protein 1 (XBP1), an important component of the UPR, is activated through a splicing mechanism to produce the active spliced form of XBP1 (XBP1s). Our previous work has demonstrated that hepatic deletion of XBP1 impairs bile acid metabolism and reduced the synthetic activity of cholesterol 7 alpha-hydroxylase (CYP7A1), the rate-limiting enzyme in the classic pathway of bile acid synthesis. Despite lower activity, the hepatic gene and protein expression of CYP7A1 were higher in liver-specific XBP1 knockout mice compared with control mice. In this study, we investigated the potential regulatory mechanisms of CYP7A1 by XBP1. **Methods:** Liver-specific doxycycline-inducible XBP1s transgenic (TG) mice and their WT littermate control mice were fed chow supplemented with doxycycline (200 mg/kg) for 48 hr to induce hepatic XBP1s overexpression. Liver tissues were collected for RNA and protein expression analysis. WT C57BL/6 mice were also treated with the selective XBP1 activator IXA4 (50 mg/kg, ip) or vehicle for 2 hr. XBP1 ChIP-seq and ATAC-seq were performed on whole liver tissues and analyzed with HOMER. Mouse liver cell lines AML12 and Hepa 1-6 cells were co-transfected with a mouse *Cyp7a1* promoter luciferase reporter construct and a plasmid overexpressing mouse XBP1s. A reporter assay was performed to examine m*Cyp7a1* promoter activity. **Results:** In TG mice, hepatic overexpression of XBP1s with doxycycline-feeding significantly reduced the gene expression of *Cyp7a1* in the liver of both female and male mice compared to WT littermate controls (female: 84% reduction, $P < 0.05$; male: 82% reduction, $P < 0.01$). Hepatic CYP7A1 protein expression was also decreased in female XBP1s TG mice after doxycycline feeding (37% reduction, $P < 0.05$). The hepatic gene expression of small heterodimer partner (SHP), a transcriptional repressor of *Cyp7a1*, did not change in female XBP1s TG mice while slightly increased in male XBP1s TG mice after doxycycline feeding (0.7-fold increase, $P < 0.05$). XBP1 ChIP-seq analysis revealed putative binding of XBP1s protein to the promoter region of mouse *Cyp7a1* in IXA4-treated mice. ATAC-seq analysis demonstrated similar chromatin accessibility at the *Cyp7a1* promoter region in both IXA4 and vehicle-treated groups. In vitro, overexpression of mouse XBP1s decreased *Cyp7a1* promoter activity in both AML12 (30% reduction, $P < 0.01$) and Hepa 1-6 cells (29% reduction, $P < 0.001$). **Conclusion:** Our data indicates that the UPR protein XBP1s negatively regulates the expression of the key bile acid synthetic enzyme CYP7A1, at least in part, through a SHP-independent transcriptional mechanism. This study demonstrates a novel regulatory mechanism of bile acid metabolism by ER stress and UPR.

0053 | DFNA5-MEDIATED SECONDARY NECROSIS PROMOTES TNF/NF-κB SIGNALING DURING HEPATOCARCINOGENESIS

Tomoya Hamabe[1] Yoshinobu Saito[2] Yoichi Sasaki[3] Kazuhiro Murai[3] Hayato Hikita[2] Takahiro Kodama[4], [1]The University of Osaka, [2]Osaka University Graduate School of Medicine, [3]The University of Osaka, Graduate School of Medicine, [4]Osaka University

Background: Hepatocyte death plays a central role in the progression of chronic liver disease. We previously demonstrated that persistent hepatocyte apoptosis promotes hepatocarcinogenesis. However, the contribution of non-apoptotic cell death to chronic liver disease-associated hepatocarcinogenesis remains unclear. Dfna5, also known as GSDME or Gasdermin E is a key mediator of secondary necrosis. Nevertheless, its role in hepatocarcinogenesis has not been fully elucidated. **Methods:** Alb-Cre Mcl-1 fl/fl mice, which exhibit persistent hepatocyte apoptosis and spontaneous HCC development, were used as a chronic liver disease-associated hepatocarcinogenesis model. DFNA5 was silenced in AML12, murine hepatocytes, using siRNA, and apoptosis was induced with the Bcl-xL inhibitor ABT-737. Cell death was assessed by LDH release assay and Annexin V/propidium iodide

(PI) flow cytometry. Co-culture experiments were performed using AML12 and RAW264.7, murine macrophages. Clinical relevance was evaluated using TCGA-LIHC datasets. **Results:** Hepatocyte-specific Mcl-1 knockout mice showed increased hepatic *Tnf* expression. Depletion of Kupffer cells with clodronate liposomes abolished this *Tnf* upregulation, suggesting that Kupffer cells are the major source of TNF in this model. Hepatocyte-specific deletion of Dfna5 in Mcl-1 knockout mice did not alter liver-to-body weight ratio, serum ALT levels, or TUNEL-positive cells. However, bulk RNA-seq analysis demonstrated suppression of TNF/NF-κB signaling and inflammatory cytokine-related pathway pathways.In AML12 cells, ABT-737 induced caspase-3/7 activation and Dfna5 cleavage. *Dfna5* knockdown significantly reduced LDH release and decreased the Annexin V/PI double-positive population, suggesting that DFNA5 promotes secondary necrosis. Furthermore, co-culture of ABT-737-treated AML12 cells with RAW264.7 cells induced Tnf expression in RAW264.7 cells, which was attenuated by Dfna5 knockdown in AML12 cells.HCC developed in 100% of Mcl-1 knockout mice, whereas tumor incidence was significantly reduced in Mcl-1/Tnf double-knockout mice (47.8%, 17/17 vs 11/23; $p = 0.0008$). High DFNA5 expression was positively correlated with *TNF* and *CCL2* expression and was associated with poor prognosis in TCGA-LIHC cohorts. **Conclusion:** DFNA5 mediates secondary necrosis in hepatocytes and amplifies macrophage-derived TNF/NF-κB inflammatory signaling. These findings suggest that DFNA5-TNF/NF-κB axis might promote chronic inflammation-associated hepatocarcinogenesis.

0054 | CONSTITUTIVE C-MAF EXPRESSION VIA ADENOVIRAL DELIVERY ENABLES THREE-DIMENSIONAL CULTURE OF LSEC LIKE CELLS IN VITRO

Jesus Maria Gomez Salinero[1] Juliane Baco[1] Dona Zhang[1] Yosip Kelemen[1], [1]Weill Cornell Medicine

Background: Chronic liver disease claims over 2 million lives annually worldwide; in the United States alone, 4.5 million adults are diagnosed and 50,000 die each year. Liver transplantation remains the only curative option for end-stage liver failure, yet fewer than 20% of patients in need receive a transplant due to organ scarcity, making new therapeutic strategies urgently needed. In a healthy liver, liver sinusoidal endothelial cells (LSECs) maintain organ homeostasis through paracrine signaling coordinating hepatocyte function, immune surveillance, and tissue repair. Dysregulation of the endothelial-hepatocyte axis underlies the progression from steatosis to fibrosis and liver failure. **Methods:** Our laboratory recently defined the transcriptional identity of LSECs and identified the transcription factor c-Maf as the master orchestrator of their sinusoidal program (Gomez-Salinero et al., Cell Stem Cell 2022). Doxycycline-inducible overexpression of c-Maf in naïve endothelial cells in vitro recapitulates sinusoidal gene expression and supports stable long-term hepatocyte co-culture. However, these studies relied on two-dimensional monolayer cultures, or spheroids, that don't capture the three-dimensional structure of the hepatic sinusoids, limiting our capacity to accurately model liver disease. **Results:** To overcome this limitation, we developed an adenoviral vector strategy for constitutive c-Maf expression that enables LSEC engineering under three-dimensional conditions. Compared to control ECs, c-Maf LSECs in 3D culture adopt a distinct morphology forming large, open intercellular spaces that recapitulate the hepatic sinusoidal architecture. Building on this technology, we have established co-cultures of c-Maf LSECs with hepatocyte organoids under healthy conditions, as well as exposed to free fatty acids modeling lipotoxic stress during liver disease. **Conclusion:** This platform enables the study of the crosstalk of endothelial cells and hepatocytes during the progression of liver disease, allowing the study to drug response and analysis of defined immune cell populations deliver under pathological conditions. Long-term, we envision transplanting c-Maf LSEC vascularized hepatocyte organoids as a

0056 | DISTRIBUTION OF NATURAL HISTORY STAGES IN CHILDREN AGED 1–12 YEARS WITH CHRONIC HEPATITIS B VIRUS INFECTION: A REAL-WORLD MULTICENTER RETROSPECTIVE STUDY

Xue-Jing Yu[1] Shi-Xi Zhang[2] Yu-Fu Wang[3] Yan-Qin Ai[4] Qing-Lei Zeng[1], [1]The First Affiliated Hospital of Zhengzhou University, China, [2]Shangqiu Municipal Hospital, China, [3]Zhumadian Traditional Chinese Medicine Hospital, China, [4]Xuchang Central Hospital, China

Background: Real-world epidemiological data regarding the natural history of chronic hepatitis B virus (HBV) infection in children aged 1–12 years remain limited. This study aimed to investigate the distribution of disease stages and virological characteristics among untreated children with chronic HBV infection, and to provide evidence to inform clinical management strategies. **Methods:** We retrospectively collected data from untreated children aged 1–12 years with chronic HBV infection who had consecutive follow-up data at four teaching hospitals in Henan Province, China, between 2022 and 2026. Natural history staging was performed according to the *AASLD IDSA Practice Guideline on treatment of chronic hepatitis B (2025 Edition)*. **Results:** A total of 340 children with chronic HBV infection were identified across the four participating hospitals during the study period, and all were screened for eligibility, and 232 untreated children with chronic HBV infection who had consecutive data were ultimately included (Table 1). Among them, 99 (42.67%) were classified as being in the immune-tolerant phase, 107 (46.12%) in the immune clearance (HBeAg-positive immune active) phase, 1 (0.43%) in the inactive (HBeAg-negative) phase, 4 (1.72%) in the reactivation (HBeAg-negative immune active) phase, and 21 (9.05%) in the indeterminate phase. Due to the limited sample sizes in the inactive and reactivation phases, these groups were excluded from intergroup analyses. Median HBV DNA levels in the immune tolerance, immune clearance, and indeterminate groups were 8.20 (8.07–8.45), 7.85 (7.36–8.21), and 6.45 (3.85–7.41) $\log_{10}$ IU/mL, respectively, while median HBsAg levels were 4.70 (4.50–4.86), 4.19 (3.83–4.40), and 3.68 (3.37–3.87) $\log_{10}$ IU/mL, respectively. Significant differences in HBV DNA and HBsAg levels were observed among the three groups (all $P < 0.001$). **Conclusion:** A substantial proportion of untreated children aged 1–12 years with chronic HBV infection were already in the immune clearance phase rather than the immune-tolerant phase. These findings challenge the traditional view that most children remain in immune-tolerant phase and may not require antiviral therapy. Large-scale prospective studies are warranted for further validation.

Table 1 Distribution of natural history stages and virological characteristics in children with chronic hepatitis B virus infection

Parameters	Immune tolerance phase	Immune clearance phase	Inactive phase	Reactivation phase	Indeterminate phase
n, %	99 (42.67%)	107 (46.12%)	1 (0.43%)	4 (1.72%)	21 (9.05%)
Age, years	7.0 (5.0, 10.0)	7.5 (5.0, 10.0)	11.0 (11.0, 11.0)	8.0 (3.5, 11.0)	7.0 (4.0, 11.0)
Male, n (%)	57 (57.6%)	60 (61.7%)	1 (100.0%)	2 (50%)	7 (33.3%)
HBV DNA, log10 IU/mL	8.20 (8.07, 8.45)	7.85 (7.36, 8.21)	8.00 (8.00, 8.00)	8.03 (7.78, 8.18)	6.45 (3.85, 7.41)
HBsAg, log10 IU/mL	4.70 (4.50, 4.86)	4.19 (3.83, 4.40)	2.96 (2.96, 2.96)	4.80 (4.50, 4.97)	3.68 (3.37, 3.87)
ALT, U/L	19.00 (15.00, 23.00)	62.00 (41.25, 101.75)	15.00 (15.00, 15.00)	152.85 (130.75, 695.02)	20.00 (15.50, 25.00)

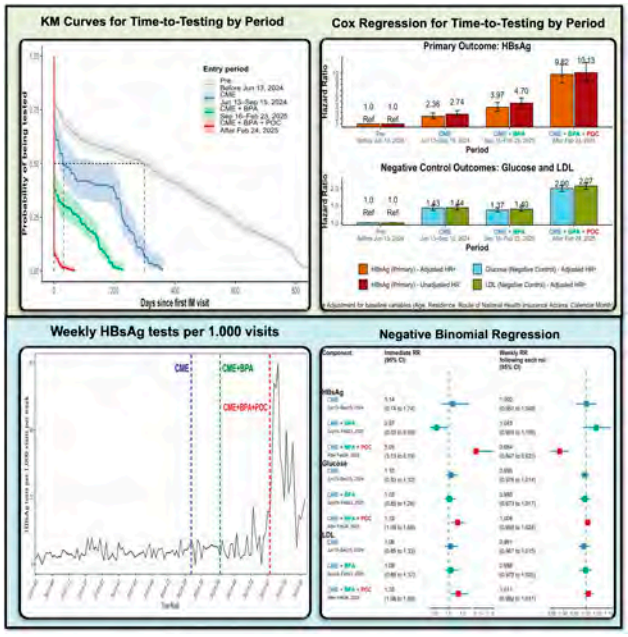
★ 0057 | INTEGRATING HEPATITIS B SCREENING INTO PRIMARY CARE IN A HIGH-BURDEN LMIC: A MIXED-METHODS IMPLEMENTATION STUDY FROM VIET NA



Thanh Kim[1] Trang Ngoc Doan Pham[2] Doan Dao[3] Diem Dao[4] Loc Phan[5] Linh Le[1] Toan Le[6] Thuy Tran[6] Vu Dang[6] Trang Nguyen[7] Khanh Tran[6] Anh Le[8] Cong Ly[6] Hung Vo[6] Tung Do[6], [1]Pham Ngoc Thach University of Medicine, [2]Harvard Medical University, [3]Mass General Hospital, [4]Vietnam Viral Hepatitis Alliance, [5]Vietnam Viral Hepatiits Alliance, [6]Le Van Thinh Hospital, Viet Nam, [7]Le Van Thinh Hospital, [8]Viet Nam Viral Hepatitis Alliance

Background: Globally, 290 million people live with chronic hepatitis B (CHB), yet only 13% are diagnosed and <3% receive treatment. HBsAg screening is the essential first step in the care cascade. Viet Nam represents a high-burden LMIC where 70% of individuals with CHB remain unaware of their infection. In routine primary care, HBsAg testing is typically symptom-driven, resulting in major gaps in diagnosis and linkage to care. Scalable strategies to integrate HBV screening into routine primary care are urgently needed. **Methods:** We conducted a quasi-experimental, mixed methods implementation trial at a large public

primary care hospital in Ho Chi Minh City, Viet Nam. A three-component strategy, guided by the Consolidated Framework for Implementation Research (CFIR), was introduced sequentially over 12 months: continuing medical education (CME), an electronic best practice advisory (BPA), and point-of-care (POC) HBsAg rapid testing. Implementation outcomes (adoption, reach) and service outcomes (weekly HBsAg testing per 1,000 visits) were assessed using electronic medical records. Time-to-testing was analyzed using Kaplan–Meier and Cox regression models, and trends were evaluated using segmented negative binomial interrupted time-series. LDL and glucose testing served as netative controls. Qualitative data were analyzed using a CFIR-guided framework to delineate mechanisms and contextual factors. **Results:** Among 225,209 outpatient visits and 46,857 patients, CME improved provider knowledge but led to minimal increases in screening. BPA reminders were frequently bypassed during high-volume work flows. In contrast, introduction of free POC HBsAg rapid testing resulted in a rapid and sustained increase in testing rates and significantly reduced time-to-testing. These effects were substantially greater than negative control outcomes. Qualitative findings demonstrated that removal of financial and procedural barriers was the primary driver of uptake, while workflow integration and task-sharing influenced implementation success. **Conclusion:** In a high-burden LMIC setting, integrating HBV screening into primary care is feasible but requires addressing structural barriers. Point-of-care testing, rather than education or electronic prompts alone, was the dominant driver of screening uptake. This model provides a scalable, real-world strategy to expand HBV diagnosis and accelerate progress toward global elimination targets.

0058 | HEPATITIS B VIRUS PREVALENCE AMONG US-BOUND REFUGEES, 2018–2023

Erin Mann[1] Kelly Searle[1] Jose Debes[1], [1]University of Minnesota

Background: Hepatitis B virus (HBV) prevalence is highly heterogeneous globally. Refugees originating from regions such as Asia or sub-Saharan Africa are thought to be at high risk, but recent prevalence estimates among US-bound refugees are limited, making successful care assignment and cascade decisions difficult. **Methods:** We analyzed HBV screening data from refugees undergoing overseas health assessments through the United States Refugee Admissions Program between October 2018 and September 2023. Prevalence was estimated by region, nationality, age (0–5y, 6–17y, ≥18 y), sex, and year. Log-binomial regression estimated adjusted risk ratios. For the two largest nationalities, we compared adjusted prevalence among adults by country of evaluation, a proxy for ethnic group and migration pathway. Among minors aged 11–17, we compared HBV prevalence between unaccompanied minors and accompanied minors, adjusting for nationality, age, sex, and year using conditional logistic regression. **Results:** Of 190,247 refugees screened, 3,545 (1.86%) tested HBsAg-positive. Prevalence declined from 3.13% in 2018 to 1.46% in 2023, persisting after adjustment for region, age, and sex (aRR 0.66, 95% CI 0.58–0.76). Prevalence rose with age (0–5y: 0.10%; 6–17y: 0.54%; ≥18y: 3.15%) and varied by region (Asia 3.62%, Africa 2.56%, Eastern Mediterranean 1.08%, Europe 0.91%, Americas 0.21%) and nationality (range 0%–13.8%). Adjusting for sex and year, adult prevalence was highest in Asia and Africa: 5.94% and 4.47% (95% CI 5.51–6.37 and 4.26–4.67 respectively); among children this reversed, with Africa exceeding Asia at ages 0–5y:

0.15% vs 0.10% (95% CI 0.09–0.21 and 0.00–0.19, respectively) and 6–17y: 0.95% vs 0.61% (95% CI 0.83–1.07 and 0.40–0.82, respectively). Interestingly, predicted adult prevalence varied by country of evaluation (despite the same country of origin): Myanmar nationals in Thailand (8.5%, 95% CI 7.6–9.5) vs. Malaysia (5.4%, 95% CI 4.8–5.9); Democratic Republic of the Congo nationals in Tanzania (5.7%, 95% CI 5.2–6.1) vs. Zambia (3.2%, 95% CI 2.3–4.1). Of 1,673 unaccompanied minors, 21 (1.3%) tested positive, with over twice the odds of accompanied peers (OR 2.05, 95% CI 1.24–3.41). **Conclusion:** HBV prevalence among refugees has declined but remains substantial and heterogeneous. The adult-to-child reversal between Asia and Africa may reflect differing transmission dynamics and progress in pediatric vaccination. Our findings can inform screening, vaccination, and linkage to care for displaced populations worldwide helping in elimination strategies.

★ 0059 | GENERATIONAL SHIFTS IN U.S. HEPATITIS B VACCINE-DERIVED IMMUNITY AFTER UNIVERSAL INFANT VACCINATION

Giovanni Roldan[1] Eva Enns[1] John Lake[1] Jesse Fletcher[1] Timothy Davie[1] Kartik Dapke[2] Serena Brosten[1] Anna Strauss[1] Prowpanga Udompap[3], [1]University of Minnesota, [2]Saint Vincent Hospital, [3]Minneapolis VA Medical Center

Background: The licensure of the hepatitis B (HBV) vaccine in 1982 and the subsequent 1991 U.S. ACIP recommendation for universal infant vaccination reshaped HBV epidemiology. However, how vaccine-derived serologic immunity evolves across birth cohorts has not been directly characterized at the population level. We analyzed NHANES serologic data using birth-cohort trajectories to both quantify generational shifts in HBV vaccine-derived serologic immunity and to characterize changes in detectable anti-HBs positivity over time. **Methods:** We analyzed thirteen National Health and Nutrition Examination Survey (NHANES) waves spanning from 1988 to 2023 (N = 84,996). Survey-weighted prevalence of vaccine-derived HBV immunity (anti-HBs positive/anti-HBc negative) was estimated within 23 five-year birth cohorts born from 1905–1909 to 2015–2019 and mapped to attained age, estimated as survey midpoint year minus birth-cohort midpoint year. Weighted linear models assessed age-related change within pre-vaccination (born 1940-1979), transitional (1980–1994), and universal-vaccination (born 1995 and later) strata. Anti-HBc trajectories were analyzed in parallel to assess HBV exposure across eras. **Results:** Pre-1980 cohorts had persistently low vaccine-derived immunity throughout adulthood (weighted mean prevalence, 12.7%; +1.1 percentage points per decade of attained age). Transitional cohorts born 1980–1994, reflecting infant and catch-up adolescent vaccination, reached the highest observed prevalence, peaking at 67.0–67.5% — more than five-fold higher than pre-vaccination cohorts — and showed only modest decline (−2.6 points/decade), with prevalence of 50.2% at age 35.7 years in the 1985–1989 cohort and 45.8% at age 30.7 years in the 1990–1994 cohort. Universal-vaccination-era cohorts born after 1995 achieved high initial rates of vaccine-derived immunity (48.0–56.2% in early childhood), confirming strong population-level vaccine uptake. Detectable anti-HBs positivity in these cohorts declined by 20.1 percentage points per decade of attained age (95% CI, 16.3–23.8; $P < 0.001$). Anti-HBc prevalence declined across eras, from 5.44% in pre-vaccination cohorts to 1.07% in transitional and 0.31% in universal-vaccination cohorts, confirming a marked generational reduction in HBV exposure. **Conclusion:** Birth-cohort trajectory mapping demonstrates that universal HBV vaccination produced a transformative, more than five-fold generational increase in U.S. vaccine-derived HBV serologic immunity and a marked reduction in HBV exposure. Detectable anti-HBs positivity declines substantially with attained age in universal-vaccination-era cohorts, yet anti-HBc prevalence remains very low, consistent with durable clinical protection despite serologic waning. Population-level surveillance of prior vaccination policies can guide future changes in HBV vaccine recommendations.

★ 0060 | "METABOLIC HEPATITIS B" (MET-B): A DISTINCT CLINICAL PHENOTYPE CARRIES A HIGHER RISK OF HEPATOCELLULAR CARCINOMA DEVELOPMENT DESPITE EFFECTIVE ANTIVIRAL THERAPY - A LARGE HISTOLOGY BASED LONGITUDINAL COHORT STUDY

Phool Chand[1] Shiv Kumar Sarin[2] Manoj Sharma[3] Vinod Arora[2] Varsha Shasthry[2] Ankit Bhardwaj[4] Ravi Nishad[2] Jaifrin Daniel[2] Satender Singh[2] Ankur Jindal[2] Chhagan Bihari[2] Archana Rastogi[4] Guresh Kumar[4] Mahima Chaudhary[2], [1]Institute of Liver and Biliary Sciences (ILBS), New Delhi, [2]Institute of Liver and Biliary Sciences, New Delhi, [3]Institute of Liver and Biliary Sciences, [4]Institute of Liver and Biliary Sciences, New Delhi.

Background: The impact of metabolic dysfunction–associated steatotic liver disease (MASLD) on hepatocellular carcinoma (HCC) risk in chronic hepatitis B (CHB) remains controversial. Histology-driven longitudinal data evaluating the interaction between metabolic dysfunction, antiviral response, and hepatocarcinogenesis are limited. We evaluated the impact of metabolic dysfunction on virologic outcomes, liver histology, and long-term HCC risk in a biopsy-characterized CHB cohort. **Methods:** We conducted a retrospective longitudinal cohort study of HBsAg-positive CHB patients who underwent liver biopsy between 2010 and 2024. Met-B was defined as presence of CHB with ≥ 1 cardiometabolic risk factor. Patients with coinfection, baseline HCC, significant alcohol intake, prior transplantation, or inadequate follow-up were excluded. Among 1,920 screened patients, 1,333 comprised the final analytic cohort: 833 Met-B and 500 HBV-alone patients. **Results:** Median follow-up was 8.0 ± 4.2 years in Met-B and 10.6 ± 4.5 years in HBV-alone ($p < 0.001$). Met-B patients had higher prevalence of diabetes (57.7%), hypertension (42.9%), dyslipidemia (75.4%), and cirrhosis (31.5%) (all $p < 0.001$). Liver biopsy demonstrated significantly greater fibrosis, steatohepatitis, perisinusoidal fibrosis, inflammatory activity, ductular reaction, and cholestatic injury in Met-B (all $p < 0.001$). Met-B patients also demonstrated inferior virologic response (50.1% vs 68.2%), biochemical response (55.5% vs 77.6%), HBeAg seroconversion (10.0% vs 16.2%), HBsAg clearance (3.5% vs 7.2%), and functional cure (2.0% vs 5.8%) (all $p \leq 0.002$). During follow-up, incident HCC occurred in (143/833)17.2% of Met-B patients versus (36/500)7.2% in HBV-alone (HR 2.24, 95% CI 1.55–3.23; $p < 0.001$).Independent predictors of HCC development included AFP ≥ 20 ng/mL (aHR 5.41), PIVKA-II ≥ 40 mAU/mL (aHR 5.39), steatohepatitis (aHR 10.11), METAVIR F2 fibrosis (aHR 2.35), METAVIR F3/F4 fibrosis (aHR 2.11), diabetes mellitus (aHR 1.57), and elevated quantitative HBsAg (aHR 1.30) (all $p < 0.05$). **Conclusion:** Metabolic dysfunction identifies a biologically aggressive CHB phenotype characterized by impaired antiviral response, delayed serologic clearance, advanced steatohepatitis, and substantially increased HCC risk despite antiviral therapy. These findings support incorporation of metabolic and histologic profiling into HCC risk stratification frameworks for chronic hepatitis B.

0061 | LIVER STIFFNESS PREDICTS HCC IN NON-CIRRHOTIC HBEAG NEGATIVE PATIENTS WHO DO NOT MEET TREATMENT CRITERIA BASED ON HBV DNA AND ALT – RESULTS FROM THE GLOBAL RADICAL CONSORTIUM

Lisa van Velsen[1] Gabriele Ricco[2] Norah Terrault[3] Karen Cheuk Ying Ho[4] Zillah Cargill[5] Marc Ghany[6] Elena Vargas-Accarino[7] Mai Kilany[8] Sara Battistella[9] Özgür Muhammet Koc[10] Stéphanie Narguet[11] Bettina Hansen[12] Jef Verbeek[13] Frederik Nevens[13] Tarik Asselah[14] Dirk Posthouwer[10] Yao-Chun Hsu[15] Sabela Lens[9] Jordan Feld[16] Maria Buti[17] Kosh Agarwal[5] Maud Lemoine[18] Wai-Kay Seto[19] Man-Fung Yuen[19] Maurizia Brunetto[20] Harry Janssen[21] Milan Sonneveld[1],
[1]Erasmus University Medical Center, [2]University Hospital of Pisa, [3]University of Southern California, [4]The University of Hong Kong, Hong Kong, [5]King's College Hospital, [6]NIH/NIDDK, [7]Hospital Universitari Vall d'Hebron, [8]Toronto Centre for Liver Disease, [9]Hospital Clinic Barcelona, [10]Maastricht University Medical Center, [11]AP-HP Hôpital Beaujon, [12]Erasmus MC Rotterdam, [13]KU Leuven University Hospital Leuven, [14]Hôpital Beaujon, [15]I-Shou University, [16]Toronto General Hospital, [17]Hospital Valle Hebron, [18]Imperial college London, [19]The University of Hong Kong, [20]University of Pisa, [21]Erasmus MC

Background: HBeAg negative patients who do not meet treatment criteria based on HBV DNA and ALT levels remain at risk of hepatocellular carcinoma (HCC), requiring long-term follow-up for accurate disease staging and phase classification. We hypothesized that a single liver stiffness measurement (LSM) could be helpful in HCC risk stratification. **Methods:** The current study utilized data collected for the global RADICAL study, which examines long-term outcomes in CHB patients who do not meet treatment criteria. We extracted data from HBeAg negative patients without cirrhosis who did not meet criteria for antiviral therapy according to HBV DNA and ALT criteria set forth in the 2025 EASL guideline. We then assessed HCC risk stratified for baseline LSM in the overall population, and in the subset of patients who were classified as being in the 'grey-zone' (GZ) based on laboratory data obtained during the first year of follow-up. For this analysis, the GZ was defined as not meeting criteria for HBeAg negative chronic infection (previously known as inactive carrier, defined as persistently HBeAg negative, without significant fibrosis (LSM $\leq$7 kPa, or F0-1 on biopsy), and maintained ALT $\leq$40 U/L with HBV DNA $<$2000 IU/mL). **Results:** In total, 2542 patients were included. Median age was 43 years (IQR 34-53), 48% were male, 45% were Asian and 29% were Caucasian. Baseline ALT was 25 U/L (IQR 19-34), HBV DNA was 2.8 log10 IU/mL (IQR 2.0-3.5), and LSM was 4.8 kPa (IQR 4.1-5.8). Patients were followed for a median of 7.8 (IQR 5.3-9.2) years. In the overall cohort, the 10-year cumulative incidence of HCC was 0.3%. Baseline LSM $>$7 kPa was highly predictive of HCC (HR: 14.8, 95% CI 3.5-62, $p<0.001$). Amongst patients with an LSM $\leq$7 kPa, the 10-year cumulative incidence of HCC was 0.1%, compared to 2.4% in patients with an LSM $>$7 kPa ($p<0.001$) (Figure 1). Based on laboratory assessments obtained in the first year after inclusion, 50% of patients were categorized as GZ, and 50% as HBeAg negative chronic infection. Amongst 1262 GZ patients, 48% were male, and 45% were Asian, 28% were Caucasian, with median baseline ALT of 29 U/L and HBV DNA of 3.5 log10 IU/mL. Amongst GZ patients, 64% had HBV DNA $\geq$2000 IU/mL with ALT $\leq$40 U/L and 24% had HBV DNA $<$2000 IU/mL but ALT $>$40 U/L, and 13% had fluctuating HBV DNA or ALT levels. In line with the observations in the overall cohort, GZ patients with an LSM $>$7 kPa (n=149) had a higher risk of HCC compared to patients with an LSM $\leq$7 kPa (0.2% vs 3.4% at 10 years, $p<0.001$). **Conclusion:** In HBeAg negative patients not meeting EASL treatment criteria based on ALT and HBV DNA levels, LSM $>$7 kPa identifies those at increased risk of HCC. LSM can therefore be used to select patients who could benefit from antiviral therapy and who are in need of HCC surveillance.

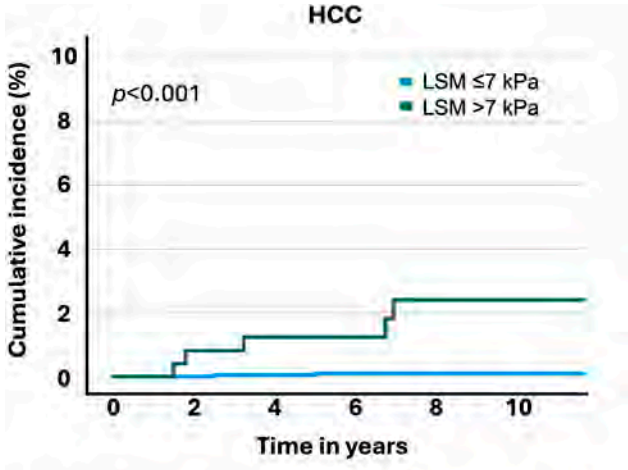

Figure 1. Cumulative incidence of HCC stratified for baseline liver stiffness measurement (LSM) ≤7 kPa and >7 kPa.

0062 | HRS-4729, A NOVEL GLP-1/GIP/GLUCAGON TRIPLE-RECEPTOR AGONIST, REDUCES LIVER FAT IN PARTICIPANTS LIVING WITH METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE (MASLD) AND OBESITY: A RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED PHASE 1B STUDY

Qing Wen[1] Kun He[1] Cuigang Li[1] Lei Diao[2] Hong Chen[2] Lin Wang[2] Mengshan Ni[2] Pingan Yao[2] Hui Liu[2] Hui Dong[2], [1]Central Hospital Affiliated to Shandong First Medical University, [2]Jiangsu Hengrui Pharmaceuticals

Background: HRS-4729, a novel long-acting triple agonist of GLP-1, GIP, and glucagon receptors, has shown therapeutic potential in animal models of MASLD and obesity. Here, we present data on liver fat, weight, lipid profiles, and safety of HRS-4729 in participants living with MASLD and obesity, from a randomized, double-blind, placebo-controlled, multiple ascending dose study. **Methods:** Adults aged 18–55 years with a BMI of 28–40 kg/m2 were randomized (5:1 per dose cohort) to receive weekly SC HRS-4729 (1 mg fixed; 4, 8, or 12 mg titration) or placebo for 12 weeks. The MASLD subgroup included participants with a liver fat content of $\geq$5%, measured by MRI-PDFF. Efficacy outcomes included percentage change from baseline (CFB) in liver fat; proportion of participants achieving liver fat reduction targets;

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

percentage CFB in body weight, waist circumference, and lipid profiles at week 12. **Results:** Of the 48 randomized participants, 34 had MASLD (30 treated with HRS-4729, and 4 with placebo). Of those with MASLD, 58.8% participants were male; the mean weight was 87.75 kg (SD, 8.02); and the mean liver fat content was 13.4% (SD, 8.8%). The mean percentage CFB in liver fat was -63.9% with HRS-4729 (1, 4, 8, and 12 mg cohorts: -41.0%, -67.2%, -81.0%, and -55.4%, respectively), compared with -41.0% with placebo. A higher proportion of HRS-4729–treated participants achieved ≥30%, ≥50%, and ≥70% reductions in liver fat (83.3%, 70.0%, and 46.7%, respectively) versus placebo (50.0%, 50.0%, and 25.0%). Liver fat <5% was achieved by 83.3% of participants treated with HRS-4729, compared with 25.0% with placebo. Of those with baseline liver fat ≥8% (n=17) and ≥10% (n=12), a greater degree of liver fat reduction following HRS-4729 was observed, with a maximum reduction of 89.8% (Table); and 100% of participants in 8 and 12 mg cohorts achieved liver fat <5%. Among all MASLD participants, mean percentage CFB in body weight was greater with HRS-4729 compared with placebo (-13.6% vs. -4.8%), and a dose-dependent trend was observed with HRS-4729 (Table). The mean percentage CFB in waist circumference was also larger with HRS-4729 (-11.1% vs. -6.4%). Reductions in lipids (such as LDL-C, triglycerides, and cholesterol) generally favored HRS-4729. Treatment-emergent adverse events (TEAEs) following HRS-4729 were mostly mild gastrointestinal events, consistent with incretin-based therapies. No severe or serious TEAEs occurred, and no TEAEs led to treatment discontinuation. **Conclusion:** HRS-4729 reduced liver fat, body weight, and waist circumference in participants with liver fat ≥5%, and was safe and well tolerated, supporting further development of HRS-4729 for MASLD.

Table. Effects of HRS-4729 on liver fat, body weight, and waist circumference in participants with baseline liver fat ≥5%, ≥8%, and ≥10%.

0063 | PEMVIDUTIDE TREATMENT RESULTS IN CONCURRENT REDUCTIONS IN MULTIPLE NON-INVASIVE TESTS FOR HEPATIC INFLAMMATION AND FIBROSIS: 48-WEEK RESPONDER ANALYSES OF THE IMPACT PHASE 2B TRIAL IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS

Naim Alkhouri[1] Mazen Noureddin[2] Shaheen Tomah[3] John Suschak[4] Scot Roberts[5] Rachel Garner[5] Christophe Arbet-Engels[5], [1]Summit Clinical Research, [2]Houston Methodist Hospital, [3]Altimmune, [4]Altimmune, Inc, [5]Altimmune, Inc.

Background: Pemvidutide is a balanced 1:1 glucagon/GLP-1 dual receptor agonist in development for the treatment of metabolic dysfunction-associated steatohepatitis (MASH). IMPACT was a phase 2b, randomized, placebo-controlled, double-blind trial in patients with biopsy-confirmed MASH and fibrosis stage F2 or F3 (NCT05989711). Histologically, pemvidutide treatment yielded statistically significant MASH resolution and high rates of fibrosis improvement within 24 weeks. Pemvidutide also resulted in statistically significant reductions in individual non-invasive tests (NITs) of hepatic inflammation and fibrosis that continued to improve over time. A reduction of ≥30% in liver fat content (LFC) is associated with improvements in MASH and a reduction of ≥17 IU/L in alanine aminotransferase (ALT) is predictive of histologic response. Similarly, reductions of ≥0.5 in enhanced liver fibrosis (ELF) score or ≥30% in liver stiffness measurement (LSM) are associated with fibrosis regression. While individual NITs may be indicators of therapeutic effect, composite analyses using multiple overlapping NITs may provide a more rigorous assessment of therapeutic improvement as they increase diagnostic accuracy and stringency. Here we present 48-week responder analyses of composite NITs from the IMPACT trial. **Methods:** 212 patients were randomized 1:2:2 to receive once-weekly subcutaneous pemvidutide (1.2 mg or 1.8 mg) administered without dose titration, or placebo. Secondary endpoints included the NITs for LFC, ELF score, LSM, and ALT. **Results:** The mean age was 53 yrs, the mean BMI was 39 kg/m^2, 58% were female, and 43% had type 2 diabetes. With respect to MASH improvement, a greater percentage of patients receiving either dose of pemvidutide achieved concurrent responses in LFC (≥30% reduction), ALT (≥17 U/L reduction), and LSM (≥30% reduction) compared to placebo [1.2 mg

(34.3%; p = 0.0001); 1.8 mg (42.9%; p < 0.0001); placebo (3.3%)]. Similarly, a greater percentage of patients receiving either dose of pemvidutide achieved concurrent responses in two markers of fibrosis improvement, ELF score (≥ 0.5 reduction) and LSM (≥ 30% reduction) compared to placebo [1.2 mg (27.8%; p = 0.0003); 1.8 mg (32.4%; p < 0.0001); placebo (3.2%)]. In a more stringent analysis of concurrent responses in LFC (≥ 50% reduction), ELF score (≥ 0.5 reduction), and LSM (≥ 30% reduction), pemvidutide also resulted in a higher percentage of patients achieving a response compared to placebo [1.2 mg (17.1%; p = 0.0018); 1.8 mg (25.8%; p < 0.0001); placebo (0.0%)]. **Conclusion:** Pemvidutide treatment led to statistically significant increases in the percentage of patients achieving concurrent responses in multiple NITs of MASH improvement and hepatic fibrosis at 48 weeks.

0064 | LIVER-DIRECTED RNA INTERFERENCE TARGETING CELL DEATH-INDUCING DFFA-LIKE EFFECTOR B (*CIDEB*) NORMALIZES LIVER FAT AND LOWERS SERUM TRANSAMINASE LEVELS IN METABOLIC DYSFUNCTION-ASSOCIATED LIVER DISEASE (MASLD)

Jorg Taubel[1] Gavin Imperato[2] Sonya Aziz-Zaman[2] Jane Witkin[2] Jutta Miller[2] Terri Swanson[2] Xiping Cheng[2] Jessica D'Antonio[2] Shehla Habib[2] David Workman[2] Justin Cho[2] Yogesh Patel[2] Vidya Xavier[2] Kusha Mohammadi[2] Shunguang Wang[2] Chao Chen[2] Sean Smith[2] Susana Pereira[2] Donato Forlenza[2] Joette Pindar[2] Meredith Crosby[2] Shawn Fidotta[2] Mauricio Leal[2] Viktoria Gusarova[2] Mark Sleeman[2] Niek Verweji[2] Luca Lotta[2] Aris Baras[2] Gary Herman[2] David Lederer[2], [1]Richmond Pharmacology, [2]Regeneron Pharmaceuticals, Inc

Background: The Regeneron Genetics Center discovered that loss-of-function variants in *CIDEB*, which encodes a structural protein of hepatic lipid droplets, are associated with a profound reduction in the risk of steatotic liver disease and cirrhosis. Nonclinical models corroborate these findings, with *CIDEB* knockdown reducing hepatic steatosis, inflammation, and fibrosis in murine metabolic dysfunction-associated steatohepatitis (MASH). We hypothesized that therapeutic suppression of hepatic *CIDEB* expression would reduce liver fat and improve markers of liver disease in people with MASLD. **Methods:** In the phase 1 portion of an ongoing randomized, double-blind, placebo-controlled, phase 1/2a trial (NCT06836609), adults with MASLD and baseline liver fat content $\geq$8.5% by magnetic resonance imaging-proton density fat fraction (MRI-PDFF) were randomized (3:1) to receive single ascending doses of ALN-CIDEB—a subcutaneously administered, liver-targeted small interfering RNA (siRNA) designed to reduce hepatic *CIDEB* messenger RNA expression—or placebo. The primary endpoint was incidence and severity of treatment-emergent adverse events (TEAEs). Key pharmacodynamic endpoints included change from baseline in liver fat content by MRI-PDFF and serum transaminase levels. **Results:** Interim data from 47 participants are reported. ALN-CIDEB was well tolerated at all dose levels. All TEAEs were mild or moderate in severity except for one serious TEAE of hyperglycemia that was graded severe but not attributed to the study drug by the investigator. Across all dose levels, ALN-CIDEB resulted in rapid, profound, and durable reductions in liver fat vs placebo. At Week 12, mean reductions from baseline reached approximately 70% (Figure), with mean liver fat content near or below the upper limit of normal (5%) for all dose levels. Treatment effects were sustained through 24 weeks of follow-up. At Week 12, mean serum alanine aminotransferase levels declined from baseline by 18–35% across ALN-CIDEB dose levels, consistent with attenuation of hepatocellular injury. **Conclusion:** In this first-in-human trial of a first-in-class liver-specific siRNA targeting *CIDEB*, a single dose of ALN-CIDEB was well tolerated and rapidly and sustainably normalized liver fat, accompanied by improvements in serum transaminases. Concordant with human genetics data and nonclinical MASH models, these findings support the continued clinical development of hepatic *CIDEB* knockdown as a therapeutic strategy for MASH.

Figure. Mean percent change (+/−SE) from baseline in liver fat by MRI-PDFF over time in participants with MASLD after a single dose of ALN-CIDEB or placebo

Number of participants

Placebo	10	10	10	10	5
Dose level 1	6	6	5	5	5
Dose level 2	9	9	9	8	8
Dose level 3	9	9	9	8	
Dose level 4	6	5	6	6	

MASLD, metabolic dysfunction-associated liver disease; MRI-PDFF, magnetic resonance imaging-proton density fat fraction; SE, standard error.

0065 | STAGE-STRATIFIED COMPARATIVE EFFECTIVENESS OF TIRZEPATIDE VERSUS SGLT2 INHIBITORS IN TYPE 2 DIABETES (T2DM) ON MAJOR ADVERSE LIVER OUTCOMES (MALO) AND MAJOR ADVERSE CARDIOVASCULAR EVENTS (MACE) WITH MASLD/MASH

Mohammad Alabbas[1] Akram Alnounou[2] Ahmad Alhusen[3] Mohammad Alali[4] Omar Sims[1] Richard Sterling[5], [1]Cleveland Clinic Foundation, [2]Department of Internal Medicine, Western Michigan University Homer Stryker M.D. School of Medicine,, [3]Department of Internal Medicine, Advocate Illinois Masonic Medical Center, Chicago, IL, USA, [4]Henry Ford Macomb Hospital, [5]Virginia Commonwealth University

Background: Tirzepatide and SGLT2 inhibitors (SGLT2i) are increasingly used in T2DM with MASLD/MASH, but comparative outcomes across liver-disease stage remain uncertain. We compared 1- and 3-year hepatic, cardiovascular, hospitalization, kidney, and mortality outcomes after tirzepatide versus SGLT2i initiation in noncirrhotic MASLD/MASH and MASLD/MASH-related compensated cirrhosis. **Methods:** TriNetX Research Network data from 110 health care organizations were used to identify adults with T2DM and MASLD/MASH initiating tirzepatide or SGLT2i on/after June 1, 2022. Mutually exclusive cohorts were noncirrhotic disease and compensated cirrhosis, defined by cirrhosis codes without prior ascites, variceal bleeding, encephalopathy, jaundice/hepatic failure, hepatorenal syndrome, spontaneous bacterial peritonitis, or malignant ascites. Exclusions included prior comparator exposure, competing liver disease, malignancy, transplant, ESRD/dialysis, HIV, and baseline decompensation; baseline cirrhosis was excluded from the noncirrhotic cohort. Groups were 1:1 propensity-score matched on demographics, comorbidities, medications, and labs. Primary outcome was MALO (decompensation-related events, HCC, transplant, or death); secondary outcomes included hospitalization, first decompensation, ascites-related complications, MACE, mortality, AKI, and incident cirrhosis. **Results:** In noncirrhotic MASLD/MASH, 12,260 pairs were matched at 1 year and 18,291 at 3 years. Tirzepatide was associated with lower 1-year MALO (0.8% vs 1.4%; RR 0.57; $P < 0.001$), hospitalization (13.3% vs 15.2%; RR 0.88; $P < 0.001$), MACE (7.6% vs 12.4%; RR 0.61; $P < 0.001$), mortality (0.3% vs 0.6%; RR 0.43; $P < 0.001$), and AKI (1.8% vs 2.2%; RR 0.82; $P = 0.037$). At 3 years, lower MALO (1.6% vs 2.3%; RR 0.67; $P < 0.001$), MACE (9.9% vs 15.3%; RR 0.64; $P < 0.001$), mortality (0.6% vs 1.2%; RR 0.50; $P < 0.001$), AKI (3.1% vs 3.9%; RR 0.78; $P < 0.001$), and incident cirrhosis (1.2% vs 1.5%; RR 0.79; $P = 0.011$) persisted, without increased ascites. In compensated cirrhosis (816 pairs), tirzepatide was associated with lower 1-year hospitalization (18.4% vs 22.3%; RR 0.82; $P = 0.049$) and MACE (11.9% vs 20.0%; RR 0.60; $P < 0.001$). At 3 years, tirzepatide was associated with lower MALO (8.3% vs 11.5%; RR 0.72; $P = 0.031$) and MACE (15.0% vs 23.4%; RR 0.64; $P < 0.001$), with no excess AKI or ascites-related outcomes. **Conclusion:** In this large stage-stratified active-comparator study of T2DM with MASLD/MASH, tirzepatide initiation was associated with lower hepatic and cardiometabolic events in noncirrhotic disease and lower MACE plus 3-year MALO in compensated cirrhosis, without ascites-related harm. Prospective studies should confirm integrated liver and cardiometabolic risk reduction across MASLD/MASH severity.

0066 | EFRUXIFERMIN DRIVES MULTIDIMENSIONAL HISTOLOGIC IMPROVEMENT IN COMPENSATED CIRRHOSIS: AN AI-BASED ANALYSIS FROM THE SYMMETRY RANDOMIZED CONTROLLED TRIAL

Mazen Noureddin[1] Jörn Schattenberg[2] Vlad Ratziu[3] Ylaine Gerardin[4] Alyson Warr[4] Jacqueline Brosnan-Cashman[4] Doreen Chan[5] Erik Tillman[5] Reshma Shringarpure[5] Mary Rinella[6], [1]Houston Methodist Hospital, [2]Saarland University Medical Center, Saarland University, Homburg, Germany, [3]Service D' Hepatogastroenterologie (FR), [4]PathAI, [5]Akero Therapeutics, a Novo Nordisk Company, [6]The University of Chicago

Background: In the Phase 2b SYMMETRY trial (NCT05039450) in participants with compensated cirrhosis (F4c) due to MASH, efruxifermin (EFX) significantly improved fibrosis by conventional pathology at 96 weeks. To further explore EFX- and time-dependent changes in liver histopathology in F4c MASH beyond categorical, semi-quantitative CRN scores, we conducted a retrospective analysis of SYMMETRY utilizing two AI-powered tools, LiverExplore* and AIM-MASH+*. **Methods:** The analysis comprised N = 154 SYMMETRY participants with available baseline, week 36 (w36) and week 96 (w96) liver biopsies from the placebo (Pbo), 28 mg EFX (EFX28), or 50 mg EFX (EFX50) study arms. Paired H&E- and trichrome-stained slides were analyzed with AIM-MASH+, which provides sub-ordinal, continuous NAS (cNAS) and fibrosis (cFib) scores. H&E slides were also analyzed with LiverExplore to quantify liver histology features, such as fibrosis and cell type proportions. For each EFX arm and timepoint, changes in cNAS and cFib scores and feature fold-changes were compared to Pbo using ANCOVA. **Results:** AIM-MASH+ revealed EFX effects on continuous NAS and fibrosis scores (Fig. 1A). At w36, cNAS decreased by 1.7 points from baseline in EFX28 and 1.6 in EFX50 compared to -0.3 in Pbo ($p < 0.001$). Early (w36) trends towards improvement in cFib (-0.2 in EFX28 and -0.1 in EFX50, vs 0.01 in Pbo) expanded at w96 to significant reductions of 0.4 in both EFX28 and EFX50, compared to 0.1 in Pbo ($p = 0.01$ and $p = 0.002$, respectively). The expansion of antifibrotic effects was further corroborated by LiverExplore: reductions in total fibrosis and component patterns increased in magnitude from w36 to w96 for EFX28 and EFX50 (Fig. 1B). Notably, at w96, advanced (complete septal and nodular) fibrosis decreased from baseline by 42% in EFX28 and 48% in EFX50, compared to -16% in Pbo ($p = 0.02$ and $p = 0.003$, respectively). Steatotic and ballooned hepatocytes were also significantly decreased across EFX doses at both timepoints, accompanied by increased normal hepatocytes. **Conclusion:** AI-powered histology analyses of SYMMETRY revealed significant reductions in subordinal, continuous histopathologic scores, as well as decreased prevalence of specific fibrosis subtypes. Combined with reduced steatotic and ballooned hepatocytes and increased normal hepatocytes, these results support the improvements in histology and non-invasive metrics of fibrosis and liver injury observed with EFX treatment in F4c MASH. *For Research Use Only. Not for use in diagnostic procedures.

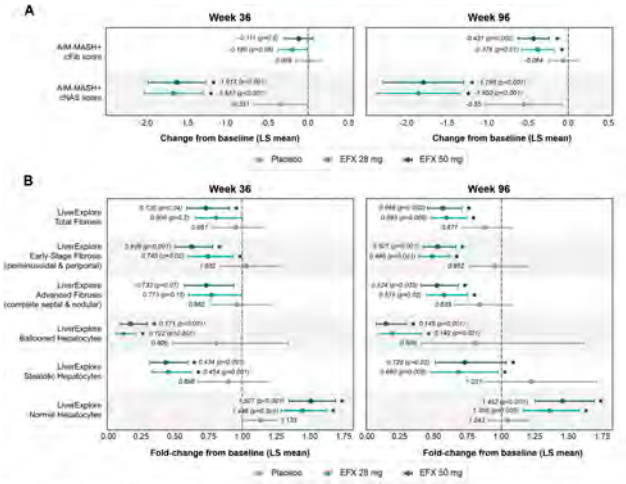

Figure 1. ANCOVA results for AIM-MASH+ continuous scores (A) and LiverExplore features (B). Point estimates and 95% confidence intervals are shown. In (B), fibrosis features represent the fraction of total evaluable tissue area belonging to each fibrosis class, and hepatocyte features represent the proportion of total cells belonging to each cell class. All p-values are for nominal difference between treatment arm and placebo; stars indicate $p<0.05$. EFX: efruxifermin; LS: least squares; cFib: continuous fibrosis score; cNAS: continuous NAS score.

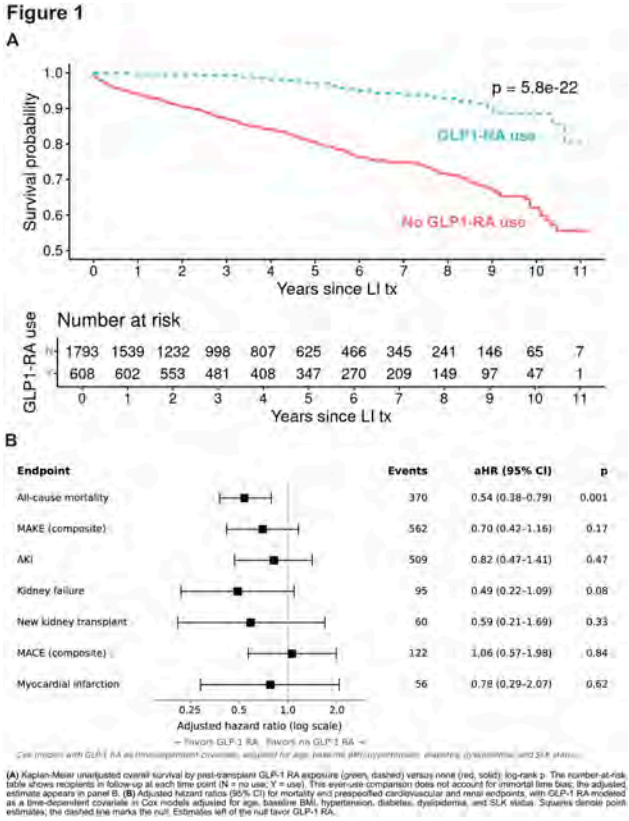
★ 0067 | GLP-1 RECEPTOR AGONIST USE AFTER LIVER TRANSPLANTATION IN MASH OR METABOLIC-RISK RECIPIENTS IS ASSOCIATED WITH IMPROVED SURVIVAL AND RENAL PROTECTION: A THREE-CENTER COHORT STUDY

Zhihao Li[1] Kai-Philipp Seeger[1] Jie Na[1] Randi Ryan[1] Alexander Cortez[1] Tayyab Diwan[1] Timucin Taner[2] Kymberly Watt[1] Amit Mathur[3] Blanca Lizaola-Mayo[1] David Chascsa[3] Dana Perry[4] Liu Yang[1] Julie Heimbach[2], [1]Mayo Clinic, [2]Mayo Clinic Rochester, [3]Mayo Clinic Arizona, [4]Mayo Clinic Florida



Background: Metabolic dysfunction-associated steatohepatitis (MASH) is now a leading indication for liver

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

transplantation in the United States, and recipients with MASH or cardiometabolic comorbidities remain at substantial risk for cardiovascular events and chronic kidney disease driven by persistent cardiometabolic dysfunction and calcineurin inhibitor exposure. GLP-1 receptor agonists (RA) improve glycemic control, weight, and cardiorenal outcomes in non-transplant populations. However, whether posttransplant GLP-1 RA use confers survival or renal benefit in this transplant population remains undefined. **Methods:** We conducted a retrospective cohort study of adult liver transplant recipients across three Mayo Clinic sites (2015–2025) with MASH or cirrhosis with diabetes or BMI > 30. Simultaneous liver-kidney (SLK) recipients were retained; peri-operative deaths were excluded. GLP-1 RA exposure was modeled as a time-dependent covariate, with separate terms for pre- and post-transplant initiation to address immortal time bias. The primary endpoint was overall survival; secondary endpoints were major adverse kidney events (MAKE; ≥ 40% eGFR decline, CKD G5, dialysis, or kidney transplant) and major adverse cardiovascular events (MACE; myocardial infarction or stroke). Multivariable Cox models adjusted for age, baseline BMI, hypertension, diabetes, dyslipidemia, and SLK status. Longitudinal lipid and HbA1c trajectories were modeled with linear mixed-effects regression on log-transformed values, separating effects of treatment initiation from cumulative exposure. **Results:** Among 2,401 MASH or metabolic-risk liver transplant recipients (median age 61, 66% male, MELD 20), 608 (25%) initiated GLP-1 RA post-transplant at a median 2.5 years after transplantation; baseline BMI was higher in initiators (32.9 vs 31.7, p < 0.001). Over a median follow-up of 4.0 years, 370 deaths, 562 MAKE, and 122 MACE events occurred. Kaplan-Meier analysis demonstrated superior unadjusted survival among GLP-1 RA users (log-rank p < 0.001, Fig.1A). In time-dependent Cox models, post-transplant GLP-1 RA exposure was associated with a 46% reduction in all-cause mortality (aHR 0.54, 95% CI 0.38–0.79, p = 0.001). A trend toward protection was observed for kidney failure (aHR 0.49, 95% CI 0.22–1.09, p = 0.08) and overall MAKE (aHR 0.70, 95% CI 0.42–1.16, p = 0.17), while no association was seen with MACE (aHR 1.06, 95% CI 0.57–1.98, p = 0.84) or AKI (aHR 0.82, p = 0.47, Fig.1B). LDL was 8% lower on treatment (p < 0.001), and HbA1c showed progressive improvement with longer exposure (interaction p = 0.008). **Conclusion:** In MASH or metabolic-risk liver transplant recipients, post-transplant GLP-1 RA use was associated with substantially improved survival, a trend toward renal protection, and favorable lipid and glycemic trajectories. Validation of these results with external health system data will be a valuable next step.

Figure 1

(A) Kaplan-Meier unadjusted overall survival by post-transplant GLP-1 RA exposure (green, dashed) versus none (red, solid); log-rank p. The number-at-risk table shows recipients in follow-up at each time point (N = no use; Y = use). This ever-use comparison does not account for immortal time bias; the adjusted estimate appears in panel B. (B) Adjusted hazard ratios (95% CI) for mortality and prespecified cardiovascular and renal endpoints, with GLP-1 RA modeled as a time-dependent covariate in Cox models adjusted for age, baseline BMI, hypertension, diabetes, dyslipidemia, and SLK status. Squares denote point estimates; the dashed line marks the null. Estimates left of the null favor GLP-1 RA.

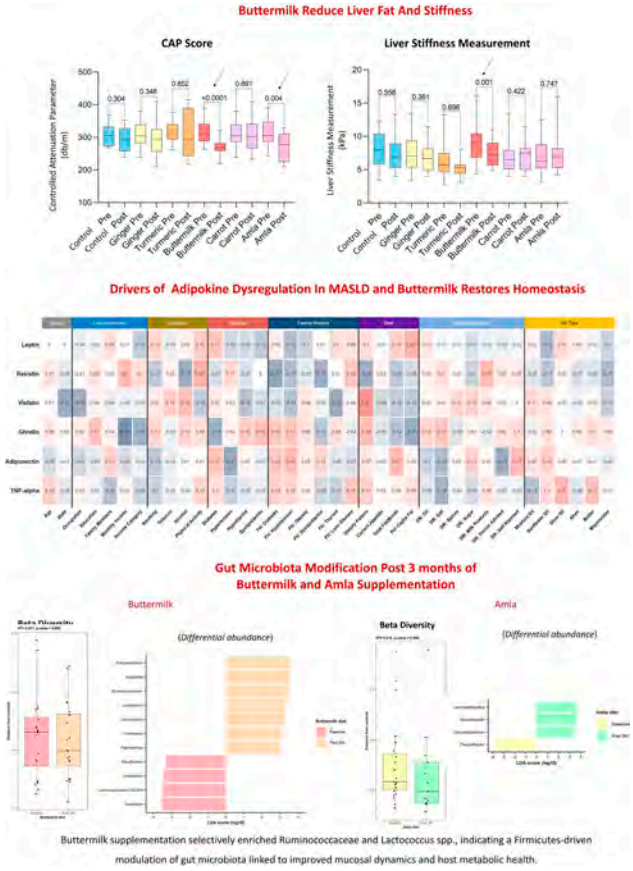
0068 | BUTTERMILK SUPPLEMENTATION AMELIORATES HEPATIC STEATOSIS IN METABOLIC DYSFUNCTION ASSOCIATED STEATOTIC LIVER DISEASE



Vibhuti Jakhmola[1] Sukriti Baweja[2] Aduonuo Ziephru[1] Ashmit Mittal[2] Shiv Kumar Sarin[2], [1]Institute of Liver and Biliary Sciences, [2]Institute of Liver and Biliary Sciences, New Delhi, India

Background: MASLD is a rapidly progressive metabolic disorder with limited effective therapeutics. Known

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

to be driven by hepatic steatosis, adipokine dysregulation, and gut-liver axis dysfunction. Although dietary modification is central to MASLD management, the therapeutic potential of specific food items remains unclear. We evaluated the potential of specific functional foods in management of MASLD. **Methods:** Patients with clinically confirmed MASLD n = 216 {CAP > 250; LSM < 10}; were enrolled and randomized into five dietary supplementation groups (n = 32 each group); buttermilk, amla, turmeric, carrot and ginger. Twentyone placebo served as controls. All subjects underwent pre- and post-intervention laboratory tests, serum adipokine measurements, anthropometry and Fibroscan for estimation of hepatic fat by controlled attenuation parameter (CAP) and liver fibrosis by liver stiffness measurement (LSM). They were advised exercise and lifestyle alterations. Gut microbiome profiling via 16S rRNA sequencing was performed. **Results:** At baseline, MASLD patients exhibited significantly impaired hepatic, metabolic, and anthropometric parameters($p < 0.0001$) compared to controls. Among the dietary interventions after 3 months, buttermilk supplementation produced the most comprehensive therapeutic effects, improving CAP score($p = 0.0004$), transaminases($p < 0.05$), triglycerides and cholesterol ($p < 0.05$). Buttermilk was the only intervention to suppress leptin, resistin, visfatin(all $p < 0.001$), and TNF-α ($p = 0.0002$), while significantly increasing adiponectin($p < 0.0001$) and ghrelin($p = 0.0002$), reflecting broad adipokine axis restoration. Amla supplementation also showed significant reduction in CAP ($p = 0.0001$), and liver enzymes ($p < 0.05$), with increase in ghrelin levels ($p = 0.037$). Ginger and carrot interventions produced selective reductions in leptin and visfatin ($p < 0.05$), whereas turmeric lowered serum triglyceride levels ($p = 0.035$). Post buttermilk and amla microbiome profiling revealed significant inter-group beta diversity divergence($p = 0.001$). Buttermilk selectively enriched short-chain fatty acid–producing taxa, including Ruminococcaceae and Lactococcus spp., while depleting dysbiosis-associated genera such as Clostridium and Desulfovibrio ($p < 0.001$). PICRUSt functional annotation revealed enrichment of N-glycan biosynthesis pathways. Similarly, amla enriched Lacticaseibacillus and reduced Flavonifractor abundance than controls. **Conclusion:** This is the first study to reveal the functional benefits of natural food products in MASLD. Our data provides a catalogue from which specific food items singularly or in combination can be used in MASLD patients. Buttermilk supplementation, enriched in probiotics, acts through N-glycan biosynthesis mediated gut microbial restoration, positioning it as a promising dietary intervention for MASLD management.

0069 | STRUCTURED LIFESTYLE INTERVENTION BASED ON COGNITIVE-BEHAVIORAL THERAPY PRINCIPLES REDUCES HEPATIC STEATOSIS AND IMPROVES METABOLIC PARAMETERS IN PATIENTS WITH MASLD: PRELIMINARY RESULTS OF A RANDOMIZED CONTROLLED STUDY

Vaclav Smid[1] Jakub Klevar[1] Frantisek Novak[1] Marie Rysankova[1] Lukas Lambert[1] Iva Malkova[2] Libor Vitek[3] Radan Bruha[4], [1]General University Hospital and First Faculty of Medicine, [2]STOB Prague, [3]General University Hospital in Prague, [4]Charles University in Prague, 1st Faculty of Medicine

Background: Although new pharmacological therapies for MASLD are becoming available, lifestyle modification remains a necessary component of treatment and a prerequisite for optimal therapeutic outcomes. Therefore, it is essential to identify effective and sustainable ways to implement these changes in clinical practice. We hypothesize that individualized counselling focused on lifestyle modification, based on cognitive-behavioral therapy (CBT) principles and expert nutritional intervention, will reduce hepatic steatosis and improve non-invasive markers of liver disease in patients with metabolic syndrome and MASLD. **Methods:** During the 12-month study, patients were randomized to either a standard-of-care group or an intensive lifestyle intervention group. Fifty patients were enrolled in a specialized program based on CBT principles, including mindfulness-based approaches. Under expert supervision, participants were encouraged to modify their dietary and physical activity habits, both of which were assessed before and after the intervention. The control group consisted of fifty patients receiving standard hepatological care, including regular outpatient follow-up and standard recommendations regarding weight loss and lifestyle modification. During the one-year follow-up, all patients underwent repeated assessments including anthropometric measurements, bioimpedance analysis, biochemical testing, transient elastography for liver stiffness measurement, and nuclear magnetic resonance spectroscopy. The study is registered at ClinicalTrials.gov (NCT05816915). **Results:** In patients who have already completed the 12-month intervention (n = 37), a statistically significant reduction in hepatic fat content was observed in the intervention group compared with the control group (6.1% vs. 1.4%, $p < 0.05$). The reduction in hepatic fat was accompanied by a significant decrease in the FAST score, reaching values below the 0.35 cutoff. Significant improvements were also observed in liver enzyme levels (ALT decreased from 45.2 ± 16 to 35.2 ± 10 U/L, $p < 0.05$) and glucose metabolism parameters (glucose decreased from 6.52 ± 1.8 to 5.29 ± 0.45 mmol/L, $p < 0.05$; insulin decreased from 21.54 ± 6.3 to 14.74 ± 4.5 mIU/L, $p < 0.01$). In contrast, no significant changes in ALT, glucose metabolism parameters, hepatic fat content, or FAST score were observed in the control group (n = 28). **Conclusion:** Our preliminary results suggest that an intensive lifestyle intervention based on CBT principles and nutritional counselling may significantly improve hepatic steatosis, liver enzyme levels, and glucose metabolism in patients with MASLD and metabolic syndrome. These findings further support structured lifestyle modification as a key component of MASLD management. Supported by: MH CZ – DRO – VFN00064165 and by AZV MHCZ NU23-01-00288.

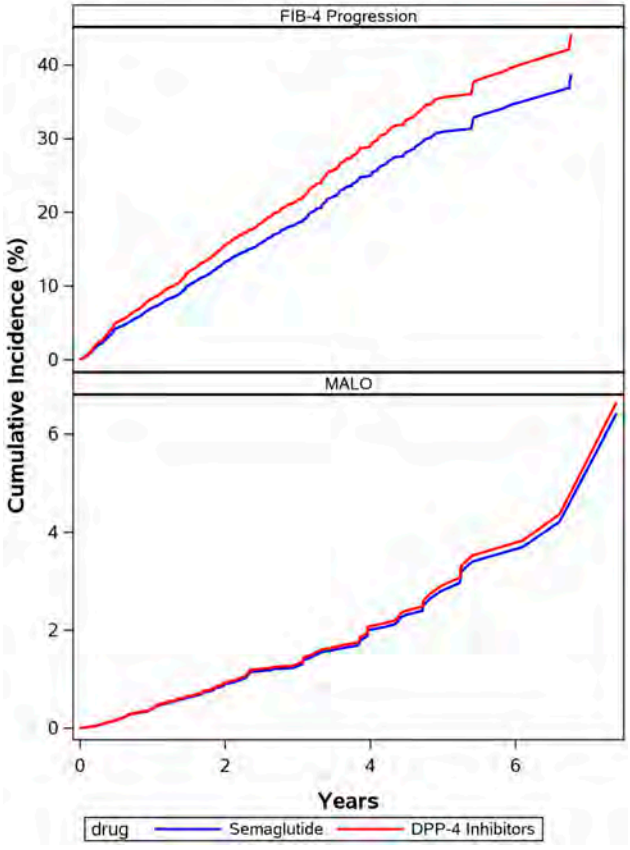
0070 | SEMAGLUTIDE AND FIBROSIS PROGRESSION IN MASLD: A TARGET TRIAL EMULATION COMPARING SEMAGLUTIDE VERSUS DPP-4 INHIBITORS IN A NATIONAL COHORT



Binu John[1] Samuel Soon[2] Bassam Dahman[2], [1]University of Miami and Miami VA, [2]Virginia Commonwealth University

Background: Semaglutide is approved for the treatment of metabolic dysfunction-associated steatohepatitis (MASH) with stage 2-3 fibrosis; However, its effect on liver fibrosis progression across the broader spectrum of metabolic dysfunction-associated steatotic liver disease (MASLD) without established advanced fibrosis remains poorly defined. remains unclear. We aimed to examine the association between semaglutide and the risk of fibrosis progression and major adverse liver outcomes (MALO) relative to DPP-4 inhibitors (DPP4i) in a large national Veterans cohort. **Methods:** This was an active comparator, new-user target trial emulation study of adults from Veteran's Health Administration comparing new users of Semaglutide and DPP4i in patients with MASLD between 9/5/17 and 10/14/25. Adults with MASLD, identified by steatosis on imaging via validated natural language processing combined with at least one cardiometabolic risk factor and absence of harmful alcohol use, who initiated semaglutide or a DPP4i with baseline FIB-4 < 2.67 were eligible. Groups were balanced on baseline characteristics using inverse probability of treatment weighting (IPTW). The primary outcome was fibrosis progression, defined as transition from low or intermediate (FIB-4 < 2.67) to high fibrosis risk (FIB-4 > 2.67), confirmed on two separate measurements obtained 3-12 months apart. The secondary outcome was MALO, defined as the composite of hepatocellular carcinoma, decompensation, liver transplantation, or liver-related death. Progression-free survival was modeled using multivariable Fine and Gray competing risk incorporating IPTW adjustment. Patients were followed from treatment initiation until discontinuation, treatment switching, death, or loss to follow-up; FIB-4 progression analyses were additionally censored at the last available measurement. **Results:** A total of 14,182 semaglutide and 7,678 DPP4i initiators were identified (median age 64.2 years [IQR 17.2]; 86.1%

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

male). Median treatment duration was 1.2 years (IQR 1.4) for semaglutide versus 1.1 years (IQR 1.6) for DPP4i. Fibrosis progression occurred in 1,715 participants (7.0%) and MALO in 228 (1.0%). Semaglutide was associated with a significantly reduced hazard of FIB-4 progression compared to DPP4i (aHR 0.84 [95% CI 0.78–0.90]; $p < 0.0001$). No statistically significant differences in MALO was observed. **Conclusion:** In this large national target trial emulation, semaglutide was associated with a 16% reduction in fibrosis progression risk compared to DPP4i among MASLD patients without advanced fibrosis at baseline. The absence of a significant MALO difference likely reflects insufficient follow-up duration and low event rates rather than a true null effect. Longer-term real-world studies are needed to determine whether semaglutide-mediated fibrosis attenuation translates into reduced liver-related morbidity and mortality in MASLD.

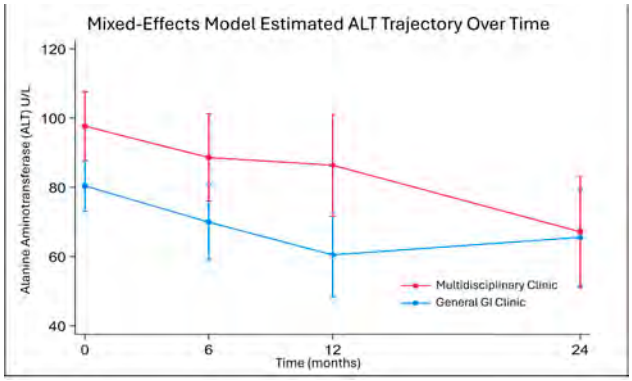
★ 0071 | IMPACT OF MULTIDISCIPLINARY CARE ON LONGITUDINAL ALT OUTCOMES IN CHILDREN WITH MASLD



Brandon Perumpail[1] Sarah Abu-Alreesh[2] Andrea Tou[3] Jennifer Panganiban[4], [1]Children's Hospital of Philadelphia, [2]Al Jalila Children's Hospital, [3]Children's Hospital of Philadelphia, [4]The Children's Hospital of Philadelphia

Background: Lifestyle intervention remains the cornerstone of pediatric metabolic dysfunction-associated steatotic liver disease (MASLD) therapy. In children receiving standard of care (SOC) lifestyle advice only 22% of patients at 1 year and 31% after 2 years had improved. Multidisciplinary care models for MASLD have been strongly endorsed by expert opinion and guidelines, yet there are no pediatric studies directly comparing multidisciplinary care to SOC and long-term outcomes remain unclear. **Methods:** Retrospective longitudinal cohort study of children in a tertiary care center, aged 3-20 years with serial alanine aminotransferase (ALT) measurements who were managed in either a multidisciplinary (MM) clinic lead by a gastroenterologist, dietician, and activity specialist with obesity expertise versus a general gastroenterology (GG) clinic from 2016-2026. Baseline and longitudinal ALT trends were evaluated including usage of mixed-effects models adjusting for age, sex, and race/ethnicity at 6, 9, 12, and 24 months after first visit. **Results:** A total of 209 patients were included in the MM cohort (mean age 13.2 years; 73% male; 38% Hispanic) and 378 in the GG cohort (mean age 12.2 years; 61% male; 22% Hispanic). Baseline ALT was significantly higher in the MM cohort compared with the GG cohort (101.6 vs 78.5 U/L, $p = 0.003$), and a greater proportion of MM patients had ALT > 80 U/L (47.9% vs 31.7%, $p < 0.001$). In mixed-effects models adjusting for demographic variables, ALT improvement over time was similar between cohorts, although there was a trend toward greater ALT reduction in the MM cohort at 24 months ($p = 0.15$). Adjusted mean ALT change from baseline at 24 months in the MM cohort was −30.5 U/L ($p < 0.01$) vs −12.9 U/L ($p < 0.01$) in the GG cohort; however, between-group differences were not statistically significant. In a restricted adjusted analysis of the 12- to 24-month interval, the MM cohort demonstrated a 22.3% greater ALT reduction compared with the GG cohort ($p = 0.028$), whereas ALT improvement in the GG cohort plateaued during this period.In secondary unadjusted exploratory analyses at 24 months, ALT change from baseline was -41.4 U/L ($p < 0.01$) in MM vs

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

-16.5 U/L ($p < 0.01$) in GG. In both cohorts 50% achieved an ALT reduction of ≥ 17 U/L and 45% achieved a ≥ 40% reduction in ALT at 24 months (inter-group $p > 0.05$). **Conclusion:** This is the first real-world study comparing a dedicated multidisciplinary clinic to standalone general GI care in the management of pediatric MASLD. Both models improve ALT outcomes compared to baseline over 24 months. Despite higher baseline ALT levels, patients in the MM clinic demonstrated ALT reduction comparable to those in a GG clinic, with continued improvement beyond 12 months, while ALT trajectories plateaued in the GG cohort. These findings suggest multidisciplinary care models as a strategy to promote sustained biochemical improvement in the management of pediatric MASLD and warrant prospective evaluation.

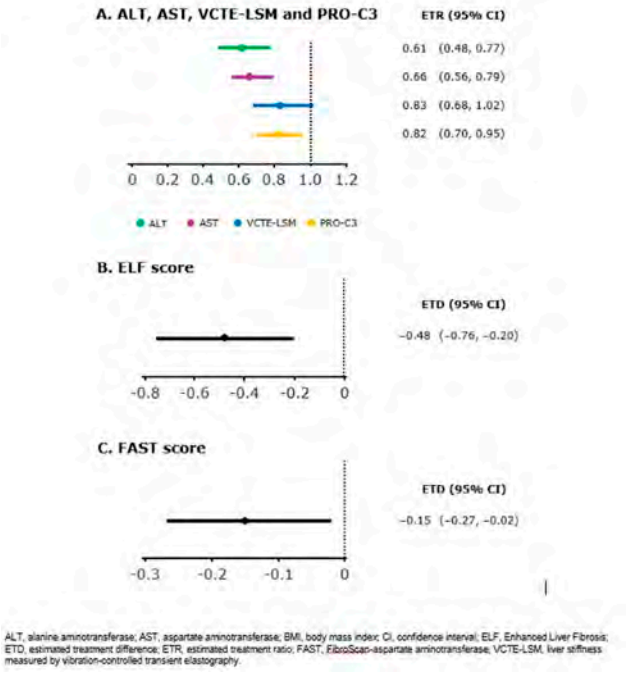
0072 | SEMAGLUTIDE IMPROVES LIVER HEALTH IN NON-OBESE PARTICIPANTS WITH MASH: A POST HOC ANALYSIS FROM THE PHASE 3 ESSENCE TRIAL



Jörn Schattenberg[1] Matthew Armstrong[2] Igor Bakulin[3] Anja Geerts[4] Jacob George[5] Ewa Janczewska[6] Niels Krarup[7] Chun-Jen Liu[8] Håvard Midgard[9] Ahsan Shoeb[7] Thea Vestergaard[7] Michael Roden[10], [1]Department of Internal Medicine II, Saarland University Medical Center, Homburg, Germany, [2]University of Birmingham, Birmingham, UK, [3]North-Western State Medical University, St Petersburgh, Moscow, Russia, [4]Department of Gastroenterology & Hepatology, University Hospital Ghent, Ghent, Belgium, [5]Westmead Hospital New South Wales, Sydney, Australia, [6]Hepatology Outpatient Clinic, ID Clinic, Mysłowice, Poland, [7]Novo Nordisk A/S, Copenhagen, Denmark, [8]Department of Internal Medicine, National Taiwan University College of Medicine, Taipei, Taiwan, [9]Department of Gastroenterology, Oslo University Hospital, Oslo, Norway, [10]Heinrich Heine University of Düsseldorf, Düsseldorf, Germany

Background: In the 72-week interim analysis of part 1 of the ongoing phase 3 ESSENCE trial (NCT04822181), once-weekly subcutaneous semaglutide 2.4 mg improved both primary histological endpoints—resolution of steatohepatitis without worsening of liver fibrosis, and improvement in liver fibrosis without worsening of steatohepatitis—in non-obese (body mass index [BMI] < 27 kg/m^2) participants with metabolic dysfunction-associated steatohepatitis (MASH) and liver fibrosis. We aimed to further explore the effects of semaglutide on liver health-related parameters in this population. **Methods:** This *post hoc* analysis evaluated changes in liver-related parameters from baseline to week 72 in the subgroup of participants with a baseline BMI of < 27 kg/m². The analysis was conducted using the same predefined endpoints and statistical methods as in the primary trial analyses. Assessments included alanine aminotransferase (ALT), aspartate aminotransferase (AST), liver stiffness measured by vibration-controlled transient elastography (VCTE-LSM), Enhanced Liver Fibrosis (ELF) score, FibroScan-AST (FAST) score, and the fibrogenesis biomarker PRO-C3. Treatment effects were reported as estimated treatment ratios (ETRs) or estimated treatment differences (ETDs) for semaglutide versus placebo. **Results:** Out of 800 randomized participants included in the interim analysis, 106 had a BMI of < 27 kg/m²: 67.9% were female, 68.9% were of Asian race, and 52.8% had type 2 diabetes, highlighting the metabolic and ethnic heterogeneity of non-obese MASH. At week 72, semaglutide treatment was associated with improvements in ALT (ETR 0.61; 95% confidence interval [CI] 0.48, 0.77), AST (ETR 0.66; 95% CI 0.56, 0.79), FAST score (ETD −0.15; 95% CI −0.27, −0.02), and VCTE-LSM (ETR 0.83; 95% CI 0.68, 1.02), compared with placebo (**Figure**). Improvements in non-invasive fibrosis biomarkers favored semaglutide over placebo for both ELF score (ETD −0.48; 95% CI −0.76, −0.20) and PRO-C3 (ETR 0.82; 95% CI 0.70, 0.95) (**Figure**), with additional improvement in cardiometabolic risk factors. **Conclusion:** In non-obese individuals with MASH and liver fibrosis, once-weekly semaglutide 2.4 mg resulted in meaningful improvements across multiple liver health-related measures after 72 weeks of treatment. These findings complement the observed histological benefits and support the potential role of semaglutide in improving disease activity and fibrosis in individuals with MASH and a BMI below 27 kg/m².

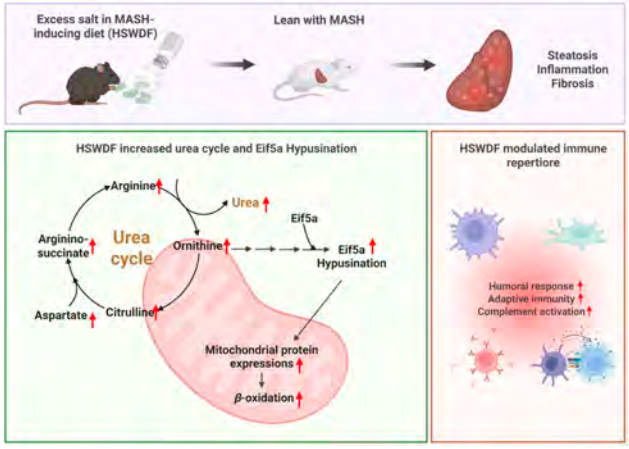
0073 | HIGH SALT SUPPLEMENTATION OF A MASH-INDUCING DIET CAUSES LEAN MASH PHENOTYPE WITH INCREASED HEPATIC UREA CYCLE ACTIVITY AND EIF5A HYPUSINATION



Shaopeiwen Luo[1] Norihiko Morisawa[1] anissa anindya widjaja[1] Brijesh Kumar Singh[1] Derek Hausenloy[2] Paul Yen[3] Jin Zhou[1], [1]Duke-NUS Medical School, [2]Duke-NUS Medical School; National Heart Research Institute Singapore; University College London, [3]Duke-NUS Medical School; Duke University School of Medicine; National Heart Centre Singapore

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most prevalent chronic liver disease worldwide. Metabolic dysfunction-associated steatohepatitis (MASH) is the more aggressive form of MASLD. Approximately 19% of individuals with MASLD/MASH are lean, challenging the traditional view that MASLD/MASH occurs only in obesity. Lean patients with MASLD/MASH are at higher risk for all-cause mortality and liver-related events than obese patients; however, little is known about the pathogenesis of lean MASH. Several epidemiological studies have suggested that there may be an association between high salt intake and the prevalence of lean MASH. Excess salt consumption also increases the risk of hepatic fibrosis and cirrhosis. Therefore, it is intriguing to speculate that increased high salt consumption could be an environmental factor contributing to the higher prevalence of lean MASH. **Methods:** Mouse models, biochemical assays, liver histology, qRT-PCR, Western blotting, cell cultures, targeted metabolomics, and single-cell RNA-sequencing were performed. **Results:** We previously showed that mice fed Western diet plus fructose (WDF) for 16 weeks, compared to mice fed normal chow diet (NCD), developed obesity and hepatic steatosis, inflammation and fibrosis, and decreased hypusination of the translation factor, Eif5a ($Eif5a^{H}$), which is essential for the efficient synthesis of several mitochondrial proteins that regulate mitochondrial activity and β-oxidation capacity. Here, we demonstrated these mice also decreased hepatic urea cycle activity, mitochondrial biogenesis, and β-oxidation, and increased pro-inflammatory responses than mice fed NCD. Surprisingly, high salt supplementation of WDF (HSWDF) generated mice with lean MASH phenotype

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

with decreased adiposity, reduced hepatosteasis, and similar hepatic inflammation and fibrosis as mice fed WDF. Mice fed HSWDF also had improved urea cycle activity, hypusination of translation factor Eif5a (Eif5a^{H}), and β-oxidation of fatty acids than mice fed WDF which may account for the reduced hepatosteatosis seen in mice fed HSWDF.Single-cell RNA sequencing (scRNA-seq) of hepatic immune cells showed major changes in the immune profiles of mice fed HSWDF compared to WDF. We observed coordinated changes of gene expression in pathways relating to humoral immune response, adaptive immunity, and complement activation in both innate and adaptive immune cells from the liver of mice fed HSWDF compared to WDF . These additional effects were likely due to high salt intake. Treatment of RAW264.7 macrophages with additional salt with or without fat also showed increases in fibrotic and inflammatory gene expression. **Conclusion:** Our study showed for the first time that high salt intake can play a causal role in the development of lean MASH in mice . We believe that we have also generated the first model of lean MASH that is dependent upon only dietary factors.

0074 | LONG-ACTING FGF21 ANALOGUE PEGOZAFERMIN INDUCES FIBROSIS REVERSAL AND PREVENTS HEPATOCELLULAR CARCINOMA IN A MURINE MASH CIRRHOSIS MODEL

Zaur Abilov[1] Chandra S Shankar[1] Pinzhu Huang[1] Zhensheng Zhang[1] Yoshiko Nanki[1] Andrew Farag[1] Arvo Justice[1] Ayushi Maity[1] Victor Turkowski[1] Kristin Lichti-Kaiser[2] Cynthia Hartsfield[2] Jorge Alfonso Ross Terres[3] Leo Tseng[2] Yury Popov[1], [1]Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, United States, [2]89bio Inc, a member of the Roche Group, San Francisco, CA, United States, [3]Genentech, Inc, San Francisco, CA, United States

Background: There are currently no therapeutic options available for metabolic dysfunction-associated steatohepatitis (MASH) in late-stage (F4) disease. Treatments to reverse cirrhosis or prevent progression to decompensation in MASH are a critical unmet need to prevent liver transplant. Here, we investigated the efficacy of pegozafermin (PGZ), an FGF21 analogue, in advanced stages of a murine model of MASH cirrhosis and hepatocellular carcinoma (HCC). **Methods:** Cirrhotic MASH was induced in male C57BL/6J mice by HF-CDAA feeding as previously described[1] . PGZ treatment was initiated for 12 weeks at three doses (0.1, 1.0 and 6 mg/kg every 3 days s/c) after induction of 1) established fibrosis, stage F3 (12 weeks on diet) or 2) compensated cirrhosis, stage F4 (20 weeks on diet). Animals (10-12 per group) were kept on HF-CDAA diet throughout and liver fibrosis and HCC burden were analyzed at the end of the study. **Results:** In both study arms, 12 weeks of PGZ therapy resulted in significant improvement of hepato- and splenomegaly and robust reduction in serum ALT levels. A dose dependent moderate weight loss was observed in both arms. In animals with F3 fibrosis, PGZ therapy prevented the development of histological cirrhosis signs (bridging fibrosis, regenerative nodules) and reduced hepatic collagen content well below control levels. Additionally, 42% of the animals in the placebo arm (5/12) developed HCC at the 24-week study endpoint. Development of HCC was highly suppressed by PGZ 1.0 mg/kg (9.1%, 1/11) and completely prevented in 6.0 mg/kg group (0/11). In mice with compensated cirrhosis (F4), PGZ therapy resulted in robust improvement in ALT levels and reduction in hepatic collagen content below pre-treatment levels. Histologically, PGZ treated groups demonstrated marked slowing of fibrosis progression in 1.0 mg/kg dose and clear signs of cirrhosis reversal in 6.0 mg/kg dose with fibrotic septa fragmentation and disappearance of regenerative nodules compared to placebo. In the late-treatment group, 100% of mice (11/11) in the placebo arm developed HCC, which was reduced by PGZ to 67% in the 1.0 mg/kg arm (8/12) and to 33% in the 6.0 mg/kg arm (4/12). **Conclusion:** In this mouse model of cirrhotic MASH, pegozafermin demonstrated robust antifibrotic activity with strong evidence of fibrosis reversal, even when treatment started after development of compensated cirrhosis. These data also suggest that pegozafermin may have the potential to suppress cirrhosis-associated HCC.1. Wei et al, Am J Physiol G&L 2019

0076 | PRIMARY CILIA–HEDGEHOG SIGNALING REGULATES HEPATOCYTE PLASTICITY

Anna Mae Diehl[1] Raquel Maeso-Diaz[1] Rajesh Dutta[1] Seh-Hoon Oh[1] Sarah Goetz[1], [1]Duke University

Background: Primary cilia (PC) are signaling organelles that regulate metabolism and tissue repair. Human ciliopathies, including Alström syndrome, are associated with insulin resistance, steatosis, and fibrosis. Hedgehog signaling requires Smoothened (SMO) trafficking to primary cilia for activation. We previously demonstrated that hepatocyte-specific Smo deletion induces insulin resistance, steatotic liver disease, and fibrosis in mice, despite the prevailing view that unlike cholangiocytes, adult hepatocytes do not possess primary cilia, creating a paradox. **Methods:** High-resolution confocal microscopy was performed to detect ciliary markers (IFT88+, Arl13b, TTBK2) and SMO in adult mouse liver and primary hepatocytes. Single-nucleus RNA sequencing of 48,059 hepatocytes from healthy and MASLD human livers was analyzed using Seurat v5. SMO+ hepatocytes were defined by detectable normalized Smo transcripts. A composite cilia score was generated from 303 SYSCILIA Gold Standard genes. Independent RNA-seq datasets from regenerating mouse livers after partial hepatectomy were analyzed for ciliogenesis-associated pathways. Hepatocyte-specific TTBK2-deficient mice were generated to disrupt ciliogenesis and evaluated following acute CCl4 liver injury. **Results:** A distinct hepatocyte subpopulation expressed primary cilia markers and ciliary transcriptional signatures. In human liver, ~35% of hepatocytes were SMO+, and 85% of these cells were enriched for ciliary gene programs. SMO co-localized with IFT88 in hepatocytes, supporting hepatocyte ciliary signaling machinery. Compared with SMO− hepatocytes, SMO + hepatocytes exhibited significantly higher cilia scores and increased expression of genes that, when dysregulated, cause Alström syndrome and related ciliopathies that lead to steatotic liver disease and fibrosis. Mice with SMO- hepatocytes developed worse MASH and liver fibrosis than control mice when fed MASH-inducing diets. To determine whether ciliogenesis is dynamically regulated during tissue repair, we analyzed two independent mouse hepatocyte RNA-seq datasets following partial hepatectomy and observed induction of ciliogenesis pathways 48 hours after liver resection. Functionally, hepatocyte-specific TTBK2 deletion impaired ciliogenesis and suppressed recovery from CCl4 liver injury, increasing AST, bilirubin, and liver-to-body weight ratio. **Conclusion:** Adult human hepatocytes contain ciliary signaling machinery linked to distinct ciliary transcriptional programs. Hepatocyte ciliogenesis is induced during liver regeneration and is required for appropriate injury responses. Loss of primary cilia–Hedgehog signaling exacerbates liver damage by disrupting regenerative adaptation, establishing primary cilia as critical regulators of hepatic homeostasis.

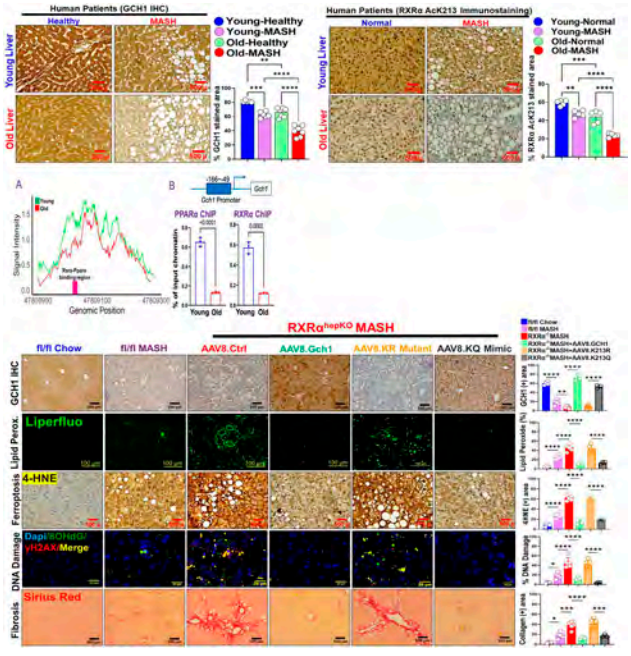
0077 | CD74+ EFFEROCYTIC MACROPHAGES SUPPRESS CATHEPSIN C EXPRESSION THROUGH METHIONINE METABOLIC REPROGRAMMING IN MASLD AND LIVER FIBROSIS

Yang Xiao[1] Tian Lan[1] Jinhang Gao[1] Yuanshui Long[1] Zhiyin Huang[1] Chengwei Tang[1], [1]West China hospital

Background: In metabolic dysfunction-associated steatohepatitis (MASH) and liver fibrosis, the persistence of dead hepatocytes suggests that macrophages are unable to clear these cells efficiently via efferocytosis. Given the heterogeneity among macrophage populations, it is critical to identify those subsets that possess a superior capacity to efferocytose dead hepatocytes, and explore targeted therapies for MASH and fibrosis. **Methods:** To characterize macrophage phenotypes following efferocytosis, RNA-sequencing (RNA-seq) and metabolomics analyses were conducted. Macrophage-specific *Cd74* knockout mice, macrophage-specific cathepsin C (*Ctsc*) knockout mice and littermate control mice were fed a CDAHFD diet for 12 weeks to establish a MASH model. Single-cell RNA-sequencing (scRNA-seq), spatial transcriptomics, and multiplex immunofluorescence *in vivo*, and fluorescence-activated cell sorting and live-cell imaging *in vitro* were performed to assess CD74+ macrophages-mediated efferocytosis. Mechanistically, the histone modification compounds library and immunoprecipitation-mass spectrometry were employed to explore how CD74+ macrophages-mediated efferocytosis influences CTSC expression. DOT1L inhibitor, WDR5 inhibitor, and CTSC inhibitor were used in MASH and liver fibrosis models to conduct pharmacological intervention. **Results:** Based on RNA-seq and metabolomics, we found that macrophages exhibited distinct response patterns after efferocytosis of hepatocytes undergoing different forms of programmed cell death. Furthermore, we identified CD74+ macrophages as a potential subset with high efferocytic capacity, which can approach and efferocytose dead hepatocytes through MIF and GAS6. ScRNA-seq and spatial transcriptomics revealed that macrophage-specific *Cd74* knockout impaired efferocytosis and exacerbated MASLD and liver fibrosis, whereas overexpression of CD74 alleviated liver fibrosis by enhancing efferocytosis. Metabolomics showed that CD74-mediated efferocytic macrophages reduced the expression of CTSC through methionine metabolism reprogramming. Moreover, the metabolic reprogramming of efferocytic macrophages suppressed CTSC via blocking the histone methyltransferase DOT1L/WDR5-STAT1 axis. Macrophage-specific *Ctsc* knockout ameliorated fibrosis by reducing activated TGFβ. In pharmacological intervention, we found that the inhibitor of CTSC, DOT1L or WDR5 significantly alleviated MASH and liver fibrosis. **Conclusion:** CD74+ macrophage-mediated efferocytosis suppresses expression of DOT1L/WDR5-STAT1 axis-induced CTSC via methionine metabolism reprogramming, thereby providing novel therapeutic targets for treating MASH and liver fibrosis. **Disclosures:** Yang Xiao:Nothing to Disclose, Tian Lan:Nothing to Disclose, Jinhang Gao:Nothing to Disclose, Yuanshui Long:Nothing to Disclose, Zhiyin Huang:Nothing to Disclose, Chengwei Tang:Nothing to Disclose.

0078 | AGING-IMPAIRED RXRα ACETYLATION DRIVES GCH1 LOSS AND FERROPTOSIS-PROMOTED SENESCENCE IN MASH



Mayank Choubey[1] Munichandra Tirumalasetty[1] Rashu Barua[1] Md Wahiduzzaman[1] Mohammad Sarif Mohiuddin[1] Qing Miao[1], [1]NYU Grossman Long Island School of Medicine

Background: Elderly patients with MASLD progress more rapidly to MASH with severe fibrosis, suggesting aging compromises hepatic resilience. Ferroptosis, an iron-dependent, lipid peroxidation–driven cell death, triggers inflammation, mitochondrial damage, and fibrosis in MASH, but the mechanisms governing its susceptibility in the aged liver are unclear. Reanalysis of human liver snRNA-seq data identified GTP cyclohydrolase 1 (GCH1), a key anti-ferroptotic regulator, as the predominant ferroptosis gene lost in aged hepatocytes. We hypothesized that acetylation of Retinoid X Receptor alpha (RXRα) preserves RXRα–PPARα-mediated GCH1 transcription, and that its impairment in the aged liver causes GCH1 loss, ferroptosis, and mitochondrial dysfunction. **Methods:** Publicly available human liver snRNA-seq (GSE210077, GSE189600) and ATAC-seq (GSE243630) datasets were re-analyzed for ferroptosis and senescence signatures and nuclear receptor occupancy. Human patient liver tissue arrays were stained for GCH1 and acetylated RXRα-K*. Hepatocyte-specific RXRα knockout (hepKO) and aged (24-month) mice were studied by ChIP-qPCR and RNA-seq. RXRα acetylation was characterized by mass spectrometry, CRISPR/Cas9 knockout, and co-immunoprecipitation. Mitochondrial function was assessed by Seahorse XF, TMRE, and mitochondrial 8-OHdG. AAV8-TBG delivered liver-specific GCH1 and RXRα-K* mutants. **Results:** GCH1 transcript and protein declined with aging and were further

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

suppressed in MASH; GCH1-negative hepatocytes were enriched for both ferroptosis and senescence signatures. ATAC-seq and ChIP-qPCR showed reduced RXRα/PPARα occupancy at the GCH1 promoter in aged liver. We identified a novel acetylation site on RXRα, K*, acetylated by CBP and required for heterodimerization with PPARα; this acetylation was selectively impaired by TNFα via CBP phosphorylation. GCH1 knockdown impaired mitochondrial membrane potential, spare respiratory capacity, and ATP production, with mitochondrial 8-OHdG accumulation. RXRα hepKO mice on a MASH diet developed GCH1 loss, ferroptosis, mitochondrial damage, and fibrosis. AAV8-GCH1 or the acetylation-mimic RXRα-K*Q (but not K*R* Ac mutant) restored GCH1, reduced lipid peroxidation by ~80% and Sirius Red fibrosis by ~70%, and attenuated mitochondrial DNA damage. Acetylated RXRα-K* was reduced ~3-fold in livers of elderly MASH patients versus young healthy controls ($P < 0.05$). **Conclusion:** RXRα acetylation at K* is an aging-regulated resilience factor that preserves PPARα-mediated GCH1 transcription, anti-ferroptotic capacity, and mitochondrial integrity. Inflammation-driven loss of RXRα acetylation in the aged liver causes GCH1 deficiency, ferroptosis-promoted mitochondrial damage, and fibrosis. Targeting RXRα acetylation or restoring GCH1 represents a novel therapeutic strategy for age-related MASH and fibrosis, a major unmet need in elderly patients.

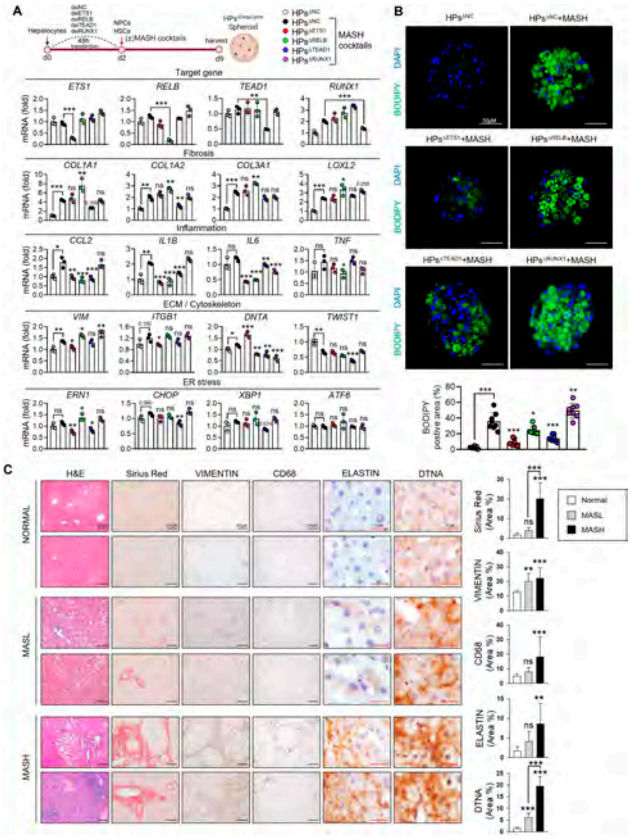
0079 | MULTI-OMIC AND FUNCTIONAL CHARACTERIZATION OF FIBROSIS-ASSOCIATED HEPATOCYTE PROGRAMS IN MASLD



JeongSu Park[1] Xiao Liu[1] Karin Diggle[1] Charlene Miciano[1] Allen Wang[1] David Brenner[2] Tatiana Kisseleva[1], [1]University of California San Diego, [2]Sanford Burnham Prebys Medical Discovery Institute

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) progresses from steatosis to metabolic dysfunction-associated steatohepatitis (MASH) with fibrosis; however, the hepatocyte-specific regulatory mechanisms driving disease progression remain incompletely understood. We leveraged a human liver multi-omic atlas to define fibrosis-associated hepatocyte (Fib-a) programs during MASLD progression. **Methods:** Integrated single-cell, spatial transcriptomic, and epigenomic datasets across MASLD stages were analyzed to identify Fib-a regulatory networks. To functionally validate candidate transcription factors (TFs), primary human hepatocytes were transfected with dsiRNAs targeting ETS1, RELB, TEAD1, or RUNX1 and incorporated into multicellular human liver spheroids under MASH-like conditions. Expression of inflammatory, extracellular matrix (ECM), fibrogenic, and ER stress-related genes was analyzed by qRT-PCR, and lipid accumulation was assessed by BODIPY staining. Human liver tissues were analyzed by western blotting and histology. **Results:** Multi-omic profiling identified Fib-a hepatocytes enriched for inflammatory, cytoskeletal remodeling, ECM, and stress-response pathways, with increased activity of ETS1, RELB, TEAD1, and RUNX1 regulatory networks. Spatial analyses localized Fib-a hepatocytes adjacent to fibrotic regions, supporting their association with active tissue remodeling during MASLD progression. Fib-a-associated injury signatures were validated in human liver tissues. Keratin-associated stress programs were enriched in Fib-a hepatocytes, and KRT8/18 protein expression was significantly increased in MASLD and MASH livers compared to normal controls. Histological analyses demonstrated progressive increases in fibrosis and inflammatory features, including enhanced Sirius Red, Vimentin, and CD68 staining. DTNA expression was also increased in parenchymal regions of MASLD and MASH livers, consistent with hepatocyte structural remodeling. Functional perturbation studies demonstrated distinct TF-specific roles under MASH-like conditions. ETS1 knockdown suppressed inflammatory and ER stress-associated pathways. RELB knockdown reduced inflammatory signaling but enhanced fibrogenic programs. TEAD1 perturbation broadly suppressed inflammatory, mesenchymal remodeling, and ER stress pathways, whereas

RUNX1 knockdown selectively altered cytoskeletal remodeling and increased lipid accumulation. **Conclusion:** These findings identify fibrosis-associated hepatocyte regulatory programs and provide functional validation of key Fib-a TF networks. Integration of human multi-omic analyses with spheroid modeling highlights hepatocyte-intrinsic pathways as potential therapeutic targets for MASH and liver fibrosis.

0080 | EFFICACY AND SAFETY OF BELAPECTIN FOR THE PREVENTION OF ESOPHAGEAL VARICES IN MASH CIRRHOSIS: A MULTI-DOSE META-ANALYSIS

Rahul Falodia[1] Ehsanullah Alokozay[2] Farhan Murtaza[3] Muhammad Junaid Azhar[4] Rameen Khalid[5] Waqas Anwar[6] Muhammad Hammad ul Hassan[7] Ahmed Ibrahim[8] Abdul Wahab Ali[5] Muhammad Ikram[9] Bacel Nseir[10] Miriam Michael[4], [1]All India Institute of Medical Sciences, Jodhpur, [2]Faculty of Medicine, Kandahar University, Kandahar, Afghanistan, [3]Program Director, HCA Houston healthcare/ University of Houston Program, [4]Howard University Hospital, [5]Rawalpindi Medical University, [6]Wyckoff heights medical center, [7]South Brooklyn Health NY, [8]University at Buffalo, Catholic Health System, [9]Allama Iqbal Memorial Teaching Hospital Sialkot, [10]HCA Houston healthcare/ University of Houston Program

Background: Preventing esophageal varices development in metabolic dysfunction-associated steatohepatitis (MASH) cirrhosis remains an unfulfilled clinical priority. Belapectin (GR-MD-02), a galectin-3 inhibitor, has shown preclinical and clinical promise in reducing portal hypertension, but its non-linear exposure-response profile requires robust validation. This meta-analysis systematically synthesizes multi-dose clinical trial data across phases to define its therapeutic window, efficacy, and safety profile. **Methods:** Randomized, double-blind, placebo-controlled trials assessing Belapectin in advanced chronic liver disease were included. Multi-dose subgroup models evaluated the incidence of new varices in baseline-free patients and severe toxicities (CTCAE Grade > 3 treatment-emergent adverse events [TEAEs]) using Risk Ratios (RRs) and 95% confidence intervals (CIs). Continuous trajectories of Liver Stiffness Measurements (LSM) were pooled using Standardized Mean Differences (SMDs). **Results:** Across all consolidated doses, Belapectin significantly protected against variceal progression (Overall RR = 0.59; 95% CI: 0.38–0.91). Stratified by dose tiers, the optimal therapeutic window was confirmed at 2 mg/kg, which achieved a significant reduction in new esophageal varices (RR = 0.52; 95% CI: 0.27–0.99). Reflecting target-mediated drug disposition, higher concentrations failed to demonstrate traditional dose-response scaling (4 mg/kg RR = 0.71; 95% CI: 0.39–1.32; 8 mg/kg RR = 0.24; 95% CI: 0.03–1.86). Continuous LSM changes similarly favored active treatment over placebo across cohorts (Overall SMD = -0.14; 95% CI: -0.29 to 0.01). Safety pooling revealed that Grade > 3 TEAE risks were not significantly elevated at 2 mg/kg (RR = 1.32; 95% CI: 0.91–1.92), with highly balanced cross-arm safety distributions overall (Overall Safety RR = 1.30; 95% CI: 1.00–1.69) showing absolute trial homogeneity (I^2 = 0%, p = 0.84). No adjudicated drug-induced liver injury or anaphylactic events were observed. **Conclusion:** Belapectin at 2 mg/kg safely and reproducibly mitigates new esophageal varices development in compensated MASH cirrhosis and portal hypertension. Its non-monotonic exposure-response profile highlights that maintaining dosing parameters strictly within the targeted macrophage-saturation window is essential for maximizing clinical benefit in future trial designs.

0081 | ELECTROACUPUNCTURE ATTENUATES EXPERIMENTAL MASLD VIA NEUROIMMUNE REMODELING OF HEPATIC MACROPHAGE RESPONSES

Shangze Jiang[1] Huayu Yang[1] Yilei Mao[1], [1]Peking Union Medical College Hospital

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is driven by metabolic stress, lipotoxic injury, and chronic hepatic inflammation. Lifestyle modification remains the cornerstone of management, but safe and mechanism-informed adjunctive strategies are limited. Electroacupuncture has been implicated in autonomic and immune regulation; however, whether it attenuates MASLD through coordinated neuroimmune remodeling remains unclear. **Methods:** A diet-induced murine MASLD model was established and treated with electroacupuncture. Liver phenotype was assessed by body and liver indices, serum biochemical markers, histology, lipid staining, and inflammatory/metabolic gene analyses. Neural pathway engagement and hepatic immune remodeling were evaluated using tracing-related approaches, immunostaining, and single-cell profiling. To enhance human relevance, a 3D bioprinted human hiHep MASLD model was generated under lipid-overload conditions to test macrophage-associated anti-inflammatory protection against hepatocellular injury. **Results:** Electroacupuncture improved experimental MASLD phenotypes, including liver-to-body weight changes, serum injury/metabolic indices, hepatic steatosis, and inflammatory activation. Histology and lipid staining showed reduced lipid deposition after treatment, accompanied by attenuation of injury-associated inflammatory features. Mechanistic profiling suggested engagement of an autonomic neuroimmune pathway and remodeling of the hepatic immune landscape. Among immune populations, macrophages represented the most treatment-responsive compartment. Single-cell analysis showed a shift away from inflammatory activation and toward reparative, lipid-handling, and tissue-restorative programs. In the 3D bioprinted human hiHep MASLD model, macrophage-associated anti-inflammatory modulation reduced lipid accumulation, improved cell viability, and partially normalized transcriptomic patterns related to lipid transport, extracellular remodeling, and immune repair. These concordant in vivo and human bioprinted findings support macrophage remodeling as a central effector process linking electroacupuncture to MASLD improvement. **Conclusion:** Electroacupuncture attenuates experimental MASLD and is associated with neuroimmune remodeling of hepatic macrophage responses. By integrating animal phenotyping, single-cell immune profiling, and 3D bioprinted human hiHep validation, this study provides translational evidence supporting electroacupuncture as a potential non-pharmacological strategy for MASLD and highlights hepatic macrophage remodeling as a key direction for further investigation.

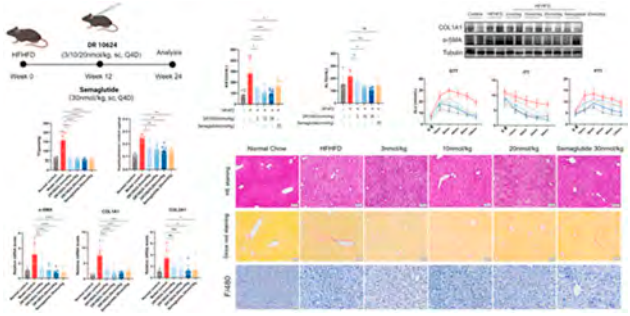
0082 | DR10624, A NOVEL FIBROBLAST GROWTH FACTOR 21 (FGF21)



Yixuan Zhu[1] Jie Li[2], [1]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University, Nanjing, [2]Nanjing Drum Tower Hospital, Affiliated Hospital of Medical School, Nanjing University

Background: DR10624 is a novel triple agonist targeting FGF21R, GCGR, and GLP-1R. This study aimed to evaluate the therapeutic effects of DR10624 on MASH-related liver fibrosis both in vivo and in vitro, and to further elucidate the underlying molecular mechanisms. **Methods:** Two murine models of MASH-associated liver fibrosis were established: an 8-week choline-deficient, L-amino acid-defined, high-fat diet (CDA-HFD) model and a 24-week high-fat/high-fructose diet (HFHFD) model. Mice were treated with DR10624 at doses of 3, 10, and 20 nmol/kg, while semaglutide (at dose of 30 nmol/kg) was used as a positive control. Histopathological analyses were performed to assess hepatic steatosis, inflammation,

ballooning, and fibrosis. In addition, body weight, liver function, and glucose and lipid metabolic parameters were also evaluated. RNA sequencing of liver tissues was conducted to explore the potential mechanisms underlying the therapeutic effects of DR10624, followed by mechanistic validation in LX-2 cells. **Results:** DR10624 exerted significant therapeutic effects in both models of MASH-associated liver fibrosis. Treatment with DR10624 reduced body weight and serum ALT and AST levels, improved dyslipidaemia, enhanced glucose tolerance and insulin sensitivity, and alleviated metabolic dysfunction. Histopathological analyses further demonstrated that DR10624 markedly attenuated hepatic steatosis, inflammatory infiltration, and collagen deposition. At the molecular level, DR10624 dose-dependently reduced the mRNA and protein expression of α-SMA, Col1a1, and Col3a1 in liver tissues and TGF-β-stimulated LX-2 cells. Moreover, DR10624 also inhibited LX-2 cell migration, proliferation, and collagen contraction capacity, thereby suppressing hepatic stellate cell activation. RNA sequencing analysis revealed that DR10624 primarily regulated pathways associated with glucose, lipid, and cholesterol metabolism, with the most pronounced effects observed in glycolytic pathways. Further investigation demonstrated that DR10624 significantly inhibited pyruvate kinase activity. Lentiviral overexpression of PKM2 partially reversed the inhibitory effects of DR10624 on fibrosis-related markers in TGF-β-stimulated LX-2 cells. In addition, DR10624 enhanced K48-linked ubiquitination of PKM2, suggesting that its anti-fibrotic effects may be mediated through promotion of PKM2 degradation. **Conclusion:** This study is the first to demonstrate that DR10624, a novel FGF21R/GCGR/GLP-1R tri-agonist, exerts potent anti-fibrotic effects against MASH-associated liver fibrosis both in vivo and in vitro, with superior efficacy compared with the GLP-1R mono-agonist semaglutide. Mechanistically, these effects may be associated with enhanced K48-linked ubiquitination of PKM2, suppression of glycolysis, and inhibition of hepatic stellate cell activation.

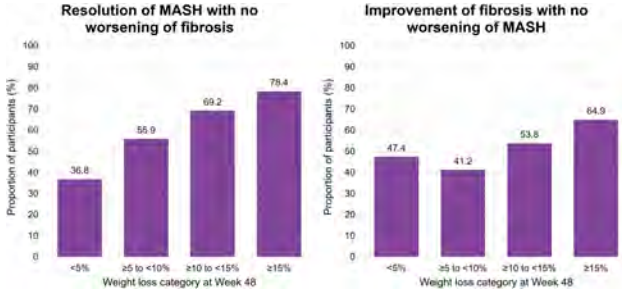
0083 | EFFICACY OF SURVODUTIDE TREATMENT ASSESSED BY LIVER ENDPOINTS ACROSS WEIGHT-REDUCTION CATEGORY AT END OF TREATMENT: RESULTS FROM A PHASE 2 TRIAL OF SURVODUTIDE IN PEOPLE WITH METABOLIC DYSFUNCTION–ASSOCIATED STEATOHEPATITIS AND FIBROSIS



Elisabetta Bugianesi[1] Quentin Anstee[2] Eric Lawitz[3] Mazen Noureddin[4] Naim Alkhouri[5] Jörn Schattenberg[6] Mandy Fraessdorf[7] Ahmad Alhussein[8] Corinna Schoelch[7] Luiza Borowska[8] Arun Sanyal[9], [1]University of Turin, [2]Newcastle upon Tyne Hospitals NHS Trust, [3]University of Texas Health San Antonio, [4]Houston Methodist Hospital, [5]Arizona Liver Health, [6]Saarland University Medical Center, [7]Boehringer Ingelheim Pharma GmbH & Co. KG, [8]Boehringer Ingelheim International GmbH, [9]Virginia Commonwealth University

Background: Survodutide is a glucagon receptor/glucagon-like peptide-1 receptor dual agonist being investigated in phase 3 trials for metabolic dysfunction–associated steatohepatitis (MASH), and obesity. In a phase 2 trial in people with biopsy-confirmed MASH and F1–F3 liver fibrosis, survodutide improved both steatohepatitis and liver fibrosis. We evaluated the efficacy of survodutide treatment assessed by liver endpoints by weight reduction categories at Week 48. **Methods:** Among 295 people aged 18–80 years randomized to once-weekly s.c. survodutide 2.4, 4.8, or 6.0 mg, or placebo (PBO) for 48 weeks, 170 participants who had F2–F3 fibrosis stage at baseline and paired liver biopsy results at baseline and end of trial were included in this analysis. Weight reduction categories at Week 48 included $<5\%$, ≥ 5 to $<10\%$, ≥ 10 to $<15\%$, and $\geq 15\%$. Liver endpoints included resolution of MASH (absence of ballooning [score of 0], no or mild inflammation [score of 0 or 1], and any value of steatosis [score of 0 to 3]) with no worsening of fibrosis, improvement in fibrosis (≥ 1 stage decrease) with no worsening of MASH, ≥ 0.5 reduction in enhanced liver fibrosis (ELF™) score, $\geq 20\%$ reduction in propeptide of type III collagen (PRO-C3), $\geq 30\%$ reduction in liver fat content (LFC; magnetic resonance imaging proton density fat fraction assessed), $>30\%$ reduction in liver stiffness measurement (LSM; FibroScan®), and relative change in alanine aminotransferase (ALT) and aspartate aminotransferase (AST). **Results:** Among 54 participants treated with placebo, 85.2% (46) had a weight reduction of $<5\%$ at Week 48. Among 116 survodutide-treated participants, 16.4% (19) had a weight reduction of $<5\%$, 29.3% (34) had ≥ 5 to $<10\%$, 22.4% (26) had ≥ 10 to $<15\%$, and 31.9% (37) had $\geq 15\%$; 36.8, 55.9, 69.2, and 78.4%

had resolution of MASH without worsening of fibrosis (figure); 47.4, 41.2, 53.8, and 64.9% had an improvement in fibrosis without worsening of MASH (figure); 41.2, 56.3, 64.0, and 70.6% had a ≥0.5 reduction in ELF™; 18.8, 50.0, 76.0, and 58.8% had a ≥20% reduction in PRO-C3, 31.6, 72.7, 100, and 100% had a >30% reduction in LFC; and 36.8, 52.9, 53.8, and 78.4% had a ≥30% reduction in LSM, per weight reduction category. The relative change in ALT was −22.5, −50.5, −59.4, and −42.0%, and AST were −21.5, −45.9, −49.2, and −27.6%, per weight reduction category. **Conclusion:** Liver endpoints were improved with survodutide treatment at Week 48, even at the <5% weight reduction category. Liver improvements increased with increased weight reduction, although the magnitude was more pronounced in steatohepatitis-related endpoints than fibrosis-related endpoints, suggesting improvements in steatohepatitis-related endpoints were largely associated with weight reduction, consistent with the metabolic drivers of the disease, whereas fibrosis-related endpoints could be attributed to a direct hepatic effect of survodutide.

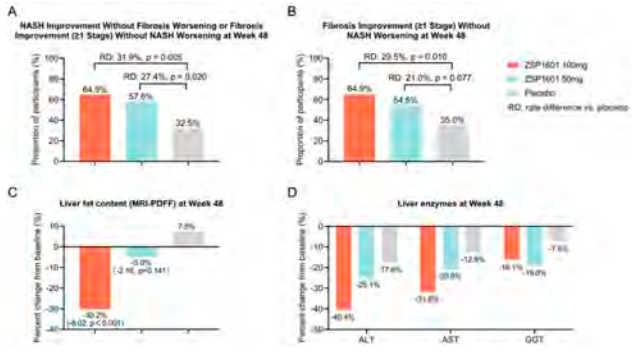
0084 | POSITIVE PHASE 2B CLINICAL RESULTS OF NOVEL FIRST-IN-CLASS PAN-PDE INHIBITOR ZSP1601: SAFETY, ANTIFIBROTIC AND METABOLIC IMPROVEMENT IN MASH PARTICIPANTS WITH F2/F3 FIBROSIS



Jinlin Hou[1] Junqi Niu[2] Jinjun Chen[1] Xieer Liang[1] Qiya Huang[3] Qianguo Mao[4] Yongning Xin[5] Shenghong Zhang[6] Xiaoping Wu[7] Jing Li[8] Yun Peng[8] Haijun Li[8] Xiaoxin Chen[8], [1]Nanfang Hospital, Southern Medical University, [2]The First Hospital of Jilin University, [3]The Affiliated Qingyuan Hospital(Qingyuan People's Hospital), Guangzhou Medical University, [4]Xiamen Hospital of Traditional Chinese Medicine, [5]Qingdao Municipal Hospital, [6]The First Affiliated Hospital, Sun Yat-sen University, [7]The First Affiliated Hospital of Nanchang University, [8]Guangdong Raynovent Biotech Co., Ltd

Background: ZSP1601, a first-in-class pan-phosphodiesterase (Pan-PDE) inhibitor targeting multiple PDE subtypes, has previously demonstrated improvements in non-invasive liver markers of inflammation, steatosis, and fibrosis in MASH. This phase 2b trial aimed to assess the safety and efficacy of ZSP1601 in patients with non-cirrhotic MASH and F2–F3 stage fibrosis. **Methods:** This multi-center, randomized, double-blind, placebo-controlled phase 2b trial enrolled adults with biopsy-confirmed MASH and F2/F3 fibrosis (using the NASH-CRN scoring system). Eligible participants were randomized in a 1:1:1 ratio to receive oral ZSP1601 twice daily (BID) at a dose of 50 mg or 100 mg or placebo for 48 weeks. The primary endpoint was the proportion of participants achieving either NASH improvement (NAFLD activity score reduction ≥ 2

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

points, ballooning decrease ≥1 point, no steatosis increase) without worsening of fibrosis, or fibrosis improvement (decreased ≥1 stage) without worsening of NASH at week 48. Key secondary outcomes included change in liver fat content by MRI-PDFF, changes in serum biomarkers (ALT, AST, GGT), and the overall safety profile. **Results:** Of 181 randomized patients, 110 with baseline biopsy-proven F2-F3 MASH and evaluable paired biopsies formed the primary analysis population. Baseline characteristics were balanced across groups: mean age 37.0 yrs, 74.5% male, mean BMI 29.78 kg/m^2, 30.0% with diabetes, ALT 86.9 U/L, AST 47.6 U/L. At week 48, the proportion of participants achieving the primary endpoint was 64.9% in the ZSP1601 100 mg group ($p = 0.005$ vs. placebo), 57.6% in the ZSP1601 50 mg group ($p = 0.02$ vs. placebo), and 32.5% in the placebo group. For fibrosis improvement (≥1 stage) without NASH worsening, the placebo-adjusted rate differences were 29.50% (100 mg; $p = 0.01$) and 21.00% (50 mg; $p = 0.077$); for improvement of ≥2 stages , the differences were 10.60% (100 mg; $p = 0.036$) and 2.58% (50 mg; $p = 0.358$). ZSP1601 reduced liver fat content, with mean percent changes from baseline of -30% (100 mg) and -5% (50 mg) vs. +7% (placebo). Reductions in ALT and AST were dose-dependent, while GGT reductions were similar between the two active treatment groups. The incidence of treatment-emergent adverse events (TEAEs) was similar across groups, with no deaths reported. Grade ≥3 TEAEs occurred in 9.8% (50 mg), 13.3% (100 mg), and 18.3% (placebo). No dose-related safety signal was observed. **Conclusion:** In MASH patients with F2/F3 fibrosis, 48 weeks of ZSP1601 (50 mg or 100 mg BID) treatment significantly improved histological endpoints, including fibrosis, compared with placebo, with a favorable safety profile. These findings support the further development of ZSP1601 for MASH.

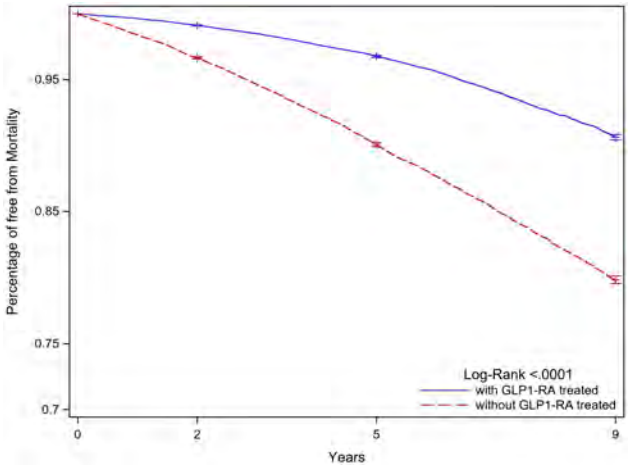
★ 0085 | IMPACT OF GLUCAGON-LIKE PEPTIDE-1 RECEPTOR AGONISTS (GLP-1 RA) ON METABOLIC DYSFUNCTION ASSOCIATED STEATOHEPATITIS (MASH) CIRRHOSIS



Olufunso Agbalajobi[1] Peng Yan[2] Claire Durkin[3] Adeel Butt[4] Obaid Shaikh[5], [1]University of Pittsburgh Medical Center, [2]VA Pittsburgh Healthcare Center, [3]University of Pittsburgh School of Medicine, [4]Hackensack Meridian Medical Group, [5]VA Pittsburgh Healthcare System

Background: Glucagon-like peptide-1 receptor agonists (GLP-1 RA) improve metabolic risk factors, have been shown to improve steatohepatitis, and may improve fibrosis in metabolic dysfunction-associated steatohepatitis (MASH). However, their impact on major adverse liver outcomes (MALO) in patients with MASH cirrhosis remains incompletely characterized. We aimed to evaluate the association between GLP-1 RA exposure and MALO among veterans with MASH cirrhosis. **Methods:** We performed a retrospective cohort study using Veterans Health Administration data from 1/1/2016 to 12/31/2025. Veterans with MASH cirrhosis were identified. We excluded patients with non-MASH liver diagnoses, baseline hepatic decompensation and hepatobiliary malignancy, extra-hepatic malignancy, transplantation, or missing body mass index. GLP-1 RA-treated and untreated patients were propensity score matched in a 1:1 ratio based on age, race, and sex. Cox regression models evaluated associations between GLP-1 RA exposure and outcomes, adjusting for age, sex, race, obesity, diabetes, dyslipidemia, hypertension, cardiovascular disease, and pulmonary disease. We defined MALO as incident hepatic decompensation, hepatobiliary malignancy, or death. Hepatic decompensation was defined as ascites, encephalopathy, or variceal hemorrhage. Follow up time was from cirrhosis diagnosis to development of MALO, censoring for liver transplant, loss to follow up, and end of the study. **Results:** The matched cohort included 104,120 veterans with MASH cirrhosis. The median age was 56 years, 87% were male, and 16.5% were Black. Compared with untreated patients, GLP-1 RA-treated patients had higher rates of obesity (88% vs 67%), diabetes (81% vs 40%), dyslipidemia (90% vs 79%), hypertension (85% vs 71%), cardiovascular disease (49% vs 38%), and chronic pulmonary disease (18% vs 17%; all with $p < 0.001$). GLP-1 RA use was associated with lower risk of hepatic decompensation in both univariable (HR 0.70, 95% CI

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

0.64–0.76; p < 0.001) and multivariable (adjusted HR [aHR] 0.53, 95% CI 0.49–0.58; p < 0.001) analyses, though this relationship exhibited non-proportional hazards over time. GLP-1 RA was associated with lower risk of hepatobiliary malignancy in univariable (HR 0.78, 95% CI 0.70–0.86; p < 0.001) and multivariable (aHR 0.62, 95% CI 0.55–0.70; p < 0.001) analyses. GLP-1 RA was also associated with lower risk of death in univariable analysis (HR 0.39, 95% CI 0.37–0.40; p < 0.001). **Conclusion:** In this national cohort of veterans with MASH cirrhosis, GLP-1 RA treatment was associated with lower risk of hepatic decompensation, hepatobiliary malignancy, and death. These findings support a potential liver-protective association of GLP-1 RA therapy in MASH cirrhosis and warrant prospective validation.

0086 | INITIATING GLP-1 RECEPTOR AGONISTS IN PATIENTS WITH DECOMPENSATED ALCOHOL-ASSOCIATED CIRRHOSIS IS RELATED TO BETTER PROGNOSIS: AN INVERSE PROBABILITY WEIGHTING TARGET TRIAL EMULATION

Mao-Yuan Chen[1] Vivek Rudrapatna[1] Jin Ge[2], [1]UCSF, [2]University of California, San Francisco

Background: Disease-modifying management options for decompensated cirrhosis remain limited outside of liver transplantation. Although GLP-1 receptor agonists (GLP-1RA) and SGLT-2 inhibitors (SGLT2i) have been demonstrated to improve metabolic dysfunction-associated steatohepatitis, their role in alcohol-related liver disease is unclear. We aimed to explore the association of GLP-1RA, DPP-4 inhibitors (DPP4i), and SGLT2i with hepatic outcomes among patients with decompensated alcohol-associated cirrhosis. **Methods:** We queried structured health records data at our institute to identify patients with decompensated alcohol-associated cirrhosis and first-time medication orders for GLP-1RAs (reference group), SGLT2is, or DPP4is between 1/1/2012 and 4/30/2026. Hepatic decompensation, ascertained by ICD codes, was defined as ascites, variceal hemorrhage, hepatic encephalopathy, jaundice, or hepatic renal syndrome. Patients who received initiated medications prior to the diagnosis of decompensated cirrhosis or underwent liver transplantation prior to medication initiation were excluded. Patients who underwent liver transplantation, deceased, or lost to follow-up within 30 days of medication initiation were also excluded. Our outcome was the time to the first occurrence of liver transplant, hepatic decompensation, or death. Inverse probability weighting Cox proportional hazards model with intention-to-treat analysis was performed and 95% confidence intervals (95% CI) were estimated by bootstrapping with 1,000 replications. **Results:** Among 184 patients contributing 389 person-years of follow-up (median follow-up: 1.38 years), 71 (38.6%), 66 (35.9%), and 47 (25.5%) patients were initiated with GLP-1RA, SGLT2i, and DPP-4i after diagnosis of decompensated cirrhosis, respectively. The median baseline MELD 3.0 score was 12.0 ([Q1, Q3]: [9.4, 17.3]) and was a predictor in inverse probability. Twenty-seven (14.7%) patients experienced the outcome. After weighting (standardized mean differences < 0.1), the respective effective sample size for the groups were 66, 62, and 44. Compared with GLP-1RA initiation, SGLT2i initiation was associated with a higher hazard of the outcome (weighted HR 4.12, 95% CI 1.10–45.7, Figure). No significant difference was observed between DPP4i and GLP-1RA. Nine patients (4.9%) developed acute pancreatitis (3 patients each group), but no significant difference was present between groups (p = 0.85). **Conclusion:** Among patients with decompensated alcohol-associated cirrhosis, GLP-1RA initiation was associated with a lower risk of hepatic complications compared with SGLT-2i initiation. Given the limited sample size and potential survivorship bias related to the exclusion criteria, the findings are interpreted as hypothesis-generating. Prospective randomized controlled trials are required to determine the efficacy and safety of GLP-1RA.

0087 | EFFECTS OF ZALFERMIN, CAGRILINTIDE, AND SEMAGLUTIDE ON NON-INVASIVE FIBROSIS BIOMARKERS IN ALCOHOL-RELATED LIVER DISEASE: A PHASE 2 RANDOMIZED TRIAL

Vijay Shah[1] Juan Pablo Arab[2] Ramon Bataller[3] Jerome Boursier[4] Jacob George[5] Lise Lotte Gluud[6] Kenichi Ikejima[7] Maria Rodrigo-Domingo[8] Mazen Noureddin[9] Kwabena Opuni[8] Jörn Schattenberg[10] Ahsan Shoeb[8] Irina Yoffe[8] Aleksander Krag[11], [1]Division of Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota, USA, [2]Virginia Commonwealth University School of Medicine, Richmond, VA, USA, [3]Institut d'Investigacions Biomediques August Pi i Sunyer (IDIBAPS), Barcelona, Spain, [4]Angers University Hospital, Angers, France, [5]Westmead Hospital New South Wales, Sydney, Australia, [6]Gastro Unit, Copenhagen University Hospital Hvidovre, Hvidovre, Denmark, [7]Department of Gastroenterology, Juntendo University Graduate School of Medicine, Tokyo, Japan, [8]Nordisk A/S, Denmark, [9]Summit & Pinnacle Clinical Research, Houston Methodist Hospital, Houston, TX, USA, [10]Department of Medicine, University Medical Centre, Johannes Gutenberg University Mainz, Germany, [11]Odense University Hospital, Odense, Denmark

Background: Alcohol-related liver disease (ALD) is a leading cause of cirrhosis, hepatocellular carcinoma, liver transplantation, and liver-related mortality. Sustained alcohol abstinence is central to management but difficult to achieve, and no approved therapies target the underlying fibrogenic process. ALD and metabolic dysfunction-associated steatohepatitis (MASH) share overlapping liver-injury pathways and so therapies effective in MASH may also benefit ALD. We evaluated agonists of the FGF-21 (zalfermin), GLP-1 (semaglutide), and amylin (cagrilintide) receptors to assess their potential to improve fibrosis in ALD. **Methods:** This was a phase 2, multinational (13 countries, 87 sites), randomized, double-blinded, placebo-controlled trial (RCT) evaluating the effect of once-weekly subcutaneous zalfermin 30 mg, cagrilintide 2.4 mg, and semaglutide 2.4 mg alone or in combinations vs placebo on markers of liver fibrosis and alcohol use (NCT06409130). Eligible participants were aged ≥18 years, with a ≥5-year history of unhealthy alcohol consumption (mean of ≥50 grams/day [g/d] for males and ≥40 g/d for females in the preceding year), and an Enhanced Liver Fibrosis (ELF) score of ≥9.0. The primary endpoint was change in ELF score from baseline to week 28. Secondary endpoints evaluated after 28 weeks of treatment included change in liver stiffness measured by vibration-controlled transient elastography (VCTE-LSM), PRO-C3, alcohol use assessed by Timeline Follow-Back (TLFB), safety, and tolerability. **Results:** A total of 270 participants were randomized (Zalfermin + semaglutide [n = 46], Zalfermin [n = 45], semaglutide [n = 43], cagrilintide + semaglutide [n = 46], cagrilintide [n = 46], placebo [n = 44]): 25.9% were female, had a mean age of 59.7 years, mean BMI of 32.4 kg/m^2, and 26.3% had type 2 diabetes. Baseline alcohol use was high (TLFB 81 g/d); 59.3% had an Alcohol Use Disorders Identification Test score of ≥15. Liver disease was advanced (mean ELF score 10.2; geometric mean VCTE-LSM 10.1 kPa). The primary endpoint of change in ELF score was met for all active treatments with greater reductions vs placebo (+0.12), including −0.41 for zalfermin + semaglutide, −0.44 for zalfermin, −0.38 for semaglutide, −0.45 for cagrilintide + semaglutide, and −0.25 for cagrilintide (**Figure**), and accompanied by consistent improvements in both VCTE-LSM and PRO-C3. Although a trend for decreased alcohol consumption was observed in all treatment groups, no significant differences vs placebo were observed for TLFB. No unexpected safety concerns were identified for the active treatments, with safety profiles consistent with prior studies in other indications. **Conclusion:** This is the first RCT to show that pharmacological treatment can drive improvements in fibrosis biomarkers in people with ALD, with effects evident across the study population and independent of changes in alcohol consumption.

Figure. Estimated mean change in ELF score from baseline to week 28.

ELF score was analyzed using a linear model with treatment group as the categorical factor, adjusted for type 2 diabetes status (yes/no) at screening and baseline ELF score. Missing data were handled by unconditional reference-based multiple imputation, i.e., imputation of missing data was informed by participants assigned to placebo.
ELF, Enhanced Liver Fibrosis.

Background: Hepatorenal syndrome-acute kidney injury (HRS-AKI) is a serious complication of advanced liver disease, frequently occurring in alcohol-associated hepatitis (AH), a population with high inflammatory burden and multi-organ failure. Terlipressin is the only FDA-approved therapy for HRS-AKI, but whether treatment response, safety, and short-term outcomes differ in patients with AH is not well defined. **Methods:** We analyzed consecutive adults with HRS-AKI treated with terlipressin at 16 U.S. academic centers. AH was defined per NIAAA criteria. Primary outcome was overall response (complete or partial) and secondary outcome was 90-day mortality. Multivariable logistic regression models were used to evaluate the association between AH and overall response. Fine-Gray competing risk models were used to evaluate the association between AH and mortality, treating liver transplantation (LT) as a competing event. **Results:** Among 242 patients, 58 (24%) had AH. Patients with AH were younger (53 vs 58 yrs, $p < 0.01$), more often male (74% vs 60%, $p = 0.04$), and had greater illness severity, including higher MELD 3.0 (34 vs 31; $p < 0.01$) and more ACLF grade 3 (62% vs 39%; $p < 0.01$) compared to patients without AH. Overall response was 47% in AH vs 58% in non-AH patients ($p = 0.19$) and was similar among patients with ACLF grade 3 (44% vs 46%, $p = 0.90$). After adjustment for age, sex, and ACLF grade, AH was not associated with overall response (OR 0.81, 95%CI 0.42-1.54; $p = 0.50$). Renal replacement therapy was identical (31% vs 31%) and discontinuation for respiratory failure was similar (12% vs 9%; $p = 0.61$). Overall at 90 days, 42% died and 27% underwent LT, with significantly lower LT rates in AH (12% vs. 32%, $p = 0.01$). The cumulative incidence of death was numerically higher in patients with AH [50% (95% CI 36-62)] compared to those without AH [40% (95%CI 32-47)] (**Figure)** . However, this difference was not statistically significant [sHR 1.54 (95%CI 0.98-2.43), $p = 0.06$]. AH was not associated with death after adjustment for age and MELD 3.0 [sHR 1.58 (95%CI 0.97-2.56) $p = 0.07$) or age, sex, and ACLF grade [sHR 1.39 (95%CI 0.86-2.24) $p = 0.20$]. **Conclusion:** In this multicenter cohort, terlipressin-treated patients with HRS-AKI and AH had similar treatment response and 90-day mortality compared to those without AH. These findings suggest that AH alone should not deter terlipressin use and highlight the importance of early transplant evaluation in this high-risk population.

0089 | RIFAXIMIN-α AFFECTS GUT MICROBIOME FUNCTION AND REDUCES CIRCULATING CCL-20 IN PATIENTS WITH ALCOHOL-RELATED LIVER DISEASE

Nikolaj Torp[1] Evelina Stankevic[2] Suguru Nishijima[3] Julie Dubourg[4] Marisa Keller[3] Diënty Hazenbrink[3] Stine Johansen[5] Laura Pikkupeura[6] Johanne Hansen[1] Camilla Dalby Hansen[5] Ida Villesen[1] Sönke Detlefsen[1] Helene Bæk Juel[7] Maximilian Joseph Brol[8] Robert Schierwagen[9] Dennis Pohl[3] Anthony Fullam[3] Christian Schudoma[3] Diana Leeming[10] Morten Karsdal[10] Mary Rinella[11] Maja Thiele[12] Mani arumugam[7] Jonel Trebicka[13] Michael Kuhn[3] Peer Bork[3] Torben Hensen[7] Aleksander Krag[14] Mads Israelsen[1], [1]Odense University Hospital, [2]University of Copenhagen, [3]Molecular Systems Biology Unit, European Molecular Biology Laboratory, Heidelberg, Germany, [4]Eccogene Inc., Boston, Massachusetts, USA, [5]Department of Gastroenterology & Hepatology, Odense University Hospital, Odense, Denmark, [6]Novo Nordisk Foundation Center for Basic Metabolic Research University of Copenhagen, [7]Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Copenhagen, D, [8]University Hospital Münster, [9]University Hospital Muenster, [10]Nordic Bioscience, [11]The University of Chicago, [12]Evido.health, [13]Department of Internal Medicine B, University of Münster, Munster, Germany, [14]University of Southern Denmark

Background: Fibrosis progression in alcohol-related liver disease (ALD) is driven in part by gut dysbiosis, increased microbial translocation, and epithelial immune activation. These early gut–liver axis disturbances provide a rationale for microbiome-targeted therapy. Rifaximin-α, a widely used gut-restricted antibiotic and pregnane X receptor agonist, has demonstrated anti-inflammatory activity in advanced liver disease, but its mechanistic effects remain unclear. We therefore examined whether rifaximin-α alters microbial functional pathways and systemic inflammatory signaling in the randomized GALA-RIF trial with comprehensive validation in independent cohorts and in vitro and ex vivo models. **Methods:** This prespecified mechanistic study analyzed samples from the randomized, double-blind, placebo-controlled GALA-RIF trial, testing the effects of rifaximin-α in ALD (n = 136). Stool metagenomics (n = 134) and plasma proteomics (n = 131) were obtained at baseline, 1 month, and 18 months. Outcomes included rifaximin-associated changes in microbial composition and function, circulating proteins, and their clinical correlations. Findings were validated *in vitro*, in the RIFSYS trial, and through population-scale proteomic–phenomic associations in the UK Biobank. **Results:** Rifaximin-α preserved overall microbial diversity and load but produced selective shifts in microbial guilds implicated in barrier disruption, including reductions in oral-derived and mucin-degrading taxa (e.g., *Veillonella*, *Haemophilus*, *Roseburia*) and enrichment of short-chain fatty acid-associated species such as *Flavonifractor plautii* (**Figure**). In both the derivation and validation cohorts, microbial functional analysis showed that rifaximin-α induced a significant shift towards lower lipopolysaccharide (LPS) synthesis and increased starch, sucrose, and galactose metabolism (**Figure**). Rifaximin-α significantly reduced circulating CCL20 (FDR < 0.05). CCL20 levels correlated strongly with biochemical and histological markers of liver injury and fibrosis and predicted incident liver disease in the UK Biobank. In vitro and ex vivo experiments validated rifaximin sensitivity of affected taxa. **Conclusion:** Rifaximin-α selectively reprograms gut microbial function and attenuates LPS-linked epithelial chemokine signaling, notably CCL20, a candidate mediator of gut–liver immune crosstalk. These findings provide a mechanistic rationale for targeting the gut-liver axis in ALD to reduce liver fibrosis progression.

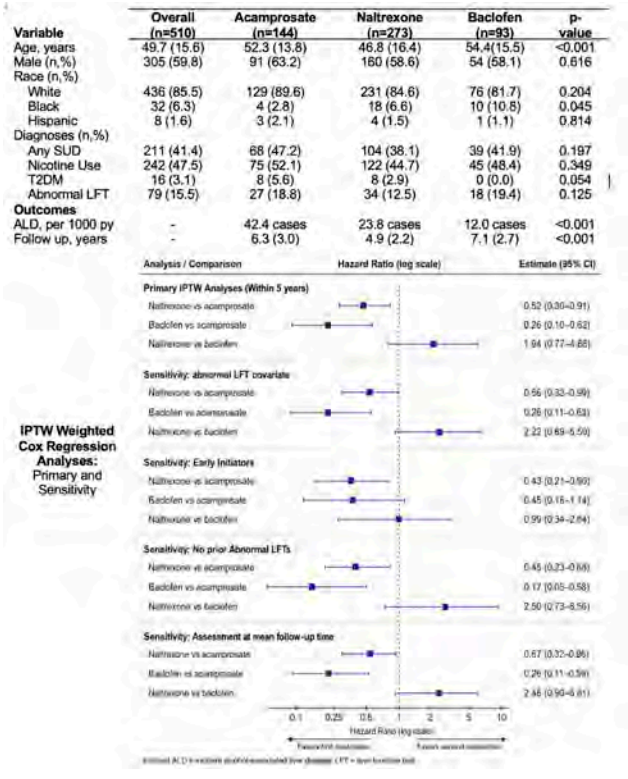
0090 | NALTREXONE AND BACLOFEN ARE ASSOCIATED WITH LOWER INCIDENT OF LIVER DISEASE COMPARED TO ACAMPROSATE IN ALCOHOL USE DISORDER: A PROPENSITY-WEIGHTED COHORT STUDY OF A LONGITUDINAL BIOBANK REPOSITORY



Katherine Cooper[1] Rachael Mahle[1] Sanjana Rane[1] Russell Goodman[2] Esperance Schaefer[3] Wei Zhang[2] Eric Przybyszewski[2] Jay Luther[2], [1]Massachusetts General Hospital, Harvard Medical School, [2]Massachusetts General Hospital, [3]Brigham and Women's Hospital

Background: Pharmacotherapy for alcohol use disorder (AUD) is associated with improved alcohol-related outcomes, but comparative data on liver outcomes in patients initiating medications for AUD (mAUD) remain limited. **Methods:** We performed a target trial emulation (TTE) among patients diagnosed with AUD between 2005-2020 without viral hepatitis or pre-existing alcohol associated liver disease (ALD) who newly initiated a mAUD within 5 years of AUD diagnosis. Time zero was defined as the date of medication initiation. The primary outcome was incident ALD, assessed over 10-year follow-up. Unadjusted incidence rates were calculated up to 10 years. Target trials were then conducted with pairwise comparisons between naltrexone, acamprosate, and baclofen. Stabilized inverse probability of treatment weights (IPTW) were estimated using age, sex, race, ethnicity, tobacco use, other substance use disorder, and type 2 diabetes mellitus. Weighted Cox proportional hazards models were used to estimate hazard ratios. Sensitivity analyses were performed in patients with early initiation of mAUD, defined as within 2 years of AUD diagnosis, and after excluding patients with any history of abnormal baseline liver function test (LFT). **Results:** Among 510 eligible patients with mean age 50.5 years were included (273 naltrexone, 144 acamprosate, 93 baclofen). Prior to weighting, demographics varied by

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

group (Table 1). Crude incidence of ALD was higher among acamprosate initiators (42.4 per 1000 py) than naltrexone (23.8 per 1000 py) and baclofen (12.0 per 1000 py). In independent target trials, both naltrexone (HR 0.52, 95% CI 0.30-0.91; p = 0.021), and baclofen (HR 0.26, 95% CI 0.10–0.62; p = 0.003) were associated with lower incident ALD compared to acamprosate. The association was attenuated but remained significant when evaluating ALD or death among baclofen compared to acamprosate initiators (HR 0.46, 95% CI 0.24-0.87, p = 0.017). Adding abnormal LFTs to the IPTW-model did not change results, and findings were directionally consistent in sensitivity analyses restricted to treatment initiation within 2 years and after excluding patients with abnormal LFTs (Figure 1). In exploratory stratified analyses, findings were similar in males and females, and in those with BMI < 30 and BMI ≥ 30 (*not shown*). **Conclusion:** In this TTE of patients diagnosed with AUD without pre-existing liver disease, incident ALD rates differed by mAUD type. Compared with acamprosate, naltrexone and baclofen were associated with lower risk of incident ALD, with findings generally consistent across sensitivity analyses that consider both time to initiation and baseline risk. These results suggest that mAUD selection may have implications for downstream liver disease risk, although prospective studies are needed to confirm these findings.

0092 | FDA APPROVED PDE4-SPECIFIC INHIBITOR ROFLUMILAST DEMONSTRATES REMARKABLE THERAPEUTIC EFFICACY IN MOUSE MODEL OF ALD

Diego Montoya-Durango[1] Mary Nancy Walter[1] Yali Wang[1] Jingwen Zhang[1] Jing Feng[1] Dibson Gondim[1] Mercia Gondim[1] Xiang Zhang[1] Shirish Barve[2] Craig McClain[1] Leila Gobejishvili[1], [1]University of Louisville, [2]University of Louisville and Norton Neuroscience Institute Cressman Parkinson's Research Team

Background: Alcohol-associated liver disease (ALD) is a major health problem with no FDA-approved therapy. Preclinical studies identified phosphodiesterase 4 (PDE4) as a therapeutic target for ALD. Importantly, our group showed that patients with ALD have higher hepatic levels of PDE4 enzymes. We also showed that the first FDA-approved PDE4 inhibitor for COPD, Roflumilast, significantly attenuated endotoxin-inducible inflammatory cytokine production in *ex vivo* whole blood of patients with ALD. To date three PDE4 inhibitors have been approved by FDA for various inflammatory and fibrotic diseases, however the studies evaluating their efficacy in ALD are lacking. **Methods:** C57Bl/6J mice were subjected to a 16-week ALD model (Western diet with alcohol in drinking water). The control group had access to drinking water, while the alcohol group drank alcohol (alternating 10%/20% weekly). 10 weeks after alcohol, one group of mice received Roflumilast (PDE4i) (3 mg/kg body weight) three times a week, while another received placebo for the remaining six weeks of alcohol drinking. Plasma levels of liver injury markers (ALT, ALP, keratin 18), total bile acids, cholesterol, soluble CD14 (sCD14, a marker of systemic inflammation) were measured at 10 and 16 weeks. Liver sections were evaluated for steatosis; real time qPCR and Western blot analyses were performed. Liver lipid composition and functional lipidomic analysis were carried out using mass spectrometry and visualized using R language and LipidOne. One-Way ANOVA statistical testing using GraphPad Prism was performed. **Results:** Roflumilast prevented alcohol-induced increases in liver injury markers, bile acids, cholesterol and sCD14 compared to placebo. Liver/white adipose tissue-to-body weight ratios were also significantly lower. PDE4i prevented alcohol-induced steatosis, lowered both liver triglyceride levels and the expression of lipogenic genes (*CD36*, *Plin2*, and *Fasn*) while increasing CPT1a levels.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

PDE4i decreased pro-apoptotic (*Bim*, *Bak*, *Bax),* and ER stress genes (*Chop, Aft3, Atf4, Gadd45b*), genes involved in oxidative stress (*Gst1a*, *Gpx2*, *Gpx4)* and inflammation (*Ccl2*, *Ccr2*) compared to placebo. Functional lipidomic analysis revealed that 10-week alcohol lowered antioxidant protection and membrane fluidity, elevated mitochondrial/lysosomal activity and altered endosomal trafficking. Prolonged alcohol drinking for 16 weeks increased oxidized phospholipids, lipid storage and accumulation, reduced cardiolipins and lipolysis, indicating increased oxidative stress, mitochondrial dysfunction and membrane destabilization. In comparison, PDE4i treatment increased cardiolipin and polar lipids, and lipid turnover/mobilization compared to placebo. **Conclusion:** Roflumilast effectively prevented ALD progression by modulating multiple pathogenic pathways, including beneficial hepatic lipid remodeling, strongly supporting its use in ALD patients.

0093 | THE THBS2–SPP1 AXIS IN HSC-DRIVEN LIVER FIBROGENESIS: A SYNERGISTIC TARGET FOR ANTIFIBROTIC THERAPY

Hong Li[1] Ning Zhang[1] Wen Zhang[1] Wenyue Wu[1] Ziyan Pan[1] Haodong Ma[1] Caihong Wang[1] Ruoyu Gao[1] Zhi Chen[1] Qiushuang Ji[1] Xunzhen Yan[1] Aiting Yang[1] Aiting Yang[1] Wei Chen[1] Hong You[1], [1]Beijing Friendship Hospital, Capital Medical University

Background: Thrombospondin-2 (THBS2) is markedly upregulated in fibrotic livers and correlates with fibrosis stage independently of etiology. This study aimed to elucidate the role and underlying mechanisms of hepatic stellate cell (HSC)-derived THBS2 in the progression of liver fibrosis. **Methods:** HSC-specific *Thbs2* knockout (*Thbs2*$^{\Delta HSC}$) and human *THBS2* knock-in (h*THBS2*$^{KI\ HSC}$) mice were generated. Liver fibrosis was induced by carbon tetrachloride (CCl_4) injection or bile duct ligation (BDL). The functional role of the THBS2–SPP1 axis was investigated using a dual targeting strategy: extracellular SPP1 was neutralized by intraperitoneal administration of an anti-mouse SPP1 antibody (inVivoMAb), while intracellular SPP1 was suppressed via AAV6-GFAP-sh*Spp1*. Additionally, a THBS2-specific inhibitor was identified and combined with an SPP1-targeting small molecule to evaluate the therapeutic potential of dual THBS2–SPP1 inhibition in liver fibrosis **Results:** *Thbs2*$^{\Delta HSC}$ mice exhibited markedly attenuated hepatic inflammation and fibrosis in both CCl_4- and BDL-induced models. Conversely, h*THBS2*$^{KI\ HSC}$ mice showed significantly aggravated inflammation and fibrotic progression. Mechanistically, *Thbs2* knockdown in HSCs markedly suppressed the expression of the pro-fibrotic mediator SPP1, whereas THBS2 overexpression robustly increased both SPP1 expression and secretion—findings consistently validated in vitro. Moreover, molecular interaction analyses revealed that THBS2 directly interacts with SPP1. Importantly, both anti-SPP1 neutralizing antibody administration and AAV6-GFAP-sh*Spp1*-mediated gene silencing significantly attenuated fibrotic progression in CCl_4treated h*THBS2*$^{KI\ HSC}$ mice, indicating that SPP1 plays an essential role in THBS2-mediated liver fibrogenesis. Furthermore, a novel THBS2 inhibitor was identified through integrated virtual drug screening combined with surface plasmon resonance (SPR) validation. Pharmacodynamic analyses demonstrated that this compound exerted significant antifibrotic effects in both CCl_4- and 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC)-induced liver fibrosis models, accompanied by marked histopathological improvement. Notably, combined targeting of the THBS2–SPP1 axis produced synergistic anti-fibrotic effects in CCl_4treated h*THBS2*$^{KI\ HSC}$ mice. **Conclusion:** Our findings demonstrate that HSC-derived THBS2 drives liver fibrogenesis through regulation of SPP1. Coordinated targeting of the THBS2–SPP1 axis represents a promising therapeutic strategy to substantially mitigate liver fibrosis.

0094 | SPATIAL EPIGENOMICS, *IN VIVO* CRISPRI, AND $^{13}C_6$-GLUCOSE TRACING REVEAL GLYCOLYSIS-TO-HISTONE ACETYLATION TO DRIVE HEPATIC STELLATE CELL ACTIVATION AND SUBSEQUENT MURINE AND HUMAN LIVER FIBROSIS

Alexander Washington[1] Zeba Firdaus[1] Jeff Meridew[1] Ya Li[1] Chunmiao Cai[1] Patrick Starlinger[1] Timucin Taner[2] Julie Heimbach[2] Vijay Shah[2] Petra Hirsova[2] Kirk Wangensteen[1] Saigopalakrishna Yerneni[1] Alexandre Maia[1] Taro Hitosugi[1] Enis Kostallari[2], [1]Mayo Clinic, [2]Mayo Clinic Rochester

Background: Activated hepatic stellate cells (HSCs) in fibrotic regions drive liver fibrosis through enhanced glycolysis. Glycolysis-derived pyruvate may generate acetyl-coenzyme A (Ac-CoA) through pyruvate dehydrogenase (PDH). Ac-CoA, which may be generated through several metabolic pathways, fuels histone acetylation. Nonetheless, how glycolysis directly regulates the epigenomic landscape of activated HSCs and liver fibrosis remains unknown and is the focus of this study. **Methods:** Patient-derived healthy or cirrhotic liver tissues were analyzed by spatial epigenomics (CUT&TAG) and precision-cut liver slices (PCLS). *In vitro*, primary human HSCs were activated by platelet-derived growth factor B (PDGF) and analyzed by western blot (WB), transwell assay, 5-ethynyl-2′-deoxyuridine (EdU) uptake, liquid chromatography mass spectrometry (LC/MS), and chromatin immunoprecipitation sequencing (ChIP-seq). *In vivo*, dCas9-Krab^{HSC} mice expressing *dCas9-Krab* selectively in HSCs were injected retro-orbitally with lipid nanoparticle (LNP) carrying single guide RNAs (sgRNA) to repress lysine acetyltransferase 2B (Kat2b). Liver fibrosis was induced by carbon tetrachloride (CCl_4). **Results:** We previously showed that PDGF specifically increased histone 3 lysine 9 acetylation (H3K9ac) (TLM2025), an epigenetic mark associated with active gene promoter regions. To understand whether glycolysis is directly involved in H3K9ac, $^{13}C_6$-glucose carbons were traced by LC/MS. PDGF increased 2.5-fold glucose-derived carbons in Ac-CoA compared to vehicle (incorporation of 2 heavy isotopes: M+2, $p < 0.05$). Inhibiting glycolysis-derived Ac-CoA through PDH1 inhibitor Devimistat reduced 3-fold PDGF-mediated H3K9ac (WB $p < 0.05$), suggesting that glycolysis directly promotes H3K9ac. To determine the H3K9ac-dependent gene program regulator in the human fibrotic niche, we integrated spatial epigenomics H3K9ac CUT&TAG from healthy and cirrhotic human livers, and ChIP-seq from primary human HSCs. Motif analysis of H3K9ac CUT&TAG demonstrated that compared to non-fibrotic regions and healthy control, H3K9ac in fibrotic regions was associated with gene programs that were upregulated by early growth response 1 (EGR1). ChIP-seq revealed EGR1 as one of the top regulators of PDGF-mediated pro-migratory and pro-proliferative genes in primary human HSCs. EGR1 knockdown reduced 2.7-fold PDGF-mediated HSC proliferation (EdU, $n = 6$, $p < 0.05$) and 3.1-fold migration (transwell, $n = 6$, $p < 0.05$). In dCas9-Krab^{HSC} mice, CCl_4-induced collagen deposition (19.1-fold by Sirius Red, 20.1-fold by IF, $p < 0.05$) was reduced by LNP-delivered sgKat2b specifically to HSCs (2.1-fold by Sirius Red, 3.2-fold by IF, $p < 0.05$, 5 mice/group). Ex vivo, H3K9ac-selective inhibitor CPTH6 reduced 4.5-fold collagen deposition in cirrhotic human PCLS (WB, $n = 5$, $p < 0.05$). **Conclusion:** Glycolysis-derived H3K9ac upregulates an EGR1-dependent fibrogenic gene program leading to HSC activation and subsequent liver fibrosis.

0097 | ITPR1-DEPENDENT MITOCHONDRIA–ER CONTACT REMODELING PROMOTES HEPATIC STELLATE CELL ACTIVATION AND LIVER FIBROSIS.

Rui Zhang[1] Hui Han[1], [1]China Pharmaceutical University

Background: Hepatic stellate cell (HSC) activation leads to extracellular matrix deposition. Mitochondria-endoplasmic reticulum contact sites (MERCs) coordinate inter-organelle Ca^{2+} transfer and regulate mitochondrial metabolism. However, whether profibrogenic signaling is coupled with structural remodeling of MERCs and whether this process contributes to liver fibrosis remains unclear. We hypothesized that MERC remodeling enhances Ca^{2+} transfer to support HSC activation, thereby promoting liver fibrosis. **Methods:** Human and mouse single-cell datasets were analyzed to assess the expression of MERC-related genes in HSCs during liver fibrosis. MERCs were quantified in vivo using a split-GFP MERC reporter and proximity ligation assay (PLA). Tamoxifen-inducible HSC-specific *Itpr1* knockout mice (*Itpr1*$^{\Delta HSC\text{-}ERT2}$) were generated and subjected to the CDAA-HFD MASH-induced fibrosis model. LX-2 human HSCs were used for functional and mechanistic studies *in vitro*. **Results:** The MERC-localized Ca^{2+} channel ITPR1 (or *Itpr1*) was upregulated in HSCs from fibrotic human (or mouse) livers. Both split-GFP MERC reporter imaging and PLA demonstrated increased MERCs in HSCs during MASH-induced fibrosis. *Itpr1*$^{\Delta HSC\text{-}ERT2}$ mice showed attenuated liver fibrosis compared to controls, as evidenced by reduced Sirius Red-positive area, HSC activation markers (*Col1a1*, *Acta2*), and collagen deposition, with relatively limited effects on steatohepatitis. In LX-2 cells, TGFB stimulation recapitulated the increase in MERCs observed *in vivo*. TGFB increased expression of HSC activation markers (*COL1A1*, *ACTA2*, *FN1*, *COL3A1*), as well as mitochondrial Ca^{2+} levels, while these effects were suppressed by *ITPR1* siRNA. Pharmacological inhibition of the mitochondrial Ca^{2+} uniporter (MCU) that receives Ca^{2+} transferred from ITPR1, using MCU-i4, recapitulated the effects of ITPR1 siRNA. Conversely, forced enhancement of MERCs by transfection of a mitochondria-ER linker facilitated TGFB-induced activation, whereas this effect was attenuated by ITPR1 silencing. **Conclusion:** HSCs undergo MERC remodeling during activation, which contributes to liver fibrosis progression. This process is at least partly mediated by ITPR1-dependent mitochondrial Ca^{2+} transfer. Future studies will investigate the upstream mechanisms driving MERC remodeling.

0098 | HUMAN LIVER PROGENITOR CELL-DERIVED EXTRACELLULAR VESICLES DRIVE CONVERGENT ANTIFIBROTIC RESPONSES THROUGH MODEL-DISTINCT IMMUNE REMODELING IN MURINE MASH

Kiminori Kimura[1] Noriyo Okamoto[1] Juntaro Matsuzaki[2] Kenichi Harada[3] Takahiro Ochiya[4], [1]Tokyo Metropolitan Komagome Hospital, [2]Keio University Faculty of Pharmacy, [3]Kanazawa University Graduate School of Medical Sciences, [4]Tokyo Medical University

Background: Stem/progenitor cell-derived extracellular vesicles (EVs) are emerging as cell-free therapeutics for chronic liver disease, yet their antifibrotic mechanisms are typically defined in a single model, leaving unclear whether they act through a shared or context-specific program. Using human chemically induced liver progenitor cell-derived EVs (hCLiP-EV) in two distinct murine MASH models (CDAHFD and GAN diet), we tested whether hCLiP-EV converge on a common antifibrotic endpoint while engaging model-dominant fibrogenic and immune programs. **Methods:** In CDAHFD, mice were fed a CDAHFD for 16 weeks and received hCLiP-EV (1×10^9 or 1×10^{10} particles, tail vein) weekly for four weeks from week 12, after fibrosis was established. In the GAN diet model, the same regimen began at week 20 or 28, with livers harvested at week 24 or 32. Fibrosis and hepatic stellate cell (HSC) activation were assessed by Sirius Red, hydroxyproline, and fibrogenic markers (αSMA/Acta2, Col1a1, Ccn2/CTGF), with serum ALT and hepatic triglyceride. Mechanisms were examined by bulk RNA-seq with GSEA, immunostaining, flow cytometry, and spatial transcriptomics. **Results:** hCLiP-EV attenuated fibrosis in both models. In CDAHFD, it reduced Sirius Red-positive area ($P = 0.0039$) and hydroxyproline at both doses ($P = 0.0095$, $P = 0.002$), with direct HSC deactivation (reduced αSMA, Col1a1). Transcriptomic responses were dose-dependent: low-dose EVs induced regenerative programs (cell cycle; NES = +1.97) while suppressing ECM/TGF-β signaling (NES = −1.87), whereas high-dose EVs restored hepatocyte metabolism (NES = +2.03; Cyp2c54, Ces1d) with sustained ECM suppression (NES = −1.60). These accompanied reduced Clec4f/F4/80-positive populations and LCN2, indicating attenuated Kupffer cell/macrophage inflammation; spatial transcriptomics confirmed reduced fibro-enriched niches. In the GAN diet model, hCLiP-EV reduced hydroxyproline at 24 and 32 weeks ($P = 0.0318$, $P = 0.0022$), whereas serum ALT was unchanged. In contrast to CDAHFD, regenerative programs and collagen genes (Col1a1/Col1a2/Col3a1) were unchanged; instead, fibrosis attenuation

was driven by selective suppression of the fibrogenic master regulator Ccn2/CTGF and B-cell/immunoglobulin-associated programs (Cd19, Cd79a/b, Ig genes), with reduced hepatic B-cell accumulation. **Conclusion:** hCLiP-EV exerted antifibrotic effects across two MASH models, converging on reduced hepatic fibrosis through divergent, model-dominant mechanisms: in CDAHFD, direct HSC deactivation with attenuated Kupffer cell/macrophage inflammation; in GAN-diet MASH, selective CTGF suppression and reduced B-cell activation. These findings support hCLiP-EV as a cell-free therapeutic engaging context-specific fibrogenic and immune niches across distinct MASH microenvironments.

0099 | SIRNA-MEDIATED GLT25D1 SILENCING ATTENUATES LIVER FIBROSIS VIA IMPAIRMENT OF COLLAGEN O-GLYCOSYLATION, ER RETENTION, AND DEGRADATION OF MISFOLDED PROCOLLAGEN

Ziteng Wang[1] Hongshan Wei[1], [1]Beijing Ditan Hospital, Capital Medical University, Beijing, China

Background: Effective antifibrotic therapies remain limited because signaling-directed interventions are often compensated by redundant inflammatory and TGF-β pathways. Collagen export and fibril stability depend on hydroxylysine O-glycosylation during procollagen maturation. GLT25D1 catalyzes this modification, but its role in liver fibrosis remains unclear. **Methods:** More than 100 chemically modified GLT25D1 siRNAs were screened in LX-2 cells and primary hepatic stellate cells (HSCs) for silencing efficiency, specificity, cytotoxicity, and innate immune activation. Lead liver-directed siRNAs were evaluated in CCl_4- and methionine/choline-deficient (MCD) diet-induced murine fibrosis models. Therapeutic efficacy was assessed using histology, Ishak scoring, immunostaining, serum biochemistry, hematology, and scanning electron microscopy (SEM). Mechanistic studies included glycosylation assays, mass spectrometry, immunofluorescence confocal imaging, ubiquitination analysis, RNA sequencing, and ER-associated degradation (ERAD) evaluation. **Results:** Nine siRNAs reduced GLT25D1 expression by ≥70% in HSCs, and four optimized candidates demonstrated improved serum stability without cytotoxicity or interferon-like responses. In both CCl_4 and MCD fibrosis models, siD19 dose-dependently reduced collagen deposition, fibrotic septa formation, and Ishak fibrosis scores, accompanied by decreased COL1 and α-SMA expression. SEM revealed remodeling of dense collagen networks into thinner and loosely organized fibrils. Mechanistically, GLT25D1 inhibition reduced procollagen hydroxylysine O-glycosylation, resulting in defective procollagen folding and impaired triple-helix maturation. Mass spectrometry confirmed reduced collagen glycosylation and accumulation of immature collagen intermediates. Immunofluorescence confocal imaging demonstrated procollagen retention within the endoplasmic reticulum together with increased co-localization with GRP78, indicating activation of ER stress responses. Ubiquitination assays further showed enhanced targeting of misfolded procollagen toward ER-associated degradation, leading to accelerated intracellular clearance and reduced secretion of mature collagen. These changes were accompanied by extracellular matrix remodeling and attenuation of mechanosensitive FAK/YAP/TAZ profibrotic signaling. Transcriptomic profiling revealed broad remodeling of pathways involved in cellular stress adaptation, extracellular matrix regulation, and profibrotic signaling. **Conclusion:** Targeting GLT25D1 with siRNA suppresses fibrosis by disrupting collagen structural maturation and promoting clearance of misfolded procollagen, representing a structure-oriented antifibrotic strategy beyond conventional signaling inhibition.

0100 | CIRRHOTIC LIVER EXTRACELLULAR MATRIX REVEALS MATRISOME REMODELING AND SERVES AS A SCAFFOLD FOR ADVANCED HUMAN *IN VITRO* MODELS

Fuchen Dong[1] Alan Gorter[2] Feiyan Yang[1] Damian Hofstra[3] Catherine Fahmy Moawad[2] Alienke Pijkeren[4] Guinevere Lageveen-Kammeijer[4] Linda Brouwer[5] Janette Burgess[5] Marluce Mantovani[1] Mari Sogayar[6] Klaas Faber[7] Marco Harmsen[5] Vincent de Meijer[8] Peter Horvatovich[8] Peter Olinga[1] Marina Lima[1], [1]Department of Pharmaceutical Technology and Biopharmacy, Groningen Research Institute of Pharmacy, [2]Department of Pharmaceutical Technology and Biopharmacy, Groningen Research Institute of Pharmacy,, [3]Groningen Research Institute of Pharmacy, University of Groningen, [4]Department of Analytical Biochemistry, Groningen Research Institute of Pharmacy, [5]University Medical Centre Groningen, Department of Pathology and Medical Biology, [6]Cell and Molecular Therapy NUCEL Group, School of Medicine, University of São Paulo, [7]Department of Gastroenterology and Hepatology, University Medical Center Groningen, [8]Department of Surgery, Division of Hepato-Pancreato-Biliary Surgery and Liver Transplantation, UMCG

Background: The liver extracellular matrix (ECM) is a dynamic regulator of cellular behavior and is extensively remodeled during chronic liver disease. In cirrhosis, ECM remodeling involves changes in matrix composition and organization that reshape the hepatic microenvironment. However, comprehensive characterization of the cirrhotic liver matrisome remains limited. Here, we aimed to characterize ECM protein composition in cirrhotic liver and assess whether human liver-derived decellularized ECM (dECM) supports repopulation by cholangiocyte organoid-derived cells and their differentiation towards hepatocytes. **Methods:** Human control and cirrhotic liver tissues were decellularized and analyzed by LC–MS/MS-based proteomics. Protein group data were log2-transformed, median-scale normalized, and analyzed for differential expression using limma with Benjamini–Hochberg correction. Ultrastructural organization of control and cirrhotic dECM was assessed by scanning electron microscopy (SEM). dECM samples were repopulated with dissociated human cholangiocyte organoids, cultured for 15 days in hepatocyte differentiation media, and evaluated by H&E staining and immunostaining for cholangiocyte-associated markers (SOX9, CK17, CK19) and albumin (ALB). **Results:** Decellularization enriched ECM components, increasing matrisome abundance from 3.2% in native tissue to 45.7% in dECM. Proteomic analysis of dECM identified 1,907 protein groups, including 157 matrisome-associated protein groups across multiple ECM functional classes. Principal component analysis showed clear separation between control and cirrhotic dECM. Differential analysis identified 20 matrisome protein groups significantly upregulated in cirrhosis, including collagens and glycoproteins associated with fibrosis-related processes. SEM revealed altered matrix architecture in cirrhotic dECM compared with control dECM. Following repopulation, nuclei were detected on H&E staining in both control and cirrhotic dECM. Successful repopulation of dECM control and cirrhotic livers was confirmed by the presence of nuclei on H&E staining. Immunostaining demonstrated expression of cholangiocyte-associated markers (SOX9, CK17, and CK19). ALB expression was detected in differentiated hepatocyte-like cells seeded onto both control and cirrhotic dECM, confirming hepatocyte-lineage differentiation. **Conclusion:** Human liver-derived dECM from control and cirrhotic tissues supports engraftment of organoid-derived cells. Cirrhotic dECM displays distinct ultrastructural organization, altered matrisome protein composition, and favors hepatocyte differentiation compared to control dECM. Our findings establish human cirrhotic dECM as a disease-specific matrix platform that captures cirrhosis-associated matrisome remodeling and serves as a scaffold for human *in vitro* cirrhotic modeling and drug screening.

0101 | IDENTIFYING AN OUTCOME-BASED LIVER FRAILTY INDEX CUTOFF TO DEFINE ROBUSTNESS AS A TARGET FOR FRAILTY INTERVENTION

Stephanie Zhang[1] Amy Shui[2] Avesh Thuluvath[3] Andres Duarte-Rojo[4] Daniel Ganger[4] Elizabeth Verna[3] Daniela Ladner[5] Robert Rahimi[6] Amit Tevar[7] Elizabeth King[8] Meredith Pearson[9] Marwan Ghabril[10] Matthew Kappus[11] Jennifer Lai[12], [1]School of Medicine, University of California-San Francisco, [2]Department of Epidemiology and Biostatistics, University of California-San Francisco, [3]Center for Liver Disease and Transplantation, Columbia University Irving Medical Center, [4]Northwestern University Transplant Outcomes Research Collaborative (NUTORC), Northwestern Medicine, [5]Northwestern University Transplant Outcomes Research Collaborative (NUTORC), Northwestern University, [6]Annette C. and Harold C. Simmons Transplant Institute, Baylor University Medical Center, [7]Thomas E. Starzl Transplantation Institute, University of Pittsburgh, [8]Department of Surgery, John Hopkins University School of Medicine, [9]Division of Gastroenterology, University of Washington, [10]Division of Gastroenterology and Hepatology, Indiana University, [11]Division of Gastroenterology and Hepatology, Duke University, [12]Division of Gastroenterology and Hepatology, University of California-San Francisco

Background: The Liver Frailty Index (LFI) predicts waitlist mortality (WLM) in cirrhosis, with an established cut-point ($\geq$4.4) identifying "frail" patients at increased risk. No corresponding threshold defines "robust"—the LFI below which patients are no longer at increased risk. The robust cut-point of 3.2 currently in use was derived distributionally, designated as the 20th percentile of LFI scores in the derivation cohort, rather than from clinical outcomes data. An outcomes-based threshold of "robust" is essential to identify a specific target for frailty-directed interventions. We aimed to address this gap. **Methods:** We analyzed data from ambulatory adults with cirrhosis without HCC listed for liver transplant (LT) at 11 centers in the Functional Assessment in Liver Transplantation (FrAILT) Study from 2012-24. Fine-Gray models, with competing risk deceased donor LT and adjusted for MELD 3.0, age, and sex, evaluated dichotomous LFI cut-points from 3.0 to 4.3 in 0.1 increments for association with WLM at 3 mos. Replacing LFI cut-points with continuous LFI, the same adjusted models with restricted cubic splines models visualized inflection points. Considering significance and effect size from the cut-point models and inflection points from the spline models, we determined an LFI cut-point for "robust". Using adjusted Fine-Gray models stratified by the derived robust cut-point, we assessed the association between continuous LFI and 3-mo WLM; 6- and 12-mo WLM were evaluated as secondary endpoints. **Results:** Among 3,017 LT candidates, 42% women; median (Q1-Q3) age 58y (49.7-64.0), MELD 3.0 18 (14-22), LFI 4.0 (3.5-4.4); 26% were frail (LFI $\geq$ 4.4). WLM at 3, 6, and 12 mos was 3%, 6%, and 10%. Spline modeling revealed an inflection point near LFI 3.6, above which 3-mo WLM rose more steeply. Dichotomous cut-point analysis identified LFI 3.6 as the threshold below which patients experienced meaningfully lower 3-month mortality. Each 0.1-unit LFI increase was significantly and positively associated with 3-, 6-, and 12-month WLM among patients with LFI $\geq$ 3.6 (SHR 1.07-1.10) but not among those with LFI $<$ 3.6 (SHR 0.98-1.04; Table). **Conclusion:** An LFI of 3.6 identified a threshold of "robust" below which LFI was no longer significantly associated with 3-, 6-, and 12-mo WLM. This outcome-based cutoff offers a clinically meaningful target for interventions aimed at optimizing frailty status in patients with cirrhosis awaiting LT.

Table. Association Between Continuous LFI and WL Mortality by LFI Subgroup

WL Mortality	LFI Subgroup	N (Events)	SHR for continuous LFI per 0.1 unit (95% CI)	p-value
3-month	<3.6	895 (8)	0.98 (0.88-1.09)	0.73
	≥3.6	2122 (71)	1.10 (1.07-1.13)	<0.001
6-month	<3.6	895 (20)	1.04 (0.95-1.15)	0.39
	≥3.6	2122 (138)	1.08 (1.06-1.11)	<0.001
12-month	<3.6	895 (41)	1.01 (0.93-1.10)	0.81
	≥3.6	2122 (216)	1.07 (1.05-1.09)	<0.001

Abbreviations: LFI = Liver Frailty Index; SHR = subdistribution hazard ratio; CI = confidence interval.
Notes: Models are adjusted for MELD 3.0, age, and sex.

0102 | COGNITIVE IMPAIRMENT IS HIGHLY PREVALENT AFTER LIVER TRANSPLANTATION AND ASSOCIATED WITH PRE-TRANSPLANT FRAILTY

Kacey Berry[1] Fawzy Barry[1] Matthew Kappus[2] Andres Duarte-Rojo[3] Daniel Ganger[4] Daniela Ladner[5] Avesh Thuluvath[6] Elizabeth Verna[7] Marwan Ghabril[8] Elizabeth King[9] Amit Tevar[10] Amy Shui[1] Robert Rahimi[11] Meredith Pearson[12] Katherine Possin[1] Elena Tsoy[1] Lawren VandeVrede[1] Jennifer Lai[1], [1]University of California, San Francisco, [2]Duke University, [3]Northwestern Medicine, [4]Northwestern Memorial Hospital, [5]Northwestern University, [6]Columbia University Irving Medical Center, [7]Columbia University Medical Center, [8]Indiana University, [9]Johns Hopkins Medicine, [10]University of Pittsburgh, [11]Baylor University Medical Center, [12]University of Washington Medicine

Background: Liver transplantation (LT) is widely understood to reverse neurocognitive sequelae of cirrhosis, namely, hepatic encephalopathy (HE). Emerging evidence suggests that a significant subset of LT recipients experience cognitive impairment (CI) that persists beyond the post-operative period—yet prevalence estimates have been hampered by small sample sizes, insensitive instruments, and lack of long-term testing. The prevalence of CI years after LT and associated factors remain undefined. **Methods:** To assess prevalence of post-LT CI and its associated factors, we enrolled ambulatory English-fluent adult LT recipients at 8 U.S. sites. CI was assessed at a post-LT visit via the Tablet-based Cognitive Assessment Tool-Brain Health Assessment (TabCAT-BHA), a validated 10-minute digital screener used worldwide for detecting neurodegenerative cognitive decline. Cognitive impairment (CI) was defined as a TabCAT-BHA z-score $\leq$ -1.5 (in other words, cognitive performance that was 1.5 or more standard deviations below age-, sex- and education-adjusted regression-based norms). Pre-LT and peri/post-LT factors were investigated. Linear regression associated pre- and post-LT factors with CI. **Results:** Of 690 post-LT participants, median age was 61y (IQR 54-69), 38% were female, and median years of education was 14y (IQR 12-16). Median months since LT was 18 (IQR 12-40). Median TabCAT-BHA z-score was -1.3 (IQR -2.2 – (-0.47)); **43% met criteria for CI**. Notably, neither median TabCAT-BHA z-score nor rates of CI differed by post-LT year (Figure 1A and 1B). Pts with vs. without CI were younger (60 v 62y), more likely non-white non-Hispanic (35% v 23%), had fewer median years of education (14 v 15y), higher rates of pre-LT HE (63% v 53%), and increased LT length of stay (9 v 8d). Median pre-LT LFI was higher for those with vs. without CI (4.0 v 3.8). In univariable linear regression, increased pre-LT frailty was associated with worse post-LT cognitive performance: every 0.1 unit increase in LFI was associated with 0.03-unit lower TabCAT-BHA z-score [coeff -0.027, 95% CI -0.040- (-0.015); $p < 0.001$], which persisted after adjusting for age, sex, education, race/ethnicity, pre-LT HE, and post-LT length of stay [coeff -0.026, 95% CI -0.030 – (-0.013); $p < 0.001$]. **Conclusion:** In this multicenter cohort of 690 LT recipients, cognitive impairment was present in over 40%. This rate approximates the prevalence of cognitive impairment in 80-84-year-old community dwelling adults, roughly 20 years older than the median age of our study participants, suggesting accelerated cognitive aging in this population. Pre-LT frailty emerged as a risk factor, including after controlling for co-variates, pointing to a potentially modifiable upstream contributor. Our study provides motivation for routine screening for cognitive impairment after liver transplantation and demonstrates a need to reduce the burden of cognitive impairment in liver transplant recipients.

0103 | OUTCOMES OF GLP-1 USE IN LIVER TRANSPLANT RECIPIENTS WITH DIABETES AND OBESITY: A NATIONAL TARGET TRIAL EMULATION STUDY

Babak Orandi[1] Kelly Terlizzi[2] AnnMarie Liapakis[3] Karim Halazun[4] Brian Lee[5] Christine Haugen[6] Dorry Segev[2] Allan Massie[2], [1]New York University, [2]NYU Langone, [3]NYU Langone Transplant Institute, [4]New York University Langone Medical Center, [5]Keck School of Medicine, [6]University of Cincinnati

Background: Liver transplant (LT) recipients with diabetes and obesity are at greater risk of graft failure and mortality. GLP-1s may improve outcomes, though LT recipients have been excluded from phase III clinical trials of GLP-1s. We sought to characterize the outcomes of GLP-1s in LT recipients with obesity and diabetes. **Methods:** Using Epic Cosmos, a national electronic health record (EHR) database, we identified adult deceased donor LT recipients 2019-June 2024 with BMI 30+ who were diagnosed with type 2 diabetes prior to LT. Exposed patients included cases prescribed GLP-1 medications approved for weight loss (tirzepatide, liraglutide, semaglutide). Using a target trial emulation framework, we selected one counterfactual control without replacement for each case in which age at transplant was +/-5 y, imputed index date post-LT was +/-30 days, and most recent BMI measurement was +/-5 units of the matched case. We calculated recipients' mean weight in 3-month windows and used inverse probability of treatment weighting (IPTW) to account for potential reporting bias. We plotted weight, A1c, and eGFR trajectories for those with eGFR < 60 at study initiation, as well as survival post-GLP-1 initiation or index date and obtained p-values from linear regression. We also examined safety outcomes. **Results:** 1,038 LT recipients with obesity and diabetes prescribed a GLP-1 were matched to 1,038 counterfactuals. Both groups were comparable in terms of age at LT (mean 60.0 for both groups; p = 0.9), race (72.6% vs 71.6% White, 2.3% vs 3.8% Black; p = 0.2), Hispanic ethnicity (17.2% vs 17.7%; p = 0.8), BMI (34.2 vs 33.8; p = 0.54), and baseline eGFR (55.8 vs 55.9; p = 0.5). GLP-1 recipients were more likely to be female (39.1% vs 33.3%; p = 0.006), have MASH as the etiology of their liver disease (47.9% vs 43.2%; p = 0.042), to have a higher baseline A1c (6.6 vs 6.1%; p < 0.001), and to be on insulin at baseline (85.7% vs 70.6%; p < 0.001). Mean adjusted total body weight loss (Fig 1A), change in A1c (Fig 1B), and eGFR (Fig 1C) at 3 years were -9.16% (95%CI: -9.99 to -8.33), -0.37% (95%CI: -0.61 to -0.14), 2.08 mL/min/1.73 m² (95%CI: 0.68 to 3.49) in GLP-1 recipients vs counterfactuals, respectively. Mortality was 53% lower in the GLP-1 group (Fig 1D; aHR: 0.47; 95%CI: 0.30-0.75), but at an increased risk of developing cholangitis (aHR: 2.42; 95%CI: 1.07-5.48). **Conclusion:** GLP-1 medications lead to greater weight loss, improved A1c, and better eGFR in LT recipients with type 2 diabetes and obesity compared to those who do not take them. They also were associated with improved survival but at the increased risk of developing cholangitis.

0104 | METABOLIC FRAILTY PHENOTYPING AND MACHINE LEARNING FOR PREDICTING GRAFT FAILURE AFTER LIVER TRANSPLANTATION FOR MASH

Sri Harsha Boppana[1] Subash Gurappa[2] Sachin Sravan Kumar Komati[2] Gautam Maddineni[3] Raja Chandra Chakinala[4] Venkata Sunkesula[5] Pradeep Yarra[6] Christina Awad[6], [1]Nassau University Medical Center, [2]Florida International University, [3]Creighton university, [4]Guthrie Robert Packer Hospital, [5]Case Western Reserve University, [6]UT health San Antonio

Background: Metabolic dysfunction-associated steatohepatitis (MASH) is a growing indication for liver transplantation (LT), yet the prognostic value of a pre-LT metabolic frailty phenotype remains uncertain. We evaluated whether a "metabolic trifecta" consisting of class II obesity, diabetes, and functional dependence improves prediction of post-LT graft failure in adult MASH recipients. **Methods:** We performed a retrospective cohort study of adult, single-organ, first LT recipients transplanted for MASH from 2014-2024 who survived ≥30 days post-LT. The trifecta was defined as body mass index ≥35 kg/m2, diabetes, and functional dependence at transplant; patients were classified by component count. Outcomes were graft failure at 90 days, 1 year, and 3 years. Multivariable Cox models adjusted for recipient, donor, operative, and waitlist factors. Five-fold cross-validation compared full logistic regression, trifecta-only logistic regression, gradient boosting, and XGBoost for 3-year graft failure prediction. **Results:** Among 2,787 recipients, median age was 59 years; 1,644 (59.0%) were male. Class II obesity, diabetes, and functional dependence were present in 375 (13.5%), 812 (29.1%), and 1,521 (54.6%), respectively; 76 (2.7%) had the full trifecta. Three-year graft failure occurred in 542 recipients. Three-year graft failure increased incrementally with greater phenotype burden. Each additional trifecta component was associated with higher 3-year graft failure risk (HR 1.21, 95% CI 1.08-1.36; p = 0.001). In component models, diabetes (HR 1.28, 95% CI 1.07-1.53; p = 0.007) and functional dependence (HR 1.21, 95% CI 1.02-1.45; p = 0.034) predicted 3-year graft failure, whereas body mass index ≥35 did not. Diabetes remained associated with 1-year graft failure (HR 1.32, 95% CI 1.01-1.73; p = 0.045) but not 90-day graft failure. Model discrimination was limited: Cox C-index 0.588; cross-validated AUCs were 0.584 for full logistic regression, 0.507 for trifecta-only logistic regression, 0.579 for gradient boosting, and 0.576 for XGBoost. Top XGBoost predictors included diabetes, donation after circulatory death, male sex, donor age, and waitlist time. (Figure 1) **Conclusion:** In contemporary MASH LT recipients, diabetes and functional dependence—not severe obesity alone—drive the association between metabolic phenotype and 3-year graft failure. Advanced ML models did not achieve strong discrimination underscoring the challenge that pre-transplant variables alone are insufficient to predicant graft outcomes in MASH recipients.

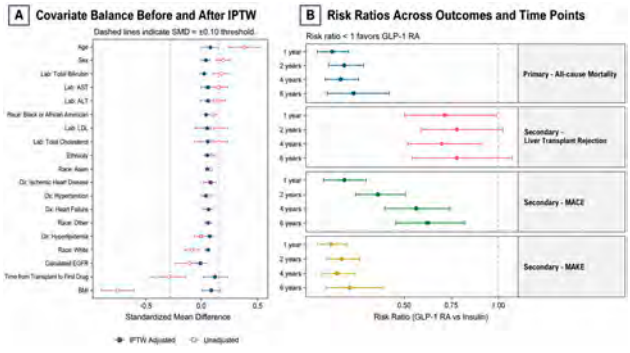
0105 | GLP-1 RECEPTOR AGONISTS ARE ASSOCIATED WITH IMPROVED SURVIVAL AND CARDIO-KIDNEY OUTCOMES WITHOUT INCREASED REJECTION IN LIVER TRANSPLANT RECIPIENTS WITH DIABETES: A NATIONWIDE TARGET TRIAL EMULATION



Kavish Patidar[1] Corneilius Rosenbaum[1] Sudha Kodali[1] Tamneet Basra[1] Michele Pauley-Jones[1] Mazen Noureddin[1] Stephen Jones[1] Luma Succar[1] Constance Mobley[1] Ashish Saharia[1] Caroline Simon[1] Yee Lee Cheah[2] Ashton Connor[1] Urmi Sengupta[1] Linda Moore[1] Mohammad Siddiqui[3] Sumeet Asrani[4] Andrew Allegretti[5] Giuseppe Cullaro[6] R. Mark Ghobrial[7] David Victor III[1], [1]Houston Methodist Hospital, [2]Houston Methodist, [3]University of Virginia, [4]Liver Consultants of Texas, [5]Massachusetts General Hospital, [6]Columbia University, [7]Houston Methodist JC Walter Transplant Center

Background: Liver transplant (LT) recipients with diabetes have high risk of cardiovascular disease, advanced chronic kidney disease, and premature mortality. Although GLP-1 receptor agonists (GLP-1RAs) improve cardiometabolic and kidney outcomes in the general diabetes population, their effectiveness and immunologic safety after LT remain poorly defined. **Methods:** Using Epic Cosmos data from >250 U.S. health systems, we performed an active-comparator, new-user cohort study emulating a target trial

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

of GLP-1RA versus long-acting insulin (LAI). We included adult LT recipients who were ≥1 yr post-LT and newly initiated GLP-1RA or LAI between 1/1/2007 and 12/31/2025. Treatment groups were mutually exclusive, and the index date was the first prescription date. Patients were followed for up to 6 years, until outcome occurrence, or study end (5/5/2026), whichever occurred first. The primary outcome was all-cause mortality. Secondary outcomes included major adverse cardiovascular events (MACE; composite of incident myocardial infarction, stroke, or death), major adverse kidney events (MAKE; composite of incident CKD stage 4/5, renal replacement therapy, or death), and LT rejection. Inverse probability of treatment weighting (IPTW) balanced baseline covariates, including time from LT to index date. Weighted Cox proportional hazards models with delayed entry estimated all-cause mortality; time-specific risk ratios at 1, 2, 4, and 6 years, derived from weighted survival estimates, summarized treatment effects across outcomes. **Results:** Among 1,697 LT recipients, 809 initiated GLP-1RA and 888 initiated LAI. Before IPTW, GLP-1RA initiators were younger (median age, 60 vs. 62 yrs), more often female (40% vs. 30%), and more frequently White (86% vs. 79%) compared with LAI initiators. GLP-1RA initiators also had higher median BMI (32 vs 28), longer median interval from LT to treatment initiation (668 vs. 547 days) and lower median HbA1c (5.8% vs. 6.3%) Cardiovascular comorbidities were similar between groups. After IPTW, all measured covariates were well balanced, with standardized mean differences <0.1 (**Figure A**). Over a median follow-up of 4.1 yrs (IQR 2.5–5.9), GLP-1RA initiation was associated with substantially lower all-cause mortality versus LAI (HR 0.12, 95% CI 0.08–0.20). Risk ratio estimates consistently favored GLP-1RA for all-cause mortality, MACE, and MAKE at 1, 2, 4, and 6 yrs (**Figure B**). GLP-1RA initiation was not associated with increased LT rejection, with risk estimates favoring GLP-1RA early and attenuating toward the null over time. **Conclusion:** In this nationwide target trial emulation of LT recipients with diabetes, GLP-1RA initiation was associated with improved survival and favorable cardiovascular and kidney outcomes compared with LAI, without an increased rejection signal. These findings support prospective evaluation of GLP-1RAs as a cardiometabolic risk-reduction strategy after LT.

0106 | CARDIOVASCULAR-KIDNEY-METABOLIC SYNDROME STAGE AT ONE YEAR PREDICTS CARDIOVASCULAR, RENAL, AND TRANSPLANT OUTCOMES AFTER LIVER TRANSPLANTATION

Joseph Gunderson[1] Ludovic Saba[2] Saket Girotra[1] Sarah Lieber[1] Arjmand Mufti[1] Madhukar Patel[1] Lisa VanWagner[1], [1]University of Texas Southwestern Medical Center, [2]UT Southwestern Medical Center

Background: Cardiovascular disease (CVD) is the leading cause of non-graft-related death after liver transplantation (LT), yet tools to integrate cardiometabolic risk in this population are limited. The American Heart Association cardiovascular-kidney-metabolic (CKM) syndrome staging framework defines a continuum of risk from ideal health (stage 0), excess adiposity (Stage 1), metabolic risk factors or chronic kidney disease (Stage 2), subclinical or high CVD risk (Stage 3), to clinical CVD (Stage 4) and predicts cardiovascular events (CVEs) in the general population. However, its relevance in LT recipients (LTRs) is unknown. We aimed to define CKM burden after LT, assess outcomes, and identify modifiable drivers of progression.

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Methods: We conducted a retrospective cohort study using the TriNetX Global Collaborative Network, a federated research network of 171 healthcare organizations, including adult LTRs (2009-2026) surviving to one-year post-LT; multi-organ recipients were excluded. CKM stage at one year was categorized as non-advanced (Stages 1-2) or advanced (Stages 3-4) using diagnosis (ICD-10-CM), laboratory (LOINC), and procedural (CPT) codes. The primary outcome was three-year incident CVEs (myocardial infarction, stroke, or revascularization). Secondary outcomes included all-cause mortality, graft failure, and new dialysis. Time-to-event outcomes were analyzed using Cox proportional hazards models in cohorts balanced via 1: 1 propensity score matching for demographics, comorbidities, and medication exposures. Among LTRs with non-advanced CKM, we evaluated associations between immunosuppression strategy (steroid-free vs. steroid-containing; tacrolimus vs. cyclosporine) and progression to advanced CKM. **Results:** Among 69,630 LT recipients (mean age 61.8 years, 61.9% male, 64.2% White), CKM staging at one year demonstrated substantial cardiometabolic burden (Stage 1: 4.8%, Stage 2: 29.2%, Stage 3: 16.0%, Stage 4: 9.3%).After 1: 1 propensity matching non-advanced (Stages 1-2) and advanced (Stages 3-4) cohorts ($n = 22,724$), advanced CKM was associated with three-year risk of CVEs (2.5% vs. 0.6%; HR 4.46, 95% CI 3.39-5.86), all-cause mortality (HR 1.75, 1.55-1.99), graft failure (HR 1.97, 1.76-2.21), and incident dialysis (HR 11.60, 7.05-19.08).Among LTRs with non-advanced CKM, corticosteroid-containing immunosuppression at one year was associated with increased progression to advanced CKM (5.5% vs. 3.7%, HR 1.49, 1.28-1.75), whereas calcineurin inhibitor choice (tacrolimus vs. cyclosporine was not associated with progression (HR 0.71, 0.46-1.09). **Conclusion:** Advanced CKM stage at one-year post-LT is strongly associated with adverse cardiovascular, renal, and transplant outcomes. These findings support CKM staging as a clinically relevant risk stratification tool in LTRs and identify corticosteroid exposure as a potentially modifiable factor associated with CKM progression.

Table. Relationship Between Advanced CKM stage on Adverse outcomes post-LT

Outcome	Advanced CKM (Stages 3-4)**	Non-Advanced CKM (Stages 1-2)**	HR	95% CI	*P*-value
CVE*	237 (2.5%)	65 (0.6%)	4.46	3.39-5.86	<0.001
All-cause mortality	657 (5.8%)	400 (3.5%)	1.75	1.55-1.99	<0.001
Graft failure	831 (7.3%)	460 (4.0%)	1.97	1.76-2.21	<0.001
New-onset dialysis	176 (1.7%)	17 (0.2%)	11.60	7.05-19.08	<0.001

*Defined as myocardial infarction, stroke, or revascularization

**Cohort sizes given after propensity matching for age, sex, race, ethnicity, liver disease etiologies, behavioral history (alcohol use, tobacco use), hepatocellular carcinoma, body mass index, serum laboratory tests (cholesterol, hemoglobin A1c, estimated glomerular filtration), medications (antihypertensives, lipid lowering therapies, glucagon-like-peptide-1 receptor agonists, sodium-glucose cotransporter 2 inhibitors, mineralocorticoid receptor antagonists, antiplatelets), immune suppression, family history of cardiovascular disease. (total cohort size: $n = 22,724$)

0107 | META-ANALYSIS OF ALCOHOL-ASSOCIATED LIVER CIRRHOSIS IDENTIFIED NEW RISK LOCI

Callie Zaborenko[1] Marco Abreu[1] Samer Gawrieh[1] Marijana Vujkovic[2] Kyong-Mi Chang[2] Devanshi Seth[3] Timothy Morgan[4] Tae-Hwi Schwantes-An[1], [1]Indiana University School of Medicine, [2]University of Pennsylvania, [3]University of Sydney, [4]VA Long Beach Healthcare System

Background: Alcohol-associated liver cirrhosis (ALC) and metabolic dysfunction-associated steatotic liver disease (MASLD) cirrhosis share remarkably similar genetic architectures, with the strongest GWAS loci consistently overlapping across both conditions. These findings raise the question of whether ALC represents a genetically distinct disease entity or a phenotypic manifestation along a shared biological spectrum of progressive liver injury. However, genetic discovery in ALC has been limited by substantially smaller cohort sizes compared with MASLD cirrhosis studies, reducing statistical power for locus discovery and fine-mapping. Here, we present the largest meta-analysis GWAS of ALC to date to define its genetic architecture and compare it with MASLD cirrhosis. **Methods:** In total, three new and three previously published cohorts are included in this meta-analysis. Million Veterans Project, Indiana Biobank, and GenomALC retrospective cohort were newly analyzed and GenomALC prospective cohort, UK Biobank, and Buch et al. represent three previously published cohorts. Cases were defined as having clinician confirmed diagnosis of ALC or having at least one instance of ICD-9/10 codes for ALC. Controls were defined as problematic drinkers without any known liver diagnoses. All analyses were conducted in participants who clustered with EUR reference samples. Individual site analyses were conducted using logistic regression models while adjusting for age, sex, and two principal components of genetic ancestry. Meta-analysis of variants available in at least 4 cohorts

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

was conducted using *METAL* with genomic control option to adjust for study heterogeneity. **Results:** In total, 13,739 cases and 57,828 controls were included in the meta-analysis. Rs4248168, an intergenic variant upstream of *HLA-DQB1* was genome-wide associated with the risk of ALC (OR = 1.10; 95% CI 1.07-1.13; $p = 2.74x10^{-9}$. There were six additional suggestive ($p = 5x10^{-6}$ to $5x10^{-8}$) associated loci. Also, we replicated previously reported associations in *PNPLA3*, *TM6SF2*, *SERPINA1*, *HSD17B13*, and *MARC1* genes. **Conclusion:** We report an association between *HLA* locus and risk for developing ALC in the largest up-to-date meta-GWAS. In addition to the genome-wide associated locus, we identified 6 suggestive associations that are in or nearby genes that have been implicated glucose dysregulation and lipid metabolism changes due to alcohol. Our findings suggest additional genetic factor drive risk for ALC.

★ 0108 | LOSS OF Y CHROMOSOME IS A NOVEL SOMATIC ANEUPLOIDY AND POTENTIAL BIOMARKER IN HEPATOCELLULAR CARCINOMA

Gopanandan Parthasarathy[1] Renumathy Dhanasekaran[1] Siddhartha Jaiswal[1], [1]Stanford University

Background: Loss of Y chromosome (LOY) is the most common somatic aneuploidy in males and affects proliferative cell types such as hematopoietic cells. Mosaic LOY has been described in several solid cancers and associated with poor outcomes. However, its prevalence, cell-type specificity, and mechanistic consequences in hepatocellular carcinoma (HCC) are undefined. **Methods:** LOY was identified in 1026 male HCC patients across three orthogonal platforms: single-cell RNA-seq (n = 81, 7 cohorts), bulk microarray (n = 731, 7 cohorts), and whole-exome sequencing (n = 214, The Cancer Genome Atlas Program, TCGA). Per-cell LOY was scored using a 9-gene Y-signature to cohort-reference and LOY defined as tumor/reference ratio < 0.5. To characterize mechanistic implications downstream of LOY genes, cancer-testis antigen (CTA) and senescence-associated secretory phenotype (SASP) signatures were co-quantified at single-cell and pseudobulk resolution. Population-level hematopoietic LOY was assessed in the UK Biobank (UKB; n = 214,915 males) and All of Us (AoU; n = 172,711) using array-based bioinformatic pipelines and correlated with liver disease prevalence with age-adjusted Cox regression. **Results:** LOY was present at a concordant rate of 21–26% of all male patients with HCC across platforms (Fig 1A). Among LOY+ tumors, a median of 66% of malignant cells have LOY suggesting clonality. Within tumors, hepatocyte LOY was not correlated with hematopoietic LOY, and neither was correlated with age. LOY+ tumors showed higher TP53 mutation rates (OR = 2.41, $P < 0.05$), greater genomic instability and macrophage enrichment. In TCGA, mosaic LOY was associated worse overall survival (median 11.7 vs 20.7 months, log-rank $P < 0.01$) (Fig 1B). Given loss of KDM5D (an H3K4me3 demethylase), LOY+ tumors exhibited 4-fold greater CTA upregulation in tumor versus matched normal liver ($P < 0.001$) (Fig 1C). Pretreatment CTA expression was predictive of immunotherapy response across two independent cohorts (n = 38; $P < 0.05$) (Fig 1D). Separately, at the patient level, LOY was correlated with reduced SASP expression, particularly the profibrotic signature driven by MMP9, IGFBP3, and SERPINE1 (r = 0.583, FDR Q < 0.05). In UKB and AoU (n = 387,626 combined), hematopoietic LOY in peripheral blood was correlated with age (r = -0.25, $P < 0.01$) and overall mortality, but showed no association with MASLD, cirrhosis, or HCC after age adjustment (all $P > 0.05$). **Conclusion:** We describe for the first time that LOY occurs in 25% of HCC across multi-platform methods and is correlated with poorer outcomes. Mechanistically, LOY leads to CTA de-repression and profibrotic SASP with potential therapeutic implications. Large-scale population data confirm hematopoietic LOY is correlated with age but not liver disease progression. Tumor-compartment LOY represents a novel, orthogonally validated biomarker axis warranting prospective evaluation in HCC and immunotherapy response.

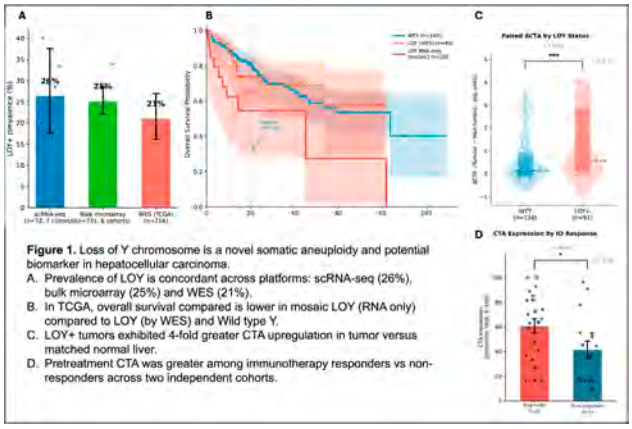

Figure 1. Loss of Y chromosome is a novel somatic aneuploidy and potential biomarker in hepatocellular carcinoma.
A. Prevalence of LOY is concordant across platforms: scRNA-seq (26%), bulk microarray (25%) and WES (21%).
B. In TCGA, overall survival compared is lower in mosaic LOY (RNA only) compared to LOY (by WES) and Wild type Y.
C. LOY+ tumors exhibited 4-fold greater CTA upregulation in tumor versus matched normal liver.
D. Pretreatment CTA was greater among immunotherapy responders vs non-responders across two independent cohorts.

0109 | SINGLE-CELL, SINGLE-NUCLEI, AND SPATIAL TRANSCRIPTOMICS REVEALS SIGNATURE-SPECIFIC MICROENVIRONMENTS IN HEPATOBLASTOMA

Abhishek Murti[1] Elise Lelou[2] Bruce Wang[1] Cindy Ament[1] Nikita Sajai[1] Phoebe Miller[1] Amar Nijagal[2] Alejandro Sweet-Cordero[1] Soo-Jin Cho[1] Saphia Nguyen[1] Simon Bucher[1], [1]UCSF, [2]University of California, San Francisco

Background: Hepatoblastoma (HB), the most common pediatric liver cancer, exhibits intra- and inter-tumoral heterogeneity that challenges clinical risk stratification. Current prognostic tools rely primarily on histology and serum alpha-fetoprotein (AFP), leaving a gap in molecular biomarkers for precision oncology. We previously identified five tumor transcriptomic signatures across 9 patients using single-cell RNA sequencing (scRNA-seq), but were limited by small cohort size, absence of high-risk cases, and reliance on scarce fresh tissue. **Methods:** We developed an integrated multimodal framework across three platforms. First, we expanded scRNA-seq profiling to 12 patients, including the first high-risk case. Second, to overcome constraints imposed by fresh tissue, we established a single-nuclei RNA sequencing (snRNA-seq) pipeline for frozen biobank specimens, using SNP-based genetic demultiplexing of multiplexed lanes. Rigorous QC, including ambient RNA removal and doublet filtering, ensured high-quality nuclear transcriptomes. Third, we applied Xenium spatial transcriptomics to 17 HB samples using a custom 480-gene panel derived from our single-cell atlas, and developed a graph-based algorithm leveraging spatial connectivity and gene expression to assign tissue regions to tumor interior, interface, or exterior. **Results:** Single-cell profiling revealed six distinct tumor signatures shared across patients: Hepatoblast I-III, fibroblast, erythroid, and neuroendocrine. A newly identified Hepatoblast_III signature, enriched in AFP and aggressive-disease genes, was linked to the high-risk patient. Cross-platform validation confirmed that snRNA-seq from frozen specimens reproduced identical signatures, with cells clustering by biological identity rather than platform, enabling a 40% cohort expansion via nine additional biobanked samples. Spatial transcriptomics revealed that distinct tumor signatures create fundamentally different microenvironments: Hepatoblast signatures were enriched for vascular endothelial cells and tumor-associated fibroblasts at the tumor-stroma interface, with HGF-MET and EGF-family signaling identified by ligand-receptor analysis, while neuroendocrine signatures exhibited somatostatin autocrine signaling and SLIT-mediated fibroblast crosstalk. **Conclusion:** Integrating single-cell, single-nuclei, and spatial transcriptomics across 17 patients and over one million cells, we established a comprehensive molecular atlas of HB heterogeneity. Our multimodal approach uncovered clinically relevant tumor signatures with potential for improved risk stratification and identified signature-specific microenvironmental interactions as candidate therapeutic targets. The computational tools developed—including the graph-based spatial region algorithm and cost-effective demultiplexing pipeline—are broadly applicable across tumor types.

0110 | EPIGENETIC-METABOLIC PHOSPHOLIPID REPROGRAMMING BY BAP1 LOSS CONFERS CHOLANGIOCARCINOMA RESISTANCE TO FERROPTOSIS

Yu Zhao[1] Peyton Classon[2] Danielle Carlson[1] Hidemi Nishi[1] Millender Jayla[1] Irene Yan[1] Muhammed Dogukan Aksu[1] Caitlin Conboy[1] Sumera Ilyas[2] Rory Smoot[2] Gregory Gores[1] Tushar Patel[3] Davide Povero[2], [1]Mayo Clinic, [2]Mayo Clinic Rochester, [3]Mayo Clinic Florida

Background: BAP1 loss-of-function mutations occur in 26-32% of cholangiocarcinoma (CCA) cases,

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

conferring chemotherapy resistance and poor prognosis. We hypothesized that BAP1 loss rewires membrane phospholipid composition to evade ferroptosis, defining a targetable vulnerability. **Methods:** Isogenic BAP1-deficient models were generated by shRNA/siRNA and CRISPR/Cas9 in CCLP1, HuCCT1, TFK-1 human and FAC, SB1, KPPC murine CCA cells. Ferroptosis was quantified by CellTiter-Glo (dose-response to RSL3/IKE/Erastin/JKE-1674), C11-BODIPY, MitoPeDPP, MitoCLox, and MitoFerroGreen. Lipid remodeling was profiled by species-resolved LC-MS/MS phospholipidomics and TMT proteomics (n = 3/arm). Syngeneic orthotopic SB1/FAC (C57BL/6J, n = 7-20/group) and BAP1-mutant PDX were used to assess ferroptosis *in vivo*. EpCAM-aptamer coated siRNA-packaged lactosomes (siGPX4, 2×10^{12} particles, 3×/week i.v.) were used to induce tumor-selective ferroptosis in syngeneic orthotopic models (n = 15-20/group). TCGA-CHOL, GSE308455 organoids, Mayo Clinic Tempus CCA cohort (n = 191; 12% BAP1-altered) were used for translational studies. **Results:** LC-MS/MS phospholipidomics in isogenic shBAP1 vs shControl CCLP1 revealed depletion of ferroptosis-promoting PUFA-PLs (PUFA-PE log2FC -0.369, $p < 0.01$; PUFA-PC -0.420, $p < 0.01$; PUFA-PI -0.798, $p < 0.05$) and enrichment of ferroptosis-blocking lipids (sphingomyelin +0.425, $p < 0.01$; non-PUFA PE +0.130, $p < 0.05$). TMT proteomics identified TLCD1 (phosphatidylethanolamine acyltransferase, log2FC +0.41) and LPCAT1 (log2FC +0.66, q = 0.0017) as top candidates. Cross-cohort REML meta-analysis confirmed TLCD1 elevation in BAP1-mutant CCA: pooled log2FC +0.41 [95% CI +0.13, +0.68], p = 0.004, $I^2 = 44\%$; TCGA-CHOL log2FC +0.82, FDR = 0.045; GSE308455 organoids log2FC +0.44, FDR = 0.001. TLCD1 amplification correlated with BAP1 loss in TCGA (p = 0.03, n = 51). ChIP-PCR analysis showed that BAP1 loss increased H2A ubiquitination at the TLCD1 promoter. TLCD1 knockdown in BAP1-deficient CCLP1 and TFK-1 significantly restored sensitivity to RSL3 and IKE. IKE (30 mg/kg/day i.p.) reduced SB1 orthotopic tumor burden by 57% vs vehicle (n = 7/group). JKE-1674 alone and combined with gemcitabine/cisplatin reduced PAX103 PDX burden by 29% and 68%, separately. EpCAM-aptamer lactosomes reduced Gpx4 mRNA 60%, suppressed tumor growth by 43%, elevated Ptgs2, reduced Ki67, with no systemic toxicity. **Conclusion:** BAP1 loss drives ferroptosis evasion through TLCD1-mediated MUFA-PL enrichment and PUFA-PL depletion, validated across isogenic lines, organoids, and two human cohorts. siRNA-based nanotherapeutics siGPX4 delivery suppresses CCA *in vivo*, establishing a biomarker-stratified therapeutic strategy for BAP1-mutant cholangiocarcinoma.

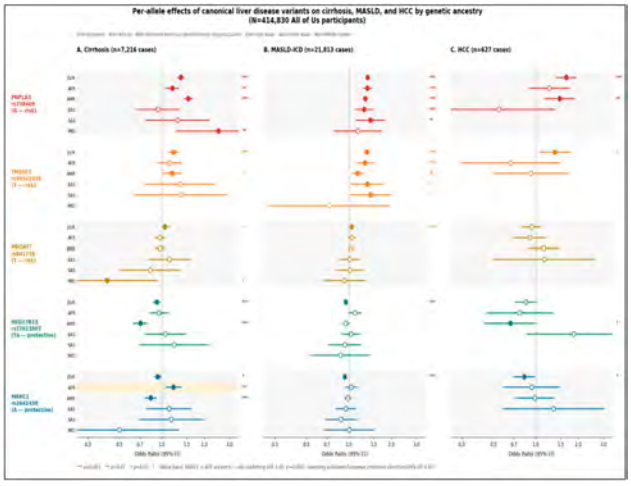
0111 | MULTI-ANCESTRY WHOLE-GENOME STUDY IDENTIFIES POPULATION-SPECIFIC EFFECTS OF *PNPLA3*, *TM6SF2*, *MBOAT7*, *HSD17B13*, AND *MARC1* ON CIRRHOSIS, MASLD, AND HEPATOCELLULAR CARCINOMA IN 414,830 ALL OF US PARTICIPANTS



Hyunseok Kim[1] Walid Ayoub[1] Alexander Kuo[2] Paul Martin[2] Aarshi Vipani[2] Yun Wang[2] Yee Hui Yeo[2] Debiao Li[2] Stephen Pandol[2] Suthat Liangpunsakul[3] Juan Pablo Arab[4] Shelly Lu[2] JuDong Yang[2], [1]Cedars-Sinai Medical Center, [2]Cedars Sinai Medical Center, [3]Indiana University Medical Center, [4]Virgina Commonwealth University Medical Center

Background: Five variants (*PNPLA3* rs738409, *TM6SF2* rs58542926, *MBOAT7* rs641738, *HSD17B13* rs72613567, and *MARC1* rs2642438) shape risk of cirrhosis, metabolic dysfunction-associated steatotic liver disease (MASLD), and hepatocellular carcinoma (HCC). Per-allele effects derive predominantly from European-ancestry cohorts (UK Biobank, GenomALC); generalizability to U.S. admixed and African-ancestry populations is unclear. We characterized variant frequencies, U.S. population burden, and ancestry-specific liver disease associations in the largest multi-ancestry whole-genome sequencing (WGS) cohort to date. **Methods:** We analyzed 414,830 All of Us participants with short-read WGS (CDR v8; median age 60, 61% female; 52% Non-Hispanic White, 19% Hispanics, 18% Non-Hispanic Black, 3% Asian). Participants were assigned to gnomAD-derived ancestry groups: European (EUR; n = 234,353, reference), African (AFR; n = 84,148), Admixed American (AMR; n = 79,106, predominantly Hispanics), East Asian (n = 10,099), South Asian (n = 5,579), and Middle Eastern (n = 1,545). Outcomes: cirrhosis (n = 7,216), ICD-coded MASLD (n = 21,813), HSI ≥ 36-based MASLD (as a sensitivity definition, n = 124,074), and HCC (n = 627). Per-allele logistic regression adjusted for age, sex, BMI, diabetes, heavy alcohol exposure, and 5 ancestry PCs. U.S. burden estimates used AoU allele frequencies × Census 2024 adult distributions. **Results:** Allele frequencies matched gnomAD v4 (e.g., PNPLA3 G: EUR 0.23, AFR 0.14, AMR 0.45). Projected U.S. burden: ~114M carry the PNPLA3 G risk allele,

95M the HSD17B13 TA protective allele, and 107M the MARC1 A protective allele. PNPLA3 showed substantial ancestry variation for cirrhosis (EUR OR 1.36, 95% CI 1.30-1.43; AFR 1.18, 1.06-1.31; AMR 1.54, 1.44-1.65), with similar pattern for MASLD-ICD; HCC effect was 1.64 in EUR ($p < 0.0001$) and 1.48 in AMR ($p < 0.01$) but null in AFR (1.24, $p = 0.20$). TM6SF2 was risk-conferring overall (cirrhosis OR 1.18, 1.10-1.26). MBOAT7 showed minimal cirrhosis association (OR 1.01, $p = 0.67$) despite high allele frequency, challenging European-derived estimates. MARC1 showed directional heterogeneity: protective in EUR (OR 0.94, 0.89-0.99) and AMR (0.83, 0.76-0.91) but risk-conferring in AFR (1.20, 1.06-1.37, $p < 0.01$), reversing the protective direction reported in UK Biobank European estimates (OR 0.87). HSD17B13 was broadly protective for cirrhosis (overall OR 0.87, $p < 0.0001$), with markedly stronger protection in AMR (OR 0.70, $p < 0.0001$). **Conclusion:** In a multi-ancestry U.S. population, canonical liver disease variants demonstrated substantial ancestry-specific heterogeneity in effect size and direction. European-ancestry estimates replicated in EUR but diverged in AMR and AFR, most strikingly for MARC1, which reversed direction. European-derived risk estimates may not uniformly generalize across diverse U.S. populations and support ancestry-aware genetic risk stratification.

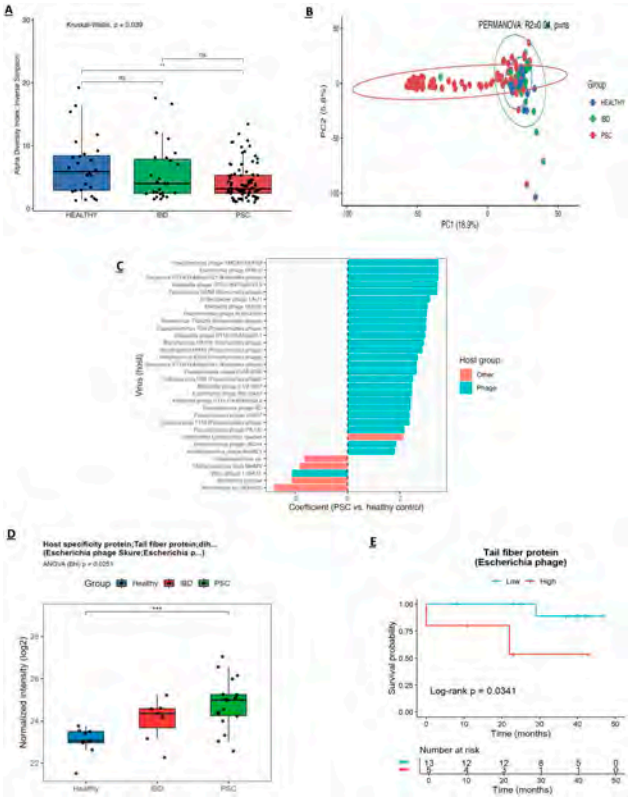
★ 0112 | FECAL VIROME IS ASSOCIATED WITH CLINICAL OUTCOMES IN PRIMARY SCLEROSING CHOLANGITIS



Srishti Saha[1] Burcin Özdirik[2] Frank Tacke[3] Derrick Fouts[4] Igor Wierzbicki[1] David Gonzalez[1] Bernd Schnabl[5], [1]University of California San Diego, [2]UCSD, [3]Charité-Universitätsmedizin Berlin, Germany, [4]J. Craig Venter Institute, [5]University of California, San Diego

Background: Growing evidence supports a role of the gut microbiome in primary sclerosing cholangitis (PSC), however, there are no studies exploring the virome. In this single-center study, we comprehensively studied the fecal virome in PSC and its link with clinical outcomes. **Methods:** Individuals with PSC, inflammatory bowel disease (IBD) and healthy controls (HC) were recruited from Charité-Universitätsmedizin Berlin, Germany. Fecal viruses were extracted using sequential filtration, concentration, nuclease treatment. Illumina NovaSeq X Plus (7 million 150bp paired end reads), hecatomb pipeline were used for viral read processing. For 16S, StrainID kit (spanning full 16S and partial 23S rRNA genes), SBanalyzer 2.4 (Shoreline Biome) were used for read mapping and annotation using PacBio-compatible barcoded primers with DADA2 for amplicon sequence variant inference. Proteomics was done on Thermo Scientific Orbitrap Astral mass spectrometer, analyzed with a custom UniProt-based database of identified viral species. Primary outcome was transplantation-free survival (survival free of transplantation and/or liver-related death). **Results:** The study included 141 participants (PSC = 86, IBD = 27, HC = 28). Viral alpha diversity was lower in PSC *vs* HC ($p = 0.04$, **Fig 1A**) and correlated with MELD (rho = 0.3, $p = 0.007$) and Mayo Risk Score (MRS; rho = 0.3, $p = 0.02$). Beta diversity was similar amongst the three groups (**Fig 1B**). Several viruses eg. *Pseudomonas*, *Escherichia*, *Klebsiella* phages, were enriched in PSC (**Fig 1C**). There was an inverse correlation between viral and bacterial alpha diversity (rho = -1.8, $p = 0.05$), though no concordance in their community structures (Procrustes $r = 0.11$, $p = 0.44$). Distance-based redundancy analysis revealed that the bacteriome composition significantly explained variation in the virome in HC, but not in PSC or IBD. Fecal proteomics revealed 150 viral proteins; those in PSC patients differed from HC ($p = 0.009$). Specifically, tail fiber protein of an *Escherichia* phage ($p = 0.025$) and TCP-1/cpn60 chaperonin family protein of a *Vibrio* phage ($p = 0.025$) were enriched in PSC (Tukey HSD

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

p < 0.001; **Fig 1D**). Survival analysis showed that high abundance of *Escherichia* phage tail fiber protein correlated with poorer transplant-free survival (p = 0.034; **Fig. 1E**), cirrhosis (p = 0.0025), higher MELD (p = 0.005) and higher MRS (p = 0.04). **Conclusion:** Fecal virome in PSC is enriched in phages infecting pathogenic gram-negative bacteria and healthy phage-bacteria coupling is lost in PSC. Viral alpha diversity, and fecal viral proteins-specifically an *Escherichia* phage tail fiber protein-correlate with disease severity and clinical outcomes.

0113 | LONG-READ METAGENOMICS REVEALS DISTINCT TRANSKINGDOM MICROBIAL SIGNATURES AND PHAGE-BACTERIA INTERACTIONS ACROSS THE CHOLESTATIC LIVER DISEASE SPECTRUM

Prooksa Ananchuensook[1] Jiaxian Shen[1] Shruti Patel[1] Yael Nobel[2] Etienne Nzabarushimana[1] Jordan S. L. Jensen[3] Daniel Sikavi[1] Jeremy Wilkinson[4] Gregory Gores[5] Andrew Chan[1] Curtis Huttenhower[3] Kelsey Thompson[3] Daniel Pratt[1] Long Nguyen[6], [1]Massachusetts General Hospital, [2]Columbia University Irving Medical Center, [3]Harvard T.H. Chan School of Public Health, [4]Pacific Biosciences of California, [5]Mayo Clinic, Rochester, Minnesota, USA, [6]Harvard University Medical School

Background: Primary sclerosing cholangitis (PSC) is a progressive cholestatic liver disease with no approved therapy. Its association with inflammatory bowel disease (IBD) implicates the gut-liver axis. However, prior 16S rRNA studies produced inconsistent bacterial signatures and ignored the gut virome, which may drive disease through phage-mediated bacterial shifts. No prior PSC microbiome study has employed long-read metagenomic sequencing, which enables strain-level bacterial and high-confidence viral profiling. Here, we leverage these advantages to define microbial signatures and phage-bacteria interactions in cholestatic liver disease. **Methods:** We prospectively enrolled 44 patients at Massachusetts General Hospital (2024 to 2026) with primary biliary cholangitis (PBC), PSC with IBD (PSC-IBD), or PSC without IBD (PSC-only). Stool underwent PacBio HiFi long-read metagenomic sequencing. Microbial species-level genome bins (SGBs) were profiled with MetaPhlAn v4. Viral genome bins (VGBs) were profiled with BAQLaVa v0.5, a high-resolution reference-based, assembly-free viral profiler for bulk metagenomes. Phage-bacterial host pairs were predicted with iPHoP and tested for covariation. Between-group differences used α/β diversity and linear discriminant analysis effect size. **Results:** Among 44 patients (21 PBC, 10 PSC-IBD, 13 PSC-only), PSC patients were younger (median 51 vs. 67 years) and more often male. Microbial and viral diversity trended highest in PSC-only (Fig. 1a). Microbial composition differed significantly across groups (PERMANOVA R2 = 5.8%, p = 0.038) with viral trending similarly (Fig. 1b). Pairwise comparisons revealed both overlapping and disease-specific signals, supporting our study's ability to disentangle PSC-specific features from those attributable to cholestasis or IBD comorbidity (Fig. 1c). PSC-only was enriched for Enterobacter hormaechei, a pro-inflammatory Proteobacterium (Fig. 1d). PSC-only emerged as the most ecologically distinctive subgroup, harboring 14 uniquely enriched SGBs (Fig. 1e), including Streptococcus

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

raffinosi, an oral-typical microbe. Among iPHoP-predicted phage-host pairs, Caudoviricetes and Oscillospiraceae, among several others, were strongly correlated in PSC-only (R = 0.77, p = 0.0089; Fig. 1f), consistent with network-structured, disease-specific multi-kingdom dysbiosis. **Conclusion:** Long-read transkingdom metagenomics reveals distinct microbial and viral signatures of cholestatic liver disease, particularly those attributable to PSC rather than cholestasis or concomitant IBD. Multicenter expansion, untargeted metabolomics, and strain-resolved genomics are underway to nominate bioactive microbial determinants and prioritize novel targets.

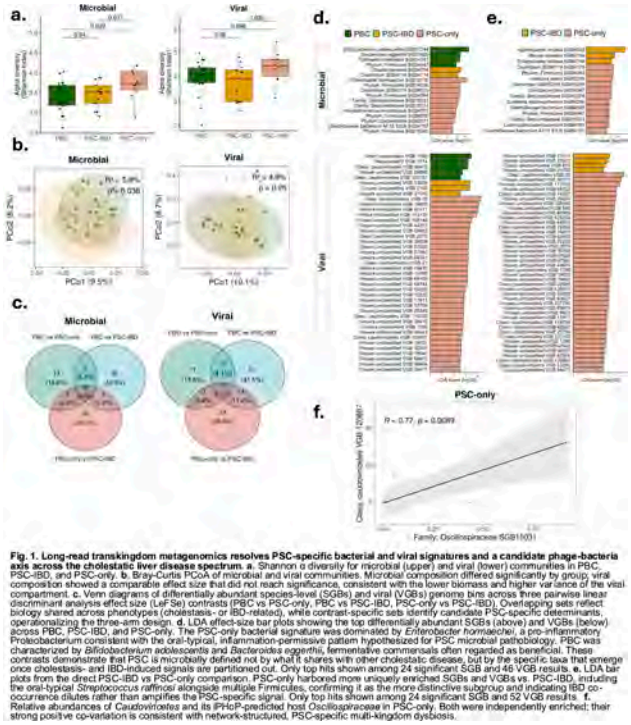

Fig. 1. Long-read transkingdom metagenomics resolves PSC-specific bacterial and viral signatures and a candidate phage-bacteria axis across the cholestatic liver disease spectrum. a. Shannon α diversity for microbial (upper) and viral (lower) communities in PBC, PSC-IBD, and PSC-only. **b.** Bray-Curtis PCoA of microbial and viral communities. Microbial composition differed significantly by group; viral composition showed a comparable effect size that did not reach significance, consistent with the lower biomass and higher variance of the viral compartment. **c.** Venn diagrams of differentially abundant species-level (SGBs) and viral (VGBs) genome bins across three pairwise linear discriminant analysis effect size (LeFSe) contrasts (PBC vs PSC-only, PBC vs PSC-IBD, PSC-only vs PSC-IBD). Overlapping sets reflect biology shared across phenotypes (cholestasis- or IBD-related), while contrast-specific sets identify candidate PSC-specific determinants, operationalizing the three-arm design. **d.** LDA effect-size bar plots showing the top differentially abundant SGBs (above) and VGBs (below) across PBC, PSC-IBD, and PSC-only. The PSC-only bacterial signature was dominated by *Enterobacter hormaechei*, a pro-inflammatory Proteobacterium consistent with the oral-typical, inflammation-permissive pattern hypothesized for PSC microbial pathobiology. PBC was characterized by *Bifidobacterium adolescentis* and *Bacteroides eggerthii*, fermentative commensals often regarded as beneficial. These contrasts demonstrate that PSC is microbially defined not by what it shares with other cholestatic disease, but by the specific taxa that emerge once cholestasis- and IBD-induced signals are partitioned out. Only top hits shown among 24 significant SGB and 46 VGB results. **e.** LDA bar plots from the direct PSC-IBD vs PSC-only comparison. PSC-only harbored more uniquely enriched SGBs and VGBs vs. PSC-IBD, including the oral-typical *Streptococcus raffinosi* alongside multiple Firmicutes, confirming it as the more distinctive subgroup and indicating IBD co-occurrence dilutes rather than amplifies the PSC-specific signal. Only top hits shown among 24 significant SGB and 52 VGB results. **f.** Relative abundances of Caudoviricetes and its iPHoP-predicted host *Oscillospiraceae* in PSC-only. Both were independently enriched; their strong positive co-variation is consistent with network-structured, PSC-specific multi-kingdom dysbiosis.

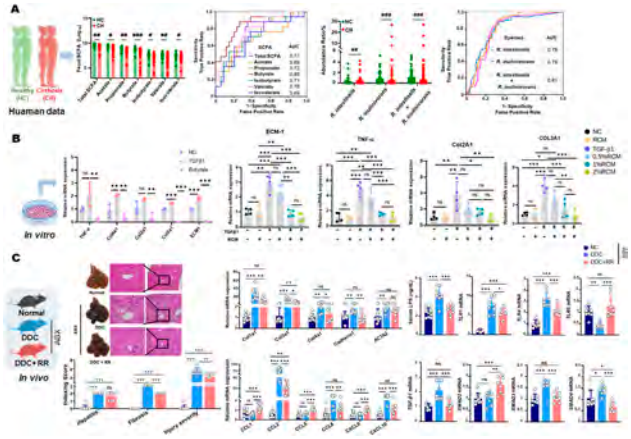
0114 | BUTYRATE-PRODUCING *ROSEBURIA* SPECIES RESTORATION ATTENUATES LIVER FIBROSIS BY GUT-LIVER LPS/TLR4/SMAD AXIS.



Satya Priya Sharma[1] HoYeong Yoon[2] Jeong Min Kim[2] Su A Kim[2] Hee-Jin Park[2] Goo Hyun Kwon[2] Kyeong Jin Lee[2] Jung A Eom[2] In Gyu Park[2] Sang Jun Yoon[2] Sung-Min Won[2] Ki-Kwang Oh[2] Gwang Ho Baik[2] Dong Joon Kim[2] Ki Tae Suk[2], [1]Institute for Liver and Digestive Diseases, [2]Institute for Liver and Digestive Diseases, Hallym University, Chuncheon, Republic of Korea

Background: Gut dysbiosis–mediated metabolic reprogramming critically influence cirrhosis progression thus health-promoting metabolite producing microbes become key regulators in cirrhosis. Here, we demonstrate that loss of butyrate-producing *Roseburia* functionally contributes to liver fibrosis. **Methods:** Fecal SCFAs (HC n = 17, cirrhosis n = 34) and microbiome abundance (HC n = 52, cirrhosis n = 142) were compared and evaluated by ROC analysis. Series of *in vitro* and *in vivo* experiments were conducted to define the functional role of butyrate-producing *Roseburia* in liver fibrosis. **Results:** In human cirrhosis data analysis, fecal microbial-metabolite profiling revealed broad depletion of SCFAs, and butyrate-producing *Roseburia* species. Total SCFAs and individual SCFAs were reduced, with butyrate showing the strongest diagnostic performance among SCFAs (AUC 0.85), while total SCFA yielded an AUC of 0.77. Consistently, *R. intestinalis* and *R. inulinivorans* were significantly decreased in cirrhosis, with individual AUCs of 0.78 and 0.79 and a combined *Roseburia* AUC of 0.81. *Roseburia* abundance positively correlated with SCFAs, albumin and platelets, and inversely correlated with MELD score, AST/ALT, bilirubin, INR and GGT, linking *Roseburia* species loss to impaired hepatic function and disease severity and identified a cirrhosis-associated loss of the *Roseburia*-butyrate axis. *In vitro*, this microbiome-metabolite axis showed direct antifibrotic activity. In LX-2 cells, butyrate and *Roseburia*-inoculated medium attenuated TGF-β1-driven stellate-cell activation, significantly suppressing ***TNF-***α, ***ECM1*** and collagen gene expression, with maximal inhibition at 1–2% RCM ($p < 0.05$–0.001). In antibiotic-depleted DDC mice, oral *R. intestinalis* + *R. inulinivorans* (RR) improved terminal body weight, reduced histologic fibrosis and injury severity scores (DDC vs RR: fibrosis 3 to 2; injury severity ~5 to ~4; $p < 0.01$–0.001), and improved AST, ALT, ALP, bilirubin and cholesterol. RR also suppressed hepatic extracellular-matrix and inflammatory markers, including ***Col1a1***, ***Col3a1***, ***Col4a1***, ***TGF-β1***, ***TNF-***α, ***IL-1beta***, ***CCL2***, ***CCL8*** and ***CXCL10***. Mechanistically, RR reduced serum LPS (~4.3 to ~2.7 ng/dL), ***TLR1*** (~7.5 to ~5.5), ***TLR4*** (~3.0 to ~2.0), *SMAD3* (~1.7 to ~1.1) and ***SMAD4*** (~1.4 to ~0.6), while ***TLR5*** increased toward normal and ***SMAD2*** showed a divergent increase. In non-antibiotic DDC mice, RR retained antifibrotic activity by reducing ALP, bilirubin, histologic hepatitis/fibrosis/injury scores and ***Col1a1*** / ***Col3a1*** expression, although AST, ALT and cholesterol were not significantly changed. **Conclusion:** Depletion of *Roseburia* and butyrate defines a

cirrhosis-associated microbiome-metabolite signature. Repletion with *R. intestinalis* + *R. inulinivorans* limited liver injury, fibrosis, endotoxemia, TLR4 and SMAD3/4 signaling, supporting *Roseburia*-based gut-liver axis restoration as a candidate antifibrotic approach.

★ 0115 | HUMORAL IMMUNE DYSFUNCTION DEFINES HIGH-RISK CIRRHOTIC ASCITES

Arielle Klepper[1] Matt Zinter[1] Tamara Roach[1] Ravi Dandekar[1] Sammer Ganem[1] Sukhman Sidhu[1] Zoe Berman[1] Ishaan Dureja[1] Karina Perlaza[1] Bryan Castillo-Rojas[1] Kelsey Zorn[1] Jacquelyn Maher[1] Jody Baron[1] Matthew Yocum[1] Andrew Lai[1] Jennifer Lai[1] Joseph DeRisi[1], [1]University of California, San Francisco

Background: Among patients with cirrhosis, infection is a leading driver of acute decompensation and mortality. Spontaneous bacterial peritonitis (SBP), one of most common infections, occurs predominantly in the ascites fluid of patients with cirrhosis. However, the host and microbial determinants of SBP and mortality in cirrhosis remain incompletely defined. **Methods:** To identify ascites-associated factors linked to mortality in cirrhosis, we collected ascitic fluid from 111 patients: 61 patients with cirrhosis and 50 non-cirrhotic controls (primarily malignancy or heart failure). RNA-based metagenomic next-generation sequencing (mNGS) was used to simultaneously profile host and microbial transcriptomic signatures. Host cell subtypes in ascites were classified using spectral flow cytometry, cell sorting, and single-cell RNA sequencing. Humoral effector responses were measured directly in ascites, including B cell receptor sequencing, Ig subclass measurement, and IgA dimerization state. **Results:** Among patients with cirrhosis, host transcriptomic analysis revealed a marked downregulation of B cell and plasma cell genes, emerging as one of the predominant differences relative to non-cirrhotic ascites. In parallel, microbial mNGS demonstrated an absolute increase in oropharyngeal taxa known to be associated with cirrhosis: Viridans group streptococcus species (e.g. S. mitis) and anaerobes (e.g. F. nucleatum). We hypothesized that patients with cirrhosis would have reduced plasma cell numbers associated with the observed microbial changes. To measure immune cell populations in ascites, we performed flow cytometry in 8 patients (4 with cirrhosis, 4 without). Patients with cirrhosis demonstrated a marked reduction in the ratio of memory B cells (CD19+/CD27+) to naïve B cells (CD19+/IgD+; $p < 0.029$). We sorted CD19+ B cells from 4 patients (2 with cirrhosis, 2 without) and performed single-cell RNA sequencing. We observed a >10-fold reduction in plasma cells in cirrhosis, particularly IgG producing plasma cells. We measured ascites immunoglobulin levels in 81 patients (45 with cirrhosis, 36 without). Patients with cirrhosis had lower ascites IgG, which was associated with increased S. mitis abundance ($p < 0.05$). We also measured the fraction of monomeric versus dimeric IgA in ascites, revealing that a reduced fraction of dimeric IgA was associated with a significant increase in 90-day mortality in cirrhosis. **Conclusion:** We identified defining features of cirrhotic ascites: a marked reduction in the number of plasma cells and a commensurate decrease in the amount of IgG and dimeric IgA. Loss of dimeric IgA is known to impair mucosal IgA secretion and promote microbial translocation and inflammation in murine models. Our findings in human ascites parallel these observations, supporting a model in which impaired humoral immunity is a central determinant of microbial translocation and poor outcomes in cirrhosis.

0116 | EXERCISE REPROGRAMS A *BACTEROIDES UNIFORMIS*-CENTRIC MICROBIAL NETWORK TO ACTIVATE GLYCOSAMINOGLYCAN DEGRADATION IN PEDIATRIC MASLD

Yan Ni[1], [1]Zhejiang University School of Medicine Affiliated Children's Hospital

Background: Childhood obesity is strongly associated with MASLD progression, yet exercise-responsive microbial mediators that directly link physical activity to hepatic improvement remain undefined. We hypothesized that exercise acts through a discrete responder species capable of reprogramming the gut–liver metabolic axis. **Methods:** Two pediatric cohorts and a preclinical model were integrated. *Cohort 1 (n = 285):* Children with MASLD *(n = 180)*, obese controls *(n = 50)*, and healthy controls *(n = 55)* underwent fecal metagenomic sequencing with network reconstruction, metabolomic profiling, and correlation with liver injury markers ALT/AST.*Cohort 2 (n = 28):* Overweight/obese children (aged 8–17) completed a structured 3-week exercise program; paired pre/post metagenomics and metabolic profiling were performed.*Preclinical: Bacteroides uniformis* (BU) from healthy donors was administered to HFD-obese mice (2×10^9 CFU/mL, 3×/week, 12 weeks) with multi-omics analysis. **Results:** In Cohort 1, pediatric MASLD was characterized by depletion of *B. uniformis*, *Phocaeicola vulgatus*, and *Parabacteroides distasonis*. BU was the strongest negative correlate of ALT and AST ($p < 0.05$), identifying it as a central hub linking microbial community structure to hepatic injury. In Cohort 2, exercise significantly improved BMI Z-score, TC, TG, and LDL. Metagenomics demonstrated consistent enrichment of BU as the dominant exercise-responsive species. Functionally, exercise induced coordinated activation of glycosaminoglycan (GAG) degradation—a distinct post-exercise metabolic signature absent at baseline and orthogonal to the carbohydrate dysregulation defining MASLD. In HFD mice, BU supplementation recapitulated the human responder phenotype, reducing weight gain, improving glucose tolerance, and decreasing ALT/AST. Integrated metagenomics and transcriptomics confirmed BU-driven GAG degradation in gut microbiome and hepatic tissue, with downstream improvement in lipid metabolic homeostasis. **Conclusion:** *Bacteroides uniformis* is a keystone exercise-responsive species linking physical activity to hepatic improvement in pediatric MASLD. Exercise rewires the gut–liver axis through a BU-driven GAG degradation program—a previously unrecognized hepatoprotective mechanism. BU-associated GAG metabolism represents a novel biomarker of exercise response and therapeutic target for microbiome-based intervention in pediatric MASLD.

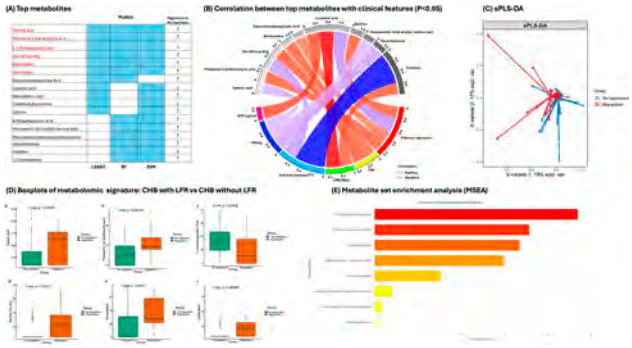
0117 | A MACHINE LEARNING-DERIVED GUT METABOLOMIC SIGNATURE PREDICTS REVERSAL OF LIVER FIBROSIS IN PATIENTS WITH CHRONIC HEPATITIS B



Lu Li[1] Saisai Zhang[1] Zhe Zhang[1] Ning Ma[1] Wenyi Tan[1] Wenjie Li[1] Lung-Yi Mak[1] Man-Fung Yuen[1] Wai-Kay Seto[1], [1]The university of Hong Kong

Background: Gut bacterial metabolites mediate host-microbe interactions via the gut-liver axis and influence disease progression, their contribution to liver fibrosis regression (LFR) in chronic hepatitis B (CHB) remains unknown. Here, we aimed to identify gut microbiota-derived metabolic signatures for predicting LFR in CHB. **Methods:** We enrolled CHB patients who had received nucleos(t)ide analogue therapy (serum HBV DNA < 10 U/mL for ≥ 12 months), a baseline liver stiffness measurement (LSM) ≥ 7 kPa recorded at least 3 years prior, and a follow-up LSM at enrollment. LFR was defined as an absolute LSM decrease > 30% from baseline, and fecal samples were collected for untargeted metabolomic profiling. Three machine learning (ML) models, including least absolute shrinkage and selection operator (LASSO), support vector machine (SVM), and random forest (RF), were applied to identify metabolic biomarkers for predicting LFR. Metabolite set enrichment analysis (MSEA) was performed to characterize pathway alterations between patients with and without LFR. **Results:** A total of 124 CHB patients (72.5% male, 61.3% liver steatosis, 63.7% type 2 diabetes) were included and all three models successfully differentiated patients with LFR (n = 36) from those

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

without LFR (n = 88), with the highest accuracy of 0.84. To identify key metabolites for LFR, we selected the top 20 from each of three models and defined those identified by all three models as 'metabolomic signatures', which included testolic acid, phenazine-1,6-dicarboxylic acid, L-2-Hydroxyglutaric acid, Glu-Gln-Lys-Arg, strictosidine, and telmisartan. Among these, five showed significantly higher levels in LFR samples (t-test, P < 0.05). Sparse partial least squares discriminant analysis (sPLS-DA) constructed from the 'metabolomic signatures' revealed a clear separation between samples with and without LFR. Correlation analysis between metabolites identified by at least two models and clinical features shows that phenazine-1,6-dicarboxylic acid (p = 0.017), glycochenodeoxycholic acid (p = 0.039),quinine (p = 0.017) were all significantly positively correlated with LFR, whereas levullinic acid shows negative correlation with LFR (p = 0.002) and positive correlation with higher LSM (p = 0.003). Metabolite set enrichment analysis (MSEA) revealed the significant enrichment of pentose phosphate pathway in the patients with LFR (ER = 23.53,p = 0.042). **Conclusion:** This study identified a metabolomic signature for LFR by ML models, offering new insights into gut bacterial metabolites in CHB patients. Our findings provide a scientific basis for further exploration of non-invasive biomarkers and therapeutic targets for CHB. This study was supported by Shenzhen Natural Science Foundation Basic Research Fund-General Program (JCYJ20250604180826035).

0118 | DISPARITIES IN ELECTRONIC HEALTH RECORD PATIENT PORTAL ENGAGEMENT AMONG ADULTS WITH CIRRHOSIS: AN EPIC COSMOS STUDY

Oren Fix[1] Sasha Deutsch-Link[2] Hersh Shroff[2], [1]University of North Carolina at Chapel Hill, [2]UNC Chapel Hill

Background: Electronic health record (EHR) patient portals are increasingly central to communication and care coordination in hepatology. However, because of the digital divide, portal-based care may worsen inequities if access is uneven. We evaluated demographic and socioeconomic differences in EHR patient portal engagement among adults with cirrhosis. **Methods:** We conducted a retrospective, cross-sectional analysis using aggregate data from March 2020-May 2026 in Epic Cosmos, a dataset created in collaboration with a community of Epic health systems representing over 300 million patient records. The cohort included adults ≥ 18 years residing in the United States with billed ICD-10 codes for cirrhosis (K70.3, K70.31, K70.30, K74.6, K74.69, or K74.60). Outcomes were current active patient portal (MyChart, Epic Systems, Verona, WI) status and patient portal access within the preceding 90 days. Portal engagement was compared across age, sex, race, ethnicity, language, primary payer, Rural-Urban Commuting Area (RUCA), Area Deprivation Index (ADI), and Social Vulnerability Index (SVI). Analyses used aggregate counts with chi-square tests, unadjusted odds ratios (ORs), and trend tests for

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

ordered variables. **Results:** Among 1,713,212 adults with cirrhosis, 1,010,251 (59.0%) had active MyChart status and 618,435 (36.1%) had portal access within 90 days (see Table). Active portal status declined from 80.4% among patients aged 18-24 years to 56.0% among those aged ≥65 (OR 0.31, 95% CI 0.29-0.33). Compared with White patients (37.7%), Black/African American (27.9%; OR 0.64, 95% CI 0.63-0.65) and American Indian/Alaskan Native patients (28.5%; OR 0.66, 95% CI 0.64-0.67) demonstrated lower engagement as measured by recent portal access. Lower portal engagement was also observed with male sex, Hispanic ethnicity, non-English language preference, non-commercial insurance, micropolitan/small town/rural residence, and higher ADI and SVI. All comparisons and trend analyses were statistically significant ($p < 0.001$). **Conclusion:** In this large Epic Cosmos cohort of adults with cirrhosis, substantial disparities in EHR patient portal engagement were observed across sociodemographic variables. Given the large cohort size, statistical significance was expected for many comparisons; however, the observed absolute differences and effect sizes support clinically meaningful inequities in portal engagement. Recent portal access may more accurately reflect active patient engagement than activation status alone because many health systems automatically activate MyChart accounts during routine clinical workflows. These findings suggest that increasing reliance on portal-based healthcare delivery may risk amplifying existing inequities in hepatology care without targeted digital inclusion strategies and nonportal communication pathways.

Table: Variables associated with EHR patient portal engagement among adults with cirrhosis

	N	Active Portal Status N (%)	Active Portal Status OR (95% CI)	Recent Portal Access N (%)	Recent Portal Access OR (95% CI)

0119 | SOCIAL DETERMINANTS OF HEALTH, RATHER THAN DISEASE SEVERITY, DRIVE SECOND-LINE THERAPY ESCALATION IN PRIMARY BILIARY CHOLANGITIS

Liliana Vittini-Hernandez[1] Lital Aliasi-Sinai[1] Christopher Kim[1] Jihae Jeon[1] Francina Collado[1] Douglas Dieterich[1] Anna Mageras[1] Frances Lee[1], [1]Icahn School of Medicine at Mount Sinai

Background: Patients with primary biliary cholangitis (PBC) and inadequate biochemical response to ursodeoxycholic acid (UDCA) are candidates for second-line (2L) therapy. Prior work in our cohort showed race and insurance status resulted in differences in 2L escalation. Here, we sought to determine whether laboratory markers of disease severity or hepatic fibrosis stage were associated with prescription of 2L therapy. **Methods:** This was a single-center retrospective cohort study from 2000-2025. Adults with PBC (ICD-10 code), ALP >200 IU/L, and active UDCA for ≥12 months were considered eligible for 2L therapy. The primary outcome was 2L therapy prescription. Covariates included age, sex, race, preferred language, marital status, insurance type, laboratory values (bilirubin, albumin, platelets, INR), and transient elastography (TE) results. Firth penalized logistic regression was used for univariable and multivariable analyses using R. A separate multivariable model incorporating lab variables was constructed. Hepatic fibrosis stage or liver stiffness measurements (LSM) on TE were assessed in 88 patients using Fisher's exact test and Cochran-Armitage trend test. **Results:** Among 262 eligible patients, the mean age was 64 years; 88% were female, 51% White, 12% Hispanic, 7% Black, and 8% uninsured. Overall, 76 patients (29%) received 2L therapy. 73.7% had no documented discussion of escalation, and no Black patients received 2L therapy (0/19). Only 1 of 22 uninsured patients (4.5%) received 2L therapy. In the demographics-only multivariable model, Black race (aOR 0.051, 95% CI 0.000–0.404, $p = 0.001$) and uninsured status (aOR 0.147, 95% CI 0.016–0.639, $p = 0.008$) were the only independent negative predictors of escalation. After incorporation of laboratory values ($n = 248$), these associations persisted for Black race (aOR 0.051, 95% CI 0.000–0.423, $p = 0.002$) and uninsured status (aOR 0.166, 95% CI 0.018–0.724, $p = 0.014$), while no laboratory variable was independently associated with 2L therapy initiation. Among 88 patients with TE data, escalation rates were similar across LSM (Fisher's exact test (OR 0.84, 95% CI 0.31–2.25, $p = 0.821$), Cochran-Armitage trend test ($Z = -0.23$, $p = 0.821$)). **Conclusion:** Black race and

uninsured status remain the sole predictors of failure to escalate treatment, even after accounting for laboratory markers of disease severity and hepatic fibrosis stage. These findings suggest that social determinants of health, rather than clinical disease burden, may be the primary drivers of 2L treatment disparity. Targeted interventions addressing racial and insurance-based barriers are needed to promote equitable escalation of PBC therapy. Future studies should evaluate physician-, system-, and patient-level barriers to 2L initiation to better understand missed opportunities for treatment escalation.

0120 | UNEQUAL ACCESS TO CURATIVE THERAPY: RACIAL AND ETHNIC DISPARITIES IN DIRECT-ACTING ANTIVIRAL TREATMENT FOR CHRONIC HEPATITIS C IN THE UNITED STATES

Abbas Syed[1] Mohammad Dawar Zahid[2] Victor Akinditan[1] Syed Hasan[1] Khurram Bari[3], [1]University of Cincinnati, [2]AGA KHAN UNIVERSITY, [3]University of Cincinnati, University Hospital Inc Program

Background: Direct-acting antivirals (DAAs) have transformed the treatment of chronic hepatitis C virus (HCV) infection and offer the potential for cure in most treated patients. However, equitable access to DAA therapy remains essential to achieving HCV elimination goals. We performed a systematic review and meta-analysis evaluating racial and ethnic disparities in DAA treatment initiation among adults with chronic HCV infection in the United States. **Methods:** A systematic review of PubMed and Scopus identified U.S based studies published from 2014 onward evaluating racial and ethnic disparities in DAA treatment initiation among adults with chronic HCV infection. Of 685 identified studies, 70 duplicates were removed and 46 studies underwent full text review following title and abstract screening. Twelve observational studies met inclusion criteria, comprising 660,513 patients. Two reviewers independently screened studies and extracted data, with disagreements resolved by consensus. As most included studies utilized multivariable analyses to reduce confounding, adjusted odds ratios (aORs) were preferentially used for pooled analysis. Random-effects meta-analyses were performed to calculate pooled odds ratios (ORs) with 95% confidence intervals (CIs), and heterogeneity was assessed using the I^2 statistic. **Results:** Twelve observational studies comprising 660,513 patients with chronic HCV infection were included. Black patients demonstrated lower odds of receiving DAA therapy compared with White patients (pooled OR 0.88, 95% CI 0.80–0.98; $I^2 = 86.1\%$). Hispanic patients similarly demonstrated lower odds of DAA treatment initiation (pooled OR 0.74, 95% CI 0.57–0.96; $I^2 = 88.0\%$). In the overall comparison of non-White versus White patients, minority populations had lower odds of receiving DAA therapy (pooled OR 0.83, 95% CI 0.75–0.91; $I^2 = 86.4\%$). Although substantial heterogeneity was observed across analyses, the direction of effect was largely consistent across studies (as seen in forest plot in Image 1), with most demonstrating lower treatment uptake among racial and ethnic minority populations despite differences in study populations and healthcare settings. **Conclusion:** Racial and ethnic disparities in access to curative HCV therapy persist in the DAA era in the United States, with lower odds of DAA treatment initiation among Black, Hispanic, and overall non-White patients compared with White patients. Future research should focus on identifying the underlying drivers of these disparities and developing targeted interventions to ensure equitable access to curative HCV therapy.

0121 | SOCIAL DETERMINANTS OF HEALTH AND HCC SURVEILLANCE RECEIPT IN PATIENTS WITH CIRRHOSIS: A MULTICENTER COHORT STUDY

Mohammed Al-Hasan[1] Nicole Rich[1] Lisa Quirk[1] Juana Campos[2] Yan Liu[2] Mohammad Jarrah[1] Eunice Amador[1] Samantha Rangel Silos[1] Kayleen Sorto[1] Jahna Anyanwu[2] Amanda Gibbons[2] Valeria Londono[2] Gabriela Morales Pielago[2] Aaron Nguyen[2] Dalal Youssef[2] Jennifer Kramer[2] Fasiha Kanwal[3] Amit Singal[1], [1]University of Texas Southwestern Medical Center, [2]Baylor College of Medicine, [3]Michael E. DeBakey VA Medical Center

Background: Social determinants of health (SDOH) contribute to failures across the cancer care continuum for several cancer types; however, their association with hepatocellular carcinoma (HCC) surveillance receipt among patients with cirrhosis remains understudied. **Methods:** We prospectively enrolled patients with cirrhosis from four large health systems in the U.S. All patients were required to have at least one outpatient visit in the previous year, demonstrating connectedness to clinical care. Patient completed validated surveys to capture SDOH factors including education, income, insurance, health literacy, housing stability, and barriers to liver care. We collected clinical and HCC surveillance data from electronic medical records. Surveillance was defined as receipt of either abdominal ultrasound, contrast-enhanced MRI, or multiphase CT at semi-annual or annual intervals during the year before and after survey administration. We also defined proportion of time covered (PTC) over an 18-month window (6 months prior and 12 months after survey), with 6 months of coverage provided for each imaging study. Multivariable ordinal logistic and Tobit regression models were used to examine factors associated with surveillance. **Results:** Of 1,326 eligible patients (median age 62 years, 59.3% men, 42.0% non-Hispanic White), 29.6% had HCV-, 26.9% alcohol-, and 27.3% had MASLD-related cirrhosis; 60.0% had Child Pugh A cirrhosis. Although most patients (61.4%) completed annual surveillance, only 25.9% completed semi-annual surveillance. The median PTC was 65.5% (IQR 33.5-85.2%). Factors associated with surveillance are detailed in **Table 1**. In multivariable analysis, semi-annual surveillance was positively associated with higher educational attainment (college vs. high school or less: OR 1.50, 95% CI 1.15-1.96), alcohol-associated liver disease (OR 1.60, 95% CI 1.16-2.21), and Child-Pugh C cirrhosis (vs. Child Pugh A: OR 1.80, 95% CI 1.19-2.73), while it was inversely associated with female gender (OR 0.73, 95% CI 0.58-0.93), Spanish language (OR 0.64, 95% CI 0.42-0.98), Medicaid insurance (OR 0.55, 95%CI 0.34-0.86), and self-reported barriers to liver care (4th vs. 1st quartile: OR 0.60, 95% CI 0.44-0.82). Results were similar for factors associated with annual surveillance and PTC (**Table 1**). **Conclusion:** Only a few patients with cirrhosis completed semi-annual HCC surveillance. Beyond traditional demographic and clinical factors, several SDOH including educational attainment, insurance coverage, and patient-reported barriers to care are associated with surveillance receipt. Addressing barriers to liver care and a focus on underinsured patients belonging to high-risk subgroups may improve surveillance utilization and early-stage HCC detection.

0122 | SAME DISEASE, DIFFERENT HOSPITAL: RURAL VS. URBAN OUTCOMES IN ALCOHOL-ASSOCIATED HEPATITIS

Het Patel[1] Daniel Guirguis[1] Erik Dehkes[1] Hammad Liaquat[1], [1]St. Luke's University Healthcare Network

Background: Alcohol-associated hepatitis is a severe form of liver disease associated with high inpatient morbidity and mortality. Differences in healthcare access and hospital resources between rural and urban settings may influence management and outcomes. This study evaluated differences in patient characteristics and clinical outcomes between rural and urban hospitalizations using a nationally representative database. **Methods:** We conducted a retrospective cohort study using the National Inpatient Sample (NIS) database, identifying adults hospitalized between 2019 and 2022 with alcohol-associated hepatitis without cirrhosis and comparing demographics, comorbidities, hospital characteristics, and inpatient complications in rural versus urban hospitals. Univariate analyses were performed using STATA software. **Results:** Of the 47,295 patients who met inclusion criteria, the majority (57%) were male, with a mean age of 44 years in both rural and urban groups ($p \geq 0.05$). White (OR 1.670 95% CI 1.439-1.938) and Native American patients (OR 4.436 95% CI 3.319-5.929), as well as patients with COPD (OR 1.447 95% CI 1.133-1.846), were more likely to receive care at rural hospitals, whereas Black (OR 0.380 95% CI 0.288-0.501), Hispanic (OR 0.352 95% CI 0.259-0.477), and Asian (OR 0.192 95% CI 0.071-0.518) patients were less likely. No significant differences were observed in gender distribution or Charlson Comorbidity Index (CCI) between groups ($pP \geq 0.05$). Rural hospitals had higher odds of ascites (OR 1.270 95% CI 1.107-1.457) and spontaneous bacterial peritonitis (OR 1.786 95% CI 1.107-2.882), but lower odds of sepsis (OR 0.753 95% CI 0.577-0.984). Hospital mortality did not differ between groups (≥ 0.05). No differences were observed in variceal bleeding, paracentesis, acute kidney injury, hepatic encephalopathy, vasopressor use, acute liver failure, liver transplantation, ICU admission, mechanical ventilation, length of stay and total hospitalization charges ($p \geq 0.05$). **Conclusion:** Despite prior population-level studies demonstrating higher alcohol-associated liver disease mortality in rural populations, inpatient mortality and major clinical outcomes were similar between rural and urban hospitals in our cohort. These findings suggest comparable inpatient management and outcomes for alcohol-associated hepatitis across both settings, potentially reflecting effective triage and transfer systems with improved treatment protocols in rural settings. Further prospective studies could help investigate this further.

Table 1: Demographics

	Rural Hospital (n = 5,845)	Urban Hospital (n = 41,450)	p value	Odds Ratio (95% Confidence Interval)
Mean Age, years	44.7	44.3	0.365	-

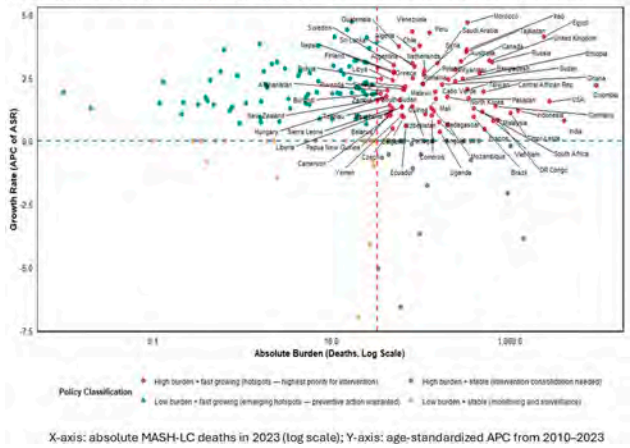
0123 | METABOLIC DYSFUNCTION-ASSOCIATED STEATOHEPATITIS (MASH) OUTPACING ALCOHOL-ASSOCIATED LIVER DISEASE (ALD) AS THE PRINCIPAL DRIVER OF RISING STEATOTIC LIVER DISEASE-ASSOCIATED LIVER CANCER

Eliabe Abreu[1] James Paik[1] Manal Abdelmalek[2] Robert Wong[3] Khalid AlNaamani[1] Saleh Alqahtani[4] Zobair Younossi[5], [1]Global NASH/MASH Council, [2]Mayo Clinic Rochester, [3]Stanford/VA Palo Alto Healthcare System, [4]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [5]The Global NASH/MASH Council



Background: Steatotic liver disease (SLD), fueled by rising epidemics of obesity, diabetes, and hazardous alcohol use, has been recently incorporated into the WHO global noncommunicable disease agenda. We evaluated global trends in SLD-associated liver cancer (SLD-LC) from 2010 to 2023, characterizing the burden and growth of MASH versus ALD. **Methods:** SLD-LC was defined by combining MASH- and ALD-attributable LC from GBD 2023 per multi-society nomenclature. Annual percent change (APC) in age-standardized rates was estimated using Joinpoint Regression for 2010–2023, 2010–2019, and 2019–2023. Countries were classified into four policy-relevant quadrants based on median absolute MASH-LC deaths in 2023 and APC > 0 as thresholds to identify nations where high disease burden coincides with rising trends, requiring urgent intervention: high burden + fast growing (hotspots), high burden + stable, low burden + fast growing, and low burden + stable. **Results:** Between 2010 and 2023, prevalent SLD-LC cases increased from 147,686 to 216,947 (+46.9%). In 2023, SLD-LC accounted for 24.0% of all LC deaths globally, with an estimated 136,789 deaths. SLD-LC was the only major etiology group with a consistently positive age-standardized APC across all four burden measures: deaths (+0.36%), incidence (+0.35%), prevalence (+0.33%), and DALYs (+0.42%), while HBV [range: -0.57% to -0.37%], HCV [-0.88% to -0.48%], and overall LC [-0.32% to -0.26%] all declined after age adjustment. MASH accounted for 28.9% of SLD-LC deaths in 2010, increasing to 30.5% by 2023 (Figure A). Despite this modest proportional shift, the APC for MASH-LC deaths (+0.85%) was six-times that of ALD (+0.15%), as MASH-LC never declined across any timeframe or burden measure, in contrast to ALD which decreased from 2010 to 2019 before accelerating post-2019. A marked inflection was observed after 2019: MASH-LC APC accelerated from +0.22% (2010–2019) to +2.30% (2019–2023), with the sharpest acceleration seen in DALYs (+2.69% post-2019). MASH-LC APC exceeded ALD-LC in 17 of 21 GBD regions, with the highest growth in Southern Latin America (+3.59%), North Africa and Middle East (+2.95%), and Australasia (+2.92%). Notably, 27 countries had MASH comprising more than 50% of SLD-LC deaths, predominantly in North Africa and the Middle East, including Saudi Arabia (79.9%), Iran (65.2%), and Egypt (61.8%). Policy classification identified 84 (41%) countries as MASH-LC hotspots, with the highest APC observed in Morocco, Venezuela, and Peru (Figure B) **Conclusion:** SLD-LC burden increased globally from 2010 to 2023, driven principally by MASH-LC, which never declined across any burden measure and accelerated markedly after 2019. Policy classification identified nations requiring immediate public health prioritization, underscoring the urgent need for metabolic disease management and targeted LC surveillance strategies worldwide.

Figure. Global Burden and Policy Classification of MASH-Associated Liver Cancer, 2010–2023.

(A) Proportion of MASH versus ALD within SLD-associated liver cancer deaths by GBD region for 2010 and 2023, sorted by 2023 MASH proportion in descending order.

(B) Country-level policy classification matrix of MASH-associated liver cancer mortality.

X-axis: absolute MASH-LC deaths in 2023 (log scale); Y-axis: age-standardized APC from 2010–2023

0124 | HISPANIC/LATINO LIVER TRANSPLANT CANDIDATES HAVE LOWER ACCESS TO LIVING DONOR LIVER TRANSPLANTATION IN THE UNITED STATES: A NATIONAL COMPETING-RISK ANALYSIS

Tulio L Correa[1] Leandro Sierra[2] Ximena Parraga[3] Luiz A Díaz[4] Douglas Simonetto[5] Juan Pablo Arab[6],
[1]University of Pittsburgh, [2]Cleveland Clinic Foundation, [3]Virginia Commonwealth University School of Medicine, [4]Departamento de Gastroenterologia, Escuela de Medicina, Pontificia Universidad Catolica de Chile, [5]Mayo Clinic Rochester, [6]Virginia Commonwealth University

Background: Living donor liver transplantation (LDLT) expands access to liver transplantation, yet Hispanic/Latino patients remain underrepresented among transplant recipients despite a high burden of chronic liver disease. We aimed to evaluate disparities in access to LDLT between Hispanic/Latino and non-Hispanic White candidates using a national competing-risk analysis. **Methods:** We performed a retrospective cohort study using the OPTN/UNOS STAR registry of adult candidates listed for first-time, single-organ liver transplantation between 2014 and 2024. The primary exposure was Hispanic/Latino ethnicity. The primary outcome was receipt of LDLT. Fine-Gray competing-risk models were used to estimate subdistribution hazard ratios (sHRs) for LDLT, adjusting for age, sex, body mass index, MELD at listing, diabetes mellitus, liver disease etiology, insurance type, educational attainment, employment status, and citizenship/residency status. Deceased donor liver transplantation (DDLT) and waitlist death/removal were treated as competing events. **Results:** Among 118,385 candidates, 23,915 (20.2%) were Hispanic/Latino and 94,470 (79.8%) were non-Hispanic White. Hispanic/Latino candidates were younger (54.1 vs 55.2 years), more frequently female (40.1% vs 36.7%), and had higher rates of type 2 diabetes (35.1% vs 27.1%) and renal replacement therapy requirement (8.9% vs 6.1%) (all $P < 0.001$). They also had lower educational attainment, lower employment (21.2% vs 27.1%), greater Medicaid/public insurance use (54.3% vs 42.7%), and lower U.S. citizenship rates (80.6% vs 98.4%) (all $P < 0.001$). In addition, they spent longer on the waiting list (309.2 vs 281 days) and had higher final MELD-Na scores at transplant/removal (22.5 vs 21.6; both $P < 0.001$). LDLT receipt was significantly lower among Hispanic/Latino candidates (2.7% vs 3.8%, $P < 0.001$), as was DDLT receipt (51.3% vs 56.0%, $P < 0.001$). In adjusted competing-risk analysis, Hispanic/Latino ethnicity remained independently associated with lower likelihood of LDLT (sHR 0.86, 95% CI 0.76–0.96, $P = 0.009$) (Figure). **Conclusion:** Hispanic/Latino liver transplant candidates experienced significantly lower access to LDLT compared with non-Hispanic White candidates, even after adjustment for clinical and socioeconomic factors and competing events. Our findings may inform tailored strategies to improve access to LDLT among Hispanic/Latino candidates.

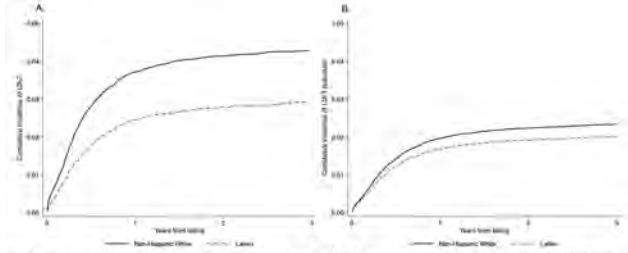

Figure. *Cumulative incidence of living donor liver transplantation among adult liver transplant candidates, by Latino ethnicity, OPTN/UNOS registry, 2014–2024.* ***Figure A.*** *Unadjusted cumulative incidence of living donor liver transplantation (LDLT) estimated using nonparametric competing-risk methods, treating deceased donor liver transplantation and waitlist death or removal as competing events. Three years after listing, the cumulative incidence of LDLT was 4.3% in non-Hispanic White candidates and 2.9% in Latino candidates.* ***Figure B.*** *Adjusted cumulative incidence of LDLT predicted from the Fine-Gray subdistribution hazard model (Table 3). After adjustment, Latino candidates had a 14% lower subdistribution hazard of LDLT receipt than non-Hispanic White candidates (subdistribution hazard ratio 0.86, 95% confidence interval 0.76–0.96, P=0.009). Abbreviations: LDLT, living donor liver transplantation; MELD-Na, Model for End-Stage Liver Disease–Sodium score; OPTN, Organ Procurement and Transplantation Network; UNOS, United Network for Organ Sharing.*

0125 | GEOGRAPHIC DISPARITIES LEAVE PATIENTS IN THE WESTERN US WITH UNEQUAL ACCESS TO LIVER TRANSPLANT FOR ALCOHOL-ASSOCIATED LIVER DISEASE

Sharmitha Yerneni[1] Russell Rosenblatt[2] Eytan Palte[1] Giuseppe Cullaro[1] Elizabeth Verna[1] Gene Im[1], [1]NYP - Columbia University Irving Medical Center, [2]Weill Cornell Medicine

Background: Alcohol-associated liver disease (ALD) is the leading indication for liver transplantation (LT) in the United States, however access to LT continues to vary across geographic regions. Examining population-based access to LT using disease-attributable mortality can identify barriers to equitable access to life-saving care. **Methods:** We conducted a retrospective study using data from the UNOS and CDC WONDER databases from 2011 to 2024. Adults aged 18 and older waitlisted for LT for either alcohol-associated cirrhosis or alcohol-associated hepatitis, and deaths attributed to these conditions, were included. The primary outcome was the listing-to-death ratio (LDR), defined as the ratio of LT waitlist registrations to ALD-related deaths. LDR provides a population-based measure of access to LT. Secondary outcomes included transplant-to-death ratio (TDR) and state-level Social Deprivation Index (SDI). Pearson correlation analysis was performed to evaluate associations between LDR, TDR, and SDI. **Results:** A total of 48,820 LT listings for ALD and 262,909 ALD-related deaths over 13 years were analyzed. At the state and UNOS region-levels, the LDR for ALD ranged from the lowest in Alaska and its UNOS region 6 (0.04, 0.06, respectively) to the highest in Maryland and its UNOS region 2 (0.63, 0.29, respectively), a greater than 15- and 4-fold difference, respectively (Figure A). There was significant interstate heterogeneity in LDR for ALD, with states in the highest quartile having LDRs 2-5 times greater than those in the lowest quartile; median 0.18 (IQR 0.12-0.23; Figure B). At the US census regional level, the West demonstrated a significantly lower LDR compared with the South (0.12 vs. 0.21, $p < 0.001$) and Midwest (0.12 vs. 0.19, $p < 0.001$), with the largest disparity observed relative to the Northeast (0.12 vs. 0.31, $p < 0.001$). Similar associations were observed for TDR. LDR was moderately inversely associated with state-level SDI ($r = -0.386$, $p = 0.005$), indicating lower LT access in states with greater socioeconomic deprivation (Figure C). **Conclusion:** Substantial geographic variation in access to LT for ALD was observed across the US, leaving patients in the Western US with unequal access compared to the Northeast. Causes of these disparities to access are complex, but specific to ALD, may include center-level variations in candidate selection and patient-level socioeconomic status factors.

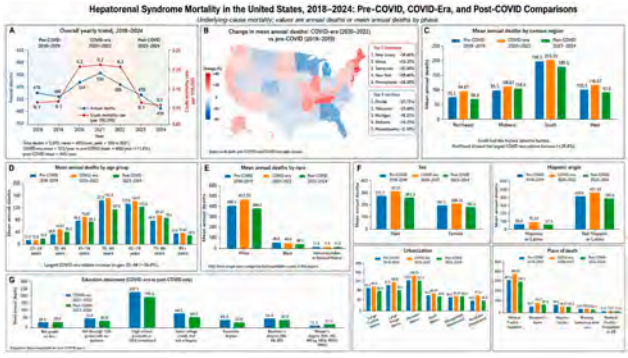
0126 | HEPATORENAL SYNDROME MORTALITY IN THE UNITED STATES, 2018–2024: PRE-COVID, COVID-ERA, AND POST-COVID NATIONAL TRENDS AND DISPARITIES



Naga Anvesh Kodali[1] Sri Ram Charan Gundapaneni[1] Pragathi Munnangi[2] Serene Sara John[3] Mounika Kotte[4] Jagadish Koyi[5] Hardik Dineshbhai Desai[6] Izuchukwu Nwakoby[1], [1]UCF/HCA Florida Ocala Hospital, Ocala, Florida, United States, 34471, [2]BronxCare Health System, Bronx, New York - 10457, [3]Detroit medical center, Detroit, Michigan, 48201, [4]Prime south consortium, Weslaco, Texas, USA,78596, [5]Integris Health, Oklahoma City, Oklahoma. USA. 73112, [6]AB Plus Multispecialty Hospital

Background: Hepatorenal syndrome (HRS) is a severe complication of advanced liver disease with high short-term mortality, but U.S. population-level mortality patterns across the COVID-19 period are poorly characterized. We evaluated national HRS mortality before, during, and after the COVID-19 era. **Methods:** We analyzed U.S. underlying-cause-of-death data for HRS from 2018–2024. Annual deaths, crude mortality rates, and age-adjusted mortality rates were assessed overall and by census region, state, urbanization, age, sex, race, Hispanic origin, education attainment, and place of death. Pre-COVID (2018–2019), COVID-era

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(2020–2022), and post-COVID (2023–2024) periods were compared using mean annual deaths. Annual percent change (APC) was estimated using log-linear regression. **Results:** From 2018–2024, 3,395 HRS deaths occurred in the United States (mean 485/year). Annual deaths rose from 476 in 2018 and 460 in 2019 to 514 in 2020 and peaked at 550 in 2021, then declined to 506 in 2022, 470 in 2023, and 419 in 2024. Mean annual deaths increased from 468/year pre-COVID to 523/year during COVID-era (+11.8%), then fell to 445/year post-COVID (-5.0% vs pre-COVID). The South had the highest absolute burden (1,368 total deaths; mean 198.5, 203.3, and 180.5 across pre-, COVID-, and post-COVID phases), while the Northeast showed the largest COVID-era relative increase (73.5 to 94.7/year; +28.8%). States with the greatest COVID-era increases versus pre-COVID were New Jersey (+38.5%), Illinois (+33.3%), Tennessee (+30.0%), New York (+28.5%), and Pennsylvania (+26.5%); the largest declines were in Florida (-27.7%), Wisconsin (-23.1%), Michigan (-18.5%), Alabama (-14.3%), and Massachusetts (-12.5%). Males consistently exceeded females (273.5 vs 194.5 pre-COVID; 317.0 vs 206.3 during COVID-era; 262.5 vs 182.0 post-COVID). The largest COVID-era relative increase by age occurred in 35–44 years (26.0 to 40.7/year; +56.4%), while the highest absolute counts were in 55–64 years (137.5 to 142.0) and 65–74 years (127.0 to 133.0). By race, mean annual deaths increased among White individuals (398.5 to 453.3; +13.8%) and slightly among American Indian/Alaska Native individuals (11.0 to 11.5; +4.5%), but decreased among Black individuals (48.0 to 46.0; -4.2%). Among Hispanic groups, deaths increased from 52.0 to 70.3/year (+35.3%) in Hispanic/Latino persons and from 415.0 to 451.3/year (+8.8%) in non-Hispanic/Latino persons. **Conclusion:** HRS mortality in the United States demonstrated a clear COVID-era surge followed by post-COVID decline, despite relatively stable population-level mortality rates. The burden remained concentrated in the South, men, and middle-to-older adults, with disproportionately large COVID-era relative increases in the Northeast, rural noncore areas, younger adults aged 35–44 years, and deaths occurring at home.

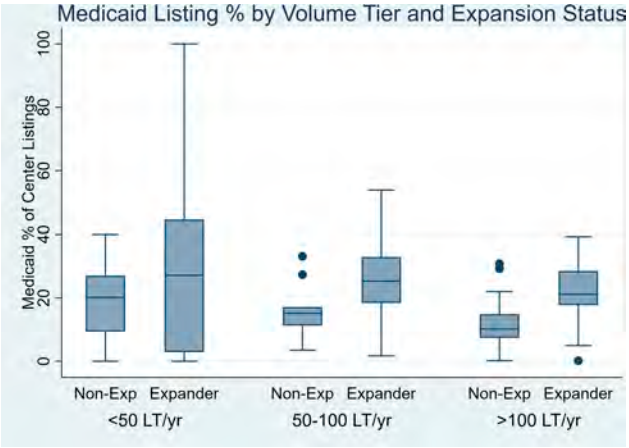
0127 | HAVING INSURANCE IS NOT ENOUGH: MEDICAID INSURED PATIENTS STILL LACK EQUITABLE ACCESS TO LISTING FOR LIVER TRANSPLANT



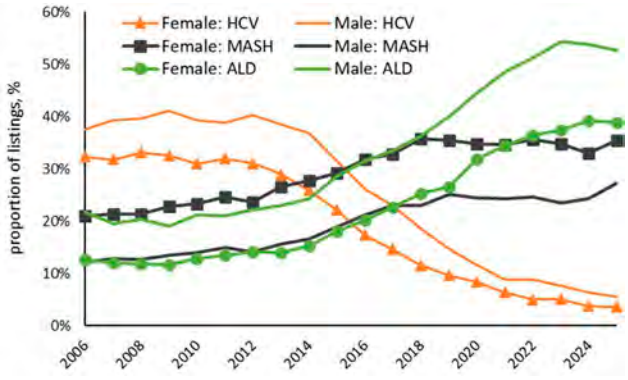
Russell Rosenblatt[1] David Goldberg[2], [1]Weill Cornell Medicine, [2]University of Miami

Background: Medicaid expansion increased insurance access to millions of Americans starting in 2014. This in turn has resulted in increased listings in patients listed for liver transplant (LT) in expansion states. However, it remains unclear if Medicaid patients have equitable access to all LT centers within each state. Therefore, we performed a state-level analysis to compare Medicaid patient listing rates in centers, stratified by Medicaid expansion status. **Methods:** Adults at time of listing from the UNOS STAR file from 2014-2024 were included. We compared states that expanded Medicaid in 2014 or never expanded. States with ≥ 3 centers were included. LT centers were assigned to states if $\geq 50\%$ of listed patients were from a single state. The primary outcome was the percentage of patients listed having Medicaid insurance. Outcomes were also stratified by center annual volume - low (<50), medium (50–100), or high (>100). Outcomes and distributional differences were compared using Wilcoxon rank-sum and two-sided Kolmogorov-Smirnov test, respectively. Finally, waitlist mortality by insurance type was assessed by multivariable competing risk regression, with covariates selected *a priori*. **Results:** This study included 114,778 patients listed in 33 states (21 expander, 12 non-expander) in 142 centers. 60.4% of patients in 93 centers were in expander states. More patients were listed with Medicaid insurance in expander states (23.6% vs 10.0%, $p<0.001$), with all non-expander centers $<40\%$ of listing being Medicaid-insured. There were significant differences in center-level distribution of Medicaid patients ($p<0.001$). As center volume increased, Medicaid listing proportion decreased among both cohorts and was most pronounced among highest volume (>100 LTs/year) centers – 23.2% vs 9.8%, $p<0.001$. As an example, in one non-expander state, two larger centers with a combined 2,800 listings during the study period each had 0.2% of patients with Medicaid insurance, while a center with 222 listings had 26.6% of patients with Medicaid insurance. Notably, LT volume alone did not

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

account for Medicaid proportion (p = 0.15). Transplant rates were not significantly different among expander status (p > 0.05). Finally, waitlist mortality was significantly lower in privately insured patients in both expander (sHR 0.82, 95% CI 0.76-0.89) and non-expander states (sHR 0.83, 95% CI 0.74-0.93), but Medicare was not significantly different in either cohort. **Conclusion:** Listing for LT in patients with Medicaid varies significantly among both centers and states. Understandably, Medicaid non-expanding states have worse access to LT listing for patients with Medicaid. This gap is even more pronounced in the highest-volume LT centers, further exacerbating disparities. Further research is needed to investigate why Medicaid patients continue to face disparities in access to the LT waitlist.



Disclosures: Russell Rosenblatt: Gilead: Grant/Research Support, David Goldberg: Nothing to Disclose.

0128 | SEX DISPARITIES IN THE LIVER TRANSPLANT JOURNEY: FROM CANDIDACY TO LONG-TERM OUTCOMES IN A 20-YEAR US COHORT

Linda Henry[1] Maria Stepanova[1] Giacomo Germani[1] Adrian Gadano[1] Patrizia Burra[1] Rohit Satoskar[2] Khalid AlNaamani[1] Saleh Alqahtani[1] Zobair Younossi[1], [1]The Global NASH/MASH Council, [2]Georgetown University Hospital

Background: Sex-related differences in chronic liver disease (CLD) epidemiology may influence liver transplantation (LT) listing and outcomes. We assessed sex-specific trends in CLD etiologies among LT candidates and recipients in the US. **Methods:** Adult LT candidates and recipients with CLD were identified from the Scientific Registry of Transplant Recipients (SRTR, 2006–2025). Etiologies included hepatitis B (HBV), hepatitis C (HCV), metabolic-dysfunction associated steatohepatitis (MASH), autoimmune hepatitis (AIH), alcohol-related liver disease (ALD), ALD+HCV, primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC), and other CLD. Sex-specific outcomes were compared. **Results:** Among 214,827 LT candidates, 78,610 (36.6%) were female. Males more likely to have ALD (34.5% vs. 24.4%), HCV (24.5% vs. 17.1%), HBV (3.0% vs. 1.3%), ALD+HCV (5.5% vs. 2.0%), and PSC (4.8% vs. 4.1%), whereas females more commonly had MASH (30.3% vs. 19.8%), AIH (6.3% vs. 1.4%), and PBC (6.9% vs. 0.7%) (all p < 0.0001).HCV listings declined in both sexes: 32.3% to 3.6% (females) and 37.6% to 5.6% (males). Steatotic liver disease increased with divergent patterns. Females: MASH 21.0%→35.5%, ALD 12.6%→38.8%. Males: ALD 21.7%→52.7%, MASH 12.2%→27.2%. By 2025, ALD and MASH represented the first and second most common etiologies in both sexes. The third and fourth etiologies differed by sex: PBC (5.4%) and AIH (5.0%) in females versus HCV (5.6%) and PSC (4.2%) in males.Males had lower MELD (20.8 ± 10.1 vs. 21.5 ± 10.4) and higher transplantation rates (64.8% vs. 61.1%). Females had higher crude waitlist mortality (10.8% vs. 9.2%), deterioration (9.4% vs. 8.9%) (p < 0.01). Multivariable competing-risk analyses showed female sex was not independently associated with waitlist mortality in any etiology group (all p > 0.05). Common predictors of waitlist mortality included advanced age, elevated MELD, poor functional status, life support, ascites, encephalopathy, and HCC.Five-year post-LT mortality was higher in males (21.9% vs. 20.1%). Male sex was independently associated with higher post-LT mortality in HBV (aHR = 1.31, 95% CI 1.07–1.62), HCV (aHR = 1.09, 1.04–1.14), MASH (aHR = 1.17, 1.12–1.23), PBC (aHR = 1.55, 1.31–1.83), and PSC (aHR = 1.26, 1.11–1.42), but not AIH, ALD, or ALD+HCV (p > 0.05). Post-LT mortality predictors included advanced age, diabetes, public insurance, reduced functional status, life support, and prior transplantation (p < 0.01). **Conclusion:** CLD epidemiology requiring liver transplantation has substantially changed with pronounced sex-specific trends. Waitlist mortality showed no independent sex differences within etiology groups, while male sex was an independent risk factor for higher post-transplant mortality across most CLD etiologies.

0129 | BURDEN OF HEALTH-RELATED SOCIAL NEEDS ARE INDEPENDENTLY ASSOCIATED WITH FRAILTY AND MINIMAL HEPATIC ENCEPHALOPATHY IN COMPENSATED CIRRHOSIS: A LIVER CIRRHOSIS NETWORK STUDY

Ani Kardashian[1] Abigail Smith[2] Ann Kan[2] Elliot Tapper[3] Mandana Khalili[4] Srinivasan Dasarathy[5] Nicole Welch[5] Elizabeth Verna[6] Robert Brown[7] Matthew Kappus[8] Cynthia Moylan[8] Douglas Simonetto[9] Vijay Shah[9] Patricia Denise Jones[10] Andrew Scheinberg[10] Neehar Parikh[3] Rohit Loomba[11] Monica Tincopa[11] Bilal Hameed[4] Jasmohan Bajaj[12] Arun Sanyal[12] Norah Terrault[1], [1]University of Southern California, [2]Northwestern University, [3]University of Michigan Medical Center, [4]University of California, San Francisco, [5]Cleveland Clinic, [6]Columbia University Medical Center, [7]Weill Cornell Medicine, [8]Duke University, [9]Mayo Clinic Rochester, [10]University of Miami, [11]University of California, San Diego, [12]Virginia Commonwealth University

Background: Health-related social needs (HRSNs) are understudied in compensated cirrhosis, with prior data limited to a single domain (e.g. food insecurity) and a comprehensive evaluation of social risk lacking. We hypothesize that HRSNs influence frailty and minimal hepatic encephalopathy (MHE), often the earliest signs of decompensation and reduced quality of life, through competing demands, poor nutrition, financial stress, and limited access to care. In turn, frailty and MHE limit patients' capacity to address their social needs, fueling a self-reinforcing cycle. This study evaluated the association of individual and cumulative HRSN burden with frailty and MHE in a well-characterized multicenter cohort of adults with compensated cirrhosis. **Methods:** The Liver Cirrhosis Network Cohort Study includes adults from 10 US sites with compensated cirrhosis. Four core (housing instability, utility needs, food insecurity, transportation insecurity) and two supplemental (social support, financial strain) HRSNs were assessed at baseline by the Accountable Health Communities HRSN and USDA Household Food Security Surveys. Frailty was measured by Liver Frailty Index (LFI) and MHE by Stroop test using age-adjusted validated cutoffs. Multivariable linear and logistic regression models adjusted for age, race-ethnicity, sex, cirrhosis etiology, MELD 3.0, alcohol use, Charlson Comorbidity Index, and BMI examined associations of individual and cumulative HRSN burden (0, 1, ≥ 2) with frailty and MHE. **Results:** Among 859 participants, 234 (27%) had ≥ 1 core HRSN, 12% were frail (LFI > 4.5), and 56% had MHE. Among HRSN ≥ 1 vs HRSN = 0, median [IQR] LFI was higher (3.97 [3.60-4.34] vs 3.73 [3.26-4.11]) and MHE prevalence was greater (63% vs 54%). In multivariable analysis, all six HRSNs were independently associated with greater frailty: housing (b = 0.27, 95%CI [0.15-0.38]), food (b = 0.29 [0.15-0.44]), utility (b = 0.32 [0.12-0.52]), transportation (0.29 [0.12-0.47]), social (b = 0.40 [0.26-0.54]) and financial (b = 0.29 [0.18-0.39]) (**Figure**). For MHE, food (OR = 1.88, 1.16-3.13), social (OR = 1.85, 1.15-3.05), and financial (OR = 1.78, 1.26-2.53) insecurities were associated with greater odds. Incremental increase in core HRSN burden was associated with progressively greater frailty (b = 0.19 [0.08-0.30] for HRSN = 1, b = 0.43 [0.27-0.59] for HRSN ≥ 2) and MHE (OR = 1.82 [1.07-3.20] for HRSN ≥ 2) in multivariable models. **Conclusion:** In this large multicenter study of compensated cirrhosis, 1 in 4 adults reported ≥ 1 HRSN, highlighting the need for routine HRSN screening. A strong, graded association was observed between HRSNs and both frailty and MHE. While this cross-sectional analysis cannot establish directionality, these findings suggest that HRSNs may represent a modifiable barrier to the clinical management of frailty and MHE, particularly in compensated cirrhosis when disease trajectory may still be amenable to intervention.

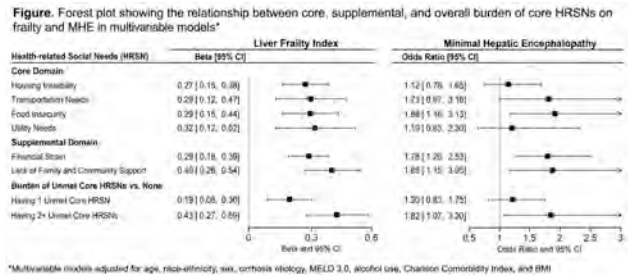

Figure. Forest plot showing the relationship between core, supplemental, and overall burden of core HRSNs on frailty and MHE in multivariable models*

*Multivariable models adjusted for age, race-ethnicity, sex, cirrhosis etiology, MELD 3.0, alcohol use, Charlson Comorbidity Index, and BMI

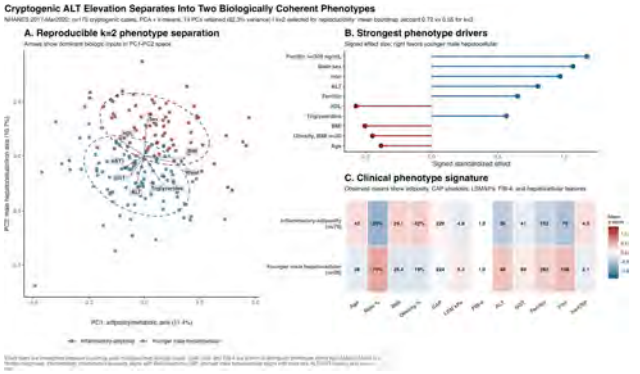
0130 | MACHINE LEARNING-BASED PHENOTYPING OF CRYPTOGENIC HEPATOCELLULAR INJURY IN THE US ADULT POPULATION



Kartik Dapke[1] Timothy Davie[2] Jesse Fletcher[2] Serena Brosten[2] Anna Strauss[2] Giovanni Roldan[3] Prowpanga Udompap[4], [1]Department of Medicine, Saint Vincent Hospital, Worcester, MA, [2]Department of Medicine, University of Minnesota, [3]Division of Gastroenterology, Hepatology and Nutrition, University of Minnesota, [4]Division of Gastroenterology, Minneapolis VA Medical Center

Background: Alanine aminotransferase (ALT) is the primary serum marker of hepatocellular injury. Despite a structured diagnostic workup, a significant proportion of ALT elevations have no identifiable etiology. Defined as a diagnosis of exclusion, the prevalence and clinical characteristics of this cryptogenic subset remain unknown. **Methods:** This cross-sectional study analyzed NHANES 2017–March 2020 data from adults aged ≥20 years with measured ALT. Elevated ALT was defined as >33 U/L in men and >25 U/L in women. To identify cryptogenic cases, we applied rigorous, prespecified adjudication rules using vibration controlled transient elastography (VCTE), laboratory, medications, and survey data to exclude individuals with Metabolic Dysfunction Steatotic Liver disease (MASLD), MASLD with increased alcohol intake (MetALD), alcohol-associated liver disease, viral hepatitis (B or C), iron overload, suspected autoimmune hepatitis, or drug-induced liver injury. National prevalence estimates were calculated using NHANES sample survey weights. For the cryptogenic population, distinct phenotypes were identified using principal component analysis followed by k-means clustering, validated by silhouette width and bootstrap Jaccard coefficients. **Results:** Among 7,880 adults with ALT measured, representing 225.7 million (M) U.S. adults, 1,501 had elevated ALT, corresponding to a weighted prevalence of 18.1% (95% CI 16.5–19.8) or 40.8M U.S. adults. Of these, 884 elevated ALT adults with complete etiologic adjudication, 175 had cryptogenic hepatocellular injury, corresponding to a weighted prevalence of 21.1% (95% CI 17.1–25.9) or an estimated of 6.2M U.S. adults. Internal validation supported a 2-cluster solution over 3 clusters (silhouette 0.093 vs 0.089; minimum bootstrap Jaccard 0.706 vs 0.491). Cluster 1 (n = 96) was younger, male-predominant (79%), and had higher ALT (47.9 vs 35.9 U/L) and ferritin (261.6 vs 101.5 ng/mL). Cluster 2 (n = 79) was older, less often male (20%), and showed greater adiposity (BMI 29.1 vs 26.4 kg/m²) and inflammatory burden (CRP 3.98 vs 2.13 mg/L). (Figure 1) **Conclusion:** Cryptogenic hepatocellular injury affects an

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

estimated 6.2 million U.S. adults and comprises two clear phenotypes: a younger, male-predominant cohort with suspected iron-mediated injury, and an older, female-predominant cohort with an adiposity and inflammatory profile highly consistent with MASLD. This second cluster exposes a critical systemic vulnerability, where true metabolic liver disease is likely missed due to the inherent diagnostic limitations of VCTE. These results underscore that a "cryptogenic" designation should not lead to clinical watch-and-wait approaches. Instead, when unexplained transaminitis mirrors a patient's metabolic and inflammatory risk profile, clinicians must look past negative elastography scores and aggressively pursue secondary screening and early metabolic management.

0131 | SOCIODEMOGRAPHIC AND STRUCTURAL BARRIERS AMONG INDIVIDUALS WITH HEPATITIS B IN THE US: ANALYSIS OF THE ALL OF US DATABASE

Xiaohan Ying[1] Jacky Choi[2] Himel Mallick[2] Tatyana Kushner[2], [1]NewYork Presbyterian/Weill Cornell, [2]Weill Cornell Medicine

Background: Chronic hepatitis B (HBV) remains a leading cause of cirrhosis and hepatocellular carcinoma worldwide. In the United States its burden is increasingly concentrated among socially and economically marginalized populations. The extent to which structural inequities in socioeconomic status, insurance coverage, and healthcare access contribute to barriers to care is not clearly defined. We aimed to further evaluate sociodemographic characteristics and structural barriers using the All of Us Database as well as to examine whether HBV status is independently associated with poor health status. **Methods:** We performed a cross-sectional analysis of all patients enrolled in the All of Us Research Database, a National Institute of Health funded database focused on recruiting those historically underrepresented in biomedical research. Individuals with HBV were identified through ICD-10 codes or positive HBV surface antigen and/or HBV DNA. Sociodemographic characteristics, insurance coverage, healthcare access, and patient-reported overall health were compared between HBV and non-HBV populations. Chi-square tests were used for categorical and Wilcoxon rank-sum tests were used for continuous variables. Multivariable logistic regression examining self-reported health was adjusted for age, sex, race, ethnicity, and income. **Results:** Of 626,383 participants, 2,323 (0.4%) individuals had a diagnosis of HBV. Individuals with HBV were older (median 64 vs 57 years), more likely to be male (52% vs 36%), foreign born (24% vs 15%), and more likely to be Black (37% vs 19%) or Asian (11% vs 4.2%) compared to participants without HBV, all $p < 0.001$. Patients with HBV were more likely to have income $\leq$\$50K (70% vs 47%) and lower educational attainment (college or above: 30% vs 47%). They were less likely to have employer-sponsored insurance (17% vs 36%) and more likely to be covered by Medicaid (31% vs 19%) or Medicare (16% vs 13%), with all comparisons $p < 0.001$. Patients with HBV were more likely to experience greater barriers to care, including higher rates of delayed care due to transportation (12% vs 8.6%, $p < 0.001$), and difficulty affording prescription medications (15% vs 13%, $p = 0.025$). Patients with HBV were more likely to self-report poor/fair health (40% vs 23%, $p < 0.001$). In adjusted analysis, positive HBV status was independently associated with worse self-reported health (OR 1.90, 95% CI 1.7-2.1, $p < 0.001$) after adjusting for age, race/ethnicity, and income (Table 1). **Conclusion:** In a large, nationally diverse cohort, HBV status was associated with substantial structural and socioeconomic disadvantages as well as worse self-reported health. These findings highlight structural inequities that require policy and health system interventions addressing affordability, access barriers, and equitable delivery of care to ensure optimal care for patients with HBV.

Characteristics	OR	95% CI	p-Value
HBV Status	1.9	1.70, 2.11	**<0.001**

0132 | SEQUENTIAL ALGORITHMS USING FIB-4, FOLLOWED BY VCTE OR ELF TO DETECT ADVANCED FIBROSIS: VALIDATION OF RISK STRATIFICATION STRATEGY IN THE UNITED STATES (U.S.) PRIMARY CARE SETTING

Zobair Younossi[1] James Paik[2] Leyla de Avila[1] Maria Stepanova[1] Markos Kalligeros[1] Annette Paik[1] Khalid AlNaamani[1] Saleh Alqahtani[1] Linda Henry[1], [1]The Global NASH/MASH Council, [2]Global NASH/MASH Council

Background: In the U.S., MASLD risk stratification algorithms endorse sequential non-invasive tests (NITs) with FIB-4 followed by VCTE or ELF. Performance of these algorithms in primary care, where prevalence of AF is lower than the referral centers, remains unquantified. We report three-zone evaluation of sequential NITs performance with guideline-based clinical action, anchoring registry-based NITs performance to NHANES-derived prevalence of AF which is closer to population seen at primary care. **Methods:** NHANES 2017–2020 data (N = 5,969) were used to estimate AF prevalence (LSM ≥ 12 kPa) among adults with type 2 diabetes (T2D) and medically complicated obesity without T2D (MCOB) in primary care. Other causes of chronic liver diseases and excessive alcohol use were excluded. Sensitivity and specificity of NITs were derived from our biopsy-confirmed MASLD registry patients (n = 17,978) with available FIB-4 (T2D n = 8,370 [AF 50.8%]; MCOB n = 6,540 [25.0%]) and adjusted for fibrosis stage distribution differences expected between the registry and primary care. Based on algorithms, VCTE or ELF were performed only in patients with FIB-4 ≥ 1.3 (FIB-4+VCTE: T2D n = 5,285 [53.6%], MCOB n = 3,216 [29.4%]; FIB-4+ELF: T2D n = 3,354 [74.2%], MCOB n = 1,488 [50.2%]). Adjusted performance was applied using Bayesian correction at age-specific NHANES AF prevalence (Table), classifying patients into Rule-Out (FIB-4 < 1.3), Indeterminate (FIB-4 ≥ 1.3 but 2nd line NIT below threshold), or Rule-In zones (FIB-4 ≥ 1.3 and 2nd NIT above threshold) and further stratified into MASH F2–F3, AF without cirrhosis, and cirrhosis according to 2026 consensus thresholds (Table). **Results:** In primary care, FIB-4 followed by VCTE or ELF classified 67% of T2D and 78% MCOB patients as Rule-Out for AF (NPV 95% and 97%, respectively). In contrast, 15% of T2D and 8% of MCOB were Rule-In (PPV 83% and 71%, respectively). Of all patients tested, 9% of T2D and 5% of MCOB were identified as MASH F2–F3, 3% and 1% had AF without cirrhosis, both eligible for pharmacotherapy, and 3% and 2% had probable cirrhosis and not candidates for pharmacotherapy (Table). The remaining patients fell into the Indeterminate zone, subdivided into low-risk followed by primary care and at-risk after 2nd NIT which required clinical decision about pharmacotherapy (Table).Age-stratified analysis showed that 2nd NITs added greatest value in patients ≥ 65 years, where FIB-4 specificity was lowest (68% in T2D; 61% in MCOB) and FIB-4-alone had inadequate PPV (17% in T2D; 4% in MCOB). VCTE raised Rule-In PPV in this group to 88% and 80% and Rule-Out NPV reached 95% and 99%. **Conclusion:** The recommended two-NIT sequential algorithm excludes AF for most high-risk patients (T2D and MCOB) in primary care. Confirmatory 2nd line NITs (VCTE or ELF) improved PPV. This approach was most valuable in patients aged ≥ 65 years, where initial FIB-4 step was inadequate for rule-in decisions.

Table. Performance of the Sequential Risk Stratification Algorithm at Primary Care Advanced Fibrosis Prevalence

Cohort/Age Group	Prevalence Advanced fibrosis	Rule-Out	Intermediate low risk	Intermediate at risk	Rule-In MASH F2–F3	Rule-In Adv Fibrosis	Rule-In Probable Cirrhosis	Rule-out NPV, %	Rule-in PPV, %
First line NIT		FIB-4 <1.3	FIB-4 ≥1.3						
Second Line VCTE			VCTE <8	VCTE 8–10	VCTE 10–15	VCTE 15–20	VCTE ≥20	Rule-out NPV, %	Rule-in PPV, %
T2D Overall	9.7%	67%	11%	7%	9%	3%	3%	95%	83%
T2D 35–64	10.4%	66%	12%	7%	9%	3%	3%	94%	82%
T2D ≥65	9.0%	65%	10%	8%	10%	3%	3%	95%	88%
OB Overall	6.0%	78%	10%	4%	5%	1%	2%	97%	71%
OB 35–64	8.0%	73%	12%	5%	6%	2%	2%	97%	70%
OB ≥65	2.4%	60%	16%	9%	10%	3%	2%	99%	80%
Second Line: ELF			ELF <9.2	ELF 9.2-9.8	ELF 9.8-10.5	ELF 10.5-11.3	ELF ≥11.3	Rule-out NPV, %	Rule-in PPV, %
T2D Overall	9.7%	67%	11%	9%	8%	4%	2%	95%	90%
T2D 35–64	10.4%	66%	12%	10%	7%	3%	2%	94%	91%
T2D ≥65	9.0%	65%	10%	9%	8%	6%	2%	95%	88%
OB Overall	6.0%	78%	11%	5%	4%	2%	1%	97%	81%
OB 35–64	8.0%	73%	13%	6%	5%	2%	1%	97%	80%
OB ≥65	2.4%	60%	18%	7%	8%	4%	3%	99%	87%

Zone proportions estimated at age-specific NHANES advanced fibrosis prevalence among adults with T2D and medically complicated obesity (OB) using a conditional independence approximation applied to registry-derived sensitivity and specificity.

"Rule-Out"-Low risk; maintain primary care management; lifestyle intervention; retest in 1–3 years based on cardiometabolic risk factors.
Indeterminate-Low risk: Primary care management; lifestyle intervention; retest in 1–3 years.
Indeterminate-At risk: Clinical judgment based on cardiometabolic risk factors; may treat as MASH F2–F3.
"Rule-In"- MASH F2–F3: Refer to specialist; lifestyle intervention; eligible for resmetirom or semaglutide.
"Rule-In"- Advanced fibrosis excluding cirrhosis: Use second-line NIT to exclude cirrhosis; if excluded, treat as MASH F2–F3.
"Rule-In"- Probable cirrhosis : Specialist referral for cirrhosis care; resmetirom and semaglutide not recommended.

T2D, type 2 diabetes; OB, medically complicated obesity without T2D; VCTE, vibration-controlled transient elastography; ELF, Enhanced Liver Fibrosis score; NPV, negative predictive value; PPV, positive predictive value; NHANES, National Health and Nutrition Examination Survey; LSM, liver stiffness measurement; CMR, cardiometabolic risk factor; MASH, metabolic dysfunction-associated steatohepatitis

★ 0133 | LIVER TRANSPLANT QUALITY MEASURES AFFECT HEALTH OUTCOMES: A MULTICENTER ANALYSIS OF THE CONSORTIUM FOR THE HOLISTIC ASSESSMENT OF RISK IN TRANSPLANT

Jacqueline Henson[1] Katherine Ross-Driscoll[2] Alexandra Strauss[3] Elizabeth Aby[4] Lisa McElroy[1] Marina Serper[5], [1]Duke University, [2]Indiana University School of Medicine, [3]Johns Hopkins University, [4]University of Minnesota, [5]University of Pennsylvania Health System

Background: The American Association for the Study of Liver Diseases (AASLD) recently published pre-transplant quality measures; however, their feasibility and clinical relevance in real-world practice remain uncertain. We used electronic health record (EHR) data from a multicenter transplant consortium to evaluate the feasibility of operationalizing these measures, variation across centers, and associations with outcomes. **Methods:** Among 18,657 referred patients, we analyzed 9,888 who underwent outpatient LT evaluation (2016-2022) across seven centers in the Consortium for the Holistic Assessment of Risk in Transplant. We assessed the feasibility of operationalizing 32 post-referral AASLD pre-transplant quality measures and quantified center-level variation. Associations between evaluation timing measures and downstream outcomes were evaluated using Fine-Gray competing risk models adjusted for patient sociodemographic and clinical characteristics and center. **Results:** Of 32 post-referral measures, 13 (41%) were operationalized. Most non-operationalized measures relied on documentation not captured in structured EHR fields. Among evaluated patients, 4,694 (50%) were waitlisted and 2,927 (30%) underwent LT. Median times from referral to evaluation initiation and completion were 21 days (IQR 10-35) and 85 days (IQR 39-168), with substantial variation across centers (medians ranging from 7-33 days and 37-112 days, respectively). Among waitlisted patients, 13% experienced dropout due to death or clinical deterioration (center range 8-17%) and 62% underwent transplantation (center range 52-77%). Center-level variation in evaluation and waitlist outcomes persisted after adjustment. Earlier evaluation initiation ($\leq$30 days vs. >30 days) was associated with increased likelihood of waitlist placement (sHR 1.24, 95% CI 1.16-1.32) and higher pre-transplant mortality (sHR 1.20, 95% CI 1.04-1.38), though the latter was attenuated in sensitivity analyses limited to patients with available MELD-Na data (**Figure**). Longer time to evaluation completion, particularly beyond 90 days (vs. 46-90 days), was associated with increased waitlist dropout due to death or being too sick (91-120 days: sHR 1.32, 95% CI 1.02-1.71; >120 days: sHR 1.23, 95% CI 1.00-1.51) and reduced likelihood of transplantation (91-120 days: sHR 0.88, 95% CI 0.78-1.00; >120 days: sHR 0.76, 95% CI 0.68-0.84; **Figure**). **Conclusion:** Nearly half of AASLD post-referral pre-transplant quality measures could be operationalized using real-world EHR data. Among feasible measures, evaluation timing demonstrated substantial inter-center variation and was associated with clinically meaningful transplant outcomes. These findings support the use of measurable, EHR-based process metrics such as time to evaluation initiation and completion as potential benchmarks for quality improvement in pre-transplant care.

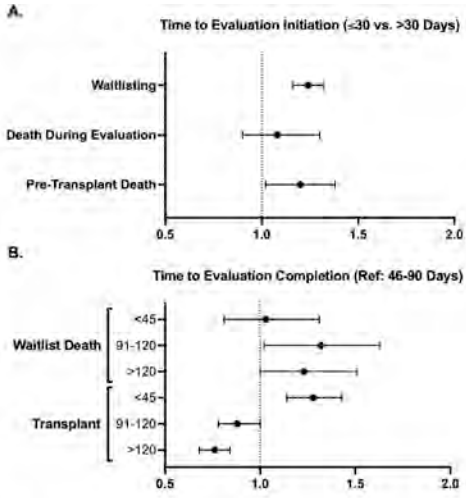

Figure. Association between evaluation timing and transplant outcomes. Multivariable Fine-Gray competing risk models evaluating associations of (A) time to evaluation initiation (≤30 vs. >30 days) and (B) time to evaluation completion (reference: 46-90 days) with downstream outcomes. Points represent subdistribution hazard ratios; error bars represent 95% confidence intervals. Pre-transplant mortality represents death at any time after evaluation initiation. Waitlist death includes removal for clinical deterioration.

0134 | HEPATOCELLULAR CARCINOMA IN INCARCERATED INDIVIDUALS: PREVALENCE, RISK FACTORS, AND TRENDS IN A LARGE U.S. CORRECTIONAL COHORT, 2015–2023

Mahnur Haider[1] Biai Emir Digbeu[2] Gwen Baillargeon[2] Raakhi Menon[2] Hari Movva[2] Hisham Alsharif[2] Muhammad Mushtaq[2] Jessica Khan[2] Jacques Baillargeon[3] Olugbenga Ojo[2] Owen Murray[2] Sreeram Parupudi[2], [1]Georgetown University, [2]University of Texas Medical Branch, [3]Baylor University

Background: The epidemiology of hepatocellular carcinoma (HCC) among incarcerated individuals remains poorly defined despite the high burden of risk factors, particularly chronic hepatitis C virus (HCV). We aimed to describe the burden of HCC within the Texas Department of Criminal Justice (TDCJ) prison system. **Methods:** Individuals ≥ 18 years incarcerated in TDCJ facilities for any duration between January 1, 2015, and December 31, 2023, were included. HCC was identified using ICD-9/10 codes and verified with chart review. Demographics, incarceration duration, HCV status and hepatitis B infection were extracted from the electronic medical record. Prevalence was calculated annually per 100,000 individuals and stratified by key variables. **Results:** Among 519,964 incarcerated individuals (mean incarceration 3.5 years, SD 2.5), 408 HCC cases were identified. The overall prevalence of HCV was 8.1% (8096.3 per 100,000). Among those with HCC, mean incarceration was of 4.7 years (SD 2.4); 97.8% were male, 38.5% White, 37.0% Hispanic, and 47.6% ≥60 years old. HCC prevalence rose from 27.8 per 100,000 in 2015 to highest in 2021 (71.7 per 100,000). Prevalence was consistently higher in males (peak 76.4 per 100,000 in 2021) than females (peak 25.2 per 100,000 in 2021). Prevalence was highest among those ≥60 years, peaking at 640.0 per 100,000 in 2021, versus 80.6 per 100,000 in the 50–59 age group and less than 25 per 100,000 in younger groups. Hispanics had the highest early prevalence (40.3 per 100,000 in 2015), while Whites increased overtime with highest in 2021 - 85.3 per 100,000. Blacks had consistently lower prevalence (38.1–56.1 per 100,000). Those with HCV had substantially higher HCC prevalence than those without HCV (647.8 vs. 7.2 per 100,000 in 2021). Individuals with HCV viral clearance showed a paradoxical rise in HCC prevalence, reaching 1,044 per 100,000 by 2022 versus 898 per 100,000 among those without clearance. HBV infection was associated with elevated HCC prevalence (peak 1,176 per 100,000 in 2022), though interpretation is limited by small case counts. **Conclusion:** This is the largest characterization of HCC prevalence in a U.S. correctional system, revealing a substantial and growing burden driven by chronic HCV. The paradoxical rise in HCC prevalence among individuals achieving HCV viral clearance may be explained by persistent risk even after HCV eradication, survivor bias, or increased detection through closer follow-up. A better understanding of HCC epidemiology in this high-risk population is essential for improving outcomes and for guiding strategies to identify, treat, and ultimately eliminating HCV. Successful antiviral treatment programs within the prison system offer an opportunity to reduce HCC incidence, eliminate HCV, and prevent ongoing transmission within and outside the prison population.

HCC Prevalence Heatmap — TDCJ 2015–2023

0135 | TELEHEALTH VS IN-PERSON EARLY PALLIATIVE CARE FOR PATIENTS WITH CIRRHOSIS: RESULTS FROM THE PAL-LIVER MULTI-CENTER TRIAL

Manisha Verma[1] Marina Serper[2] Andrzej Kosinski[3] Victor Navarro[4] Richard Kalman[1], [1]Thomas Jefferson University, [2]University of Pennsylvania Health System, [3]Duke University, [4]Jefferson Health System

Background: Patients with cirrhosis experience substantial symptom burden, impaired quality of life (QoL), and limited access to palliative care (PC). Telehealth may improve access to PC, but comparative data

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

evaluating telehealth versus in-person delivery in cirrhosis are limited. We compared outcomes of telehealth and in-person early PC delivery among patients with cirrhosis enrolled in the PAL LIVER trial. **Methods:** This is an ancillary analysis of the PAL-LIVER comparative effectiveness cluster RCT conducted at 19 U.S. centers. All enrolled patients received PC either from PC specialist or trained hepatologist, according to their assigned site model by randomization. Of the 935 enrolled, 816 patients were included (modified ITT population who had at least one intervention visit). Participants received 4 structured PC visits over 3 months and were categorized by delivery modality: in-person only, telehealth only, or mixed.The primary outcome was change in QoL at 3 months measured by the Functional Assessment of Cancer Therapy-Hepatobiliary (FACT-Hep). Secondary outcomes included symptom burden (ESAS), depression (PHQ-9) and satisfaction (FAMCARE-P). Adjusted analyses used mixed linear models accounting for differences in baseline characteristics, intervention arms and clinical setting. **Results:** The mean [SD] age was 62.9 [10.3] years; 29% were female. 37% received in-person PC, 31% telehealth-only, and 32% mixed. Mean MELD 3.0 score was 14.4 (5.2). Participants who self-reported as Hispanic, Black, with high-school or less, and without insurance were more likely to receive in-person only visits. The mean FACT-Hep total score significantly increased for each intervention modality: 6.28 points for in-person, 6.79 points for telehealth, and 8.59 points for mixed. The increase in scores for the mixed modality reached the MCID threshold (8-9 points) for clinical significance. There was no significant difference in the change in FACT-Hep scores from baseline to 3 months by intervention modality ($p = 0.40$). Among those in mixed modality, patients who had their initial visit in-person had a clinically significant improvement in FACT-Hep (+9 points, $p < 0.001$) when compared to those with initial telehealth.Symptom burden decreased similarly across modalities (−5.09, −6.42, and −6.98). Depression also improved in all groups (-1.14, -1.16 and -0.72) without any difference between groups. Satisfaction improved in the in-person and mixed groups but not significantly in the telehealth-only group; between-group differences were not significant. Intervention fidelity was high and comparable across modalities. **Conclusion:** Telehealth delivery of PC for cirrhosis was associated with improvements in QoL, depression and symptom burden comparable to in-person care, supporting telehealth as a scalable model to expand access without compromising outcomes. Mixed modality with initial in-person visit can be a feasible strategy.

Table 1: **Adjusted mean change in primary and secondary outcomes at 3 months**

Outcome (change from baseline to 3 months)	In-person (N=305) Adjusted mean (95% CI)	P-value	Telehealth (N=250) Adjusted mean (95% CI)	P-value	Mixed (N=261) Adjusted mean (95% CI)	P-value	overall P-value between group difference
FACT-Hep total score	6.28 (3.76, 8.80)	<0.001	6.79 (3.96, 9.63)	<0.001	8.59 (6.08, 11.09)	<0.001	0.40
FACT-Hep subscales							
Physical Well Being (PWB)	1.02 (0.30, 1.75)	0.005	1.55 (0.76, 2.34)	<0.001	1.16 (0.44, 1.87)	0.002	0.58
Social Well-Being (SWB)	0.43 (-0.27, 1.12)	0.23	0.39 (-0.38, 1.16)	0.32	1.17 (0.48, 1.85)	<0.001	0.17
Emotional Well-Being (EWB)	1.11 (0.54, 1.68)	<0.001	0.48 (-0.16, 1.13)	0.14	1.20 (0.63, 1.76)	<0.001	0.22
Functional Well-being (FWB)	1.01 (0.27, 1.75)	0.008	1.05 (0.22, 1.88)	0.013	1.17 (0.43, 1.90)	0.002	0.95
Modified ESAS Total score (13 items)	-5.09 (-7.52, -2.66)	<0.001	-6.42 (-9.12, -3.71)	<0.001	-6.98 (-9.37, -4.59)	<0.001	0.53
PHQ-9 (Depression)	-1.14 (-1.77, -0.51)	<0.001	-1.16 (-1.87, -0.45)	0.001	-0.72 (-1.33, -0.10)	0.022	0.57
DT (Distress)	-0.14 (-0.48, 0.20)	0.42	-0.30 (-0.68, 0.08)	0.13	-0.48 (-0.82, -0.15)	0.005	0.38
FAMCARE-P13 (Satisfaction)	2.97 (1.77, 4.16)	<0.001	1.04 (-0.33, 2.41)	0.14	1.74 (0.52, 2.95)	0.005	0.092

Higher scores reflect better QoL (FACT-hep total score and all subscales). Higher ESAS means higher symptom burden, PHQ-9 -higher depression, FAMCARE P13- better patient satisfaction.

safety of the monoclonal antibody tobevibart and an interfering RNA (siRNA) elebsiran in combination in participants with chronic HDV infection, with or without compensated cirrhosis, on NRTI therapy (NCT05461170). **Methods:** Antiviral efficacy, including patterns of HDV RNA responses, was assessed in participants receiving combination therapy with elebsiran 200 mg plus tobevibart 300 mg subcutaneously (SC) every 4 weeks (elebsiran+tobevibart Q4W) through 96 weeks. **Results:** At week 96, 88% (28/32) of participants receiving elebsiran+tobevibart Q4W achieved undetectable HDV RNA (target not detected [TND], no amplification by PCR) and 53% (17/32) achieved ALT normalization (missing equals failure analysis). More participants reached undetectable HDV RNA over time: 66% (21 out of 32) achieved it after 48 weeks of treatment, and 88% achieved it after 96 weeks. After achieving undetectable HDV RNA, no confirmed virologic rebound >LLOQ was observed through week 96. Participants receiving elebsiran+tobevibart Q4W had substantial reduction in HBsAg, with ~91% achieving HBsAg <10 IU/mL by week 48 and these reductions were maintained through week 96. Treatment-emergent adverse events were primarily Grade 1-2 and transient, with influenza-like syndrome (ILS) being the most common reported AE. Ninety-seven percent of ILS was associated with first dose administration and generally resolved within the first 24-48 hours. No treatment-related serious adverse events occurred. We will present detailed summaries of HDV RNA response patterns, including the time to achieving undetectable HDV RNA after treatment initiation and durability of this response, as well as correlation with measures of liver disease, through 96 weeks of elebsiran+tobevibart Q4W therapy. **Conclusion:** Elebsiran+tobevibart Q4W combination therapy resulted in rapid and maintained HDV RNA suppression, with 88% achieving undetectable HDV RNA by week 96. Robust HBsAg reductions and ALT normalization were also observed. Adverse events were generally mild to moderate and transient. These results support further development of elebsiran+tobevibart Q4W, which is now being evaluated in the registrational ECLIPSE program for chronic HDV infection.

Background: Chronic Hepatitis D (CHD) is the most severe form of viral hepatitis, and current treatments are limited. Brelovitug (BJT-778) is a fully human monoclonal antibody against Hepatitis B surface antigen. Brelovitug is currently being evaluated in AZURE-1(NCT06907290), a global, randomized, Phase 2b/3 trial versus delayed treatment (DT) in adults with CHD. Brelovitug was shown to be safe and effective through 24 weeks of treatment for CHD with and without cirrhosis in the phase 2b portion of AZURE-1. Here we report on data beyond 24 weeks from AZURE-1 phase 2b. **Methods:** Participants were randomized 2: 2: 1 to receive brelovitug 300mg subcutaneous (SC) weekly (QW) self-administered at home, 900mg SC every 4 weeks (Q4W) administered in the clinic, or delayed treatment (DT) for 24 weeks followed by brelovitug 300mg QW. Key inclusion criteria included hepatitis D virus (HDV) RNA > 500 IU/mL, ALT > upper limit of normal (ULN), and Child-Pugh Score < 7; HIV co-infection and compensated cirrhosis with or without portal hypertension were allowed. There were no exclusion criteria for liver stiffness, bilirubin, albumin, INR or maximum ALT. The primary endpoint (PE) was a composite of virologic response (HDV RNA $\geq$ 2 log10 IU/mL decrease or < LLOQ/TND) and ALT normalization at W24. **Results:** 53 participants were enrolled; 21 to 300mg QW, 20 to 900mg Q4W, and 12 to DT groups. The mean (SD) age overall was 46 (8.2) years, 49 (92%) were White, 37 (70%) were male, and 28 (53%) had cirrhosis. Mean (SD) baseline HDV RNA was 5.5 (0.83) log10 IU/mL and ALT was 124 (95.3) U/L, including 11 (21%) with ALT $\geq$ 5xULN, 8 (15%) with liver stiffness > 25kpa, and 4 (14%) with CTP score of 6.At W24, PE was achieved in 45% (9/20) p = 0.003, 35% (7/20) p = 0.024, and 0% (0/12) for the 300mg QW, 900mg Q4W, and DT groups, respectively. A virologic response was observed in 100% (20/20), 75% (15/20), and 0% (0/12) for the 300mg QW, 900mg Q4W, and DT groups, respectively. ALT normalization occurred in 45% (9/20), 40% (8/20), and 8% (1/12) of patients, respectively. 7 participants (17%) reported mild injection site reactions in both 300 mg QW and 900 mg Q4W groups and 1 (5%) reported mild flu-like symptoms in the 900 mg Q4W groups. There were no treatment-related SAEs, Grade $\geq$ 3 AEs, or AEs leading to study discontinuation. After W24, additional ALT normalization and virologic suppression were observed. Among those with data at W36, a 100% virologic response was observed in both 300 mg (6/6) and 900 mg (6/6) groups. ALT normalization occurred in 67% of patients in both the 300 mg (4/6) and 900 mg (4/6) groups. Complete W48 results will be shared at the time of presentation as the trial is ongoing. **Conclusion:** In individuals with CHD, brelovitug demonstrated continued improvements in both HDV RNA and ALT and was well-tolerated with continued treatment beyond 24 weeks. The AZURE-1 Phase 3 trial and other phase 3 trials in CHD patients are ongoing.

Background: Bulevirtide (BLV) 2 mg/day is approved for the treatment of chronic hepatitis Delta (CHD), but real-world data on virological breakthroughs (VBK) during long-term BLV monotherapy remain limited. We evaluated the incidence and timing of VBK during BLV 2 mg/day monotherapy in two multicenter real-life cohorts (SAVE D and D SHIELD). **Methods:** CHD patients treated with BLV 2 mg/day monotherapy from the retrospective/prospective multicenter, observational, real-world SAVE-D and D-SHIELD studies with available paired baseline-week 24-48-72 or 96 data were included. VBK was defined as ≥ 1 Log_{10} HDV RNA increase compared to a previous timepoint (nadir). Virological (HDV-RNA undetectable or ≥ 2 Log_{10} decline *vs.* baseline), biochemical (BR, ALT < 40 U/L), combined response (CR, biochemical+virological), HDV RNA undetectability and liver-related events were also assessed. **Results:** Among a total of 900 CHD patients enrolled in the SAVE-D and D-SHIELD studies, a total of 276 patients with available paired baseline-W72 data (111 with available week 96 data) were included: at baseline (BLV start), median age was 52 (IQR 42-60) years, 55% males, 73% with cirrhosis, median ALT 81 (45-144), liver stiffness measurement (LSM) 14.0 (6.1-25.0) kPa, HBsAg 3.7 (3.2-4.2) Log_{10}IU/mL, HDV RNA 5.3 (3.9-6.4) Log_{10}IU/mL. Overall, rates of response at week 48 were 68% (VR), 67% (BR), 52% (CR) and 28% (HDV RNA undetectable), while the corresponding figures at week 96 were 68% (VR), 65% (BR), 50% (CR) and 38% (HDV RNA undetectable), respectively. During BLV monotherapy, a VBK occurred in 15 (5%) patients at week 48, 24 (9%) at week 72 and 8 (3%) at week 96. At VBK, a BR was maintained in 7/15 (47%) patients at week 48, 10/24 (42%) at week 72, and 7/8 (87%) at week 96. Occurrence of VBK was independent of baseline ALT levels ($p = 0.08$), HDV RNA ($p = 0.72$) and cirrhosis status ($p = 0.15$). VBK was stable at two consecutive timepoints in 7 (15%) patients, while in the remnants VBK was only transient and resolved at the following treatment timepoint. None of the patients with

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

VBK developed a de novo liver-related event. **Conclusion:** During BLV 2 mg/day monotherapy up to 96 weeks, 17% of the patients experienced a VBK. Nevertheless, most cases of VBK were transient and not associated with increased ALT levels.

Background: Hepatitis delta virus (HDV) infection is the most severe form of chronic viral hepatitis and is associated with accelerated fibrosis progression and early hepatic decompensation. Despite its clinical relevance, HDV remains underdiagnosed due to inconsistent screening strategies among HBsAg-positive individuals. We aimed to evaluate the epidemiology, diagnostic cascade and clinical profile of HDV infection in Spain. **Methods:** We conducted a nationwide multicenter observational study including a retrospective evaluation of HDV prevalence and diagnostic cascade among HBsAg-positive individuals (2022–2024) and a prospective cohort launched in 2024 as part of the DDR Spain project. Demographic, clinical and virological variables were systematically collected in a centralized REDCap database. Multivariable logistic regression analyses identified factors independently associated with active HDV infection and advanced fibrosis. **Results:** Between 2022 and 2024, 65,763 HBsAg-positive individuals were evaluated in 80 centers from 16 Spanish Autonomous Communities. Anti-HDV prevalence remained stable over time (5.6% in 2022, 4.9% in 2023 and 5.3% in 2024). However, only 40.1%, 31.6% and 31.0% of anti-HDV-positive individuals had confirmatory HDV-RNA testing in 2022, 2023 and 2024, respectively, highlighting important gaps in the diagnostic cascade.By March 2026, 1,112 anti-HDV-positive individuals had been prospectively enrolled. Median age was 54 years (IQR 43–61), 60% were male and 49% were born in Spain. HIV and HCV coinfection were present in 20% and 21% of patients, respectively. Active HDV infection was detected in 42%, with a median HDV viral load of 4.1 log IU/mL. HDV

genotype 1 predominated (90%). Advanced liver disease was frequent: 41% presented METAVIR F3–F4 fibrosis, median liver stiffness was 7.8 kPa and 18% had previous hepatic decompensation. HIV and HCV coinfection were associated with higher rates of active infection and advanced fibrosis. In multivariable analysis, HBV treatment and active HDV infection were independently associated with advanced fibrosis, while younger age, higher platelet count and higher albumin levels were associated with lower probability of active HDV replication. **Conclusion:** This nationwide study provides updated epidemiological and clinical data on HDV infection in Spain and identifies persistent deficiencies in the diagnostic cascade. The high burden of advanced liver disease and active viral replication reinforces the need for systematic HDV screening and optimized clinical management strategies.

0140 | HEPATIC RECOMPENSATION, SAFETY AND VIRAL SUPPRESSION IN PATIENTS WITH ADVANCED DECOMPENSATED CHRONIC HEPATITIS DELTA TREATED WITH BULEVIRTIDE:

Magdalena Meszaros[1] Georges-Philippe Pageaux[2] Mauro Viganò[3] Elisa Farina[3] Filomena Conti[4] Sébastien Dharancy[5] Teresa Antonini[6] Stefano Fagiuoli[3] Alessandro Loglio[3], [1]Liver Transplantation and Hepatogastroenterology Unit, CHU Montpellier, CHU Montpellier, Montpellier, [2]Liver Transplantation and Hepatogastroenterology Unit, CHU Montpellier, Montpellier, France, [3]Gastroenterology, Hepatology and Transplantation Division, ASST Papa Giovanni XXIII, Bergamo, Italy, [4]Hepatology Unit, Pitié Salpêtrière, Assistance Publique-Hôpitaux de Paris, Paris, France, [5]Hepatology Unit, Claude Huriez Hospital, CHU Lille, Lille, France, [6]Hepatology Unit, Hôpital de la Croix- Rousse, Lyon, France

Background: Bulevirtide (BLV) is currently approved only for patients with compensated Chronic Hepatitis D (CHD). However, its potential to induce hepatic recompensation, as defined by the Baveno VII criteria, in decompensated CHD patients has not yet been established. **Methods:** This retrospective multicentre longitudinal study included all CHD patients under evaluation or listed for liver transplantation (LT) due to decompensated [Child-Pugh (CP) score B/C with ascites or variceal bleeding or hepatic encephalopathy) disease treated with BLV 2 mg/day in Italy and France. Hepatic recompensation was defined as achievement of all the following criteria: undetectable HDV-RNA, absence of new decompensation events for $\geq$12 months, and improvement to a MELD score $<$10

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

and/or CP A score, sustained for at least 6 months. **Results:** Eleven coinfected (HBV/HDV) patients were included: 64% male, 44 (32-68) years, CP C score 55% [median 10 (7-12)], MELD 15 (7-32), ALT 79 (32-1,345) U/L, albumin 3.0 (2.0-3.9) g/dL, bilirubin 43 (24-444) µmol/L; HDV-RNA 3.7 (1.4-7.4) Log_{10} IU/mL, 100% HBeAg and HBV-DNA negative; all had severe portal hypertension [platelets 35 (26-275)*10^3 /mmc, spleen 19 (15-26) cm, esophageal varices (large in 45%)] while one had also an HCC BCLC B. During 22 (2-67) months of treatment, BLV induced a significant reduction in HDV-RNA, with 7/9 evaluable patients having undetectable HDV-RNA at week 48, and 7/9 with normal ALT [median 32 (22-114) U/L]. Marked liver function improvement was observed at week 48: MELD decreased to 13 (8-17), while CP A5 score was achieved in 5/9 [median 5 (5-8), with an improvement of 2 (1-7) points]. Four patients (36%) were delisted following clinical improvement. Six patients (55%) underwent LT (after 2, 9, 12, 21, 22 and 34 months on BLV), one for ESLD and two for HCC during the first year, while for a virological breaktrought in the remaining 3 patients. Among the 3 patients eligible for the 1-year recompensation assessment (alive, no LT within 12 months, ≥12 months follow-up), achieved full Baveno VII recompensation only a female patient still HDV-RNA undetectable after 67 months. Overall, fully recompensation rate was 1/11 (9%). **Conclusion:** In decompensated CHD patients treated with BLV, significant improvements in MELD and CP scores were observed, leading to LT delisting in 36% of patients, while hepatic recompensation according to the Baveno VII criteria was achieved in 9%. Overall BLV, in this setting of young patients with severe liver disease, is safe and may postpone LT although close clinical management at expert Centers remains essential.

0141 | DURABLE AND NEWLY EMERGENT TREATMENT RESPONSE DURING A 24-WEEK FOLLOW-UP IN A FINITE LONAFARNIB TREATMENT REGIMEN: EXTENDED ANALYSES FROM THE PHASE 3 D-LIVR TRIAL

Robert Taylor[1] Ohad Etzion[2] Saeed Hamid[3] Tarik Asselah[4] George Gherlan[5] Maria Buti[6] Pietro Lampertico[7] Turcanu Adela[8] George Stancu[9] Liliana-Simona Gheorghe[9] Natalia Voronkova[10] Natalia Barsukova[11] Soo Aleman[12] Jordan Feld[13] Jean-Karl Sirois[14] Armaan Hirani[15] Hebaalla Agha[15] Leen Kawas[16] Nancy Reau[17] Christopher Koh[18] Theo Heller[19] Cihan Yurdaydin[20] Xue Hua[15] Jeffrey Glenn[21], [1]EIT Pharma, Inc, [2]Soroka University Medical Center, Beersheba, Israel, [3]Aga Khan University, Karachi, Pakistan, [4]Hôpital Beaujon, [5]Carol Davila University of Medicine and Pharmacy/Dr. Victor Babes Foundation, Bucharest, Romania, [6]Hospital Valle Hebron, [7]University of Milan, [8]The State University of Medicine and Pharmacy, Republic of Moldova, [9]Institutul Clinic Fundeni, Bucharest, Romania, [10]H-Clinic, LLC, Moscow, Russia, [11]Center for Targeted Therapy, LLC, Moscow, Russia, [12]Karolinska Universitetssjukhuset, Huddinge, Sweden, [13]Toronto General Hospital, [14]YBR Analytics, Inc., [15]EIT Pharma, Inc., [16]EIT Pharma Inc., [17]Rush University Medical Center, [18]Liver Disease Branch, NIDDK, NIH, Bethesda MD, USA, [19]NIH/NIDDK, [20]Koc University School of Medicine, Istanbul, Turkey, [21]Stanford University School of Medicine

Background: Lonafarnib (LNF) boosted with ritonavir (LNF/RTV) is the only oral therapeutic under development for the treatment of chronic hepatitis D (CHD). LNF inhibits host farnesyltransferase to both disrupt HDV virion assembly and promote immune response in infected hepatocytes. LNF/RTV either with or without peg-interferon alfa-2a is being developed as a finite therapy for patients living with CHD. **Methods:** D-LIVR was a Phase 3 randomized placebo-controlled HDV study (N = 407) evaluating LNF/RTV with or without peginterferon alfa-2a (PEG) and is the largest placebo-controlled clinical trial in CHD patients to date. Both LNF-containing finite regimens met the primary composite efficacy endpoint compared to placebo (LNF/RTV: p = 0.004, LNF/RTV + PEG: p < 0.0001), defined as a ≥ 2 log reduction in HDV RNA and ALT normalization compared to baseline at 48-weeks on-treatment (end of treatment [EOT]). D-LIVR also included a 24-week off-treatment follow-up period to evaluate durability of treatment response after a finite regimen (end of study [EOS]). **Results:** The composite response rate improved up to 40% after 24 weeks off treatment in both the LNF/RTV treatment arm (EOS composite response rate of 14.2% compared to 10.1% at EOT) and in the LNF/RTV + PEG treatment arm (EOS composite response rate of 26.4% compared to 19.2% at EOT). There were no EOS composite responses in the placebo group. EOT composite responses were durable through EOS in 44.4% and 41.7% of EOT composite responders in the LNF/RTV and LNF/RTV + PEG treatment arms, respectively. In addition, among patients who were not composite responders at EOT, newly emergent composite response was observed in 10% of the LNF/RTV treatment group and 22.8% of the LNF/RTV + PEG treatment group.Transient mild ALT elevations (ALT measurement > 2X reference or > 3X ULN) were common among LNF/RTV and LNF/RTV + PEG

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

patients in the post-treatment follow-up period (LNF/RTV: 47.3% [70 of 148], LNF/RTV + PEG: 40.9% [45 of 110]) and these elevations were typically followed by rapid decline in HDV RNA viral load, ALT normalization, and were not associated with any decompensation events. **Conclusion:** Oral LNF/RTV is a first-in-class CHD therapy with efficacy and safety in patients with CHD and substantial benefit after treatment cessation. Durability of response and newly emergent composite responders in a 24-week off-treatment follow-up period supports the continued development of lonafarnib-based therapy as a finite treatment regimen for CHD either with or without PEG.

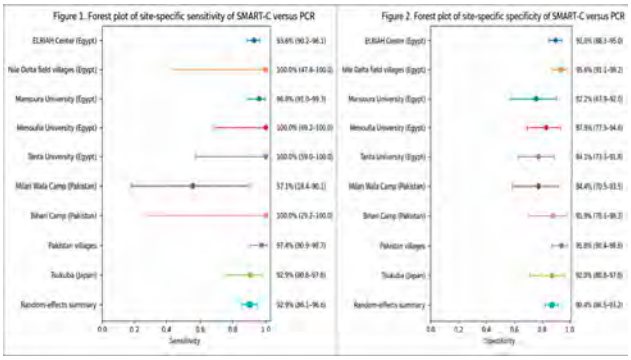
★ 0142 | A NOVEL POINT OF CARE TEST FOR DETECTION OF HCV ANTIGENS USING SMART POLYMER TECHNOLOGY: A PROSPECTIVE MULTINATIONAL STUDY



Riham Soliman[1] Mitsuhiro Ebara[2] Ayman Hassan[3] Hidenori Toyoda[4] Mohammed Abdelsameea[5] Yosra Khalifa[5] Eman Abbdelsameea[5] Ahmed Farahat[1] Dina Ziada[6] Asad Choudhry[7] Auj Chaudhry[7] Hafsa Asad[7] Hossam Galbt[5] Ahmed Nabil[2] Gaston Picchio[8] Gamal Shiha[9], [1]Egyptian Liver Research Institute and Hospital (ELRIAH), Sherbin, El Mansoura, Egypt, [2]National Institute for Materials Science (NIMS), Tsukuba, Ibaraki 305-0044, Japan, [3]Higher Technological Institute of Applied Health Sciences, Sherbin, Mansoura, Egypt, [4]Department of Gastroenterology and Hepatology, Ogaki Municipal Hospital, Ogaki, Japan, [5]National Liver Institute, Menoufia University, Shebin El-kom, Egypt, [6]Faculty of Medicine, Tanta University, Tanta, Egypt, [7]PARSA Trust Liver Clinic, Gujranwala, Pakistan, [8]Independent free-lance consultant, New Jersey, USA., [9]Faculty of Medicine, Mansoura University, Egypt.

Background: There is an unmet need for a rapid, affordable, highly sensitive point-of-care HCV antigen test suitable for decentralised settings. We developed a thermo-responsive smart polymer–based platform for the extraction and enrichment of HCV antigens. This platform was coupled to colloidal gold nanoparticles and integrated into a lateral-flow format (SMART-C). Here, we report the first large multicentre prospective clinical validation of SMART-C against PCR. **Methods:** We conducted a multinational, multicentre, prospective diagnostic accuracy study (2022–2026) at hospital and field sites in Egypt, Pakistan, and Japan. Paired samples were tested blindly using SMART-C and quantitative HCV RNA PCR as the reference standard. Sensitivity, specificity, accuracy, positive predictive value (PPV), and negative predictive value (NPV) were calculated following the STARD guidelines. In addition, prospectively-collected samples from 20 patients initiating direct-acting antiviral (DAA) therapy were tested

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

with SMART-C and PCR to assess the performance of SMART-C during treatment and after cure. **Results:** Among 1,353 paired samples, sensitivity was 94.6% (474/501, 95% CI 92.3–96.3) and specificity 91.3% (778/852, 89.2–93.0), with accuracy 92.5%, positive predictive value 86.5%, and negative predictive value 96.6%. Agreement with PCR was high ($\kappa = 0.843$). In the bivariate model, summary sensitivity was 92.9% (86.1–96.6; prediction interval 73.7–98.4) and specificity 90.4% (86.5–93.2; 79.0–95.9). SMART-C paralleled PCR-defined viral decline during therapy. **Conclusion:** SMART-C demonstrates robust performance with high sensitivity and specificity and detection at very low viral levels. Delivered as a rapid, single-step assay suitable for decentralised use, and could support progress towards WHO hepatitis C elimination targets.

0143 | POST-SVR LIVER STIFFNESS MEASUREMENT AND RISK OF MAJOR ADVERSE LIVER OUTCOMES AND HEPATOCELLULAR CARCINOMA IN VETERANS WITH CHRONIC HEPATITIS C AND WITHOUT CIRRHOSIS

Binu John[1] Samuel Soon[2] Dustin Bastaich[2] Bassam Dahman[2], [1]University of Miami and Miami VA, [2]Virginia Commonwealth University

Background: While patients with HCV cirrhosis are recommended to continue ongoing HCC surveillance even after SVR, residual risk of hepatocellular carcinoma (HCC) and major adverse liver outcomes (MALO) persist after SVR even in the absence of cirrhosis. While Liver stiffness measurement cut-offs for HCV were derived from viremic patients, there is limited data on LSM cut-offs in patients after SVR. We evaluated the association of post-SVR liver stiffness measurement (LSM) with major adverse liver outcomes (MALO) and HCC among Veterans with HCV without cirrhosis to identify patients who may benefit from HCC surveillance. **Methods:** This was a retrospective cohort study using Veteran Health Administration data of individuals with HCV without cirrhosis who achieved SVR after 03/09/2000 and underwent a Vibration controlled transient elastography after SVR, with follow-up until 9/24/2025. The baseline assessment was the first eligible post-SVR VCTE; invalid measurements (IQR% >30%, or <10 valid acquisitions) were excluded. Follow-up began 6 months after the first post-SVR LSM to mitigate reverse causation. LSM was categorized as <5, 5–9.9, 10–14.9, and ≥15 kPa and evaluated continuously per 5-kPa increase. MALO was defined as a composite of HCC, liver decompensation, liver transplantation, or liver-related death. Multivariable time-dependent Cox models adjusted for age, sex, race/ethnicity, BMI, diabetes, time-updated AUDIT-C and platelet count, treatment type, and time from SVR to VCTE. Incidence rates were estimated per 1,000 person-years using Poisson regression. **Results:** The cohort included 6,269 Veterans (median age 64.9 years [IQR 8.0]; 96.0% male; 44.3% Black). LSM was distributed as: <5 kPa (n = 1,556), 5-9.9 kPa (n = 3,703), 10-14.9 kPa (n = 668), and ≥15 kPa (n = 342). During follow-up, 366 participants (5.8%) experienced a MALO - most commonly decompensation (3.9%), and 112 (1.8%) developed HCC. MALO incidence increased across LSM strata: 11.30, 11.97, 15.94, and 18.36 per 1,000 person-years. HCC incidence followed the same graded pattern: 2.82, 3.93, 5.54, and 5.98 per 1,000 person-years. HCC incidence was above the cost-effectiveness threshold for HCC surveillance at LSM of ≥8.5 kPa. Compared with LSM <5 kPa, LSM ≥15 kPa was independently associated with higher risk of MALO (aHR 1.65, 95% CI 1.08–2.52) and HCC (aHR 2.34, 1.10–4.98). Each 5-kPa increase was associated with 11% higher MALO risk (aHR 1.11, 1.05–1.17) and 15% higher HCC risk (aHR 1.15, 1.06–1.24). Diabetes (aHR 1.97) and older age (aHR 1.26 per 5 years) (both $p < 0.0001$) were the strongest independent predictors of MALO. **Conclusion:** Among Veterans with HCV and without cirrhosis who achieved SVR, higher post-SVR LSM was independently associated with increased risk of MALO and HCC with a post-SVR LSM of ≥8.5 kPa having a HCC risk high enough for cost-effective HCC surveillance.

0144 | SAFE-HCV SCORE FOR HEPATOCELLULAR CARCINOMA SURVEILLANCE

Doan Dao[1] Jonggi Choi[2] Megan Michta[3] Raymond Chung[3] Ji won Yang[4], [1]Mass General Hospital, [2]University of Ulsan, Asan Medical Center, [3]Massachusetts General Hospital, [4]Asan Medical Center

Background: Patients with chronic hepatitis C achieving sustained virologic response (SVR) after direct-acting antivirals (DAAs) remain at risk for hepatocellular carcinoma (HCC), but optimal surveillance strategies are unclear. We developed the SAFE-HCV (Surveillance After Fibrosis Evaluation in Hepatitis C Virus) score to guide risk-stratified HCC surveillance in post-SVR patients with significant fibrosis. **Methods:** We included 1,183 SVR patients with significant fibrosis (FIB-4 ≥1.45 or transient elastography ≥8 kPa) from Mass General Brigham (2010-2024), excluding those with HIV or HBV co-infection. Using Fine-Gray competing-risk regression accounting for death and liver transplantation as competing events, we developed a simple clinical score incorporating age ≥60 years (1 point), male sex (1 point), albumin <3.5 g/dL (1 point), and advanced fibrosis or cirrhosis (2 points), yielding scores from 0-5. Advanced fibrosis or cirrhosis was defined as FIB-4 ≥3.25, liver stiffness ≥12 kPa, or radiologic evidence of cirrhosis. External validation was performed in 808 SVR patients from Asan Medical Center, South Korea. **Results:** During median follow-up of 7.4 years (training) and 4.4 years (validation), 107 (9.0%) and 70 (8.7%) HCC events occurred. The SAFE-HCV score achieved C-index of 0.789 (95% CI: 0.730-0.841) in validation. Risk stratification identified low-risk patients (score 0-1, 30.9% of cohort) with very low HCC incidence (0.09-0.35 per 100 person-years), intermediate-risk (score 2-3, 44.3%) with moderate incidence (1.32-1.36), and high-risk (score 4-5, 24.8%) requiring intensive surveillance (2.97-4.67). Performance was superior to PAGE-B, FIB-4, THRI and aMAP score. **Conclusion:** The SAFE-HCV score enables personalized HCC surveillance strategies in post-SVR patients, identifying low-risk individuals who may benefit from de-escalated surveillance and high-risk patients requiring intensive monitoring.

0145 | NMR-BASED SERUM METABOLOMICS IDENTIFIES A 7-METABOLITE PANEL THAT DISCRIMINATES HCV-RELATED CIRRHOSIS FROM CHRONIC HEPATITIS C

Sumit Rungta[1] Amar Deep[2] Shweta Kumari[3], [1]KGMU, [2]King George's Medical University Lucknow, UP, India, [3]King George's Medical University Lucknow, India

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Non-invasive tools to stage fibrosis in chronic hepatitis C (CHC) remain imperfect, while biopsy is invasive and prone to sampling variability. We evaluated whether proton NMR-based serum metabolomics can discriminate HCV-related liver cirrhosis (CHC-LC) from non-cirrhotic CHC and define candidate metabolic biomarkers and pathways of disease progression. **Methods:** Serum from well-annotated adults with CHC (n = 57 total enrolled; analyzable cohort as per protocol) was collected after overnight fast and profiled on an 800-MHz spectrometer using 1H CPMG acquisition. Spectra were processed with Chenomx for metabolite identification/quantification and analyzed in MetaboAnalyst 5.0. Multivariate models (PCA, PLS-DA with permutation testing), univariate statistics (Student's t test), and ROC analyses (including SVM-based multivariate ROC and MCCV) were applied. Pathway impact and enrichment were assessed using MetPA. **Results:** PCA showed partial overlap between CHC and CHC-LC, whereas supervised PLS-DA achieved satisfactory separation ($R2 = 0.66$, $Q2 = 0.55$; permutation $p = 0.01$). Twenty metabolites differed between groups (VIP ≥ 1.0, $p < 0.05$), predominantly amino acids and intermediates linked to energy/protein metabolism (e.g., alanine, glutamine, serine, valine, citrate, urea), with consistent decreases in cirrhosis. A 7-metabolite panel—glutamine, asparagine, threonine, valine, creatine, serine, and citrate—demonstrated strong diagnostic performance (AUC 0.95). An SVM model using the top two features (glutamine, serine) yielded AUC 0.93 (95% CI 0.83–0.99); inclusion of broader features increased AUC to 0.97 (95% CI 0.90–1.00). Pathway analysis highlighted significant perturbations in glycine/ serine/ threonine metabolism, aminoacyl-tRNA biosynthesis, alanine/aspartate/glutamate metabolism, glyoxylate/dicarboxylate metabolism, arginine biosynthesis, and ammonia recycling, consistent with impaired TCA cycle fueling, nitrogen handling, and altered protein turnover in cirrhosis. **Conclusion:** High-field 1H NMR serum metabolomics delineates a reproducible metabolic signature distinguishing HCV-related cirrhosis from non-cirrhotic CHC. A concise 7-metabolite panel achieves high accuracy and maps to biologically plausible pathways of energetic and amino acid dysregulation. These findings support metabolomics as a scalable, non-invasive adjunct for cirrhosis detection and monitoring in CHC. Validation in larger, multi-center cohorts with external calibration and assessment of antiviral treatment effects is warranted.

0146 | AN OPPORTUNISTIC LIS-BASED STRATEGY TO RECAPTURE PATIENTS WITH ACTIVE HCV: EFFICACY AND COST-EFFECTIVENESS OF PROLINK-C IN SPAIN

Alberto Vázquez Blanquiño[1] Ana Fuentes[1] Raquel Domínguez Hernández[2] Ana Belén Pérez Jiménez[3] Francisco Franco Álvarez de Luna[4] Carolina Freyre[5] Teresa Trujillo[6] Natalia Montiel[6] Carmen Rodríguez Baños[7] Inmaculada López[8] Jesús Machuca[9] Carmen Lozano[10] Antonio Sampedro[11] Isabel Viciana[12] Jaime Borrego[13] Juan Carlos Galán[14] Alejandro Gonzalez-Praetorius[15] Federico Garcia[1], [1]Hospital Universitario Clínico San Cecilio, [2]PORIB - Pharmacoeconomics & Outcomes Research Iberia, [3]Hospital Universitario Reina Sofía, [4]Hospital Universitario Juan Ramón Jiménez, [5]Hospital Universitario de Puerto Real, [6]Hospital Universitario Puerta del Mar, [7]Hospital Universitario Torrecárdenas, [8]Hospital Universitario Costa del Sol, [9]Hospital Universitario Infanta Elena, [10]Hospital Universitario Virgen del Rocío, [11]Hospital Universitario Virgen de las Nieves, [12]Hospital Universitario Virgen de la Victoria, [13]Hospital Universitario Poniente, [14]Hospital Universitario Ramón y Cajal, [15]Hospital Universitario de Guadalajara

Background: Chronic hepatitis C virus infection remains a major public health concern despite the widespread availability of direct-acting antivirals (DAA). Identifying individuals previously diagnosed with HCV but never treated, or without documented sustained virological response (SVR), remains a key challenge in the final stages of HCV elimination. Retrospective searches based on historical records have shown limited efficiency. ProLINK-C is a multicentre project implementing an opportunistic, fully automated, LIS-based strategy to re-engage such patients during routine healthcare encounters. We present data on the effectiveness of this strategy, together with a cost-effectiveness analysis (CEA). **Methods:** A daily automated process was implemented in the Laboratory Information System (LIS) across participating centres in Spain. The system generated lists of patients with a previous positive anti-HCV antibody result and a currently available serum sample submitted to the laboratory for any reason. Laboratory records and electronic medical records were reviewed to identify evidence of DAA and/or documented SVR. When no such evidence was found, HCV-RNA testing was reflexively performed using the available serum sample. A validated lifetime Markov model of the natural history of chronic HCV infection was adapted to compare ProLINK-C with no intervention. The model incorporated Spanish epidemiological data, SVR rates, and healthcare costs obtained of the study data. The analysis was conducted from the perspective of the Spanish National Health System. An annual discount rate of 3% was applied to healthcare costs and outcomes. **Results:** Between May 2023 and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

March 2026, reflex HCV-RNA quantification was performed on 696 patients. Of these, 212 patients had detectable HCV-RNA, confirming active HCV infection and constituting the study cohort. Among the 169 patients eligible for DAA, 116 initiated therapies, corresponding to 68.6% of eligible patients, and 64 have achieved SVR to date.Compared with no intervention, ProLINK-C increased short-term diagnostic costs by €68,406 but reduced lifetime costs associated with advanced liver disease by €2,546,640. The strategy was associated with reductions in decompensated cirrhosis, hepatocellular carcinoma, liver transplantation, and liver-related mortality, by 64%, 56%, 61%, and 59%, respectively. The results of the CEA showed that ProLINK-C was a dominant strategy (low costs and better health outcomes. **Conclusion:** ProLINK-C provides a scalable, reproducible, and efficient opportunistic strategy to re-engage untreated patients with chronic HCV infection who are already in contact with the healthcare system. In addition to its clinical impact, ProLINK-C is cost-effective in Spain, maximizing health benefits while reducing costs. These findings provide strong evidence to support the national implementation of ProLINK-C as part of HCV elimination policies.

0147 | CHANGES IN PREVALENCE OF HEPATITIS C AND SELF-REPORTED HEPATITIS C TESTING, DIAGNOSIS, AND TREATMENT AMONG PERSONS WHO INJECT DRUGS — NATIONAL HIV BEHAVIORAL SURVEILLANCE, 2018, 2022, AND 2024

Megan Hofmeister[1] Lauren Peretz[1] Hasan Symum[1] Brooke Hoots[1] Dita Broz[1] Eyasu Teshale[1] Cyprian Wejnert[1] Kathryn Lee[1] Johanna Chapin-Bardales[1], [1]Centers for Disease Control and Prevention

Background: In the United States, persons who inject drugs (PWID) are disproportionately affected by hepatitis C virus (HCV) infection. Hepatitis C prevalence estimates and longitudinal data assessing changes in prevalence over time among PWID are limited in the United States. **Methods:** We sought to characterize changes in prevalence of HCV antibody, HCV RNA, and self-reported hepatitis C outcomes among PWID in select U.S. cities (10 in 2018, 9 in 2022, and 10 in 2024), using data from the Centers for Disease Control and Prevention's National HIV Behavioral Surveillance (NHBS). HCV antibody and HCV RNA tests were performed among eligible participants who consented to hepatitis testing; HCV RNA testing was performed regardless of HCV antibody result. We assessed temporal changes by calculating relative percent change between survey cycles (2018, 2022, and 2024) and conducting t-tests or Fisher exact tests for each pair-wise comparison. Statistical significance was defined as $P < .05$. **Results:** Among 12,300 eligible participants (5,200 in 2018; 2,477 in 2022; 4,623 in 2024) who met inclusion criteria, 12,152 (98.8%) received an HCV antibody test with a valid result and 9,290 (75.5%) received HCV RNA testing with a valid test result. Overall, prevalence of HCV antibody was 62.4% in 2018, 45.0% in 2022, and 38.5% in 2024 (-38.3% relative decrease from 2018 to 2024; $P < .05$), while prevalence of HCV RNA was 44.2% in 2018, 27.1% in 2022, and 16.7% in 2024 (-62.1% relative decrease from 2018 to 2024; $P < .05$). From 2018 to 2024, the percentage of PWID self-reporting ever tested for hepatitis C decreased slightly (-3.5% relative decrease, $P < .05$; 2018: 82.1%; 2022: 79.9%; 2024: 79.2%), the percentage ever diagnosed with hepatitis C among those tested decreased (-30.5% relative decrease, $P < .05$; 2018: 56.1%; 2022: 44.7%; 2024: 39.0%), and the percentage that reported ever being treated for hepatitis C among those ever tested and diagnosed increased (62.2% relative increase, $P < .05$; 2018: 31.5%; 2022: 46.8%; 2024: 51.0%). **Conclusion:** These data show that the prevalence of HCV antibody and RNA among PWID in select U.S. cities decreased significantly from 2018 to 2024. To ensure that this progress towards HCV elimination endures, continued efforts are needed to provide access to testing, treatment, and preventive services among PWID.

0148 | MULTIMODAL IMAGE-BASED DEEP LEARNING FOR PREOPERATIVE PREDICTION OF MICROVASCULAR INVASION IN HEPATOCELLULAR CARCINOMA

Rex Wan-Hin Hui[1] Yan Miao[1] Keith Chiu[2] Ho-Ming Cheng[1] Chenlu Wang[1] Lung Yi Mak[1] Man-Fung Yuen[1] Philip Leung-Ho Yu[3] Wai-Kay Seto[1], [1]The University of Hong Kong, [2]Queen Elizabeth Hospital, [3]The Education University of Hong Kong

Background: Histological microvascular invasion (MVI) is a risk factor for recurrence after curative resection of hepatocellular carcinoma (HCC). Preoperative MVI prediction may improve risk stratification and guide patient selection for neoadjuvant treatment. **Methods:** The MATCH (M ultimodal A ttention T ransformer for C haracterizing H CC) model integrates preoperative triphasic CT scans and clinical parameters to predict histological MVI. The architecture utilizes a 3D ResNet with a Convolutional Block Attention Module for CT data, and a multilayer perceptron for clinical parameters. The imaging and clinical data were integrated by a transformer-based multimodal fusion module to enable binary MVI prediction. The preoperative CT scans were obtained from a multicenter patient cohort who had surgical resection for HCC. MVI was ascertained from the resected HCC specimens by expert pathologists. The MATCH model was evaluated on a 15% testing holdout against a CT-only deep learning model and an IBSI-compliant radiomics random forest baseline. **Results:** Among 1231 patients with resected HCC (age 62.4 years, 83.1% male, 30.6% steatosis, 40.7% cirrhosis), 591 patients (48.0%) had histological MVI. The MATCH model achieved AUC of 0.809 (95%CI 0.775-0.839) in predicting MVI (Sensitivity 0.777, specificity 0.726, positive predictive value 0.790, negative predictive value 0.711), significantly outperforming the radiomics model (AUC 0.750, 95%CI 0.715-0.787) and the CT-only deep learning model (AUC 0.712, 95%CI 0.673-0.751) (both $p < 0.001$). The MATCH model had robust performance across steatosis and cirrhosis subgroups (AUC $\geq$ 0.78), consistently outperforming the CT-only deep learning model (all $p < 0.05$). When assessing model explainability, the dominant HCC lesion size and tumor shape (elongation and sphericity) were the most important radiological features in predicting MVI, whereas the most important clinical feature was serum alpha-fetoprotein level. **Conclusion:** The MATCH model enabled accurate and non-invasive prediction of MVI in HCC. Multimodal image-based deep learning may improve preoperative prognostication and clinical care pathways in potentially resectable HCC.

0149 | A PLASMA DNA METHYLATION BIOMARKER PANEL FROM THE WHOLE-BODY ATLAS™ ENABLES ACCURATE DETECTION OF EARLY-STAGE HCC

Aneesha Tewari[1] Salwan Butrus[1] Jiajie Xiao[1] Nicole Ramza[1] Sarah Yang[1] Alvin Lau[1] Areta Buness[1] Micaela Vierra[1] Christine Shieh[1] Travis Lee[1] Rebecca Culver[1] Marine Schlotter[1] Brandon Giang[1] Akiko Mizuta[2] Mayumi Maeda[2] Sneha Deodhar[3] Manaf Alsudaney[4] Osama Khattab[4] Daniel Legaspi[4] Chung-Feng Huang[5] Chih-Wen Wang[5] Matthew DeMaio[6] Cheng-Hao Tseng[7] Naoshi Odagiri[8] Naoto Saito[9] Chuba Oyolu[1] Shan Wang[1] Alice Chen[1] Ritish Patnaik[1] Takeshi Hatanaka[9] Masaru Enomoto[10] Kazuhiro Nouso[11] Hidenori Toyoda[12] Yao-Chun Hsu[13] Neehar Parikh[14] Ming-Lung Yu[15] Nicole Rich[16] Prasun Jalal[17] Ju-Dong Yang[4] Nathan Hunkapiller[1] Mindie Nguyen[2] Amit Singal[18], [1]Curve Biosciences, [2]Stanford University Medical Center, [3]UT Southwestern Medical Center, [4]Cedars-Sinai Medical Center, [5]Kaohsiung Medical University Hospital, Kaohsiung Medical University, [6]University of Michigan, [7]E-Da Cancer Hospital/I-Shou University, [8]Osaka Metropolitan University Graduate School of Medicine, [9]Gunma Saiseikai Maebashi Hospital, [10]Osaka Metropolitan University Graduate School of Medicine, Osaka City General Hospital, [11]Okayama City Hospital, [12]Ogaki Municipal Hospital, [13]I-Shou University, [14]University of Michigan Medical Center, [15]Kaohsiung Medical University/ Kaohsiung Medical University Hospital, [16]University of Texas Southwestern Medical Center, [17]Baylor College of Medicine, [18]UT Southwestern Medical Center/Curve Biosciences

Background: Ultrasound plus alpha fetoprotein (AFP), the current standard hepatocellular carcinoma (HCC) surveillance strategy, is limited by poor adherence, operator dependency, and suboptimal sensitivity for early-stage detection. Blood-based biomarkers may improve surveillance effectiveness; however, prior biomarker discovery efforts have been limited by small sample sizes and restricted diversity of tissues, resulting in residual background noise from non-hepatic tissues. **Methods:** We used 80,000 tissue specimens from >100 healthy and diseased tissue types within the Whole-Body Atlas to identify methylation biomarkers specific to HCC among patients with chronic liver disease. Candidate biomarkers were incorporated into a next-generation sequencing assay with AFP, and an HCC classifier was trained using plasma samples from 885 patients with cirrhosis or chronic HBV infection (373 HCC cases; 512 controls) enrolled across 22 centers in the United States and Asia. A locked classifier was subsequently tested in a blinded, independent test set of 597 patients (262 HCC cases; 335 controls). HCC cases were defined by characteristic imaging (LI-RADS 5) or histology. Controls had no evidence of HCC on imaging at time of blood draw. The primary outcome was sensitivity for early-stage HCC detection and specificity was a secondary outcome. **Results:** The independent test set included 93.1% individuals from the U.S. and 6.9% from Asia, with a median age of 63 years; 60.3% were men. Most participants (57.3%) had Child Pugh A cirrhosis. Liver disease etiologies included 34.7% MASLD, 28.1% ALD, 25.6% HCV, and 10.1% HBV. Sensitivity for early-stage HCC was 82.6% (90/109) for tumors within Milan criteria and 85.3% (110/129) for BCLC stage 0/A disease. Sensitivity increased with greater tumor burden, reaching 97.4% (149/153) for tumors beyond Milan criteria and 98.0% (96/98) for BCLC stage B/C disease. Overall sensitivity was 91.2% (239/262) with 81.5% (272/335) specificity. The test detected 77.8% (21/27) of 1-2 cm HCC, 88.4% (107/121) for >2-5 cm HCC and 97.3% (107/110) of those >5cm. Test performance was consistent across age, gender, BMI, and liver disease etiology subgroups. Among detected HCC cases, 53.6% were identified by both methylation markers and AFP, 43.9% by methylation markers alone, and 2.5% by AFP alone. Methylation scores correlated with tumor size (Spearman $r = 0.71$, $p < 0.0001$). Among 11 controls with high false positive results and follow-up imaging, 4 (36%) were diagnosed with HCC within 2-8 months. **Conclusion:** A novel plasma DNA methylation biomarker panel demonstrated high sensitivity and specificity for early-stage HCC detection in a multicenter case-control validation study. These findings support efforts to further prospectively evaluate this approach for HCC surveillance.

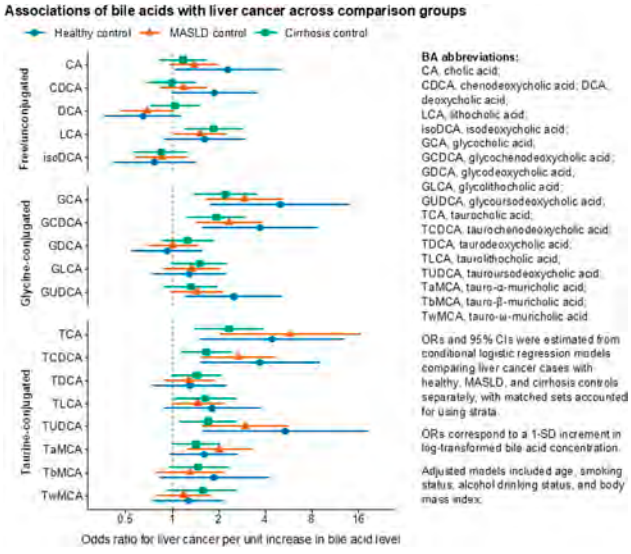
0150 | PREDIAGNOSTIC CIRCULATING BILE ACID PROFILES AND LIVER CANCER RISK ACROSS THE CHRONIC LIVER DISEASE SPECTRUM



Loggang Zhao[1] Xinyuan Zhang[2] Tamar Taddei[3] Katherine McGlynn[4] Huiping Zhou[5] Xuehong Zhang[3], [1]Yale School of Nursing, [2]Brigham and Women's Hospital, [3]Yale University, [4]National Cancer Institute, [5]Virginia Commonwealth University

Background: Bile acids regulate hepatic metabolism, inflammation, and gut–liver axis signaling and have been implicated in hepatocarcinogenesis. Prior studies linked circulating bile acids to liver cancer risk, but most used general controls, leaving unclear whether bile acid alterations distinguish liver cancer from MASLD or cirrhosis. We evaluated associations between prediagnostic bile acids and liver cancer in the Mass General Brigham Biobank (MGBB) using disease-spectrum controls (healthy, MASLD, and cirrhosis), and synthesized prospective evidence through meta-analysis. **Methods:** We conducted a nested case-control study of 59 incident liver cancer cases with plasma collected $\geq$6 months before diagnosis, 111 cirrhosis controls, 113 MASLD controls, and 59 healthy controls. Controls were matched on age, sex, race, and blood collection year; cirrhosis/MASLD controls were additionally matched on time from blood collection to event, and healthy controls on Charlson comorbidity index group. Bile acids were assayed by LC-MS/MS. Conditional logistic regression accounting for matched sets and adjusted for age, smoking, alcohol use, and BMI estimated ORs and 95% CIs per 1-SD increment in log-transformed levels. Random-effects meta-analysis pooled high-versus-low estimates from seven published prospective studies plus MGBB, comprising 2,136 cases and 2,916 controls. **Results:** In MGBB, conjugated bile acids were higher in liver cancer cases than healthy and MASLD controls. Per 1-SD increment in log-transformed levels, GCA, TUDCA, TCA, TCDCA, and GCDCA were associated with greater odds of liver cancer versus healthy controls (ORs 3.72 to 5.40);

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

similar associations were observed versus MASLD controls (ORs 2.34 to 5.80). Associations were attenuated but persisted versus cirrhosis controls for the same bile acids (ORs 1.67 to 2.35). In meta-analysis, conjugated primary bile acids showed the strongest pooled associations, including GCA, GCDCA, TCA, and TCDCA (ORs 2.90 to 6.01). **Conclusion:** Higher prediagnostic levels of circulating conjugated bile acids were associated with liver cancer in MGBB and supported by meta-analysis. Associations persisted, although attenuated, among cirrhosis controls, suggesting that bile acid dysregulation may capture hepatobiliary dysfunction relevant to hepatocarcinogenesis beyond advanced liver disease alone. These findings support further evaluation of bile acid profiling to refine liver cancer risk stratification across the chronic liver disease spectrum.

0151 | EFFECTIVENESS OF A STRUCTURED SURVEILLANCE PROGRAM FOR EARLY DETECTION OF HEPATOCELLULAR CARCINOMA IN CONTEMPORARY PATIENTS WITH ADVANCED CHRONIC LIVER DISEASE

Georg Kramer[1] Carina Pichler[2] Lorenz Balcar[2] Benedikt Simbrunner[1] Georg Semmler[1] Mathias Jachs[2] Lukas Hartl[2] Benedikt Hofer[2] Christian Sebesta[2] Paul Thoene[2] Marlene Hintersteininger[2] Michael Trauner[2] Thomas Reiberger[1] Matthias Pinter[2] Bernhard Scheiner[1], [1]Medical University of Vienna, [2]Medical University of Vienna, Vienna, Austria

Background: Hepatocellular carcinoma (HCC) surveillance is recommended for patients with advanced chronic liver disease (ACLD), but real-world adherence is variable and often measured using binary or semi-quantitative approaches. We aimed to quantify surveillance adherence longitudinally using a continuous time-based metric and to assess its association with clinical outcomes. We additionally evaluated the diagnostic yield of a structured re-linkage initiative for patients overdue for routine surveillance. **Methods:** We analyzed 639 ACLD patients enrolled in the prospective Vienna Cirrhosis Study (VICIS; NCT03267615) between 2017 and 2024 who received regular care in our center. Surveillance adherence was assessed using the proportion of time covered (PTC), assigning six months of coverage to each imaging examination. Associations between PTC and outcomes were analyzed using adjusted Cox regression and internally validated in a propensity score-matched cohort balanced for age, sex, etiology, and Child-Pugh score (CPS), using Fine-Gray competing-risk models. Overdue patients were prospectively identified and re-linked to imaging through a structured program. **Results:** Median imaging-based PTC was 83% (IQR 60-98%). During a median follow-up of 43 months, 47 patients (7.4%) developed HCC, of whom 47% were diagnosed at an early stage (Barcelona Clinic Liver Cancer 0/A). PTC showed a non-linear association with early HCC detection, with a marked increase above 85% surveillance coverage. Biannual imaging was associated with a 6.6-fold higher likelihood of early HCC detection compared with annual imaging (HR 6.57; 95% CI 2.38-18.11). After propensity score matching, high adherence (PTC $\geq$85%) was independently associated with early HCC detection (adjusted SHR 2.44; $p = 0.015$) and curative treatment option (adjusted SHR 2.60; $p = 0.024$), with a trend toward improved post-HCC survival (SHR 0.37; $p = 0.087$). Among 52 overdue patients actively re-linked to imaging, 8 (15%) had newly detected suspicious hepatic lesions, including one biopsy-confirmed HCC. **Conclusion:** In this contemporary ACLD cohort, sustained high adherence to HCC surveillance was associated with earlier tumor detection and option for curative treatment. Continuous time-based metrics such as PTC may provide a more precise assessment of surveillance quality, while structured re-linkage of overdue patients represents a simple strategy to strengthen HCC surveillance in routine care.

0152 | CHANGING CLINICAL PATTERNS AND OUTCOMES OF HEPATOCELLULAR CARCINOMA ACROSS TREATMENT ERAS: A MULTICENTER COHORT STUDY

Karim Seif El Dahan[1] Nicole Rich[2] Patrick Hazelrigg[3] Andrew Moon[3] Naomy Kim[4] Ju Dong Yang[4] Reena Salgia[5] Madeline Smith[6] Rashmita Raghunathan[6] Neehar Parikh[6] Prasun Jalal[7] Anjana Pillai[8] Lisa Quirk[1] Amit Singal[1], [1]UT Southwestern Medical Center, [2]University of Texas Southwestern Medical Center, [3]University of North Carolina, [4]Cedars-Sinai Medical Center, [5]Henry Ford Health, [6]University of Michigan Medical Center, [7]Baylor College of Medicine, [8]University of Chicago

Background: Advances in antiviral therapy, surveillance strategies, and expanded eligibility for curative treatments may have influenced patterns of hepatocellular carcinoma (HCC) presentation, management, and outcomes over time. We characterized temporal trends in clinical characteristics, treatment patterns and outcomes of patients with HCC in a large multicenter U.S. cohort. **Methods:** We conducted a retrospective cohort study across nine large health systems from the HCC-Live Consortium including patients diagnosed with HCC between 2008 and 2023. We defined three eras based on major changes in HCC management: group 1 (2008–2012, sorafenib/pre-direct-acting antiviral [DAA] era); group 2 (2013–2017, DAA era); and group 3 (2018–2023, expanded downstaging and immunotherapy era). Multivariable logistic regression was used to assess associations between era and early-stage HCC detection (BCLC stage 0/A), surveillance receipt, and curative treatment (liver transplant, surgical resection, or local ablation). Multivariable Cox regression was used to evaluate associations with overall survival. **Results:** Among 5,428 patients with HCC (group 1: n = 621; group 2: n = 2,442; group 3: n = 2,365), median age was 63.3 years, and 26.4% were women. The cohort was racially and ethnically diverse (48.3% White, 21.9% Hispanic, 20.0% Black). Over time, the median age at diagnosis increased (58.2, 62.8, and 65.0 years), as did the proportion of women (22.7%, 26.3%, and 27.5%). HCV-related HCC decreased over time (66.2%, 63.2%, and 51.5%; $p < 0.001$), whereas MASLD (7.2%, 12.4%, and 18.8%; $p < 0.001$) and ALD-related HCC (11.8%, 11.8%, and 16.9%; $p < 0.001$) increased. Surveillance receipt remained low across eras (37.0%, 52.2%, and 41.5%; group 3 vs. group 1: OR 1.05, 95%CI 0.87–1.28). Early-stage HCC detection increased modestly over time (36.7%, 39.1%, and 40.3%) with higher odds in group 3 vs. group 1, although this did not reach statistical significance (OR 1.17, 95%CI 0.96–1.41). Compared with group 1, patients in group 2 (OR 2.23, 95%CI 1.79–2.78) and group 3 (OR 1.88, 95%CI 1.51–2.35) were more likely to receive curative treatment. Median overall survival improved over time (12 (95%CI, 9.8–15), 26 (95%CI, 24–28), and 20 (95%CI 18–22) months, respectively). In adjusted analyses groups 2 (HR 0.65, 95%CI 0.58–0.72) and 3 (HR 0.78, 95%CI 0.70–0.87) had lower mortality than group 1. **Conclusion:** Overall survival among patients with HCC has improved substantially over time, coinciding with advances in antiviral therapy and curative treatment approaches. However, surveillance receipt and early-stage detection remained suboptimal, highlighting persistent gaps in HCC surveillance and early detection.

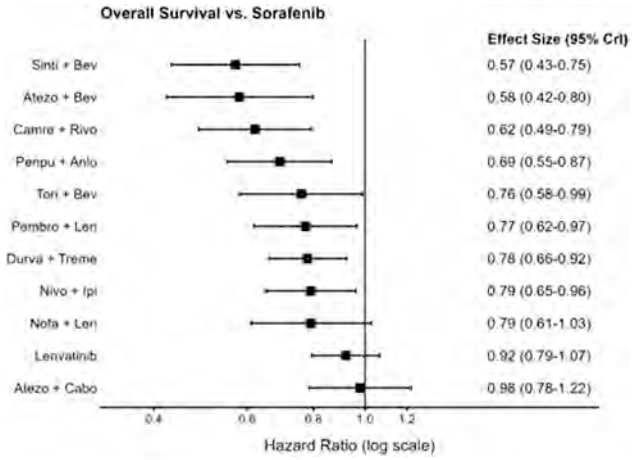
0153 | CIRCULATING TUMOR DNA FOR EARLY RECURRENCE DETECTION AND MOLECULAR RESIDUAL DISEASE MONITORING IN HEPATOCELLULAR CARCINOMA AND BILIARY TRACT CANCER: A REAL-WORLD MULTICENTER ANALYSIS

Maen Abdelrahim[1] Abdullah Esmail[2] Adham Jurdi[3], [1]Houston Methodist Neal Cancer Center, Houston, Tx, [2]Section of GI Oncology, Department of Medicine, Houston Methodist Cancer Center, Houston, TX 77030, [3]Natera, Inc., Austin, TX, United States

Background: Hepatocellular carcinoma (HCC) and biliary tract cancer (BTC) carry high recurrence rates following curative-intent resection or liver transplantation (LT), and existing biomarkers such as AFP and CA19-9 have limited postoperative prognostic utility. Circulating tumor DNA (ctDNA) has emerged as a promising tool for molecular residual disease (MRD) assessment and recurrence detection across gastrointestinal malignancies. We evaluated the clinical utility of a personalized, tumor-informed ctDNA assay across both HCC and BTC in real-world practice. **Methods:** This retrospective, multicenter real-world study analyzed 1,472 plasma samples from 292 patients, 125 with HCC and 167 with Stage I–III resected BTC, who underwent serial ctDNA testing using a personalized 16-plex mPCR-NGS assay (Signatera™, Natera, Inc.). In HCC, patients were monitored post-LT or post-resection across four cohorts. In BTC, samples were collected pre-operatively, in the MRD window (2–12 weeks post-resection), and during longitudinal post-definitive treatment surveillance. ctDNA results were correlated with relapse-free survival (RFS), overall survival (OS), and radiographic recurrence, and compared to concurrent standard biomarkers (AFP for HCC; CA19-9 and CEA for BTC). Multivariable analyses identified independent predictors of recurrence in both tumor types. **Results:** Median follow-up was 40 months (range 1.5–60) for HCC and 21 months (range 2–97) for BTC. In HCC, ctDNA positivity in the MRD window strongly predicted clinical recurrence (HR 7.2, 95% CI 2.6–20.0; $p < 0.0001$), and ctDNA positivity during surveillance was even more strongly associated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.



with recurrence (HR 18.0, 95% CI 3.9–85.0; $p < 0.0001$). ctDNA demonstrated a significantly longer lead time over AFP for recurrence detection (7.9 vs. 2.2 months). In BTC, ctDNA positivity was the strongest independent predictor of inferior RFS during the MRD window (HR 15.86, 95% CI 4.69–53.6; $p < 0.001$) and surveillance (HR 14.93, 95% CI 5.33–41.9; $p < 0.001$) on multivariable analysis, outperforming both CA19-9 and CEA, which were not independently prognostic in either setting. ctDNA identified radiographic recurrence a median of 3.7 months before imaging in BTC. Across both tumor types, longitudinal ctDNA dynamics correlated with treatment response and helped resolve equivocal imaging findings. **Conclusion:** In this combined real-world analysis of 292 patients across HCC and BTC, serial personalized ctDNA testing was the strongest independent predictor of recurrence and survival, consistently outperforming standard biomarkers with clinically meaningful imaging lead times. These findings establish ctDNA-based MRD monitoring as a superior postoperative surveillance strategy across primary liver and biliary cancers, warranting prospective validation and integration into adjuvant therapy decision-making frameworks.

0154 | COMPARATIVE EFFICACY AND SAFETY OF FIRST-LINE SYSTEMIC COMBINATIONS IN UNRESECTABLE HEPATOCELLULAR CARCINOMA (UHCC): A BAYESIAN NETWORK META-ANALYSIS OF 11 PHASE III TRIALS

Rahul Falodia[1] Maheen Afzal[2] Ubaid Ahmed[3], [1]All India Institute of Medical Sciences Jodhpur, [2]University of Alabama at Birmingham, Montgomery, [3]Dow University of Health Sciences, Karachi, Pakistan

Background: The treatment landscape for uHCC has rapidly evolved with the introduction of immune checkpoint inhibitors (ICI) combined with anti-VEGF therapy, tyrosine kinase inhibitors (TKI), or a second ICI (CTLA-4). In the absence of head-to-head randomized controlled trials, optimal first-line regimen selection remains uncertain. This network meta-analysis evaluates the comparative efficacy and safety of modern first-line combinations to guide treatment sequencing. **Methods:** A systematic review identified Phase III trials of first-line systemic therapies for uHCC. Risk of bias was assessed using Cochrane RoB 2. A Bayesian network meta-analysis (fixed-effects model) was performed using gemtc in R. Primary endpoints were overall survival (OS) and progression-free survival (PFS). Secondary endpoints included objective response rate (ORR) and class-specific grade ≥ 3 adverse events (hypertension, hemorrhage/variceal bleeding, hepatitis, and colitis). Certainty of evidence was assessed using the GRADE framework. Sorafenib served as the common reference node. **Results:** Eleven Phase III RCTs comprising 7,495 patients were included. Overall risk of bias was generally low. For OS, ICI–anti-VEGF and ICI–TKI combinations demonstrated the highest efficacy (moderate GRADE certainty). Sintilimab plus bevacizumab (HR 0.57, 95% CrI 0.44–0.75), atezolizumab plus bevacizumab (HR 0.58, 0.43–0.79), and camrelizumab plus rivoceranib (HR 0.62, 0.49–0.80) showed the most significant OS improvements compared with sorafenib. Dual immune checkpoint blockade (ICI–ICI) regimens, including nivolumab plus ipilimumab (HR 0.79, 0.65–0.96) and durvalumab plus tremelimumab (HR 0.78, 0.65–0.93), also improved OS but ranked lower than ICI–anti-VEGF/ICI–TKI strategies.For PFS (low-to-moderate GRADE certainty), ICI–TKI regimens such as penpulimab plus anlotinib (HR 0.52, 0.41–0.66) showed the highest probability of being the best treatment.Regarding safety, distinct toxicity profiles emerged. ICI–anti-VEGF and ICI–TKI regimens were associated with higher odds of grade ≥ 3 hypertension and hemorrhage compared with sorafenib. Conversely, ICI–ICI regimens had the lowest risk of vascular toxicities but showed increased odds of severe immune-mediated adverse events, specifically grade ≥ 3 hepatitis and colitis. **Conclusion:** This network meta-analysis shows that multiple combination strategies significantly outperform standard-of-care TKIs in first-line uHCC, with distinct efficacy and safety profiles. ICI–anti-VEGF and selected ICI–TKI combinations provide the greatest survival benefit but increase vascular toxicity. In contrast, ICI–ICI combinations achieve higher objective response rates with lower bleeding risk, despite inferior progression control. These results provide quantitative evidence to support treatment selection based on efficacy–toxicity trade-offs.

0155 | AUGMENTING THE TUMOR BOARD: A MULTI-AGENT AI PIPELINE FOR LIVER CANCER TREATMENT RECOMMENDATIONS

Richie Manikat[1] Vetri Elango[2] Renumathy Dhanasekaran[1], [1]Stanford University School of Medicine, [2]Arithmedics, Inc.

Background: Multidisciplinary tumor boards are essential to hepatocellular carcinoma (HCC) management, yet preparing each case requires significant physician time to extract and synthesize unstructured clinical, laboratory, and imaging data, stage tumors, and formulate personalized treatment plans. We developed a custom multi-agent AI tool, anchored in our institution's tumor board protocols and powered by a Retrieval-Augmented Generation (RAG) framework, to automate this workflow end-to-end. **Methods:** We built a three-agent workflow: (1) an Extraction Agent that converts unstructured clinical notes, radiology reports, and pathology reports into structured formats; (2) a Synthesis and Staging Agent that extracted parameters to generate summaries, assign BCLC stage, and provide Stanford-specific treatment recommendations as a starting point; and (3) a Tumor Board Report Agent that produces presentation-ready reports for use in live multidisciplinary tumor boards. In Phase 1, we validated the tool on 25 simulated cases spanning all four BCLC stages, benchmarking performance against GPT-4.0 and an expert hepatologist. In Phase 2, the tool was applied to de-identified real-world data extracted from the Stanford Research Repository (STARR) to test feasibility at scale on unstructured EHR data. **Results:** In Phase 1, the HCC-AI Tool accurately generated narrative summaries and BCLC staging from unstructured clinical notes across all 45 cases, achieving 100% concordance with the expert hepatologist and outperforming GPT-4.0 (80%). The Tumor Board Report Agent produced presentation-ready outputs that have been used in actual case presentations at our institutional tumor board. In Phase 2, STARR retrieved raw unstructured EHR data for 93 HCC patients. The Extraction Agent successfully identified and structured key staging parameters (AFP, MELD, tumor size and number, vascular invasion, extrahepatic spread, performance status) across clinical notes, lab results, and radiology reports. The Synthesis and Staging Agent assigned BCLC classification for 58% of patients, identifying 19 who met Milan criteria for liver transplant evaluation and 35 who did not. The remaining 39 patients had incomplete data due to missing laboratory values (n = 9), incomplete tumor characterization from outside-institution imaging (n = 20), or indeterminate findings requiring clinical correlation (n = 10). **Conclusion:** The HCC-AI Tumor Board Tool demonstrates strong performance in automating HCC tumor board preparation, achieving expert-level staging accuracy and presentation-ready reports. Real-world deployment confirmed feasibility at scale within a PHI-compliant institutional framework. These findings underscore the importance of institution-specific customization in clinical AI and highlight the potential to extend expert-level HCC decision-making to centers without dedicated multidisciplinary tumor boards.

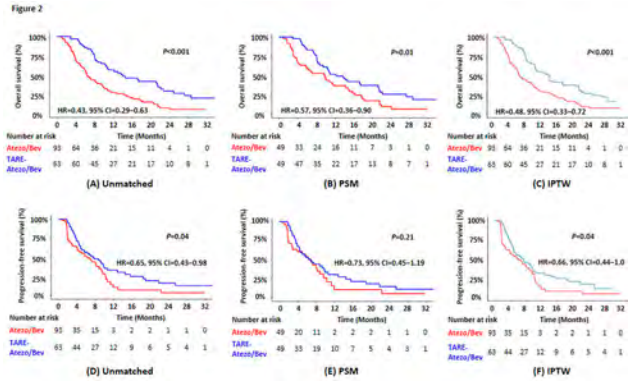
★ 0156 | SEQUENTIAL TRANSARTERIAL RADIOEMBOLIZATION AND ATEZOLIZUMAB PLUS BEVACIZUMAB IMPROVES SURVIVAL IN ADVANCED HEPATOCELLULAR CARCINOMA: A PROPENSITY SCORE-MATCHED ANALYSIS



Yunmi Ko[1] Yoon Jun Kim[2], [1]Inha University Hospital, [2]Seoul National University Hospital

Background: Yttrium-90 transarterial radioembolization (TARE) combined with immune checkpoint inhibitors has been investigated as a potential therapeutic strategy for advanced hepatocellular carcinoma (HCC); however, evidence supporting its addition to current standard systemic therapy remains limited. We aimed to compare clinical outcomes in patients with advanced HCC treated with TARE followed by atezolizumab plus bevacizumab (TARE–Atezo/Bev) and Atezo/Bev alone. **Methods:** This retrospective cohort study included systemic therapy-naïve patients with advanced HCC treated with Atezo/Bev alone or TARE–Atezo/Bev at a single tertiary hospital between 2018 and 2025. Baseline characteristics were adjusted using propensity score matching (PSM) and inverse probability of treatment weighting (IPTW). The primary outcome was overall survival (OS), and the secondary outcome was progression-free survival (PFS). **Results:** A total of 156 eligible patients were enrolled, including 93 in the Atezo/Bev group and 63 in the TARE–Atezo/Bev group. In the unmatched cohort, median OS was significantly longer in the TARE–Atezo/Bev group than in the Atezo/Bev group (14.1 vs. 6.4 months; hazard ratio = 0.43, 95% confidence interval = 0.29–0.63; $P < 0.001$), with consistent results after PSM ($P = 0.01$) and IPTW ($P < 0.001$). Although PFS was comparable between groups in the overall cohort, patients with Child-Pugh

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

class A (OS: 14.6 vs. 7.1 months; PFS: 7.7 vs. 6.3 months) or ALBI grade 1 (OS: 21.4 vs. 8.3 months; PFS: 8.1 vs. 5.7 months) had significantly longer OS and PFS in the TARE–Atezo/Bev group, with similar results after adjustment. **Conclusion:** Sequential TARE–Atezo/Bev may improve survival compared with Atezo/Bev alone in patients with advanced HCC and well-preserved liver function.

0157 | MAGNETIC PARTICLE IMAGING GUIDES DOSING OF ID3-ENHANCED, TGFBR2-DELETED IPSC-DERIVED CAR MACROPHAGES FOR HEPATOCELLULAR CARCINOMA

Tuo Shao[1] Chao Tang[1] Xin Feng[2] Hui Hui[2] Raymond Chung[3] Jie Tian[2], [1]The First Affiliated Hospital of Soochow University, [2]CAS Key Laboratory of Molecular Imaging, Institute of Automation, Chinese Academy of Sciences, [3]Division of Gastroenterology and Hepatology, Mass General Brigham

Background: Hepatocellular carcinoma (HCC) remains resistant to cellular immunotherapy because of poor effector-cell infiltration and a strongly immunosuppressive tumor microenvironment. Induced pluripotent stem cell (iPSC)-derived chimeric antigen receptor macrophages (CAR-iMac) may offer an off-the-shelf myeloid platform, but their antitumor state, resistance to transforming growth factor-β (TGF-β), and in vivo exposure remain difficult to control. We developed an ID3-enhanced, TGFBR2-deleted, glypican-3 (GPC3)-targeted CAR-iMac and used magnetic particle imaging (MPI) to guide dosing in preclinical HCC. **Methods:** Human cord blood CD34+ cells were reprogrammed into iPSCs, engineered with an anti-GPC3 CAR containing ID3, and further edited by CRISPR-Cas9 to delete TGFBR2. Differentiated CAR-iMac were assessed by flow cytometry, transcriptomics, tumor-cell killing/phagocytosis assays, orthotopic HCC mouse models, SPION-based MPI/CT tracking, PBMC-humanized safety/efficacy models, and patient-derived HCC organoids co-cultured with autologous CD3+ T cells. **Results:** ID3-endowed CAR-iMac retained pluripotency before differentiation, maintained CAR expression during myeloid differentiation, and showed stronger GPC3-dependent clearance of HepG2 and Huh7 cells than truncated CAR-iMac, with limited activity against GPC3-negative SK-Hep-1 cells. TGFBR2 deletion further enhanced antitumor function, increased CD80/CD86, reduced CD163/CD206, enriched inflammatory and chemotaxis programs, and produced the greatest suppression of orthotopic HCC growth. SPION labeling preserved viability and macrophage-marker profiles, and MPI signals were linearly related to cell number. Longitudinal MPI showed hepatic localization and dose-dependent persistence: 1×10^6 cells decayed rapidly, 5×10^6 persisted to day 30 but did not improve efficacy, whereas 2.5×10^6 cells plus pro-inflammatory support achieved better early-to-mid tumor suppression and a higher M1-associated fraction. In PBMC-humanized HCC mice, split dosing (2.5×10^6 cells on days 0 and 15) reduced high-dose inflammatory toxicity, maintained lower tumor burden, and prolonged survival. In patient-derived HCC organoids, TGFBR2-deleted CAR-iMac cooperated with autologous T cells to reduce organoid size, increase IL-2, IL-6, IL-1β, IL-8, and TNF-α, and enhance LDH-defined cytotoxicity. **Conclusion:** Dual ID3 enhancement and TGFBR2 deletion generates a potent, scalable, and monitorable GPC3-targeted CAR-iMac platform for HCC. MPI-defined exposure reveals that intermediate, fractionated dosing may be superior to maximal single dosing by preserving antitumor activity while limiting inflammatory toxicity and M2-like reprogramming.

0158 | ETIOLOGY DISSOCIATES THE CAUSES OF DEATH AFTER LIVER TRANSPLANT FOR HEPATOCELLULAR CARCINOMA: A COMPETING-RISKS ANALYSIS OF 12,001 DAA-ERA RECIPIENTS

Mohamed Nadeem[1] Islam Mohamed[2] Basil Jalamneh[1] Sobia Laique[3] Shilpa Junna[3], [1]Cleveland Clinic Foundation, [2]The Cleveland Clinic Foundation-Fairview hospital, [3]Cleveland Clinic

Background: The etiology of cirrhosis and associated hepatocellular carcinoma has been gradually evolving, with the increasing global incidence of MASH-related liver disease. The role of cirrhosis etiology in predicting post-LT HCC recurrence is not well known. **Methods:** We analyzed 12,001 adult HCC-exception first-time liver-only transplants with etiology-classifiable cirrhosis in OPTN/UNOS STAR (2014–2023, direct-acting-antiviral era), linked to explant pathology, post-LT malignancy follow-up, and exception files. Etiology of cirrhosis (HCV/HBV/MASLD/MetALD/ALD) was assigned via a viral-dominant hierarchy on primary and secondary diagnoses, with ALD plus ≥ 1 cardiometabolic risk factor reclassified as MetALD. Cardiometabolic risk factors included Type 2 diabetes mellitus and obesity. Additional information regarding the cohort can be found in Table 1.Composite recurrence of malignancy, recurrence-attributed graft failure, and recurrence-attributed cause of death were collected. Fine-Gray subdistribution hazards modeled recurrence of HCC (reference MASLD); a second Fine-Gray model, with non-recurrence death as the primary event, tested whether differences in patient characteristics and medical comorbidities accounted for the etiology-related differences in mortality. **Results:** Composite recurrence of HCC occurred in 1,445 recipients (12.0%); with a median follow-up of 5.0–6.4 years. Adjusted recurrence sHR versus MASLD: HCV 1.39 (1.18–1.64, $p < 0.001$), ALD 1.67 (1.12–2.48, $p = 0.011$), HBV 1.25 (NS), MetALD 1.14 (NS). Five-year recurrence cumulative incidence: ALD 13.0%, HCV 11.7%, HBV 9.9%, MetALD 8.0%, MASLD 7.4% (Gray's $p < 0.001$). Recurrence was the principal late-mortality driver (time-dependent HR 13.4, 11.9–15.0). Five-year recurrence-related versus non-recurrence death ratios diverged by etiology: HBV 1.34 and ALD 1.07 (recurrence-dominant), HCV 0.85, MetALD 0.56, MASLD 0.42 (non-recurrence dominant). MASLD recipients were older (mean 63.7 years) and more often diabetic (68.8%) than HCV recipients (27.0% diabetic). An adjusted Fine-Gray for non-recurrence death attenuated HCV versus MASLD from sHR 0.71 ($p < 0.001$) to 0.89 ($p = 0.040$), with diabetes sHR 1.40 ($p < 0.001$) consistent with the case mix rather than a distinct metabolic-liver effect. **Conclusion:** Patients with a component of viral or alcohol related liver disease and associated HCC had higher rates of recurrence, compared to their counterparts with MASLD-associated HCC after LT in the DAA era, with ALD showing the highest cumulative incidence. The post-LT mortality of MASH-related HCC patients is instead driven by cardiometabolic events. Etiology-specific surveillance and cardiometabolic risk reduction merit integration into post-LT care of HCC patients.

Table 1. Baseline recipient, tumor, and donor characteristics by etiology

Variable	HCV	HBV	MASLD	MetALD	ALD

0159 | ZDHHC4+ CAFS ESTABLISH AN IMMUNOSUPPRESSIVE CMXT NICHE IN HEPATOCELLULAR CARCINOMA

Suiqing Zhou[1] Chunyao Fang[1] Xuehao Wang[1], [1]Nanjing Medical University

Background: The immune microenvironment of hepatocellular carcinoma is organized into spatially coordinated niches rather than random cellular aggregates. Immunotherapy response depends not only on immune cell abundance, but also on their spatial localization, functional state, and interactions with stromal cells. However, the key spatial niches and molecular drivers of immune suppression in hepatocellular carcinoma remain unclear. **Methods:** We integrated CODEX imaging, Visium HD spatial transcriptomics, spatial metabolomics, single-cell RNA sequencing, metabolomics, RNA-seq, IP/MS, and palmitoyl-proteomics to map cellular interactions in hepatocellular carcinoma. Fibroblast-specific Zdhhc4 knockout mice, DEN/CCL4-induced liver cancer models, orthotopic tumor models, primary CAF-macrophage co-culture, isotope tracing, multiplex immunofluorescence, Co-IP, PLA, GST pull-down, and anti-PD-1 treatment assays were used for validation. **Results:** Spatial analysis identified a tricellular niche composed of CAFs, macrophages, and exhausted CD8+ T cells, termed the CMxT niche. High CMxT abundance was associated with poor overall survival independently of total immune infiltration. ZDHHC4 expression in CAFs negatively correlated with the distance to neighboring macrophages and exhausted CD8+ T cells, suggesting a niche-driving role. Fibroblast-specific Zdhhc4 deletion reduced tumor burden and impaired local enrichment of OXGR1+ macrophages and exhausted CD8+ T cells. Mechanistically, ZDHHC4 palmitoylated the glutamine transporter SNAT2, enhanced SNAT2-TRIM11 interaction, promoted K63-linked ubiquitination and membrane localization of SNAT2, and increased glutamine flux and α-ketoglutarate release from CAFs. α-Ketoglutarate acted as an endogenous OXGR1 ligand to recruit OXGR1+ macrophages and promote CD8+ T-cell exhaustion. In clinical samples, ZDHHC4+ CAFs, OXGR1+ macrophages, exhausted CD8+ T cells, and local α-ketoglutarate levels were spatially correlated. Targeting ZDHHC4 in CAFs disrupted this niche axis and enhanced anti-PD-1 efficacy. **Conclusion:** This study defines a ZDHHC4+ CAF/OXGR1+ macrophage/exhausted CD8+ T-cell CMxT niche in hepatocellular carcinoma and reveals a ZDHHC4-SNAT2-α-ketoglutarate-OXGR1 axis driving spatial immune suppression. CAF-intrinsic ZDHHC4 may represent a therapeutic target to remodel the tumor immune microenvironment and improve anti-PD-1 therapy.

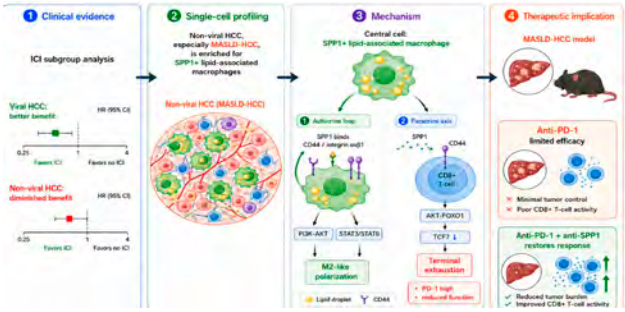
0160 | LIPID-ASSOCIATED SPP1+MACROPHAGES DRIVE ATTENUATED RESPONSES TO IMMUNE CHECKPOINT INHIBITORS IN MASLD-ASSOCIATED HEPATOCELLULAR CARCINOMA



Enrui Xie[1] Xinyuan He[1] Xu Gao[1] Taotao Yan[1] Yue Zhang[1] Siyuan Wang[2] Xiao Yuan[1] Xindi Huang[1] Jiaxuan Hou[3] Yidi Zhao[1] Qian Wang[1] Xiaofan Song[4] Baohua Li[4] Ting La[4] Wen Kang[5] Pengfei Liu[4] Shuo Jin[2] Taotao Huo[4] Fanpu Ji[4], [1]The Second Affiliated Hospital of Xi'an Jiaotong University, [2]Beijing Tsinghua Changgung Hospital, [3]The First Affiliated Hospital of Xi'an Jiaotong University, [4]The Second Affiliated Hospital of Xi'an Jiaotong University, [5]Fourth Military Medical University

Background: The efficacy of immune checkpoint inhibitor (ICI)-based therapy varies across hepatocellular carcinoma (HCC) etiologies, but the mechanisms underlying poor responses in non-viral HCC remain unclear. **Methods:** We performed a meta-analysis of 16 phase III RCTs and integrated publicly available scRNA-seq datasets from viral and non-viral HCC. Findings were validated using a methionine- and choline-deficient (MCD) diet–induced orthotopic MASLD-HCC mouse model and mechanistic in vitro assays targeting SPP1-mediated macrophage–T cell crosstalk. **Results:** ICI-based therapy improved overall survival in advanced HCC, but its benefit was attenuated in non-viral HCC. Public scRNA-seq analyses revealed enrichment of SPP1+ lipid-associated macrophage(LAM)-like cells in non-viral and steatotic HCC, accompanied by increased CD8+ T-cell terminal

exhaustion. In MASLD-HCC mice, reduced anti-PD-1 efficacy was associated with elevated macrophage SPP1 expression. Mechanistically, SPP1 promoted immunosuppression via macrophage autocrine CD44/integrin αvβ1–PI3K/AKT–STAT3/STAT6 signaling and $CD8^+$ T-cell paracrine CD44–AKT–FOXO1 signaling, thereby driving macrophage immunosuppressive polarization and T-cell exhaustion. Dual SPP1 and PD-1 blockade synergistically suppressed MASLD-HCC progression and enhanced antitumor immunity. **Conclusion:** Non-viral HCC shows an attenuated response to ICI-based therapy associated with $SPP1^+$ LAM-like macrophage. Combined SPP1 and PD-1 blockade may offer an immunotherapy strategy for MASLD-associated HCC.

Background: Intrahepatic cholangiocarcinoma (iCCA) is an aggressive liver cancer with a poor prognosis and limited therapies. PI3K/PTEN/AKT activation and loss of primary cilia (PC) are common features of iCCA. However, their mechanistic relationship remains poorly understood. This study investigated how biliary Pten loss and PC dysfunction drive iCCA development. It also elucidated the underlying molecular mechanisms and identified potential therapeutic targets. **Methods:** Biliary epithelial cell (BEC)-specific knockout of Pten, Kif3a (PC loss), or both was achieved using CK19CreERT-driven recombination in adult mice. Thioacetamide (TAA) was used to induce chronic liver injury and fibrosis. Experimental treatments were administered from week 17 to 20 post-TAA. Liver tissues were analysed by histopathology and RNA-sequencing. **Results:** Under conditions of chronic liver injury, BEC-specific Pten deletion induced iCCA with cystic biliary lesions and marked PC loss in adult mice, highlighting the critical role of inflammation in tumour initiation. PC loss accelerated tumour progression, supporting its role as a tumour suppressor in iCCA. Mechanistically, Pten loss triggered PC disassembly via the CK1ε–Dvl2–AurKA axis. Activation of this pathway promoted ciliary loss and tumour progression, whereas CK1ε inhibition reduced tumour progression and immune cell infiltration in a PC-dependent manner.Transcriptomic analyses revealed that the Pten/PC-deficient (PKO) iCCAs recapitulated key features of poor-prognosis inflammatory human iCCA subtype, including enrichment of integrins, matrix remodelling genes, innate immune signatures, and immune checkpoint-associated genes. Furthermore, membrane-associated carbonic anhydrases (CA4, CA9, and CA12) were markedly upregulated, particularly in PC-deficient tumours. CA inhibition with acetazolamide significantly reduced tumour progression and altered the immune microenvironment (Fig. 1). **Conclusion:** Pten loss and PC dysfunction synergistically drive iCCA progression during chronic injury. Targeting the CK1ε–Dvl2–AurKA pathway and membrane-associated carbonic anhydrases offers potential therapeutic targets. The PKO mouse model closely recapitulates aggressive, inflammatory human iCCA.

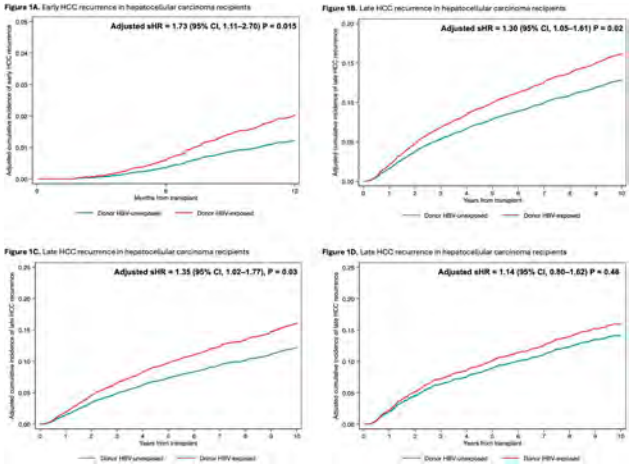
0162 | DONOR HBV EXPOSURE STATUS IS ASSOCIATED WITH INCREASED RECURRENCE OF HEPATOCELLULAR CARCINOMA AFTER LIVER TRANSPLANTATION: A NATIONAL REGISTRY ANALYSIS WITH PROPENSITY-SCORE AND WEIGHTING-BASED COMPETING-RISKS MODELS



Leandro Sierra[1] Rachael Mahle[2] Katherine Cooper[2] Abigail Scherrer[2] Teresa Rice[2] Irun Bhan[2] Eric Przybyszewski[2] Amit Singal[3] Emily Bethea[2],
[1]Cleveland Clinic Foundation, [2]Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA, [3]The University of Texas Southwestern Medical Center, Dallas, TX, USA

Background: Use of donor grafts with hepatitis B virus (HBV) exposure has expanded in liver transplantation (LT) for hepatocellular carcinoma (HCC). HBV-exposed grafts may harbor covalently closed circular DNA and integrated viral sequences capable of reactivation under immunosuppression. Prior U.S. studies show comparable survival with HBV-exposed grafts, but the association with HCC recurrence and whether it differs by recipient HBV serostatus, remains unexplored. **Methods:** We conducted a retrospective study using the Scientific Registry of Transplant Recipients from 2013 to 2025. Adults receiving first deceased-donor LT for HCC with explant pathology were compared by donor HBV exposure: unexposed (all serology negative) versus exposed (anti-HBc, HBsAg, or HBV NAT positive). Recipients were classified as HBV-naïve (negative anti-HBc, HBsAg, and HBV DNA) or HBV-exposed (any marker positive). Primary outcome was HCC recurrence, modeled with Fine-Gray competing-risks regression at 1-year (early recurrence) and 10-year (late recurrence), with death without recurrence as the competing event. Robustness was confirmed by two parallel study designs: 1: 1 propensity-score matching and inverse probability of treatment weighting. Additional sensitivity analyses excluded HBV/HDV coinfection, restricted to within-Milan recipients, applied a 30-day landmark, and adjusted for transplant year and region. All models were adjusted by recipient demographics, MELD, tumor burden and differentiation, AFP, locoregional therapy, donor risk index (DRI), and satellite lesions. **Results:** Of 16,426 LT recipients with HCC, 1,078 (6.6%) received HBV-exposed grafts. HBV-related HCC was overrepresented among recipients of HBV-exposed grafts (8.7% vs 5.0%, $p < 0.001$), and DRI was higher (2.0 vs 1.3, $p < 0.001$). At 10 years, cumulative HCC recurrence was higher among HBV-exposed versus non-exposed grafts (16.2% vs 12.9%, $p < 0.001$). Donor HBV exposure was independently associated with increased early recurrence (sHR 1.73, 95% CI 1.11–2.70, $p = 0.015$) and late recurrence (sHR 1.30, 95% CI 1.05–1.61, $p = 0.02$). The association with late recurrence was moderated by recipient HBV serostatus, with increased risk among HBV-naïve recipients (sHR 1.35, 95% CI 1.02–1.77, $p = 0.03$) but not HBV-exposed recipients (sHR 1.14, 95% CI 0.80–1.62, $p = 0.46$). Early recurrence did not differ by recipient HBV status. Donor HBV exposure was not associated with mortality (10-year HR 1.06, 95% CI 0.90–1.23, $p = 0.46$). Findings were robust across all sensitivity analyses (early sHR range 1.71–2.25; late sHR range 1.29–1.42). **Conclusion:** Donor HBV exposure is associated with increased post-LT HCC recurrence, particularly among HBV-naïve recipients. This may reflect impaired tumor surveillance by donor-derived HBV antigens in the absence of pre-existing HBV immunity. Findings support enhanced HCC surveillance in HBV-naïve

0163 | INTEGRATING BULK, SINGLE-CELL, AND SPATIAL TRANSCRIPTOMICS REVEALS POTENTIAL BIOMARKERS OF TERTIARY LYMPHOID STRUCTURE-RELATED GENES IN PROGNOSIS AND IMMUNOTHERAPY RESPONSE IN HEPATOCELLULAR CARCINOMA

Yuexi Yu[1] Huiru Liu[1] Fengmei Wang[1], [1]Tianjin First Central Hospital

Background: Tertiary lymphoid structures (TLS) are closely associated with the efficacy of anti-tumor immunotherapy; however, their value and significance in hepatocellular carcinoma (HCC) remain unclear. **Methods:** TLS-related genes were identified through AUCell analysis based on integrated single-cell RNA sequencing (scRNA-seq) and bulk transcriptomic data. Data from five HCC cohorts were analyzed to develop a tertiary lymphoid structure-related signature (TLSRS) using 10 machine-learning algorithms and their 101 combinations. Validation was performed using six immunotherapy cohorts (IMvigor210 and melanoma cohorts) as well as spatial transcriptomics datasets. Finally, Spearman correlation analysis identified the key gene **CCT3**, and loss-of-function experiments were conducted to explore the biological function of CCT3 in HCC. **Results:** The TLSRS, composed of 10 genes, demonstrated high accuracy in predicting the prognosis of patients with HCC. TLSRS effectively predicted outcomes in patients receiving immunotherapy and was positively associated with immunotherapy resistance. Patients with different TLSRS scores showed distinct patterns of immune cell infiltration, immune cell gene markers, and immune checkpoint–related marker expression. **CCT3** was identified as a key gene in the TLSRS (correlation = 0.7, $p < 0.001$). In vitro experiments showed that knockdown of **CCT3** significantly inhibited the proliferation and migration of HCC cells. **Conclusion:** TLSRS provides a precise risk stratification tool and guidance for immunotherapy in patients with hepatocellular carcinoma. **CCT3**, as a key gene within TLSRS, may serve as a potential therapeutic target for HCC.

0164 | AARS2-MEDIATED LACTYLATION DRIVES CCR4⁺ TREG RECRUITMENT AND IMMUNOTHERAPY RESISTANCE IN HEPATOCELLULAR CARCINOMA

Chunyao Fang[1] Suiqing Zhou[1] Xuehao Wang[1], [1]Nanjing Medical University

Background: Hepatocellular carcinoma exhibits extensive metabolic reprogramming and an immunosuppressive tumor microenvironment, limiting the efficacy of immune checkpoint blockade. Although lactate metabolism and protein lactylation are increasingly recognized as regulators of tumor immunity, we observed that not all patients with high lactate metabolism display immunosuppressive features, suggesting the existence of key molecular mediators that determine lactate-driven immune escape. **Methods:** We integrated single-cell RNA sequencing, spatial transcriptomics, multiplex immunofluorescence, CyTOF, and HCC patient cohorts to define lactate-associated immune programs. Hepatocyte-specific Aars2 knockout mice, primary hepatocarcinogenesis models, and orthotopic HCC models were used to assess AARS2 function. Mechanistic studies included IP-MS, lactylome profiling, Co-IP, GST pull-down, PLA, ChIP-qPCR, luciferase assays, phosphorylation analysis, and rescue experiments. Structure-based screening identified inhibitors of the AARS2–YBX1 interaction, followed by SPR validation and therapeutic testing. A Fisetin-loaded ZIF-8 nanoplatform was developed and combined with anti-PD-1 therapy. **Results:** Lactate-associated metabolism was enriched in malignant HCC cells and spatially aligned with immunosuppressive tumor regions. AARS2 was identified as a key lactylation-related regulator enriched in lactate-high niches, and high AARS2 expression predicted poor prognosis and poor response to PD-1 blockade. Aars2 deficiency significantly reduced tumor burden and decreased intratumoral CCR4$^+$ regulatory T cell infiltration. Spatial analyses showed that AARS2-high malignant regions preferentially recruited CCR4$^+$ Tregs. Mechanistically, AARS2 directly interacted with YBX1 and catalyzed its lactylation at K296, enhancing YBX1–AKT1 interaction, YBX1 phosphorylation, and nuclear translocation. Nuclear YBX1 transcriptionally activated CCL17, thereby promoting CCR4$^+$ Treg recruitment and immune evasion. Fisetin disrupted the AARS2–YBX1 interaction, inhibited YBX1 nuclear translocation, reduced CCR4$^+$ Treg infiltration, and improved anti-PD-1 efficacy. ZIF-8-based nanodelivery enhanced tumor targeting of Fisetin and synergized with PD-1 blockade in orthotopic HCC models. Pan-cancer spatial analyses further showed that AARS2 is upregulated in digestive malignancies and associated with CCR4$^+$ Treg enrichment. **Conclusion:** This study reveals an AARS2–YBX1–AKT1–CCL17–CCR4$^+$ Treg axis linking lactate-driven lactylation to immune evasion and immunotherapy resistance in HCC. Targeting AARS2 with Fisetin nanodelivery may provide a promising strategy to overcome Treg-mediated resistance to PD-1 blockade.

0165 | LIVER FUNCTION STABILITY FOLLOWING YTTRIUM-90 RESIN MICROSPHERE RADIOEMBOLIZATION IN HEPATOCELLULAR CARCINOMA: RESULTS FROM THE DOORWAY90 STUDY (NCT04736121)

Sudha Kodali[1] Armeen Mahvash[2] Ammar Sarwar[3] Gregory Nadolski[4] Eric Wehrenberg-Klee[5] Nima Kokabi[6] S Kappadath[7], [1]Houston Methodist, [2]UT MD Anderson Cancer Center, [3]Beth Israel Deaconess Medical Center, [4]University of Pennsylvania, [5]Massachusetts General Hospital, [6]University of North Carolina, [7]University of Texas MD Anderson Cancer Center

Background: DOORwaY90 is a prospective, multicenter, open-label, single-arm study that evaluated the safety and efficacy of radioembolization with yttrium-90 (Y-90) resin microspheres as first-line treatment for local tumor control in unresectable hepatocellular carcinoma (HCC). Maintaining hepatic functional reserve is critical in the setting of underlying cirrhosis and disease progression. This analysis of prospectively collected data from a large patient cohort focuses on

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

the safety outcomes and stability of liver-related laboratory values following treatment. **Methods:** All patients enrolled in DOORwaY90 (N = 100) completed a minimum of 12 months of safety follow-up. Inclusion criteria: confirmed HCC ineligible for resection or ablation, maximal single lesion size ≤ 8 cm, sum of diameters ≤ 12 cm, and preserved baseline organ function. Other key inclusion criteria: platelet count > 50,000/μL (without transfusion or growth factor support); hemoglobin > 8.5 g/dL; AST and ALT < 5x upper limit of normal (ULN); total bilirubin ≤ 2.0 mg/dL; albumin > 3.0 g/dL; INR ≤ 2.0; and GFR > 50 mL/min. Laboratory tests were performed at screening/baseline, at the time of the radioembolization procedure, and at follow-up visits at 1, 2, 4, 6, 9, and 12 months. **Results:** Laboratory findings for liver biomarkers remained stable throughout the 12-month follow-up period. Analysis of liver function indicators, including AST, ALT, total bilirubin, and albumin, demonstrated less than 3% deviation from normal limits at each recorded visit. Over 95% of patients maintained stable liver function after radioembolization, with biomarkers remaining within the normal range across all follow-up timepoints. No hepatic decompensation (as measured by albumin, bilirubin, or INR) or severe hematologic toxicity (hemoglobin or platelet count) were observed. **Conclusion:** The DOORwaY90 study demonstrates that radioembolization with Y-90 resin microspheres for HCC is associated with a high degree of safety and preservation of hepatic function. The high rate of biomarker stability (> 95%) through 12 months suggests that radioembolization can be delivered with minimal impact on liver reserve, even in a population at risk for disease-related functional decline.

0166 | HIGH-THROUGHPUT DRUG-INDUCED LIVER INJURY RISK PREDICTION USING MORPHOLOGICAL PROFILING AND MACHINE LEARNING IN PATIENT-DERIVED HUMAN LIVER ORGANOIDS

Jonathan Sexton[1] Robert Fontana[2] Max Garcia[3] Neil Zhao[3] Sophia Meyer[3] Matthew McConnachie[3] Jesse Wotring[3] Joel Yates[3] Diana Flores-Diaz[3] Charles Zhang[3], [1]University of Michigan Medical Center, [2]University of Michigan Hospitals and Health Centers, [3]University of Michigan

Background: Drug-induced liver injury (DILI) is a leading cause of clinical trial failure for new agents and post-marketing withdrawal. Existing in vitro models miss human-specific liabilities, cytotoxicity-based screening misses sublethal perturbations, and single-donor systems fail to capture inter-individual susceptibility. We hypothesized that patient-derived human liver organoids (HLOs) coupled with high-content imaging and machine learning (ML) can predict hepatotoxicity with high sensitivity and specificity while preserving donor-specific responses. **Methods:** Six iPSC lines from DILIN-enrolled patients with high single-drug causality scores and one healthy donor (72.3) were differentiated into HLOs, dissociated, seeded into collagen-coated 384-well plates, and exposed for 72 h to 74 compounds (54 hepatotoxicants, 20 non-hepatotoxic) across 5 concentrations in triplicate. Cells were stained for nuclei, lipids, mitochondria, HNF4α, and cytoplasm, imaged on the Yokogawa CV8000, and segmented in CellProfiler. Well-aggregated, MAD-robustized features trained AutoGluon classifiers with compound-grouped 5-fold cross-validation. Benchmark dose (BMD) modeling used BMDExpress3, and TNFα co-treatment was tested with sulindac. **Results:** Per-donor classifiers achieved AUROC 0.88-0.91 and balanced accuracy 0.81-0.84. Cross-donor consensus yielded 94.4% sensitivity, 85.0% specificity, and 89.7% balanced accuracy, outperforming cytotoxicity (84.6% vs 43.8% in HLOs) and the same ML pipeline in immortalized cell lines (73.3%). BMD modeling showed significant inter-donor variability for all 54 hepatotoxicants, with up to 13-fold differences (tamoxifen) and non-overlapping confidence intervals. Unsupervised Leiden clustering identified four mechanism-associated clusters: mitochondrial toxicity, phospholipidosis, apoptotic/nuclear stress, and lipid accumulation. Sulindac, a persistent false negative under basal conditions (ML probability 0.30), was reclassified as true positive (0.71-0.78) with TNFα co-treatment, demonstrating detection of inflammation-potentiated hepatotoxicity. **Conclusion:** Multi-donor patient-derived HLOs combined with high-content morphological profiling and ML provide a scalable, human-relevant NAM platform for DILI risk prediction that outperforms cytotoxicity and immortalized cell lines, captures inter-individual variability, supports mechanism-driven hypothesis generation, and detects inflammation-dependent idiosyncratic DILI with cytokine priming.

0167 | NOVEL GENETIC VARIANTS ASSOCIATED WITH IMMUNE-MEDIATED LIVER INJURY FROM CHECKPOINT INHIBITORS: RESULTS FROM THE DILIN REGISTRY AND AN INDEPENDENT COHORT

Linnea Swanson[1] Yi-Ju Li[2] Andrew Dellinger[2] Andrew Tucker[1] LaVana Greene-Higgs[1] Venkata Sai Jasty[1] Jessica Sheehan[1] Vincent Chen[1] Robert Fontana[3], [1]University of Michigan, [2]Duke University, [3]University of Michigan Hospitals and Health Centers

Background: Immune-mediated liver injury from checkpoint inhibitors (ILICI) arises in 10 -15% of oncology patients receiving immune checkpoint inhibitors (ICIs) and can result in therapy interruption, discontinuation and need for corticosteroids. The aim of our study was to identify novel genetic variants for ILICI using a cohort of high causality ILICI cases compared to ICI exposed and unexposed controls. **Methods:** Patients with high causality ILICI and genetic data were identified in the Michigan Genomics Institute (MGI; n = 67, 2010-2024) and the Drug-Induced Liver injury Network database (DILIN; n = 65, 2012-2023). Liver injury was defined as AST or ALT $\geq$ 5x ULN, ALP $\geq$ 2x ULN, bilirubin $\geq$ 2.5, or INR $\geq$ 1.5. Causality assessment was based on DILIN expert opinion. Two sets of controls were compared: 1) ICI-exposed controls (patients exposed to ICI but not develop ILICI, n = 741); and 2) unexposed controls (n = 2440). Genome-wide association studies (GWAS) were conducted for ILICI cases in Non-Hispanic Whites (NHW) with SNPs meeting $p < 5x10^{-8}$ considered genome-wide significant. **Results:** The median age (65.6 vs 61.3; p = 0.14), proportion male (53.7% vs 63.1%; p = 0.36), prevalence of melanoma (59.7% vs 44.6%; p = 0.15), and proportion of hepatocellular injury (34.3 vs 50%; p = 0.13) were similar in MGI and DILIN cohorts. Ipilimumab, nivolumab, and pembrolizumab were the most frequently implicated agents in both cohorts. Rates of corticosteroid use (70.1% vs 86.2%, p = 0.67) and 6-month survival (14.1 vs 25.9%; p = 0.24) were also comparable between cohorts. Compared to those without liver injury, patients with ILICI from MGI had lower rates of cancer progression (40.3% vs 52.1%; p < 0.001) and death (37.3% vs 51.2%; p < 0.001). Compared with MGI cases, DILIN cases demonstrated more severe liver injury with higher AST, ALT and total bilirubin at onset and peak as well as greater need for mycophenolate (44.6% vs 7.5%, p < 0.001) compared to MGI. In the GWAS analysis of the combined 111 NHW ILICI cases, three SNPs reached genome-wide significance ($p < 5x10^{-8}$) (**Table 1**): rs991262 in SLCO1B1, rs164752 in CHMP1A, and rs258322 in CDK10. Among them, CDK10 rs258322 ranked at the top with OR of 3.44 (CI 2.27, 5.2; $p = 4.73 \times 10^{-9}$) against non-exposed controls and OR 1.7 (CI 1.17, 2.48; p = 0.006) against ICI-exposed controls. As this CDK10 SNP was previously associated with melanoma, a secondary analysis by tumor type was undertaken that showed CDK10 rs258322 remained significant in both melanoma and non-melanoma cases. **Conclusion:** Three novel SNPs associated with ILICI were identified in a large cohort of adjudicated ILICI cases compared to ICI exposed controls and unexposed controls. The variant in CDK10 is of particular interest as the gene has previously been identified as suppressor of tumor immune surveillance and warrants further validation.

0168 | ADDITIONAL SAFETY AND EFFICACY RESULTS FROM HELIOS: A PHASE 2, OPEN-LABEL, LONG-TERM EXTENSION STUDY OF BITOPERTIN IN ERYTHROPOIETIC PROTOPORPHYRIA

Amy Yeung[1] Gayle Ross[2] Sioban Keel[3] Herbert Bonkovsky[4] Peter Stewart[5] Karl Anderson[6] Manisha Balwani[7] Cynthia Levy[8] Manish Thapar[9] Bruce Wang[10] Brendan McGuire[11] Will Savage[12], [1]Harvard Medical School and Massachusetts General Hospital, [2]Royal Melbourne Hospital, [3]University of Washington, [4]Wake Forest University School of Medicine and Atrium Health Wake Forest Baptist, [5]Royal Prince Alfred Hospital, [6]University of Texas Medical Branch, [7]Icahn School of Medicine at Mount Sinai, [8]University of Miami, [9]Temple University, [10]University of California San Francisco Porphyria Center, [11]University of Alabama at Birmingham, [12]Disc Medicine

Background: Erythropoietic protoporphyria (EPP) and X-linked protoporphyria (XLP) are characterized by accumulation of photoreactive protoporphyrin IX (PPIX) in the skin and liver. PPIX accumulation causes phototoxic skin reactions upon sunlight exposure and, in some cases, life-threatening protoporphyric hepatopathy. Bitopertin is a selective, orally bioavailable inhibitor of glycine transporter 1 (GlyT1), which imports extracellular glycine into erythroid precursor cells for heme biosynthesis. In prior EPP/XLP studies, treatment with bitopertin resulted in significant reductions in PPIX levels associated with improved light tolerance.[1,2] **Methods:** HELIOS (NCT05883748) is a multi-center, open-label, long-term extension study of bitopertin in participants who completed prior studies. The aims of the study are to evaluate the long-term safety, tolerability, and efficacy of bitopertin in participants with EPP or XLP. The study is being conducted in the US and Australia, with additional sites opening in the UK and EU, and includes participants $\geq$12 years of age with confirmed EPP or XLP. Participants receive once-daily oral bitopertin 60 mg. Primary endpoints are safety and tolerability. Secondary endpoints include changes in whole-blood metal-free PPIX and light tolerance. Additional endpoints include patient-reported outcomes measures. **Results:** As of 01 Nov 2025, 86 participants (including 3 adolescents) were enrolled. Median total exposure was 25.3 months (range: 13.8-32.7). To date, 61 of 86 (71%) participants reported adverse events (AEs). One adult participant involved in a motor vehicle accident reported multiple serious AEs, not related to study drug. The only other Grade 3 event was a nonserious unrelated AE of hypertransaminasaemia. All other AEs were mild or moderate. The most common AEs (>5 participants) were COVID-19 (12%), nasopharyngitis (9%), and headache (7%). Participants initially randomized to placebo had significant reductions in whole blood metal-free PPIX at Week 24 (-32.8%; $p < 0.001$). Participants treated with bitopertin in AURORA/BEACON and HELIOS had sustained reductions through 1 year. Light tolerance also improved through Week 24, with significant increases vs baseline in total hours in light (+4.9 hours; $p < 0.001$) and time to prodrome (+101.8 minutes; $p < 0.001$). Data from patient-reported outcomes measures will be presented. **Conclusion:** By reducing PPIX levels, bitopertin targets the underlying pathophysiology of EPP and XLP. HELIOS results, including >2.5 years of exposure, support longer-term efficacy and safety in adult and adolescent patients.References 1. Ross G, et al. Clin Exp Dermatol. ★ 0169 | NOVEL ACETAMINOPHEN FORMULATION AT SUPRATHERAPEUTIC DOSES WITH A FAVORABLE HUMAN LIVER SAFETY PROFILE: PREVENTING TOXIC METABOLITE FORMATION

Yuhan Lin[1] Te-Yu Lin[2] Ting-Yi Chiang[1] Yung-Chih Wang[2] Chi-Chi Chou[1] Cheng-Huei Hsiong[1] Hsin-Tien Ho[1] Kai-Min Chu[1] Yoa-Pu Hu[3], [1]Sinew Pharma Inc., [2]Tri-Service General Hospital, [3]Taipei Medical University

Background: Acetaminophen (APAP) overdose causes severe hepatotoxicity primarily via CYP-mediated formation of the reactive metabolite NAPQI. Furthermore, contrary to previous reports, our preclinical data demonstrates APAP-Cys protein adducts formation within the brain tissue of mice and rats. Given the potentially underestimated scope of APAP toxicity, we developed SafeTynadol®, a novel APAP formulation that co-delivers safe modulators of key CYP enzymes to suppress NAPQI generation. When administered within the therapeutic range, the modulator concentration remains very low, resulting in no significant inhibitory effect. Consequently, no drug–drug interactions occur. In practice, the safe modulators accumulate to inhibit enzyme activities, thereby suppressing NAPQI formation under overdose conditions and clinically preventing hepatotoxicity. Preclinical safety success motivated this clinical evaluation at supratherapeutic doses. **Methods:** We performed a multiple-dose clinical trial in 48 healthy adults. Participants received Panadol® 4 g/d or SafeTynadol® 4–12 g/d as four doses within 24 h, with pharmacokinetic (PK) and safety assessments through 168 h. The primary endpoint was alanine aminotransferase (ALT), with systemic APAP-Cys protein adduct quantification and a hepatic-failure composite as key secondary measures. **Results:** ALT levels were within the reference range in all cohorts, with no predefined hepatotoxicity occurring. The highest mean APAP-Cys protein adduct levels were 12.3 ± 8.64 ng/mL at 12 g/d (~4.1% of the toxicity threshold). Adverse events were mild and transient (14.6%), consistent with high-dose APAP exposure. **Conclusion:** Inhibiting NAPQI formation with SafeTynadol® preserved hepatic safety up to 12 g/d, supporting further development as a safer APAP option, including settings at risk for overdose.

0170 | A SEMI-AUTOMATED ARTIFICIAL INTELLIGENCE (AI) BASED ALGORITHM TO PRIORITIZE POTENTIAL DRUG INDUCED LIVER INJURY (DILI) CASES FROM CLINICAL TRIALS FOR HUMAN CLINICAL REVIEW

Aaron Waddell[1] Mark Gordon[1] Jasmine Amirzadegan[1] Mark Avigan[2] Paul Hayashi[1], [1]Food and Drug Administration, [2]Food and Drug Adminstration

Background: Drug applications may have 50-100 liver injury cases needing review, but most cases will not be DILI. Drug exposure-to-injury course (EIC) is the foundation of a DILI diagnosis, so DILI Team reviewers (DT-r) prioritize cases for review using EIC line graphs showing liver blood tests by study day & drug exposure. We hypothesized that an AI-based program (AI-p) could assist DT-r prioritization, thereby increasing efficiency & providing early insights into overall DILI risk. Our aim was to create an AI-p to prioritize liver injury cases for human review using EIC data. **Methods:** We used RStudio and FDA's AI tool, Elsa (Gemini 2.5), to create an AI-p using 154 cases from 5 drug applications. All cases were in eDISH Temple's Corollary (TC) quadrant with ALT >5x ULN or in Hy's law (HL) quadrant. We created training and validation sets. Using only EIC graphs, a DT-r (PHH) categorized cases into A (high), B (moderate), and C (low) priority. DT-r categorization was the standard. AI-p categorized each training set case into A, B, and C categories based on EIC data. With iterative DT-r input, AI-p was refined to maximize performance with a conservative bias, favoring higher AI-p priority compared to DT-r in marginal cases. AI-p then prioritized validation set cases. **Results:** Of 91 training set cases, DT-r assigned 23 As (25%), 40 Bs (44%), & 28 Cs (31%)

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

vs AI-p's 31 As (34%), 35 Bs (38%), & 25 Cs (27%). A1-p & DT-r agreed in 80 (88%; kappa 0.82). Of 63 validation cases, DT-r had 29 As (46%), 30 Bs (48%), & 4 Cs (6%) vs AI-Ps 42 As (67%), 19 Bs (30), & 2 Cs (3%). There was agreement on 46 (73%; kappa 0.51). AI-p accurately identified all 52 DT-r high priority (A) cases from both sets (Figure). A1-p prioritization was never off by more than one category from DT-r in both sets. Under conservative programming (over prioritization on marginal cases), AI-p had minimal under-prioritization error of 1-2%. AI-p categorized as a lower priority than DT-r once in training and once in validation, both were AI-p C vs. DT-r B. **Conclusion:** AI-p may be able to rapidly prioritize liver injury cases for in-depth human assessment. This proof-of-concept AI-p tool correctly identified all DT-r high priority cases. Using conservative programming (favoring higher priority on marginal cases), A1-p agreed with or gave a higher priority than DT-r in 99% and 98% of training and validation sets respectively. Ultimately, AI-p prioritization labels (A, B, or C) could be added next to plotted points in eDISH HL and TC quadrants providing another layer of case categorization that may correlate with a later DILI diagnosis made by humans, thereby increasing efficiency of DILI risk assessment. This abstract's content is the responsibility of the authors and does not necessarily represent the official views of the Food and Drug Administration.

Training Set

DT-r \ AI-p	A	B	C	Totals
A	23	0	0	23
B	6	33	1	40
C	2	2	24	28
Totals	31	35	25	91

Kappa = 0.82

Complete agreement rate: 88% (black boxes)

Complete agreement or AI-p with higher rating than DT-r: 99% (black + grey boxes)

Validation Set

DT-r \ AI-p	A	B	C	Totals
A	29	0	0	29
B	13	16	1	30
C	0	3	1	4
Totals	42	19	2	63

Kappa = 0.51

Complete agreement rate: 73% (black boxes)

Complete agreement or AI-p with higher rating than DT-r: 98% (black + gray boxes)

Figure DT-r (DILI Team reviewer) versus AI-p (Artificial intelligence-based program) categorization of 154 liver injury cases from five different drug applications split into Training and Validation Sets. DT-r and AI-p categorized cases based on drug exposure-to-injury course (EIC) data including line graphs (liver blood tests by study day and drug exposure). Categories were high (A), moderate (B), and low (C) concern for potential DILI. AI-p aligned with DT-r on all cases in the black boxes. Those in gray boxes were over-calls by AI-p (i.e., higher priority than DT-r) and those in white boxes were under-calls by AI-p (i.e. lower priority than DT-r).

0171 | ART4, A TRANSLATION-ENHANCING ANTISENSE OLIGONUCLEOTIDE, RESTORES JAG1 EXPRESSION AND IMPROVES LIVER DISEASE IN PRECLINICAL MODELS OF ALAGILLE SYNDROME

Lingdi Zhang[1] Nima Niknejad[1] Jian Li[1] Lansha Peng[1] Surendra Jain[1] Rich Thai[1] Xing Xian Yu[1] Yanfeng Wang[1] Xuehai Liang[2], [1]ARNATAR THERAPEUTICS INC, [2]Arnatar Therapeutics, Inc

Background: Alagille syndrome (ALGS) is a rare autosomal dominant disorder caused primarily by JAG1 haploinsufficiency, resulting in impaired Notch signaling, bile duct paucity, cholestasis, and progressive liver disease. Current therapies are largely supportive and do not address the underlying genetic defect. ART4 is a novel antisense oligonucleotide (ASO) developed using Arnatar's ACT-UP1™ platform to selectively enhance endogenous JAG1 translation. **Methods:** ART4 was evaluated in human, rodent, and non-human primate cells for its ability to increase JAG1 protein expression by Western blot. Pharmacodynamic studies were performed in wild-type mice, and efficacy studies were conducted in Jag1+/– ALGS mouse models following subcutaneous administration. ART4 was tested across multiple dose levels (1, 3, and 6 mg/kg) and dosing paradigms initiated at postnatal day 1, 7, or 14, including repeat dosing. Endpoints included hepatic JAG1 expression, bile duct morphology, liver histopathology, serum biomarkers, necrotic lesion assessment, and body weight. Downstream Notch pathway RNA markers were analyzed by qRT-PCR. Safety and tolerability were evaluated in rodent and non-human primate toxicology studies. **Results:** ART4 increased JAG1 protein expression by 40–80% across multiple cell types, including ALGS patient-derived cells. In vivo, subcutaneous administration increased hepatic Jag1 protein levels by up to 2-fold, with sustained activity observed for up to four weeks after dosing. In Jag1+/– ALGS mice, ART4 treatment improved bile duct development and reduced cholestatic and liver injury biomarkers, including bile acids, total bilirubin, ALT, and AST, across multiple dose levels and dosing schedules. ART4-treated animals also demonstrated improved body weight gain and reduced hepatic necrotic lesions. Downstream Notch pathway RNA markers showed modest and transient activation during the early post-dose period. Similar pharmacologic activity was observed in non-human primates, supporting translational relevance and the potential feasibility of monthly clinical dosing. ART4 was well tolerated in juvenile rodent and non-human primate studies, supporting a projected therapeutic index greater than 30-fold relative to the proposed clinical

starting dose. **Conclusion:** ART4 is a first-in-class ASO therapeutic designed to selectively enhance endogenous JAG1 translation. In preclinical ALGS models, ART4 restored JAG1 expression, improved bile duct development, and ameliorated liver disease phenotypes, supporting its continued development as a potential disease-modifying therapy for ALGS. Currently, ART4 is being evaluated in ALGS patients in an investigator-initiated clinical trial.

0172 | CLOSING THE MATURATION GAP: MACHINE LEARNING-DRIVEN OPTIMIZATION OF HPSC-DERIVED HEPATOCYTE FUNCTION

Christian Elabd[1] Yaniv Ovadia[1] Sherry Li Zheng[1] Vandya Juneja Shah[1] Frank Li[1], [1]Stately Bio, Inc.

Background: Hepatocyte transplantation is an intriguing clinical approach for treating liver failure, but it is limited by the availability of high-quality primary cells. Differentiating human pluripotent stem cells (hPSCs) into hepatocytes offers a promising solution; however, existing differentiation protocols yield immature, fetal-like cells lacking the function of primary human hepatocytes (PHHs).We developed machine learning (ML) models capable of predicting hepatocyte maturation directly from live, label-free phase contrast images. This enabled non-destructive, real-time monitoring of differentiation status in high-throughput protocol screens to improve hepatocyte maturation. **Methods:** Baseline hPSC differentiation was established using a published protocol. ML models were trained on paired phase contrast and immunofluorescence images of 8 markers related to hepatic metabolism, detoxification, and protein synthesis, collected at various stages of differentiation. These models were then used to predict cell count, marker expression, and functional readouts – directly from phase contrast imaging. Validated ML models were used to score maturation in phenotypic screening experiments, where differentiating hPSC-derived hepatocytes were exposed to small molecules and biologics at varying concentrations, durations, and combinations in iterative cycles to improve maturation. To quantify maturation against a meaningful benchmark, we established a panel of in vitro assays of clinically-relevant liver functions (albumin secretion, ammonia detoxification, coagulation factor secretion, and phase II metabolism) and characterized cellular function head-to-head against PHHs. **Results:** ML predictions from phase contrast images showed strong correlations with immunofluorescence data, achieving < 15% mean absolute error in percent-positivity for each of the 8 markers. Leveraging these predictions for screening, we identified novel differentiation protocols showcasing significantly enhanced maturation. Albumin secretion, urea secretion, factor VII secretion, and UDP-glucuronosyltransferase activity reached median per-cell performance of 201%, 57%, 51%, and 71% that of adult PHH on direct comparison. **Conclusion:** Our approach highlights a significant improvement in hPSC-derived hepatocyte maturation, with immediate clinical implications. It also showcases the utility of ML-driven imaging as a platform technology for optimizing differentiation protocols broadly.

0173 | PEMVIDUTIDE TREATMENT REDUCES ALCOHOL INTAKE IN A LEAN GOLDEN SYRIAN HAMSTER MODEL

Maynara Lucca Andrade[1] John Suschak[1] Francois Briand[2] Scot Roberts[3], [1]Altimmune, Inc, [2]Physiogenex, [3]Altimmune, Inc.

Background: There are an estimated 28.1 million patients in the United States with alcohol use disorder (AUD). Left untreated, chronic, excessive alcohol use can result in alcohol-related liver disease (ALD), characterized by liver inflammation and hepatic fibrosis. Approximately 2.0% of AUD patients are treated with medication, and the currently available treatments are limited by undesirable side effects or lack of efficacy. Pemvidutide is a balanced 1: 1 glucagon/GLP-1 dual receptor agonist in development for the treatment of AUD and ALD. Recent data suggests that GLP-1 receptor agonists can reduce alcohol intake, but GLP-1 agonists do not have direct effects on the liver. Preclinical and clinical studies evaluated pemvidutide's effects on hepatic steatosis, inflammation, and fibrosis, potentially important attributes in the treatment of AUD and ALD. Here we present data demonstrating the effects of pemvidutide on alcohol intake in a golden Syrian hamster model of AUD. **Methods:** During a 4-week induction period, golden Syrian hamsters were allowed free access to a

standard chow diet and either normal tap water or 15% alcohol-enriched water. After a 4-week induction period with free-choice access to alcohol, hamsters were randomized into two treatment groups (n = 12 per group) and were treated once daily with vehicle or pemvidutide 10 nmol/kg subcutaneously for three weeks while maintaining the same diet. Fluid intake was monitored throughout the study. **Results:** Following the free-choice induction period, hamsters showed a strong preference for 15% alcohol-enriched water compared to normal tap water, with a mean percent alcohol intake [mL 15% alcohol-enriched water / (mL 15% alcohol-enriched water + mL tap water)] of 66%. After three weeks of treatment with pemvidutide, a maximal reduction in mean percent alcohol intake of approximately 80% from treatment initiation was achieved. The reduced alcohol intake remained consistent throughout the remainder of the study and coincided with an increase in tap water consumption. Conversely, the mean percent of alcohol intake increased by approximately 5% by the end of the study in vehicle-treated hamsters. Additionally, the mean cumulative 15% alcohol-enriched water intake during the 3-week treatment period was significantly reduced in the pemvidutide group (55.7 mL, $p < 0.0001$) compared to vehicle (143.1 mL). **Conclusion:** Pemvidutide treatment resulted in a rapid reduction in alcohol intake in a golden Syrian hamster model of AUD. These data suggest that pemvidutide may decrease alcohol-craving and alcohol intake, providing evidence for further investigation in a clinical setting.

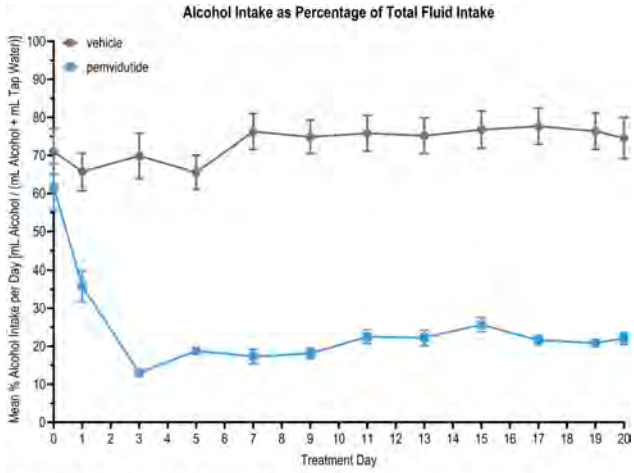

Figure 1. Mean percent alcohol intake during 3-week treatment period.

0174 | CIRCULATING PROTEIN BIOMARKERS ASSOCIATED WITH REDUCTIONS IN LIVER FAT AND VISCERAL AND SUBCUTANEOUS ADIPOSITY IN ADULTS WITH OBESITY AND MASLD WITH RETATRUTIDE TREATMENT

YoSon Park[1] Matthew Coghlan[1] James Trevaskis[1] Colm O'Dushlaine[1] Paul Titchenell[1] Melissa Thomas[1], [1]Eli Lilly

Background: Retatrutide (Reta) is a triple GIP/GLP-1/glucagon receptor agonist. In a phase 2 trial, adults with obesity showed dose-dependent weight loss up to 24.2% at 48 weeks with substantial reductions in MRI-assessed liver fat (MHFF, PCBL = -86%), visceral adipose tissue (VAT, PCBL = -44.5%), and abdominal subcutaneous adipose tissue (ASAT, PCBL = -43.5%) with Reta treatment. **Methods:** Fasting serum samples were collected at baseline, 24 weeks, and 48 weeks in the phase 2 MASLD substudy (NCT04881706). Participants with ≥ 10% MHFF at baseline received once-weekly subcutaneous Reta (1/4/8/12 mg; n = 14/16/14/14) or placebo (n = 10) for 48 weeks. Liver fat content was measured by MRI-PDFF, and VAT and ASAT measured by MRI. Circulating proteins were measured via Olink ExploreHT in 229 subjects from the full trial cohort. PCBL of protein abundance was estimated using MMRM at 24 and 48 weeks per treatment group. Spearman correlations and multivariable regression, with FDR corrections for multiple comparisons, were used to estimate proteomics changes with MHFF, ASAT and VAT for pooled Reta-treated completers (n = 58). **Results:** Reta treatment produced dose-dependent changes for biomarkers associated with MASH pathologies, MHFF, ASAT and VAT. Among 38 proteins significantly associated with MHFF PCBL at week 24, MSTN ($\rho = 0.58$, FDR = 9.35×10^{-6}) and TLR3 ($\rho = 0.56$, FDR = 2.89×10^{-5}) were positively correlated, and STC2 ($\rho = -0.50$, FDR = 0.002) was negatively correlated with reductions in MHFF. At 48 weeks, STC2 and TGFBR3 continued to show strong negative correlation with reductions in MHFF ($\rho = -0.45$, FDR = 2.0×10^{-3}; $\rho = -0.49$, FDR = 9.0×10^{-3}). A total of 49 proteins were significantly correlated with VAT reduction at week 48 (FDR < 0.05). LEP ($\rho = 0.70$, FDR = 2.95×10^{-8}), GHR ($\rho = 0.69$, FDR = 6.47×10^{-8}), and MSTN ($\rho = 0.63$, FDR = $2.02 \times^{-6}$) showed positive correlation to VAT reduction. IGFBP1 ($\rho = -0.73$, FDR = $2.06 \times^{-9}$) and COL4A1 ($\rho = -0.69$, FDR = 3.45×10^{-8}) were negatively correlated with VAT reduction. 41 of 49 VAT-correlated proteins also significantly correlated with ASAT changes. Biomarkers independently associated with lobular inflammation (ACY1, TXNRD1 and FCGR3B_FCGR3A) and steatosis (PTGR1 and GUSB) were significantly reduced in Reta 4, 8, and 12 mg

groups. **Conclusion:** In the MASLD substudy, Reta treatment was associated with significant changes in MHFF, VAT and ASAT. Additionally, changes in MHFF with Reta were associated with changes in proinflammatory biomarkers and multiple intracellular signaling pathways. Changes in proteins correlated with VAT and ASAT changes with Reta were associated with insulin resistance, adipose stores and tissue remodeling. Consistent with our observations from liver fat and body composition, biomarkers independently associated with MASH/MASLD pathology including steatosis, lobular inflammation and fibrosis showed significant reduction at 24 and 48 weeks across all dose groups in the obesity trial subjects.

0175 | TARGETING BILE COMPOSITION IN PSC: RTY-406, A DUAL-ACTING ABCB4/BSEP POSITIVE FUNCTIONAL MODULATOR REDUCES DISEASE-RELEVANT MARKERS IN A MOUSE MODEL AND NON-HUMAN PRIMATE

Eric Bell[1] Nathan Fuller[2] Youhwa Jo[1] Jennifer Truong[1] John Miller[1] Pol Boudes[1] Robert Hughes[1], [1]Rectify Pharmaceuticals, [2]Rectify Pharmacueticals

Background: Primary Sclerosing Cholangitis (PSC) is a progressive bile duct disease characterized by changes in bile composition, biliary inflammation, ductular reaction, cholestasis, and fibrosis, with no approved therapy. The canalicular transporters ABCB4/MDR3 and ABCB11/BSEP transport phospholipid (PL) and bile acids (BA) from hepatocytes to bile ducts, respectively, and are important for maintaining bile composition and bile flow. RTY-406 is a first-in-class dual-acting ABCB4/BSEP positive functional modulator (PFM) that increases transporter proteins levels to increase biliary PL secretion and enhance BA efflux. Selected preclinical endpoints included markers with established clinical relevance for PSC. **Methods:** RTY-406 was dosed orally twice daily for 6 weeks in a mouse model of PSC[1] . Serum BA, alkaline phosphatase (ALP), biliary PL, and gallbladder cholesterol crystal formation were monitored for proof of mechanism of increased ABCB4/BSEP action. Liver gene expression, chemokines, and histology were assessed for ductular reaction, cholangitis, and fibrosis endpoints associated with PSC to determine efficacy. RTY-406 was also evaluated in naïve Cynomolgus monkeys dosed orally once daily for 28 days to determine impact on ALP, gamma-glutamyl transferase (GGT) and total cholesterol. **Results:** In the PSC mouse model, RTY-406 increased biliary PL and reduced liver BA levels, demonstrating target modulation. Gallbladder crystal formation, serum BA and ALP were all reduced by RTY-406. Dose-dependent reductions were observed in clinically relevant markers: Cxcl-1 (murine equivalent of IL-8), which is associated with native liver survival in PSC[2], Spp1/osteopontin, a marker correlated with PSC fibrosis severity and transplant-free survival[3], and Timp-1, an ELF test component and validated predictor of transplant-free survival[4]. Histology confirmed reductions in ductular reaction, biliary immune cell infiltration, and fibrosis. In the non-human primate repeat-dose study, RTY-406 reduced total cholesterol, ALP, and GGT, markers consistent with target modulation. **Conclusion:** RTY-406, a first-in-class orally active dual PFM for ABCB4/BSEP, reduced clinically relevant markers of cholestasis, cholangitis, and fibrosis in a PSC mouse model, and demonstrated translational evidence of target modulation and proof of mechanism in non-human primates. These data support the advancement of RTY-406 into the clinic as a disease modifying therapy for PSC and related hepatobiliary diseases.1. Bell et al, Liver Int Comm 2026 DOI: 10.1002/lci2.700402. 0176 | SUITABILITY OF INTRAVENOUS ADMINISTRATION OF REGENERATIVE MACROPHAGE THERAPY FOR THE TREATMENT OF DECOMPENSATED CIRRHOSIS

Jessica Llewellyn[1] Joanna Sweetman[1] Philip Starkey Lewis[1] Anna Hoy[1] Lara Campana[1], [1]Resolution Therapeutics Ltd

Background: There are no approved medical therapies for the treatment of decompensated cirrhosis, beyond clinical symptoms management. The sole curative solution is liver transplantation, a surgery hampered by its complexity, shortage of organs, and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

need for lifelong immunosuppression. Regenerative Macrophage Therapy (RMT) has shown significant promise for the treatment of advanced cirrhosis in the clinic, with non-engineered RMT showed statistically significant increase in transplant free survival at 4 years post-treatment. Key to the mechanism of action of these cells are their anti-inflammatory and anti-fibrotic properties. Further development led to engineer IL10 and MMP9 to bolster the anti-inflammatory and anti-fibrotic mechanisms of action (lead candidate RTX001), opening the opportunity to treat patients shortly after an acute decompensation to improve transplant free survival. RMTs need in-depth biodistribution studies post-intravenous administration to support their regulatory journey. In this project, we robustly assess biodistribution of RTX001 and non-engineered RMT with various methods and in distinct models of disease. **Methods:** We utilised non-injured, immunocompromised mouse models to test BD of non-engineered and RTX001 RMT. We then performed BD studies as part of our GLP-Toxicology and in-house safety studies to support Phase 1/2 initiation utilising Alu-qPCR. Further, we developed surrogate mouse (m) RMTs to perform BD studies in immunocompetent backgrounds, including (i) pilot studies using *in vivo* imaging of non-engineered RMT in healthy mice; (ii) in-depth studies of mRTX001 biodistribution in distinct models of liver disease. Finally, surrogate mRTX001 was utilised for BD studies in embryos and placenta. **Results:** Once injected intravenously, RMTs exit the circulation within minutes, and within hours distribute to the lung. RMT then localises to the liver from 24h where, according to PCR-based methods, it remains for up to two weeks. A small signal is detected in spleen and kidney in the early stages. No presence of RMT in organs other than in the liver was found beyond one week. These data confirm that the therapy efficiently reaches its target organ, the liver, after a transient passage in the lung. The well-tolerated nature of RMT upon injection, and the lack of notable histological finding highlights that the passage through the lung is largely safe. Interestingly, surrogate mRTX001 shows a slightly distinct pattern of distribution in CDAA-HFD models in comparison with TAA models. Finally, lack of distribution to the embryo and placenta negated the need for dedicated repro-Tox studies. **Conclusion:** Post-i.v. administration, RMT distributes primarily to the liver, with little persistence in other organs past 72h. Lack of distribution to gonads, embryos and placentas further corroborates its tolerability profile and suitability for treatment of patients with advanced cirrhosis.

0177 | THE PD-L1 INTRACELLULAR DOMAIN LIMITS MYELOID CELL ACTIVATION AND FIBROSIS IN METABOLIC-DYSFUNCTION ASSOCIATED STEATOHEPATITIS

Jessica Olivas-Corral[1] Lucy Fry[1] Uma Kantheti[1] David Orlicky[1] Beth Tamburini[1], [1]University of Colorado Anschutz

Background: Programmed death ligand-1 (PD-L1) binds to programmed cell death protein-1 (PD-1) leading to downregulation of the T cell receptor, decreased T cell proliferation and thus dampening of the T cell response. PD-L1 also binds to CD80 in cis on myeloid cells, PD-L1: CD80 interactions prevent PD-L1: PD-1 inhibitory interactions without impeding CD80: CD28 activating interactions. Thus, an intricate interplay between these immune checkpoint activators and inhibitors can tune the magnitude of the immune response. To build upon these findings we recently demonstrated the importance of PD-L1 for DC migration via cis CD80: PD-L1 interactions, rather than PD-1: PD-L1 interactions, in myeloid dendritic cells for initiating signaling through the PD-L1 intracellular domain. Three amino acid residues, TSS, within the PD-L1 intracellular domain have proven critical for cellular movement and responses to innate cytokines. Therefore, we investigated the consequences of mutation of the intracellular PD-L1 TSS residues to alanine in the liver during liver injury. We implemented both a carbon tetrachloride (CCl_4) injury model, and an established high fat and high cholesterol diet-based model of Metabolic-dysfunction Associated Steatohepatitis (MASH). **Methods:** For analysis of the contribution of the PD-L1 intracellular domain to liver injury, WT and *Pdl1*^{CyMt} mice were fed a high fat (40% kcal fat) and high cholesterol (2%) diet (HFHC) for 15 (N = 10 mice/group) or 22 (N = 15 mice/group) weeks or intraperitoneally administered carbon tetrachloride in corn oil for 4 weeks. Samples were taken for histology, immunofluorescence, RNA isolation, and flow cytometry. Mice were perfused after euthanasia and prior to removal of liver tissue for histology and staining. The remainder of the liver tissue was used for flow cytometric analysis of isolated non-parenchymal cells. Bulk RNA sequence analysis was performed on isolated RNA from FACs sorted CD11c +MHCII+ cells from the above indicated mice using an Illumina Nova Seq X platform with paired-end reads (N = 5mice/group). For in vitro evaluation of myeloid cell cytokine secretion, metabolism and function, we used bone marrow derived dendritic cells (BMDC) or macrophages (BMDM) from WT and *Pdl1*^{CyMt} mice, bred in-house. Myeloid cells were activated for 4-48 hours with 200ng/lipopolysaccharide (LPS) at 37C followed by cytokine quantification of the supernatants and metabolite analysis of the cell lysate. **Results:** Here, we demonstrate that *Pdl1*^{CyMt} -expressing mice displayed

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

increased liver pathology during diet induced MASH, but not CCl_4, characterized as increased tissue scarring and inflammation scoring compared to WT mice. CD11c +MHCII$^+$ frequencies of CD45+ cells were similar between *Pdl1^{CyMt}* and WT MASH livers as assessed by immunofluorescence and flow cytometric analysis of the immune compartment isolated from liver parenchyma. We observed increased collagen gene *Col1a1*, *Ccr2*, and *Tgfb* transcripts suggesting that in the diet induced MASH model the disease is accelerated and may result from increased myeloid cell recruitment, as shown with CCR2 expression. In late stages of disease (fibrosis), analysis of FACs sorted myeloid cells followed by RNA sequencing of WT and *Pdl1^{CyMt}* livers revealed pathways of myeloid cell activation were upregulated in *Pdl1^{CyMt}* myeloid APCs. Furthermore, glycolysis and redox systems were also upregulated in *Pdl1^{CyMt}* sorted myeloid cells with increased gene expression of *Pgam1* and *Prdx1*. These data were corroborated by metabolite analysis of LPS-stimulated *Pdl1^{CyMt}* compared to WT BMDCs, which showed a reduction of the metabolite a-ketoglutarate and increase in glycerone phosphate. While T cell activation and effector functions were similar between WT and *Pdl1^{CyMt}* mice early on in disease (~15 weeks on diet), T cells displayed increased production of effector cytokines during the fibrotic stage of the disease (22 weeks on diet) as assessed by both immunofluorescence and flow cytometry. **Conclusion:** Together, these data establish the importance of PD-L1 intrinsic signals for myeloid cell activation and regulation of metabolism in a diet-induced murine model of MASH. Our observations demonstrate that the intracellular domain of PD-L1 is important for restraining immunopathology. Overall, these data support a previously unknown mechanism that limits myeloid cell activation and guides downstream T cell responses. Thus, the PD-L1 intracellular domain provides an important immune regulatory mechanism within myeloid cells that limits pathological outcomes in chronic liver disease.

0178 | GM-CSF TREATMENT PROMOTES IMMUNE REGULATORY MACROPHAGE POLARIZATION AND REDUCES HEPATIC INJURY IN OBSTRUCTIVE CHOLESTASIS

Kathryn Kilpatrick[1] Eric Katz[1] Ioannis Ziogas[2] William Janssen[3] Ronald Sokol[4] Katherine Hisert[3] Sarah Taylor[5], [1]University of Colorado Anschutz Medical Campus, Children's Hospital Colorado, [2]University of Colorado, [3]National Jewish Health, [4]University of Colorado School of Medicine, [5]Children's Hospital Colorado

Background: Obstructive cholangiopathies carry a high burden across the lifespan with limited medical therapies. GM-CSF (granulocyte-macrophage colony-stimulating factor) has been associated with improved outcomes in biliary atresia but its therapeutic role has not been explored. We aimed to define the mechanism by which GM-CSF modulates macrophage function and liver injury in the mouse model of bile duct ligation (BDL). **Methods:** BDL or sham surgery (control) was performed in adult wild-type (WT) C57BL/6 or whole body GM-CSF knock-out (KO) mice. WT BDL mice were treated with daily intra-peritoneal GM-CSF (0.09µg/g) vs saline starting at post-operative day 0 (POD0). POD3 outcome analyses included single-cell RNA-sequencing (scRNA-seq) analysis (KO experiments only), biochemical markers of liver injury, histologic evaluation of inflammatory liver injury (modified Ishak score), and flow cytometry of macrophage subsets. **Results:** Compared to WT BDL mice, GM-CSF KO BDL mice at POD3 exhibited increased alkaline phosphatase, direct bilirubin, and Ishak score (ANOVA $p < 0.05$ for all) with no differences for sham surgery by genotype. Flow cytometry analysis showed reduced frequency of recruited macrophages (RM) in KO BDL ($p = 0.002$, **Fig 1A**) with MHCII+ RM proportion of total macrophages decreased by 41% compared to WT BDL. Tissue-resident macrophages (i.e. Kupffer Cells) were similarly decreased in both BDL groups compared to their sham controls. scRNA-seq analysis of KO BDL RMs showed enrichment for pro-inflammatory pathways while pathways associated with phagocytosis and antigen presentation were decreased. Ligand–receptor analysis (CellChat R package) demonstrated a shift in KO RMs from reparative Mif-Cd74 and Cd45-Mrc1 signaling toward maladaptive Sirp-Cd47 and Tgfb signaling (**Fig 1B-C**). WT BDL mice treated with GM-CSF exhibited reduced Ishak liver injury scores at POD3 and greater proportion of RMs by flow cytometry (**Fig 1A**) with MHCII+ RM proportion of total macrophages increased by 55% compared to WT BDL mice treated with saline. **Conclusion:** Our data support a critical role for GM-CSF in maintaining a coordinated immune response among RMs characterized by active antigen presentation and debris removal (Cd74/ Mrc1 pathways). In contrast, GM-CSF insufficiency may result in impaired Sirp-associated clearance of apoptotic cells by RMs and increased Tgfb signaling. These findings align with the emerging appreciation of an anti-inflammatory role for GM-CSF in specific disease states and highlight it's potential as an immune-regulatory therapy in early stages of obstructive cholestasis.

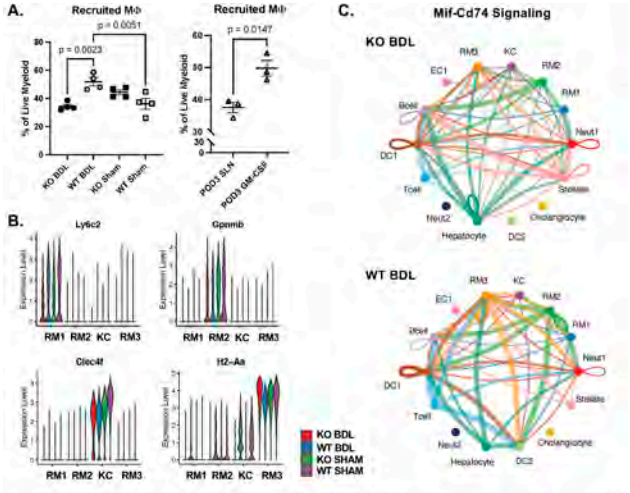

Figure 1. A. Flow cytometry analysis of macrophages (MΦs) demonstrated decreased proportion of recruited macrophages (RM) in GM-CSF knock-out (KO) mice at post-operative day (POD) 3 after bile duct ligation (BDL). GM-CSF treatment in wild-type BDL mice increased the proportion of RMs at POD 3. ANOVA with Šidák correction and two-tailed t-test was used for statistical comparisons. **B.** scRNA-seq analysis identified 3 subsets of RMs of which RM3 exhibited high expression for MHCII genes. **C.** CellChat ligand-receptor analysis identified increased MΦ migration inhibitory factor (Mif) signaling with Cd47 (MHCII invariant chain) in WT BDL mice particularly in RM3. RM - recruited MΦ, KC - Kupffer cell, Neut - neutrophil, DC - dendritic cell, EC - endothelial cell.

0179 | FROM INFLAMMATION TO SURVEILLANCE: INTRAHEPATIC NK CELL REMODELLING WITH TOBEVIBART AND ELEBSIRAN IN CHRONIC HEPATITIS D - A TRANSLATIONAL SUB-STUDY OF THE SOLSTICE TRIAL

Upkar Gill[1] Jantarika Arora[1] Chanelle Fernandes[1] Akhilesh Mulay[1] Gerard Hernandez-Mir[1] Andrew Watson[1] Almuthana Mohamed[1] Apostolos Koffas[1] Michael Chattergoon[2] Patrick Kennedy[1], [1]Blizard Institute, Barts and The London, School of Medicine, QMUL, London, [2]Michael Chattergoon

Background: Chronic HDV infection is the most severe form of viral hepatitis. Although immune-mediated, antigen-specific adaptive responses are weak, placing NK cells at the centre of immunopathogenesis and viral control. In chronic HDV, NK cells are functionally compromised, skewed towards CD56bright subsets producing excess IFNγ and TNFα. Despite evidence that NK cells eliminate HDV-infected hepatocytes via a TRAIL/TRAIL-R2 axis and that bulevirtide restores NK immune checkpoint expression (TIGIT), the intrahepatic NK transcriptional landscape and its remodelling by HBsAg-targeting therapy remains uncharacterised. **Methods:** Five chronic HDV patients (n = 3 tobevibart monotherapy; n = 2 tobevibart + elebsiran) underwent paired PBMC and fine-needle aspiration (FNA) liver sampling at baseline and 6 months within the SOLSTICE study. Median baseline HDV RNA was 26,273 IU/mL (range 599–4,640,855) and HBsAg 4,780 IU/mL (range 1,504–20,928). Single-cell RNA sequencing of 197,191 cells identified 7,518 NK cells (FNA: 3,263; PBMC: 4,255), annotated into seven subsets. Differential gene expression (DEG) (FindMarkers; $|avg\_log_2FC| \geq 0.5$, $p < 0.05$) and KEGG pathway enrichment (gprofiler2) were performed per subset, pre- vs. post-treatment. **Results:** At 6 months, all patients achieved undetectable HDV RNA, with mean HBsAg decline of 2.91 log_{10}IU/mL (range 2.01–3.99). Pre-treatment, intrahepatic NK cells showed broad metabolic activation (ACADM, NAMPT, CPT1A) and cytokine-receptor upregulation (XCL1, FASLG, IL2RB), with IFN-activated NK cells dominated by IRF9 and OAS1. Following therapy, adaptive NK cells increased towards a surveillance phenotype (NFKB1, STAT2, KLRB1, FOXO1, CXCR6). IFN-activated NK cells showed reduced interferon dominance with post-treatment IL10RA and MTOR, suggesting immunomodulatory reprogramming. Proliferating NK cells expanded, upregulating cell cycle (CDK1, BIRC5) and PI3K-Akt genes (MTOR, FOXO3), indicating intrahepatic renewal. CXCR4 was upregulated across FNA NK subsets. Peripheral blood showed limited remodelling, with IFIT1 as the leading DEG. **Conclusion:** HBsAg-targeting therapy induces coordinated intrahepatic NK cell remodelling in chronic HDV, largely absent from peripheral blood. The shift from IFN-driven inflammation towards adaptive NK enrichment, proliferative renewal, and immunomodulatory reprogramming suggests a transition to a more controlled intrahepatic immune state, providing novel mechanistic insight into regimens effectively targeting HBsAg.

0180 | STREM2 ENHANCES CD4+ T CELL ACTIVATION AND DRIVES T CELL-MEDIATED REJECTION FOLLOWING LIVER TRANSPLANTATION

Aiwei Zhou[1] Qi Pan[1] Hongyuan Liu[1] Bingran Wang[1] Yongbo Liu[1] Yuan Liu[1] Qiang Xia[1], [1]Renji Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China

Background: T cell-mediated rejection (TCMR) remains a major clinical challenge following liver transplantation (LT), lacking reliable non-invasive biomarkers and mechanistic clarity. This study investigated soluble triggering receptor expressed on myeloid cells 2 (sTREM2) as both a diagnostic biomarker and pathogenic driver of TCMR. **Methods:** We enrolled 63 pediatric LT recipients classified by biopsy as normal (n = 38), TCMR (n = 17), or antibody-mediated rejection (AMR, n = 8). Plasma sTREM2 was measured by ELISA and evaluated for diagnostic performance. Single-cell RNA sequencing (scRNA-seq) was performed on liver allografts and peripheral blood to identify cellular sources of TREM2. A fully MHC-mismatched murine LT model (C57BL/6→C3H/He) evaluated sTREM2 function in vivo. In vitro, CD4+ T cells were activated with anti-CD3/CD28 in the presence or absence of sTREM2, and the status of activation, proliferation, and signaling were assessed. Affinity purification-mass spectrometry (AP-MS) and Co-IP mapped the sTREM2 receptor. A TREM2-specific monoclonal antibody (4D9) was evaluated for therapeutic potential. **Results:** Plasma sTREM2 was significantly elevated in TCMR patients compared to normal allografts (AUROC = 0.7477, p = 0.0036), with specificity against AMR. scRNA-seq revealed that TREM2 upregulation was predominantly localized to intrahepatic macrophages. In the murine LT model, sTREM2 administration significantly exacerbated TCMR severity and enhanced CD4+ T cell effector function. Mechanistically, sTREM2 directly promoted CD4+ T cell activation, evidenced by upregulated activation marker (CD69 and CD25) and enhanced ERK-MAPK signaling. RNA-seq analysis showed that sTREM2 upregulated T cell activation genes (IL2, CXCR3, CCR4, and ETS1), and GSEA revealed significant enrichment of the AP-1 signaling pathway. AP-MS and Co-IP identified RalA as the sTREM2-interacting protein and RalA knockdown abolished sTREM2-enhanced ERK phosphorylation downstream of the T cell receptor (TCR). Therapeutically, a TREM2-specific antibody (4D9) significantly ameliorated TCMR in LT mice by inhibiting sTREM2 shedding, neutralizing its pathogenic function and enhancing TREM2-dependent anti-inflammatory signaling. **Conclusion:** sTREM2 is a non-invasive biomarker and pathogenic mediator of TCMR. The sTREM2-RalA-ERK axis defines a myeloid-T cell crosstalk mechanism driving alloreactive CD4+ T cell activation.Targeting TREM2 with therapeutic antibodies may offer a precision immunotherapy strategy for TCMR management.

0181 | T CELL RECEPTOR SEQUENCING REVEALS A UNIQUE T CELL IMMUNE REPERTOIRE SHARED BETWEEN BLOOD AND LIVER IN DECOMPENSATED CIRRHOSIS

Elsa Solà[1] Pari Waghela[2] Chunlin Wang[3] Ana Jimena Pavlovitch-Bedzyk[3] Deeksha Lahori[3] Jie Zhang[3] Adrià Juanola[4] Allison Kwong[5] Natalie Torok[6] Paul Kwo[5] Pere Gines[7] Carlos Esquivel[5] Mark Davis[3], [1]Division of Gastroenterology and Hepatology, Stanford University, [2]Department of Abdominal Transplantation, Stanford University, [3]Institute for Immunity, Transplantation and Infection, Stanford University, [4]Hospital Clinic i Provincial de Barcelona, [5]Stanford University Medical Center, [6]Division of Gastroenterology and Hepatoloy, Stanford University, [7]Liver Unit, Hospital Clinic Barcelona

Background: T cell activation contributes to cirrhosis-associated immune dysfunction. Data regarding the specific drivers of T cell activation remain limited. We aimed to investigate the T cell receptor (TCR) repertoire in cirrhosis to determine whether there are shared specificities and to identify potential differences between circulating blood and intrahepatic T cells. **Methods:** Peripheral blood mononuclear cells and intrahepatic lymphocytes were isolated from paired blood and liver tissue samples from patients with decompensated cirrhosis undergoing liver transplantation. We performed combined single-cell and bulk TCR sequencing. TCR clustering was performed using the GLIPH2 algorithm, which clusters together TCRs with a high probability of sharing antigen specificities. To determine whether TCR clusters are unique to cirrhosis or common in the general population, we combined the cirrhosis data with data from healthy controls and public sequences with known antigen specificities (i.e., CMV, EBV). **Results:** We obtained 14,786 unique TCR sequences derived from paired liver and blood samples from patients with alcohol-related decompensated cirrhosis (n = 3). Cirrhosis data was combined with 9,970 TCR sequences from healthy controls and controls with known antigen specificities. Clustering analysis revealed 2,278 clusters including only sequences from patients with cirrhosis out of a total of 16,876 clusters. Interestingly, 704 out of the 2,278 cirrhosis-specific clusters included TCR sequences derived from all 3 patients, suggesting that T cells from different patients with cirrhosis respond to the same antigens. Notably, among the cirrhosis-specific clusters we identified 11 clusters that included TCR sequences present in both blood and liver across all 3 patients, suggesting that T cell clones with same antigen specificity are shared between different patients with cirrhosis and present in both blood and liver. Comparison with public data showed that the sequences from these 11 clusters do not present any overlap with sequences from healthy controls with known antigen specificities and therefore do not correspond to T cells responding to common antigens seen in the general population. **Conclusion:** Our findings demonstrate a distinct T cell repertoire in patients with decompensated cirrhosis. The same T cell clones are present in the peripheral blood and the intrahepatic compartment. The presence of shared clones with no overlap with healthy individuals suggests that liver-disease specific antigens drive T cell activation in cirrhosis and shape the immune response both at the peripheral blood and the intrahepatic compartments. This offers new insights into the drivers of cirrhosis-associated immune dysfunction and helps investigate novel preventive or therapeutic approaches.

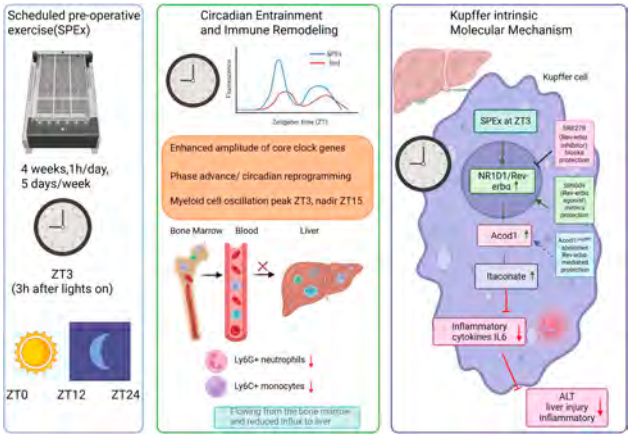
0182 | SCHEDULED PREOPERATIVE EXERCISE THERAPY MODULATES CIRCADIAN-DEPENDENT ITACONATE METABOLISM IN KUPFFER CELLS TO PROTECT AGAINST LIVER ISCHEMIA-REPERFUSION INJURY



Ti Yang[1] Yi Jiang[1] Jiannan Hu[1] Xingping Huang[1] Grace Wu[1] Ameilia Solan[1] Meihong Deng[1] Hai Huang[2], [1]Feinstein Institute for Medical Research, [2]Feinstein Institutes for Medical Research

Background: Hepatic ischemia/reperfusion (I/R) injury remains a major cause of morbidity following liver surgeries and transplantation, driven by immune and metabolic dysregulation. We recently demonstrated that pre-operative exercise therapy (PEx) triggers anti-inflammatory trained immunity in Kupffer cells (KCs) and reshapes bone marrow hematopoiesis. Given that exercise is a potent modulator of circadian rhythms, and that nuclear receptor NR subfamily 1 group D member 1 (NR1D1 gene, encodes Rev-erbα) regulates both circadian biology and inflammation, we hypothesized that scheduled PEx confers hepatic protection by entraining circadian-dependent immunometabolic reprogramming in Kupffer cells. **Methods:** Circadian profiling of bone marrow, blood, liver tissue, and nonparenchymal cells was performed across

multiple time points (ZT3, ZT6, ZT9, ZT12, ZT15, and ZT21) after exercise at ZT3. 70% patrial hepatic I/R was induced at ZT3. Pharmacologic modulation of Rev-erbα was achieved using the antagonist SR8278 and agonist SR9009. Hepatic damage, inflammation, circadian genes, and immune cell subpopulations were assessed. KC-specific metabolic responses were evaluated by qPCR and immunoblotting following *in vivo* and *in vitro* manipulation, and Kupffer cell-specific ACOD1 knockout (*Acod1*$^{\Delta Kupffer}$) mice were used to assess functional dependency on itaconate metabolism. **Results:** Myeloid cell populations exhibited circadian oscillations, peaking at ZT3 and reaching a nadir at ZT15. SPEx significantly reduced Ly6C^{high} monocytes and Ly6G^{+} neutrophils in bone marrow at ZT3 and in the liver at ZT12, indicating time-dependent suppression of inflammatory cell mobilization. PEx enhanced the amplitude of core clock gene expression and alter the phase or period to advance. Notably, *Nr1d1* expression was significantly upregulated in KCs and liver tissue at ZT3 following PEx. Pharmacologic inhibition of Rev-erbα abrogated PEx-mediated hepatoprotection, as evidenced by elevated ALT and IL-6 levels and exacerbated liver injury, whereas Rev-erbα activation recapitulated protective effects. Mechanistically, Rev-erbα modulated expression of *Acod1*, a key enzyme that generates the anti-inflammatory metabolite itaconate, thereby linking circadian signaling to KC immunometabolism. Importantly, the protective effects of Rev-erbα activation were lost in *Acod1*$^{\Delta Kupffer}$ mice, demonstrating a KC-intrinsic NR1D1-ACOD1 axis. **Conclusion:** In summary, our findings provide compelling evidence that scheduled preoperative exercise therapy entrains circadian immunity to protect against liver I/R injury through an Rev-erbα -ACOD1-itaconate metabolic axis in Kupffer cells. These findings establish a mechanistic link between circadian regulation, exercise, and immunometabolic reprogramming, and suggest that targeting this pathway may enable chronotherapy-based strategies for perioperative liver protection.

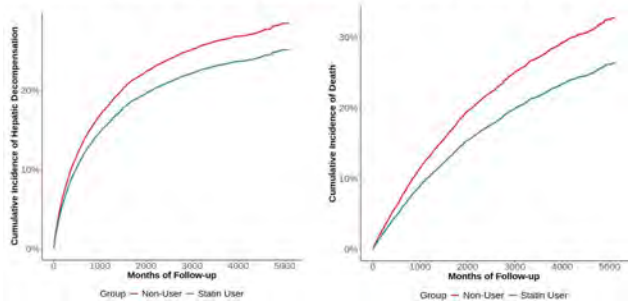
0183 | STATINS BEYOND CHOLESTEROL: REDUCED DECOMPENSATION AND OVERALL MORTALITY IN 18,560 ADULTS WITH COMPENSATED CIRRHOSIS

Monica Tincopa[1] Xinlian Zhang[2] Lars Eckmann[2] Rohit Loomba[1] Bernd Schnabl[2], [1]University of California, San Diego, [2]UCSD



Background: Statins have demonstrated pleiotropic antinflammatory and antifibrotic properties, making them of particular interest in cirrhosis. However, large-scale data evaluating statin therapy in compensated cirrhosis are lacking. The aim of this study was to assess the association of between statin use and risk of hepatic decompensation overall mortality in a large, population-based, multi-site cohort of adults with compensated cirrhosis. **Methods:** Using the University of California (UC) Health Data Warehouse comprised of patients seen at UC health facilities 2012-present, we identified patients with cirrhosis and no prior history of hepatic decompensation using validated ICD-10 algorithms. A new-user design was employed, requiring ≥90-day period following cirrhosis diagnosis with no statin exposure or outcome attainment. Statin users were defined as those with a new statin prescription after cirrhosis diagnosis with continuous statin exposure ≥ 90 days. The primary outcome was composite hepatic decompensation [ascites, SBP, variceal bleeding, hepatic encephalopathy, or hepatorenal syndrome (HRS)] and the secondary outcome was overall mortality. Liver transplant and death were considered competing events. Inverse probability of treatment weighting (IPTW)-adjusted Cox proportional hazards regression models were used to estimate cumulative incidence and adjusted subhazard ratios (aSHR). Propensity score calculation included demographics, alcohol and tobacco use, cirrhosis etiology, medical comorbidities (diabetes, CKD, CAD, dyslipidemia, malignancy), and labs (MELD, platelets, AST, ALT). **Results:** A total of 18560 subjects were included in the analysis. The median age of the overall cohort was 58 at diagnosis, 44% female and 51% White with a median follow-up time of 7.9 years after diagnosis of cirrhosis. Cumulative incidence of decompensation and mortality was 18.2% and 14.6% in the statin and 22.7% and 21.2% in the non-statin users over the entire study period. After adjusting for baseline (index date) confounding via IPTW and accounting for competing risks, statin initiation was associated with a statistically

significant reduction in the risk of composite hepatic decompensation (aSHR = 0.86, 95%CI: 0.78-0.96, p = 0.008) and overall mortality (aSHR = 0.77, 95% CI: 0.68–0.87, p < 0.001). **Conclusion:** In a large population-based IPTW-adjusted cohort of adults with compensated cirrhosis, statin therapy was associated with significantly lower rates of hepatic decompensation and overall mortality over 8 years of follow-up. These data suggest potential preventive benefit of statin therapy in adults with compensated cirrhosis that should be further assessed in randomized clinical trials.

Figure. Cumulative Incidence of A) Hepatic Decompensation and B) Overall Mortality by Statin use

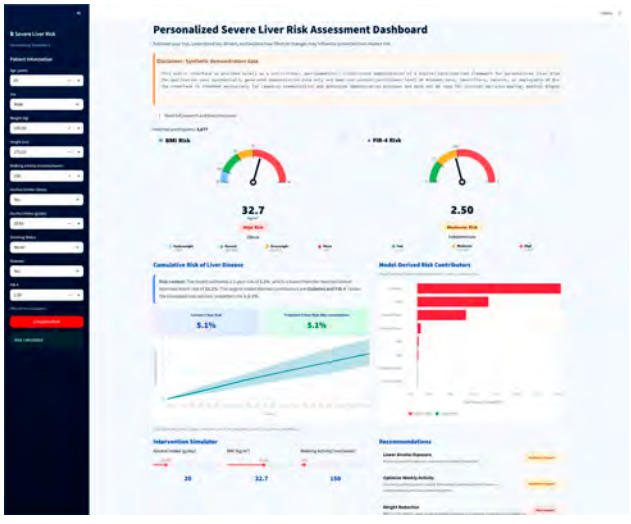
0184 | TOWARDS A DIGITAL-TWIN-INSPIRED FRAMEWORK FOR PERSONALIZED 5-YEAR LIVER DISEASE RISK PREDICTION AND PREVENTION IN INDIVIDUALS WITH ELEVATED FIB-4



Thriveni Basavanapura Raju[1] Benjamin Laevens[2] Corinna Meeβen[2] Tobias Seibel[1] Jan Clusmann[3] Saleh Alqahtani[4] Kai Markus Schneider[5] Sandra Geisler[6] Carolin Schneider[1], [1]University Hospital RWTH Aachen, Department of Internal Medicine III, Aachen, Germany, [2]University Hospital RWTH Aachen, Department of Internal Medicine III, Gastroenterology, Germany, [3]Else Kroener Fresenius Center for Digital Health, Medical Faculty Carl Gustav Carus, Dresden, Germany, [4]King Faisal Hospital and Research Centre Riyadh, Saudi Arabia, [5]University Hospital Carl Gustav Carus Dresden, Department of Medicine1, Dresden, Germany, [6]Data Stream Management and Analysis, RWTH Aachen University, Aachen, Germany

Background: Individuals with elevated FIB-4 scores are at increased risk for major adverse liver outcomes (MALO), yet current risk stratification tools remain static and provide limited support for individualized prevention. We developed a digital-twin-inspired prototype with an interactive website that identifies clinically similar individuals, estimates individualized 5-year MALO risk and explores scenario-based risk changes under alternative lifestyle profiles. **Methods:** Baseline UK Biobank individuals with elevated fibrosis risk (FIB-4 $\geq$ 1.3) (n = 137709) were included. The outcome was incident MALO, defined using linked hospital episode statistics (HESIN) records and ICD-10 codes: K74, C22, K72, K76.6, I85, R18. Clinically similar individuals were identified by shared sex, age group ($\geq$ 50 years) and same BMI group (BMI $\geq$ 18.5), while demographic, clinical, biochemical, and lifestyle predictors were incorporated to predict MALO risk. A 5-year risk was estimated using a penalized Cox proportional hazards

model. Risk estimation was restricted to clinically similar subgroups with at least 150 observed MALO events, which was chosen to reduce sparse-data bias and unstable subgroup-specific risk estimates, corresponding to approximately ≥10 outcome events per effective predictor parameter, while penalization and bootstrap resampling were used to further mitigate overfitting. Scenario-based risk estimates were generated by modifying selected potentially modifiable predictors, including alcohol use, BMI, and physical activity, while keeping all other covariates constant and applying the coefficients from the multivariable penalized Cox model within the same matched risk set. Internal validation of the model was performed using bootstrap resampling (1000 iterations), where the model was repeatedly trained and tested using randomly sampled participants from the cohort. **Results:** Among 137709 UK Biobank participants with elevated FIB-4, 1760 developed incident MALO over a median follow-up of 8.7 years. Internal validation of the model demonstrated good discrimination in identifying individuals at higher risk of developing MALO with those at lower risk, with an optimism-corrected C-index of 0.70 (95% CI 0.69-0.71) and a 5-year AUROC of 0.73 (95% CI 0.70-0.76). Calibration was acceptable, with a calibration slope of 0.87 and calibration-in-the-large of 0.03. An interactive web-based prototype interface, accessible via https: //liver-digital-twin-prototype.streamlit.app/, was developed for demonstration using synthetic data designed to reflect the training cohort without including participant-level UKB records. No UK Biobank data can be accessed, calculated or displayed through the public interface. **Conclusion:** The framework provides a foundation for personalized liver risk assessment. Current limitations include the use of baseline-only covariates without longitudinal updating.

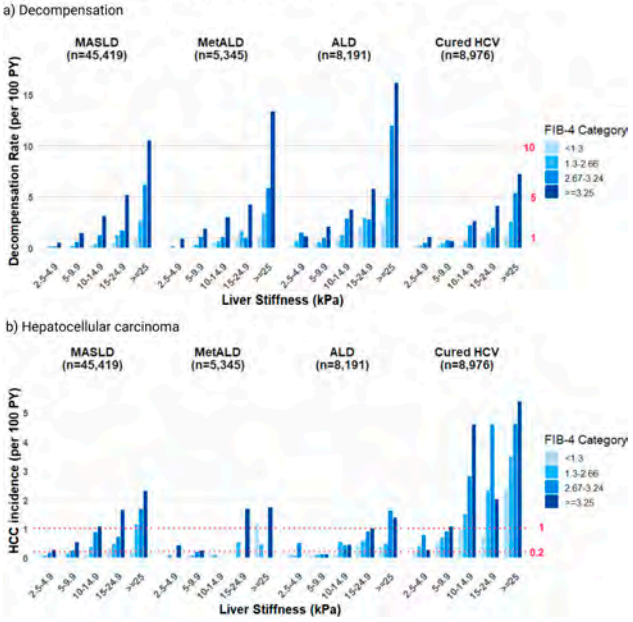
0185 | COMBINING LIVER STIFFNESS WITH FIB-4 CATEGORIES TO STRATIFY RISK OF MAJOR ADVERSE LIVER OUTCOMES ACROSS MASLD, METALD, ALD AND CURED HCV

Philip Vutien[1] Nicole Kim[1] Abbey Barnard Giustini[2] Andrew Moon[3] Chunnan Hsu[4] Kay Johnson[5] Trang VoPham[6] Bret Mecham[7] Vyshnika Sriskantharajah[8] George Ioannou[2], [1]Division of Gastroenterology, University of Washington Medical Center, [2]Division of Gastroenterology, Veterans Affairs Puget Sound Health Care System, [3]Division of Gastroenterology and Hepatology, The University of North Carolina at Chapel Hill, [4]Division of Perioperative Informatics, Anesthesiology, University of California, San Diego, [5]Hospital and Specialty Medicine Service, Veterans Affairs Puget Sound Health Care System, [6]Public Health Sciences Division, Fred Hutchinson Cancer Center, [7]Research and Development, Veterans Affairs Puget Sound Health Care System, [8]Research and Development, Veterans Affairs Puget Sound Health Care System, Seattle, Washington



Background: The prognostic value of jointly interpreting liver stiffness (LS) and Fibrosis-4 (FIB-4) across chronic liver diseases is uncertain. We evaluated how the risk of hepatic decompensation, hepatocellular carcinoma (HCC), and mortality vary across combined LS/FIB-4 categories in metabolic dysfunction-associated steatotic liver disease (MASLD), metabolic and alcohol-associated liver disease (MetALD), alcohol-associated liver disease (ALD) and cured hepatitis C virus (HCV). **Methods:** We identified 67,931 patients (67% MASLD, 8% MetALD, 12% ALD, and 13% cured HCV) who underwent LS measurement by transient elastography from 2014-2024, excluding those with prior decompensation, HCC, or liver transplantation. Patients were classified into five LS strata (2.5–4.9, 5–9.9, 10–14.9, 15–24.9, ≥25 kPa) and further subclassified into four FIB-4 strata (<1.3, 1.3–2.66, 2.67–3.24, ≥3.25). Follow-up extended from date of LS measurement through 9/2025 for hepatic decompensation, HCC, and all-cause mortality. **Results:** Median age was 61 years and 92% were male. Across all etiologies, incidence of hepatic decompensation, HCC, and mortality increased stepwise with higher LS and was further stratified by FIB-4

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

in a near-monotonic dose–response pattern (Figure). In patients with MASLD, HCC incidence ranged more than 100-fold from 0.02 to 2.3 per 100 person-years (PYs) and risk of decompensation from 0.06 to 10.5 per 100 PYs across LS/FIB-4 strata. Marked heterogeneity in risk, often exceeding ten-fold, was observed within LS strata by FIB-4 (e.g., decompensation in MASLD at LS 15–24.9 kPa was 0.45 per 100 PYs for FIB-4 <1.3 vs. 5.13 per 100 PYs for FIB-4 ≥ 3.25). All-cause mortality followed a similar stepwise pattern, ranging from 0.7 to 11.4 per 100 PYs in MASLD across LS/FIB-4 strata, with comparable gradients observed across other etiologies. For decompensation, MetALD consistently demonstrated intermediate risk between MASLD and ALD (e.g., at LS ≥ 25 kPa and FIB-4 ≥ 3.25: 10.5, 13.3, and 16.1 per 100 PYs, respectively). MetALD also exhibited the highest mortality at the highest LS/FIB-4 stratum (14.2 per 100 PYs vs. 11.4 for MASLD and 11.6 for ALD). At comparable LS/FIB-4 levels, cured HCV consistently exhibited the highest HCC risk (up to 5.38 per 100 PYs), whereas ALD showed the highest risk of hepatic decompensation (up to 16.1 per 100 PYs). **Conclusion:** Combined LS/FIB-4 categorization provides a pragmatic framework for stratifying risks of decompensation, HCC, and death. Distinct etiology-specific patterns—highest HCC risk in cured HCV and highest decompensation risk in ALD—highlight the value of interpreting LS and FIB-4 by liver disease etiology.

★ 0186 | PARADOXICALLY ELEVATED SLEEP-STAGE HEART RATE VARIABILITY IS ASSOCIATED WITH COGNITIVE IMPAIRMENT IN CIRRHOSIS INDEPENDENT OF LIVER DISEASE SEVERITY

Adam Buckholz[1] Himel Mallick[2] Alec Chang[2] Avesh Thuluvath[3] Lara Phipps[2] Edwin Kan[4] Ana Krieger[2] Robert Brown[5], [1]New York Presbyterian Hospital Program, [2]NewYork-Presbyterian/Weill Cornell Medical Center, [3]Columbia University Irving Medical Center, [4]Cornell University, [5]Weill Cornell Medicine

Background: Autonomic dysfunction and sleep disturbance are common in cirrhosis and hepatic encephalopathy (HE), yet biomarkers capable of identifying covert cognitive impairment remain limited. Heart rate variability (HRV), a noninvasive marker of autonomic function associated with cirrhosis severity and outcomes, may be particularly informative during sleep because it can be measured passively and longitudinally under stable physiologic conditions. We evaluated whether nocturnal HRV measured using wearable devices discriminates cognitive status in patients with cirrhosis. **Methods:** We analyzed longitudinal nocturnal HRV recordings from 102 patients with cirrhosis wearing a commercial wearable device. Participants included had ≥ 14 valid wear days with $\geq 80\%$ wear time and analyzable sleep-stage HRV. HRV was measured as root mean square of successive differences (RMSSD, ms) across 30-second epochs of scored sleep and averaged across overall nocturnal sleep as well as deep, light, and REM sleep stages. Cognitive status was assessed using the Psychometric Hepatic Encephalopathy Score (PHES), with covert HE (CHE) defined as PHES $\leq$ -4. Mixed-effects models with subject-level random intercepts evaluated associations between HRV and both continuous PHES performance and CHE status. Adjusted models included age, MELD 3.0, and beta-blocker use. **Results:** Contrary to the expected reduction in HRV observed with worsening cirrhosis severity, cognitive impairment was associated with paradoxically elevated nocturnal RMSSD across sleep stages. In the full cohort, CHE patients demonstrated significantly higher adjusted RMSSD compared to non-CHE patients during overall sleep (+5.50 ms, $p = 0.014$), deep sleep (+5.16 ms,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

p = 0.030), light sleep (+5.83 ms, p = 0.010), and REM sleep (+5.65 ms, p = 0.013). Among HE-treated patients, associations were most pronounced during REM sleep, where CHE was associated with 7.28 ms higher adjusted RMSSD (p = 0.023). Importantly, similar findings persisted among untreated patients without prior overt HE, where untreated CHE was associated with significantly higher nocturnal RMSSD across overall, deep, and light sleep stages after adjustment for age, with similar effect sizes observed following additional adjustment for MELD 3.0 and beta-blocker use (overall +7.44 ms, p = 0.045; deep +8.06 ms, p = 0.038; light +8.13 ms, p = 0.029). **Conclusion:** Paradoxically elevated nocturnal HRV was observed in cognitive impairment across sleep stages independent of age, beta-blocker use, and partially independent of liver disease severity. The consistency of these findings, including among untreated patients without prior overt HE suggests that altered nocturnal autonomic regulation may represent an early physiologic manifestation of HE. Wearable-derived sleep-stage HRV may represent a novel digital biomarker for longitudinal assessment of covert cognitive dysfunction in cirrhosis.

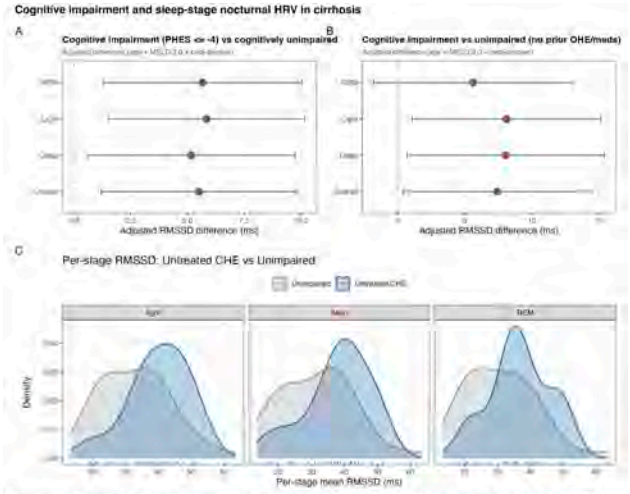

Figure 1. Cognitive impairment and sleep-stage nocturnal heart rate variability (HRV) in cirrhosis. Cognitive status was defined by the Psychometric Hepatic Encephalopathy Score (PHES), with cognitive impairment defined as PHES ≤ -4. HRV was quantified as the root mean square of successive differences (RMSSD, ms) from Oura ring inter-beat intervals on 30-second sleep-staged epochs, summarized per subject within each sleep stage (deep, light, REM) and as a per-night nocturnal average across stages ("Overall"). Wake epochs were excluded. (A) Adjusted difference in RMSSD between cognitively impaired (PHES ≤ -4) and cognitively unimpaired patients by sleep stage, from linear mixed-effects models with a subject-level random intercept, adjusted for age, MELD 3.0, and beta-blocker use. Points are the estimated mean difference (ms), horizontal bars are 95% Wald confidence intervals, and the dashed line marks no difference; values to its right indicate higher RMSSD in the cognitively impaired group. (B) Restricted to patients with no prior overt hepatic encephalopathy (OHE) and no hepatic encephalopathy medication use, reference = cognitively unimpaired. Model structure and adjustment (age, MELD 3.0, beta-blocker use) are identical to panel A. This panel tests whether the association in A persists in patients whose impairment is not attributable to prior OHE or to ongoing treatment. (C) Subject-level per-stage RMSSD distributions for the same no-prior-OHE, untreated subgroup, shown as kernel densities for cognitively unimpaired versus untreated covert hepatic encephalopathy (CHE) patients across light, deep, and REM sleep. Tick marks (rug) denote individual subjects.

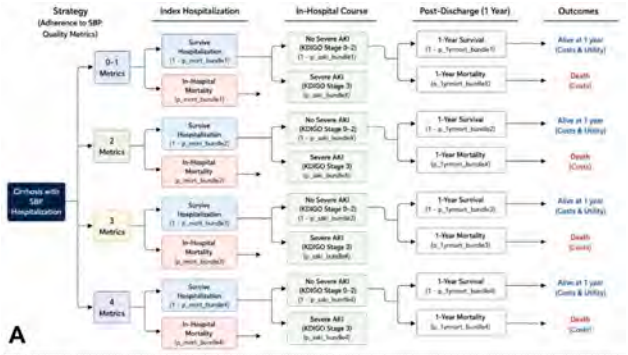
0187 | COST-EFFECTIVENESS OF ADHERENCE TO SPONTANEOUS BACTERIAL PERITONITIS QUALITY METRICS IN CIRRHOSIS HOSPITALIZATIONS: A DECISION-ANALYTIC MODEL



Claudio Salinas[1] Marina Serper[2] David Kaplan[3] Siqi Zhang[3] Nadim Mahmud[1], [1]Hospital of the University of Pennsylvania, [2]University of Pennsylvania Health System, [3]University of Pennsylvania

Background: Spontaneous bacterial peritonitis (SBP) is associated with substantial morbidity, mortality, and healthcare utilization in patients with cirrhosis. Although guideline-recommended quality metrics for SBP management have been established and recently shown to be associated with clinical outcomes, the economic and clinical value of achieving higher adherence to these metrics remains poorly defined. We aimed to evaluate the cost-effectiveness of increasing adherence to SBP quality metrics during cirrhosis hospitalizations. **Methods:** We developed a decision-analytic model using TreeAge Pro to evaluate strategies based on achievement of 0-1, 2, 3, or 4 SBP quality metrics during hospitalization (antibiotics within 48 hours, albumin per guidelines, SBP discharge code, repeat paracentesis at 48 hours; Figure Panel A). Model pathways incorporated in-hospital mortality, severe acute kidney injury (AKI; KDIGO stage 3), and 1-year post-discharge mortality; utilities were derived from published health utility literature. Transition probabilities were derived from granular Veterans Health Administration cohort data stratified by quality metric adherence level. Costs were estimated from observed healthcare expenditures and stratified by hospitalization survival and severe AKI status. Health outcomes were expressed as quality-adjusted life years (QALYs) over a 1-year horizon. Incremental cost-effectiveness ratios (ICERs) were calculated from a healthcare system perspective using a willingness-to-pay threshold of $100,000/QALY. Deterministic one-way sensitivity analyses and probabilistic sensitivity analyses were performed. **Results:** Strategies achieving 0-1 and 2 quality metrics were absolutely dominated, demonstrating higher costs and lower effectiveness compared with higher-adherence strategies. Achieving 3 quality metrics was associated with the lowest expected cost ($59,194) and an effectiveness of 0.34 QALYs. Achieving 4 quality metrics increased effectiveness to 0.40 QALYs at an incremental cost of $2,837, corresponding to an ICER of $49,896/QALY gained (Figure Panel B). One-way sensitivity analyses demonstrated that results were most sensitive to post-hospitalization costs among survivors without severe AKI,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

baseline utility estimates, and in-hospital mortality probability. Across plausible parameter ranges, the 4-metric strategy remained cost-effective at a willingness-to-pay threshold of $100,000/QALY. **Conclusion:** Greater adherence to SBP quality metrics during cirrhosis hospitalization was associated with improved clinical outcomes and favorable cost-effectiveness. Achieving all 4 quality metrics was cost-effective compared with lower-adherence strategies, supporting efforts to improve implementation of evidence-based SBP care.

B

Strategy	Dominance Status	Expected Cost ($)	Expected QALYs	Incremental Cost ($)	Incremental QALYs	ICER ($/QALY)	Net Monetary Benefit ($)*

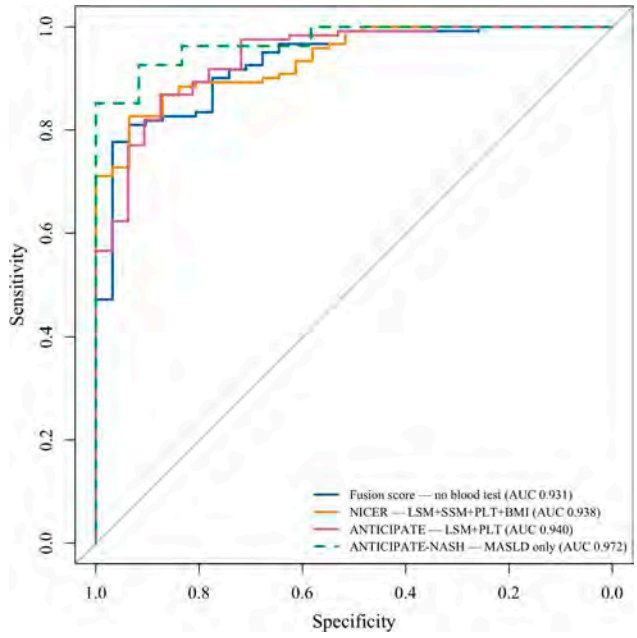
0188 | A BLOOD-TEST-FREE LSM–SSM FUSION SCORE FOR POINT-OF-CARE DIAGNOSIS OF CLINICALLY SIGNIFICANT PORTAL HYPERTENSION (CSPH): A MULTICENTRE STUDY



Lucia Parlati[1] Lucile Moga[2] Alexis Dupre[1] Pierre-Emmanuel Rautou[2] Vincent Mallet[1], [1]AP-HP.Centre Université Paris Centre, Groupe Hospitalier Cochin Port Royal, [2]AP-HP.Nord Université Paris Centre, Hôpital Beaujon

Background: Non-invasive evaluation of CSPH fails up to half of compensated advanced chronic liver disease (cACLD) patients, leaving them in a grey zone that requires invasive hepatic venous pressure gradient (HVPG) measurement. Existing models improve reclassification but depend on blood tests. We derived and locked a fully blood-test-free fusion score combining liver stiffness measurement (LSM) and spleen stiffness measurement (SSM) for point-of-care CSPH classification, with a primary focus on grey zone reclassification. **Methods:** Consecutive patients with cACLD (LSM $\geq$10 kPa) from three French tertiary hepatology centres underwent same-session LSM and SSM using FibroScan® (Echosens) or Hepatus® (Mindray). CSPH was defined by oesophageal varices, prior hepatic decompensation, or HVPG $\geq$10 mmHg. The fusion score $s = \alpha \cdot z(\text{LSM}) + (1-\alpha) \cdot z(\text{SSM})$ was derived by grid search on the FibroScan® cohort; all parameters (α, μ and σ for LSM and SSM, Youden threshold) were locked in a version-controlled package and applied without recalibration in every downstream analysis. The score was tested cross-platform, and against ANTICIPATE and NICER with a pre-specified non-inferiority margin of $\Delta\text{AUC} \geq -0.03$, and across pre-specified sensitivity analyses [HVPG-confirmed CSPH, non-alcohol-related liver disease (ALD), non-censored measurements, Child-Pugh A]. **Results:** Between 2022 and 2025, 156 patients with cACLD were included (median age 58 years, 66% male, 63% ALD, 26% MASLD; CSPH prevalence 79%). On the derivation cohort (N = 115, CSPH 80%), the optimal fusion weight was α = 0.86 (median; IQR 0.76–0.94; 95% CI 0.43–0.98), with AUC 0.937 [95% CI 0.887–0.987]. Cross-platform evaluation on Hepatus® (N = 41, CSPH 78%) yielded AUC 0.935 [95% CI 0.857–1], equivalent after propensity-score matching (p = 0.97). Against HVPG-confirmed CSPH (N = 126), non-inferiority to both ANTICIPATE (ΔAUC +0.004 [95% CI -0.023, +0.031]) and NICER (ΔAUC +0.015 [95% CI -0.025, +0.052]) was formally demonstrated on the −0.03 margin, without any blood test. On the broader composite-CSPH cohort, the point estimate against both comparators remained negligible (ΔAUC -0.007 and -0.007). In the combined Baveno VII/VIII grey zone (N = 37, CSPH 35%) — patients unclassifiable by both LSM-based and SSM-based blood-test-free criteria — the fusion score achieved NPV 100% (14/14 true negatives, zero CSPH missed) and reclassified 73% of patients. Sensitivity analyses confirmed stable AUC across HVPG-only (0.91), non-ALD (0.88), non-censored (0.9), and Child-Pugh A scenarios. **Conclusion:** A two-measurement, blood-test-free LSM–SSM fusion score was formally non-inferior to ANTICIPATE and NICER against HVPG-confirmed CSPH and achieved NPV 100% in the combined Baveno VII/VIII grey zone where current blood-test-free criteria fail (NPV 12.5%). These findings

0189 | INCREASING DEPENDENCE ON MELD-EXCEPTION ALLOCATION IN CONTEMPORARY LIVER TRANSPLANTATION: DISEASE-SPECIFIC DIFFERENCES AND WAITLIST OUTCOMES

Shiv Patel[1] Jonathan Smith[1] Brian Wentworth[1] Zachary Henry[1] Curtis Argo[1] Nicolas Intagliata[1] Neeral Shah[1] Stephen Caldwell[1] Anya Mezina[1] Yazan Al-Adwan[1] Shawn Pelletier[1] Stephanie Silpe[1] Juan Guerra[1] Mohammad Siddiqui[1] Anh Bui[2], [1]University of Virginia, [2]Virginia Commonwealth University

Background: MELD exception (eMELD) pathways allow liver transplant (LT) prioritization for disease processes inadequately captured by laboratory MELD. Despite major allocation policy changes and evolving waitlist composition, contemporary data evaluating trends in eMELD utilization and their impact on waitlist outcomes remain limited. We evaluated national trends in eMELD dependence and comparative waitlist outcomes between eMELD and conventional MELD-dependent (cMELD) pathways, with emphasis on metabolic dysfunction-associated steatohepatitis (MASH). **Methods:** Using SRTR/UNOS data, we performed a retrospective cohort study of adult LT candidates listed between 2003-2023. Candidates were classified as cMELD or eMELD according to approved exception status. 1-year transplant probability and transplant-free waitlist survival were assessed using Kaplan-Meier and multivariate Cox proportional hazard models. Disease-specific analysis focused on MASH, alcohol, and cholestatic liver diseases. **Results:** Among the 207,935 waitlist candidates included in the overall cohort, 49,992 (19.6%) were listed via eMELD pathway. The eMELD utilization increased progressively over the study period, with the largest increase among MASH candidates (9.2% to 20.8%, **Fig. 1A-C**). The most common indication for eMELD was HCC/cholangiocarcinoma followed by pulmonary complications including hepatopulmonary syndrome and portopulmonary hypertension. Although cMELD candidates demonstrated greater early transplant probability, eMELD candidates had significantly higher 1-year transplant probability (log-rank $p < 0.0001$, **Fig. 1D, F-H**). eMELD candidates also had better 1-year transplant-free waitlist survival (log-rank $p < 0.001$, **Fig. 1E**), with the largest survival differential observed in MASH (**Fig. 1I-K**). In adjusted multivariate analysis, eMELD was independently associated with lower waitlist mortality (aHR 0.39, 95% CI 0.38-0.41, $p < 0.001$) and greater transplant likelihood (aHR 1.61, 95% CI 1.59-1.63, $p < 0.001$). These associations were observed across etiologies, with greater benefits observed in MASH candidates. **Conclusion:** Contemporary LT increasingly depends on exception-based allocation. MASH cirrhosis has emerged as one of the populations most dependent on exception-based allocation, suggesting the laboratory MELD may incompletely capture transplant urgency in this patient population. The striking outcome differential between eMELD and cMELD candidates exposes a critical gap in the current allocation policy, underscoring the need to reassess how transplant urgency is measured.

0191 | THE PALM (PREDICTING ACCESS IN LOW MELD) SCORE: A NEW METHOD TO IDENTIFY HIGH MORTALITY RISK WITH LOW TRANSPLANT ACCESS AMONG LOW MELD WAITLIST CANDIDATES

Xiaohan Ying[1] Brett Fortune[2] Russell Rosenblatt[3], [1]NewYork Presbyterian/Weill Cornell, [2]Miami Transplant Institute/Jackson Health, [3]Weill Cornell Medicine

Background: The MELD score is the foundation of liver allocation in the United States and prioritizes candidates based on short-term mortality risk. However, low MELD patients often experience a discordance between clinical urgency and access to liver transplant (LT). We aimed to identify high-risk low-access (HRLA) candidates with high waitlist (WL) mortality and low probability of LT by creating and validating the PALM score. **Methods:** We used the UNOS STAR file and included adult LT candidates listed from 2/4/20-12/31/25. We excluded candidates listed with status 1A, multiorgan, exception points, prior LT, and MELD > 23 (median MELD of our cohort). The cohort was split randomly 50: 50 into derivation and validation groups. Competing-risk regression including *a priori* covariates estimated WL mortality and LT. Candidates were stratified into 3x3 risk categories based on predicted WL mortality and LT probability. HRLA candidates were defined by having the highest WL mortality risk and lowest LT probability within 1 year of listing.Multivariable logistic regression was performed using *a priori* covariates present at listing to identify those who are more likely to be HRLA. These covariates were used to create the PALM score and were applied to the validation cohort. Discrimination was assessed using the area under the curve. We then compared PALM vs MELD estimation of 1-year mortality within MELD < 15 and 16-23 cohorts. **Results:** Among 14,311 derivation cohort candidates, 595 (4.2%) met HRLA criteria. HRLA candidates were more likely to be older (aOR 1.3), have blood type O (aOR 11.9), and grade 3/4 hepatic encephalopathy (HE) (aOR 3.3) **,** medium functional status (aOR 1.21), and poor functional status (aOR 1.49). Male sex (aOR 0.2), higher MELD (aOR 0.7), and alcohol liver disease (ALD) (aOR 0.2) were inversely associated with HRLA status. HRLA candidates have higher WL mortality (11.3% vs 6.8%) and lower LT rates (36.1% vs 49.4%), $p < 0.001$. The PALM score incorporated eight variables above along with height, due to its association with decreased organ access: Age (+1 per year), Male (-5), MELD (-1 per point), ALD (-4), Blood Type O (+8), Grade 3/4 HE (+2), Medium Functional Status (+2), Low Functional Status (+3), Height (+2 if < 166cm). The median score was 42, with the highest quartile cutoff (≥ 51) capturing every HRLA patient. In the validation cohort, the PALM score improved discrimination for WL mortality compared to MELD alone (AUC 0.60 vs 0.55, $p = 0.001$). Critically, the PALM score estimated mortality more accurately in patients with MELD < 15 and 15-23 (mean absolute error 0.3% vs 6.4%) **Figure 1**. **Conclusion:** In the post–acuity circles era, low MELD adult LT candidates can have discordance between risk of WL death and LT access. The PALM score outperforms MELD in informing patients and providers about prognosis and LT access, thereby empowering them to consider alternative strategies such as living donation or expanded donor acceptance.

Figure 1. Comparison of PALM Score and MELD in prediction of 1-year mortality in WL patients with MELD < 15 and MELD 15-23

0192 | HEPATIC ENCEPHALOPATHY INDEPENDENTLY PREDICTS WAITLIST MORTALITY AND REDUCES TRANSPLANT PROBABILITY IN CIRRHOTIC PATIENTS: EVIDENCE FOR MELD-BASED ALLOCATION REFORM

Neev Mehta[1] Hisham Habib[1] Marwa Elmahi[1] Dafallah Miqdad[2] Raza Malik[3], [1]Lahey Clinic, [2]BWH, [3]Lahey Hospital & Medical Center

Background: Overt hepatic encephalopathy (HE) develops in up to 40% of patients with cirrhosis and carries a 1-year mortality of nearly 60% without liver transplantation (LT). Despite this prognosis, HE receives no formal weight in the Model for End-Stage Liver Disease (MELD) score, which governs deceased donor organ allocation in the United States. Patients with HE may therefore be systematically disadvantaged, dying on the waitlist before an organ is available, yet not prioritized by the current scoring. **Methods:** We analyzed data from a published retrospective cohort study (Lee et al., *Transplantation Direct*, 2024) examining **39,025 adult liver transplant candidates** listed in the OPTN database between January 2016 and December 2021. Candidates were grouped by complication status at listing: neither moderate HE nor ascites, moderate ascites alone (mAscites), moderate HE alone (mHE), or both. Supplementary data on national transplant volume and rates were drawn from the OPTN/SRTR 2022 Annual Data Report (Kwong et al., *Am J Transplant*, 2024). The primary outcome was **one-year waitlist mortality** (death or delisting for being too sick to transplant). We examined **cumulative transplant probability** at 3, 6, and 12 months, which accounts for the competing risk of waitlist death. Adjusted hazard ratios (HRs) were obtained from multivariable Cox models reported in Lee et al., controlling for MELD 3.0, age, sex, race/ethnicity, and primary liver diagnosis. All data derived from published literature; no primary patient-level data or SRTR Standard Analysis Files used. **Results:** Waitlist mortality increased with complication burden. Patients listed with HE had more than twice the 1-year waitlist mortality of those without complications (38% vs. 17%), with an adjusted HR of 2.24 (95% CI 1.88–2.67), a risk that exceeded that of ascites alone (HR 1.76) and was independent of MELD 3.0 score. The combination of HE and ascites was the highest-risk subgroup, with nearly half of patients dying or becoming too ill for transplant within 12 months. Patients with HE are far less likely to reach transplantation. At 12 months, cumulative transplant probability fell from 46.1% in patients without complications to 29.3% in those with HE alone and 22.5% in those with both HE and ascites, reductions of 37% and 51%, respectively. **Conclusion:** HE independently predicts waitlist mortality and reduces the probability of achieving liver transplantation, even after adjustment for MELD 3.0 score. The current allocation system does not account for HE, leaving a clinically vulnerable group at disproportionate risk of dying before transplant. These findings add to the growing evidence supporting the incorporation of objectively documented HE for example, via hospitalization records for grade 2 or higher episodes, into MELD. We are currently pursuing a primary analysis to validate these findings at the patient level and examine outcomes by HE grade and etiology of cirrhosis.

Table 1. *One-year waitlist mortality by complication status (OPTN 2016–2021; Lee et al., 2024)*

Complication group	N (%)	1-yr waitlist mortality	Adjusted HR (vs. neither)	95% CI
Neither HE nor ascites	~23,415 (60%)	17%	Reference	—
Moderate ascites only	~11,318 (29%)	30%	1.76	1.55–2.00
Moderate HE only	~1,171 (3%)	38%	2.24†	1.88–2.67
Both moderate ascites + HE	~3,122 (8%)	47%	3.12†	2.71–3.59

†P < 0.001 vs. reference. HR adjusted for MELD 3.0, age, sex, race/ethnicity, and primary diagnosis. Source: Lee BT et al., Transplantation Direct 2024. doi:10.1097/TXD.0000000000001625.

Table 2. *Cumulative probability of achieving liver transplant at 3, 6, and 12 months, by complication group*

Complication group	3 months	6 months	12 months
Neither HE nor ascites	13.8%	26.2%	46.1%
Moderate ascites only	11.0%	20.7%	35.8%
Moderate HE only	9.0%	17.0%	29.3%
Both moderate ascites + HE	6.8%	12.9%	22.5%

Estimates derived from competing risk analyses in Lee et al. 2024 and overall transplant probability data from the OPTN/SRTR 2022 Annual Data Report. Accounts for competing risks of waitlist death and non-transplant removal.

0193 | EXPLORING THE EFFECT OF NEGATIVE PRESS ON DECEASED DONOR LIVER DONATION

Chelsea Pan[1] Nicole Kim[2] Elizabeth Aby[3] Howard (Tzu-Hao) Lee[4] Hersh Shroff[5] Jin Ge[1], [1]University of California, San Francisco, [2]University of Washington Medical Center, [3]University of Minnesota, [4]Baylor College of Medicine, [5]UNC Chapel Hill

Background: Organ donation and transplantation rely on sustained public trust. Recent negative media

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

coverage of the U.S. organ transplantation system in major outlets, including the New York Times (NYT), Washington Post, and Associated Press, may influence confidence in organ allocation systems. This study evaluated whether intensified negative media coverage was associated with changes in deceased liver donation rates. We hypothesized that negative media attention may temporarily reduce donor registration, family authorization, and hospital referral, ultimately decreasing liver donation. **Methods:** We performed a retrospective interrupted time series analysis using negative binomial regression of the UNOS STAR database. Adult deceased liver donors from Jan 1, 2024 to Mar 31, 2026 were included. The pre-intervention period was Jan 1, 2024 to Feb 25, 2025. Assuming gradual media exposure, two one-month intervention periods were defined using peaks in media intensity identified via ProQuest U.S. Major Dailies and Google Trends searches for “organ donation” and “organ transplant". The first intervention period (Feb 26 to Mar 26, 2025) corresponded to NYT investigative reports published on Feb 26 and Feb 27, 2025 that alleged ignored transplant waitlists and the second intervention period (July 21 to Aug 21, 2025) corresponded to U.S. Department of Health and Human Services announcements on July 21, 2025 to reform organ procurement policies. Immediate change was defined as the difference between observed and predicted donations at intervention onset; sustained change was defined as the change in slope before versus after each intervention period. We adjusted for day of week and month to control for cyclical variation. Subgroup analyses assessed variation across 11 UNOS regions. **Results:** There was a significant pre-intervention upward trend in liver donations of 0.12% per day (~55% annually; IRR 1.00, p = 0.04). Intervention period 1 showed a significant immediate increase in donations (+12.4%, IRR 1.12, p = 0.04) without sustained change. Intervention period 2 showed a non-significant immediate decrease (−9.5%, IRR 0.91, p = 0.09) without sustained change. Region 6 (Pacific Northwest) demonstrated a significantly greater immediate decline in donation counts relative to Region 1 (New England) after intervention period 2, without sustained change (interaction IRR 0.57, p = 0.002). Overall trends remained stable. **Conclusion:** Intensified negative media coverage was not associated with significant short- or long-term declines in deceased liver donation, suggesting sustained public trust. A non-significant reduction between intervention periods may reflect temporary hesitation, though this did not reach statistical significance. The lack of effect may reflect the complexity of donation decision-making, inability to directly assess donor registration, and concurrent policy changes.

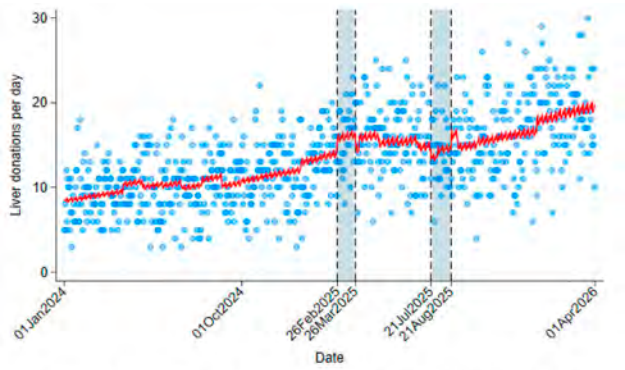

Figure 1. Daily deceased donor liver donation rates between Jan 1, 2024 and to Mar 31, 2026 with intervention periods 1 and 2 highlighted in blue.

0194 | SEX-BASED DISPARITIES IN LIVER TRANSPLANT ALLOCATION AMID MELD 3.0 AND THE EMERGENCE OF MACHINE PERFUSION

Tomohiro Tanaka[1] David Axelrod[2] Jennifer Lai[3], [1]University of Iowa, [2]University Hospitals Cleveland Medical Center, [3]University of California, San Francisco

Background: Despite MELD 3.0, sex-based disparities in liver transplant (LT) access persist. Normothermic machine perfusion (NMP) has expanded the donor pool, potentially altering size-mismatch-driven access gaps. We examined sex disparities in LT access, waitlist mortality, and offer acceptance, stratified by center-level NMP utilization and MELD 3.0 era, testing whether alternative body-size metrics better capture residual disparity. **Methods:** Using OPTN data, we identified adult candidates listed pre-MELD 3.0 (1/2022-6/2023) and post-MELD 3.0 (10/2023-9/2025). LT centers were classified as High or Low NMP by upper-tertile NMP utilization (NMP livers / total LTs per center). Fine-Gray models estimated subdistribution hazard ratios (sHR) for LT access and WL mortality,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

sequentially adjusting for confounders and body size. Offer-level multilevel models assessed top-5 acceptance with attenuation by recipient height and estimated liver volume ratio (eLVr); NMP vs. non-NMP LT characteristics were also compared. **Results:** Among 43,636 candidates (17,645 female), females had lower 90-day LT access across all strata (adjusted sHR 0.71-0.89, all 95% CI < 1) while WL mortality was low (1.4-2.6%) with no sex difference (sHR 0.92-1.27, all CI crossing 1). Height attenuated LT access disparity at Low NMP centers (sHR 0.89→0.96 [0.90-1.03]; 69% mediated) but not High NMP (0.85→0.88 [0.81-0.95]; 22%). In offer-level analysis (206,825 offers) at High NMP centers post-MELD 3.0, eLVr attenuated the sex gap (OR 0.78→0.91 [0.83-1.001]; 67% mediated) beyond recipient height; center random effects showed no variation in sex-based acceptance. Among 30,359 large-for-size offers (eLVr > 1.2), female acceptance was lower at High NMP (OR 0.71 [0.57-0.88]) but not Low NMP centers (0.84 [0.70-1.01]). Sensitivity analyses (top-40% NMP threshold, top-3/10 offers, donor-recipient weight ratio replacing eLVr) corroborated these findings. Among 29,599 LTs (7,335 NMP), recipient sex was similar, while NMP LTs had lower MELD, higher eLVr, yet shorter recipients (all p < .01). Adjusted mean eLVr for males was higher with NMP (0.962) vs non-NMP (0.942, p < .001) grafts, whereas females remained equivalently oversized (1.038 vs 1.039, p = .84); the adjusted estimate of the sex-by-NMP interaction (β = −0.021 for female vs male NMP differential, p = .002) indicated that NMP's eLVr gain did not extend to females. **Conclusion:** Sex disparities in LT access persist post-MELD 3.0 despite WL mortality convergence, challenging mortality as the sole equity benchmark. At Low NMP centers, candidate body size largely attenuated the disparity, but at High NMP centers, donor-recipient size ratios contributed to the disparity due to limited acceptance of larger livers for female candidates. Match-based size compatibility in allocation, rather than candidate-side adjustments alone, may better address sex-based disparities amid NMP expansion.

Table: Key Estimates of Sex-Based Disparity by NMP Tier and MELD 3.0 Era

LT access rate	sHR (95%CI)	P	*Offer acceptance*	OR (95%CI)	P
High-NMP			**High-NMP**

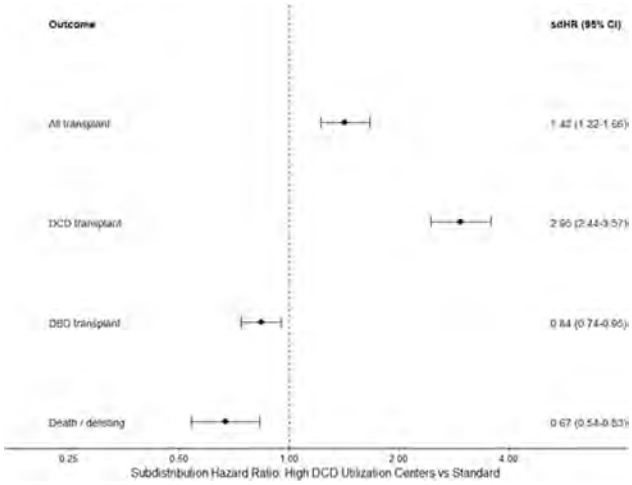
★ 0195 | CENTER-LEVEL VARIATION IN DONATION AFTER CIRCULATORY DEATH LIVER TRANSPLANTATION AND ITS ASSOCIATION WITH ACCESS AND OUTCOMES



Katie Ross-Driscoll[1] Casey Woods[1] Sarah Huber[1] James Butler[1] Chandrashekhar Kubal[1] Lauren Nephew[1], [1]Indiana University

Background: Donation after circulatory death (DCD) grafts now comprise an increasingly important source of donor livers in the United States, yet adoption of DCD transplantation remains highly variable across centers. We evaluated whether center-level DCD utilization influences access to liver transplantation and post-transplant outcomes. **Methods:** Using Scientific Registry of Transplant Recipients data, we identified adult liver transplant candidates listed and recipients transplanted between 1/1/2022 and 12/31/2025. Centers in the highest quartile of DCD utilization (> 29.2% of recipients receiving DCD grafts) were classified as high utilizers. We estimated time to transplant using Fine-Grey regression, accounting for competing risks of death and delisting. **Results:** Among 52,925 waitlisted candidates across 118 centers, 30 centers were classified as high DCD utilizers (n = 15,415 candidates). Candidates listed at high-utilization centers were less likely to be Hispanic (13.8% vs 21.6%), more likely privately insured (52.7% vs 49.4%), and from less socioeconomically deprived communities (all p < 0.001). Median time to transplant was substantially shorter at high-utilization centers (62 vs 149 days). After adjustment, listing at a high-utilization center was associated with increased cumulative incidence of transplant (sdHR 1.42, 95%CI 1.22-1.66), driven specifically by increased DCD transplantation (sdHR 2.95, 95%CI 2.44-3.57) (**Figure 1**). Among 37,547 recipients, 9,657 (25.7%) received DCD grafts; patients transplanted at high-utilization centers were twice as likely to receive DCD (RR 2.02, 95%CI 1.94-2.14). Post-transplant graft failure, death, or re-listing did not differ between DCD and DBD recipients. **Conclusion:** In the contemporary era, transplant center utilization of DCD grafts is a major determinant of transplant opportunity. Centers with greater DCD expertise and infrastructure achieve substantially higher transplant rates without compromised short-term outcomes. Broader dissemination of the technical expertise, clinical workflows, and

0196 | DEFINING THE HEPATIC SECRETOME IN WILSON DISEASE USING A LIPID NANOPARTICLE GENE DELIVERY SYSTEM FOR PROXIMITY BIOTINYLATION OF SECRETED PROTEINS

Robert Hughes[1] James Hamilton[1] Svetlana Lutsenko[1],
[1]Johns Hopkins University

Background: Wilson Disease is an autosomal recessive disorder caused by mutations in ATP7B, a copper-transporting ATPase localized to the trans-Golgi network and essential for hepatobiliary copper excretion. Inactivation of ATP7B results in copper accumulation in various tissues including the liver, but clinical presentation and disease severity do not necessarily correlate with hepatic copper content. While the genetic cause of Wilson Disease is clear, the mechanism of disease remains only coarsely defined. Copper-dependent enzymes such as ceruloplasmin, lysyl oxidase, and peptidylglycine α-amidating monooxygenase (PAM) are essential for post-translational processing of secretory proteins. Therefore, we hypothesized that ATP7B deficiency disrupts these copper-dependent pathways and alters the hepatocyte secretome to favor chronic inflammation and injury independent of hepatic copper accumulation. **Methods:** We utilized a Sec61b-TurboID proximity biotinylation system to label endoplasmic reticulum-transiting proteins in *Atp7b*knockout murine hepatocytes as well as *ATP7B*$^{-/-}$ induced pluripotent stem cell (iPSC)-derived human hepatocytes. For targeted gene delivery to the liver in our *in vivo* model system, we used a lipid nanoparticle formulation optimized by collaborators at the Johns Hopkins Institute for Nanobiotechnology. Mass spectrometry was then employed to profile differentially secreted proteins in serum and liver lysates (*in vivo* model) or conditioned media (human iPSC model) from ATP7B knockout versus wild-type samples. **Results:** Initial analysis suggests that copper imbalance in ATP7B knockout systems substantially affects protein secretion, as shown by reduced abundance of secreted proteins, including ceruloplasmin, compared with wild-type controls. However, a subset of proteins is significantly increased in ATP7B knockout models and may be functionally relevant to disease pathogenesis. Pathway enrichment analysis reveals that these candidates are primarily associated with extracellular matrix turnover, cytokine signaling, and vitamin D metabolism. These candidates will be tested further using neutralization or knockdown assays to determine whether and how they modify the Wilson Disease phenotype. **Conclusion:** By studying secreted proteins from the liver in a model of Wilson Disease, we hope to better understand the intercellular communication pathways involved in its pathophysiology. In addition, the Wilson Disease hepatic secretome may reveal novel biomarkers to aid in early diagnosis and better predict clinical outcomes. Lastly, the lipid nanoparticle gene delivery system is a powerful tool currently being used in clinical trials for gene therapy, and we highlight its utility here as a discovery platform.

0197 | BEYOND CIRRHOSIS: MAJOR ADVERSE LIVER OUTCOMES ACROSS PIMZ, PISZ, AND PIZZ GENOTYPES IN ALPHA-1 ANTITRYPSIN DEFICIENCY

Dustin Bastaich[1] Bassam Dahman[2] Austen Hentschel[3] Andres Samos[4] Chitra Karki[5] Tami Nussbaum[5] Suna Park[5] Seth Spector[6] Gregory Bigford[7] Brian Garnet[6] Michael Campos[6] Binu John[6], [1]Virginia Commonwealth University, [2]Virginia Commonwealth University and Miami VA, [3]Florida International University and Miami VA, [4]Washington University and Miami VA, [5]Takeda, [6]University of Miami and Miami VA, [7]Miami VA

Background: Alpha-1 antitrypsin deficiency (AATD) increases susceptibility to chronic liver disease, yet data on major adverse liver outcomes (MALO) across heterozygous and homozygous Z-allele genotypes remains limited, due to the abence of large populatkion based cohorts with longitudinal follow up and fibrosis staging. We assessed the risk of MALO-encompassing decompensation, hepatocellular carcinoma (HCC), liver transplantation (LT), and liver-related death (LRD), across AATD protease inhibitor MZ (PiMZ), PiSZ, and PiZZ genotypes compared to PiMM. **Methods:** This retrospective cohort study utilized the Veterans Analysis of Liver Disease (VALID) cohort (January 2000-April 2025). Veterans with classifiable AATD genotypes and a baseline fibrosis stage (via biopsy, elastography, FIB-4, or APRI) were included. Those under 18 or with MALO within 90 days of baseline were excluded. Genotypes were identified using validated natural language processing, shown previously to have a high agreement with manual chart review ($\kappa = 0.89$). Multivariable Cox proportional hazards models (with censoring at non-liver-related death or the end of study period) estimated the hazard of MALO, adjusting for fibrosis stage, age, BMI, sex, race, and co-existing liver disease etiologies. **Results:** Of 22,537 participants with genotype testing, 19,665 were PiMM, 1,656 PiMZ, 281 PiSZ, and 935 PiZZ with 352,612 person years of follow up and a median follow up per patient of >16 years. Median age was 50 years (IQR = 15); 92.5% were male. MALO risk increased sequentially with allele burden: PiMZ (aHR 1.24, 95% CI 1.11-1.39), PiSZ (aHR 1.50, 1.17-1.94), and PiZZ (aHR 1.87, 1.65-2.12), versus PiMM. MALO incidence rates for PiMM, PiMZ, PiSZ, and PiZZ, respectively were 11.3 (ref), 13.0 ($p < 0.01$ vs. ref), 14.6 ($p = 0.05$ vs. ref), and 19.2 ($p < 0.0001$ vs. ref) per 1,000 person-years respectively, while five-year MALO probability was 3.5%, 5.5%, 5.4%, and 8.1% respectively. PiZZ was associated with significantly increased risk of all individual MALO components: decompensation (aHR 1.91, 95% CI 1.67- 2.19), HCC (aHR 1.68, 95% CI 1.27-2.21), LT (aHR 5.29, 95% CI 3.84-7.27), and LRD (aHR 3.12, 95% CI 2.46-3.94). PiSZ and PiMZ were associated with higher risk of decompensation, LT, and LRD, but not HCC. Findings were consistent in a sensitivity analysis restricted to participants with MASLD. **Conclusion:** In this large cohort, MALO risk increased in a stepwise fashion across AAT genotypes carrying a Z allele, from PiMZ to PiSZ to PiZZ. Although prior studies have examined progression to cirrhosis, we believe this is the first study sufficiently powered to examine MALO in homozygous and heterozygous Z-allele carriers in a longitudinal cohort including patients across all stages of fibrosis. Notably, even heterozygous carriers demonstrated elevated MALO risk, underscoring the need for timely diagnosis, genetic counseling, and enhanced clinical surveillance.

0198 | RESIDUAL HEPATIC, NEUROLOGIC, AND PSYCHIATRIC DISEASE BURDEN IN TREATMENT-EXPERIENCED PATIENTS WITH WILSON DISEASE: BASELINE FINDINGS FROM THE FOCUS PHASE 3 TRIAL

Frederick Askari[1] Valentina Medici[2] Thomas Sandahl[3] Chandler Robinson[4] Andrew Cittadine[4] Declan Tuffy[4] Karl Heinz Weiss[5] Aftab Ala[6], [1]University of Michigan Medical Center, [2]University of California Davis Medical Center, [3]Aarhus University Hospital, [4]Monopar Therapeutics, [5]Krankenhaus Salem, [6]Kings College Hospital

Background: Wilson disease (WD) is a rare, progressive, autosomal-recessive disorder of copper accumulation that drives hepatic, neurologic, and psychiatric morbidity. Real-world cohorts have documented persistent disease across these domains despite long-term treatment with penicillamine, trientine, and/or zinc, the current standard-of-care (SoC) therapies. To characterize the residual disease burden among patients receiving SoC, we analyzed baseline data from the FoCus trial (NCT03403205), the largest randomized controlled WD trial conducted to date. **Methods:** The FoCus trial was a multicenter Phase 3 randomized controlled trial evaluating tiomolibdate choline (TMC; ALXN1840) head-to-head against SoC. Patients aged ≥ 12 years with a confirmed diagnosis of WD (Leipzig score ≥ 4) were eligible for enrollment at clinical centers in 22 countries, including North America, Europe, and Asia. Exclusion criteria included severe hepatic (MELD > 13), neurologic (inpatient care required), and renal (ESRD) comorbidities. Patients were categorized based on prior WD treatment history as t reatment-naïve (TN, ≤ 28 days) or -experienced (TE, > 28 days). Baseline disease burden was characterized using cirrhosis status, Unified WD Rating Scale (UWDRS), Brief Psychiatric Rating Scale (BPRS-24), 24-hour urine copper excretion (UCE), and non-ceruloplasmin-bound copper (NCC). **Results:** Of 207 patients (189 adult, 18 adolescent) enrolled in the FoCus trial, 77% were TE with a median 9.3 yrs of prior WD treatment. Cirrhosis was present at baseline in 39% of TE patients and 30% of TN patients. Neurologic symptoms were frequent, with UWDRS Part II or Part III score > 0 in 79% of TE and 83% of TN patients. UWDRS Part III scores were greater than the minimum clinically important difference (4.67 points) in 55% of TE and 51% of TN patients. Psychiatric symptoms were present in 75% of TE and 70% of TN patients. In the TE group, 47% had NCC within the target range per treatment guidelines (5–15 µg/dL). Among patients on SoC > 12 months, 31% had a baseline 24-hour UCE above guideline-directed targets for maintenance treatment. **Conclusion:** After a median of nearly 10 years on SoC, TE patients with WD continued to exhibit substantial multi-system disease, including cirrhosis in nearly 40%, persistent neurologic or psychiatric symptoms in the majority, fewer than half within the guideline-recommended NCC target range, and approximately one-third with 24-hour UCE above guideline-directed maintenance targets. These data underscore the inability of existing WD therapies (penicillamine, trientine, and/or zinc) to fully address the disease burden of WD and the high unmet need for novel therapeutic approaches.

Background: Acute hepatic porphyrias (AHPs) are rare disorders of hepatic heme synthesis resulting in elevated levels of the toxic metabolites δ-aminolevulinic acid (ALA) and porphobilinogen (PBG). Patients may present to hepatologists with recurring acute attacks characterized by severe abdominal pain, nausea, and neuropsychiatric symptoms, and may also experience chronic symptoms and low health-related quality of life (HRQoL). In the phase 3 ENVISION trial (NCT03338816), givosiran, an RNA interference therapeutic approved for AHP treatment, led to reduction of ALA/PBG levels, sustained reductions in annualized attack rate (AAR), and improved HRQoL. This *post hoc* analysis investigated how early fluctuations in ALA/PBG influenced AAR and HRQoL with givosiran treatment. **Methods:** Patients with AHP ≥12 years old with ≥2 attacks requiring hospitalization, urgent care, or intravenous hemin at home in the 6 months (M) before randomization entered a placebo (PBO)-controlled 6M double-blind (DB) period followed by a 30M open-label extension, in which all patients received givosiran (givo). Patients within each treatment sequence arm (PBO/givo and givo/givo) were split into tertiles (T) by standard deviation (SD) in ALA or PBG levels recorded between 0.5M and 6M of the DB period. **Results:** The analysis included 94 patients. Most patients (n = 89) had acute intermittent porphyria, among whom the most common *HMBS* variant was c.517C > T (n = 12 patients); 2 patients had AIP without an identified variant. Variant distribution was similar across tertiles. During the DB period (> 0-6M), patients in the PBO/givo group with low ALA/PBG fluctuation (T1) had a lower mean (SD) AAR than those in the medium (T2) and high (T3) fluctuation tertiles (ALA, 6.1 [6.1] vs 20.3 [16.4] and 16.4 [12.7], respectively; PBG, 8.7 [9.2] vs 17.4 [16.2] and 16.5 [13.7], respectively). AAR decreased with givosiran initiation in all tertiles of both treatment sequences and continued to decrease with each 6M interval (**Figure**). Mean percentage reductions from baseline in AAR were similar across treatment sequences and ALA tertiles by > 30-36M of treatment (PBO/givo, −97%, −94%, and −93%; givo/givo, −99%, −94%, and −90%; for T1, T2, and T3, respectively). Similar findings were observed in the analysis of PBG (**Figure**). An increase from baseline in EQ-VAS scores was observed in all groups at 36M. Apart from ALA T3 and PBG T2 in the PBO/givo group, all groups achieved a clinically meaningful increase of ≥7-8 points on the EQ-VAS at 36M (mean change from baseline between 11.2 [PBO/givo PBG T3] and 22.1 [givo/givo ALA T3] points). **Conclusion:** Patients with higher ALA/PBG fluctuation during the first 6M had greater attack burden. However, AAR decreased with continued givosiran treatment and converged across all tertiles by 36M. HRQoL improvements were also observed. The results support that long-term benefits of givosiran extend even to patients with early fluctuations in AHP metabolites.

Tertile Thresholds and Mean AAR Change From Baseline by ALA Fluctuation (A) and PBG Fluctuation (B)

Tertiles were defined separately within each treatment sequence and biomarker using the SD of ALA or PBG during the DB period (excluding baseline). Inset figure panels show tertile thresholds for each biomarker and treatment sequence; median values for SD in ALA/PBG within each tertile are shown by horizontal lines and crosses.
AAR, annualized attack rate; ALA, δ-aminolevulinic acid; DB, double-blind; M, month; PBG, porphobilinogen; SD, standard deviation; T, tertile.

0200 | ATP7B INACTIVATION DISRUPTS HEPATIC METABOLIC ZONATION AND DRIVES DIET-DEPENDENT STEATOHEPATITIS IN A MOUSE MODEL OF WILSON DISEASE.

Mugagga Kalyesubula[1] Abigael Muchenditsi[1] Som Dev[1] Andreas Patsalos[1] Oscar Ospina[1] Svetlana Lutsenko[1] James Hamilton[1], [1]Johns Hopkins University

Background: Wilson disease (WD) is caused by inactivating mutations in ATP7B, the hepatic copper (Cu) transporter, resulting in progressive Cu accumulation and liver injury. Hepatic steatosis is an early and clinically significant manifestation of WD; however, its mechanistic basis remains poorly defined. Critically, hepatic Cu burden does not correlate with the severity of steatosis, suggesting secondary pathogenic determinants. The liver executes metabolic functions in a spatially segregated manner along the periportal-to-pericentral axis, with copper handling and fatty acid oxidation concentrated in the peri-portal area and lipogenesis in the peri-central area. How Atp7b deficiency affects this zonation remains unknown. **Methods:** snRNAseq was conducted on the livers of our established in vivo model of WD, of Atp7b -/- mice, and het controls. Transcription factor regulon activity was inferred by SCENIC. Findings were validated by immunofluorescence (IF) and RNAscope. LXR agonist treatment was administered to Atp7b$^{-/-}$ mice to assess pathway rescue. Atp7b$^{-/-}$ mice were subjected to a high-calorie diet to model WD-related steatohepatitis. **Results:** Atp7b inactivation induced significant hepatocyte depletion with reciprocal expansion of non-parenchymal cells, including stellate cells, endothelial cells, and cholangiocytes, confirmed by IF. The decrease in hepatocytes was accompanied by a loss of periportal-to-pericentral metabolic zonation, with SCENIC analysis implicating downregulation of the Tcf7l2 regulon as a candidate transcriptional mechanism. IF also revealed a pan-hepatocyte increase in β-catenin alongside disruption of its pericentral compartmentalization, pointing to a broad dysregulation of the zonation program. Intercellular communication analysis identified suppression of LXR multicellular signaling in Atp7b$^{-/-}$ livers. LXR agonist treatment restored the Tcf7l2 regulon, rescued hepatic zonation, and normalized non-parenchymal cell composition, thereby implicating the LXR pathway as a potential therapeutic target for WD. These findings prompted investigations into whether a lipogenic high-carbohydrate diet deficient in LXR agonists exacerbates hepatic pathology during copper overload. This dietary regimen stimulated steatohepatitis in the Atp7b mice, generating a long-sought-after animal model for studying the prevalent dysregulated hepatic fat accumulation in WD. **Conclusion:** These findings show that Atp7b inactivation in WD promotes hepatic pathology by altering metabolic periportal-pericentral zonation through the downregulation of the Tcf7l2 regulon. LXR pathway activation represents a candidate therapeutic strategy warranting further investigation. A high-calorie diet devoid of LXR agonists triggers steatohepatitis in the context of copper overload, establishing nutritional status as a secondary determinant of excessive hepatic lipid accumulation in WD.

0201 | REAL WORLD EVIDENCE OF THERAPY IMPACT IN UNSTABLE WILSON DISEASE USING NON-CERULOPLASMIN BOUND COPPER BY SPECIATION AS A NOVEL MONITORING TOOL

Michael Schilsky[1] Regino Gonzalez-Peralta[2] Amanda Cheung[3] Valentina Medici[4] James Hamilton[5] Cynthia Levy[6] Kalyan Bhamidimarri[7] Steven Lobritto[8] Amy Brown[9] C.Omar Kamlin[10] Jamie Heise[11] Brenda Gorsett[10] Nick Manamley[12] Frederick Askari[13], [1]Yale University Medical Center, [2]AdventHealth for Children, [3]Northwestern Memorial Hospital/Northwestern University, [4]University of California Davis Medical Center, [5]Johns Hopkins University, [6]University of Miami, [7]Cleveland Clinic, [8]Columbia University, [9]Vanderbilt University, [10]Orphalan, [11]Orphalan Inc, [12]Orpahalan, [13]University of Michigan Medical Center

Background: Monitoring of efficacy and adherence in Wilson disease (WD) remains challenging, underscoring a substantial unmet need for accurate and clinically practical biomarkers to tailor treatment. Non-ceruloplasmin bound copper by speciation (NCC-Sp) measures circulating bioavailable copper and as a monitoring tool has been associated with better biochemical outcomes in treated WD patients (Ott P. et al JHEP Rep 2024). **Aim:** To describe changes in NCC-Sp in a real-world setting of biochemically unstable WD patients on standard of care over 12 months by different treatment modalities. **Methods:** REASON (NCT05783687) was a prospective, non-interventional study conducted across 9 U.S. sites from

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

June 2023 to October 2025. Adult biochemically unstable (determined by AST, ALT or urinary copper excretion [UCE]) WD patients (n = 42) on treatment > 1 year were enrolled. Serum samples were collected and NCC-Sp measurements performed after study completion, with treating physicians blinded to results at the time of clinical decision-making. Changes from baseline (BL) to end of study (EOS) in NCC-Sp, 24-hour UCE, AST and ALT were evaluated for patients receiving chelators, zinc, or combination therapy. Only patients with both BL and EOS values were included. **Results:** NCC-Sp (ng/ml), mean (SD) declined from BL to EOS across all three treatment groups: chelators -26.0 (57.73), zinc -14.1 (19.72), and combination -40.6 (54.42), though high standard deviations reflect considerable inter-individual variability. UCE (mcg/d) decreased at EOS by -62.7 with chelators and -53 in combination therapy, while zinc patients most often were changed to chelators or combination zinc + chelator with an increase (+90.0). Chelators demonstrated the most consistent liver enzyme improvements with reductions in both ALT (-18.2 IU/L) and AST (-16.5 IU/L). Zinc revealed modest reductions in both enzymes. Combination therapy showed minimal changes in AST and ALT (see table). **Conclusion:** The fact that NCC-Sp declined across all therapy groups in biochemically unstable WD patients suggests NCC-Sp can be used to track treatment responses. In patients on combination therapy, NCC-Sp may be the most useful biomarker to follow given the variability and unknown targets for UCE. NCC-Sp as a measure of bioavailable copper has the potential to improve current recommended monitoring, including personalizing therapy. Larger studies are needed to validate these findings.

Unstable patients with both BL and EOS results	Chelators (n=30)	Zinc (n=6)	Combination (Zinc + Chelator) (n=6)
NCC-Sp (ng/ml) BL, mean (SD)*	100.5 (73.41)	95.2 (29.32)	102.6 (38.58)
Change from BL	- 26.0 (57.73)	-14.1 (19.72)	-40.6 (54.42)
24h UCE (mcg/d) BL, mean (SD)**	375.1 (275.78)	91.7 (23.73)[†]	278.4 (227.84)
Change from BL	- 62.7 (250.63)	90.0 (209.07)	- 53.0 (148.08)
ALT (IU/L) BL, mean (SD)***	89.3 (72.11)	77.5 (39.13)	72 (33.83)
Change from BL	-18.2 (61.42)	-13.5 (31.55)	3.8 (20.11)
AST (IU/L) BL, mean (SD)***	56.7 (53.96)	42.0 (21.40)	67.5 (42.19)
Change from BL	-16.5 (52.42)	-5.0 (13.59)	-15.8 (38.78)

*All patients had both BL and EOS results
** Numbers with results at both time periods: 15/30 on chelators, 5/6 on zinc, and 3/6 on combination
*** Numbers of patients with results at both time periods: 22/30 on chelators, 4/6 on zinc, and 4/6 on combination
All patients were on chelators or combination zinc + chelator by EOS

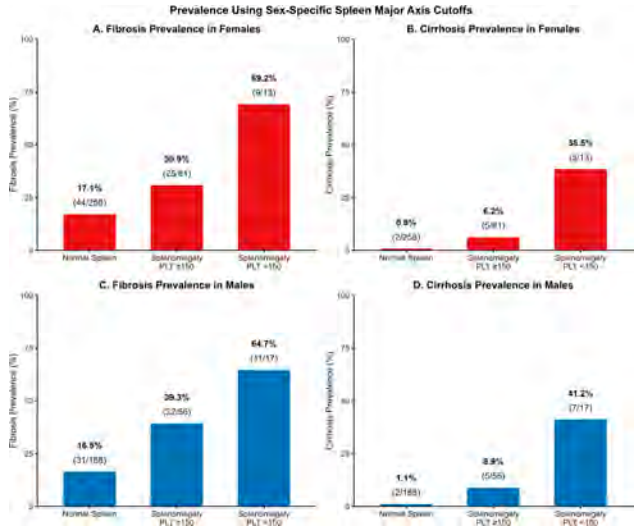
0202 | SPLEEN SIZE CORRELATES WITH INCREASED LIVER STIFFNESS MEASUREMENT ON MRI BUT HAS LOW POSITIVE PREDICTIVE VALUE FOR CIRRHOSIS IN MASLD



Kyle Rodrigues[1] Brian Derstine[1] Grace Su[2] Vincent Chen[1], [1]University of Michigan, [2]University of Michigan Medical Center

Background: The presence of splenomegaly is often a trigger for portal hypertension concern and cirrhosis. However, data are limited about the association between spleen size and liver disease severity, especially in non-cirrhotic conditions like Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD). In this study of MASLD patients, we aim to better characterize the relationship between spleen size parameters and liver stiffness measurements (LSM) to elucidate the extent to which spleen size predicts fibrosis and cirrhosis. **Methods:** We included 693 adult patients with MASLD who underwent an abdominal MRI with liver elastography in the University of Michigan Health System. MRI scans were processed using TotalSegmentator for spleen measurements. Cutoffs of LSM $\geq$ 3.1 kPa were used for significant fibrosis (SF) and LSM $\geq$ 5 kPa for cirrhosis. Splenomegaly was defined as spleen major axis or spleen volume $\geq$ 2 standard deviations above a normal population mean. **Results:** The median age of the of the cohort was 53 years old; 58% were female and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

83% were Caucasian. Median BMI was 34.8 kg/m^2 and prevalence of diabetes, hypertension, and dyslipidemia was 42%, 62%, and 59% respectively. 24% of patients had SF and 5% had cirrhosis. Male sex (Spearman r = 0.23), height (Pearson r = 0.28), weight (Pearson r = 0.39), BMI (Pearson r = 0.27), and diabetes (Spearman r = 0.13) were associated with increased spleen major axis length (all p < 0.001). Spleen volume and spleen major axis length had an r $\asymp$ 0.2 correlation with LSM, and patients with SF had larger mean spleen volume and major axis length than those without. After adjusting for weight, height, age, and diabetes, each 1 cm increase in spleen major axis was associated with increased odds of SF in women (OR: 1.40, 95% CI 1.24-1.60, p < 0.001) and men (OR: 1.31, 95% CI 1.16-1.49, p < 0.001). Similar findings were seen with each 1 cm increase in spleen major axis length for cirrhosis in women (OR: 2.25, 95% CI 1.70-3.23, p < 0.001) and men (OR: 1.41, 95% CI 1.17-1.72, p < 0.001). In women, the prevalence of SF was 17.1%, 30.9%, and 69.2% in patients with spleen major axis < ULN, ≥ ULN with platelets ≥ 150x10^9 /L, ≥ ULN with platelets < 150x10^9 /L, respectively (p < 0.001). The corresponding values in men were 16.5%, 39.3%, and 64.7% (p < 0.001). A similar trend was seen for cirrhosis (Figure) and when spleen volume was used. Within each sex, spleen size, and platelet count category, obesity or diabetes were only weakly associated with higher prevalence of SF (< 25%) or cirrhosis (< 15%) after excluding comparisons of < 10 patients. **Conclusion:** Larger spleen size is associated with higher prevalence of fibrosis and cirrhosis in MASLD patients undergoing MR elastography, especially those with thrombocytopenia. However, most MASLD patients with splenomegaly and normal platelet counts did not have MR elastography evidence of SF let alone cirrhosis. Isolated splenomegaly should not be considered an indicator of cirrhosis in MASLD.

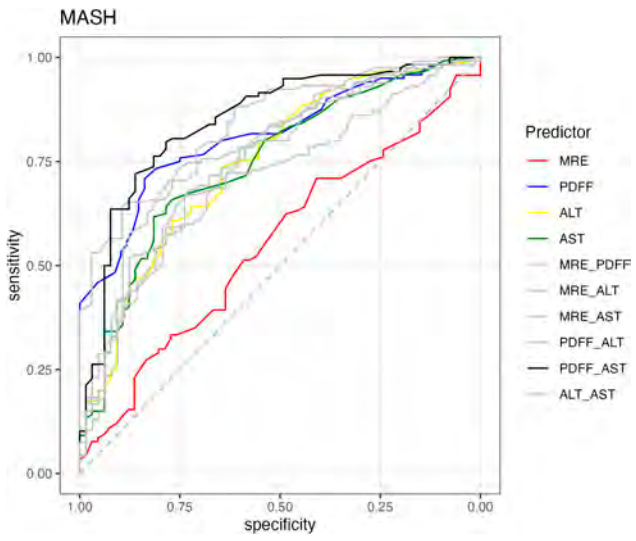
0203 | MRI-PDFF PLUS AST IDENTIFIES PEDIATRIC MASH, AND LONGITUDINAL MRI-PDFF REDUCTION PREDICTS HISTOLOGIC RESPONSE



Laurin Koenke[1] Xinlian Zhang[1] Andrea Schreck[1] Raphael Yoo[1] Rush Chewning[1] Jerry Dwek[1] Denise Malicki[1] Phillipp Hartmann[1], [1]University of California San Diego

Background: Pediatric metabolic dysfunction-associated steatotic liver disease (MASLD), particularly metabolic dysfunction-associated steatohepatitis (MASH), is associated with fibrosis, morbidity, and long-term mortality. Reliable biomarkers beyond ALT/AST to detect pediatric MASH and fibrosis are lacking. We compared MRI-based modalities, alone or combined with routine biochemical markers, for detecting MASH and fibrosis stages in children. **Methods:** We prospectively enrolled 190 children with biopsy-confirmed MASLD who underwent MR elastography (MRE) and MRI-proton density fat fraction (PDFF) within 100 days of biopsy, plus 30 healthy controls. Alanine and aspartate aminotransferases (ALT and AST) were assessed. Analyses included t-tests, logistic regression, areas under the curve (AUCs), and Pearson correlations. **Results:** Children with MASLD had mean age 13.0 years, 76.8% were boys, mean body mass index was 33.3, mean NAFLD activity score (NAS) was 3.98, and fibrosis stages were F0 n = 47, F1 n = 82, F2 n = 39, F3 n = 21, and F4 n = 1. MRI-PDFF, MRE, ALT, and AST were higher in patients with MASLD than controls. Among children with MASLD, MRE correlated with fibrosis stage (R = 0.28, p < 0.001) but not NAS, whereas MRI-PDFF correlated with fibrosis stage (R = 0.22, p = 0.002) and NAS (R = 0.5, p < 0.001). AUCs for MRE vs MRI-PDFF were 0.55 vs 0.81 for MASH, 0.56 vs 0.65 for F2-F4, and 0.73 vs 0.69 for F3-F4, respectively. Logistic regression using up to all four biomarkers achieved AUCs of 0.88 for MASH and 0.87 for F3-F4. A simplified, clinically applicable two-parameter model, the sum of PDFF and AST, detected MASH with AUC 0.85 (Figure) and F3-F4 with AUC 0.86. Of note, MRI-PDFF > 30% ruled in MASH (100% specificity/PPV), and PDFF+AST < 70 ruled out advanced fibrosis (100% sensitivity/NPV).Longitudinally, over a mean 1 year 7.5 months between biopsies, ≥ 30% relative MRI-PDFF improvement predicted MASH

resolution (odds ratio [OR] 18.33, p = 0.02; AUC 0.77; sensitivity 0.92; specificity 0.63), while ≥ 60% improvement had AUC 0.88 (sensitivity 0.75; specificity 1.00). In the important MASH F2-F3 subgroup, relative MRI-PDFF change correlated with NAS change (R = 0.76, p = 0.004) and fibrosis stage change (R = 0.7, p = 0.012), whereas MRE change did not correlate with NAS or fibrosis stage change. In this subgroup, ≥ 30% MRI-PDFF improvement had AUC 0.83 for fibrosis improvement (sensitivity 1.00; specificity 0.67), and ≥ 60% improvement had AUC 0.75 (sensitivity 0.67; specificity 0.83). For MASH resolution, ≥ 30% MRI-PDFF improvement had AUC 0.83 (sensitivity 1.00; specificity 0.67), and ≥ 60% improvement had AUC 0.92 (sensitivity 0.83; specificity 1.00). **Conclusion:** PDFF+AST detects MASH and rules out advanced fibrosis with high certainty in children. Relative PDFF improvement predicts histologic response on repeat biopsy, including in MASH with F2-F3, supporting MRI-PDFF as a pediatric MASH trial endpoint.

0204 | MAPS: A NEW NON-INVASIVE SCORE FOR IDENTIFYING MASH AND PREDICTING DISEASE PROGRESSION

Yousif Alyousifi[1] Chinmay Raut[1] Lishi Yin[1] Antonino Oliveri[2] Emma Ulrich[1] Vincent Chen[1] Yanhua Chen[1] Elizabeth Speliotes[3], [1]University of Michigan, [2]Univerity of Michigan, [3]University of Michigan Medical Center

Background: Metabolic dysfunction-associated steatohepatitis (MASH) affects up to 14% of adults and can progress to cirrhosis and hepatocellular carcinoma; however, diagnosis often requires liver biopsy or MRI, which are invasive, expensive, and not widely accessible. Current non-invasive scores are designed primarily for fibrosis detection; they may miss early MASH and have limited performance in predicting long-term progression risk. We developed MAPS (**M** ASH- **A** ssociated **P** rogression **S** core), a non-invasive score model integrating routine clinical and genetic predictors to identify MASH and predict disease progression. **Methods:** A total of 33,966 UK Biobank (UKBB) participants with MRI-derived liver phenotyping were used to develop MAPS, where MASH was defined as proton density fat fraction (PDFF) ≥ 5% and iron-corrected T1 (cT1) > 800. From 338 candidate variables, we selected seven predictors using BorutaSHAP algorithm. Six machine learning models were evaluated using 10-fold stratified cross-validation; the best model with the highest discrimination was selected as a final model. MAPS was internally and externally validated in a held-out UKBB test set and Michigan Genomics Initiative (MGI) cohort (*n* = 7,521). MAPS' prognostic performance for incident cirrhosis was evaluated and compared with existing fibrosis scores, FIB-4, SAFE, and NFS, in an independent UKBB sub-cohort with ICD-defined MASH (*n* = 11,272). **Results:** MAPS showed strong discrimination in identifying MASH, achieving an AUC of 0.88 (95% CI 0.87–0.89) in the UKBB held-out test set and 0.79 (95% CI 0.75 - 0.82) in MGI. MAPS outperformed MASH-specific scores (AUC 0.76 - 0.83), and fibrosis scores (AUC 0.56 - 0.66) in the UKBB held-out test set. Cirrhosis event rates increased across MAPS risk strata (0.12%, 0.24%, 0.83%). MAPS uniquely detected more true cirrhosis cases (198 vs 47 SAFE, 8 FIB-4, 7 NFS), and cases identified only by MAPS had a longer median time to incident cirrhosis (11.1 vs 6.5–9.3 years), consistent with earlier detection, while maintaining a rule-out negative predictive value of 0.99. **Conclusion:** MAPS accurately identifies MASH and predicts future cirrhosis earlier than other scores using seven key variables, demonstrating improved risk stratification and long-term prediction compared with these other scores across independent cohorts. Our model may help identify high-risk individuals earlier and guide timely preventive or therapeutic interventions before liver disease complications develop and become hard to treat.

0205 | PLASMA CFDNA METHYLATION ENABLES NON-INVASIVE SNAPSHOT OF LIVER PATHWAY ACTIVITY, CELL COMPOSITION, AND FIBROSIS STAGE

Anna Mae Diehl[1] Pourya Naderi Yeganeh[2] Amin Naghdloo[3] Leila Bazargan[3] Chong Lu[3] Rajesh Dutta[1] Kuo Du[1] Liuyang Wang[1] Hamed Amini[3] Rohit Loomba[4] Manal Abdelmalek[5] Soheil Damangir[3], [1]Duke University, [2]Harvard Medical School, [3]Hepta Bio, Inc., [4]University of California, San Diego, [5]Mayo Clinic Rochester

Background: Liver biopsy remains the reference for MASH histopathology but is invasive, sampling-limited, and unsuited to large-scale or longitudinal studies. Plasma cfDNA methylation carries liver-derived information, but in chronic disease the signal is distributed across millions of fragments with subtle quantitative shifts that conventional locus-by-locus analyses cannot resolve. We aimed to build an AI system purpose-built for liquid biopsy that can recover tissue-level pathway biology non-invasively from cfDNA alone. **Methods:** Using plasma samples from the Duke University Biobank, we generated whole-methylome sequencing of plasma cfDNA from 59 controls and 217 biopsy-confirmed MASLD patients. On all patients with biopsy, bulk liver RNA-seq was performed. Whole methylomes were also generated on a subset of the liver tissues ($n = 50$). Biological ground truth was first established on the data from liver tissue, and then LiquidTransformer (LT) was used to recover the established tissue biology from cfDNA. LT is a novel attention-based AI architecture that treats each of hundreds of millions of cfDNA fragments as a molecular token and learns which fragments carry disease-relevant methylation. Analyses compared F0-F1 with F3-F4 group, adjusting for age, sex, BMI, and type 2 diabetes. **Results:** In tissue, 16,699 differentially methylated CpGs and 2,183 differentially expressed genes converged at the pathway level on coordinated silencing of hepatocyte identity (HNF4A, FXR, PPARα targets) and activation of biliary lineage and developmental signaling. Permutation-based GSEA test identified FOXA2-cascade silencing as the dominant program responsible for repressing the majority of the top transcription factors ($p < 0.001$). We then looked into the recovery of those biological changes non-invasively. Conventional cfDNA analysis recovered little of this signal (Spearman $\rho = 0.07$ plasma vs tissue). LT cfDNA on the other hand recovered most of the signal (Spearman $\rho = 0.54$ LT plasma vs tissue) leading to a 87% pathway-level agreement between plasma cfDNA LT and tissue signal from RNA and methylation. Cell-type deconvolution using LT also revealed graded hepatocyte loss and biliary cell expansion with advancing fibrosis indicating that change in cell composition can also be measured non-invasively. **Conclusion:** Plasma cfDNA methylation, interpreted through purpose-built AI, provides a non-invasive virtual pathology axis of MASH that recovers pathway activity, cell composition, and fibrosis severity from a routine blood draw. LiquidTransformer has previously been shown to outperform current non-invasive tests for identifying patients with significant fibrosis. This study shows that it can read the biology underlying disease progression, supporting risk stratification, mechanistic phenotyping, and treatment selection in the rapidly evolving MASH therapeutic landscape.

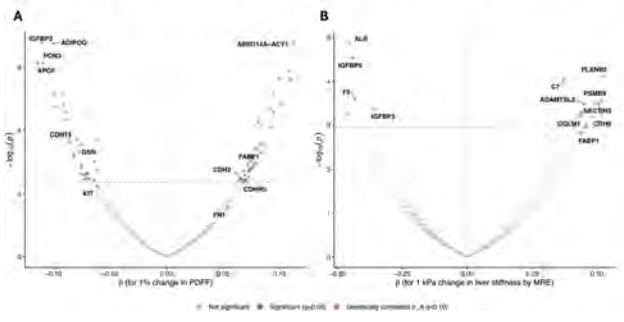
0206 | HERITABILITY OF THE SERUM PROTEOME AND SHARED GENETIC ARCHITECTURE WITH STEATOSIS AND FIBROSIS: A TWIN STUDY

Maria Mironova[1] Igor Wierzbicki[1] Chi-Hua Chen[1] Veeral Ajmera[2] Kaleb Tesfai[1] Seema Singh[1] Egbert Madamba[1] Mary Dalupang[1] Shailja Shah[1] Tatiana Kisseleva[3] Amit Majithia[1] Claude Sirlin[1] David Gonzalez[1] Rohit Loomba[3], [1]UCSD, [2]University of California San Diego, [3]University of California, San Diego



Background: We previously showed that hepatic steatosis and fibrosis in MASLD are heritable. Whether the serum proteome shares genetic determinants with these traits is unknown. Our aim was to estimate serum proteome heritability and its genetic correlation with imaging-quantified steatosis and fibrosis in a well-phenotyped twin cohort. **Methods:** From a prospective twin cohort, we identified 136 twins (46 monozygotic and 22 dizygotic pairs) for serum proteomics; 118 twins also had quantified steatosis by MRI-PDFF and fibrosis by MRE, respectively (24 twins with MASLD and 94 non-MASLD). Untargeted analysis of serum proteome was performed using Orbitrap Astral MS (~850 proteins). Univariate and bivariate AE models, which partition phenotypic variance into additive genetic (A) and unique environmental (E) components, were used to estimate heritability (h^2) and genetic correlation (rA), with age, sex, and race as covariates. A descriptive ACE check classified proteins as stable (shared environment component $c^2 < 10\%$). Differential expression was analyzed using mixed-effects models. Benjamini-Hochberg FDR was used to adjust for multiplicity: significance was defined as $q < 0.10$ (rA) and $q < 0.05$

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

(differential expression). **Results:** The serum proteome was highly heritable: 552 proteins were significantly heritable with median $h^2 = 0.48$ (range 0.24-0.86); among those 190 showed no detectable shared environment contribution. Eight proteins were genetically correlated with steatosis - negatively for CDH13, GSN, APOF, KIT, and positively for FABP1, CDH2, FN1, CDHR5. FABP1 was the only protein genetically correlated with fibrosis. Differential abundance was consistent with known MASLD pathophysiology: among proteins upregulated in steatosis were ADH4, ADH1A, SELE, AFM, ADAMTSL2, and downregulated – ADIPOQ, APOF, IGFBP2, SHBG. Among proteins upregulated in fibrosis were C7, PSMB9, CDH6, and downregulated – ALB, IGFBP3, IGFBP5, F5.(Fig 1A-B) Pathway analysis showed suppressed adaptive-immune signaling in steatosis, and upregulated gluconeogenesis/glycolysis and downregulated immune response and lipid transport in fibrosis. Six proteins met all three criteria – heritable, genetically correlated with steatosis, and differentially abundant: APOF, GSN, CDH13, CDH2, CDHR5, and FABP1. (Fig 1A) **Conclusion:** The serum proteome is highly heritable, and a set of proteins shares genetic architecture with hepatic steatosis and fibrosis, indicating that part of inherited risk for MASLD is reflected in measurable circulating proteins. Two liver-enriched proteins stand out: APOF, a lipid-handling apolipoprotein that is heritable, genetically correlated and downregulated in steatosis, and FABP1, the only protein genetically correlated with both steatosis and fibrosis. Both are candidates for genetically informed MASLD risk stratification and warrant testing by Mendelian randomization.

Figure 1. A. Differential expression on continuous MRI-PDFF (β for a 1% change in PDFF from a linear mixed-effects model with twin-pair random effects, adjusted for age, sex, and self-reported race)
B. The same model against continuous MR elastography (β for a 1 kPa change in liver stiffness).

0207 | RULING OUT CIRRHOSIS IN PATIENTS WITH ELF TEST 9–10.8 AND VCTE LSM 10–20 KPA (HIGH-RISK MASLD)

Mazen Noureddin[1] Winston Dunn[2] Elizabeth Brombosz[3] Gražina Binkauskiene[3] Rashmee Patil[2] Dimple Desai[4] Rohit Puskoor[5] David Huang[6] Nirupama Esther Jerome[5] John Poulos[7] Alaa Abousait[8] Aasim Sheikh[9] Alma Laura Ladrón de Guevara[10] Marcelo Kugelmas[11] Vlad Ratziu[12] Jörn Schattenberg[13] Naim Alkhouri[14], [1]Houston Methodist Hospital, Houston Research Institute, Summit Clinical Research Solutions, [2]Pinnacle at San Antonio, Summit Clinical Research Solutions, [3]Summit Clinical Research Solutions, [4]Pinnacle at Brownsville, Summit Clinical Research Solutions, [5]Pinnacle at Austin, Summit Clinical Research Solutions, [6]Houston Research Institute, [7]Coastal Research Institute, [8]Providence St. Joseph Hospital-Orange, [9]GI Specialists of Georgia, [10]CENTRO DE INVESTIGACION Y GASTROENTEROLOGIA, [11]South Denver Gastroenterology, [12]Service D' Hepatogastroenterologie (FR), [13]Saarland University Medical Center, [14]Summit Clinical Research

Background: There is a growing need for accurate non-invasive tests (NITs) to identify patients with MASH at the highest risk of disease progression while simultaneously ruling out cirrhosis. A combination of ELF 9-10.8 and LSM (VCTE) 10-20 kPa has been suggested to identify such patients with high-risk MASLD. However, the utility of these thresholds in ruling out F4 is unclear. This study aims to identify patients with LSM 10-20 kPa in whom cirrhosis can be accurately ruled out. This is particularly relevant, as recent FDA discussions emphasize combining high-sensitivity and high-specificity NITs when replacing biopsy for ruling out cirrhosis in clinical trials. **Methods:** A multicenter database of patients screened for enrollment in at-risk MASH and MASH cirrhosis trials was reviewed retrospectively. The analysis included patients with biopsy-proven F2-F4 MASH with LSM 10-20 kPa and ELF 9-10.8. Binary logistic regression was used to identify factors associated with biopsy-proven F4 vs F2/F3. Variables associated with F4 with $p < 0.10$ in univariable analysis were considered for inclusion in multivariable candidate models. Separate analyses were performed using predictors modeled as continuous or categorical variables. Model performance was assessed using AUROC, AIC, and likelihood ratio testing. **Results:** A total of 1316 patients were included in the analysis, of whom 29% were F4 and 71% were F2/F3. Demographically, patients with F4 were older (median, IQR: 61 [54-67] vs 58 [51-64] years; $p < 0.001$). Race ($p = 0.007$) and ethnicity ($p = 0.050$) differed between groups, with patients with F4 less likely to be Hispanic/Latino (28.4% vs 34.8%) and less likely to identify as American Indian or Alaska Native (4.1% vs 8.0%). In the multivariable analysis using continuous variables, the top-performing model incorporated LSM, ELF, BMI, MELD, and platelet count, with an AUROC of 0.840. The best-performing multivariable formula model using categorical variables included LSM, ELF, BMI, platelet count, INR, and CAP, with an AUROC of 0.845, sensitivity of 73.3%, specificity of 80.4%, PPV of 60.9%, and NPV of 87.9%. This model also had the highest observed AUROC of all models tested. **Conclusion:** A combination of LSM, ELF, platelet count, and INR can effectively distinguish patients with cirrhosis from those with high-risk MASLD. Adding platelet count and INR to existing screening algorithms can more accurately identify patients likely to have cirrhosis. This approach may enable fully biopsy-free trial designs and have broader clinical implications for ruling out cirrhosis and guiding initiation of NIT-indicated therapies.

Mounika Kotte[6] Digantkumar Patel[7] Hardik Dineshbhai Desai[8] Vinod Nookala[9], [1]NYMC ST Mary's General Hospital St Clares, [2]UCF/HCA Florida Ocala Hospital, Ocala, Florida, United States, 34471, [3]Detroit medical center, Detroit, Michigan, 48201, [4]Integris Health, Oklahoma City, Oklahoma. USA. 73112, [5]BronxCare Health System, Bronx, New York - 10457, [6]Prime south consortium, Weslaco, Texas, USA,78596, [7]Springfield Clinic, Springfield, IL, USA, [8]AB Plus Multispecialty Hospital, Ahmedabad, Gujarat, India, [9]NYMC ST Marys ST Clares

Background: Advanced liver fibrosis may remain clinically unrecognized when aminotransferases are normal. Weevaluated the burden of clinically silent advanced fibrosis and used explainable artificial intelligence toidentify metabolic, inflammatory, liver-related, and environmental predictors among U.S. adults. **Methods:** We analyzed adults from NHANES 2017–2018 with reliable transient elastography data. Hepatitis Cvirus–positive participants were excluded. Advanced fibrosis was defined as liver stiffnessmeasurement ≥ 9.7 kPa. Clinically silent advanced fibrosis was defined as advanced fibrosis withnormal alanine aminotransferase and aspartate aminotransferase. Environmental exposures includedblood lead, cadmium, mercury, and per- and polyfluoroalkyl substance markers. Machine-learningmodels included logistic regression, random forest, and gradient boosting, with permutation-basedexplainability to identify dominant predictors. **Results:** Among 4,703 adults with reliable FibroScan data, 275 had advanced fibrosis, of whom 164 hadnormal aminotransferases. Overall, 59.6% of adults with advanced fibrosis had clinically silentdisease. In the environmental-exposure analytic subset, 1,265 adults were included, with 50 clinicallysilent advanced fibrosis cases. Gradient boosting showed the highest model discrimination, with areaunder the receiver operating characteristic curve 0.796 ± 0.072, similar to random forest, 0.796 ± 0.085, and higher than logistic regression, 0.764 ± 0.084. The strongest explainable predictors werebody mass index, age, high-sensitivity C-reactive protein, waist circumference, gamma-glutamyltransferase, controlled attenuation parameter score, homeostatic model assessment of insulinresistance, high-density lipoprotein cholesterol, alanine aminotransferase, and hemoglobin A1c.Clinically silent advanced fibrosis prevalence increased from 0.95% in the lowest metabolic-risk tertileto 8.77% in the highest tertile. The highest inflammation–liver phenotype tertile showed 9.24%prevalence. High metabolic-risk tertile was independently associated with clinically silent advancedfibrosis, odds ratio 5.11, 95% confidence interval 2.57–10.16, $p < 0.001$. Toxicant burden alone was notindependently associated after metabolic adjustment. **Conclusion:** In NHANES 2017–2018, nearly 60% of adults with advanced fibrosis had normal aminotransferases,highlighting the clinical importance of silent fibrosis detection beyond routine liver enzymes.Explainable artificial intelligence identified adiposity, metabolic dysfunction, inflammation, steatosis,and liver injury markers as the dominant predictors of clinically silent advanced fibrosis, whereastoxicant burden alone was not independently associated after metabolic adjustment.

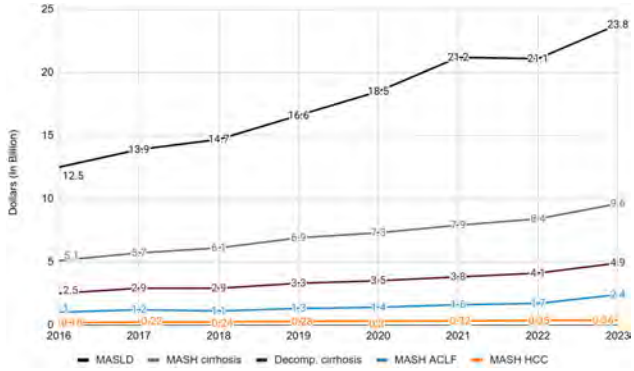
★ 0209 | CONTEMPORARY TRENDS IN HEALTHCARE AND ECONOMIC BURDEN OF MASLD, MASH CIRRHOSIS, AND ACLF AMONG HOSPITALIZED PATIENTS IN THE UNITED STATES: A NATIONWIDE ANALYSIS (2016-2023)



Aalam Sohal[1] Mariam Alamgir[1] Carol Singh[2] Kris Kowdley[1], [1]Liver Institute Northwest, [2]Dayanand Medical College and Hospital

Background: Metabolic-dysfunction associated steatotic liver disease (MASLD) has now emerged as the most common cause of chronic liver disease in the United States. Our study aims to assess the in-hospital healthcare and economic burden of MASLD and its complications among hospitalized patients in the United States between 2016 and 2023. **Methods:** Adult hospitalizations with MASLD were identified using the National Inpatient Sample from 2016 to 2023. Cirrhosis, decompensated cirrhosis, HCC, and ACLF hospitalizations were identified among patients with MASLD. The total healthcare cost was estimated using the cost-to-charge ratio and adjusted for inflation to 2023 dollars. Total hospitalization costs among patients with MASLD,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

stratified by year and by liver-related complications, were also calculated. **Results:** A total of 6.4 million hospitalizations with MASLD were identified. MASLD hospitalizations increased from 618,345 in 2016 to 1.04 million in 2023, reflecting a 68% increase. Total hospitalization costs of MASLD hospitalizations were $142.3 billion between 2016 and 2023. Total hospitalization costs among patients with MASLD nearly doubled from $12.5 billion in 2016 to $23.7 billion in 2023. MASH cirrhosis-associated hospitalizations and decompensated cirrhosis hospitalizations increased from 247,180 patients in 2016 to 411,520 in 2023 (66% increase) and from 99,405 in 2016 to 188,770 in 2023 (89% increase). MASH-related ACLF hospitalizations and HCC increased from 16,355 in 2016 to 54,595 in 2023 (233% increase) and from 7,490 in 2016 to 14,340 in 2023 (91% increase). The proportion of MASLD hospitalizations with cirrhosis remained stable, while the proportion with ACLF nearly doubled during the study period. Total hospitalization costs secondary to MASH cirrhosis, decompensated cirrhosis, ACLF, and HCC were $57 billion, $27.9 billion, $11.7 billion, and $2.3 billion, respectively. Liver transplantation (LT) increased from 2,145 in 2016 to 2,970 in 2023, a 27% increase. Total hospitalization costs increased across the spectrum of MASH, with MASH-related ACLF showing the steepest increase from $1 billion in 2016 to $2.4 billion in 2023. For LT, total hospitalization costs increased from $438 million to $606 million. The proportion of patients requiring LT decreased from 0.35% to 0.28% during the study period. In-hospital mortality decreased from 4.6% in 2016 to 4% in 2023 (with a transient spike during the COVID-19 pandemic) **Conclusion:** Our study reports a striking increase in MASLD hospitalizations and economic burden driven by rising rates of MASH cirrhosis, decompensated cirrhosis, ACLF, and HCC in the United States. Despite an alarming increase in MASLD patients, the rates of liver transplantation and in-hospital mortality have declined, suggesting better management and improved outcomes of MASH. Lifestyle modifications and new pharmacologic therapies are critical to curb this rising healthcare burden.

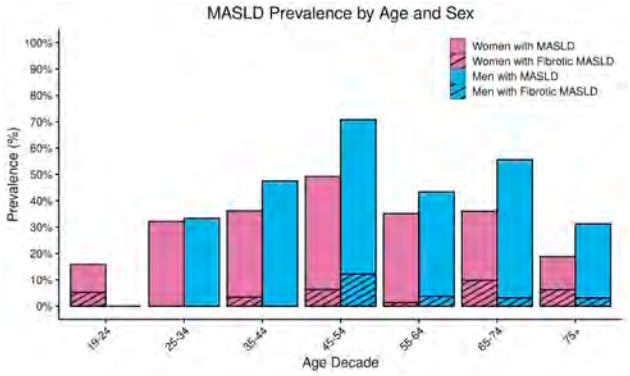
0210 | STEATOSIS IS COMMON, FIBROSIS IS SELECTIVE: PREVALENCE AND METABOLIC PHENOTYPING OF MASLD IN A PROSPECTIVE COMMUNITY SCREENING COHORT



Alina Allen[1] Olivia Bobek[2] Rachel Canning[2] Maysa Eslami[2] Joanne Benson[2] Sudhakar Venkatesh[1] Meng Yin[2] Richard Ehman[1] Graham Rondell[2] Fang-Shu Ou[2], [1]Mayo Clinic Rochester, [2]Mayo Clinic

Background: MASLD is the most common chronic liver disease globally, yet imaging-confirmed community prevalence data stratified by age, sex, and metabolic risk remain scarce. Understanding the true burden and phenotypic spectrum of previously undiagnosed MASLD, including fibrotic disease, is foundational for population-level care planning. **Methods:** The Olmsted NAFLD Epidemiology Study (TONES) is an on-going, prospective, cross-sectional community screening cohort (Olmsted County, MN; NCT04365855). All participants underwent MRI-PDFF and MRE for screening, irrespective of metabolic burden or age; liver biopsy was performed in participants with abnormal MRE findings and interpreted by one study pathologist blinded to imaging results. MASLD was defined as MRI-PDFF $>5\%$ or LSM ≥ 5 kPa irrespective of PDFF to capture burned-out cirrhosis. Fibrotic MASLD was defined by histologic fibrosis stage ≥ 2 or MRE LSM ≥ 3.1 kPa. MetSyn2 was defined as ≥ 2 metabolic syndrome components. Disease prevalence was estimated by sex, age decade, and comorbidity status. **Results:** Between January 2018 and April 2026, 621 adults with no prior history of MASLD were enrolled (mean age 53 years; 56% women; 90.0% White; mean BMI 29.2 kg/m²; 10.5% diabetes). MASLD prevalence was 254/621 (40.9%), peaking in the 45-54 decade (60/104, 57.7%) (Figure). Men had consistently higher MASLD prevalence in older (35+) age group (Figure). MetALD was present in 23/621 (3.7%). Fibrotic MASLD was identified in 25/621 (4.0%), concentrated in high-risk strata: 13/65 (20.0%) in diabetes and 24/211 (11.4%) in MetSyn2. All 25 fibrotic MASLD cases had ≥ 1 metabolic syndrome component; 24/25 (96%) met MetSyn2. A burned-out phenotype (PDFF $\leq 5\%$) was present in 6/25 (24%) of fibrotic MASLD cases. Among individuals with diabetes and fibrotic MASLD, 8/13 (62%) had normal AST and ALT. **Conclusion:** In a prospective community screening cohort with gold-standard liver imaging, undiagnosed MASLD was present in 4 of 10 adults,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

far exceeding clinically coding estimates. Fibrotic MASLD was concentrated in diabetes (20%) and metabolic syndrome (11.4%), was invisible to steatosis-based screening in one-quarter of cases and was undetectable by liver enzymes in the majority of affected individuals with diabetes. These data establish the contemporary epidemiologic foundation for metabolic risk-stratified MASLD screening.

0211 | ADVANCED FIBROSIS IN MASLD SHOWS EARLY MALE PREDOMINANCE BUT NO POSTMENOPAUSAL FEMALE SURGE

Callie Zaborenko[1] Marco Abreu[1] Samer Gawrieh[1] Jingyi Tan[2] Jie Yao[2] Xiuqing Guo[2] Jean Molleston[1] Aaron Hakim[3] Jerome Rotter[2] Naga Chalasani[4] Tae-Hwi Schwantes-An[1], [1]Indiana University School of Medicine, [2]Lundquist, [3]Beth Israel Deaconess Medical Center, [4]Indiana University Medical Center

Background: Metabolic Dysfunction-Associated Steatotic Liver Disease (MASLD) affects individuals across the lifespan, yet the extent to which sex modifies the relationship between age and fibrosis severity remains poorly understood. We examined (a) sex differences in the proportion of advanced fibrosis (AF, fibrosis stage $\geq$ 3) across the lifespan of MASLD patients and (b) age intervals in which these differences are most pronounced. **Methods:** We conducted a cross-sectional analysis of patients with biopsy-proven MASLD aged 5-75 years in the NASH CRN. Multivariable logistic regressions were conducted to examine the associations between age and AF by sex, adjusting for genetic ancestry, BMI, T2D and a 16 SNP weighted, MASLD polygenic risk score (PMIDR), via doubly robust inverse probability weighted (IPW) models. Sex-by-age interaction terms were tested, and goodness-of-fit indicators guided final models. Predicted probabilities of AF by sex across 5-year age groups were estimated. **Results:** Among 3,322 patients with MASLD (mean age 44.1 years; 53% female, 28% children), 25% had AF. There was a significant interaction between sex and age (Wald test: χ^2 = 54.5, df = 4, p = 4.1e-11) in the risk for AF. The relationship between age and the proportion of patients with AF was U-shaped, with a high prevalence in early childhood, a steep decrease until age 25, then a slow increase until age 70 for both sexes (Figure). In unweighted models, the proportion of AF was higher in boys than girls aged 5-15 and higher in women than men aged 45-55, with no significant difference between sexes at other ages. However, in IPW models, the proportion of AF was higher in boys than girls aged 5-15 (age 5-10: OR = 2.00, 95% CI 1.11-3.61, p = 0.022, age 10-15: OR = 1.60, 95% CI 1.02-2.50, p = 0.039), but there was no longer a difference at age 45-55. There were differences in the rate of change, with the proportion of AF decreasing faster for males aged 5-25, then increasing more slowly for males aged 25-40 (all p < 0.05). We did not observe an inflection point for AF among women around menopausal age. **Conclusion:** Sex differences in AF among MASLD patients are age-dependent, with males bearing a disproportionately higher frequency of AF in childhood. Notably, we did not observe an acceleration in the risk for AF in postmenopausal women. These findings highlight the importance of considering age-specific biologic mechanisms when evaluating fibrosis risk in MASLD.

0212 | IS MASLD PART OF CARDIOVASCULAR-KIDNEY-METABOLIC SYNDROME? GENETIC EVIDENCE FOR A CAUSAL, METABOLICALLY-MEDIATED CKM-TO-ALT EFFECT

Eleonora Scorletti[1] Guoyi Yang[2] Daniel Rader[2] Marijana Vujkovic[3], [1]Johns Hopkins University, [2]University of Pennsylvania, [3]Univerrsity of Pennsylvania

Background: The 2023 AHA cardiovascular-kidney-metabolic (CKM) statement placed metabolic dysfunction-associated steatotic liver disease (MASLD) within CKM pathophysiology but not stage definitions. MASLD is increasingly recognized as part of a broader, multi-organ syndrome of metabolic dysfunction, and recent cardiometabolic consensus literature has argued it should be a defining CKM component. Genetic adjudication will require multiple complementary tests. As a first step, we used a European-ancestry CKM construct from 10 metabolic and kidney GWAS to test whether genetic CKM liability is associated with ALT, what biology drives the effect, and to characterize the overlap between CKM lead variants and known liver-specific MASLD loci. **Methods:** We used genomic structural equation modeling (SEM) to model the shared genetic architecture of CKM components, leveraging ten European-ancestry genome-wide association study (GWAS) summary statistics for adiposity, metabolic risk factors, and kidney function. We conducted a multivariate CKM GWAS (Neff = 1,135,862). We performed clustered Mendelian randomization (MR) analyses to identify variant clusters with distinct causal effects of CKM syndrome on MASLD proxied by chronic elevation of alanine aminotransferase (cALT, N = 90,408 cases and 128,187 controls). Variant clusters were mapped to KEGG/Reactome pathways. **Results:** We identified 544 independent variants genome-wide significant for shared CKM components. Because the CKM construct included no liver or ALT input, canonical liver-specific MASLD lead loci were largely absent from the CKM lead set by construction (except PPP1R3B and MTARC1), which does not indicate that MASLD is genetically distinct from CKM. Each 1-SD higher genetic liability to CKM was associated with higher odds of cALT [OR = 1.86 (95% CI 1.68–2.07), p = 3×10^{-30}]. Clustered MR identified three substantive variant clusters with heterogeneous effects on cALT. Most CKM variants showed a moderate effect (metabolic-mainline pattern; Fig.1). However, a smaller insulin-resistance and atherogenic-dyslipidemia cluster, including IRS1, GRB14, MSL2, and SH2B3, showed a stronger effect on cALT. In contrast, a discordant cluster including SHROOM3 and FADS2 indicated an inverse association with cALT. Pathway enrichment supported this biology: the metabolic-mainline cluster was enriched for Maturity-Onset Diabetes of the Young (KEGG), and the insulin-resistance cluster for Receptor Tyrosine Kinase signaling (Reactome). **Conclusion:** Genetically predicted CKM is associated with higher ALT, consistent with a causal effect driven primarily by insulin-resistance/atherogenic-dyslipidemia variants, with a discordant cluster showing an inverse effect. These data establish a strong, metabolically mediated CKM-to-ALT genetic signal; analyses formally testing MASLD's inclusion in CKM are ongoing.

0214 | SEQUENTIAL BLOOD- AND ELASTOGRAPHY-BASED STRATEGIES FOR MASLD FIBROSIS CASE-FINDING IN PRIMARY CARE: PROSPECTIVE VALIDATION OF ELF AND MASEF IN THE LIVERSEEK PROGRAM

Luis Ibáñez Samaniego[1] Susana Sanchez Berdial[1] Laura Suárez[1] Carmen Corps[1] María Sasía[1] Eduardo Montenegro[1] Sonia Irisarri Vega[1] Zhanhui Wang Jiang[1] Andres Conthe[1] Jacobo Caride[1] Francisco Antonio Bernabeu-Andreu[2] Isabel Peligros[1] Luis Menchen[3] Carmen Lorenzo[1] Rafael Bañares[4] Rodolfo Romero[1] Magdalena Salcedo[1], [1]Hospital General Universitario Gregorio Marañón, [2]Hospital Universitario Puerta de Hierro, [3]Hospital General Universitario Gregorio Marañón. Universidad Complutense de Madrid, [4]Universidad Complutense de Madrid, CIBEREHD

Background: Scalable primary care (PC) case-finding for MASLD with significant fibrosis (~1.6% of European adults) is lacking, and ELF and MASEF lack prospective validation in PC. LiverSeek is a laboratory-information-system-driven, passive reflex-testing program for MASLD-related fibrosis case-finding in PC. We aimed to: 1) quantify the yield of LiverSeek for previously undiagnosed MASLD-related fibrosis; 2) prospectively validate ELF and MASEF in PC for significant fibrosis (≥F2); 3) compare sequential NIT strategies combining FIB-4 with ELF, MASEF, VCTE or FAST for hepatology referral in high-metabolic-risk PC patients. **Methods:** Over 6 months, blood samples from individual patients were screened at 11 PC centres in Madrid serving approximately 350,000 residents. Patients aged 50-75y meeting any cardiometabolic criterion — BMI > 30 + HbA1c > 6.5%, HbA1c > 6.5% + ALT > ULN, or BMI > 30 + ALT > ULN — triggered automatic FIB-4 with age-adjusted cutoffs (≥1.30 if <65y; ≥2.00 if ≥65y). When positive, reflex ELF and MASEF were measured and a nurse-led FibroScan scheduled; any positive NIT prompted hepatology referral. Four sequential strategies (FIB-4 + VCTE, FAST, ELF or MASEF) were assessed against: i) histologic ≥F2; ii) chronic liver disease with fibrosis (CLD-fib) defined using LiverScreen-consistent criteria: biopsy F1-F4 or ultrasound with ≥2 CLD/portal-hypertension signs or two consecutive VCTE ≥10 kPa. AUROCs with 95% CIs were compared with DeLong's test; sens, spec, PPV and NPV were computed at prespecified cutoffs (VCTE ≥8 kPa, FAST ≥0.35, ELF ≥9.8, MASEF ≥0.33). **Results:** 38,325 unique-patient samples were screened; 1,664 (4.3%) were high-metabolic-risk. FIB-4 was elevated in 373 (22%); 303 completed reflex testing and elastography (age 61.5 ± 5.7y, 41% female, BMI 31.5 ± 5.1, T2D 62%); 81/303 (27%) had VCTE ≥8 kPa. Biopsied and non-biopsied patients had similar demographic, metabolic and baseline NIT profiles. Yield of previously undiagnosed MASLD-related fibrosis: CLD-fib confirmed in 37%; 67 biopsied (≥F2 60%, at-risk MASH 21%). For ≥F2 (biopsy), AUROCs were FIB-4+VCTE 0.87 (0.77–0.94), FIB-4+FAST 0.86 (0.76–0.95), FIB-4 +MASEF 0.78 (0.65–0.88) and FIB-4+ELF 0.74 (0.60–0.86). For CLD-fib, FIB-4+MASEF (0.79; 0.72–0.85) outperformed FIB-4+ELF (0.68; 0.60–0.75; $p < 0.05$) and showed similar AUROC to FIB-4+VCTE (0.79); FIB-4+MASEF reached sens 89% and NPV 90%. **Conclusion:** (1) The LiverSeek program identifies previously undiagnosed MASLD-related fibrosis at high yield (37% CLD-fib among evaluable; 60% ≥F2 among biopsied).(2) FIB-4+MASEF outperforms FIB-4 +ELF for CLD-fib and performs comparably to FibroScan-based strategies, supporting MASEF as the most informative blood-based reflex test within this PC pathway.(3) For histologic ≥F2, FibroScan-based strategies (FIB-4+VCTE/FAST) remain most accurate; FIB-4+MASEF is a viable one-step blood-based alternative when elastography is unavailable.

0215 | ENGINEERING INJURY-RESISTANT FUNCTIONAL BILIARY TREES WITH ENHANCED DRUG EFFLUX CAPACITY

Jun Li[1] Shiwen Ma[1] Jiaxian Chen[1] Meiqian Hu[1] Jiaojiao Xin[1] Jing Jiang[1] Dongyan Shi[1], [1]The First Affiliated Hospital, Zhejiang University School of Medicine

Background: The reconstruction of functional biliary trees (FBTs) is crucial in the development of bioengineered liver. However, the decellularized liver scaffolds (DLS) as the scaffold of FBTs exhibit mechanical instability that leads to luminal collapse and subsequent hypoxic stress, severely compromising FBT functions. Furthermore, existing engineered biliary structures lack sufficient injury resistance to withstand toxic stress. **Methods:** This work aimed to generate macro-scale FBTs with drug efflux capacity and injury resistance using DLS as templates and mouse primary cholangiocytes as the cellular source. FBTs were assessed using functional assays, transcriptomic profiling, and hepatotoxic injury testing to validate their structural stability and injury resistance. **Results:** The FBTs generated with genipin-crosslinked DLS exhibited improved structural stability and fluid mechanical properties, which facilitated cholangiocyte adhesion and alleviated hypoxic stress, as supported by downregulation of the HIF pathway. By day 7, FBTs formed relatively stable biliary tree-like structures with greater biliary tree continuity and cell viability than non-crosslinked controls, accompanied by preserved mitochondrial membrane potential as confirmed by JC-1 staining. Morphological evaluation revealed that FBTs recapitulated key features of native biliary networks, including multilevel branching architecture, organized luminal epithelial lining, and proper apical-basal polarity. Scanning electron microscopy further revealed elongated primary cilia projecting toward the biliary lumen and organized epithelial cell-cell junctions. Functionally, compared with conventional Matrigel-cultured cholangiocyte organoids, FBTs showed a more mature biliary epithelial phenotype, characterized by strengthened polarity and barrier integrity together with enhanced biliary transport and P-glycoprotein (P-gp)-mediated drug efflux capacity. Notably, these functional advantages translated into superior resistance to toxic stress, as FBTs better maintained cellular homeostasis and biliary function than organoids following chlorpromazine (CPZ)-induced injury. Verapamil-mediated inhibition of P-gp activity partially compromised this protection, suggesting that P-gp-mediated efflux contributes in part to FBT injury resistance. **Conclusion:** These injury-resistant FBTs with enhanced drug efflux capacity provide a promising functional biliary network for bioengineered liver construction and future translational applications.

0216 | BILIARY GENE THERAPY

Pervin Choksi[1], [1]UCSF

Background: Delivery of therapeutic genetic cargo to biliary epithelial cells (BECs) is an unmet need for cholangiopathies and cholangiocarcinoma (CCA). The characteristic liver tropism of adenoassociated viral (AAV) capsids applies to hepatocytes, but not BECs. Here, we sought to identify an AAV capsid capable of efficient and specific BEC targeting in healthy and diseased livers. **Methods:** Using next-generation sequencing of the principal liver cell populations we screened a library of 82 barcoded AAV capsids in mice. We validated a lead candidate, AAV-BEC, in mouse models of liver homeostasis, cholestasis and CCA using single-cell RNA sequencing, flow cytometry and 3D imaging. We investigated the translational potential in mice in which mouse BECs were replaced by human

BECs. All mice were intravenously injected with the same AAV-BEC vector dose of 4×10^{11} viral genomes. **Results:** An AAV-BEC vector expressing Cre recombinase from the ubiquitous CMV promoter achieved 78% transduction of naive BECs, accompanied by off-targeting of hepatocytes (53.6%) and macrophages (10.7%), in fluorescent reporter mice. Equipping the vector with a Prom1 promoter and binding sites for miR-122 and miR-142 reduced off-targeting ($<0.5\%$) while achieving 45% transduction of BECs. In a mouse model of cholangiopathy due to *Abcc12* gene knockout, AAV-BEC-mediated ABCC12 delivery restored biliary function as evidenced by improved bile-duct morphology and reduced blood levels of ALP. In mice with cholestasis due to DDC diet, AAV-BEC-mediated CRISPR knockout of the Notch signaling effector gene *Rbpj* reduced the number of reactive BECs but worsened blood markers of liver injury, consistent with the ductular reaction affording bile drainage. In mice with CCAs induced by the oncogenes NICD and AKT, an AAV-BEC vector achieved 40% transduction of malignant BECs. Moreover, using AAV-BEC for diphtheria toxin-mediated cell ablation in diphtheria toxin receptor-transgenic mice with CCAs efficiently reduced tumor burden as evidenced by the total number of BECs decreasing from 10.8% to 0.35% of non-hepatocyte liver cells. In mice in which the biliary system was partially humanized an EYFP-expressing AAV-BEC vector achieved 40% transduction of human BECs. **Conclusion:** AAV-BEC facilitates efficient and specific in vivo gene delivery to naive, reactive and malignant BECs, providing an opportunity for development of gene therapies for a broad range of biliary diseases.

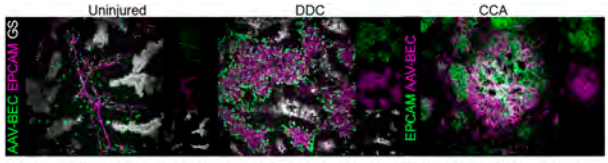

Figure. 3D imaging of uninjured (left) and DDC-injured (middle) livers transduced with an AAV-BEC vector detargeted from hepatocytes and macrophages, and of a CCA in a liver (right) transduced with an AAV-BEC vector with unaltered tropism.

0217 | LIVER-SPECIFIC TJP2 DEFICIENCY IN A HUMANIZED BILE ACID MOUSE MODEL DRIVES CHOLESTATIC INJURY VIA IMMUNE ACTIVATION AND METABOLIC SUPPRESSION

Thi Hao Vu[1] Kota Tsuruya[2] Yusuke Mishima[2] Yutaka Inagaki[3] Akira Honda[4] Tatehiro Kagawa[1] Akihide Kamiya[3], [1]Tokai University, [2]Tokai University School of Medicine, Japan, [3]Tokai University School of Medicine, [4]Tokyo Medical University Ibaraki Medical Center, Japan

Background: Progressive familial intrahepatic cholestasis type 4 (PFIC4) is caused by mutations in tight junction protein 2 (TJP2) gene, leading to paracellular bile leakage and progressive liver injury. Conventional *Tjp2*-deficient mice exhibit only mild phenotypes, likely due to the predominance of hydrophilic murine bile acids. We aimed to establish a physiologically relevant PFIC4 model by utilizing a humanized bile acid background. **Methods:** We utilized Cyp2a12/Cyp2c70 double-knockout (CYPDKO) mice to mimic a human-like hydrophobic bile acid profile. Liver-specific Tjp2 deletion was induced via AAV8-mediated CRISPR/Cas9 genome editing. Phenotypic changes were evaluated through serum biochemistry, histology (Sirius Red, IHC for F4/80 and CK19), and transmission electron microscopy. Comprehensive transcriptomic analysis (RNA-seq) and bioinformatic modeling were performed to identify key differentially expressed genes and altered signaling pathways **Results:** Liver-specific *Tjp2* deletion was induced in Cyp2a12/Cyp2c70 double-knockout (CYPDKO) mice using AAV-mediated CRISPR/Cas9 genome editing. Compared to controls, TJP2-deficient CYPDKO mice developed severe liver injury, with elevated serum transaminases and alkaline phosphatase, periportal fibrosis, ductular reaction, and macrophage infiltration. Electron microscopy revealed disrupted tight junction architecture with significantly reduced junctional width.Transcriptomic analysis identified 594 differentially expressed genes (DEGs), characterized by the robust induction of interferon-stimulated genes, innate immune activation, extracellular matrix remodelling, and epithelial stress pathways. Conversely, key metabolic pathways were markedly suppressed, including PPARα signalling, fatty acid oxidation, bile acid transport, and xenobiotic metabolism. These findings suggest that TJP2 deficiency under hydrophobic bile acid conditions triggers a coordinated response involving barrier disruption, interferon-driven inflammation, and metabolic reprogramming. **Conclusion:** Liver-specific *Tjp2* deficiency in a humanized bile acid background recapitulates the key structural, inflammatory, and metabolic features of PFIC4. This model supports a “two-hit” mechanism in which junctional instability and bile acid hydrophobicity synergistically drive liver injury. Our findings establish a physiologically relevant platform for PFIC4 research and highlight nuclear receptor–mediated metabolic pathways as potential therapeutic targets

0218 | BEYOND GILBERT SYNDROME: HETEROZYGOUS UGT1A1 C.41_40DUP DEFINES A DISTINCT CHOLANGIOPATHIC PHENOTYPE IN YOUNG ADULTS WITH UNEXPLAINED CHRONIC CHOLESTASIS

Mario Romeo[1] Fiammetta Di Nardo[1] Carmine Napolitano[1] Paolo Vaia[1] Claudio Basile[1] Giusy Senese[1] Marco Niosi[1] Marcello Dallio[1] Alessandro Federico[1], [1]University Hospital Luigi Vanvitelli, Piazza Miraglia 2, 80138, Naples, Italy

Background: Unexplained chronic cholestasis (UCC) in young adults is traditionally viewed as a disorder of hepatocellular secretion or canalicular transport. However, in a subset of patients, the underlying process may be better explained by a cholangiopathy driven by alterations in bile composition. Uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) is a key enzyme involved in bilirubin conjugation. The heterozygous UGT1A1 c.41_40dup variant, commonly linked to Gilbert syndrome (GS), is frequently detected in individuals without overt manifestations of GS. Even in this context, reduced UGT1A1 activity may shift bilirubin conjugation toward a higher proportion of bilirubin monoglucuronide (BMG) and a lower proportion of bilirubin diglucuronide (BDG). We therefore investigated whether this variant may contribute to a bile composition–driven cholangiopathic phenotype associated with chronic biliary epithelial injury. **Methods:** In this prospective proof-of-concept study, 34 UDCA-naïve young adults with UCC and normal serum bilirubin were enrolled. Patients were stratified as: Group A, isolated heterozygous UGT1A1 c.41_40dup (n = 10); Group B, UGT1A1 c.41_40dup plus additional cholestasis-related variants (n = 11); and Group C, non-carriers with other variants only (n = 13). All underwent targeted next-generation sequencing, liver biopsy, and assessment of hepatic UGT1A1 activity and bilirubin conjugate composition by HPLC. Patients received UDCA (15 mg/kg/day) and were followed for 12 months. At 12 months, biochemical evolution was assessed using ALP levels (> 1.9× ULN) as a pragmatic benchmark. **Results:** Patients harboring the UGT1A1 c.41_40dup variant showed markedly lower hepatic UGT1A1 activity and a significantly higher BMG/BDG ratio than non-carriers (both p < 0.0001), together with a greater prevalence of gallstone-related manifestations. Despite normal serum bilirubin levels, variant carriers displayed persistent elevation of ALP and GGT and a higher prevalence of advanced fibrosis (p = 0.0022). Overall, this constellation of clinical, biochemical, and histological findings was consistent with a cholangiopathy-like phenotype suggestive of ascending cholestatic injury. After 12 months, ALP levels > 1.9× ULN were observed more frequently in variant carriers than in non-carriers (70% vs 28%; p < 0.0001). In exploratory analyses, reduced UGT1A1 activity was associated with this outcome. **Conclusion:** The heterozygous UGT1A1 c.41_40dup variant may act as a non-canonical modifier of bile composition, contributing to a bile composition-driven cholangiopathic phenotype characterized by gallstone disease, hepatocellular injury, fibrosis progression, and reduced UDCA responsiveness. These hypothesis-generating findings support the potential role of UGT1A1 testing in refining phenotypic stratification of young adults with UCC.

Background: Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by progressive bile duct inflammation and fibrosis. Although diverse immune cells, including neutrophils, infiltrate the periportal region in PSC, the mechanisms and consequences of their liver recruitment are unknown. The cyclic GMP–AMP synthase–stimulator of interferon genes (cGAS-STING) signaling pathway is a key mediator of inflammatory gene expression in response to cellular stress, but its role in cholestatic disease is undefined. Here, we investigated the role of biliary cGAS-STING signaling in homing neutrophils to the bile duct and modulating their function to promote inflammation and fibrosis in PSC. **Methods:** Human PSC liver tissues were interrogated by GeoMx DSP, Phenocycler, and immunofluorescence (IF) and enzyme linked immune assay (ELISA). Murine models of PSC (Mdr2-/- and DDC-diet) were used for neutrophil directed treatment (anti-Ly6G or Cl-Amidine). Mice with cholangiocyte-selective STING deletion were fed a DDC diet to investigate immune cell infiltration using mass cytometry (CyTOF). Liver enzymes and histology were also assessed. Human cholangiocytes with TNFα stimulus and STING intervention were used for RNA sequencing. Human neutrophil migration was assessed using microfluidic devices. Neutrophil phenotypes (i.e., phagocytosis, NETosis) were measured by flow cytometry. **Results:** Human and mouse PSC livers showed significant periportal neutrophil accumulation by IF and enhanced neutrophil extracellular traps (NETs) deposition by IF and ELISA. Both neutrophil depletion with anti-Ly6G or pharmacological inhibition of NETs formation with Cl-amidine in the $Mdr2^{-/-}$ mouse model significantly reduced liver damage markers including ALT (p = 0.0017), AST (p = 0.0024), and ALP (p = 0.0114) and fibrosis (8.954 vs 3.931; p = 0.0255). RNA sequencing revealed that STING knockdown in human cholangiocytes significantly reduced TNFα-induced chemokine expression and signaling. Healthy human neutrophils exposed to an inflammatory cholangiocyte milieu depicted enhanced migration, NET formation (p = 0.001), and reduced phagocytosis (p = 0.0192). Consistently, both pharmacological inhibition and genetic deletion of STING in DDC-diet model of PSC reduced neutrophil infiltration, as assessed by IF and CyTOF analysis (17.65 vs 0.04000; p = 0.0064). Congruently, DDC- induced liver fibrosis, measured by picrosirius red, was also significantly reduced with cholangiocyte-selective STING deletion (9.797 vs 3.009; p = 0.0188). **Conclusion:** Neutrophil recruitment and inflammatory amplification in PSC are driven by cholangiocyte-intrinsic cGAS–STING signaling. By producing NETs, neutrophils actively contribute to biliary damage and fibrosis. Targeting STING signaling and NETs may be a promising therapeutic approach to reduce inflammation and slow the progression of biliary fibrosis in PSC.

0220 | LOSS OF BILIARY ADHERENS JUNCTIONS RESULTS IN PRIMARY SCLEROSING CHOLANGITIS-LIKE CHOLESTATIC INJURY

Vik Meadows[1] Yekaterina Krutsenko[1] Chang Kyung Kim[1] Zachary Cannova[1] Hiroki Inada[1] Jia-Jun Liu[1] Shuchang Liu[1] Minakshi Poddar[1] Sucha Singh[1] Satdarshan (Paul) Monga[1], [1]University of Pittsburgh

Background: Loss of β-catenin in adherens junctions (AJ) is compensated by γ-catenin, a homologous desmosomal protein. We have shown dual loss of β- and γ-catenin in all liver epithelial cells leads to progressive intrahepatic cholestasis and high mortality indicated by cytoplasmic instead of membranous E-cadherin followed by E-cadherin degradation and loss. Here, we investigate the impact of dual catenin loss from cholangiocytes. **Methods:** We utilized Ctnnb fl/fl; Jup fl/fl mice with Opn-iCreERT2+/- to delete both β-catenin (*Ctnnb1*) and γ-catenin (*Jup*) from cholangiocytes in both male and female mice. Littermate control

with no Opn-iCreERT2+/+ were used as controls. Mice received four (DKO4) intraperitoneal injections of tamoxifen (100 mg/kg) dissolved in corn oil. DKO4 mice were sacrificed at various time points within two weeks of the first injection, with >30% body weight loss as the endpoint for serum analysis, histology, and RNA sequencing. PSC patient livers were also examined for β-catenin and E-cadherin histology. **Results:** DKO4 mice showed significant mortality associated with severe weight loss, visible jaundice, and elevated liver enzyme levels (ALT, AST, ALP) as early as 11 days after first injection compared to controls. Histologically, the earliest changes were visible at 11 days after first injection in the form of inflammation, loss of membranous E-cadherin, and increased onion skin portal fibrosis. At 14 days, DKO4 mice displayed extensive biliary infarcts and worsening inflammation and fibrosis. There was negligible bile flow through extrahepatic bile duct and india ink injection revealed bile duct paucity and interstitial leakage from intrahepatic ducts. Due to histological resemblance, we queried DKO4 for any molecular overlap with primary sclerosing cholangitis (PSC). Bulk RNAseq of DKO4 livers showed significant overlap with end-stage PSC patients, especially in the fibrotic gene signature. snRNA sequencing and transcriptional factor enrichment analysis showed DKO4 cholangiocytes and PSC patients displaying common transcriptional programs. Biopsies and explanted PSC livers showed a significant subset of cases to have decreased membranous b-catenin and E-cadherin (+/-cytoplasmic staining). **Conclusion:** The simultaneous loss of β- and γ-catenin from cholangiocytes is evident in notable subset of patients with PSC and their dual loss in cholangiocytes in mice mimic PSC like disease thus providing novel insights into the pathogenesis of this heterogenous and complex disease.

★ 0221 | MULTI-COMPARTMENT DNA METHYLATION ANALYSIS REVEALS IMMUNE AND INFLAMMATORY EPIGENETIC REMODELING IN ALCOHOL-ASSOCIATED HEPATITIS

Brandon Peiffer[1] Yongchun Wang[1] Chris Umbricht[1] Maria Parra[1] Francisco Lopez[1] Jamal Masri[1] Zhe Deng[1] Niket Harsh[1] Leslie Cope[1] Zhaoli Sun[1], [1]The Johns Hopkins School of Medicine

Background: Dysregulation of DNA methylation (DnaM) has been implicated in many human diseases; however, the role of epigenetic alterations in alcohol-associated liver disease (ALD) remains poorly understood. Although genome-wide methylation studies in alcohol use disorder (AUD) have identified clear alcohol-related changes, the role of the epigenome in the development of ALD has not been systematically studied to date. To address this gap, we analyzed DnaM profiles in alcohol-associated hepatitis (AH), alcohol-associated cirrhosis (AC), and metabolic dysfunction-associated steatohepatitis (MASH), a non-alcohol–associated chronic liver disease comparator included to distinguish alcohol-specific epigenetic alterations from shared inflammatory and fibrotic pathways. **Methods:** Liver tissue samples were collected from explanted livers obtained during transplantation from patients with AH, AC, or MASH. Tissues were either snap-frozen or enzymatically digested with collagenase to isolate non-parenchymal cells (NPCs). Peripheral blood was collected prior to transplantation, and leukocytes were isolated following red blood cell lysis. Neutrophil subsets with high or low IL8 expression were further isolated by flow cytometric sorting. Differential methylation (diffM) analyses were performed across hepatic and peripheral immune compartments. All human samples were collected from consented patients under Johns Hopkins IRB protocol IRB00107893. **Results:** Distinct DnaM signatures clearly separated AH from both AC and MASH in bulk liver and NPCs. The resulting differential methylation was disproportionately concentrated in gene enhancer regions. indicating extensive epigenetic remodeling in severe alcohol-associated liver injury. Cellular deconvolution analysis further revealed enrichment of neutrophils within the NPC compartment of AH livers relative to other disease groups. KEGG pathway analysis of transcription factors predicted to bind differentially methylated regions in AH demonstrated enrichment of pathways associated with cytokine signaling, infection, and addiction-related processes. In peripheral blood, IL8-high and IL8-low neutrophil populations exhibited markedly distinct DnaM profiles,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

including differential methylation at key CpG loci commonly used for epigenetic neutrophil identification. **Conclusion:** ALD, particularly AH, is associated with distinct and compartment-specific DNA methylation alterations characterized by enhancer hypomethylation and inflammatory epigenetic remodeling. The identification of epigenetically distinct neutrophil subsets further highlights immune heterogeneity in AH. These findings suggest that DNA methylation profiling may provide mechanistic insights into ALD pathogenesis and support development of novel biomarkers and epigenetic-targeted therapies for severe ALD.

0222 | UBC9 PHOSPHORYLATION REPROGRAMS SRC EXPRESSION THROUGH JUNB/AP-1 FEEDBACK AXIS DURING MACROPHAGE INFLAMMATORY ACTIVATION IN ALCOHOL-ASSOCIATED LIVER DISEASE

Manisha Dagar[1] Swati Chandla[1] Youngyi Lim[1] Joshua Martinez[1] Komal Ramani[2] Maria Lauda Tomasi[1], [1]Cedars Sinai Medical Center, [2]Cedars-Sinai Medical Center

Background: Alcohol-associated liver disease (ALD) is driven in part by gut-derived endotoxin, which activates Kupffer cells (KCs) and promotes inflammatory signaling via SRC kinase and NF-κB pathways. Ubiquitin-conjugating enzyme 9 (UBC9), the sole E2 enzyme for SUMOylation, regulates transcription by modifying the DNA-binding activity of nuclear factors. We previously reported that LPS decreases UBC9 levels but induces SRC-mediated phosphorylation of UBC9 at Y68, possibly compensating for UBC9 reduction and altering SUMOylation-dependent transcription. Here, we examined if UBC9 phosphorylation regulates SRC expression via a SUMO-sensitive promoter feedback mechanism. **Methods:** RAW 264.7 and THP-1 cells were used for in vitro studies, and KCs from NIAAA-fed and pair-fed mice were used to assess ALD relevance. UBC9 phosphorylation status was modeled using unphosphorylated and phosphomimetic UBC9 Y68 peptides and disrupted by CRISPR/Cas9-mediated editing. SRC expression/promoter activity, UBC9 stability, and pUBC9 interactors were assessed by RT-qPCR, western blotting, luciferase assay, cycloheximide (CHX) chase, and co-IP/mass spectrometry. **Results:** Unphosphorylated UBC9 Y68 mimetic peptide decreased SRC expression in LPS-treated RAW 264.7 and THP-1 cells, whereas the Y68 phosphomimetic peptide increased SRC expression. These opposing effects suggest that UBC9 phosphorylation status differentially regulates SRC transcription, with phosphorylated UBC9 promoting SRC upregulation. Importantly, in vivo and in vitro CRISPR/Cas9-CD68 editing of UBC9 Y68 prevented SRC induction in KCs and RAW 264.7 cells, supporting a requirement of pUBC9 in this response. CHX chase assays showed that pUBC9 remained detectable in the time course despite LPS-associated reduction of total UBC9, suggesting that the pUBC9 pool may be preferentially maintained and less susceptible to degradation. To identify transcriptional mediators linking pUBC9 to SRC regulation, we analyzed the UBC9 interactome in NIAAA KCs. JunB, an AP-1 family transcription factor and regulator of macrophage activation, strongly interacted with pUBC9, showing a 9-fold higher association in alcohol-fed compared with pair-fed control KCs. Because JunB/AP-1 promotes SRC promoter activity through an AP-1 site and JunB SUMOylation at K237 supports DNA binding, these findings identify JunB as a strong SUMO-sensitive candidate mediator linking pUBC9 to SRC promoter activation. **Conclusion:** These findings suggest that UBC9 Y68 phosphorylation acts as a switch that promotes SRC expression and stabilizes pUBC9 in macrophages. The strong pUBC9-JunB interaction supports a SRC–pUBC9–JunB/AP-1 feedback axis that may sustain macrophage inflammatory activation in ALD.

0223 | ETHANOL INDUCED HEPATOCELLULAR STEATOSIS IS A CATABOLIC LIPOPHAGY DEFECT RESULTING FROM LYSOSOME DAMAGE.

Sandhya Sen[1] Eugene Krueger[1] Carol Casey[2] Mark McNiven[3], [1]Mayo Clinic, [2]University of Nebraska Medical Center, [3]Mayo Foundation for Medical

Background: Hepatocytes accumulate lipid droplets (LDs) markedly in response to EtOH exposure by unknown mechanisms. We have recently described a process utilized by hepatocytes to degrade and catabolize their lipid stores via direct action of the lysosome (lipophagy, PNAS 2020). Thus, the functional and structural integrity of the lysosome is essential for reducing lipid stores. Our IHC staining of human AFLD/ASH patient tissues revealed an elevation of known

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

lysosome-damage/repair proteins. Therefore, the **Goal of this study** was to determine if this LD accumulation from EtOH exposure represents a catabolic defect due to lysosome damage vs increased lipid synthesis. **Methods:** Primary mouse hepatocytes (PMHs) were isolated from mice fed on a 5% ethanol diet for 10 days, along with a single ethanol binge of 5g/kg orally or control mice that were pair-fed a calorically equivalent diet. Lysosomal damage and repair were induced by either EtOH and/or the lysosome-damaging agent LLOMe. Levels of damage and repair were measured by several criteria including: a reduction of the lysosomal pH gradient, or recruitment of several known lysosome repair proteins including Galectin-3 or Alix, (Gal3-mCherry or Alix-mCherry). **Results:** PMH isolated from the ethanol-fed group exhibited a 2.5 fold LD accumulation. Cells were treated with DGAT inhibitors to attenuate nascent LD synthesis, along with incubation in low nutrient media to induce catabolism. Surprisingly, EtOH damaged cells retained 64% of their LDs under these starvation conditions compared to just 22% retained by control cells; indicating a substantial lipophagic defect. To assess whether EtOH treatment induces an accumulation of damaged lysosomes that are unable to repair, PMH from control or EtOH-fed mice were treated with LLOMe for 15 mins then allowed to recover over time. Importantly, Gal3-mCh puncta accumulation on lysosomes from the ethanol-damaged cells was 2.5 fold that of control cells. Further, these EtOH-damaged lysosomes recruited 80% less of the ESCRT protein Chmp2a than control, indicating a defective lysosomal repair process. Western blot analysis of purified lysosomes from control vs EtOH-damaged hepatocytes supported these morphological findings and revealed a more than 50% reduction of these repair proteins associated with lysosomes. **Conclusion:** Taken together, these findings indicate EtOH-induced hepatocellular steatosis is a result of defective LD catabolism and provide some of the first insights into structural damage of hepatocellular lysosomes by EtOH. This study was supported by NIAAA grant RO1AA020735 to MM and CC.

0224 | TARGETING PATHOLOGIC TNF-α SIGNALING IN ALD WITHOUT SYSTEMIC CYTOKINE BLOCKADE

Armen Petrosyan[1] Carol Casey[1] Tania Kamal[1],
[1]University of Nebraska Medical Center

Background: Clinical trials targeting TNF-α in alcohol-associated liver disease (ALD), including the TNF-α inhibitor Etanercept, failed due to severe immunosuppression and increased mortality, highlighting the need for alternative approaches. We hypothesized that alcohol exposure amplifies TNF-α signaling through two coordinated mechanisms: enhanced ATF6-dependent TNF-α production by liver macrophages and MGAT5/Galectin-3 (Gal-3)–mediated clustering of TNF-α receptor 1 (TNFR1) at the hepatocyte plasma membrane (PM). We further examined whether hydroxychloroquine (HCQ), an autophagy inhibitor that restores Golgi integrity, suppresses this pathway. **Methods:** WT and ATF6 knockout (KO) mice were subjected to chronic or chronic-plus-binge ethanol (EtOH) feeding with or without HCQ treatment. Liver tissues, Kupffer cells, and hepatocytes were analyzed by IHC, IF, lectin staining, high-resolution microscopy, Sirius Red staining, and serum cytokine/aminotransferase analysis. Also, we use human ASH samples and EtOH-treated VA-13 hepatocytes. **Results:** Both chronic and chronic-plus-binge EtOH exposure induced severe Golgi disorganization accompanied by ATF6 activation, WIPI2 and LC3B-II accumulation, MGAT5 upregulation, high-molecular-weight Gal-3 complexes, and enhanced TNFR1 stabilization at the PM (two-way ANOVA, $p < 0.01$–0.0001). Human ASH liver samples similarly demonstrated Golgi fragmentation, elevated nuclear ATF6, and increased MGAT5 expression versus normal liver (unpaired t test/Kruskal-Wallis, $p < 0.05$–-0.01). In hepatocytes, EtOH-induced MGAT5-mediated glycosylation promoted Gal-3–dependent TNFR1 retention at the PM, correlating with NF-κB activation, whereas Kupffer cells exhibited ATF6-dependent TNF-α upregulation. Consistently, serum TNF-α, IL-6, and KC/GRO levels were reduced in ATF6-deficient mice, supporting attenuation of inflammatory signaling. EtOH also induced marked Perilipin-2 accumulation and collagen deposition in WT mice, both significantly reduced in ATF6-deficient and HCQ-treated animals (two-way ANOVA, $p < 0.01$–0.0001). Combined ATF6 deficiency and HCQ produced the lowest steatotic burden, indicating cooperative roles of ATF6-dependent ER–Golgi stress and autophagy in alcohol-induced steatotic remodeling and collagen accumulation. HCQ restored compact Golgi morphology and attenuated TNFR1 stabilization and downstream inflammatory signaling without suppressing YAP1-dependent regenerative signaling in hepatocytes. Unlike Etanercept, HCQ attenuated ER/Golgi stress while avoiding intracellular TNF-α accumulation and macrophage apoptosis. **Conclusion:** Alcohol amplifies TNF-α signaling through an ATF6–Golgi stress pathway linking macrophage TNF-α overproduction with TNFR1 clustering. Targeting this pathway suppresses inflammatory and steatotic signaling while preserving regenerative pathways in ALD.

0225 | A NOVEL CIRCRNA REGULATORY AXIS DRIVING SPHINGOLIPID DYSREGULATION IN ALCOHOL-ASSOCIATED LIVER DISEASE

Hongkun Lu[1] Nan Wu[1] Grayson Way[1] Meiyi Song[1] Chen Chen[1] Derrick Zhao[1] Hui Li[1] Sareh Bayatpour[1] Lianyong Su[1] Yun-Ling Tai[1] Xuan Wang[1] Emily Gurley[1] Phillip Hylemon[2] Huiping Zhou[2], [1]Virginia Commonwealth University, [2]Virginia Commonwealth University, Stravitz-Sanyal Institute for Liver Disease and Metabolic Health

Background: Alcohol-associated liver disease (ALD) remains a leading cause of preventable liver-related mortality, yet the noncoding RNA mechanisms driving progression are incompletely defined. Circular RNAs (circRNAs) are stable regulators that shape gene networks through RNA-binding protein (RBP) and miRNA interactions. Although sphingolipid dysregulation is a feature of ALD, whether circRNAs regulate sphingolipid remodeling is unknown. **Methods:** We performed circRNA array profiling of human liver samples from patients with ALD, MASH, PSC, and healthy controls (n = 8), and parallel circRNA array profiling in the NIAAA chronic-plus-binge mouse ALD model (n = 6). These original human and mouse circRNA datasets were integrated with published transcriptomic datasets from patients with severe alcohol-associated hepatitis (GSE155907, GSE143318, GSE142530) to identify conserved circRNA-associated regulatory networks. Human liver samples were also profiled by NanoString miRNA analysis to support integrated noncoding RNA network assessment. **Results:** Human circRNA array identified hsa_circ_0056939 (circCERS6), generated from CERS6 exons 2-3, as upregulated in ALD (1.32-fold, P = 0.0002). circCERS6 was also increased in MASH (1.31-fold, P = 0.003) and PSC (1.27-fold, P = 0.003), suggesting a shared chronic liver disease response. In contrast, linear CERS6 mRNA was not significantly altered across three human ALD RNA-seq cohorts, supporting circRNA-selective regulation. Mouse circRNA array and validation confirmed alcohol-responsive upregulation of hepatic circCers6, with parallel induction of Cers6 mRNA. Integration of circRNA, miRNA, mRNA, and RBP resources prioritized a circCERS6-centered network. Seven convergent candidate circCERS6-associated RBPs were identified: FUS, HNRNPL, HNRNPM, IGF2BP2, MATR3, MOV10, and UPF1. Overlay with 32 dysregulated sphingolipid genes revealed a connected network in which MATR3, FUS, and UGCG emerged as central nodes, nominating a circCERS6-RBP-sphingolipid axis. **Conclusion:** circCERS6 is dysregulated in human ALD and alcohol-exposed mice and may act independently of host-gene transcription in severe human disease. Integrated noncoding RNA and transcriptomic modeling identifies a previously unrecognized circCERS6-MATR3-UGCG axis linking circRNA regulation to sphingolipid remodeling. These findings suggest circCERS6 as a novel candidate biomarker and mechanistic regulator of progressive liver injury in ALD and other chronic liver diseases.

0226 | AN ALCOHOL-INDUCED BILE ACID INTERMEDIATE REGULATES INTESTINAL FXR-FGF15/19 SIGNALING

Weiran Wang[1] Yantao Zhao[1] Carolina Hogerty[1] Steven Weinman[1] Wei Zhong[1], [1]University of Kansas Medical Center

Background: Bile acid homeostasis is tightly regulated through gut-liver signaling pathways. Under physiological conditions, mature bile acids activate intestinal Farnesoid X receptor (FXR), inducing FGF15/19 signaling to suppress hepatic bile acid synthesis. We previously found that alcohol-associated hepatic peroxisomal dysfunction leads to accumulation of the C27 bile acid intermediate 3a,7a,12a-trihydroxycholestanoic acid (THCA) in the intestine. In the present study, we investigated the effects of THCA on intestinal FXR-FGF15/19 signaling and bile acid homeostasis. **Methods:** Male C57BL/6J mice were administered THCA (50 mg/kg) by oral gavage for 5 days. Intestinal epithelial cells and small intestinal organoids were used to evaluate the effect of THCA on FXR-FGF15/19 signaling. FXR binding and transcriptional activity were assessed using molecular docking and FXR reporter assays. **Results:** THCA treatment significantly altered serum and hepatic bile acid compositions in mice. Hepatic expression of bile acid synthesis genes, such as *Cyp7a1*, was suppressed following THCA administration. THCA-treated mice had significantly increased ileal FGF15 at both mRNA and protein levels compared with controls. This FGF15 inducing effect was recapitulated using *in vitro* models. In mouse small intestinal organoids, THCA directly stimulated FGF15 expression. Similarly, treating human-derived Caco-2 cells with THCA for 6 and 24 h significantly increased FGF19 expression. Mechanistically, we found that FXR expression in both mouse ileal tissue and Caco-2 cells was increased after THCA exposure. Molecular docking analysis demonstrated that THCA bound FXR with binding affinity comparable to the canonical FXR agonist chenodeoxycholic acid (CDCA). FXR reporter assays further demonstrated that THCA activated FXR transcriptional activity to a degree comparable to CDCA at same concentrations. **Conclusion:** These findings identify THCA as a biologically active bile acid intermediate that functions as a potent intestinal FXR agonist and regulator of enterohepatic bile acid signaling. Our study suggests that pathological bile acid interactions generated during alcohol-induced peroxisomal dysfunction and intestinal accumulation of THCA can engage physiological bile acid sensing pathways and alter gut-liver metabolic communication. This may feedback on the liver to exacerbate ALD.

0227 | OPTIMIZING DCD PROCUREMENT INITIATION WITH INTERPRETABLE MACHINE LEARNING PREDICTION OF 60-MINUTE MORTALITY AFTER WLST

Alexander Huang[1] Julie Heimbach[1] Jenny Lam[2] Umesh Goswami[3] Travis Geraci[3] Ray Kim[3] Joseph Ahn[1], [1]Mayo Clinic Rochester, [2]Scripps Health, [3]Mayo Clinic Arizona

Background: Accurate prediction of timely progression to circulatory death after withdrawal of life-sustaining therapy (WLST) in donation after circulatory death (DCD) donors is crucial to reduce extensive resources required for donor organ recoveries and may reduce donor family distress. Prior models rely heavily on neurological examinations (brainstem reflexes and GCS score) which may not be well-documented and have examiner variability. In this study, we leverage universally available electronic health record (EHR) data to develop an interpretable machine-learning model. **Methods:** Demographic and clinical data on DCD candidates from January 2019 to August 2023 were retrospectively analyzed from our local OPO (LifeSource) prospective database. Mortality within 60 minutes of WLST was the outcome. Covariates included laboratory values, patient medications, vital signs, and patient demographics. Model development utilized gradient boost methods (GBM) as a binary mortality classifier and continuous time-to-mortality predictor, Shapely additive values for interpretation, and Denoising Diffusion Probabilistic Models for variance reduction. AUROC and Kaplan-Meier (KM) curves were utilized to assess efficacy of model predictions. **Results:** A total of 356 consecutive DCD candidates were included; with 251 (72%) having 60-minute mortality. Using laboratory values, vital signs, and medications, the final GBM model achieved AUROC = 0.75 (95% CI: [0.72-0.78]). At a high-sensitivity threshold, the model achieved NPV 96% for 60-minute mortality, identifying candidates unlikely to progress within the procurement window; at a high-specificity threshold, PPV was 84% for identifying candidates highly likely to progress. SHAP analysis identified hyperchloremia, thrombocytopenia, rising BUN, and hyponatremia as dominant predictors. Patients in the

highest-risk model quintile had 4.3% 60-minute survival vs 84% in the lowest-risk quintile (log-rank $p < 0.001$; Figure). **Conclusion:** This interpretable, EHR-based machine-learning model accurately stratifies DCD candidates for 60-minute mortality after WLST using universally available HER data, overcoming the reliance on subjective neurological examination that has limited prior models. High NPV at low-risk thresholds and high PPV at high-risk thresholds support its use as a decision-support tool to reduce futile procurement attempts. Prospective multi-OPO validation is the next step toward clinical integration.

0228 | IMPACT OF NORMOTHERMIC MACHINE PERFUSION ON TRANSPLANT ACCESS, DONOR UTILIZATION, AND THE EVOLVING ROLE OF LIVING DONOR LIVER TRANSPLANTATION: A SINGLE-CENTER EXPERIENCE

Yusuf Yalcin[1] Marwa Elmahi[1] Sarah Meade[1] Raza Malik[1] Mohamed Akoad[1], [1]Lahey Hospital and Medical Center

Background: Normothermic machine perfusion has expanded use of extended-criteria donor livers, but its broader effects on transplant access, donor utilization, and the relevance of living donor liver transplantation remain incompletely defined. We evaluated its association with waitlist outcomes, donor pool expansion, and changes in living donor liver transplantation at a single center. **Methods:** We performed a retrospective single-center study using Lahey-specific United Network for Organ Sharing waitlist and transplant data from 2016–2025, supplemented by institutional normothermic machine perfusion records. Adult liver transplant recipients ($n = 938$) and waitlisted patients with completed outcomes ($n = 1293$) were grouped into pre–normothermic machine perfusion (2016–2022) and normothermic machine perfusion era (2023–2025) for program-level era comparison. To assess direct attribution of normothermic machine perfusion, transplants performed in 2023–2025 were further analyzed by comparing recipients who received normothermic machine perfusion grafts ($n = 146$) with those who did not ($n = 198$). Living donor liver transplantation rates were examined by MELD group and primary diagnosis. **Results:** Normothermic machine perfusion adoption increased from 17.4% of transplants in 2023 to 40.6% in 2024 and 70.1% in 2025. Median waitlist time decreased from 156 days (interquartile range 33–393) to 63 days (13–285). Transplant probability increased from 69.1% to 79.4% ($p < 0.001$), while waitlist mortality decreased from 10.0% to 4.2% ($p < 0.001$). Donation after circulatory death utilization increased from 0% to 30.5%, and donors aged 70 years or older from 4.9% to 14.0%. Within the normothermic machine perfusion era, normothermic machine perfusion grafts were associated with greater donor hospital distance (288 vs 166 nautical miles) and higher donation after circulatory death utilization (55.5% vs 12.1%), consistent with expanded acceptance of marginal donors. Overall living donor liver transplantation declined from 15.3% to 4.9%, with decreases observed across all diagnosis groups and MELD strata. **Conclusion:** In this single-center experience, normothermic machine perfusion adoption was associated with substantially improved waitlist outcomes and expanded utilization of marginal donors, including donation after circulatory death, older, and more geographically distant grafts. Coinciding with these changes, living donor liver transplantation declined broadly across diagnoses and MELD groups. Whether this decline reflects a true substitution effect, and whether living donor liver transplantation retains a selective role in patients with low MELD scores and high disease burden such as primary sclerosing cholangitis and polycystic liver disease, warrants further investigation in national cohort data.

0229 | PRE-PERFUSION RISK PREDICTION MODEL FOR EARLY ALLOGRAFT DYSFUNCTION IN DCD LIVER TRANSPLANTATION WITH NORMOTHERMIC MACHINE PERFUSION

Atsushi Nishimagi[1] Almokdad Mohammad[1] Jack Avedikian[1] Adhnan Mohamed[1] Ahmed Nassar[1] Abbas Al-Kurd[1] Atsushi Yoshida[1] Marwan Abouljoud[1] Shunji Nagai[1], [1]Henry Ford Hospital

Background: Normothermic machine perfusion (NMP) has reduced the incidence of early allograft dysfunction (EAD). However, the current definition of EAD was established and validated primarily in static cold storage (SCS) cohorts, and its prognostic impact and risk profile in DCD liver transplantation (LT) using NMP remain unclear. Therefore, this study aimed to evaluate the prognostic significance of EAD in DCD LT with NMP and to develop a pre-perfusion risk prediction model for EAD. **Methods:** We conducted a single-center retrospective cohort study of adult recipients who underwent DCD LT alone between January 2016 and August 2025. Patients were divided into two groups based on the use of NMP. The primary outcome was 180-day patient survival. Logistic regression analyses were performed to identify factors associated with EAD. EAD was defined according to the standard Olthoff criteria. All NMP procedures were initiated at donor hospitals as on-site NMP. In NMP cases, cold ischemia time (CIT) was defined as the interval from aortic cross-clamp to initiation of NMP. **Results:** A total of 257 DCD LT recipients were included, of whom 164 underwent LT with NMP and 93 underwent LT without NMP. The incidence of EAD was significantly lower in the NMP group than in the non-NMP group (17.1% vs. 60.2%, $p < 0.001$). EAD was associated with significantly worse 180-day survival in the NMP group ($p = 0.003$), but not in the non-NMP group ($p = 0.53$). In multivariable logistic regression analyses stratified by NMP use, older donor age was an independent predictor of EAD in the non-NMP group, but not in the NMP group. In the NMP group, older recipient age, male donor sex, higher donor BMI, and CIT ≥ 150 minutes were identified as independent predictors of EAD. The risk prediction model incorporating these factors demonstrated good discrimination, with an area under the receiver operating characteristic curve of 0.77 (95% confidence interval, 0.67–0.87). A two-dimensional risk map incorporating recipient age and a donor risk score derived from donor BMI, donor sex, and CIT ≥ 150 minutes stratified recipients into low-risk ($< 10\%$), intermediate-risk (10–30%), and high-risk ($> 30\%$) groups based on the predicted probability of EAD. The corresponding observed EAD incidences were 4.3%, 16.9%, and 40.7%, respectively ($p < 0.001$). **Conclusion:** This study demonstrates that EAD remains an important prognostic marker in DCD LT in the NMP era and suggests that its risk profile differs from that in conventional SCS cohorts. To our knowledge, this is the first pre-perfusion risk prediction model specifically developed for EAD in DCD LT with NMP. This model may help identify high-risk cases before perfusion and support more careful postoperative graft assessment and clinical follow-up.

0230 | HEPATIC ARTERIAL THROMBOSIS AFTER LIVER TRANSPLANTATION: NATIONAL INCIDENCE, HIGH-RISK PHENOTYPES, AND NEAR-UNIVERSAL EARLY GRAFT FAILURE IN 72,037 RECIPIENTS

Sri Harsha Boppana[1] Subhash Gurappa[2] Sachin Sravan Kumar Komati[2] Gautam Maddineni[3] Raja Chandra Chakinala[4] Venkata Sunkesula[5] meghana kakarla[6] Pradeep Yarra[7], [1]Nassau University Medical Center, [2]Florida International University, [3]Creighton university, [4]Guthrie Robert Packer Hospital, [5]Case Western Reserve University, [6]infirmary health, [7]UT Health San Antonio

Background: Hepatic arterial thrombosis (HAT) is an uncommon but catastrophic vascular complication after liver transplantation (LT), with potential for rapid graft loss, retransplantation, and death. Contemporary national data defining high-risk phenotypes and post-HAT outcomes remain limited. We aimed to identify independent predictors of HAT after adult LT and quantify its association with early graft failure, retransplantation, and mortality. **Methods:** We performed a retrospective cohort study of adult primary liver-only transplant recipients in the OPTN/UNOS STAR file from March 31, 2015 to December 31, 2024, the era in which post-transplant HAT was reliably captured. HAT was defined using post-transplant follow-up reporting and/or HAT listed as a contributing cause of graft failure. Multivariable logistic regression identified independent predictors of HAT. Clinical consequences were assessed by 30-day graft failure, retransplantation, and mortality after HAT. Patient survival was visualized using Kaplan-Meier analysis stratified by HAT status. **Results:** Among 72,037 adult LT recipients, 579 developed HAT, yielding a national incidence of 0.80%. HAT was predominantly an early event, occurring at a median of 21 days post-LT; 58.0% occurred within 30 days and 71.7% within 90 days. Incidence was highest after living-donor LT (1.94%) and partial/split graft transplantation (1.86%). Independent predictors included living-donor LT (adjusted OR 2.45, 95% CI 1.68–3.59; $p < 0.001$), pre-transplant portal vein thrombosis (OR 1.54, 95% CI 1.24–1.93; $p = 0.0001$), older donor age (OR 1.01 per year; $p = 0.0009$), lower donor BMI (OR 0.97 per kg/m²; $p = 0.0001$), younger recipient age (OR 0.99 per year; $p = 0.0008$), and Asian race versus White race (OR 1.57, 95% CI 1.14–2.17; $p = 0.006$). Within 30 days of HAT, graft failure occurred in 95.9%, retransplantation in 79.8%, and death in 17.4%. Thirty-day mortality was nearly ten-fold higher after HAT compared with non-HAT recipients (17.4% vs 1.8%; RR 9.5). Kaplan-Meier analysis demonstrated marked early and sustained separation in patient survival by HAT status. (Figure 1) **Conclusion:** In this contemporary national LT cohort, HAT occurred in fewer than 1% of adult recipients but was associated with near-universal early graft failure, frequent retransplantation, and substantially higher mortality. Living-donor LT, partial/split graft use, pre-transplant portal vein thrombosis, and donor-recipient factors define a clinically recognizable high-risk phenotype. These findings support targeted perioperative risk stratification and intensified early arterial surveillance in high-risk LT recipients.

Background: Immune checkpoint inhibitors (ICIs) are emerging as a downstaging strategy for liver transplantation (LT) in patients with hepatocellular carcinoma (HCC). While a long ICI washout period reduces the risk of rejection, recent studies suggested that it may also reduce antitumor efficacy and prolonged ICI exposure may increase the risk of resistance. Herein, we aimed to evaluate factors associated with successful pathologic downstaging to Milan criteria (MC), with particular attention to ICI-related variables. **Methods:** In the International Consortium on Leveraging Immunotherapy for LT in HCC (LIFT-HCC), we included patients who received ICIs and underwent LT. To assess the combined effect of ICI washout period and exposure duration, patients were stratified into six groups based on a composite variable: $\leq$30 days/ $\leq$6 months (n = 55), $\leq$30 days/ > 6 months (n = 19), 31-90 days/ $\leq$6 months (n = 95), 31-90 days/ > 6 months (n = 50), > 90 days/ $\leq$6 months (n = 106), and > 90 days/ > 6 months (n = 73). Among patients beyond MC at ICI initiation, logistic regression was performed to identify factors associated with successful pathologic downstaging to MC. **Results:** A total of 412 patients from 15 countries were included (mean age [SD], 54 [10] years; 91% male; 75% Child-Pugh A at ICI start). Median (IQR) ICI washout duration was 74 (38-169) days, and 36% had ICI exposure > 6 months. Locoregional therapy (LRT) was used in 91%, with 36% receiving LRT only before ICI. Overall, 23% were within MC on imaging at ICI start, increasing to 45% on explant pathology. During a median follow-up of 20.8 months (95% CI, 18.4-25.2), 19% experienced rejection, 26% recurrence, and 20% died. The $\leq$30 days washout and > 6 months ICI exposure group had the highest pathologic complete response rate (36.8%), with low recurrence (5.3%) but the highest rejection rate (31.6%). ICI treatment for 6 months or longer is associated with a higher likelihood of pathologic downstaging with minimal increase in the risk of rejection while ICI washout periods of > 90 days provided the best balance between low rejection and low recurrence rates (**Figure**). In multivariable analysis, with $\leq$30 days/ < 6 months as a reference group, both $\leq$30 days/ > 6 months (OR: 5.05; 95%CI: 1.02-25.04) and 31-90 days/ > 6 months (6.9; 1.68-28.40) were significantly associated with successful pathologic downstaging to MC, while > 90 days/ $\leq$6 months (3.03; 0.94-9.77) showed a borderline association. Treatment in China (0.19; 0.08-0.44), number of lesions (0.80; 0.66-0.97), Child-Pugh class B/C (0.38; 0.17-0.85), and concurrent or post-ICI LRT (2.12; 1.04-4.33) were independent predictors of downstaging to MC on explant. **Conclusion:** Balancing ICI washout period and exposure duration may help optimize the tradeoff between antitumor activity and rejection risk. Preserved liver function and concurrent or post-ICI LRT improve the chance of pathologic downstaging on explant.

Figure. Association of Immune Checkpoint Inhibitor Washout Period and Exposure Duration with Rejection (Panel A), Recurrence (Panel B), and Pathological Complete Response (Panel C) Rates
Patients were categorized into six groups according to ICI washout period (≤30 days, 31-90 days, and >90 days) and ICI exposure duration (≤6 months vs >6 months). Stacked bar plots show the percentage of outcomes within each washout-exposure category.

The category with ≤30 days of washout and >6 months of ICI exposure had the highest rejection rate, but also the highest pathological complete response rate, along with a low recurrence rate. Washout periods of ≤30 days were associated with the highest rejection rates (>25%) regardless of ICI exposure duration. Washout periods of 31-90 days showed the highest recurrence rates. Overall, ICI washout periods of >90 days provided the best balance between low rejection and low recurrence rates (both around 20%). Within the >90-day washout group, ICI exposure duration >6 months was associated with a higher pathological complete response rate, although with a slightly higher rejection rate.

Abbreviations: ICI, immune checkpoint inhibitor; d, day; mo, month

★ 0232 | TAURINE ATTENUATES SENESCENCE IN AGED LIVERS DURING NORMOTHERMIC MACHINE PERFUSION

Jianjun Zhu[1] Zhicong Zhao[1] Mingxi Zhang[1] Lei Xia[1] Qiang Xia[1], [1]Renji Hospital, Shanghai Jiaotong University

Background: Aged donor livers are increasingly used in transplantation but remain highly susceptible to steatosis, metabolic dysfunction, and ischemia-reperfusion injury. We investigated whether taurine supplementation during normothermic machine perfusion (NMP) could improve ex vivo functional recovery and attenuate senescence-associated injury in aged rat livers. **Methods:** Metabolomic profiling was performed in young and aged rat blood and liver tissues. Livers from 24-month-old rats were procured and subjected to ex vivo perfusion under three conditions: control perfusion, young-blood perfusion, and taurine-supplemented perfusion. Functional assessment included bile production, lactate clearance, perfusion pressure, perfusion flow, and perfusate injury markers. Histologic and senescence-related changes were evaluated by hematoxylin-eosin staining, RT-qPCR, western blotting, immunofluorescence, and SA-β-gal staining. A doxorubicin-induced senescent HepG2 model was used for in vitro validation. RNA sequencing and KEGG pathway enrichment analysis were performed to explore potential mechanisms. **Results:** Compared with young livers, aged livers showed reduced taurine-associated metabolism. During NMP, taurine supplementation increased bile production, accelerated lactate clearance to below 2.5 mmol/L within 2 hours, lowered perfusion pressure, and increased perfusion flow, indicating improved metabolic recovery and more stable microcirculation. Taurine-treated livers also showed lower perfusate liver enzyme levels than control and young-blood groups, together with histologic improvement in age-related fatty change. Senescence markers were markedly reduced after taurine treatment. At 6 hours of perfusion, p16INK4a expression decreased by approximately 70% and p21 by approximately 50%, whereas the corresponding reductions in the young-blood group were approximately 30%. Western blot findings were concordant. Immunofluorescence demonstrated decreased Bcl-2 and p53 expression, and SA-β-gal positivity declined over time. In senescent HepG2 cells, taurine similarly reversed p16INK4a and p21 upregulation. Transcriptomic analysis further suggested enrichment of autophagy, FOXO, and apoptosis-related pathways after taurine treatment. **Conclusion:** Taurine supplementation during NMP improves ex vivo functional recovery and attenuates senescence-associated injury in aged rat livers. These protective effects may be related to metabolic remodeling and activation of autophagy- and stress-response pathways. Taurine may represent a feasible strategy to improve the quality of aged donor livers.

Background: Clinically significant portal hypertension (CSPH) defines the hemodynamic threshold for hepatic decompensation in patients with compensated advanced chronic liver disease (cACLD). While the gold standard remains the hepatic venous pressure gradient (HVPG) measurement, noninvasive tests (NITs) are increasingly used for the diagnosis of CSPH. The VCTE-based models ANTICIPATE ± NASH (liver stiffness, platelet count ± BMI) and NICER (liver & spleen stiffness, platelet count, BMI) offer well-calibrated individual CSPH risk estimates. Baveno VIII recommends an ANTICIPATE ± NASH or NICER threshold of 75% for ruling-in CSPH. The present study provides the evidence supporting the NICER 75%-threshold and a comparison to other diagnostic criteria for CSPH. **Methods:** Four hundred and forty-seven patients were included in this retrospective multicenter study from 16 European expert centers. Paired HVPG measurement, laboratory testing and NITs were performed between 2020 and 2024. Diagnostic performance of CSPH probability was evaluated by sensitivity, specificity, NPV, PPV, LR+ and LR-. Reduction of the Baveno VII grey/indeterminate zone was assessed by sequential application of the $\geq$75% CSPH probability cutoff of the NICER model in patients who remained unclassified after evaluation according to the Baveno VII criteria (rule out: LSM $\leq$15kPa, PLT $\geq 150 \times 10^9$/L; rule in: LSM $\geq$25kPa). **Results:** The prevalence of CSPH according to the HVPG was 60.6%, the median age was 60 years, 67.8% were male and 37.8% were obese. Using the cutoff of $\geq$75%, the NICER model classified more patients as positive than the ANTICIPATE ± NASH model (47.7% vs. 37.6%). In addition, NICER achieved greater sensitivity (69.4% vs. 53.1%) with a similar level of specificity (85.8% vs. 86.4%), resulting in a lower false-negative rate for missed CSPH cases. Sequential application of Baveno VII criteria followed by NICER $\geq$75% reduced the proportion of unclassified patients from 49.0% to 32.4%. **Conclusion:** The inclusion of spleen stiffness enables NICER $\geq$75% to correctly classify more patients with CSPH than ANTICIPATE ± NASH $\geq$75%, while further decreasing the intermediate-risk area following sequential application of the Baveno VII criteria.

0235 | NON-INVASIVE DIAGNOSIS OF CLINICALLY SIGNIFICANT PORTAL HYPERTENSION USING MACHINE LEARNING MODEL BASED ON VASOMICS PLATFORM: A DEVELOPMENT AND VALIDATION STUDY

Ling Yang[1] Jiang Bai[1] Yi Xiang[2] Xiaolin Wang[2] Jiawei Zhang[2] Deqiang Ma[3] Zhenyu Dai[4] Dazhi Chen[5] Halim Bou Daher[6] Yanna Liu[7] Chuan Liu[2] Shanghao Liu[2] Yueming Lu[2] Yechong Huang[8] Tianyu Liu[9] He Zhu[10] Huiling Xiang[11] Deping Ding[3] Jie Liu[9] Chunlong Li[4] Wei Chen[12] Wei Wang[10] Sen Luo[3] Qianlong Li[4] Shoufang Dai[12] Lijun Peng[13] Haijian Guo[14] Wenjing Liu[15] Muqing Lin[16] Huajie Yu[16] Rui Hu[16] Juan Yuan[16] Wei Zhang[17] Haiyu Wang[18] Shaoting Zhang[8] Chengyan Wang[19] Don Rockey[20] Xiaolong Qi[2], [1]Zhongda Hospital, Medical School, Southeast University, [2]Zhongda Hospital, School of Medicine, Southeast University, [3]Taihe Hospital, Hubei University of Medicine, [4]Yancheng Third People's Hospital, [5]People's Hospital of Ningxia Hui Autonomous Region, [6]Saint Louis University School of Medicine, [7]Beijing Youan Hospital, Capital Medical University, [8]SenseTime Research, [9]Suining Central Hospital, [10]The Sixth People's Hospital of Shenyang, [11]Tianjin Third Central Hospital, [12]Xingtai People's Hospital, [13]Peking University People's Hospital Qingdao Hospital, [14]Jiangsu Provincial Center for Diseases Control and Prevention, [15]MEI Medical Technologies Co., Ltd., [16]Shenzhen Mindray Bio-medical Electronics Co., Ltd., [17]The Third Affiliated Hospital of Sun Yat-sen University, [18]Nanfang Hospital, Southern Medical University, [19]Shanghai Pudong Hospital and Human Phenome Institute, Fudan University, [20]Digestive Disease Research Center, Medical University of South Carolina

Background: Clinically significant portal hypertension (CSPH) is a critical prognostic determinant in chronic liver disease, yet its gold standard diagnosis via hepatic venous pressure gradient (HVPG) measurement remains invasive and limited in availability. This study aimed to develop and validate an interpretable machine learning model for non-invasive CSPH diagnosis using computed tomography (CT)-derived vasomics features. **Methods:** This multicenter retrospective study enrolled adults who underwent HVPG measurement and contrast-enhanced abdominal CT within two weeks from ten hospitals in China and the United States between November 2018 and September 2023. An automated platform extracted 64 quantitative geometric features from four key vessels (portal vein, hepatic vein, aorta, and inferior vena cava) based on vasomics three-dimensional segmentation. Routine blood biomarkers were also collected and analyzed. Feature selection was performed using least absolute shrinkage and selection operator (LASSO) regression, and multiple machine learning algorithms were evaluated. Model performance was assessed via internal bootstrap validation and external validation on a temporally and geographically independent cohort. **Results:** Among 210 included patients (median age 54 years, 64% male), 148 (70.5%) had CSPH. LASSO regression identified seven vascular geometric features reflecting distinct aspects of portal hypertensive remodeling, while all blood biomarkers were eliminated due to coefficient shrinkage. Among ten machine learning algorithms, the Adaptive Boosting (AdaBoost) model performed best for CSPH prediction, with training AUC of 0.963 (95% CI: 0.935–0.991), bootstrap-corrected AUC of 0.847 (95% CI: 0.780–0.900), and external validation AUC of 0.867 (95% CI: 0.771–0.962). At the optimal threshold, the model achieved sensitivity of 0.92 and accuracy of 0.84. Decision curve analysis and clinical impact curves confirmed clinical utility and favorable risk stratification, with well-calibrated predictions (Figure 1). Shapley Additive exPlanations (SHAP) analysis identified venous remodeling features, particularly main branch length of the inferior vena cava and portal vein, as the strongest predictors. A web application was developed using the R Shiny framework to enable CSPH risk prediction based on user-input vascular characteristics: https: //csph-prediction.shinyapps.io/publish/. **Conclusion:** We developed and validated a machine learning model based on vasomics platform that accurately diagnoses CSPH from routine CT imaging. With robust performance and good generalizability, this interpretable non-invasive approach has the potential to improve clinical decision-making and reduce reliance on invasive measurement.

0236 | UPPER ENDOSCOPY, NSBB USE, AND VARICEAL HEMORRHAGE ACROSS BAVENO ERAS IN ALBERTA: A POPULATION-BASED STUDY

Abdel-Aziz Shaheen[1] Mark Swain[1] Jason Jiang[2] Juan Abraldes[3], [1]University of Calgary, [2]Alberta Health Services, [3]University of Alberta

Background: Baveno VI/VII recommendations have encouraged selective endoscopic screening and broader nonselective beta-blocker (NSBB) use in compensated cirrhosis with suspected clinically significant portal hypertension (CSPH). Their effect on real-world upper endoscopy (EGD), endoscopic therapy, NSBB uptake, and variceal hemorrhage is unknown. **Methods:** We performed a population-based Alberta cohort study of adults with compensated cirrhosis identified from administrative data from 2012-2025. Full-cohort rates of EGD, banding/sclerotherapy and active NSBB use were calculated per 1,000 person-years and as annual proportions of alive at-risk patients. A compensated inception cohort excluded patients with decompensation within 365 days of index diagnosis and those with EGD within 7 days. Patients were assigned to Pre-Baveno VI (2012-2014), Baveno VI (2015-2020), or Baveno VII (2021-2023). Joinpoint regression evaluated temporal changes in 1-year EGD, 1-year NSBB initiation, and 3-year variceal hemorrhage. Cox models estimated hemorrhage risk by era, adjusted for sex, Charlson comorbidity, and alcohol etiology. Platelet-stratified analyses at PLT $<150\times 10^9$/L as a Baveno VI surrogate. **Results:** The full cohort included 32,570 patients. EGD and banding/sclerotherapy rates decreased markedly from 2013-2024, while NSBB use increased in contemporary years. The inception cohort included 7,507 patients: 2,280 Pre-Baveno VI, 3,953 Baveno VI, and 1,274 Baveno VII; 4,558 (60.7%) had alcohol-related cirrhosis. EGD use declined gradually without a significant joinpoint ($p=0.26$). NSBB initiation had a significant joinpoint at 2017 ($p=0.003$), changing from -2.4% annually before the joinpoint (95% CI -16.9% to 14.6%) to +39.6% annually after it (24.3% to 56.7%). Variceal hemorrhage had a joinpoint at 2015 ($p=0.001$), changing from -31.1% annually (-48.5% to -7.9%) to +12.6% annually (3.9% to 22.0%). EGD rates remained stable in alcohol-related cirrhosis (24.4% to 23.2%; $p=0.52$) but had a non-statistically significant decline in non-alcohol cirrhosis (25.1% to 18.8%; $p=0.07$). In the Baveno VII era, among patients with PLT ≥ 150, EGD use was 20.3% in alcohol vs 15.8% in non-alcohol related cirrhosis ($p=0.13$). Alcohol etiology independently predicted variceal hemorrhage (HR 1.71, 1.45–2.02; $p<0.001$). **Conclusion:** Across Baveno eras, Alberta shifted from endoscopic toward NSBB-based portal hypertension care. Our findings highlights incomplete risk-concordant implementation for EGD and NSBB delivery, especially in alcohol-related cirrhosis.

★ 0237 | UPDATED SURGICAL RISK ASSESSMENT IN PATIENTS WITH CIRRHOSIS

Christina Liava[1] Toby Weingarten[2] Moira Hilscher[2] Patrick Kamath[2], [1]MAYO CLINIC, ROCHESTER, MN, [2]Mayo Clinic College of Medicine and Science, Rochester, Minnesota

Background: Postoperative mortality trends in patients with cirrhosis have not been thoroughly assessed following the optimization and implementation of minimally invasive surgical techniques. We aimed to 1) determine the postoperative mortality rates in cirrhotic patients using updated data and 2) generate a prediction model for postoperative mortality risk that best stratifies cirrhotic patients as low- and high-risk surgical candidates. **Methods:** We conducted a single-center retrospective cohort study identifying 3,559 patients ($\geq$18 years old) with cirrhosis who underwent surgery at Mayo Clinic in Rochester, MN, between 2008 and 2023. Cirrhosis was defined by a combination of laboratory tests, imaging, and portal hypertension, or by histology. Pre-operative and operative variables with P values < 0.2 in univariate analysis were included in a forward stepwise multivariate Cox proportional hazards regression model to identify independent predictors of 30-, 90-, and 180-day postoperative mortality. These predictors were used to generate the predictive model, and subsequently, internal validation was performed. The model's discriminatory capacity was compared to the Mayo Risk Score (MRS), Veterans Outcomes and Costs Associated with Liver Disease (VOCAL)-Penn, MELD, MELD-Na, and MELD 3.0 scores. **Results:** Among the enrolled cirrhotic patients, the majority were males (56.9%) with a median age of 62 (18-97) years. The most prevalent cirrhosis etiology was alcohol-related liver disease (39%). Based on the type of surgery, the median MELD score values differed significantly [upper abdominal: 10 (6-43); neurosurgery: 7 (6-43); trauma: 12 (6-36); orthopedic: 9 (6-40); cardiovascular: 12 (6-34); head/neck/skin: 9 (6-34); and lower abdominal: 7 (6-27), $P < 0.001$]. Over half of the underweight or normal-weight patients had ascites (63.2%). At 30, 90, and 180 days, the mortality rates were 5.8%, 9.4%, and 12.3%, respectively. A predictive model that included age, underweight/normal weight, diuretic treatment, serum albumin levels, platelet count, MELD score, American Society of Anesthesiologists (ASA) classification, emergency status, and surgery type demonstrated excellent discrimination and was significantly superior to the other scores ($P < 0.005$, Figure 1A-C). On internal validation, the model exhibited excellent performance and was significantly superior to the other scores at 30 and 90 days ($P < 0.005$), while at 180 days it maintained its superiority over MRS, MELD 3.0, MELD, and MELD-Na ($P < 0.005$) and was slightly different from the VOCAL-Penn score ($P = 0.069$, Figure 1D-F). **Conclusion:** A model utilizing 8 independent clinical characteristics may be used to stratify cirrhotic patients as low- and high-risk surgical candidates. Cirrhotic patients with a predicted mortality of $\geq$ 5% at 30 days, $\geq$ 10% at 90 days, and $\geq$ 14.7% at 180 days were classified as high-risk with a sensitivity of 84-85% and specificity of 60-65%.

0238 | HAEMODYNAMIC RESPONSE TO CARVEDILOL AFTER ACUTE VARICEAL BLEED : THE "STOP BLEED STUDY" - A PROSPECTIVE DERIVATION STUDY

Harsh Tevethia[1] Aditya Chaturvedi[2] Akhil Deshmukh[3] Ibrar Ahmed[2] Ankur Jindal[2] Manoj Sharma[4] Esha Baidiya Kayal[2] Guresh Kumar[2] Shiv Kumar Sarin[2], [1]INSTITUTE OF LIVER AND BILIARY SCIENCES (ILBS),NEW DELHI, [2]ILBS, [3]Aster hospitals, [4]Institute of Liver and Biliary Sciences

Background: Hepatic venous pressure gradient (HVPG) is the gold standard to assess beta-blocker response after acute variceal bleeding (AVB), but is invasive and requires to be repeated at six weeks. Whether spleen and liver stiffness measurements (SSM, LSM) can serve as non-invasive surrogates for HVPG as well as classify responders early, is not well studied. **Methods:** This was a prospective single-centre derivation study conducted between.Altogether 244 Child-Pugh A/B patients were enrolled after index AVB and treated with carvedilol. 220 patients completed paired HVPG, SSM and LSM assessment at baseline and week 3 and 6. The primary outcome was diagnostic accuracy of serial SSM/LSM for 6-week HVPG response ($\geq$20% reduction from baseline or HVPG $\leq$12 mmHg) at 6 weeks whereas secondary objectives included 90-day rebleeding, liver-related events,. A two-marker nomogram(Score = 2×ΔSSM_6 + ΔLSM_6, in kPa) was built by multivariable logistic regression and validated by 1,000-resample bootstrap with optimism correction. **Results:** Overall 220 cirrhosis patients [mean age 50.2 ± 11.1 years, males (91.8%), mean baseline HVPG 18.8 ± 2.3 mmHg, mean MELD 15.1 ± 2.7] with predominant etiology being alcohol (41.4%) and MASLD (39.3%), completed per protocol analysis and were analysed.. HVPG response was seen in 86/220 (39.1%) patients. ΔSSM reduction correlated with ΔHVPG reduction (week 6 $r = 0.50$, week 3 $r = 0.38$; both $p < 0.001$). In multivariable regression, both ΔSSM_6 [OR 1.25 (95% CI 1.18–1.33), $p < 0.001$]and ΔLSM_6 (OR 1.11 (95% CI 1.07–1.15), $p < 0.001$) were independent predictors of HVPG response.For individual markers at week 6, ΔSSM AUROC was 0.88 (95% CI 0.84–0.93) and ΔLSM AUROC was 0.85 (0.80–0.90) and at week 3, ΔSSM AUROC was 0.82 (0.75–0.87) and ΔLSM AUROC was 0.76 (0.69–0.82). ΔSSM predicted response at both time points: $\geq$3 kPa at week 3 (sensitivity 77.9%, specificity 79.1%) and $\geq$5 kPa at week 6 (sensitivity 87.2%, specificity 76.1%) whereas ΔLSM change of $\geq$1 kPa at week 6 (sensitivity 76.7%, specificity 82.8%) predicted response. The two-marker nomogram combining week-6 ΔSSM and ΔLSM achieved bootstrap-corrected AUROC 0.90 (95% CI 0.86–0.94). A Score $\geq$10 at week 6 identified responders with sensitivity 87.2% and specificity 79.1% with PPV 72.8% and NPV 90.6%. At 90 days, ITT rebleeding was seen in 48/ 244 (19.7%) (8.0% responders vs 26.3% non-responders, $p < 0.001$) and liver-related events were seen in 36/ 244 (14.8%) (4.5% responders vs 20.5% non-responders, $p < 0.001$) patients. **Conclusion:** A simple two-marker nomogram score of $\geq$10 combining week-6 ΔSSM and ΔLSM is highly sensitive and specific for predicting carvedilol-induced HVPG response after AVB. The score non-invasively and reliably segregates carvedilol non-responders for alternative interventions to prevent rebleed.

0239 | UTILITY OF ENDOSCOPIC ULTRASOUND GUIDED PRESSURE MEASUREMENT IN ASSESSING FONTAN-ASSOCIATED LIVER DISEASE SEVERITY

Jordan Sack[1] Marvin Ryou[1] Thomas Wang[1] David Papke[1] Michelle Gurvitz[2] Fred Wu[2] Stephen Zucker[1], [1]Brigham and Women's Hospital, [2]Boston Children's Hospital

Background: There presently are no tests that reliably predict the severity of Fontan-associated liver disease (FALD). We explored whether the portal pressure gradient (PPG) measured using an endoscopic ultrasound (EUS)-guided transgastric approach correlates with liver events in patients with FALD. **Methods:** We directly measured hepatic and portal vein pressures in a cohort of 83 adult patients with Fontan circulation using an EUS-guided approach. The correlation of the PPG with liver events (ascites, hepatic encephalopathy, variceal hemorrhage, hepatocellular carcinoma) was assessed and compared with other standard measures of liver disease severity, including esophageal varices, vibration-controlled transient elastography, imaging, histology, and balloon occlusion transvenous hepatic venous pressure gradient (HVPG). **Results:** The majority of patients (89.2%) underwent EUS as an outpatient, with two mild adverse events. The mean PPG was 1.4 ± 0.9 mmHg. Liver events occurred in 7 (8.4%) patients (ascites: 4, hepatic encephalopathy: 2, and hepatocellular carcinoma: 1. PPG was significantly higher in patients who experienced a liver event (3.3 ± 0.8 v 1.3 ± 0.8 mmHg, $p < 0.0001$), **Figure A**. The odds of a liver event increased 5.6-fold for every 1 mmHg increase in PPG (95% CI 1.8-16.8, $p = 0.002$). PPG had a strong ability to discriminate liver events (AUC 0.979; $p < 0.001$), **Figure B**. Liver transplant free survival was significantly higher among patients with PPG less than 2.5 mmHg (log rank $p < 0.001$), **Figure C**. No other liver assessment tool provided independent predictive value beyond the PPG. While there was no association of esophageal varices with liver events ($p = 0.48$) or PPG ($p = 0.09$), those with distal esophageal varices had higher PPG ($p = 0.006$). There was no correlation of liver imaging or liver stiffness with liver events ($p = 0.28$, $p = 0.57$) or PPG ($p = 0.57$, $p = 0.39$), respectively. In the sub-set of patients with available liver histology, the presence of advanced hepatic fibrosis was not significantly associated with a liver event ($p = 0.11$). When all stages of hepatic fibrosis were considered, there was a linear correlation ($p = 0.049$) between higher PPG and increasing liver fibrosis; however, hepatic fibrosis stage had modest discriminatory ability for liver events. While there was generally good correlation between HVPG and PPG, HVPG significantly underestimated PPG in patients who experienced liver events (1.3 v 3.3 mmHg, $p = 0.02$), **Figure D**. **Conclusion:** PPG outperforms HVPG and other standard measures of liver disease severity in identifying adult Fontan patients experiencing liver events.

Background: Bile duct injury frequently coexists with, or evolves, in pediatric autoimmune hepatitis and is associated with worse prognosis. MRCP-based diagnosis of cholangiopathy is limited by interreader variability. We evaluated non-invasive tests for detection of large-duct disease, fibrosis progression, and prediction of liver outcomes in pediatric-onset autoimmune liver disease (AILD). **Methods:** Fifty-seven patients with AILD (median age 16 [IQR 14–18], disease duration 1 [0–3] year, 54% male, clinical diagnosis: 46% with AIH, 54% with PSC or PSC/AIH overlap syndrome) underwent multi-modal MRI including MRCP and MR elastography (MRE). Two blinded radiologists assessed PSC features, severity of intra- (grade 0–3) and extrahepatic (0–4) large duct disease (Majoie classification), and fibrosis signs (cirrhotic dysmorphology, varices, ascites, splenomegaly. MRCP+ (25 quantitative measures) and corrected (c) T1 mapping as readout for liver heterogeneity were obtained. Plasma bile acids (BA) were measured by mass spectrometry; 80 cytokines/chemokines were quantified by Luminex. **Results:** Radiologists identified PSC features in 27/57 (47%), advanced duct disease (Majoie sum score > 2) in 20/57 (35%), and advanced fibrosis in 12/57 (21%); 10 (17%) experienced endpoints of hepatic decompensation (liver transplant, variceal bleeding, ascites, or hepatic encephalopathy). Compared with age-matched, healthy controls (n = 10), most primary and secondary BA species were elevated in AILD. BA differences between PSC and non-duct AILD were limited; however, advanced duct disease showed higher total cholic acid and glycocholic acid. Highest plasma BA levels occurred prior to decompensation. Cytokines/chemokines were reduced in PSC vs AIH, notably the potent chemokine MCP1 (CCL2), and cleaved cytokine receptors, TNFRII and IL2R, whereas advanced fibrosis associated with broader immune activation. No plasma BA or routine laboratory tests (GGT, ALP) specifically identified PSC; decreased CD30 and MCP1 yielded AUC > 0.7. Quantitative MRCP+ metrics (e.g., maximal duct dilation, total duct length, biliary tree volume) achieved AUC > 0.8 for PSC diagnosis. Total taurine-conjugated (T)BA, TCDCA, APRI, cT1 IQR, and liver stiffness by MRE predicted future liver events (AUC > 0.91). LASSO regression analysis showed best PSC discrimination using plasma TDCA and G-T ratio with SCF cytokine and MRCP+ metrics; adding circulating markers did not improve imaging-based prediction of hepatic decompensation. **Conclusion:** Quantitative MRCP+ measures outperform circulating biomarkers for detecting PSC cholangiopathy in pediatric AILD. APRI, TBA, and MRE/ cT1 IQR accurately predict fibrosis progression and clinical outcomes. Most cytokines reflect fibrosis rather than ductal disease.

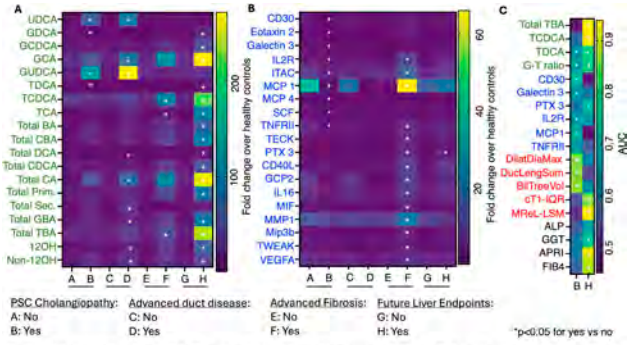

Fig 1. Fold change in plasma BA (**A**) and cytokine/chemokine concentrations (**B**) in patients with AILD relative to the mean of 10 healthy controls. Significant differences by presence of PSC cholangiopathy, advanced duct disease, advanced radiographic fibrosis, or future liver endpoints are indicated (*). (C) Area under the curve (AUC) for plasma BA, cytokines/chemokines, quantitative MRCP+ metrics, cT1 IQR, MRE–derived liver stiffness, and standard laboratory tests in discriminating large duct disease and predicting liver endpoints.

0241 | *UCA1* LONG NONCODING RNA IN CISPLATIN RESISTANT HEPATOBLASTOMA

Maryam Shaikh[1] Morgan Brown[1] Mehreen Aftab[2] Nazia Nazam[1] Pranava Nande[1] Ali Eakes[1] Abdulraheem Kaimari[1] Joel Opara[1] Elizabeth Beierle[1], [1]University of Alabama at Birmingham, [2]Jamia Hamdard

Background: Hepatoblastoma is the most common primary liver cancer in children. Surgery and platin-based chemotherapy are the mainstays of treatment, but children with recurrent disease are challenging to treat due to chemoresistance. Treatment regimens for these children are ineffective, and often result in severe long-term effects including deafness, nephrotoxicity, and cardiotoxicity, making this cohort of children the one most in need of innovative and novel therapeutics. Long noncoding RNAs (lncRNAs), have been identified as indispensable regulators in a variety of oncogenic or tumor suppressor functions, and may offer enhanced therapeutic potential compared to protein coding genes. Urothelial carcinoma associated 1 (*UCA1)*

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

lncRNA has been implicated in chemoresistance and metastasis in other malignancies, but its contribution to these processes in hepatoblastoma has not been investigated. This study investigates the role of lncRNA, *UCA1*, in chemotherapy resistance of hepatoblastoma tumor cells. **Methods:** A cisplatin resistant human hepatoblastoma cell line, HLM_2, was established by serial tail vein injections of HuH6 hepatoblastoma cell line in mice, followed by dissociation of metastatic pulmonary lesions. Murine tumor models were established by orthotopic injection of HuH6 or HLM_2 cells in the liver of NOD-SCID mice. Patient derived xenograft (PDX) models established from a metastatic hepatoblastoma patient were propagated in athymic nude mice. RNA sequencing and analysis of HLM_2 and HuH6 cells was performed. Real-time quantitative PCR confirmed the expression of *UCA1* in tumor cells and tissues. siRNA silencing of *UCA1* was performed to investigate the role of *UCA1* regulated chemoresistance mechanisms in HLM_2 cells by clonogenic assays, flow cytometry, and immunoblotting. **Results:** RNA sequence data of cisplatin resistant HLM_2 compared to parent HuH6 cells revealed significant upregulation of lncRNA *UCA1* in the HLM_2 cells. *UCA1* was also significantly upregulated in patient derived xenografts relative to normal liver controls. siRNA silencing of *UCA1* reduced clonogenicity and promoted cisplatin-induced apoptosis in HLM_2 cells. Immunoblotting revealed that siRNA mediated silencing of *UCA1* decreased Akt phosphorylation, while increasing PTEN expression, both in the presence and absence of cisplatin treatment. **Conclusion:** This study shows that upregulated transcript levels of *UCA1* is associated with cisplatin resistance in hepatoblastoma cells potentially through the activation of the Akt pathway, indicating treatments targeting *UCA1* may provide meaningful therapeutic strategies for cisplatin resistance hepatoblastoma patients.

Lurie Children's Hospital of Chicago, [24]UPMC Children's Hospital of Pittsburgh

Background: Activated T-cell pediatric acute liver failure (TC-PALF) is the most common cause of liver failure in children in North America. Work from the PALF Immune Response Network (PALF-IRN) described two distinct disease endotypes that differ by their CD8+ T-cell Perforin1 (Prf) expression: TC-PALF High Prf and TC-PALF Normal Prf (TC-PALF NL Prf). TC-PALF High Prf patients have a unique CD8 T-cell population with a transcriptional program similar to tissue effector resident memory cell (CD8 Trm) despite being in peripheral blood. However, how these endotypes evolve longitudinally is unknown. We hypothesized that CD8Trms differentiate stable TC-PALF endotypes that persist over time. **Methods:** Peripheral blood mononuclear cells samples from day 1, 21 (transplant free survival patients), and liver transplant (Tx) from patients enrolled in the PALF-IRN clinical trial, TReatment for ImmUne Mediated PathopHysiology (TRIUMPH) (NCT04862221) were utilized. Standard 10x GEM-Ex 5' single cell RNA sequencing was performed and analyzed using standard pipelines included in Seurat. Healthy control samples were integrated from a local database. Investigators remain blinded to patient study treatment arm, which included 3 arms: equine anti-thymocyte globulin, methylprednisolone or supportive care. Statistical analysis was performed using R studio 4.4.0. **Results:** Healthy controls (n = 5), indeterminate-PALF (iPALF) (n = 3), TC-PALF High Prf (n = 13), and TC-PALF NL Prf (n = 4) were compared. CD8 High Prf cells (*CD3e+,*

CD8a+, CD4-, NCAM1-, PRF1 > 3 Log_2 FC, *GZMB* > 3 Log_2 FC) and CD8 Trm cells (*CD3e+ CD8+ CD4- NCAM1- ITGAE+ CD38+ RUNX3+ PRDM1+IFNG+*) persisted at day 21 (D21) and at Tx in the High Prf group and remained absent over time in Healthy, iPALF and TC-PALF NL Prf except for one patient (Fig. 1A). To determine if CD8Trms change functionally over time, we compared differentially expressed Trm genes between D1 and D21 in High Prf patients. D21 Trms demonstrate a transcriptional program of exhaustion, including upregulation of SMARCA2, KLRG1 and NR4A2, and downregulation of GZMB, RUNX2 and CXCR3 (Fig. 1B). **Conclusion:** A CD8 Trm population persists in peripheral blood of patients with TC-PALF High Prf during recovery (D21) and at Tx. This supports the hypothesis that CD8 Trm cells in peripheral blood are a marker of a distinct endotype, rather than simply reflecting where a patient is in the disease's natural course. CD8 Trms appear transcriptionally more exhausted at D21 consistent with a model of excessive antigen stimulation in High Prf patients. Validation of these markers by flow cytometry could provide a useful minimally invasive tool to diagnose these different endotypes clinically for precision medicine approaches for these patients.

0243 | OUTCOMES BENCHMARKS IN PEDIATRIC AUTOIMMUNE LIVER DISEASE: A FOUNDATION AND A CHALLENGE FOR IMPROVEMENT FROM THE AUTOIMMUNE LIVER DISEASE NETWORK FOR KIDS (A-LINK)

Amy Taylor[1] Cyd Castro-Rojas[1] Karan Mudaliar[1] Mary Bauer[1] Catharine Whitacre[1] Mosab Alquraish[1] Mary Ayers[2] Nanda Kerkar[3] Sakil Kulkarni[4] Sindhu Pandurangi[5] Katelyn Saarela[6] Kyla Tolliver[7] Alexander Weymann[8] Shehzad Saeed[9] Christine Browner[10] Nicole Horton[10] Fionna Kopp[10] Jane Weyer[10] Lorrie Williams[10] James Squires[11] Alexander Miethke[1], [1]Cincinnati Children's Hospital Medical Center, [2]UPMC Children's Hospital of Pittsburgh, [3]Massachusetts General Brigham for Children, [4]Washington University in St. Louis, [5]UT Southwestern, Children's Medical Center Dallas, [6]Seattle Children's Hospital, [7]Indiana University, [8]Nationwide Children's Hospital, [9]Dayton Children's Hospital, [10]A-LiNK Connections, [11]Children's Hospital of Pittsburgh

Background: There is no standardized mechanism to prospectively track outcomes in children with autoimmune liver disease (AILD), hindering clinical care. Here, we define key outcome measures and establish baseline metrics for children with AILD. **Methods:** Children 1+ years old with a new or established diagnosis of AILD from 8 A-LiNK sites were prospectively enrolled. Demographics, laboratory values, medications, steroid-associated side effects, and disease complications were documented at

each clinical visit. U charts were constructed with a defined centerline after 12 consecutive months with ≥ 30 patients. Remission was defined as transaminases below the upper limit of normal (ULN) for age/sex. Flare was defined as 2 consecutive transaminase values above the ULN in those previously in remission. GGT normalization was defined as < 50 IU/L. **Results:** 266 participants were enrolled (Figure 1A): 152 with autoimmune hepatitis (AIH), 62 with autoimmune sclerosing cholangitis (ASC), and 52 with primary sclerosing cholangitis (PSC). 54% were female, 77% White, 10% Black/African American, and 86% non-Hispanic. Median age at enrollment was 15.9 yrs and median disease duration was 3.9 yrs. The remission centerline was 63.6% for those 12+ months from AIH/ASC diagnosis (Fig 1B). Steroid-free treatment was more common in those in remission (46/71, 65%) vs those not in remission (26/61, 43%). Those in remission prescribed prednisone were on lower doses than those not in remission (5.6mg/day vs 16.6mg/day, $p < 0.0001$). 21% (44/213) with AIH/ASC experienced steroid-associated side effects: 15% obesity, 3% steroid-associated diabetes, and 2% hypertension, cataract/glaucoma, and/or low bone mineral density. Flare rates were 3% per 100 patient-months, with an average of 862 patient-days between flare events (Fig 1C). GGT normalization centerline 6 months after PSC diagnosis was 54.1% (Fig 1D). The cohort complication rate was low: 4/132 (3%) experienced cholangitis; 8/266 (3%) experienced cirrhosis-associated complications; and 1 patient had a liver transplant. **Conclusion:** A-LiNK represents the largest prospective cohort of children with AILD, providing follow-up and monthly performance feedback on key outcome measures. AIH remission rates are lower than reported, and GGT normalization occurs in approximately half of PSC cases, highlighting the need to improve therapy and implement quality-improvement strategies to enhance care and long-term outcomes for children with AILD.

Figure 1

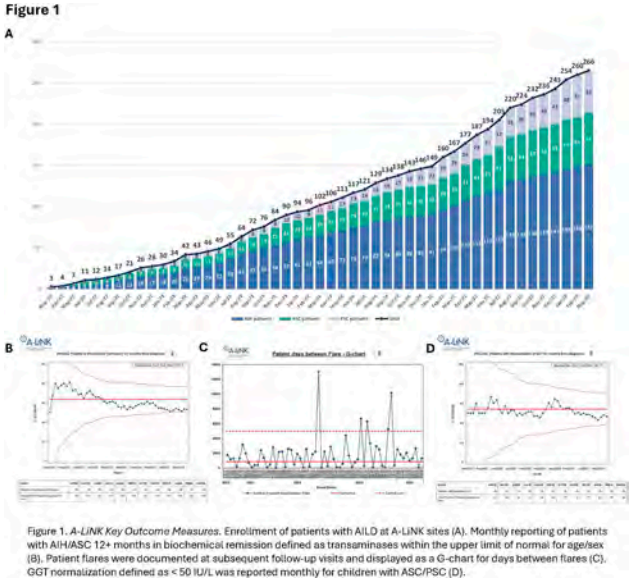

Figure 1. *A-LiNK Key Outcome Measures.* Enrollment of patients with AILD at A-LiNK sites (A). Monthly reporting of patients with AIH/ASC 12+ months in biochemical remission defined as transaminases within the upper limit of normal for age/sex (B). Patient flares were documented at subsequent follow-up visits and displayed as a G-chart for days between flares (C). GGT normalization defined as < 50 IU/L was reported monthly for children with ASC/PSC (D).

Background: Fontan procedure is the standard of care for patients with a single ventricle physiology, but over time results in development of Fontan associated liver disease (FALD). FALD is a near-universal consequence of the Fontan circulation, yet reliable predictors of adverse outcomes in children remain poorly defined. We aimed to characterize the natural history of pediatric FALD and identify non-invasive laboratory markers associated with survival and portal hypertension in a large multicenter cohort. Laboratory tests and clinical data were collected during routine visits. **Methods:** A retrospective 24 multicenter study was conducted across the Pediatric FALD (PED FALD) Network, including 1,031 children ($\leq$ 18 years old) post-Fontan. Primary outcomes were overall survival (OS), native heart survival (NHS), and event-free survival (EFS). Event-free survival was defined as the absence of a failing Fontan, heart transplant, or death. Features of portal hypertension were reported using the VAST score, which was calculated by the sum of clinical findings (Varices, Ascites, Splenomegaly, and Thrombocytopenia). A VAST score $\geq$ 2 indicated portal hypertension. Survival was analyzed using Kaplan-Meier curves and Cox proportional hazards models, including a frailty model to account for center effects. Non-invasive fibrosis scores (APRI, FIB-4) at the first available were evaluated as predictors of mortality. **Results:** The cohort (n = 1,031) had a mean age at Fontan of 3.4 ± 1.7 years. During follow-up (mean 12 ± 5 years), failing Fontan was observed in 11.8% of patients, while 5.2% required isolated heart transplants and 2.4% died. Portal hypertension-related complications, including GI bleeding and encephalopathy, occurred in 2.7% and 0.6% of patients, respectively. OS was 99.1% at 10 years, 97.2% at 15 years, 93.1% at 20 years. The proportion of patients remaining free of portal hypertension was 96.9% at 10 years, 91.2% at 15 years, and 87.5% at 20 years. Older age at Fontan was a significant independent predictor of worse OS (HR 1.47, $p < 0.001$), NHS (HR 1.32, $p < 0.001$), and EFS (HR 1.19, $p < 0.001$) after adjusting for center effects. Notably, African American race was associated with significantly lower EFS (HR 1.94, $p = 0.008$) in the fixed-effects model. Higher liver fibrosis scores were strongly associated with mortality. An APRI > 0.43 was associated with a 3.44-fold increase in mortality risk ($p = 0.031$). Similarly, a FIB-4 > 0.43 was associated with a 4.28-fold increase in mortality risk compared to the lowest tier ($p = 0.015$). **Conclusion:** In the largest pediatric FALD cohort to date, age at Fontan procedure and non-invasive fibrosis markers (APRI and FIB-4) serve as critical prognostic indicators for long-term survival. These findings suggest that higher APRI and FIB-4 levels may identify high-risk patients who require intensified surveillance or early intervention.

0245 | UTILISATION OF THROMBOELASTOGRAPHY AND AND VON WILLEBRAND FACTOR ANTIGEN PROFILE IN CHILDREN WITH BLEEDING IN LIVER TRANSPLANT

Harry Sutton[1] Akshat Goel[2] Michael Avery[2] Bethany Tucker[2] Miriam Cortescerisuelo@nhs.net[3] lara Roberts[4] Eirini Kyrana[2] Anish Gupta[5] Robert Hegarty[2] Tassos Grammatikopoulos[6], [1]Toronto Hospital for Sick Children, [2]Paediatric Liver, GI & Nutrition Centre and MowatLabs, King's College Hospital, London, UK, [3]Liver Transplant Surgery, Institute of Liver Studies, King's College Hospital, London, [4]Department of Haematological Medicine, King's Thrombosis Centre, King's College Hospital NHS Foundat, [5]Division of Liver Transplant, Anaesthetic Department, King's College Hospital NHS Foundation Trust, [6]King's College Hospital

Background: Bleeding is a common perioperative complication associated with portal hypertension and liver transplantation (LT). Thromboelastography (TEG), reflecting hemostatic status, and von Willebrand Factor Antigen (vWFAg), a vascular endothelial activation marker, can independently predict bleeding and death in liver disease with limited data in children undergoing LT. We investigated whether preoperative TEG parameters and vWFAg predict perioperative bleeding, intraoperative transfusion, and intensive care stay in children undergoing LT. **Methods:** We carried out an observational cohort study in children listed for LT at King's College Hospital between June 2021–Nov 2024, recording all TEG parameters (Citrated Rapid TEG, Kaolin, Functional Fibrinogen), vWFAg, GPIbR, and clinical and laboratory data including bleeding outcomes per departmental protocol. **Results:** 75 (m = 38, median age = 3.6yr) children with Chronic Liver Disease (CLD, n = 58) (n = 58) or Acute Liver Failure (ALF, n = 17) were included (Figure 1A). Major bleeding (defined as >/= 40ml/kg red blood cell transfusion or >/= 80ml/kg total blood products intra- or post-op) occurred in 28 (37%) children and 9 (12%) developed thrombosis peri-operatively. Lower platelet count (OR 0.99, p = 0.012), higher vWFAg (OR 1.02, p = 0.004), and weaker/slower clot formation on TEG (Kaolin Angle, Kaolin/CRT maximum amplitude and amplitude-at-10-minutes; all $p < 0.05$) predicted major bleeding, whereas clot-initiation parameters (TEG-ACT, TEG-R) did not (p = 0.60) (Figure 1B). A multivariable model (vWFAg, platelets) discriminated major bleeding well (bootstrap-corrected AUC 0.82) (Figure 1C). Clot-strength parameters predicted ICU stay ($R^2 \asymp 0.45$, $p < 10^{-5}$, aetiology-adjusted). No parameter predicted thrombosis. ALF patients experienced a significantly longer PICU stay post-transplant than the CLD patients (median 25 vs 2 days, $p < 0.0001$) and had slower clot-initiation parameters. **Conclusion:** To our knowledge, this is the first paediatric study correlating comprehensive TEG and vWFAg with LT bleeding outcomes. Preoperative platelet count, vWFAg, and TEG clot-strength parameters independently predict perioperative bleeding. ALF patients had prolonged clot initiation compared with those with CLD and had a tenfold increase in PICU length of stay. These exploratory findings highlight the complex coagulopathy present in children prior to transplant and suggest that these variables may be useful in predicting peri-transplant bleeding.

0247 | ALCOHOL EXPOSURE AND SURVIVAL IN PRIMARY SCLEROSING CHOLANGITIS: A PROPENSITY SCORE-MATCHED COHORT STUDY

Muyiwa Awoniyi[1] Jingyi Huang[1] Mariana Campuzano[1] Nicole Jordan[1] Li Tang[1] John McMichael[1], [1]Cleveland Clinic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Primary sclerosing cholangitis (PSC) is a progressive cholestatic liver disease without effective medical therapy, where liver transplantation is the only life-extending option. Despite established genetic predisposition, susceptibility loci explain less than 10% of disease liability, implicating environmental exposures as dominant, poorly characterized drivers of progression. Alcohol is a compelling candidate: a hepatotoxin disrupting bile acid homeostasis and intestinal dysbiosis through the gut-liver axis central to PSC. Evidence-based guidance is absent; prior evidence is limited to two conflicting studies with methodologic constraints. We hypothesized that alcohol independently impairs PSC survival and designed a propensity score-matched cohort study to test this. **Methods:** We performed a retrospective cohort study of PSC patients at a quaternary referral center (2015-2025), using delayed entry to account for left truncation of patients diagnosed before the observational window. Alcohol exposure was ascertained as a time-fixed binary variable via a composite algorithm of phosphatidylethanol (PEth) levels, AUDIT-C scores (sex-specific thresholds), ICD-coded alcohol use disorder diagnoses, and self-reported consumption. Primary endpoints were overall survival (OS; all-cause death) and transplant-free survival (TFS; composite of all-cause death or liver transplantation). Separate endpoint-specific 1: 4 nearest-neighbor propensity score matching was performed using age, sex, race, delayed-entry status, and baseline cirrhosis. Associations were estimated using Cox models with time-updated 3-month-interval data, adjusting for time-varying diabetes, hypertension, hyperlipidemia, and IBD; robust standard errors were clustered by patient. **Results:** Among 1,030 patients (OS) and 882 (TFS), propensity score matching yielded cohorts of 25 alcohol-exposed vs. 100 unexposed (OS) and 20 vs. 78 (TFS). All post-matching standardized mean differences (SMDs) were below 0.2, confirming adequate balance. Alcohol exposure was independently associated with significantly higher hazard of all-cause death (OS: HR 4.58, 95% CI 1.75–12.00; p = 0.002) and death or transplantation (TFS: HR 5.40, 95% CI 1.95–14.91; p = 0.001). **Conclusion:** This first propensity score-matched analysis demonstrates that alcohol exposure independently and markedly impairs both overall and transplant-free survival in PSC. These findings address the key methodologic limitations of prior conflicting studies and provide the strongest available evidence supporting formal alcohol abstinence counseling as a core component of PSC management. Cautious interpretation is warranted, given the limited absolute number of events; prospective validation in larger multicenter cohorts is needed.

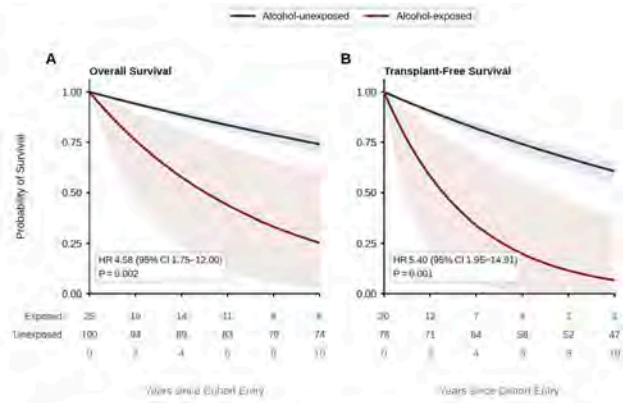

Figure 1. *Kaplan–Meier survival estimates by alcohol exposure status in propensity score–matched primary sclerosing cholangitis cohorts.*

Panel A, overall survival (OS; 25 alcohol-exposed vs. 100 unexposed); Panel B, transplant-free survival (TFS; 20 vs. 78). Cohorts matched 1:4 on age, sex, race, delayed-entry status, and baseline cirrhosis; all post-matching standardized mean differences <0.20. Hazard ratios from Cox models with time-updated 3-month interval data adjusted for time-varying diabetes, hypertension, hyperlipidemia, and IBD; robust standard errors clustered by patient. Shaded bands, 95% CI. Numbers below panels, patients at risk. CI denotes confidence interval; HR denotes hazard ratio; IBD denotes inflammatory bowel disease; OS denotes overall survival; PSC denotes primary sclerosing cholangitis; TFS denotes transplant-free survival.

★ 0248 | VITAMIN C REPROGRAMS THE HEPATIC IMMUNE LANDSCAPE TO ALLEVIATE CONA-INDUCED LIVER INJURY

Juan Lu[1], [1]The First Affiliated Hospital, Zhejiang University

Background: Autoimmune hepatitis (AIH) is a progressive liver disease with limited treatment options. Notably, vitamin C has been widely studied in metabolic liver diseases, but its role in immune-mediated liver injury remains largely unexplored. **Methods:** We first analyzed a human cohort of 48 proven AIH patients to find that serum L-ascorbic acid (vitamin C, Vit C) levels in patients with moderate-to-severe necroinflammation performance compared to healthy controls. Consistently, using an untargeted metabolomics approach in a concanavalin A (ConA)-induced mouse model of acute AIH, we identified marked depletion of Vit C, an essential micronutrient derived exclusively from dietary sources, in injured livers. To dissect the underlying mechanisms, CyTOF and scRNA-seq were employed to profile the hepatic immune microenvironment. **Results:** We found that serum L-ascorbic acid (vitamin C, Vit C) levels were significantly lower in patients with moderate-to-severe necroinflammation performance

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

compared to healthy controls, and inversely correlated with serum ALT and AST levels. We identified exogenous Vit C supplementation dose-dependently alleviated ConA-induced liver injury, as evidenced by reduced serum aminotransferases and ameliorated histopathology. Vit C treatment profoundly reprogramed the hepatic immune landscape, reducing proinflammatory neutrophils while expanding regulatory B cells, cDCs, and CD4+ T cells. CellChat analysis revealed that Vit C suppressed pro-inflammatory signaling while inducing immunomodulatory pathways. High-resolution subset analysis demonstrated that Vit C reprogrammed neutrophils from a hyper-inflammatory S100a6+ Neu-dominant state toward a regulatory Ccl2 + Neu phenotype. Similarly, Vit C reshaped macrophage subsets, upregulating MHC II and costimulatory molecules while downregulating stress/repair genes, indicating a shift toward immune-activated status. **Conclusion:** These findings reveal that vitamin C acts as a key immune regulator that orchestrates immune cell subset remodeling and intercellular communication networks, providing a mechanistic basis for Vit C as a potential safe adjunct therapy for AIH, further supported by our human cohort observation that lower Vit C levels predict higher inflammatory activity.

0249 | STATIN EXPOSURE IS ASSOCIATED WITH REDUCED HEPATIC DECOMPENSATION AND MORTALITY IN PRIMARY SCLEROSING CHOLANGITIS

Sameer Rao[1] Rohan Karkra[1] Kranthi Mandava[1] Ethan Shamsian[2] Raquel Olivo-Salcedo[3] Shivani Patel[1] Ahmed Al-Khazraji[1] Paul Gaglio[4] Nikki Duong[5], [1]Rutgers New Jersey Medical School, [2]Rutgerse New Jersey Medical School, [3]Rutgers University - New Jersey Medical School, [4]Rutgers NJ Medical School, [5]Stanford University

Background: Primary sclerosing cholangitis (PSC) is a progressive cholestatic liver disease without an established disease-modifying therapy. Statins have pleiotropic anti-inflammatory, antifibrotic, endothelial-modulating, and potential chemopreventive effects, but their association with clinical outcomes in PSC remains incompletely understood. **Methods:** We conducted a retrospective cohort study using the TriNetX United States Collaborative Network from 2015 to 2024. Adults with PSC were identified and stratified by statin exposure. Patients with prior liver transplantation, cholangiocarcinoma, hepatocellular carcinoma, or primary biliary cholangitis were excluded. Statin-treated and non-statin cohorts were matched 1: 1 using propensity scores based on demographics, comorbidities, medications, and liver disease–related laboratory parameters. Outcomes included liver disease progression, hepatic decompensation, hepatobiliary malignancies, biliary complications, liver transplantation, hospitalization, and all-cause mortality. A subgroup analysis was performed among patients with concomitant inflammatory bowel disease (IBD). Cox proportional hazards modeling was performed to evaluate predictors of the composite outcome of decompensated cirrhosis or liver transplantation. **Results:** After matching, 1,695 statin-treated patients with PSC were compared with 1,695 non-statin users. Statin use was associated with lower rates of ascites (20.77% vs 25.78%; P = .0006), cirrhosis (35.28% vs 39.47%; P = .01), decompensated cirrhosis (23.01% vs 28.55%; P = .0002), acute cholangitis (32.15% vs 35.57%; P = .03), hepatocellular carcinoma (HCC) (3.42% vs 4.84%; P = .04), all-cause hospitalization (36.54% vs 40.37%; P = .02), and all-cause mortality (17.76% vs 25.13%; P < .0001). Rates of liver transplantation were similar between groups. In patients with concomitant IBD, statin use was associated with lower rates of acute cholangitis and mortality, however, associations with cirrhosis, decompensated cirrhosis, and ascites were attenuated. In Cox proportional hazards analysis, statin use was independently associated with lower hazard of decompensated cirrhosis or liver transplantation (hazard ratio 0.76; 95% confidence interval 0.68–0.84). Immunosuppressant use, UDCA use, male sex, older age, higher INR, higher creatinine, and higher bilirubin were associated with increased hazard, while higher sodium levels were associated with lower hazard. **Conclusion:** Statin use was associated with improved liver-related and clinical outcomes in PSC, including lower risks of decompensation, acute cholangitis, HCC, hospitalization, and mortality. These associations were attenuated among patients with concomitant IBD. While causality cannot be inferred, these findings support prospective evaluation of statin exposure as a potential modifier of PSC outcomes.

Figure - Outcomes and predictors in primary sclerosing cholangitis (PSC) by statin use

0250 | VOLIXIBAT IMPROVES PRURITUS WITHOUT WORSENING IBD ACTIVITY IN PATIENTS WITH PSC: RESULTS FROM THE VISTAS STUDY IBD SUBGROUP

Kris Kowdley[1] Gideon Hirschfield[2] Mitchell Shiffman[3] Muyiwa Awoniyi[4] Deepak Joshi[5] Debra Weinstein[6] Douglas Thorburn[7] Alejandra Villamil[8] Ynto de Boer[9] Parvez Mantry[10] Aldo Montano-Loza[11] Münevver Demir[12] Adriaan Van der Meer[13] Lisa Forman[14] Jessica Dyson[15] Nimer Assy[16] Kidist Yimam[17] Walid Ayoub[18] Thomas Berg[19] Marie-Noëlle Hilleret[20] Christoph Berg[21] John Eaton[22] Claudia Couto[23] Verena Keitel[24] Palak Trivedi[25] Eli Zuckerman[26] Roger McCorry[27] Emily Schonfeld[28] Fernando Cairo[29] Marlyn Mayo[30] Julius Wilder[31] Juan Gallegos-Orozco[32] Stuart Gordon[33] William Gelson[34] Miriam Levy[35] Roman Perri[36] Suresh Venkatachalapathy[37] Gabriel Aballay Soteras[38] Marc Deschenes[39] Henry Nguyen[40] Rifaat Safadi[41] Siddharth Sood[42] Emma Culver[43] Alan Bonder[44] Janisha Patel[45] James O'Beirne[46] Nora Cazzagon[47] Mário Alvares-da-Silva[48] Fadi Abu Baker[49] Paulo Bittencourt[50] Pietro Invernizzi[51] Ira Jacobson[52] Gadi Lalazar[53] Avik Majumdar[54] Chirag Patel[55] Magdalena Salcedo[56] Rodrigo Aires[57] Ehud Zigmond[58] Victor Ankoma-Sey[59] David Bernstein[60] Brian Borg[61] Marco Carbone[62] Geraldine Dahlqvist[63] Tarek Hassanein[64] Paul Hermabessière[65] Pietro Lampertico[66] Kate Lynch[67] Mercedes Martinez[68] Sergio Rodriguez-Tajes[69] Manish Thapar[70] Richard Kalman[70] Frans van der Heide[71] Xavier Verhelst[72] David Victor[73] Hallam Gugelmann[74] Tiago Nunes[74] Erik Ness[74] David Sánchez Ramos[74] Jilliann Elliott[74] Tobias Di Marco[74] Jayshree Krishnaswami[74] Clara Kebabian[74] Sarah Sidhu[74] Emilia Radulovic[74] Jolan Terner-Rosenthal[75] Andrew McKibben[74] Raul Aguilar[76] Cory Kostrub[74] Susanna Carou-Keenan[74] Lara Longpre[74] Pam Vig[76] Joanne Quan[74] Christopher Bowlus[77] Cynthia Levy[78], [1]Liver Institute Northwest, [2]Toronto General Hospital, [3]Bon Secours Mercy Health, [4]Cleveland Clinic, [5]King's College Hospital NHS Foundation Trust, [6]Science 37, Inc., [7]Royal Free Hospital, [8]Hospital Italiano de Buenos Aires, [9]Amsterdam UMC, [10]The Liver Institute at Methodist Dallas Medical Center, [11]University of Alberta, [12]Charité -Universitätsmedizin Berlin, [13]Erasmus University Medical Center, [14]University of Colorado Anschutz Medical Campus, [15]NHS Foundation Trust, [16]Galilee Medical Center, [17]California Pacific Medical Center Research Institute, [18]Cedars-Sinai Medical Center, [19]University of Leipzig Medical Center, [20]CHU Grenoble Alpes, [21]University Hospital Tubingen Medical Clinic, [22]Mayo Clinic Rochester, [23]Federal University of Minas Gerais, [24]University Hospital Magdeburg, Otto-von-Guericke University, [25]University Hospitals Birmingham NHS Foundation Trust, [26]The Carmel Medical Center, [27]Royal Victoria Hospital Belfast Health and Social Care Trust, [28]Weill Cornell Medical College, [29]HOSPITAL EL CRUCE, [30]University of Texas Southwestern Medical Center, [31]Duke School of Medicine, [32]University of Utah, [33]Henry Ford Health System, [34]Cambridge Liver Unit, [35]Liverpool Hospital, [36]Vanderbilt Medical Center, [37]Nottingham University Hospitals NHS Trust, [38]Glenny Corp S.A., [39]Royal Victoria Hospital McGill University Health Centre, [40]University of Calgary, [41]Hadassah Medical Organization, The Liver Institute, [42]Northern Health, [43]John Radcliffe Hospital, [44]Beth Israel Deaconess Medical Center, [45]University Hospital Southampton NHS Foundation Trust, [46]UniSc Clinical Trials Birtinya, [47]University Hospital of Padova, [48]Hospital de Clínicas de Porto Alegre, [49]Hillel Yaffe Medical Center, [50]Escola Bahiana de Medicina e saude Pública, [51]Fondazione IRCCS San Gerardo dei Tintori, [52]NYU Hepatology Associates, [53]Shaare Zedek Medical Center, [54]Austin Health, [55]Galen Medical Group, [56]Hospital General Universitario Gregorio Maranon, [57]Hospital Das Clinicas Da UFG, [58]The Chaim Sheba Medical Center, [59]Liver Associates of Texas, [60]NYU Langone, [61]Southern Therapy and Advanced Research, LLC., [62]University of Milano-Bicocca, [63]Cliniques Universitaires Saint-Luc, [64]Southern California Research Center, Inc., [65]CMC Magellan, [66]University of Milan, [67]Royal Adelaide Hospital, [68]NewYork-Presbyterian, [69]Hospital Clinic Barcelona, [70]Einstein Medical Center, [71]University Medical Center Groningen, [72]Ghent University Hospital, [73]Houston Methodist Hospital, [74]Mirum Pharmaceuticals, Inc., [75]Mirum Pharamaceuticals, Inc., [76]Mirum Pharmaceuticals, [77]University of California, Davis, [78]University of Miami

Background: Primary sclerosing cholangitis (PSC) is a chronic cholangiopathy often causing severe cholestatic pruritus and associated with inflammatory bowel disease (IBD) in up to 80% of patients. Volixibat (VLX) is a minimally absorbed ileal bile acid transporter inhibitor (IBATi) that disrupts enterohepatic recirculation of bile acids and increases fecal bile acid excretion. In the Phase 2b VISTAS study, a 28-week multicenter, randomized, double blind (DB), placebo (PBO)-controlled study, VLX demonstrated statistically significant improvements in cholestatic pruritus with a safety profile consistent with IBAT inhibition. Here we report the efficacy and safety of VLX in the subgroup of patients with IBD. **Methods:** Details of the VISTAS trial design and primary endpoint have been previously reported. Descriptive subgroup analyses were

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

conducted on patients with concomitant IBD. IBD activity was assessed using Partial Mayo Index Score (PMIS) sub-scores and Crohn's Disease Activity Index (CDAI); all patients were in remission or had mild IBD activity on stable therapy. **Results:** 74% (82/111) of the VISTAS primary cohort had concomitant IBD with 71% of these patients having ulcerative colitis (UC); rates of Crohn's disease (CD) and UC were balanced across treatment arms. In the primary cohort IBD subgroup (VLX: n = 40; PBO: n = 42), VLX treatment resulted in significant reductions in cholestatic pruritus compared with PBO (LS Mean CFB in Adult ItchRO: -2.88 vs -1.39; Δ-1.50, P = 0.0018). Baseline IBD activity scores by PMIS/CDAI were assessed in all participants (i.e., includes those with mild pruritus; VLX: n = 48; PBO: n = 54): VLX remission 85% (41), mild 13% (6) and moderate 2% (1); PBO remission 96% (52), mild 4% (2). Maximum postbaseline IBD activity scores by PMIS/CDAI were: VLX remission 60% (29), mild 40% (19); PBO remission 74% (40); mild 24% (13) and moderate or severe 2% (1). In patients with UC (VLX: n = 37; PBO: n = 41), change in PMIS was driven by increased stool frequency scores (SFS). Mild increase in stool frequency (SFS 1 or 1-2 more stools/day) was reported in 38% (14) of VLX patients and 24% (10) of PBO patients. Rates of SFS of 2 (3-4 more stools/day) and 3 (>5 more stools/day) were low and similar across treatment arms. No stool frequency change was reported in 41% (15) of VLX and 59% (24) of PBO patients. Most UC patients had a maximum rectal bleeding score of 0 (89% [33] VLX, 90% [37] PBO). **Conclusion:** In the VISTAS IBD subgroup, VLX demonstrated a significant and clinically meaningful reduction in cholestatic pruritus compared with PBO. Rates of IBD activity were low across both treatment arms. Although VLX-treated UC patients had higher rates of increased SFS, there was no increase in rectal bleeding, suggesting these changes reflect the mechanism of action of IBATi rather than worsening IBD activity. These findings support VLX as a well-tolerated and effective option for cholestatic pruritus in patients with PSC and concomitant IBD.

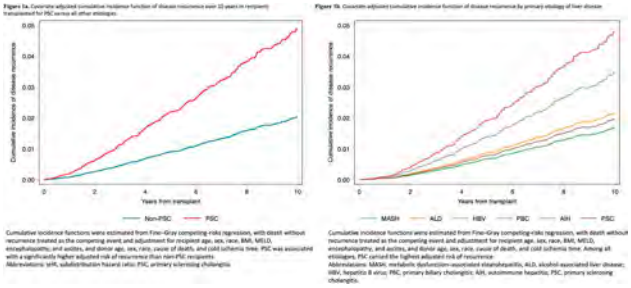
0251 | PRIMARY SCLEROSING CHOLANGITIS IS ASSOCIATED TO THE HIGHEST RISK OF RECURRENCE-RELATED GRAFT FAILURE AFTER LIVER TRANSPLANTATION: A PROPENSITY-MATCHED UNOS ANALYSIS IN THE POST-DAA ERA



Leandro Sierra[1] Nazli Begum[2] Rebeca Sierra[3] Maria Saavedra-Martinez[3] Butros Fakhoury[4] Lynette Sequeira[5] Behnam Saberi[6] Ahmet Gurakar[7], [1]Cleveland Clinic Foundation, [2]Saint Louis University, [3]Universidad De La Sabana, [4]Department of Internal Medicine, Virginia Commonwealth University School of Medicine, Richmond, Virg, [5]Johns Hopkins Hospital, [6]Beth Israel Deaconess Medical Center (BIDMC), Harvard Medical School, Boston, MA, USA, [7]Johns Hopkins University

Background: Recurrent liver disease is an increasingly recognized cause of late allograft loss after liver transplantation (LT), yet contemporary estimates of recurrence-related graft failure across LT era are lacking. PSC is clinically understood to recur and threaten the allograft, but the associated risk recurrence brings has not been evaluated in large scale populations. We aimed to quantify this risk in the national transplant registry. **Methods:** Using the UNOS/SRTR registry, we identified adults who underwent LT from 2014 to 2025. The outcome was graft failure attributed to recurrent disease, with death or graft failure from other causes treated as the competing events. PSC recipients were 1: 1 matched to non-PSC recipients by nearest-neighbor propensity matching on recipient age, sex, race, BMI, MELD, comorbidities, and key donor-related risk factors. Cumulative incidence was estimated by the Aalen–Johansen method; associations were modeled with Fine–Gray competing-risks regression and Cox regression at 1, 5, and 10 years. A secondary analysis compared PSC against each individual etiology using the same statistical approach. **Results:** Of 46,319 adult LT recipients, 1: 1 matching yielded 6,145 pairs (n = 12,290) with excellent balance (recipient age 47.0 vs 47.4 yr; MELD 22.7 vs 22.8; cold ischemia 7.2 vs 7.2 h; all $P > 0.7$). Despite matching, PSC recipients had a significantly shorter post-transplant length of stay (14.4 vs 18.2 days, $P < 0.001$). Over

10 years, 302 recurrence-related graft failures occurred (218 in PSC vs 84 in non-PSC), at a median of 4.8 years (IQR 3.1–7.2) in PSC versus 2.9 years (IQR 1.4–5.3) in non-PSC recipients. The risk was strongly time-dependent: no difference between groups at 1 year (sHR 0.61, 95% CI 0.24–1.56), with a difference emerging by 5 years (sHR 1.69, 1.24–2.31; P = 0.001), and highest at 10 years (sHR 2.44, 1.88–3.17; P < 0.001) (**Figure 1a**); Cox estimates were concordant (10-yr HR 2.46, 1.91–3.17). The 10-year cumulative incidence of recurrence-related graft failure was approximately 4.8% in PSC vs 2.0% in non-PSC recipients. Among all transplant indications (**Figure 1b**), PSC carried the highest adjusted risk of recurrence related graft failure at 10 years (sHR 2.91, 95% CI 1.06–7.96; P = 0.038). **Conclusion:** PSC confers the highest risk of recurrence-related graft failure among LT indications, a risk that is negligible early but accumulates progressively, reaching a nearly three-fold increased risk in 10 years. These findings support intensified post-transplant surveillance in PSC recipients.

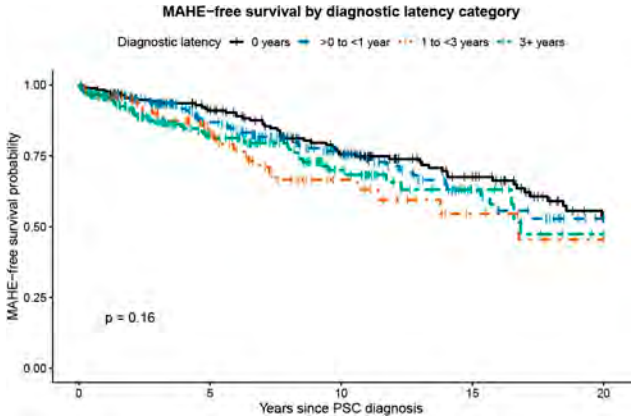
0252 | DIAGNOSTIC LATENCY AND MAJOR ADVERSE HEPATIC EVENTS IN PRIMARY SCLEROSING CHOLANGITIS: A MULTICENTER REGISTRY ANALYSIS



Eugenio Reina[1] Adrielly Martins[1] Richard Dean[2] Daniel Pratt[3] Raffi Karagozian[4] Elizabeth Carey[5] Michael Li[6] Stuart Gordon[7] Lisa Forman[8] Craig Lammert[9] Barry Schlansky[10] Walid Ayoub[11] Lei Yu[12] Christopher Bowlus[13] Cynthia Levy[14], [1]University of Miami Miller School of Medicine, [2]UC Davis Health, [3]Massachusetts General Hospital, [4]Tufts University School of Medicine, [5]Mayo Clinic Arizona, [6]University of California, San Francisco, [7]Henry Ford Health System, [8]University of Colorado Anschutz, [9]Indiana University School of Medicine, [10]Kaiser Permanente Northwest, [11]Cedars-Sinai Medical Center, [12]University of Washington, [13]University of California, Davis, [14]University of Miami

Background: Primary sclerosing cholangitis (PSC) is a progressive fibroinflammatory cholangiopathy that confers substantial risk of hepatic decompensation, liver transplantation, and hepatobiliary malignancy. Early disease may be asymptomatic, and cholestatic abnormalities may be overlooked, delaying diagnosis. Whether diagnostic latency — the interval from earliest objective evidence to formal diagnosis — independently predicts adverse hepatic outcomes has not been rigorously evaluated in a date-validated multicenter cohort. **Methods:** We analyzed patients with PSC from the North American Consortium for Autoimmune Liver Diseases (CALiD). Earliest objective evidence was defined as the first date of abnormal cholestatic biochemistry, PSC-compatible imaging, or PSC-consistent histology. Patients with unverifiable diagnosis dates or insufficient follow-up were excluded. The primary outcome was time to first major adverse hepatic event (MAHE), defined as hepatic decompensation, liver transplantation, hepatobiliary malignancy, or death. Diagnosis-anchored cox models evaluated latency continuously, per 5 years, log-transformed, and categorically, adjusting for age, sex, IBD, cirrhosis, and large-duct PSC (LD-PSC) classification. **Results:** Of 1,101 patients with PSC, 690 met inclusion criteria. Median age at diagnosis was 46 years (IQR, 34-60), 435 (63.0%) were male, 669 (97.0%) had concomitant IBD, and 558 (80.9%) had LD-PSC. Median post-diagnosis follow-up was 6.6 years and median diagnostic latency was 0.53 years (range, 0-31.0). Earliest objective evidence was abnormal cholestatic biochemistry in 562 patients (81.4%), PSC-compatible imaging in 79 (11.4%), and PSC histology in 49 (7.1%). MAHE occurred in 187 patients (27.1%); time-to-event analyses counted only the first MAHE per patient. MAHE components included liver transplantation in 104 patients (15.1%), hepatic decompensation in 95 (13.8%), hepatobiliary malignancy in 44 (6.4%), and death in 5 (0.7%). Latency was not associated with MAHE per 1-year increment (HR, 1.01; 95% CI, 0.97-1.04; P = 0.75), per 5-year increment (HR, 1.03; 95% CI, 0.87-1.22; P = 0.75), or log-transformed (HR, 1.08; 95% CI, 0.92-1.27; P = 0.34). No diagnostic latency stratum reached statistical significance after adjustment for age, sex, IBD, known cirrhosis at baseline, and LD-PSC. **Conclusion:** In this cohort, these findings suggest that the interval from earliest objective evidence to formal diagnosis does not, by itself, stratify risk of adverse hepatic outcomes. Rather, baseline disease phenotype and fibrosis burden may be more prognostically important than

elapsed time to formal diagnosis, supporting future analyses incorporating disease-stage biomarkers and evidence-source phenotype.

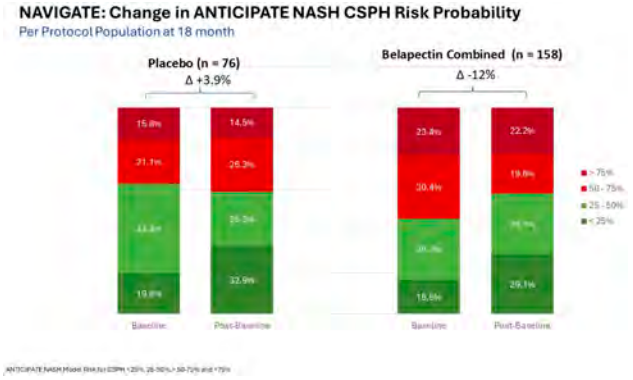
0253 | ANTICIPATE-NASH RISK STRATIFICATION PREDICTS VARICEAL DEVELOPMENT IN COMPENSATED MASH CIRRHOSIS: RESULTS FROM THE NAVIGATE TRIAL



Naim Alkhouri[1] Naga Chalasani[2] Mary Rinella[3] Raj Vuppalanchi[4] Eric Lawitz[5] Edward Mena[6] Khurram Jamil[7] Mazen Noureddin[8], [1]Summit Clinical Research. Clinical Research Institute of Ohio, [2]Indiana University Medical Center, [3]The University of Chicago, [4]Indiana University School of Medicine, [5]The Texas Liver Institute, University of Texas Health San Antonio, [6]California Liver Reasearch Instituite, [7]Galectin Therapeutics, [8]Houston Methodist Hospital

Background: The ANTICIPATE-NASH model is a validated noninvasive tool to predict clinically significant portal hypertension (CSPH; hepatic venous pressure gradient $\geq$10 mmHg) and stratify risk of liver-related events in MASH cirrhosis. NAVIGATE is a global, randomized, placebo-controlled trial evaluating belapectin, a galectin-3 inhibitor, in patients with compensated MASH cirrhosis and portal hypertension without baseline varices. Belapectin at 2 and 4 mg/kg previously demonstrated a reduction in incident varices versus placebo in the per-protocol population. Here, we evaluated the utility of ANTICIPATE-NASH risk stratification to predict variceal development and assess treatment effects **Methods:** The ANTICIPATE-NASH model incorporates liver stiffness, platelet count, and body mass index to estimate CSPH probability. Predefined thresholds of $\geq$75% probability were used to rule-in CSPH, while $\geq$50% probability identified an enrichment population for clinical trials. Subjects were categorized at baseline into probability groups (<25%, 25–50%, 50–75%, $\geq$75%) and reassessed at 18 months. Incidence of new varices was evaluated via blinded central review of endoscopy videos according to baseline risk category and changes in risk category over time in subjects receiving pooled belapectin (2 and 4 mg/kg) or placebo. **Results:** At baseline, distribution across ANTICIPATE-NASH probability categories (<25%, 25–50%, 50–75%, $\geq$75%) was 19.7%, 43.4%, 21.1%, and 15.8% in the placebo group, and 16.5%, 29.7%, 30.4%, and 23.4% in the belapectin group. A higher proportion of subjects in the belapectin arm had $\geq$50% CSPH probability at

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

baseline; however, this difference was not statistically significant.At 18 months a net category shift favored belapectin, as placebo subjects had a 3.9% net worsening to >50% CSPH probability, whereas belapectin subjects had a 12% net improvement to <50%, yielding a placebo-adjusted difference of 15.9% (p = 0.04).Incidence of varices increased across higher CSPH probability categories, with the highest rates observed in subjects with ≥75% probability. Overall incidence across categories (<25%, 25–50%, 50–75%, ≥75%) was 2.4%, 17.5%, 15.6%, and 18.4%, respectively. Across all baseline risk strata, belapectin-treated subjects demonstrated lower incidence of varices compared with placebo (0% vs 6.7%, 14.9%vs 21.2%, 12.5% vs 25%, and 16.2% vs 25%, respectively). **Conclusion:** Belapectin treatment was associated with a reduction in CSPH risk, as reflected by shifts to lower ANTICIPATE-NASH probability categories. Lower variceal incidence was observed with belapectin across all ANTICIPATE-NASH risk strata. These findings suggest that belapectin treatment is associated with favorable changes in noninvasively predicted CSPH risk, which may translate into a reduced risk of hepatic decompensation in future studies.

Shalimar[3], [1]All India Institute of Medical Sciences New Delhi, [2]Christian Medical College, Vellore, [3]All India Institute of Medical Sciences, New Delhi, [4]Amrita Institute of Medical Sciences, Kochi, [5]Medanta-The Medicity, [6]Govind Ballabh Pant Institute of Post Graduate Medical Education and Research

Background: There is no consensus on the optimal modality for secondary prophylaxis of gastric varices (GV) in patients with cirrhosis. We compared the efficacy and safety of endoscopic ultrasound-guided coil and glue embolization (EUS-CG) with balloon-occluded retrograde transvenous obliteration (BRTO) for prevention of rebleeding in patients with cirrhosis and GV hemorrhage. **Methods:** In this randomized controlled trial conducted at five tertiary care centres in India (November 2022 - May 2025), 118 patients with cirrhosis and bleeding from GV (GOV-2 and IGV-1) were randomly assigned (1: 1) to BRTO or EUS-CG for secondary prophylaxis. The primary outcome was GV-related rebleeding at 1-year. Secondary outcomes included all-cause mortality, further decompensation, change in liver function and worsening of esophageal varices at 1-year. Competing risk analysis was performed for rebleeding and further decompensation, with death as the competing event. **Results:** Baseline characteristics were similar between groups. Alcohol was the most common etiology of cirrhosis (47/118, 39.8%). The median Child-Pugh and MELD score of the cohort was 7 (6-8) and 14 (11-17) respectively, with a male predominance (90/118, 76.3%). Technical success was 100% in both groups. Complete GV obliteration rates at 4-weeks were higher with BRTO (55/57, 96.5%) than EUS-CG (47/55, 85.5%, p = 0.04). At 1-year, BRTO was associated with significantly lower rates of GV-related rebleeding (1/59, 1.7% vs 8/59, 13.6%; p = 0.03) and all-cause rebleeding (4/59, 6.8% vs 12/59, 20.3%) compared with EUS-CG; sHR for rebleeding: 0.32 (95% CI: 0.12-0.89); p = 0.03. Most GV rebleeding events after EUS-CG were related to coil extrusion ulcers. Further decompensation was comparable between groups (EUS-CG: 27/59, 45.8% vs BRTO: 20/59, 33.9%; p = 0.19) with new-onset/worsening of ascites being the most common decompensating event (EUS-CG: 27.1% vs BRTO: 28.8%; p = 0.84). Aggravation of esophageal varices occurred more frequently after BRTO than after EUS-CG (15/59, 25.4% vs 7/59, 11.9%, p = 0.05). The median change in Child-Pugh and MELD scores between both groups were similar. The 6-week mortality (EUS-CG: 4/59, 6.8% vs BRTO: 2/59, 3.4%; p = 1.0) and 1-year mortality (EUS-CG: 13/59, 22.0% versus BRTO: 8/59, 13.6%; p = 0.33) were comparable between groups. **Conclusion:** BRTO was associated with significantly lower 1-year GV-related rebleeding rates compared with EUS-CG in patients with cirrhosis and GV hemorrhage, although all-cause mortality and further decompensation at 1-year were similar between groups. [CTRI/2022/10/046363]

0255 | SAFETY AND EFFICACY OF SGLT-2 INHIBITORS IN LIVER CIRRHOSIS PATIENTS WITH REFRACTORY ASCITES: A RANDOMISED CLINICAL CONTROL TRIAL

Sunil Dadhich[1] Arihant Seth[1] Surender Kumar[1], [1]Dr. Sampurnanand Medical College, Jodhpur

Background: Refractory ascites in cirrhosis is associated with poor quality of life, frequent hospitalizations, repeated large-volume paracentesis (LVP), and high mortality. Sodium-glucose cotransporter-2 (SGLT2) inhibitors have natriuretic and diuretic properties that may provide therapeutic benefit in refractory ascites; however, data regarding their efficacy and safety in cirrhosis remain limited. This study evaluated the efficacy and safety of dapagliflozin in cirrhosis patients

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

with refractory ascites. **Methods:** In this prospective randomized controlled trial (CTRI/2025/12/098898), 73 patients with liver cirrhosis and refractory ascites were enrolled. 37 patients received dapagliflozin plus standard medical therapy, while 36 received standard medical therapy alone. The primary outcome was ascites control at 6 months, categorized as complete response, partial response, or non-response. Secondary outcomes included changes in urine sodium, urine output, body weight, abdominal girth, renal function, CTP and MELD-Na scores, LVP requirement, adverse events, and survival. Survival analysis was performed using Kaplan-Meier curves and log-rank testing. **Results:** Baseline demographic, clinical, and laboratory characteristics were comparable between groups. At 6 months, ascites control was significantly better in the dapagliflozin group compared with controls ($p = 0.036$). Complete response occurred in 8.1% (3/37) versus 0% (0/36), while partial response occurred in 27.0% (10/37) versus 13.9% (5/36) in the dapagliflozin and control groups, respectively. Dapagliflozin therapy was associated with greater improvement in urine sodium (+32.84 vs +11.28 mEq/day; $p = 0.001$), urine output (+648.65 vs +271.11 mL/day; $p = 0.002$), body weight (−5.41 vs −2.08 kg; $p = 0.028$), abdominal girth (−1.92 vs +1.27 cm; $p = 0.034$), CTP score (−1.14 vs −0.39; $p = 0.021$), and MELD-Na score (−2.35 vs −0.83; $p = 0.048$). Patients receiving dapagliflozin had lower need for paracentesis (64.9% vs 86.1%; $p = 0.036$), fewer LVP sessions (1.84 vs 3.11; $p = 0.002$), and lower cumulative albumin requirement (128.65 vs 214.72 g; $p = 0.001$). Rates of AKI, infections, hepatic encephalopathy, electrolyte disturbances, and mortality were comparable between groups. Kaplan–Meier analysis showed no significant difference in survival (log-rank $p = 0.679$). **Conclusion:** Dapagliflozin therapy in cirrhosis patients with refractory ascites was associated with improved ascites control, enhanced natriuresis and diuresis, reduced paracentesis requirement, and improvement in liver disease severity scores without significant increase in adverse events. SGLT2 inhibitors may represent a promising adjunctive therapy for refractory ascites in cirrhosis.

0256 | EARLY RESULTS OF A PROSPECTIVE MULTICENTER TRIAL OF THE LIVERTY™ TIPS STENT GRAFT WITH TAILORED EXPANSION FOR PORTAL HYPERTENSION COMPLICATIONS

K. Rajender Reddy[1], [1]University of Pennsylvania

Background: Transjugular intrahepatic portosystemic shunt (TIPS) is an established treatment for complications of portal hypertension; however, hepatic encephalopathy (HE) remains a major limitation, particularly with larger diameter shunts. This study evaluated the safety and effectiveness of the Liverty™ TIPS Stent Graft and assessed a tailored expansion procedure (TEP) enabling stepwise diameter optimization (6–10 mm) to reduce HE while maintaining clinical efficacy. **Methods:** In this prospective, multicenter study, 177 patients (mean age 58.5 years; 59.3% male) underwent successful TIPS creation across 26 centers in the United States, France, and Germany. Indications included refractory ascites (68.4%), esophageal (24.3%) or gastric (2.8%) variceal bleeding, and hepatic hydrothorax (4.5%). Final shunt diameters were ≤ 7 mm in 40.7% of patients (if TEP performed). Final shunt diameters ≤ 8 mm in the overall cohort was 83.1%, reflecting usage of a small-caliber strategy in this study. **Results:** Technical success was 100%. Mean portosystemic gradient decreased from 17.8 mmHg to 7.8 mmHg. At 6 months, 90.4% of TIPS remained patent and free of dysfunction (primary endpoint; $p = 0.0002$). No device-related major complications were observed through 30 days. Freedom from major complications through 30 days was 85.8% ($p = 0.4341$) (primary endpoint). West Haven Grade 1 and 2 HE events resolved with medical therapy and proportion of patients free from major complications was 94.3% ($p < 0.0001$), and probability of freedom from $\geq$ grade 3 HE was 95%, with no high-grade HE observed in 6–7 mm shunts.Clinical success rates (defined as freedom from occurrence of) were 78.8% for ascites, 96.7% for variceal bleeding, and 71.4% for hydrothorax. Among patients with 6–7 mm shunts, clinical success outcomes (as defined above) remained favorable (ascites 84.8%; variceal bleeding 91.7%), with 80% free from HE-related impairment at 6 months compared with 69.2% in larger (8–10 mm) shunts. Transplant-free survival at 6 months was 81.4%. Health-related quality of life remained stable with modest improvements in selected domains. **Conclusion:** The Liverty™ TIPS Stent Graft demonstrated favorable safety and efficacy

for treatment of portal hypertension complications. Use of smaller initial shunt diameters (6–7 mm) with a tailored expansion approach was associated with reduced incidence and severity of HE while preserving clinical effectiveness. These findings support a step-up strategy as a potential new standard for TIPS creation. **Disclosures:** K. Rajender Reddy: BD (Becton, Dickinson and Company): Consultant.

0257 | HIGH-INTENSITY STATIN CONTINUATION AFTER FIRST HEPATIC DECOMPENSATION IN MASLD CIRRHOSIS: A PROPENSITY-MATCHED SIGNAL CHALLENGING LOW-DOSE PARADIGMS

Mohammad Alabbas[1] Akram Alnounou[2] Riddhi Machchhar[3] Omar Sims[1] William Carey[1], [1]Cleveland Clinic Foundation, [2]Western Michigan University Homer Stryker M.D. School of Medicine, Kalamazoo, MI, USA, [3]Hackensack Meridian Health Ocean University Medical Center, Brick, NJ, USA

Background: Low-dose statins are commonly favored in cirrhosis because of safety concerns, yet whether statin intensity modifies post-decompensation outcomes is unknown. We evaluated low- and high-intensity statin continuation after first hepatic decompensation in MASLD cirrhosis. **Methods:** Using TriNetX Linked (44 healthcare organizations), we identified adults aged 18–75 years with MASLD cirrhosis receiving statins before first hepatic decompensation hospitalization. Patients with competing liver diseases, ESRD/dialysis, end-stage heart failure, pregnancy, transplant, HCC, rhabdomyolysis, INR $\geq$2.50, or bilirubin $\geq$5.10 mg/dL were excluded. Continuation was any statin prescription within 1 month after decompensation. Low-intensity continuation was atorvastatin 10–20 mg or rosuvastatin 5–10 mg; high-intensity continuation was atorvastatin 40–80 mg or rosuvastatin 20–40 mg. Each intensity group was 1: 1 propensity-score matched to no statin. Co-primary outcomes were recurrent hepatic decompensation and all-cause mortality at 6 months and 1 year; secondary outcomes included recurrent ascites, recurrent hepatic encephalopathy, MACE, and hospitalization. **Results:** Low-intensity continuation included 125 matched pairs and did not reduce liver outcomes at 6 months or 1 year: recurrent decompensation was 36.8% vs 43.2% (HR 0.76; p = 0.182) at 6 months and 43.2% vs 47.2% (HR 0.79; p = 0.252) at 1 year; mortality was 12.0% vs 14.4% (HR 0.80; p = 0.546) and 16.8% vs 18.4% (HR 0.85; p = 0.641), respectively. MACE was lower with low-intensity therapy at 6 months (24.8% vs 37.6%; HR 0.56; p = 0.007) and 1 year (27.2% vs 40.8%; HR 0.60; p = 0.011). High-intensity continuation included 159 matched pairs and showed lower 6-month recurrent decompensation (26.4% vs 44.0%; HR 0.56, 95% CI 0.38–0.82; p = 0.003), mortality (8.2% vs 17.6%; HR 0.45, 95% CI 0.23–0.88; p = 0.019), recurrent ascites (19.5% vs 36.5%; HR 0.50; p = 0.002), and recurrent encephalopathy (6.9% vs 16.4%; HR 0.38; p = 0.002). At 1 year, high-intensity continuation remained associated with lower decompensation (34.0% vs 46.5%; HR 0.66; p = 0.028), mortality (11.3% vs 21.4%; HR 0.50; p = 0.018), ascites (26.4% vs 39.6%; HR 0.62; p = 0.020), and encephalopathy (8.8% vs 19.5%; HR 0.42; p = 0.003). Hospitalization did not differ. **Conclusion:** In selected MASLD cirrhosis patients already receiving statins before first decompensation, high-intensity continuation—not low-intensity continuation—was associated with lower recurrent decompensation, mortality, ascites, and encephalopathy. This intensity-response signal is hypothesis-generating but clinically provocative and warrants prospective evaluation.

[2]Brigham and Women's Hospital, [3]Massachusetts General Hospital

Background: Patients with compensated liver cirrhosis and atrial fibrillation (AF) face both thromboembolic risk and cirrhosis progression. Whether direct oral anticoagulant (DOAC) initiation influences hepatic decompensation risk remains unclear. We evaluated the association between DOAC initiation and hepatic decompensation in patients with compensated cirrhosis and AF. **Methods:** We conducted a landmark cohort study using the Mass General Brigham Research Patient Data Registry. Patients with compensated cirrhosis and AF aged ≥18 years were identified using ICD-9/10 codes with radiologic confirmation. The index date was the first AF diagnosis. Patients with prior hepatic decompensation, hepatocellular carcinoma, liver transplantation, low CHA_2DS_2-VASc score, valvular heart disease, valve surgery, early decompensation within 90 days, recent warfarin exposure, warfarin-to-DOAC switching, or concurrent warfarin/DOAC use were excluded. Under an intent-to-treat framework, patients were classified as DOAC initiators or non-initiators based on new DOAC prescription within 90 days of the index date. A 90-day landmark was applied to reduce immortal time bias. The primary outcome was confirmed hepatic decompensation verified by chart review. The secondary outcome was confirmed non-portal hypertensive major bleeding. Death and liver transplantation were treated as competing events. Primary analysis used 1: 1 propensity score matching (PSM), with inverse probability of treatment weighting (IPTW) as sensitivity analysis. Cumulative incidence was estimated using the Aalen-Johansen method and compared using Gray's test. **Results:** Among 5,112 patients with compensated cirrhosis and AF, 1,986 met eligibility criteria (DOAC initiators n = 521; non-initiators n = 1,465). After landmark restriction, 1: 1 PSM yielded 444 matched pairs with balanced baseline characteristics. DOAC initiators had significantly lower 5-year cumulative incidence of hepatic decompensation compared with non-initiators (14.1% vs 21.8%; Gray's test p = 0.022). Absolute risk reduction at 5 years was 7.7%. In IPTW analysis (n = 1,676), weighted hazard ratio was 0.75 (95% CI 0.53–1.08), with 5-year cumulative incidence of 14.6% versus 20.0% (Gray's test p = 0.074), showing consistent directionality. There was no significant difference in confirmed non-portal hypertensive major bleeding between groups in the PS-matched cohort (5-year cumulative incidence 25.2% vs 20.7%; Gray's test p = 0.484). **Conclusion:** DOAC initiation in patients with compensated cirrhosis and AF was associated with lower risk of hepatic decompensation without increased non-portal hypertensive major bleeding. These findings suggest a potential hepatoprotective role of DOACs and warrant external validation in larger cohort

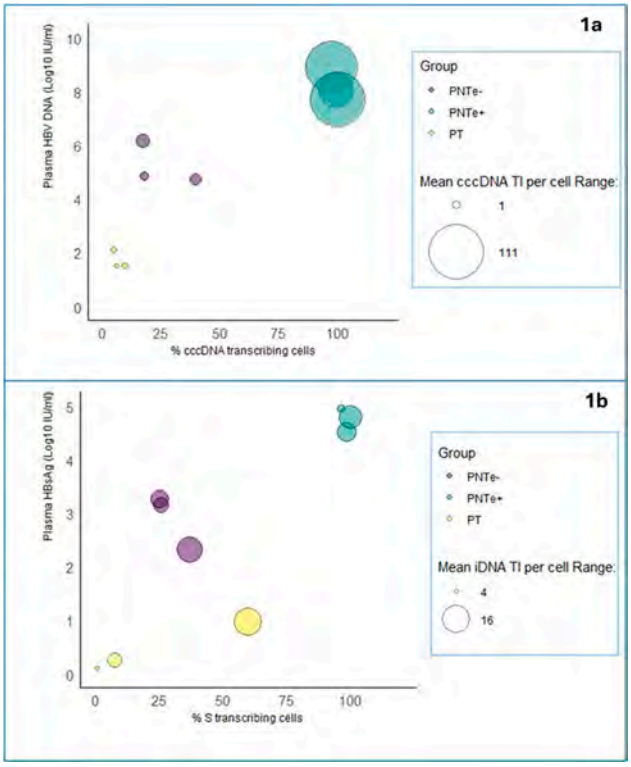
0259 | SINGLE-CELL TRANSCRIPTIONAL LANDSCAPE OF HBV IN CHRONIC HEPATITIS B INFECTION UNCOVERS LOWER CCCDNA TRANSCRIPTION DURING TREATMENT AND IN HBEAG-NEGATIVE INFECTION



Prakriti Sinha[1] Paola Sorto Quijano[1] Naomi Esrig[1] Jasneet Aneja[2] Georg Lauer[2] Scott Fung[3] Chloe Thio[1] Ashwin Balagopal[1], [1]Johns Hopkins University, [2]Massachusetts General Hospital, [3]University Health Network

Background: In chronic hepatitis B (CHB), HBV RNAs are transcribed from covalently closed circular DNA (cccDNA) and HBV DNA integrated into host genome (iDNA). Both produce hepatitis B surface antigen (HBsAg). To understand HBV transcription in people with CHB with various degrees of HBV replication and nucleos(t)ide analogue (NUC) treatment, we performed single-cell studies of liver tissue. **Methods:** We dissected 150-300 single-cell equivalents (SCE) from liver tissues of nine people with CHB: 3 people on treatment (PT), and 6 people not on treatment of which 3 were HBeAg-ve (PNTe-) and 3 were HBeAg+ve (PNTe+). From each SCE, total HBV DNA, cccDNA, and RNA transcripts at the 5'-, mid-, and 3'-HBV positions were quantified using digital PCR platforms.

Cells were considered infected with cccDNA if they were positive for any target except for mid-HBV, which can derive from cccDNA or iDNA. An iDNA transcriptional index (iDNA TI; mid-HBV: 3'-HBV ratio) was used to distinguish cells with S transcripts that encode HBsAg that derive from cccDNA vs iDNA. **Results:** Plasma HBV DNA was $\leq$2 log10IU/ml in PT, 4 to 6 log10IU/ml in PNTe-, and 7 to 9 log10IU/ml in PNTe+. The proportion of infected cells ranged from 14-28% in PT, 37-60% in PNTe-, and 97-100% in PNTe+ and correlated with plasma HBV DNA (r = 0.915, P = 0.0005). Plasma HBV DNA also correlated with the proportion of cells transcribing from cccDNA (r = 0.884; P = 0.001) as well as with the mean cccDNA transcriptional index (cccDNA TI; 5'-HBV RNA: cccDNA per cell) (r = 0.772; P = 0.01) (Fig. 1a). Per cell, the copies of HBV DNA and RNA transcripts and cccDNA TI were significantly higher in PNTe+ than in PT and PNTe- (P = 0.0001); while there were some cells with higher copies of these targets in PNTe-, these were not significantly different from PT. Lastly, while the proportion of S-transcribing cells correlated with the plasma HBsAg levels (r = 0.824; p = 0.01), mean iDNA TI per cell did not (Fig. 1b). **Conclusion:** We applied single-cell approaches to liver tissues from people with CHB and found that HBV control as observed in plasma DNA levels are reflected in the proportion of infected cells and in the cccDNA transcription per cell. In contrast, plasma HBsAg levels appear to reflect the proportion of cells that transcribe S specifically, irrespective of their DNA source.

Background: In the B-Well Phase 3 trials, a 24-week (wk) course of bepirovirsen (BPV), an antisense oligonucleotide, resulted in 19% functional cure (FC) rate in participants (pts) with chronic hepatitis B virus (HBV) infection and baseline hepatitis B surface antigen (HBsAg) level $\leq$3000 IU/mL. Higher FC rates (26%) were observed among those with HBsAg levels $\leq$1000 IU/mL. Here, we evaluated the relationship between on-treatment HBsAg levels and the likelihood of FC response to support informed early treatment-stopping discussions. **Methods:** The B-Well 1 and 2 global double-blind trials enrolled adults receiving nucleos(t)ide analog therapy for chronic HBV infection (HBV DNA $<$90 IU/mL) who had HBsAg concentrations ranging from $>$100 to $\leq$3000 IU/mL. A pre-specified net benefit (NB) analysis was conducted using combined trial data to assess HBsAg as an on-treatment predictor of FC response. Response criteria based on absolute HBsAg values or log changes from baseline at Wks 8 to 14 were evaluated across the entire cohort, as well as stratified by baseline HBsAg levels. The NB analysis facilitated comparison between response criteria to optimize early identification of individuals unlikely to achieve FC with continued treatment, while minimizing the incorrect predictions for those who ultimately attained FC. **Results:** Based on NB findings for pts with baseline HBsAg $>$1000 and $\leq$3000 IU/mL, an HBsAg value of $<$0.05 IU/mL at Wk 12 was deemed the optimal on-treatment predictor of FC response. Among those failing to meet this Wk 12 HBsAg criterion (i.e. $\geq$0.05 IU/mL), only 4/287 (1.4%; 95% confidence interval [CI]: 0.3%, 3.1%) achieved FC, whereas 22/106 (20.8%; 95% CI: 13.3%, 28.9%) who met the criteria (i.e. $<$0.05 IU/mL) achieved FC. For pts with baseline HBsAg $\leq$1000 IU/mL, an HBsAg value $<$1 IU/mL at Wk 12 was identified as the optimal on-treatment predictor of FC response. Among those failing to meet this criterion (i.e. $\geq$1 IU/mL), only 7/280 (2.5%; 95% CI: 0.8%, 4.6%) achieved FC, whereas 179/426 (42.0%; 95% CI: 37.2%, 47.0%) who met the criteria (i.e. $<$1 IU/mL) achieved FC (**Table**). **Conclusion:** A HBsAg level at Wk 12 of $\geq$0.05 IU/mL for pts with baseline HBsAg $>$1000 and $\leq$3000 IU/mL, and $\geq$1 IU/mL for those with baseline HBsAg $\leq$1000 IU/mL, predicts a low probability of achieving FC (1.4–2.5%). In contrast, a higher probability of achieving FC was predicted for those that meet the HBsAg criteria at Wk 12 and complete the treatment regimen (20.8–42%). These findings can facilitate discussions concerning the anticipated outcome of continued BPV therapy. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820).[for the B-Well Study Group]

0261 | PAIRED LIVER BIOPSY ANALYSIS OF HBV INTEGRATION DURING FIVE YEARS OF NUCLEOS (T)IDE ANALOGUE THERAPY: DECLINING EVIDENCE BURDEN AND DELAYED HBV DNA SUPPRESSION

Xinyue Meng[1] Jing Zhao[2] Pengxuan Wu[1] Jianxia Dong[1] Shan Ren[1] Xinyue Chen[1] Sujun Zheng[1], [1]First Department of Hepatology, Beijing YouAn Hospital, Capital Medical University, Beijing, China, [2]First Department of Hepatology, Beijing YouAn Hospital, Capital Medical University, Beijing,China

Background: HBV DNA integration is a durable viral-host genomic event in chronic hepatitis B (CHB), but paired-liver evidence during nucleos(t)ide analogue (NA) therapy is limited. We examined five-year changes in hepatic HBV integration burden and its viral and immune-inflammatory correlates. **Methods:** Baseline liver tissues from 22 NA-treated CHB patients were analyzed; 11 had paired biopsies after five years. HBV integration was detected by capture-based sequencing with liquid-phase probe enrichment and paired-end sequencing. Integration burden was defined by integration events, total junction-supporting reads, and split-read support. Paired changes were tested by Wilcoxon signed-rank test and correlations by Spearman analysis. **Results:** In 11 paired samples, integration evidence burden decreased after five years. Integration events declined from 7.00 to 2.00 ($P = 0.055$), total junction-supporting reads from 41.00 to 10.00 ($P = 0.018$), and split-read support from 36.00 to 8.00 ($P = 0.019$); both read-support metrics decreased in 10/11 patients. HBV DNA, HBV RNA, HBcrAg, qHBsAg, intrahepatic total HBV DNA, cccDNA, Ishak fibrosis score, and Knodell score also decreased. However, changes in integration burden were not significantly correlated with changes in HBsAg, HBsAg isoforms, HBcrAg, HBV DNA, HBV RNA, cccDNA, total intrahepatic HBV DNA, or histological scores. In the 22-patient baseline analysis, integration burden was not consistently associated with HBV DNA, HBV RNA, HBsAg, HBcrAg, or cccDNA. In contrast, baseline integration burden correlated positively with baseline RANTES levels, including integration events (rho = 0.547, $P = 0.008$), total junction-supporting reads (rho = 0.506, $P = 0.016$), and split-read support (rho = 0.520, $P = 0.013$). Baseline integration burden also correlated with higher five-year HBV DNA levels (rho = 0.584, 0.564, and 0.544 for the three integration metrics; all $P < 0.01$) and longer time to HBV DNA undetectability (rho = 0.523, 0.548, and 0.515; all $P < 0.05$). No significant differences in integration burden reduction or residual five-year integration burden were observed between ETV- and ADV-treated patients. **Conclusion:** Five years of NA therapy was associated with reduced hepatic HBV integration evidence burden. Integration changes were not synchronized with HBsAg, HBcrAg, cccDNA, or histology. Baseline serum viral markers did not reliably reflect hepatic integration burden, whereas higher baseline integration burden was associated with RANTES-related immune activity, delayed HBV DNA suppression, and higher residual HBV DNA after five years.

0262 | IMMUNE REMODELING AFTER HBV FUNCTIONAL CURE FEATURES COORDINATED ENRICHMENT OF GZMK⁺ CD8⁺ T CELLS AND ACTIVATED MEMORY B CELLS

Qi Zheng[1] Zhen Xun[1], [1]Fujian Medical University

Background: Interferon-α (IFN-α)-induced functional cure of chronic hepatitis B (CHB) offers an opportunity to examine immune changes following HBV clearance. We aimed to characterize the longitudinal dynamics of peripheral T and B cell subsets and their temporal coordination after cure. **Methods:** Peripheral blood mononuclear cells from CHB patients with PEG-IFN-α-induced HBsAg loss (n = 51) were collected. A cohort of 19 patients was analyzed by droplet-based single-cell RNA-seq. An independent cohort of 32 patients was assessed by multicolor flow cytometry. A third longitudinal cohort (n = 8) was sampled at baseline, weeks 24, 36, and 48 of PEG-IFN-α therapy. Post-cure patients were stratified by time since HBsAg loss: 6–12, 12–18, and > 18 months. CellChat was used to infer cell-cell communication. **Results:** During IFN-α treatment, peripheral GZMK⁺ CD8⁺ T cells progressively declined while GZMB⁺ CD8⁺ T cells gradually increased. After therapy discontinuation, this pattern reversed: GZMK⁺CD8⁺ cells expanded over time (> 18 months vs. 6–12 months, p = 0.038) and GZMB⁺CD8⁺ cells continued to contract. In parallel, the IgG⁺ fraction within classical memory B cells (cMBC) was significantly higher at > 18 months compared with both 6–12 months (p = 0.047) and 12–18 months (p = 0.013). The proportion of activated memory B cells (actMBC) tended to increase at > 18 months versus 6–12 months (p = 0.050), but was comparable between 12–18 months and > 18 months (p = 0.28). The increase in GZMK⁺ CD8⁺ T cells and memory B cell subsets was temporally coordinated. Phenotypically, post-cure GZMK⁺ CD8⁺cells displayed a memory precursor profile (IL7R, CD27), whereas GZMB⁺CD8⁺T cells exhibited a terminal effector signature (CX3CR1, GNLY). To investigate potential interactions between the coordinately expanding populations, CellChat analysis revealed that the MIF-CD74-CXCR4 signaling axis between GZMK⁺CD8⁺ T cells and B cells was progressively strengthened with time after cure, suggesting an evolving T-B crosstalk underlying their synchronous dynamics. While this T-B communication signal strengthened, antigen presentation pathways in B cells and monocytes declined over time after cure. **Conclusion:** In patients with IFN-α-induced HBV functional cure, GZMK⁺ CD8⁺ T cells and activated memory B cells coordinately increase over time after cure, while GZMB⁺ CD8⁺ T cells decline, indicating a shift from an effector-dominated to a memory-biased immune profile.

0263 | ISRIB AS A PROMISING SAVIOR FOR ACUTE LIVER FAILURE: MODULATING THE GUT MICROBIOTA-TRYPTOPHAN METABOLISM-IMMUNE AXIS

Qi Jiang[1] Haonan Zhang[2] Yuxi Zhao[3] Lingxiao Zhu[3] Yan Lv[3] Yan Jin[1] Wei Wang[4] Lanjuan Li[3], [1]Institute of Pathogen Biology, Chinese Academy of Medical Sciences & Peking Union Medical College, [2]Department of Ultrasound, The First Affiliated Hospital of Anhui Medical University, [3]SKLID, The First Affiliated Hospital, Zhejiang University School of Medicine, [4]Department of Stomatology, The First Affiliated Hospital, Zhejiang University School of Medicine

Background: Acute liver failure (ALF) is a rapidly progressive, life-threatening syndrome with limited effective medical therapy beyond liver transplantation and artificial liver. Increasing evidence highlights the critical role of the gut-liver axis in ALF progression. ISRIB, a selective integrated stress response inhibitor,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

has demonstrated anti-inflammatory and cytoprotective effects in multiple disease models, but its therapeutic potential and mechanistic basis in ALF remain unknown. We investigated whether ISRIB alleviates ALF by reshaping the gut microbiota, regulating tryptophan metabolism, and modulating hepatic immune responses. **Methods:** Male C57BL/6 mice were used to establish an LPS/D-galactosamine-induced ALF model. ISRIB was administered intraperitoneally 12 hours before and during ALF induction. Mice were sacrificed 6 hours after modeling. Liver injury, inflammatory cytokines, intestinal barrier integrity, and endotoxemia were evaluated by biochemical assays, histopathology, ELISA, and RT-qPCR. Gut microbial composition was profiled by 16S rRNA sequencing, fecal metabolites were analyzed by untargeted metabolomics, and hepatic immunity-related transcriptional profiles were assessed by RNA sequencing. Antibiotic depletion, fecal microbiota transplantation, probiotic intervention and metabolite supplementation were further conducted to validate microbiota-dependent mechanisms. **Results:** ISRIB significantly attenuated ALF-associated liver injury, as demonstrated by reduced serum ALT/AST levels, decreased hepatic necroinflammation and suppression of systemic inflammatory cytokines. ISRIB also partially restored gut microbial diversity and shifted the abundance of key taxa, including *Akkermansia*, *Alistipes*, and *Lactobacillus*. Metabolomic profiling identified multiple tryptophan-related and redox-associated metabolites, including 5-methoxytryptophan, together with additional lipid and oxidative stress-linked candidates. Transcriptomic analysis indicated that ISRIB reversed inflammatory and innate immune activation signatures associated with ALF, particularly pathways linked to cytokine signaling, immune remodeling, and metabolic stress responses. Integrated multi-omics analysis suggested a coordinated interaction among ISRIB-responsive gut microbes, tryptophan metabolites and hepatic immune pathways. **Conclusion:** ISRIB exerts a protective effect against experimental ALF and may represent a promising therapeutic strategy for acute liver injury. Mechanistically, ISRIB appears to ameliorate ALF through modulation of the gut microbiota-tryptophan metabolism-immune axis, highlighting a previously unrecognized gut-liver immunometabolic mechanism underlying ISRIB-mediated hepatoprotection.

0264 | MACHINE LEARNING MODEL ACCURATELY PREDICTS SPONTANEOUS SURVIVAL OF PHOSPHORUS RELATED HEPATOTOXICITY PATIENTS TREATED WITH PLASMA EXCHANGE.

Ashish Goel[1] Santhosh Kumar[1] Amirthalingam Mangaiyarkarasi[2] Kshitij Jadhav[3] S Akilesh[1] Kamya Gupta[3] Vijay Alexander[1] Gayathiri Chellaiya[1] Dolly Daniel[1] Vinoi David[1] A Nirmala[2] P Kalidas[2] Krishnasamy Narayanasamy[4] E Senthil[2] Bhavik Kanekar[5] Hannah Thomas[1] Uday Zachariah[1] C Eapen[1], [1]Christian Medical College, Vellore, [2]Coimbatore Medical College, [3]Koita Centre for Digital Health, Indian Institute of Technology Bombay, [4]The Tamil Nadu Dr MGR Medical University, [5]Koita Centre for Digital Health, Indian Institute of Technology Bombay, Mumbai

Background: Rodenticide (yellow phosphorus) induced hepatotoxicity (RH) is an hyperendemic cause of acute liver failure in India (PMID: 38638507). Plasma exchange (PLEX) has shown to improve outcomes in these patients. King's College Hospital (KCH) criteria have not been validated for RH-related acute liver failure (ALF), and the 'Kochi' criteria have not been evaluated in RH patients undergoing PLEX. The study aimed to develop and validate a machine learning (ML) model to predict in-hospital spontaneous survival in patients with RH treated with PLEX. **Methods:** In this multicenter retrospective study, clinical data were collected from RH patients treated with low-volume PLEX and low-dose steroids. The primary outcome was prediction of in-hospital survival. Predictions were evaluated at five distinct time points: admission (T1), pre-PLEX (T2), and following the first (T3), second (T4), and third (T5) PLEX sessions. Several tree-based ML models were developed, with the XGBoost model demonstrating the most consistent performance. Feature selection was guided by Shapley Additive Explanations (SHAP) values. To ensure model explainability, sigmoid curves were fitted to individual features to identify inflection points, which served as objective cutoff values for differentiating survival from mortality. **Results:** The cohort included 360 patients: 65 (18%) with uncomplicated hepatitis, 128 (35.6%) with acute liver injury, and 167 (46.4%) with ALF. Of these, 239 were discharged alive, 116 died, and 5 were excluded due to transfer. None of the patients had liver transplantation. Table 1 shows the performance of the model at the five time points for the entire cohort and among ALF subgroup with top SHAP features (with its cut-off) listed at each time point. The resulting RHPLEX model significantly outperformed the Kochi criteria. At admission (T1), the RHPLEX model achieved higher

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

accuracy compared to Kochi (80.6% vs. 59.7%), specifically demonstrating a much higher recall for mortality (76.7% vs. 24.1%). At the pre-PLEX (T2) stage, RHPLEX maintained superior accuracy (77.8% vs. 66.3%) and mortality recall (74.1% vs. 37.9%).The model demonstrated sustained accuracy at subsequent time points: T3 (80.2%), T4 (74.6%), and T5 (79.4%). SHAP analysis identified traditional markers of liver severity (bilirubin, INR, and creatinine) as key predictors, but also highlighted the prognostic importance of hematological indices, including neutrophil and lymphocyte counts and the lymphocyte-monocyte ratio. In the ALF subgroup, the RHPLEX model remained superior to KCH criteria (accuracy 76.1% vs. 60.4%). **Conclusion:** The RHPLEX model provides a robust, explainable, and early prediction of survival in patients with phosphorus-induced hepatotoxicity treated with PLEX. By outperforming established criteria, this model offers a potential clinical tool for early risk stratification, though further external validation is warranted.

Table 1: The performance of the model for the entire data set and among ALF patients and top features on Shapley and their cut-offs with arrow indicating the direction of the value to have a favourable outcome

0265 | MONOTHERAPY WITH SIRNA HRS-5635 INDUCES AN HBSAG LOSS IN CHRONIC HBV INFECTION: A MULTICENTER, RANDOMIZED, PHASE II STUDY

Xieer Liang[1] Yingli He[2] Yongning Xin[3] Xingxiang Yang[4] Sikui Wang[5] Zhihong Liu[1] Rui Hua[6] Shuqiang Ou[7] Hainv Gao[8] Dachuan Cai[9] Jun Ye[10] Shuangsuo Dang[11] Minghua Su[12] Xuebing Yan[13] Chuanmiao Liu[14] Guang-Ming Li[15] Zuxiong Huang[16] Xiaopeng Wang[17] Ying Wang[17] Lingling Xu[17] Jinlin Hou[1], [1]Nanfang Hospital, Southern Medical University, [2]The First Affiliated Hospital of Xi'an Jiaotong University, [3]Qingdao Municipal Hospital, [4]Sichuan Provincial People's Hospital, [5]Liaocheng People's Hospital, [6]The First Hospital of Jilin University, [7]Pingxiang NO.2 People's Hospital, [8]Shulan (Hangzhou) Hospital, [9]The Second Affiliated Hospital of Chongqing Medical University, [10]The Second Affiliated Hospital of Anhui Medical University, [11]The Second Affiliated Hospital of Xi'an Jiaotong University, [12]The First Affiliated Hospital of Guangxi Medical University, [13]The Affiliated Hospital of Xuzhou Medical University, [14]The First Affiliated Hospital of Bengbu Medical University, [15]The Sixth People's Hospital of Zhengzhou, [16]Mengchao Hepatobiliary Hospital of Fujian Medical University, [17]Fujian Shengdi Pharmaceutical Co., Ltd.

Background: Loss of HBsAg is the optimal but rarely achieved goal for chronic HBV infection. HRS-5635 is the first N-acetylgalactosamine (GalNAc)-conjugated siRNA advancing into phase III registrational trials, which targets all HBV mRNAs and suppresses the synthesis of viral proteins, thereby inducing HBsAg loss and ultimately achieving a functional cure of chronic HBV infection. **Methods:** Here, we present the Part A results of the multicenter phase II trial of HRS-5635. Patients with HBsAg 100-3000 IU/mL and suppressed HBV DNA while on stable nucleos(t)ide analogue (NA) therapy were randomized (1: 2: 2: 2) to receive 48 weeks of subcutaneous HRS-5635: 50 mg every 4 weeks (Arm 1), 200 mg every 4 weeks (Arm 2), 400 mg every 4 weeks (Arm 3), or 100 mg weekly (Arm 4), followed by a 24-week off-treatment follow-up. NA therapy was discontinued for eligible participants. Primary endpoint was HBsAg reduction from baseline at Week 12. Secondary endpoints included HBsAg loss, HBeAg loss, and safety. **Results:** The full analysis set comprised 15, 32, 32, and 30 participants in Arms 1 to 4, respectively. Overall, 68% of participants were male with a mean age of 43 yrs, 30% being HBeAg-positive. Mean (SD) baseline HBsAg ranged from 1058 (960) to 1200 (898) IU/mL, and 42% of participants had baseline HBsAg $\geq$1000 IU/mL. The mean (SD)HBsAg reductions (log10 IU/mL) from baseline at Week 12 were 1.3 (0.4), 2.0 (0.5), 2.1 (0.8), and 1.9 (0.5) in Arms

1 to 4, respectively. At treatment completion (Week 48), HBsAg loss was achieved in 7% (1/15), 6% (2/32), 16% (5/32), and 7% (2/30) of participants in Arms 1 to 4, respectively. The corresponding rates at Week 72 (24 weeks off treatment) were 7% (1/15), 6% (2/32), 19% (6/32), and 7% (2/30), respectively. Furthermore, in HBeAg-negative patients receiving 400 mg HRS-5635, the Week 72 HBsAg loss rate was 24% (5/21); this rate reached 33% (5/15) in those with baseline HBsAg <1000 IU/mL, whereas no HBsAg loss (0%) was observed in participants with baseline HBsAg ≥ 1000 IU/mL. The two participants with baseline HBsAg ≥ 1000 IU/mL who achieved HBsAg loss were both in Arm 4. Additionally, HBeAg loss occurred in 0%, 11% (1/9), 27% (3/11), and 11% (1/9) of participants in Arms 1 to 4, respectively, at Week 72. Treatment-emergent adverse events were generally grade 1 or 2, with no dose-dependent pattern. No treatment-related adverse events led to study discontinuation. **Conclusion:** A finite duration of 400 mg HRS-5635 therapy was well-tolerated and achieved higher HBsAg loss rates at 24 weeks post-treatment cessation. These findings warrant further clinical assessment of this regimen for pursuing functional cure of chronic HBV infection.

Waltham, MA, USA, [37]GSK, London, UK, [38]GSK, Stevenage, UK, [39]GSK, Collegeville, PA, USA

Background: Functional cure (FC) – defined as ≥24 weeks (wks) of sustained HBV DNA < lower limit of quantification (LLOQ) and hepatitis B surface antigen (HBsAg) loss after finite therapy, with or without hepatitis B surface antibody – is the treatment goal in chronic HBV infection. Bepirovirsen (BPV), an antisense oligonucleotide, is the first anti-HBV therapy in global Ph3 trials with FC as the primary outcome. **Methods:** B-Well 1 and 2 are global double-blind Ph3 trials. Non-cirrhotic adults with nucleos(t)ide analog (NA)-suppressed chronic HBV infection (HBV DNA <90 IU/mL) and HBsAg >100–≤3000 IU/mL were randomized 2: 1 to BPV 300 mg or placebo (PBO) weekly for 24 wks. Participants (pts) discontinued NAs at Wk48, if eligible. The primary outcome was FC response rate at Wk72 for all pts. Key secondary outcomes included FC response rate for pts with baseline (BL) HBsAg ≤1000 IU/mL. Pts who discontinued NAs entered the durability stage after Wk72 and were monitored for safety and durability of FC response to Wk96. **Results:** Among BPV pts, 20% (127/650) in B-Well 1 and 19% (106/570) in B-Well 2 achieved FC at Wk72. No PBO pts achieved FC. A total of 24% pts on BPV (B-Well 1, 159/650; B-Well 2, 136/570) entered the NA cessation stage at Wk48 and 24% (B-Well 1, 155/650; B-Well 2, 136/570) entered the durability stage after Wk72; no PBO pts were eligible for NA cessation. Among BPV pts with BL HBsAg ≤3000 IU/mL who stopped NAs, achieved FC at Wk72, and completed Wk96, 90% (114/127; B-Well 1) and 92% (97/105; B-Well 2) had a durable FC response at Wk96; a similar proportion of durable response was observed in BPV pts with BL HBsAg ≤1000 IU/mL who achieved FC at Wk72. Among BPV pts with BL HBsAg ≤3000 IU/mL who achieved DNA. Among pts who stopped NAs at Wk48, 5 had HBV DNA replication at Wk72, of which 1 had viral relapse and reinitiated NAs post Wk72. For pts who achieved DNA suppression at Wk72, 6 had HBV DNA replication (3 confirmed/3 unconfirmed) at Wk96. Most common AEs for BPV pts in Wks 73–96 were upper respiratory tract infection (4% [12/291]), creatinine renal clearance decreased (2% [5/291]), and nasopharyngitis (2% [5/291]). AEs related to study treatment reported in Wks 73–96 (after BPV cessation) occurred in 2% (5/291) of pts, and these were single events. **Conclusion:** FC induced by 24-wk BPV treatment was durable through to Wk96 (48 wks post-cessation of all HBV treatment, including NAs) in virologically suppressed pts with chronic HBV infection. BPV had an acceptable safety profile without any evidence of latent safety concerns associated with prior BPV treatment. These data demonstrate the potential for BPV to be a first-in-class therapy for FC. **Funding:** GSK (202009/NCT05630807; 219288/NCT05630820)[For the B-Well Study Group]

Pamela Valentino[7] Estella Alonso[8] Jean Molleston[9] Kasper Wang[10] Simon Horslen[11] Philip Rosenthal[12] Ronald Sokol[13] Binita Kamath[14] John Magee[15] Stephen Guthery[16] Saul Karpen[1] ChiLDReN Childhood Liver Disease Research Network[17], [1]VCU Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, [2]The Children's Hospital of Philadelphia, [3]University of Utah, [4]Cincinnati Children's Hospital Medical Center, [5]Children's Hospital Los Angeles, [6]Texas Children's Hospital, [7]University of Washington, [8]Ann and Robert H. Lurie Children's Hospital of Chicago, [9]Riley Hospital for Children, [10]Hospital for Sick Children, [11]UPMC Children's Hospital of Pittsburgh, [12]University of California, San Francisco, [13]University of Colorado School of Medicine, [14]Children's Hospital of Philadelphia, [15]University of Michigan Hospitals and Health Centers, [16]Intermountain Primary Children's Hospital, [17]NIH NIDDK

Background: Biliary atresia (BA) is the most clinically relevant developmental cholangiopathy of children yet has poorly understood genetic contributors. A limited number of genes have been linked to the etiology of BA, including *PKD1L1*, *ADD3*, *CFC1* and CPLANE genes; however, large-scale analyses have been constrained by small cohort sizes and a lack of matched controls. To fill this gap, we analyzed whole-exome sequencing (WES) results from the large NIDDK-supported ChiLDReN consortium and matched multi-ethnic controls to identify novel BA-associated candidate etiologic loci. **Methods:** Variants were jointly called using Illumina DRAGEN in 1,732 BA cases (187 identified as BA with splenic malformation [BASM]) from the ChiLDReN consortium and 4,853 matched controls, while 1,697 were genotyped using the Illumina 650K SNP array. Genetic ancestry was inferred via K-nearest neighbors on 1000 Genomes-projected principal components. Multiple analytical approaches were applied, including gene-based rare variant burden testing (SKAT-O, SAIGE-GENE+), variant-level association analysis (GCTA), and biallelic carrier enrichment testing. Correlations with select post-Kasai portoenterostomy (KPE) outcomes proceeded via QTL analyses. Case-only AI-based variant prioritization was performed with GEM to derive gene candidates based on variant pathogenicity, phenotype, and Mendelian disease associations. **Results:** *PKD1L1* was confirmed as a BASM risk gene (OR = 17.7, p-adj = 0.034) from WES variants. SNP array analysis confirmed enrichment of the *ADD3* lead SNP (rs17095355), particularly in inferred East Asian ancestry. Gene-based analysis identified excess variants in the PIDDosome gene *PIDD1* (a determinant of hepatocyte ploidy during development) in cases vs controls. SAIGE-GENE+ revealed *HBEGF*, an EGFR ligand suppressing cholestatic injury, as a potential candidate. Biallelic carrier analysis identified *TTLL5*, a known ciliopathy gene, as enriched in cases vs. controls. QTL analysis nominally linked rs6431625 (*UGT1A3*) and rs7665271 (*BBS12*) to elevated post-KPE 3-month total serum bilirubin (TB) levels. Using GEM, candidate genes were significantly enriched in ciliopathy-related gene sets, highlighting Mendelian candidates like *PKD1L1*, *JAG1*, *PKD2* and *DCDC2*. **Conclusion:** Application of multiple WES and SNP array analytical methodologies to a large BA case-control cohort identified new BA candidate genes including *PIDD1*, *HBEGF*, and *TTLL5*, and corroborated *PKD1L1* and *ADD3* gene variants in specific clinical and genetic ancestry groups. *UGT1A3* and *BBS12* variants were associated with elevated TB levels at 3 months post-KPE. Taken together, multiple analytical approaches of the largest BA genetic case-control cohort reported to date worldwide reveal various genetic contributions to the complex etiopathogenesis of BA from ciliary, developmental and adaptive processes.

0268 | A PHASE 2-READY ASK1 INHIBITOR SUPPRESSES POST-OBSTRUCTIVE CHOLESTATIC INFLAMMATION AND FIBROSIS IN EXPERIMENTAL BILIARY ATRESIA

Nithyananthan Subramaniyam[1] Pavithra Sudhakara[1] Reena Mourya[1] Bhargavi Mohan[1] Artur Plonowski[2] Advai Shivakumar[3] Kathleen Elias[4] Neil McDonnell[2] Pranavkumar Shivakumar[1], [1]Biliary Atresia Research and Cure (BARC) Program, GI Division, UTSW Medical Center, Dallas, TX., [2]Seal Rock Therapeutics Inc., Seattle, WA., [3]Northeast Ohio Medical University, Rootstown, OH., [4]Seal Rock Therapeutics, Inc

Background: Biliary atresia (BA) progresses rapidly from cholangiopathy to fibro-inflammatory liver injury, yet no post-Kasai pharmacotherapy prevents progression to transplant. Apoptosis signal-regulating kinase 1 (ASK1/MAP3K5), an oxidative stress-responsive MAP kinase, is activated in human BA and its inhibition restores bile duct patency in experimental BA. Here, we tested whether SRT-015, a phase 2-ready ASK1 inhibitor, attenuates progressive liver fibrosis. **Methods:** ASK1-linked pathways were evaluated in RNA-seq/proteomic datasets from normal control (NC) and BA liver/serum, and transplant-stage patient cholangiocyte organoids (BACO-Tx). Post-Kasai cholangiopathy was modeled using a murine pseudo-Kasai BA liver fibrosis (BALF) model with patent extrahepatic duct. Newborn WT mice received i.p. saline or $1.75x10^6$ ffu RRV to induce BALF, followed by daily vehicle or SRT-015 (10 or 20 mg/kg). Outcomes at day 19 post-RRV included phenotype, survival, ALT/AST/ALP, H&E and Sirius Red histology scored by Ishak modified HAI and Fibrosis Staging, immunofluorescence for ASK1, p-ASK1, p38, and p-p38 and quantified as mean fluorescence intensity (MFI) in BA-Tx and BALF livers, hepatic qPCR of MAPK/apoptotic/inflammatory/fibrotic genes, and hepatic immune cell profiling by flow cytometry. **Results:** Transcriptomic and serum proteomics analyses of BACO-Tx and livers revealed upregulated ASK1-regulated molecules, with sustained p38 (MAPK11/12), CASP1, CCL2, CXCL8, CTGF, and SPP1 from diagnosis and de novo appearance of MAP2K4/6/7, TGFβ1/β2, FN1, LCN2, ACTA2, and CCL20/28 at transplant. BA-Tx livers showed increased cholangiocyte and immune-cell MFI for ASK1, p-ASK1, p38, and p-p38 (BA 444 ± 87 vs NC 83 ± 23; $P \leq 0.0001$). At day 19, vehicle-treated BALF mice showed jaundice and growth failure, while SRT-015 resolved jaundice, restored growth, and improved survival ($P \leq 0.001$). ASK1/p-ASK1 localized to injured cholangiocytes and reduced with SRT-015. SRT-015 reduced ALT (89 ± 11 vs 130 ± 33), AST (172 ± 38 vs 245 ± 78), and ALP (242 ± 72 vs 522 ± 325), attenuated portal/bridging inflammation (Ishak HAI: 0.3 ± 0.6 vs 2.3 ± 0.6), and periportal/bridging collagen deposition (Ishak fibrosis: 0.3 ± 0.6 vs 3.6 ± 0.5). Hepatic *Map3k5*, *Map2k4/6/7*, *Casp1/3/4*, *Il1β*, *Tnfα*, and profibrotic *Ctgf*, *Acta2*, *Tgfβ1*, *Thbs1*, and *Loxl2/4* were reduced 3-8-fold ($P \leq 0.01$). Flow cytometry showed fewer $CD45^+$ $COL1A1^+$ fibrocytes, MHCII/$CCR2^+$ $CD11b^+$ $F4/80^+$ macrophages/$CD11b^+$ $Gr1^+$ neutrophils, and $CD11c^+$ $CD11b^+$ mDCs (all $P \leq 0.01$), indicating suppression of the fibro-inflammatory niche. **Conclusion:** ASK1 signaling persists during the fibrotic phase of BA. SRT-015 improved survival, attenuated MAPK activation, cholestatic injury, inflammation, collagen deposition, fibro-inflammatory immune remodeling, and preserved bile flow. These findings support clinical evaluation of post-Kasai ASK1 inhibition as a long-term antifibrotic strategy for BA.

0269 | FIBRONECTIN&NDASH; INTEGRIN α5β1 CROSSTALK IS A THERAPEUTIC EPITHELIAL-IMMUNE AXIS IN BILIARY ATRESIA

Wenqi Li[1] Nithyananthan Subramaniyam[1] Reena Mourya[1] Jorge Bezerra[1] Pranavkumar Shivakumar[1], [1]University of Texas Southwestern Medical Center

Background: Biliary atresia (BA) is driven in part by epithelial-immune crosstalk that amplifies cholangiocyte injury and obstruction. Macrophage-mediated inflammation is central to bile duct damage. Prior cholangiocyte organoid-macrophage cocultures identified fibronectin (Fn)-integrin α5β1 signaling as a candidate pathway by which cholangiocytes activate macrophages. BA cholangiocytes showed increased Fn production and enhanced macrophage-activating capacity; however, the functional contribution of the Fn-integrin α5β1 axis to BA has not been defined. **Methods:** To test patient-derived epithelial-immune mechanism across complementary platforms, we combined human BA cholangiocyte organoids (BACO), human embryonic stem cell-derived macrophages, pathway-selective perturbation, and in vivo antibody blockade. Macrophages were exposed to conditioned medium from normal control cholangiocyte organoid (NCO) or BACO. Fn-dependent signaling was inhibited

with RGDS, whereas integrin α5β1 signaling was blocked with volociximab to distinguish ligand-level from receptor-level regulation; IL-1β and IL-8 were quantified by flow cytometry. For in vivo validation, newborn BALB/c mice received $1.5x10^6$ ffu rhesus rotavirus (RRV) i.p. to induce BA and were treated every other day through day 11 with combined anti-ITGA5/anti-ITGB1 blocking antibodies or isotype control. Weight, jaundice score (0-4), and survival were measured daily, and liver and bile duct histology were assessed at day 12. This strategy links patient signals to mechanistic and anatomic rescue endpoints. **Results:** BACO conditioned medium induced macrophage inflammatory activation, increasing IL-8 and IL-1β by 1.7-1.8-fold, ($P < 0.01$). Fn inhibition with RGDS selectively reduced BACO-induced IL-1β (45.8 ± 2.3% vs 51.5 ± 0.6% in untreated control; $P = 0.02$), but not IL-8 (56.6 ± 1.3% vs 54.9 ± 0.8%; $P = 0.35$), suggesting partial Fn dependence. In contrast, direct integrin α5β1 blockade with volociximab suppressed both IL-1β (42.8 ± 0.5 vs 47.5 ± 2.0%; $P < 0.01$) and IL-8 (39.5 ± 1.6 vs 51.5 ± 1.9%; $P < 0.01$), identifying integrin α5β1 as a functional macrophage response node downstream of BA cholangiocyte-derived Fn signals. In vivo, combined ITGA5/ITGB1 blockade improved the RRV-induced BA phenotype. At day 12, antibody-treated mice had higher body weight than isotype-treated controls (5.6 ± 0.7 vs 4.5 ± 0.3 g, $P < 0.01$), markedly lower jaundice scores (0.4 ± 0.5 vs 4.0 ± 0.0, $P < 0.01$), and >80% reduction in anatomic extrahepatic bile duct atresia (16.7% vs 100%). Treated mice maintained luminal continuity and bile flow, indicating reduced clinical disease severity. **Conclusion:** BA cholangiocytes activate macrophages through Fn-integrin α5β1 signaling. Blocking this epithelial-immune axis reduced macrophage cytokine production and bile duct obstruction, identifying integrin α5β1 signaling as a translational strategy to reduce immune-mediated injury in BA.

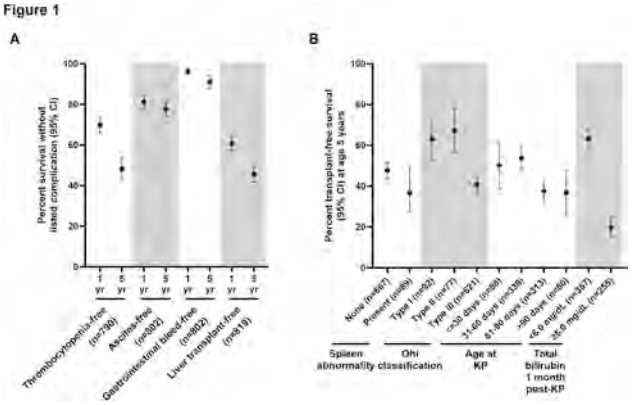
0270 | EARLY TIMEPOINTS ARE CRITICAL IN BILIARY ATRESIA: RESULTS FROM PROSPECTIVELY FOLLOWING 831 INFANTS RECEIVING THE KASAI PORTOENTEROSTOMY

Sanjiv Harpavat[1] Sindhu Pandurangi[2] Steve Guthery[3] Saul Karpen[4] Kathleen Loomes[5] Estella Alonso[6] Simon Horslen[7] Rohit Kohli[8] John Magee[9] Alexander Miethke[10] Jean Molleston[11] Philip Rosenthal[12] Pamela Valentino[13] Kasper Wang[14] Ronald Sokol[15] Benjamin Shneider[16] the Childhood Liver Disease Research Network (ChiLDReN)[17], [1]Texas Children's Liver Center - Baylor College of Medicine, [2]UT Southwestern, Children's Medical Center Dallas, [3]Primary Children's Hospital, [4]VCU Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, [5]The Children's Hospital of Philadelphia, [6]Ann and Robert H. Lurie Children's Hospital of Chicago, [7]UPMC Children's Hospital of Pittsburgh, [8]Children's Hospital Los Angeles, [9]University of Michigan Hospitals and Health Centers, [10]Cincinnati Children's Hospital Medical Center, [11]Riley Hospital for Children and Indiana University School of Medicine, [12]University of California, San Francisco, [13]University of Washington, [14]Hospital for Sick Children, University of Toronto, [15]University of Colorado School of Medicine, [16]Texas Children's Hospital and Baylor College of Medicine, [17]NIDDK



Background: Infants with biliary atresia are treated with the Kasai portoenterostomy (KP), with the goal of relieving bile retention and ultimately improving outcomes. In this study, we analyzed the largest multicenter prospective study of biliary atresia to (i) better understand the disease's natural history after KP and (ii) identify early factors that predict long-term liver transplant-free survival. **Methods:** Patients with biliary atresia, treated with the KP, and enrolled in the Childhood Liver Disease Research Network's (ChiLDReN) Prospective Database of Infants with Cholestasis (PROBE; NCT00061828) from 2004-2025 were studied. Clinical endpoints such as thrombocytopenia, ascites, and gastrointestinal bleeding were defined a priori and collected during annual follow-up visits. Cox Proportional Hazards and Kaplan-Meier analyses were used for survival estimates and analysis of prognostic factors, respectively. **Results:** There were 831 infants from the United States and Canada included, who were 54% female (n = 446), 62% white (n = 492), and 23% Hispanic (n = 189). One-year estimated survival without thrombocytopenia was 69.8%, without ascites 81.2%, and without gastrointestinal bleeding was 96.3% (Figure 1A). One-year survival with native liver was 60.7%. Between ages 1-5 years, estimates for survival without ascites and gastrointestinal bleeding dropped minimally, indicating that disease progression is less rapid in infants surviving with their native liver beyond the first year. Early non-modifiable factors that predicted better native liver survival at age 5 years included absence of splenic abnormalities ($p = 0.04$) and Ohi antomical type I and II ($p < 0.0001$) (Figure 1B). In comparison, early modifiable factors that predicted better native liver survival at age 5 years included performing the KP at ≤30 days of life or 30-60 days of life ($p = 0.0003$). Another early factor that may or may not be modifiable was improvement of bile flow immediately

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

after KP, as indicated by better native liver survival at age 5 years in those who achieved total bilirubin < 6.0 mg/dL within 1 month after KP ($p < 0.0001$). **Conclusion:** In the largest propspective study of infants with biliary atresia, signs of disease progression appeared rapidly in the first year of life but slower after the first year of life. In addition, early non-modifiable, modifiable, and possibly modifiable factors were associated with long-term outcomes. Our findings highlight the importance of the first year of life and the peri-KP period specifically in biliary atresia, and raise the possibility that interventions in a narrow early window—such as screening to accelerate the age at KP and treating immediately after KP with adjunctive therapies that promote bile flow—may be especially efficacious in improving long-term outcomes.

0271 | GENOTYPIC SPECTRUM AND CLINICAL OUTCOMES OF GENETIC LIVER DISEASES ACROSS ASIA-PACIFIC COUNTRIES: THE ANGELD STUDY

Huey-Ling Chen[1] Ayano Inui[2] Anupam Sibal[3] Ruey Terng Ng[4] Chatmanee Lertudomphonwanit[5] Jae Sung Ko[6] Byung-Ho Choe[7] Voranush Chongsrisawat[8] Winita Hardikar[9] Chia-Ray Lin[10] Bang-Yu Liou[10] Mei-Hwei Chang[1] Way-Seah Lee[4] Suporn Treepongkaruna[5] Yen-Hsuan Ni[10], [1]National Taiwan University, [2]Saiseikai Yokohamashi Tobu Hospital, Kanagawa, Japan, [3]Indraprastha Apollo Hospital, New Delhi, India, [4]University of Malaya, Malaysia, [5]Ramathibodi Hospital, Mahidol University, Bangkok, Thailand, [6]Seoul National University College of Medicine, Seoul National University Children's Hospital, Seoul, [7]Kyungpook National University School of Medicine, Korea, [8]Chulalongkorn University, Thailand, [9]Royal Children's Hospital, Melbourne, Australia, [10]National Taiwan University College of Medicine and Children's Hospital, Taipei, Taiwan

Background: Pediatric genetic liver diseases comprise a heterogeneous group of disorders, with disease spectrum and prevalence varying across geographic regions. However, the disease burden and genetic landscape in the Asia-Pacific region remain less characterized. This study aimed to investigate the causative genes and disease spectrum of pediatric genetic liver diseases in the Asia-Pacific region. **Methods:** The ANGELD study, conducted by the Asia-Pacific Network of Genetic Liver Diseases, is a multicenter collaborative consortium study. A case registry was established to collect clinical information, serum biochemical profiles, genetic testing results, and prognostic outcomes. Patients with disease onset between 0 and 18 years of age and a diagnosis of genetic liver disease between 2000 and 2023 were included. Patients with suspected genetic liver disease but without access to genetic testing were also recruited. **Results:** The registry included 718 patients, comprising 370 patients with a confirmed genetic diagnosis and 348 patients with suspected genetic liver disease but without genetic testing. Among the 370 genetically confirmed cases, 64 distinct genetic liver diseases were identified. The most common disease-associated genes were *SLC25A13*, *JAG1*, and progressive familial intrahepatic cholestasis (PFIC)-associated genes, including *ATP8B1*, *ABCB11*, and *ABCB4*. These genes, together with *ATP7B*, *TJP2*, and *HSD3B7*, were identified across more than three countries in the Asia-Pacific region. Approximately 70% of genetically confirmed cases were attributable to the eight most common genetic liver diseases, whereas the remaining 30% were distributed across

56 rare genetic liver diseases. Most patients with neonatal intrahepatic cholestasis caused by citrin deficiency (NICCD) demonstrated favorable long-term outcomes. Apart from NICCD, the 10-year native liver survival rates were 59.48% among patients with genetically confirmed liver diseases other than NICCD and 61.19% among patients without a genetic diagnosis. The 20-year overall survival rates were 79.89% and 66.75%, respectively. Kaplan–Meier analysis revealed that both native liver survival and overall survival were significantly better in patients with NICCD than in those with other genetic liver diseases or without a genetic diagnosis. (Figure) **Conclusion:** This multicenter collaborative consortium study characterized the genetic etiologies and prognostic outcomes of pediatric genetic liver diseases across Asia-Pacific countries. The findings revealed substantial etiologic diversity and disease-specific differences in prognosis. These results highlight the need for regionally coordinated strategies to improve genetic diagnosis, risk stratification, and management of children with genetic liver diseases.

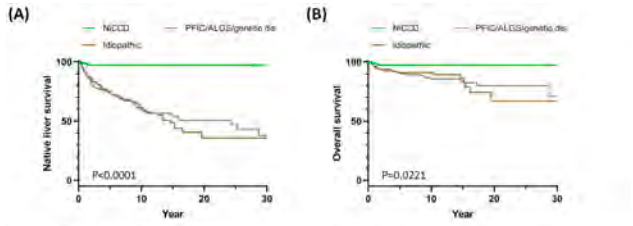

Figure (A) The native liver survival and (B) overall survival of genetic diagnostic NICCD cases (green line), case with PFIC, ALGS or other genetic defects (gray line) and idiopathic cases (brown line) (Native liver survival: NICCD vs PFIC/ALGS/other genetic disease, p < 0.0001, NICCD vs idiopathic p-value < 0.0001; Overall survival: NICCD vs PFIC/ALGS/other genetic disease, p = 0.0071, NICCD vs idiopathic, p = 0.0064)

0273 | ADJUVANT GRANULOCYTE COLONY-STIMULATING FACTOR AFTER KASAI PORTOENTEROSTOMY FOR BILIARY ATRESIA: A PHASE 2 RANDOMIZED CONTROLLED TRIAL

Anh - Hoa Pham Nguyen[1] Aixuan Holterman[2],
[1]National Children 's Hospital, [2]University of Illinois

Background: Post operative outcome for Kasai portoenterostomy (KPE) is limited from recurrent cholangitis, progressive liver failure despite a technically successful surgery., Granulocyte colony-stimulating factor (G-CSF) has been demonstrated in animal models of cholestasis to have both regenerative and immunomodulatory properties through mobilization of bone marrow–derived stem cells, enhancement of hepatocyte proliferation, activation of hepatic progenitor cells, and attenuation of intrahepatic inflammatory signaling. Experimental and clinical studies further suggest that G-CSF may reduce fibrogenesis, improve hepatic microcirculation, and preserve residual liver function. **Objective:** To evaluate the efficacy and safety of granulocyte colony-stimulating factor (G-CSF) as adjuvant therapy in patients with biliary atresia (BA) following Kasai portoenterostomy (KPE). **Methods:** In this open-label, randomized, controlled Phase 2 trial (ClinicalTrials.gov NCT04373941), 80 infants with type III BA undergoing KPE at Vietnam National Children's Hospital between November 2023 and April 2026 were randomized to standard postoperative care alone (KSt; n = 46) or standard care plus G-CSF (KG; filgrastim 10 μg/kg/day subcutaneously for 3 consecutive days starting on postoperative day 4 ± 1; n = 34). Mean follow-up was 11.3 ± 6.3 months overall (KSt 10.5 ± 5.7; KG 12.3 ± 7.1). The primary endpoint was successful biliary drainage defined as total bilirubin < 34.2 μmol/L at 3 months, analyzed by Fisher's exact test in the 75 infants who had reached the 3-month assessment by data cutoff. Two secondary endpoints (cholangitis-free transplant-free survival and transplant-free native liver survival) were analyzed by Kaplan–Meier with log-rank tests and Cox proportional hazards regression on the full intention-to-treat cohort: (composite of first cholangitis, transplant, or death). Other outcomes were reported descriptively as exploratory. **Results:** G-CSF therapy was well tolerated, with no treatment-related serious adverse events. The primary endpoint of bile drainage at 3 months, did not differ between the arms (KG 13/31 [41.9%] vs KSt 15/44 [34.1%]; Fisher p = 0.63). The proportion of subjects with Cholangitis-free transplant-free survival at 12 months was 35% in the KG group and 10% in the KSt group (10%), with log-rank p = 0.0002 and Cox HR 0.36 (95% CI 0.20–0.64); composite events occurred in 18/34 KG vs 39/46 KSt. Native liver survival at 12 months 90% (95% CI 77.8–100%) in the KG group and 59.5%, 95% CI 42.2–83.8% in the KSt group, with log-rank p = 0.014 and Cox HR 0.23 (95% CI 0.06–0.82); death or liver transplantation occurred in 3/34 KG (1 death, 2 transplants) vs 12/46 KSt (9 deaths, 3 transplants). Exploratory outcomes (longitudinal GGT trajectories, gastrointestinal bleeding, and liver-disease severity scores) all favored G-CSF **Conclusions:** Adjuvant G-CSF after Kasai portoenterostomy was safe. The primary endpoint of successful

biliary drainge did not differ between arms; while secondary endpoints of cholangitis and transplant-free survival significantly favored the G-CSF treatment group. Confirmation in larger multicenter trials with longer follow-up is warranted.

0274 | A MULTI-AGENT AI SYSTEM FOR MAINTAINING LIVER DISEASE GUIDELINES: EVIDENCE SYNTHESIS, CONSENSUS BUILDING, AND CLINICAL IMPACT

Wang Zixing[1], [1]Peking University People's Hospital

Background: The rapid expansion of hepatology evidence outpaces the updating of liver disease guidelines. Manual processes cannot match this pace, leaving clinicians with potentially outdated recommendations. To our knowledge, this is the first evaluation of a multi-agent AI system specifically benchmarked against current liver disease guidelines. **Methods:** We developed MARG (Multi-Agent Retrieval-Augmented Generation), a system where multiple AI agents independently review evidence, debate disagreements through structured rounds, and reach consensus. The system was tested on seven 2025 EASL Clinical Practice Guidelines spanning six major hepatological domains: HBV infection, HCC, autoimmune hepatitis, Wilson's disease, extrahepatic cholangiocarcinoma, TIPS, and cirrhosis with extrahepatic surgery – totaling 137 clinical decision scenarios across diagnosis, prevention, and treatment. We evaluated MARG across three dimensions: (1) evidence synthesis quality (recency, reproducibility, and Level I evidence capture, benchmarked against expert review); (2) consensus strength through structured inter-agent debate; and (3) clinical impact on hepatologists across training levels. **Results:** MARG showed 77.4% overall agreement with liver disease guidelines. Guideline-consistent rates increased stepwise with agent consensus: 45.8% under weak consensus (50-60% agreement) to 87.8% at full consensus (p-trend < 0.001). Performance varied by task: 65.5% (diagnosis), 75.0% (prevention), and 81.0% (treatment). Compared to manual review, MARG delivered superior recency (6.3% vs 0.9%), reproducibility (25.5% vs 7.5%), and Level I evidence capture (24.2% vs 8.0%). Through four structured debate rounds, the system resolved 95.8% of initial agent conflicts, achieving strong consensus (> 85% agreement) in 74.5% of final outputs – with consensus degree correlating with independent hepatology expert panels ($\kappa = 0.239$, comparable to inter-expert agreement in complex liver disease). MARG corrected 40-60% of guideline-inconsistent decisions across all experience levels, with the largest gain among early-career clinicians. **Conclusion:** Multi-agent AI offers a scalable, transparent, and training-level-adaptive solution to maintain liver disease guidelines. By resolving disagreements through structured debate, this approach addresses three unmet needs in evidence-based hepatology: keeping pace with evidence growth, surfacing disagreement hotspots across AI agents, human experts, and AI-human pairs, and supporting fellowship training.

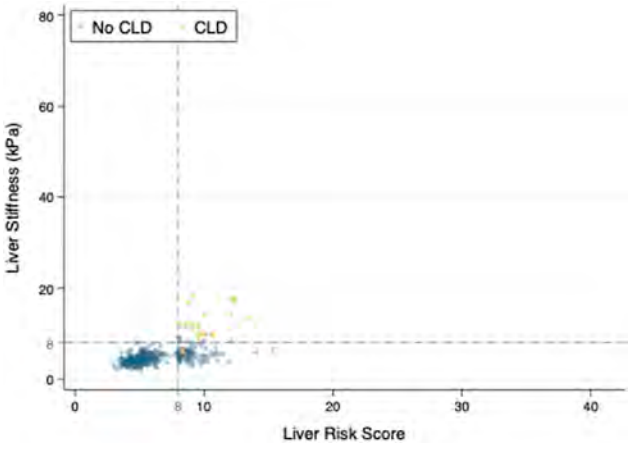
★ 0275 | LIVERRISK SCORE FOR EARLY DETECTION OF LIVER FIBROSIS IN THE GENERAL POPULATION: THE LIVERSCREEN IMPLEMENTATION STUDY



Adrià Juanola[1] Sandro Kukic[2] Julia Kahlhöfer[3] Ruth Nadal[4] Anita Madir[2] Petra Kujundzic[2] Anita Arslanow[3] Marina Vélez[5] Heiner Wedemeyer[3] Albert Albrecht[6] Kathrin Schuchardt[6] Lars Nachbar[6] Roser Ferrer[7] Albert Blanco[8] Antonio Torrejon[9] Patricia Such[9] José Mª Navarrete[9] Ana Maria de la Arada[10] Gemma Sáez-Rubio[10] Ricard Riel[11] Maria José Pardo[11] Elisa Pose[5] Isabel Graupera[5] Nuria Fabrellas[12] Miquel Serra-Burriel[13] Ivica Grgurevic[2] Frank Lammert[3] Pere Gines[5], [1]Hospital Clinic i Provincial de Barcelona, [2]Dpt. of Gastroenterology, Hepatology and Clinical Nutrition, University Hospital Dubrava, Croatia, [3]Hannover Medical School (MHH), Hannover, Germany, [4]FCRB-IDIBAPS, Barcelona, Spain, [5]Liver Unit, Hospital Clínic of Barcelona, Barcelona, Spain, [6]Volkswagen AG. Wolfsburg, Germany, [7]Biochemistry Department, Clinical Laboratories, Vall d'Hebron University Hospital, Barcelona, Spain, [8]Biochemistry Department, Clinical Laboratories, Vall d'Hebron University Hospital, Barcelona, Spain., [9]Health, Safety and Emergencies of SEAT, CUPRA and the Volkswagen Group Companies in Spain, Martorell, [10]Centre d'Atenció Primària (CAP) La Marina, Barcelona, Spain, [11]Institut Catala de la Salut (ICS), Ambit d'Atenció Primària, Barcelona, Spain, [12]Faculty of Medicine and Health Sciences, University of Barcelona, Barcelona, Spain, [13]Epidemiology, Statistics, and Prevention Institute, University of Zurich, Zurich, Switzerland

Background: LiverRisk score (LRS) is a non-invasive method for the detection of liver fibrosis based on the combination of 8 variables (age, sex, and six routinely available laboratory variables), which has been reported to outperform classical non-invasive tests such as FIB-4. The LiverScreen implementation study was a prospective cohort study in three European countries (Croatia, Germany, Spain) investigating the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

feasibility of LiverRisk score for liver fibrosis screening in routine health care. **Methods:** In this multinational, prospective cohort study performed in primary care centers and two car-making companies, participants undergoing blood tests as part of routine healthcare assessment were invited to participate. People with known chronic liver disease were excluded. The LRS value was automatically calculated by central laboratory facilities. Participants with LRS $\geq$ 8 were referred to an academic liver center for a visit that included a complete hepatology evaluation. In addition, a randomly selected subset of participants with LRS < 8 also underwent this visit as control. **Results:** Between December 2024 and January 2026, we recruited 8,708 participants, 5,559 (64%) men, most of them caucasian, with a mean age of 52 ± 9 years. An increased LRS ($\geq$ 8) was found in 176 (2%) participants, of whom 123 (70%) attended the hepatology visit. Thirty-three of the 123 participants (27%) had liver stiffness measurement (LSM), as measured by vibration-controlled transient elastography (VCTE, $\geq$ 8 kPa suggestive of liver fibrosis), whereas only 1 of the 280 participants from the control group presented with LSM $\geq$ 8 kPa. LSM was >10 kPa in 19 participants. Metabolic risk factors were more prevalent among individuals with LRS $\geq$ 8: more than 60% had two or more risk factors, compared with 20% of those with LRS < 8 (p-value < 0.001). After hepatology evaluation, 23 participants (19%) had confirmed diagnosis of chronic liver disease, with the most common etiologies being MASLD, ALD, and MetALD (56%, 13% and 9%, respectively). The AUROC of LRS for chronic liver disease diagnosis was 0.934 (0.902 - 0.966). **Conclusion:** These results demonstrate that a targeted intervention with measurement of LiverRisk score followed by VCTE and hepatology assessment can detect people with undiagnosed chronic liver disease with fibrosis. They also underscore the need for further research investigating whether screening for liver fibrosis reduces morbidity and mortality due to chronic liver diseases and liver cancer.

0276 | SUPERVISED EXERCISE TRAINING IMPROVES SKELETAL MUSCLE MITOCHONDRIAL FUNCTION AND PHYSICAL PERFORMANCE IN CIRRHOSIS: A PROSPECTIVE RANDOMIZED CONTROLLED TRIAL

Annette Bellar[1] Nicole Welch[1] Pugazhendhi Kannan,[1] Seshu Vardhan Pothabathula[1] Vandana Agrawal[1] Jasmin Cunningham[1] Saurabh Mishra[1] Srinivasan Dasarathy[1], [1]Cleveland Clinic

Background: Sarcopenia, contractile dysfunction, and skeletal muscle mitochondrial oxidative dysfunction contribute significantly to physical frailty, reduced exercise capacity, and poor outcomes in cirrhosis. Exercise has demonstrated benefits in healthy individuals with distinct functional, molecular, and mechanistic responses being different in endurance exercise (EE) and resistance exercise (RE) training. Though benefits with EE or RE have been reported in cirrhosis, data are confounded by low adherence rates and there are no reports of direct comparisons of responses to EE vs. RE in cirrhosis. **Methods:** Patients with compensated cirrhosis were randomized to supervised, structured, EE, RE, or no intervention for 12 weeks (NCT05982769). Patients had a MELD score <21, Child score 5-10, and were eligible to recieve muscle biology (INR ≤ 1.7, platelets $\geq 60{,}000$, and not on blood thinners) without recent GI bleeding or hepatic encephalopathy. Home-based cycling three times weekly for 60 minutes of physical activity at 60–70% heart rate reserve RE consisted of supervised whole-body resistance band training twice weekly. Aerobic fitness (VO_2max, duration/distance run on a treadmill, time to reach anerobic threshold), and muscular fitness by 1-repetition maximum (1RM), body composition by DEXA, patient reported outcome measures information system (PROMIS) of physical function, alcohol use. Fatigue and meaning and purpose. We also measured mitochondrial oxidative function using substrate-uncoupler-inhibitor titration protocols on muscle biopsies were determined at baseline (BL) and end of 12 weeks study (EOS). **Results:** There were 10 subjects in the EE and 9 in the RE arm, mean age (EE age 62 $\pm$ 8, range 45-74; RE age 63 $\pm$ 7, range 48-75), with 2 males and 7 females in the EE group and 5 males and 5 females in the RE group. Etiology of cirrhosis in the EE group was 67% MASLD and 33% alcohol related. In the RE group the etiology was 60% MASLD, 30% alcohol related, and 10% other etiologies of cirrhosis. All subjects achieved predefined adherence to protocol criteria (<6 missed visits over the course of 12 weeks). Body composition at baseline was similar in the 2 groups and changes from BL to EOS were not different. EE training improved treadmill exercise duration and VO_2max-related performance measures ($p<0.05$) but not strength measures of legs, arms, or core body ($p>0.05$) from BL to EOS **(Fig.1A)**. RE training improved strength measures **(Fig. 1B)** including squat, chest press, and bicep curl 1RM testing ($p<0.05$) with no change in VO_2max, VO_2 time, or exercise time ($p>0.05$). Both EE and RE improved mitochondrial respiration parameters **(Fig. 1C,D)** including ADP-supported respiration, succinate-supported respiration, and maximal respiration ($p<0.05$ for all). **Conclusion:** Supervised exercise home-based training in compensated cirrhosis achieved complete adherence with modality specific improvement in aerobic fitness and muscle strength.

0277 | THE ABCD SCORE: A LABORATORY-FREE, SEX-SPECIFIC PREDICTION MODEL FOR COMMUNITY-LEVEL STEATOTIC LIVER DISEASE SCREENING — DEVELOPMENT AND EXTERNAL VALIDATION IN INDIA

Kanica Kaushal[1] Harsh Tevethia[1] Manoj Sharma[1] Aditya Chaturvedi[1] Guresh Kumar[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences, New Delhi

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) affects nearly one in three adults globally, with the highest burden in low- and middle-income countries (LMICs). All existing non-invasive prediction tools for steatotic liver disease (SLD) require laboratory investigations unavailable at frontline primary care across most LMIC settings. No externally validated, fully laboratory-free, sex-specific SLD prediction model exists. We developed and externally validated the ABCD score — Age, BMI, Central obesity (waist circumference), and Diabetes status — for community-level MASLD screening, deployable by frontline community health workers without any biomarker requirement. **Methods:** A cross-sectional, community-based study enrolled 3,130 adults by probability-proportional-to-size cluster sampling across three tehsils of Jaipur, Rajasthan, India (February–July 2023). SLD was defined as controlled attenuation parameter (CAP) ≥248 dB/m on vibration-controlled transient elastography. Sex-specific logistic regression with 5-fold cross-validation was used; eight classifier families were compared, and the score was benchmarked against six established non-invasive scores (FLI, HSI, FIB-4, APRI, BARD, FAST). External validation was performed in an independent urban community cohort in Delhi, India (n = 3,325). **Results:** SLD prevalence was 29.5% (women 35.2%, men 26.0%). ABCD achieved AUC 0.777 (95% CI 0.763–0.791) — non-inferior to the laboratory-based Fatty Liver Index (AUC 0.776; DeLong p = 0.948) — and substantially superior to all fibrosis-optimised scores (APRI 0.535, FIB-4 0.550, BARD 0.567; all p < 0.001) and HSI (0.747; p < 0.001). BMI was the dominant predictor (70.6% of Gini impurity reduction), with a clear threshold effect at the Asian overweight cut-point (23.0 kg/m²), particularly in women. Combined BMI and waist circumference elevation conferred 8.51-fold increased odds of SLD (95% CI 6.67–10.87). At the rule-out threshold (probability < 0.20), sensitivity was 85.9% with NPV 90.1%. In external validation (Delhi SLD prevalence 54.9%), AUC was 0.769 (0.751–0.783) — ΔAUC −0.008 — with calibration slope 0.96. Sex-stratified discrimination was preserved (women 0.790, men 0.749). **Conclusion:** The ABCD score is the first fully laboratory-free, sex-specific SLD prediction model externally validated in South Asia. Discrimination matches laboratory-based steatosis tools and substantially outperforms fibrosis-focused alternatives misapplied for steatosis screening. The model provides a transferable framework for MASLD screening across LMIC primary care, deployable by frontline health workers (e.g., India's Auxiliary Nurse Midwives and ASHAs) via mobile application. It offers a scalable pathway to identifying an estimated 300 million Indians with undiagnosed SLD, extensible to other LMIC settings facing similar laboratory-access constraints.

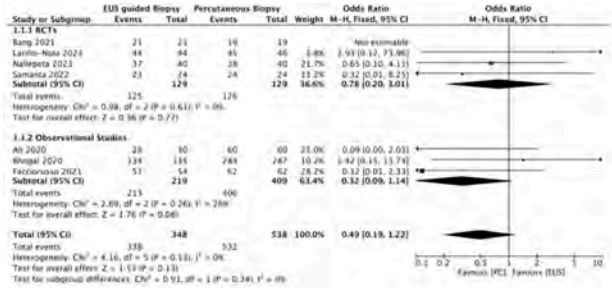
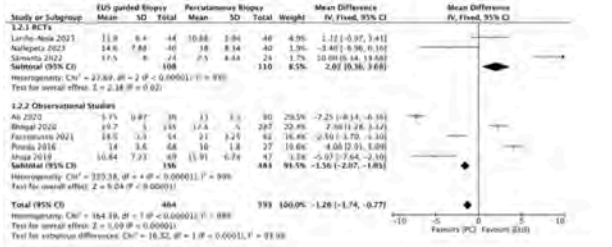
★ 0278 | COMPARISON OF ENDOSCOPIC ULTRASOUND-GUIDED VERSUS PERCUTANEOUS LIVER BIOPSY: A SYSTEMATIC REVIEW AND META-ANALYSIS



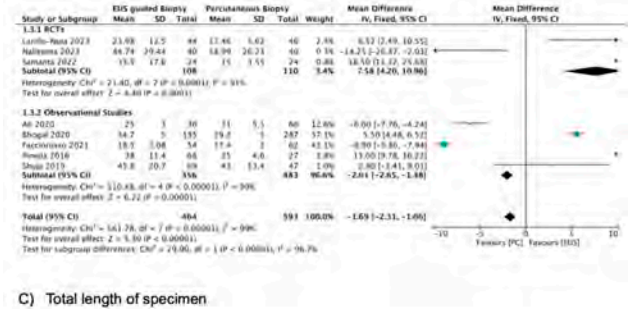
Ramsha Khan[1] Sunil Samnani[1] Moneer mohammed[1] Abdulrahman Bassam[1] Muhammad Anas Fazal[2] Matthew Collins[1] Rhea Thomas[1], [1]McMaster University, [2]University of Alberta

Background: Liver biopsy is critical for diagnosing, staging, and managing liver diseases such as fibrosis, cirrhosis, and malignancy. The traditional



Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.



percutaneous (PC) approach is common but may cause pain, complications, and variable specimen quality. Endoscopic ultrasound-guided (EUS) liver biopsy has emerged as a minimally invasive alternative. **Aim:** To compare EUS-guided and PC liver biopsies regarding diagnostic adequacy, complete portal tracts, total specimen length, adverse events, and post-procedure pain. **Methods:** A systematic review and meta-analysis was conducted following PRISMA guidelines. Databases including Medline, Embase, and CENTRAL were searched from inception to November 2025. Randomized controlled trials (RCTs) and observational studies directly comparing EUS and PC liver biopsies were included. Primary outcomes were diagnostic adequacy. Secondary outcomes included number of complete portal tracts, total biopsy specimen length, and pain score at 1 hour post-procedure. Data were pooled using fixed- or random-effects models based on heterogeneity (I2), with subgroup analyses by study design. **Results:** Nine studies were included (4 RCTs, 5 observational), encompassing 1097 procedures (485 EUS, 612 PC). Overall, diagnostic adequacy was comparable (OR 0.49, 95% CI 0.19-1.22, P = 0.13, I2 = 0%). In sensitivity analysis by study design, observational studies showed favoritism toward PC (OR 0.12, 95% CI 0.03-0.43), while RCTs showed no significant difference (OR 0.78, 95% CI 0.20-3.01), with a significant test for subgroup differences (P = 0.04). Adverse events were similar overall (OR 0.57, 95% CI 0.14-2.36, P = 0.44, I2 = 68%), with few events reported. EUS significantly reduced pain scores at 1-hour post-procedure overall (MD -2.01, 95% CI -2.47 to -1.55, P < 0.00001, I2 = 88%). Sensitivity analysis revealed a smaller reduction in RCTs (MD -1.00, 95% CI -1.82 to -0.18, P = 0.02) compared to observational studies (MD -2.75, 95% CI -3.07 to -2.43, P < 0.00001), with a significant subgroup difference (P = 0.003). PC provided more complete portal tracts overall (MD -1.49, 95% CI -2.31 to -0.67, P = 0.0004, I2 = 99%). Similarly, PC yielded longer biopsy specimens overall (MD -1.26, 95% CI -1.74 to -0.77, P < 0.00001, I2 = 98%). **Conclusion:** EUS-guided liver biopsy demonstrates similar diagnostic adequacy and adverse event rates to PC, with superior post-procedure pain control. While PC may yield higher-quality specimens overall, sensitivity analyses highlight discrepancies by study design, with observational studies favoring PC and RCTs showing neutral or EUS-favoring results, suggesting potential selection bias in observational data. EUS may be preferable for patients prioritizing comfort, but further high-quality RCTs are needed to resolve discrepancies.

A) Diagnostic adequacy

B) Number of Complete Portal Tracts

C) Total length of specimen

0279 | PREVALENCE AND PREDICTORS OF RECURRENT HELLP SYNDROME: A MULTICENTER RETROSPECTIVE STUDY ACROSS THREE HOSPITAL SYSTEMS

Jacqueline Slobin[1] Elina Stoffel[2] Clara McNatt[3] Nina Rodriguez[1] Lauren Alpert[1] Rhoda Sperling[1] Keith Sigel[1] Tatyana Kushner[3], [1]Icahn School of Medicine at Mount Sinai, [2]Vagelos College of Physicians and Surgeons, Columbia University, and New York-Presbyterian Hospital, [3]Weill Cornell Medicine

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome is a life-threatening obstetric complication. Despite its clinical significance, the risk of HELLP syndrome recurrence in subsequent pregnancies remains incompletely understood. Identifying reliable predictors of recurrent HELLP syndrome is critical for preconception counseling, antenatal surveillance planning, and risk stratification in subsequent pregnancies. **Methods:** We conducted a retrospective cohort study at three large academic medical centers in New York City. We included patients diagnosed with HELLP syndrome in their index pregnancy who subsequently had another pregnancy. Index cases of HELLP were identified by diagnosis codes and were verified by clinical notes and laboratory values in the electronic health record; recurrence was determined based on clinical notes. Data on demographics, medical history, laboratory results, and pregnancy outcomes were extracted via chart review. Wilcoxon rank sum tests, Fisher's exact tests, and Firth's penalized logistic regression were performed. **Results:** Of 853 patients identified with a HELLP diagnosis code, 91 delivered a subsequent singleton pregnancy. Mean age of 32.5 years (SD 5.6) at their index pregnancy and 35.3 years (SD 5.4) at the subsequent pregnancy; mean pre-pregnancy BMI was 24.4 kg/m2. The cohort was 63% White, 18% Hispanic, 6.7% Black and 4.4% Asian. Twelve patients (13.2%) received a clinical diagnosis of HELLP recurrence in a subsequent pregnancy. Among these patients, mean age was 31 at index pregnancy and 33 at subsequent pregnancy; 8 (67%) were White, 2 (17%) were Hispanic, and 2 (17%) were Black. Three (25%) had chronic hypertension. Of 6 patients with a pregnancy prior to their index pregnancy, 3 (50%) had a history of preeclampsia. In univariate analyses, peak ALT ($p = 0.014$) and peak AST ($p = 0.030$) during the index pregnancy were higher among patients with recurrence, whereas peak LDH and minimum platelet count did not significantly differ (Table). In Firth's penalized logistic regression adjusting for chronic hypertension and inter-pregnancy interval, higher peak ALT during the index pregnancy was associated with increased odds of recurrence (OR 1.67 per doubling of ALT; 95% CI 1.04-2.98; $p = 0.035$; AUC 0.79). **Conclusion:** In this multicenter cohort, HELLP recurred in approximately 13% of subsequent pregnancies, and higher peak ALT and AST during the index pregnancy was associated with recurrence. These preliminary findings suggest that index-pregnancy transaminase levels may warrant further investigation as a potential marker of recurrence risk. These findings should be validated in larger cohorts to help clinicians risk-stratify patients with a history of HELLP syndrome and provide more individualized preconception counseling.

0280 | TARGETABLE IL1B-DRIVEN MYELOID INFLAMMATION MEDIATES RESISTANCE TO ANTI–PD-1 THERAPY IN HEPATOCELLULAR CARCINOMA

Wenying Qiao[1] Xiaoyan Ding[1] Xi Wang[1] Ronghua Jin[1],
[1]Beijing Ditan Hospital, Capital Medical University

Background: Although immune checkpoint inhibitors have reshaped the treatment landscape of advanced hepatocellular carcinoma (HCC), most patients fail to achieve durable benefit from programmed cell death protein 1 (PD-1) blockade. HCC is frequently sustained by chronic inflammation, yet how inflammatory myeloid programs are epigenetically activated and contribute to immunotherapy resistance remains poorly defined. We hypothesized that dysregulated IL1B-driven myeloid inflammation limits antitumor T-cell immunity and promotes resistance to PD-1 blockade. **Methods:** Baseline peripheral blood mononuclear cells from

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

patients with advanced hepatitis B virus-related HCC receiving anti–PD-1 therapy were analyzed by single-cell and bulk RNA sequencing. Spatial transcriptomics and multiplex immunofluorescence were used to define the tissue distribution and immune context of IL1B-expressing myeloid cells. ATAC-seq and H3K4me3 ChIP-seq characterized chromatin accessibility and histone modification landscapes. Therapeutic relevance was evaluated in subcutaneous and orthotopic HCC models treated with anti–IL-1β, anti–PD-1, or their combination. **Results:** Integrated transcriptomic analyses identified a distinct IL1B$^+$ CD14$^+$ monocyte population enriched in non-responders to anti–PD-1 therapy and associated with heightened inflammatory activity. Spatial and multiplex immunofluorescence analyses confirmed accumulation of IL1B$^+$ myeloid cells within an immunosuppressive tumor microenvironment marked by impaired cytotoxic T-cell activity. Epigenomic profiling revealed increased chromatin accessibility and active H3K4me3 modification at the IL1B locus in non-responders. Mechanistically, KDM5A acted as an epigenetic brake on IL1B transcription by limiting H3K4me3 deposition and AP-1 recruitment at the IL1B promoter; this restraint was preserved in responders but disrupted in non-responders. Functionally, IL-1β promoted CD8$^+$ T-cell exhaustion, with increased PD-1 and TIM-3 expression and reduced cytotoxic activity. In both HCC models, combined IL-1β and PD-1 blockade suppressed tumor growth, reduced tumor-associated macrophage infiltration, and restored cytotoxic T-cell function more effectively than either monotherapy. **Conclusion:** Our findings reveal that anti–PD-1 resistance in HCC is not solely driven by T-cell exhaustion, but is actively shaped by epigenetically programmed IL1B$^+$ myeloid inflammation. Targeting IL-1β reprograms the immunosuppressive tumor microenvironment and restores sensitivity to PD-1 blockade, supporting dual IL-1β/PD-1 inhibition as a mechanistically grounded strategy for resistant HCC.

0281 | PRACTICE CHALLENGES FACING ADVANCED PRACTICE PROVIDERS IN MANAGING MASLD PATIENTS ON RESMETIROM: EXPERIENCE OF A SINGLE NON-ACADEMIC, COMMUNITY-BASED LIVER CENTER

Anna Hefner[1] Ismael Hernandez[1] Noha Abdelgelil[1] Eric Storey[1] Maryam Yasso[1] Fatma Barakat[2] Tarek Hassanein[1], [1]Southern California Liver Centers, [2]SCTI Research Foundation

Background: Fatty liver is on the rise. It is accompanied with metabolic syndrome and patients (pts) are at risk for increased fibrosis and steatosis. Resmetirom is approved to improve fibrosis in MASLD pts with a fibrosis stage 2 or 3. GLP-1 prescribed to control diabetes or weight loss might lead to decreasing steatosis in the liver. Despite these advancements, there are several challenges clinical practices. Aim: describe practice challenges a single non-academic community-based liver center faces in managing predominantly Hispanic pts with MASLD. **Methods:** This is a retrospective analysis of MASLD pts who initiated resmetirom between December 2024 and May 2026. Management plan was set in consultation with hepatologists while follow up was done primarily by Advanced Practice Providers (APP). Pts were managed according to standardized and individualized management protocols. **Results:** APPs focused on working with the pt as a team and managing medication, adherence, clinical visits, nutrition, and exercise. The plan was adjusted as needed. Initial emphasis was on educating pts about MASLD being a silent disease, its progression, establishing/maintaining a healthy lifestyle utilizing diagrams and a liver model. The approach was kept simple. Reminders were sent to the pt about completing tasks. Clinic Visits: Pts were seen every 3 months. Reviewing how the pt perceived their health and felt, going over each medication and detailed review of results (e.g. labs, elastography, ELF, and iliac crest measurement) was critical to motivating the pt to continue with the care plan. Exercise: Having an attainable goal that did not cost anything e.g. walking continuously for 5 minutes and gradually increasing it over time, showing pts chair exercises, helping them find time during the day to exercise were useful in improving adherence to exercising. Nutrition: was culturally sensitive and material provided was mainly pictorial e.g. to show the kinds of foods to eat/try to avoid. Pts found them helpful to making healthy food

choices. Medications: In addition to resmetirom, pts were typically prescribed GLP-1. However, health insurance denial was a major barrier in continuing these medications. Outcomes: 64% female. Mean age 60.7 years. 45.5% Hispanic. Refer to table for analysis of 1-year analysis data for 22 out of 161 pts. **Conclusion:** Real-world experience of a single non-academic community-based liver center confirmed that APPs are integral members of a liver pt's care team taking resmetirom. The cheer leading provided at visits and the simplicity of the education to build upon were assets. Pts who were able to see changes in their bodies or aren't as fatigued were more motivated to continue with the management plan. MASLD is a harmful silent disease but breaking it into doable lifestyle change pieces does encourage sustainable change. More individualized management is needed, especially in underserved population.

1001 | ◆ A STABILIZED FORM OF β-CATENIN FACILITATES HEPATOCYTE-TO-CHOLANGIOCYTE TRANSDIFFERENTIATION IN AN ORGANOID MODEL AND IMPROVES INJURY IN A MOUSE MODEL OF CHOLESTATIC LIVER DISEASE

Tony (Chun-Cheng) Chiang[1] Pamela Cornuet[1] Kari Nejak-Bowen[1], [1]University of Pittsburgh

Background: Cholestatic liver diseases are characterized by impaired bile flow or bile acid-mediated damage to liver parenchyma. Hepatocyte-to-cholangiocyte transdifferentiation occurs in response to biliary injury and may repair damaged bile ducts. Our preliminary data showed that canonical Wnt/β-catenin signaling is increased during hepatocyte-to-cholangiocyte transdifferentiation. Therefore, we hypothesize that overexpression of β-catenin may augment hepatocyte-to-cholangiocyte transdifferentiation, alleviate biliary injury, and restore liver function. To test this, we used a 3D organoid derived from isolated primary hepatocytes to mimic bile duct paucity, as well as a transgenic mouse overexpressing β-catenin in a biliary injury model. **Methods:** For the organoid model, transgenic (TG) serine-45-aspartate-mutated (S45D) β-catenin and wild-type (WT) mice were crossed with Rosa26-stopf/f-EYFP mice, respectively. After AAV8-TBG-Cre injection, these hepatocytes were labeled with EYFP. Mouse livers were perfused to isolate hepatocytes, which were then seeded in a collagen-precoated pleated bottle. Each bottle contains medium with specific growth factors essential for transdifferentiation. Organoids were harvested on day 21 of culture for downstream analysis.For the mouse model, TG S45D β-catenin mice bred to an mdr2 knockout, mdr2 knockout alone (KO), and their wildtype littermates, all carrying Rosa26-stopf/f-EYFP alleles, were injected with AAV8-TBG-Cre to label hepatocytes and sacrificed at various timepoints. Serum biochemical markers of liver injury were assessed. Livers were studied for histopathology, and ductular proliferation was quantified by CK19 immunohistochemistry. Hepatocyte-to-cholangiocyte transdifferentiation was traced by Sox9 and EYFP immunofluorescence staining. **Results:** Cholangiocyte-like cells and ductular structures were seen in hepatocyte organoids. Lineage tracing demonstrated that these cholangiocyte-like cells originated from hepatocytes, confirming transdifferentiation. TG organoids had a greater number of mature, HNF4a-negative cholangiocyte-like cells than WT organoids. Serum biochemistry showed that TG β-catenin reduces liver injury in KO mice. Histopathology revealed inflammation, fibrosis, and ductular reaction in KO mice, which were ameliorated in TG mice. Immunofluorescence staining showed more EYFP+ cholangiocytes and Sox9+ hepatocytes in the periportal zone of TG mice with a KO background than in KO alone mice, indicating that transdifferentiation increased when β-catenin was overexpressed in hepatocytes. **Conclusion:** S45D β-catenin enhanced hepatocyte-to-cholangiocyte transdifferentiation in organoids. TG S45D β-catenin slowed injury progression and increased transdifferentiation in mdr2 KO mice. Based on these findings, we plan to use both biased and unbiased approaches in the future to elucidate further mechanisms.

1002 | ◆ ENDOTHELIAL-SPECIFIC ARYL HYDROCARBON RECEPTOR (AHR) DELETION DRIVES A FULLY PENETRANT MURINE MODEL OF PORTOSYSTEMIC SHUNT AND HEPATOCARCINOGENESIS

Sadhana Sah[1] Piu Saha[1] Matam Vijay-Kumar[1] Beng San Yeoh[1], [1]University of Toledo

Background: Portosystemic shunt (PSS) is a vascular abnormality that diverts portal blood away from the liver into the systemic circulation, impairing hepatic clearance of gut-derived metabolites. In humans, PSS is associated with hepatic encephalopathy, metabolic dysfunction, and hepatocellular carcinoma (HCC). Our prior studies showed that spontaneous congenital PSS in C57BL/6J mice predisposes to cholestatic liver injury and HCC when fed on a purified diet supplemented with inulin (a fermentable fiber). However, the low penetrance of spontaneous PSS limits mechanistic investigation. Here, we assessed PSS incidence in an endothelial-specific aryl hydrocarbon receptor knockout mouse model (*Ahr*fl/fl;*Cdh5*-Cre) and assess its susceptibility to diet-induced liver injury and HCC.

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Methods: Male *Ahr*fl/fl;*Cdh5*-Cre mice and *Ahr*fl/fl littermate controls were evaluated for biochemical, metabolic, and histopathologic features of PSS. Serum bile acids, lipid profiles, glucose tolerance, and insulin sensitivity were measured. To induce liver injury and HCC, mice were fed an inulin-containing purified diet (ICD; 7.5% w/w) for 7 days or 6 months. A separate cohort was fed a high-fat diet (HFD) for 6 months. In addition, another group of ICD-fed mice was treated with D-galactosamine (20 mg/mouse, intraperitoneally) to assess susceptibility to acute liver injury. **Results:** *Ahr*fl/fl;*Cdh5*-Cre mice exhibited 100% penetrance of congenital PSS and demonstrated hallmark features including severe cholemia, hypolipidemia, enhanced glucose and insulin tolerance, and liver atrophy. When compared to non-PSS *Ahr*fl/fl controls, *Ahr*fl/fl;*Cdh5*-Cre mice exhibited hepatic inflammation, ductular reaction, and arteriole thickening consistent with chronic cholestatic injury. Short-term ICD feeding induced cholestatic hepatitis characterized by elevated serum transaminases, bilirubin, and bile acids, whereas prolonged ICD feeding for 6 months resulted in multifocal HCC exclusively in *Ahr*fl/fl;*Cdh5*-Cre mice and not *Ahr*fl/fl controls. *Ahr*fl/fl;*Cdh5*-Cre mice fed HFD for 6 months, however, did not develop HCC despite developing hepatic steatosis. D-galactosamine treatment, on the other hand, induced markedly more severe fulminant hepatic failure in *Ahr*fl/fl;*Cdh5*-Cre mice compared with *Ahr*fl/fl controls. **Conclusion:** Endothelial AHR deletion in mice engenders a fully penetrant congenital PSS that recapitulates key features of PSS-associated liver disease. Chronic exposure to dietary fermentable fiber, but not a high-fat diet, induced cholestatic injury and HCC development in this model. Together, these findings identify disrupted portal circulation and diet-dependent metabolic stress as drivers of HCC pathogenesis, and establish *Ahr*fl/fl;*Cdh5*-Cre mice as a tractable preclinical model for studying PSS-associated liver disease.

★ 1003 | ◆ TOLEROGENIC KLF2-EXPRESSING T CELLS CONFER PROTECTION IN A PRECLINICAL MODEL OF PRIMARY SCLEROSING CHOLANGITIS

Abigail Russi[1] Abigail Detloff[1] Dena Acton[1] Brian DeBosch[1], [1]Indiana University School of Medicine

Background: Commensal tolerance is critical to restraining aberrant inflammation in the intestines and requires a population of suppressive IL-10-producing CD4 T cells defined by Küppel-like transcription factor 2 (KLF2) and CD44 expression. This population of "Tk cells" functions independently from FOXP3+ T regulatory cells and KLF2-mediated sphingosine-1-phosphate receptor 1 (S1PR1) trafficking to selectively avert Th17-driven intestinal inflammation. Questions remain as to how Tk cells alter susceptibility and tolerance throughout the gut-liver axis. **Methods:** These experiments utilize established mouse immunology tools (flow cytometry analysis and sorting, histology, ELISA, qRT-PCR, magnetic T cell isolation and adoptive transfer) while simultaneously employing preclinical modeling of PSC using 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC). DDC induces an ascending cholangitis with biliary fibrosis and associated low-level intestinal inflammation, recapitulating the key aspects of human PSC. Comparison and figure generation of *KLF2*, *CD44*, *IL10*, and *S1PR1* gene expression in liver biopsies from patients with PSC compared to healthy (NDD) controls was obtained from the publicly available dataset from *Andrews et al.* (PMID: 38199298). **Results:** *In vitro* co-culture assays demonstrate that Tk cells maintain robust suppression of responder CD4 T cell proliferation and cytokine production under both Th17 and Th1 conditions (**Fig. 1A,B**). Notably, congenic adoptive transfer experiments confirm that Tk cells *selectively* avert aberrant Th17 inflammation *in vivo* (**Fig. 1C,D**). Importantly, IL-10 production by Tk cells is maintained under Th17 conditions (**Fig. 1E**) and Tk-derived IL-10 is critical for IL-17 suppression (**Fig. 1F**). In DDC-induced PSC, mice exhibit pathognomonic "onion-skinning" biliary fibrosis (**Fig. 2A)** and accumulate Tk cells in the livers (**Fig. 2B**). *KLF2* and *CD44* signatures significantly increase in the T cell population within the livers of patients with PSC compared to control patients, as does *IL10*. Importantly, *SIPR1* does not significantly change suggesting that this change is independent of KLF2-mediated S1PR1-dependent T cell trafficking (**Fig. 2C**). Tk-deficient mice (CD4CreKLF2FF) exhibit more severe weight loss, increased direct bilirubin, and increased alkaline phosphatase compared to their DDC-treated Cre-negative littermate controls (**Fig. 2D-F**). **Conclusion:** KLF2 identifies a new suppressive lineage of IL10-producing CD4 T (Tk) cells that selectively regulates Th17-driven aberrant inflammation in the gut-liver axis. We propose that Tk cells maintain tolerance throughout the gut-liver as their absence exacerbates cholestatic liver disease. Immediate next steps will utilize adoptive transfer, inducible Cre-mediated Tk cell depletion, and microbiota-dependent disease models to interrogate the protective mechanisms of Tk cells in the immunopathogenesis of PSC.

1004 | DECREASED YAP/TAZ COPY NUMBER LEADS TO TARGETED SMALL BILE DUCT LOSS

Laura Molina[1] Jia-Jun Liu[2] Shuchang Liu[3] Adelya Gabdulkhakova[4] Sungjin Ko[3] Satdarshan (Paul) Monga[3] Kari Nejak-Bowen[3], [1]University of Pittsburgh Medical Center, [2]University of Pittsburgh School of Medicine, [3]University of Pittsburgh, [4]University of Heidelberg

Background: We showed that deleting Yes-associated protein 1 (Yap) in early liver development leads to failure of intrahepatic bile duct development, and that its paralog TAZ could not compensate in the formation of ducts but influenced the inflammatory response in these livers. We next determined that reduced copy numbers of YAP and TAZ result in a gradual loss of small bile ducts reminiscent of vanishing bile duct injury or primary biliary cirrhosis. **Methods:** We deleted Yap and Taz during early liver development using the Foxa3 promoter to drive Cre expression. We examined male and female mice with the range of 0-4 functional copies of Yap and Taz combined, using microscopy, serum biochemistry, and single-nucleus RNA sequencing. **Results:** Our data shows that if there are two functional alleles of Yap, regardless of the status of Taz, the bile ducts will be formed properly. If there is only one functional allele of Yap, bile ducts will still be formed properly if there is at least one functional allele of Taz. However, if there is only one functional allele of Yap and no functional alleles of Taz (TKYH mice), the bile ducts will mostly form during prenatal development but will be gradually lost over the first 1-3 months of the mouse's life. These mice develop severe cholestasis over the first 3-4 months of life. This loss begins with the smallest ducts and spreads toward the hilum of the liver, accompanied by a largely lymphocytic immune reaction. The large bile ducts, hilum, and extrahepatic biliary tree are preserved, and there is some expansion of large bile ducts which preserves the overall ratio of bile ducts per portal vein despite the geographic loss of peripheral bile ducts. Single-nucleus RNA-sequencing demonstrates significant changes in cholangiocyte signaling and communication with endothelial cells, Kupffer cells, hepatic stellate cells and T cells, especially through extracellular matrix components, integrin signaling, and angiogenetic cytokine production. **Conclusion:** We show that Taz is essential for the stability and survival of murine bile duct when the function of Yap is hampered. The phenotype of TKYH mice shows features of diseases like vanishing bile duct syndrome, intrahepatic biliary atresia, primary biliary cirrhosis, and other conditions where small bile ducts are preferentially injured, such as drug-induced liver injury or ischemic injury to transplanted livers. This model illustrates molecular mechanisms that may drive the loss of small bile ducts and can be targeted to prevent or slow progression of human disease.

1005 | CHOLECYSTECTOMY BLUNTS THE RESPONSE TO GLP1 RECEPTOR AGONISTS IN TYPE 2 DIABETES: A PROPENSITY MATCHED REAL WORLD ANALYSIS

Emeka Stanley Obi[1] Chimezirim Ezeano[2] Ifelunwa Osanakpo[3] Gedion Amdetsion[4] Joshua Kalu[5] Adedeji Adenusi[6] Bright Nwatamole[7] Abdulrahman Atasi[8] Anthony Martinez[9], [1]Brookdale University Hospital and Medical Center, [2]Advocate Aurora Healthcare, [3]Carle FOundation, [4]Cook COunty, [5]Suny DOwnstate, [6]Interfaith Medical Center, [7]Zucker SOM, Vassar Brother Medical Center, [8]Brookdale University Medical Center, [9]University at Buffalo

Background: GLP1 receptor agonists (GLP1 RAs) transformed type 2 diabetes mellitus (T2DM) management but continues to elevate biliary risk, often necessitating cholecystectomy. Whether prior cholecystectomy alters GLP1 RA effectiveness remains unknown, despite plausible disruption of bile acid signaling through FXR/TGR5 pathways. As such, we aimed to determine whether prior cholecystectomy modifies metabolic, hepatobiliary, and cardiovascular outcomes during GLP1 RA therapy **Methods:** Within the TriNetX US Collaborative Network (65 HCOs), adults with Type 2 Diabetes Mellitus on any GLP1 RA were stratified by prior cholecystectomy (performed ≥ 1 month before GLP1 initiation) versus none. After 1:1 propensity score matching on demographics, comorbidities (hypertension, hyperlipidemia, CKD, ASCVD, HF, MASLD, NASH, obesity), and concomitant medications (insulin, metformin, statins), **29,087 cholecystectomy-exposed patients were matched 1:1 to 29,087 unexposed patients** drawn from a pre-matching pool of 1,299,852. All baseline standardized differences fell below 0.05 after matching. Risk and Cox hazard ratios were also computed. **Results:** Cholecystectomy significantly blunted metabolic response: HbA1c $<7\%$ attainment fell from 37.4% to 35.9% (RR 0.96; $p=0.043$) and BMI <30 from 14.7% to 13.4% (RR 0.91; $p<0.001$). Hepatobiliary risk rose sharply: choledocholithiasis nearly doubled (HR 2.13, 1.36 to 3.33) and expectedly, postcholecystectomy syndrome rose fourfold (HR 4.18, 2.48 to 7.03; both $p<0.001$); acute cholecystitis collapsed (HR 0.21). Strikingly, cholecystectomy patients showed a 30% reduction in all cause mortality (HR 0.84; $p<0.001$), 18% lower stroke (RR 0.82; $p<0.001$), and 10% lower myocardial infarction (RR 0.90; $p=0.016$). Earlier signals for pancreatitis and bariatric surgery vanished after matching, exposing baseline metabolic burden as their true driver. **Conclusion:** Prior cholecystectomy alters GLP1 outcomes, revealing a 'cholecystectomy paradox', attenuated metabolic efficacy alongside amplified hepatopancreatic risk, likely reflecting disrupted bile acid mediated FXR/TGR5 signaling. It also confers substantial mortality and cardiovascular benefit, establishing cholecystectomy as a meaningful pharmacotherapy modifier in T2D that mandates routine surgical history elicitation before GLP1 initiation, recalibrated counseling on glycemic and weight targets, and heightened biliary vigilance. Future studies should evaluate bile acid sequestrants and FXR/TGR5 modulators as adjuncts to restore GLP1 efficacy, and validate these findings in independent EHR networks with longer follow up. Interpretation is tempered by the retrospective EHR design, which limits causal inference; residual confounding and medication adherence cannot be fully excluded.

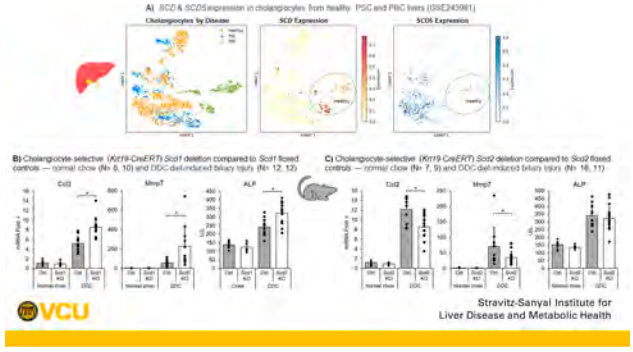
★ 1006 | CHOLANGIOCYTE STEAROYL-COA DESATURASE (SCD) ISOFORMS HAVE PARADOXICAL ROLES IN BILIARY INFLAMMATION



Sayed Obaidullah Aseem[1] Ahmed Younis[1] Grayson Way[1] Derrick Zhao[1] Yunling Tai[1] Xuan Wang[1] Emily Gurley[1] Phillip Hylemon[1] Nidhi Jalan-Sakrikar[2] Robert Huebert[2] Saul Karpen[3] Arun Sanyal[1] Huiping Zhou[1], [1]Virginia Commonwealth University, [2]Mayo Clinic

Background: Cholangiocytes orchestrate signaling that drives biliary inflammation in cholangiopathies including primary sclerosing cholangitis (PSC) and primary biliary cholangitis (PBC). These inflammatory signals require metabolomic remodeling, mediated in part by stearoyl-CoA desaturase (SCD), the rate-limiting Δ9-desaturase and central hub of lipid metabolism with a critical role in fibroinflammatory signaling. Here, we investigated distinct *SCD* isoforms (human: *SCD1*, *SCD5*; mouse *Scd1*, *Scd2*) in cholangiocytes to elucidate the molecular and metabolomic mechanisms of biliary inflammation. **Methods:** PSC and PBC transcriptomic databases (GSE243981) were interrogated using the Biomni Lab AI tool and independently verified in R (v4.3.3) with Seurat (v5.1.0). *In vitro*, human H69 cholangiocytes underwent siRNA knockdown of *SCD1* or *SCD5*. *In vivo*, cholangiocyte-selective *Scd1* and *Scd2* knockout (KO) mice were generated by crossing floxed strains with *Krt19*-Cre*ERT* mice. KO mice and respective floxed controls were challenged with an intermittent 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) diet for 24 days; hepatic markers of inflammation, serum injury enzymes, and lipid profiles were evaluated. **Results:** Transcriptomic analysis revealed a 3.2- and 4.6-log fold decrease in *SCD1* expression in PSC and PBC cholangiocytes, respectively, compared to healthy controls (FDR <0.05). Conversely, *SCD5* transcript detection increased from 4% in controls to 27% and 48% in PSC/PBC cholangiocytes, correlating significantly with *MMP7*, *CCL2*, epithelial-mesenchymal transition, and WNT/β-catenin signaling. Mdr2$^{-/-}$ and DDC-fed mouse cholangiocytes showed analogous *Scd1* downregulation and *Scd2* upregulation. In H69 cells, *SCD1* knockdown ($\geq$95%) significantly amplified TNFa-stimulated *CCL2* expression by 2.3-fold, whereas *SCD5* knockdown ($\geq$92%) significantly attenuated basal and LPS-induced *CCL2* expression. Consistently, *Scd1* KO mice on the DDC diet exhibited significantly elevated hepatic *Ccl2*, *Mmp7* and *Tnfa* compared to controls, with significantly increased serum ALP, but not ALT (N = 12 KO, 12 control). Conversely, *Scd2* KO mice showed significantly reduced expression of these inflammatory genes, without a significant change in serum ALP or ALT (N = 18 KO, 11 control). Serum total cholesterol significantly increased in both DDC-fed KO models; only *Scd1* deficiency significantly reduced serum triglycerides, consistent with known Scd1 function. **Conclusion:** These findings support divergent, paradoxical roles for cholangiocyte *SCD* isoforms in regulating biliary inflammation and lipid metabolism. Further investigation of the isoform-specific molecular and lipidomic mechanisms will provide critical insights into the pathogenesis and therapeutic targeting of cholestatic liver diseases.

1007 | FGFR SIGNALING IN PROM1-EXPRESSING LIVER PROGENITORS ACCELERATES FIBROINFLAMMATORY DUCTULAR REACTION AND LIVER FIBROSIS DURING CHRONIC CHOLESTATIC LIVER INJURY

Mallikarjuna Siraganahalli Eshwaraiah[1] Jiaohong Wang[1] Ying Li[1] Ashley Chrissan[1] August Sriwattnanon[1] Maria Lauda Tomasi[2] Akil Merchant[2] Komal Ramani[2] Nirmala Mavila[2], [1]Cedars Sinai Medical Center, [2]Cedars-Sinai Medical Center

Background: Ductular reaction (DR), chronic inflammation, and bridging fibrosis are key features of chronic cholestatic liver diseases. However, the molecular mechanisms regulating DR and its contribution to fibrosis remain unclear. This study aimed to define the role of the fibroblast growth factor receptor 1/2 (FGFR1/2) signaling axis in PROMININ1 (PROM1)$^{+}$ liver progenitor-like cells (LPCs) in driving DR and liver fibrosis. **Methods:** Human liver specimens from biliary atresia (BA) and primary sclerosing cholangitis (PSC), along with cholestatic mouse models with PROM1-cell type targeted Fgfr1/2 knockdown, were used to investigate FGFR1/2 function in fibrogenesis. GeoMX spatial transcriptomic profiling was performed on BA liver tissues to identify DR-associated molecular drivers of bridging liver fibrosis. **Results:** FGFR1/2 signaling was markedly

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

activated in liver tissues from patients with BA and PSC, as well as in multiple models of liver fibrosis. FGFR1/2 expression co-localized with PROM1^{+} LPCs, and PROM1 enhanced FGFR activation in cholangiocytes. Conditional deletion of *Fgfr1/2* in PROM1^{+} cells significantly reduced LPC expansion, inflammatory responses, and fibrosis progression in mouse models. Mechanistically, in cholangiocytes, PROM1 facilitates constitutive activation of FGFRs via a Focal Adhesion Kinase-dependent mechanism. Spatial transcriptomic analysis revealed that PROM1+ reactive cholangiocytes serve as a major source of fibro-inflammatory mediators in human BA livers. **Conclusion:** FGFR1/2 signaling in PROM1+ LPC promotes the expansion of fibroinflammatory DR during chronic liver injury. Targeting the FGFR pathway in fibroinflammatory PROM+ LPCs may represent a promising therapeutic strategy to alleviate pathological DR and limit fibrosis progression in chronic cholestatic liver diseases.

1008 | METFORMIN PROMOTES CHOLANGIOCYTE REGENERATION IN CHOLESTATIC FIBROSIS VIA HK1-GLYCOLYSIS-DEPENDENT EPIGENETIC ACTIVATION OF LGR5

Yingyu Liang[1] Paul Kwong Hang Tam[1] Yan Chen[1], [1]Macau university of Science and Technology

Background: Cholestatic liver fibrosis, characterized by impaired cholangiocyte regeneration and elevated epithelial-mesenchymal transition (EMT), lacks novel therapeutics. We adopted an alternative therapeutic strategy by exploring the repurposing of existing clinically approved drugs. Among potential candidates, metformin emerged as a particularly promising agent, yet its therapeutic properties remain unelucidated in cholestasis. **Methods:** The therapeutic effects of metformin were validated using bile duct ligation (BDL) and *Mdr2*$^{-/-}$ mouse models. Bulk RNA-seq was conducted to identify gene changes, focusing on cholangiocyte regeneration and EMT pathways. Krt19CreERT2*Hk1*$^{fl/fl}$ mice were subjected to BDL to investigate the role of HK1 in cholangiocyte regeneration and the therapeutic effects of metformin. The binding of acetylated histone H4 lysine 16 (H4K16ac) to the *Lgr5* promoter was investigated using CUT&Tag and ChIP-qPCR. **Results:** Metformin ameliorated cholestatic fibrosis in both BDL and *Mdr2*$^{-/-}$ models, with consistent results showing reduced fibrosis and enhanced cholangiocyte regeneration. Metformin also enhanced stemness and cell proliferation in cholangiocyte organoids (Cho-Orgs). Transcriptomics identified HK1-glycolysis as a key downstream pathway upregulated by metformin in BDL, *Mdr2*$^{-/-}$ mice-derived Cho-Orgs. Findings in Krt19CreERT2*Hk1*$^{fl/fl}$ mice with cholestasis revealed a promising role of HK1 in improving liver fibrosis and cholangiocyte regeneration, as well as mediating the therapeutic effects of metformin. Mechanistically, metformin promoted HK1-glycolysis in Cho-Orgs, which upregulated acetyl-CoA (acCoA), leading to increased H4K16ac at the *Lgr5* promoter and elevated LGR5 expression. These findings were corroborated in human cholestatic patient-derived organoids (PDOs). **Conclusion:** Our findings reveal HK1 as a novel therapeutic target mediating the hepatoprotective effects of metformin in cholestatic fibrosis. Metformin enhances the HK1-glycolysis-acCoA axis, upregulating the interaction of H4K16ac with the *Lgr5* promoter, thereby promoting LGR5-mediated regeneration and dampening EMT in Cho-Orgs. These findings position metformin as a promising, safe, and cost-effective candidate for drug repurposing in cholestatic fibrosis.

1009 | THE IMPLICATION OF TRIMETHYLAMINE *N*-OXIDE IN THE DEVELOPMENT OF PRIMARY SCLEROSING CHOLANGITIS IN *CYP2C70*$^{-/-}$/*CYP2A12*$^{-/-}$ MICE WITH HUMAN-LIKE BILE ACID COMPOSITION

Teruo Miyazaki[1] Hajime Ueda[1] Tadashi Ikegami[1] Akira Honda[1], [1]Tokyo Medical University Ibaraki Medical Center

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Primary sclerosing cholangitis (PSC) is characterized by extensive fibrosis around the large bile ducts (onion-skin fibrosis) and is frequently complicated by inflammatory bowel disease. Although its pathogenesis remains unclear, its development may be associated with hydrophobic (Hbic) bile acids (BAs). Trimethylamine *N*-oxide (TMAO)—an oxidized form of the gut bacteria product trimethylamine (TMA) generated via flavin-containing monooxygenase 1 (FMO1) in the liver—is implicated in atherosclerosis and cardiovascular disease, and may contribute to liver inflammation and fibrosis through BA metabolism. We previously established a PSC mouse model by orally administering low-dose lithocholic acid (LCA) to *Cyp2c70* $^{-/-}$ */Cyp2a12*$^{-/-}$ mice (HuBA) with human-like Hbic BAs. This study aimed to evaluate the role of TMAO in the pathogenesis of PSC using this mouse model and cultured human cholangiocytes (MMNK1). **Methods:** Male wild-type (Wt) and HuBA mice (5 weeks of age) were treated with LCA (75 mg/L) via drinking water for 15 weeks. TMAO and BAs levels in bile and liver, as well as expression of genes related to TMAO and BA metabolism and transport, were evaluated. MMNK1 was treated with 50 μM TMAO and/or 100 μM Hbic BAs (LCA, chenodeoxycholic acid [CDCA], or deoxycholic acid [DCA]) in media containing 5 mM (pH 6.8), 20 mM (pH 7.4), or 44 mM (pH 7.8) bicarbonate. Cell proliferation and gene expression were analyzed. **Results:** The onion-skin fibrosis area in the HuBA mice was significantly increased by LCA treatment. TMAO level and the mRNA expression of its biliary efflux transporter *Mdr1*, as well as *Fmo1*, in liver were significantly higher in the HuBA mice than in the Wt mice, and were further increased by LCA treatment in both mouse strains. In contrast, hepatic mRNA expression of the basolateral efflux transporter *Mrp4* was also significantly higher in HuBA mice but was reduced by LCA treatment. No significant difference was observed in TMAO level in bile among the groups, presumably due to individual variation of bile concentration. In MMNK1 cells, TMAO treatment did not affect cell proliferation under any pH condition. However, the mRNA expression of cell adhesion/binding factors (*Vcam1*, *Cldn1*, *Itgb6*) was increased by the Hbic BAs and was further enhanced by co-treatment with TMAO, only in 5 mM (pH 6.8) bicarbonate condition. **Conclusion:** These results suggested that TMAO oxidation and biliary excretion are promoted through the upregulation of FXR-target Fmo1 and PXR-target Mdr1 in PSC liver. In addition, increased biliary excretion of TMAO may contribute to cholangiosclerosis and inflammation in distal cholangiocytes, where the epithelial barrier by bicarbonate umbrella is weaker, thereby enhancing the effects of epithelial adhesion and fibrosis-related factors. In the bile ducts of PSC, the increased excretion of TMAO into the bile, in combination with Hibc BAs, may trigger the development of cholangiosclerosis and inflammation.

★ 1010 | BATTED REVEALS CYP7A1 AS A TARGETABLE PATHWAY IN BILIARY ATRESIA

Takahiro Ohkura[1] Shun Onishi[1] Kento Kurashima[1] Marzena Swiderska-Syn[1] Chandrashekhara Manithody[1] Marianne Dunn Parra[1] Shin Miyata[1] Ajay Jain[1], [1]Saint Louis University

Background: Biliary atresia (BA) is a leading cause of neonatal cholestasis and progressive fibrosis. Few large-animal studies reproduce BA-like cholangiopathy. CYP7A1 regulates the rate-limiting step in primary bile acid synthesis and may amplify cholestatic injury. We tested whether CYP7A1 is increased in vivo and targetable by siRNA in vitro using our patent-pending BATTED (Biliary Atresia Through Targeted Endothelial Destruction) piglet system. **Methods:** Twelve 7-day-old piglets were randomized to sham or BATTED (n = 6/group). BATTED involved cholecystectomy, 95% ethanol ductal injection, and ethanol-retainer placement. Blood and liver were collected at baseline and 6 weeks. Serum chemistries, histology, IHC, and hepatic bile acid regulatory genes were assessed. HepG2 cells were transfected with CYP7A1 or control siRNA, with expression measured at ~50 hours. Student's t-test was used; $p < 0.05$ was significant. **Results:** Six weeks after BATTED, piglets developed cholestasis and liver injury. Conjugated bilirubin rose in BATTED animals, mean Δ0.39 to 3.88 mg/dL, versus sham, Δ0.39 to 0.98 mg/dL. GGT increased Δ16.3 to 89.5 IU/L after BATTED, while sham showed minimal change, Δ9.2 to 10.4 IU/L. ALT, ALP, and bile acids were also elevated. Histology showed periportal expansion, ductular reaction, inflammatory infiltrates, and diffuse collagen deposition. Sirius Red showed periportal/bridging fibrosis with a 16-fold increase in collagen-positive area versus sham. CK7 increased 9-fold, confirming bile duct proliferation. CD3 increased 7-fold, indicating T-cell-rich portal inflammation consistent with cholangitis. Fibrogenic markers increased, including alpha-SMA, 8.85-fold, and COL1A1, 11.7-fold. CYP7A1 increased 7-fold in BATTED liver versus sham, with expanded hepatocyte CYP7A1 immunoreactivity, supporting enhanced primary bile acid synthesis as a candidate injury mechanism. FXR and SHP also increased, indicating bile acid regulatory signaling. To assess targetability, HepG2 cells were transfected with CYP7A1 siRNA. CYP7A1 expression decreased from ~1.0 in untreated cells to 0.069 and 0.028 after siRNA

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

transfection, whereas negative-control siRNA did not show comparable target suppression. These data demonstrate robust CYP7A1 knockdown and support CYP7A1 silencing as a feasible strategy for future in vivo testing. **Conclusion:** BATTED piglets reproduced key BA features. CYP7A1 activation identifies enhanced bile acid synthesis as a candidate driver of hepatocellular injury. Effective CYP7A1 knockdown in HepG2 cells supports evaluation of CYP7A1 siRNA silencing in BATTED as a potential adjunctive therapeutic strategy for BA.

1011 | A HUMAN HEPATOCYTE CHIMERIC MOUSE MODEL REVEALS CONSERVED HEPATOCYTE UPR ACTIVATION AND BILE ACID METABOLISM RESPONSES TO ER STRESS AND IBAT INHIBITION

Ryan Shaw[1] Alyssa Kriegermeier[2] Richard Green[1], [1]Northwestern Feinberg School of Medicine, [2]Ann and Robert H. Lurie Children's Hospital of Chicago

Background: Cholestatic liver diseases are driven by an accumulation of toxic bile acids (BAs) that cause hepatocyte injury, ER stress, and unfolded protein response (UPR) activation, yet effective therapies remain limited. A key barrier to translation is the hydrophilic, muricholic acid–rich murine BA pool, which is less cytotoxic than the hydrophobic human pool. Enterohepatic feedback also differs across species: ileal BAs induce FGF15 in mice and FGF19 in humans. Mouse-ileal FGF15 represses hepatic BA synthesis via FGF Receptor-4 (FGFR4), but cannot activate human FGFR4. We used FRG mice with the majority of mouse hepatocytes replaced by human hepatocytes (FRGh) as a translationally relevant model of human hepatocyte ER stress and BA homeostasis. **Methods:** FRGh mice received the pharmacologic ER stress-inducer tunicamycin (TUN; 0.5 mg/kg ip, 4 h) or vehicle (DMSO), or chow with the IBAT inhibitor maralixibat (MIBAT; 150 mg/kg/day) or normal chow (n = 2 per arm) for one week. Serum LFTs and bile acids were measured. Hepatic BA metabolism and UPR gene expression were assessed by qPCR with species-specific primers. Engrafted human hepatocyte transcriptomes were determined by bulk RNA-seq (all mice) and snRNA-seq (TUN, DMSO; n = 1) with Hallmark Gene Set Enrichment Analysis (GSEA) of TUN vs DMSO and MIBAT vs chow following alignment to a combined human–mouse reference genome. **Results:** In human hepatocytes, MIBAT vs chow GSEA showed significant induction of TNFα signaling and cholesterol homeostasis, with downward trends in UPR, fatty acid metabolism, and ROS pathways. Hepatic qPCR revealed a species-divergent BA-synthesis response: murine Cyp7a1 was fully suppressed at baseline and strongly induced by MIBAT, while human CYP7A1, lacking baseline FGFR4 repression, did not change. A parallel trend was seen for Cyp8b1/CYP8B1. Serum BAs were markedly lower in MIBAT- than chow-fed animals (24.5 vs 241.5 µmol/L). GSEA of TUN vs DMSO induced UPR, PI3K-AKT, and p53 signaling in human hepatocytes, with concordant qPCR induction of XBP1, CHOP, and ERDJ4 in human and murine hepatocytes; snRNA-seq confirmed UPR induction in human hepatocytes. **Conclusion:** In FRGh mice, MIBAT lowered serum BAs and exposed a species-divergent BA-synthesis response: murine Cyp7a1 was strongly de-repressed, while human CYP7A1 was minimally induced from its elevated baseline, though MIBAT induced broader pathway changes in human hepatocyte cholesterol and BA metabolism. This is consistent with ileal FGF15/liver FGFR4 feedback occurring only in mice, leaving human BA synthesis under cell-autonomous FXR rather than FGF19 control. TUN activated a robust UPR in engrafted human hepatocytes with concordant murine induction, demonstrating that human hepatocytes mount an ER-stress response similar to mice. These findings establish the FRGh mouse as a platform to study human hepatocyte UPR modulation and develop UPR-based therapies for cholestatic disease.

1012 | METHYLDOPA ALLEVIATES BILE ACID ACCUMULATION IN A MURINE MODEL OF INTRAHEPATIC CHOLESTASIS OF PREGNANC

Dina Manna[1] Hana Lastuvkova[1] Jolana Cermanova[1] Lenka Jandova[1] Milos Hroch[2] Martin Lenicek[3] Martin Ambroz[4] Maria Krutakova[4] Petr Pavek[4] Stanislav Micuda[2], [1]Charles University, Faculty of Medicine in Hradec Kralove, [2]Charles University, Faculty of medicine, [3]Charles University, 1st faculty of medicine, [4]Charles University, Faculty of Pharmacy

Background: Intrahepatic cholestasis of pregnancy (ICP) is the most prevalent pregnancy-associated liver disease and is defined by elevated serum bile acid (BA) concentrations, which increase placental

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

permeability and are associated with adverse fetal outcomes including preterm delivery and meconium-stained amniotic fluid. ICP frequently co-occurs with hypertensive disorders of pregnancy, including pre-eclampsia, for which methyldopa is a commonly used antihypertensive agent. Despite this clinical overlap, the effects of methyldopa on BA homeostasis have not been characterized. **Methods:** We investigated the effects of methyldopa in a well characterized murine model of estrogen-induced cholestasis. Female C57BL/6J mice were treated with ethinylestradiol (EE; 10 mg/kg, s.c.) alone or in combination with methyldopa (250 mg/kg, p.o.) for 7 days. BA profiles were quantified by LC-MS in plasma, bile, liver, urine, intestine, and feces. Total and free cholesterol were quantified in liver tissue by GC-MS. Hepatic expression of BA-regulatory enzymes and transporters was evaluated by RT-qPCR and Western blot. **Results:** Methyldopa significantly reduced total BA concentrations in plasma and liver of EE-treated mice without a compensatory increase in fecal or urinary BA excretion, indicating a reduction in BA load rather than rerouted elimination. This was accompanied by transcriptional upregulation of phase I/II biotransformation enzymes (Cyp2b10, Ugt1a1, Sult2a1) and BA transporters (Abcb11, Slc10a1, Abcc3/4) — a gene expression signature consistent with constitutive androstane receptor (CAR) activation, mediated indirectly through p-ERK downregulation. Methyldopa also reduced hepatic free cholesterol in cholestatic mice, with concurrent downregulation of Hmgcr and upregulation of Acat2, suggesting that decreased cholesterol substrate availability contributes to attenuated BA synthesis. **Conclusion:** Methyldopa attenuates estrogen-induced BA accumulation through a dual mechanism: suppression of BA synthesis and enhanced hepatic detoxification, likely via indirect CAR activation. These findings raise the clinically relevant hypothesis that methyldopa, when prescribed for hypertensive disorders of pregnancy, may simultaneously reduce BA burden and delay the progression of cholestatic injury in patients with ICP. Prospective clinical studies are needed to evaluate this potential benefit.

1013 | ASSOCIATIONS OF FIRST-TRIMESTER ALKALINE PHOSPHATASE LEVELS, URSODIOL USAGE, AND ADVERSE PREGNANCY OUTCOMES AMONG PRIMARY BILIARY CHOLANGITIS AND PRIMARY SCLEROSIS CHOLANGITIS PATIENTS

Priyanka Gaur[1] Jacky Choi[2] Himel Mallick[2] Tatyana Kushner[3], [1]Division of Maternal-Fetal Medicine, Weill Cornell Medicine, [2]Division of Biostatistics, Weill Cornell Medicine, [3]Division of Gastroenterology & Hepatology, Weill Cornell Medicine

Background: Primary sclerosing cholangitis (PSC) and primary biliary cholangitis (PBC) are rare cholestatic liver diseases with limited pregnancy-specific data to guide counseling and management. We evaluated whether first-trimester alkaline phosphatase (ALP) levels and ursodiol use were associated with adverse pregnancy outcomes (APOs) among pregnant persons with PBC and PSC. **Methods:** We performed a retrospective cohort study using the TriNetX research network. Pregnant persons with PBC or PSC were identified using electronic health record data extracted through 2025. Primary exposures were elevated first-trimester ALP (> 100 U/L) and any ursodiol use within the first 20 weeks of pregnancy. APOs were assessed from 20 weeks onward and included preterm birth, preeclampsia or gestational hypertension, gestational diabetes, cesarean delivery, fetal growth restriction, and postpartum hemorrhage. Multivariable logistic regression models adjusted for age, race, chronic hypertension, and pregestational diabetes. Sensitivity analyses restricted exposure ascertainment to 94.5 days after pregnancy onset to reduce potential reverse causation. Pre-planned subgroup analyses compared PBC versus PSC cohorts and alternative ALP thresholds (> 167 U/L and > 200 U/L). **Results:** The ALP and ursodiol analyses included 341 and 408 pregnant persons with PBC and PSC, respectively; 97 patients had elevated ALP levels. Among those with elevated ALP, 70 (77%) received ursodiol compared with 21 (23%) with normal ALP levels ($p < 0.001$). Median maternal age was 37 years (IQR 33-41), 70% were non-Hispanic White, and 5% had chronic hypertension or pregestational diabetes. Baseline demographic and clinical characteristics did not differ by ALP status. In both unadjusted and adjusted analyses, neither elevated ALP levels nor ursodiol use were significantly associated with APOs. Sensitivity and subgroup analyses yielded similar findings across exposure

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

definitions and disease subtypes. **Conclusion:** Among pregnant persons with PBC and PSC, neither elevated first-trimester ALP levels nor ursodiol use were independently associated with adverse pregnancy outcomes. However, the rarity of PBC and PSC in pregnancy and low event counts limited statistical power; therefore, findings should be considered hypothesis-generating. Larger prospective studies are needed to better define predictors of maternal and fetal risk in this population and inform multidisciplinary counseling and management strategies.

Table 1. Unadjusted and Adjusted Models Examining Elevated ALP (> 100 U/L), Ursodiol Usage, and Adverse Pregnancy Outcomes Among PBC/PSC Patients[a]

Model 1: Elevated ALP Levels as Primary Exposure (n=341)		
Adverse Pregnancy Outcomes	OR (95% CI)	aOR (95% CI)[b]
Preterm birth	1.16 (0.61-2.27)	1.24 (0.63-2.47)
Preeclampsia or gestational hypertension	0.562 (0.27-1.14)	0.516 (0.24-1.07)
Gestational diabetes	0.567 (0.26-1.21)	0.555 (0.23-1.27)
Postpartum hemorrhage	1.24 (0.60-2.60)	1.23 (0.59-2.64)
Cesarean section	0.582 (0.19-1.65)	0.587 (0.19-1.69)
Fetal growth restriction	0.960 (0.44-2.13)	0.987 (0.44-2.21)
Model 2: Any Ursodiol Usage as Primary Exposure (n=408)		
Adverse Pregnancy Outcomes	OR (95% CI)	aOR (95% CI)
Preterm birth	1.51 (0.70-3.13)	1.60 (0.73-3.37)
Preeclampsia or gestational hypertension	0.968 (0.39-2.17)	1.02 (0.43-2.39)
Gestational diabetes	1.12 (0.49-2.37)	1.13 (0.48-2.48)
Postpartum hemorrhage	1.83 (0.74-4.37)	1.76 (0.67-4.39)
Cesarean section	0.842 (0.27-2.23)	0.90 (0.28-2.44)
Fetal growth restriction	0.841 (0.30-2.07)	0.86 (0.30-2.12)

[a]Models adjusted for age, race, diabetes, and hypertension.

1014 | ETHANOL EXPOSURE ATTENUATES CHOLESTATIC LIVER INJURY IN THE HUMANIZED BILE ACID *CYP2C70*$^{-/-}$ MOUSE MODEL

Allison Paschack[1] Marko Mrdjen[1] Amy Burrows[1] Anthony Horak[1] Megan McMullen[1] Emily Huang[1] Venkateshwari Varadharajan[1] Sumita Dutta[1] Kala Mahen[1] William Massey[1] Olumuyiwa Awoniyi[1] Naseer Sangwan[1] Saul Karpen[2] Paul Dawson[3] Huiping Zhou[4] Laura Nagy[5] J. Mark Brown[1], [1]Cleveland Clinic, [2]VCU Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, [3]Emory University, [4]Virginia Commonwealth University, [5]Cleveland Clinic Foundation

Background: Bile acids (BAs) play important roles in intestinal fat absorption and initiate signaling processes that maintain lipid homeostasis throughout the body. Therefore, BA-focused therapeutic strategies have been leveraged for several diseases including diverse liver diseases. Unfortunately, differences in BA metabolism between mice and humans hamper translation of preclinical outcomes. *Cyp2c70* knockout (*Cyp2c70*$^{-/-}$) mice represent a "humanized" BA mouse model lacking the liver enzyme responsible for synthesis of 6-hydroxylated muricholate BA species that predominate in rodents. *Cyp2c70*$^{-/-}$ mice possess a more hydrophobic "human-like" bile acid composition, and as a result are prone to female-dominant progressive hepatobiliary injury and portal fibrosis. Here, we hypothesized that *Cyp2c70*$^{-/-}$ mice would have accelerated liver injury in response to alcohol consumption, given excessive alcohol exposure promotes liver damage and fibrosis. **Methods:** Age-matched cohorts of male and female *Cyp2c70*$^{+/+}$ and *Cyp2c70*$^{-/-}$ mice were subjected to 10 days of ethanol exposure, while controls were pair-fed. At necropsy, histological and biochemical markers of liver injury were quantified, hepatic bile acid composition and gut microbiome composition were analyzed. **Results:** After only 10 days of ethanol exposure, the cholestatic liver injury known to occur in *Cyp2c70*$^{-/-}$ mice was attenuated when compared to *Cyp2c70*$^{-/-}$ mice not consuming ethanol. Acute ethanol exposure unexpectedly reduced circulating markers of liver injury (ALT/AST) and improved histological and gene expression markers of fibrosis, liver inflammation, and ductular reaction normally seen in *Cyp2c70*$^{-/-}$ mice. Furthermore, ethanol-induced alterations of the gut microbiome were strikingly different in *Cyp2c70*$^{+/+}$ and *Cyp2c70*$^{-/-}$ mice. Interestingly, ethanol exposure stimulates the gene and protein expression of other related enzymes within the *Cyp2c* genetic locus, which may further shape metabolism to improve liver function. **Conclusion:** Although alcohol consumption is a predominant risk factor for liver fibrosis in humans, ethanol exposure in the fibrotic *Cyp2c70*$^{-/-}$ mouse model paradoxically improves liver injury. Results from this study provide insights into novel species-specific interactions between alcohol intake, metaorganismal (i.e. microbe and host) BA metabolism, and liver fibrosis.

1015 | COMPLEX CONTEXT-DEPENDENT CONSEQUENCES OF CONCURRENT FGF19 AND FXR SIGNALING IN A HUMANIZED MOUSE MODEL OF CHOLESTASIS: FOCUS ON FIBROTIC AND THROMBOTIC PATHWAYS

Stephen Hoang[1] Leslie Wakefield[2] Anne Vonada[2] Allison MacMillan[2] Ronnie Li[1] Thomas Andl[1] Andrew Pryor[1] Huiping Zhou[1] Paul Dawson[3] Markus Grompe[2] Saul Karpen[1], [1]VCU Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, [2]Oregon Health and Science University, [3]Emory University

Background: Cholestatic human conditions incorporate retained bile acids, liver cell damage and inflammation resulting in fibrosis and alterations of liver function. Given the complexity and often unpredictable nature of the cholestatic response, along with some contradictory findings of mouse models to the human condition, we sought to address this knowledge gap by focusing upon the two principal drivers and responders of ongoing cholestasis—hepatic FGF19 and FXR signaling—in a well-established human hepatocyte-engrafted murine model undergoing bile duct ligation (BDL). **Methods:** Human hepatocytes were engrafted for 130 days in FRGN mice followed by treatments with the FXR agonist cilofexor and/or adenoviral FGF19, in sham-operated mice or after 2 days of BDL. Serum/plasma proteomics and liver tissue transcriptomics, biochemical analyses and histology were assessed. Treatment effects were assessed on curated FXR-activated and FXR-repressed datasets with cross-layer concordance. **Results:** Mouse livers were engrafted to > 80% with human hepatocytes and showed expected as well as unanticipated responses to FGF19 and FXR signaling. Serum liver chemistries and liver bile acid analyses trended as predicted. Depending upon the treatments, fibrogenesis and fibrinolysis and well as thrombosis and thrombolysis pathways were all activated as revealed by transcriptomic and serum proteomic analyses. One example of the combinatorial contradictory responses in cholestasis, was upregulation of the FXR-repressed gene *SERPINE1/PAI-1* in both the non-BDL and BDL mice (protein > 5-fold, non-BDL; > 2-fold, BDL). *SERPINE1* RNA and protein expression was unchanged by cilofexor in non-BDL hepatocytes, minimally repressed after BDL. The directionality of gene expression regulation by cilofexor in the BDL context generally lacked coherence with reported FXR activation, consistent with contributing endogenous bile acid saturation of FXR signaling in cholestasis. However, the canonical signature of FXR agonism was restored when cilofexor was given with FGF19. **Conclusion:** The interaction of FGF19 and FXR pathways in cholestatic human livers leads to complex consequences modeled in part in our novel human hepatocyte-engrafted mouse model. Focusing on FXR-regulated thrombotic pathways mimics the contradictory nature of predicting coagulation status in human cholestasis. Studies like these help expand our understanding of the interwoven set of signals from the membrane (FGF19) to the nucleus (FXR) in cholestasis and may also help explain some features of humans exposed to FGF19 analogs and FXR agonists in clinical trials. Ongoing analyses of cell signaling and chromatin-based consequences in this model will likely reveal the molecular consequences of FGF19 and FXR mediated pathways and therapeutics in human cholestasis.

1016 | LOSS OF PRIMARY CILIA PROMOTES AUTOPHAGIC DEGRADATION OF CBL AND SUSTAINS EGFR SIGNALING IN CHOLANGIOCYTES

Kishor Pant[1] Estanislao Peixoto[2] Seth Richard[3] Branko Dubravcic[3] Naheed Arfin Borah[3] Sergio Gradilone[4], [1]The Hormel Institute (University of Minnesota), [2]University of Minnesota, [3]The Hormel Institute, [4]The Hormel Institute and Masonic Cancer Center. University of Minnesota

Background: Primary cilia are sensory organelles that regulate signaling pathways involved in cholangiocyte homeostasis, proliferation, and differentiation. Loss of primary cilia is a hallmark of cholangiociliopathies and cholangiocarcinoma (CCA), yet the molecular mechanisms linking ciliary dysfunction to sustained oncogenic signaling remain incompletely understood. Casitas B-lineage lymphoma (CBL), an E3 ubiquitin ligase that mediates epidermal growth factor receptor (EGFR) ubiquitination and degrada-

tion, is frequently dysregulated in cancer. We investigated whether loss of primary cilia promotes autophagy-dependent degradation of CBL, leading to sustained EGFR signaling in cholangiocytes and CCA. **Methods:** Primary cilia dysfunction was induced in normal human cholangiocytes through deletion or knockdown of IFT88, IFT20, and KIF3A. CBL and EGFR expression and localization were evaluated by immunoblotting and immunofluorescence. Autophagy-dependent degradation pathways were assessed using chloroquine, mefloquine, and siRNA targeting ATG5 and the selective autophagy receptor NBR1. CBL expression and ciliary status were also examined in human CCA cell lines. Restoration of ciliogenesis was induced using the HDAC6 inhibitor ACY1215 or HDAC6-shRNA in HuCCT1 cells and an orthotopic rat model of CCA. **Results:** Loss of primary cilia resulted in reduced CBL protein expression accompanied by sustained EGFR activation and downstream proliferative signaling. Similarly, cilia-deficient human CCA cells exhibited significantly lower CBL levels compared to normal cholangiocytes. Pharmacologic inhibition of autophagy or genetic suppression of ATG5 and NBR1 restored CBL protein expression, demonstrating that ciliary loss promotes selective autophagic degradation of CBL. Increased CBL expression was also observed in orthotopic rat CCA tissues following chloroquine treatment, supporting the in vivo relevance of this pathway. Restoration of primary cilia through ACY1215 treatment or HDAC6-shRNA increased ciliary localization and stabilization of CBL, enhanced EGFR degradation, reduced EGFR signaling, and suppressed CCA growth in vitro and in vivo. **Conclusion:** This study identifies a novel mechanism linking primary cilia dysfunction to sustained EGFR signaling through autophagy-dependent degradation of CBL in cholangiocytes and cholangiocarcinoma. Loss of cilia promotes selective autophagic clearance of CBL, impairing EGFR degradation and prolonging oncogenic signaling. Restoration of ciliogenesis through HDAC6 inhibition, or blockade of autophagy, rescues CBL-mediated EGFR regulation and suppresses tumor growth. These findings establish a novel cilium–CBL–EGFR signaling axis and support the therapeutic potential of ciliotherapy and autophagy-targeted approaches for cholangiocarcinoma.

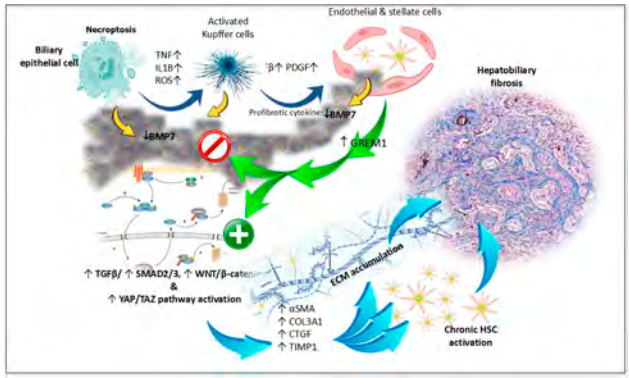
1017 | HEPATIC STELLATE CELL ACTIVATION THROUGH THE SNAI1-GREM1 AXIS ENABLES MOLECULAR DIAGNOSIS OF BILIARY ATRESIA



Akshit Vats[1] Yashwant Kumar[1] Shailesh Solanki[1] Sadhna Lal[1] Suvradeep Mitra[1] Alka Bhatia[1] Amit Arora[1], [1]PGIMER, Chandigarh, India

Background: Biliary atresia (BA) is a life-threatening pediatric cholangiopathy characterized by progressive fibrosis and biliary injury leading to liver failure. Aberrant molecular signaling disrupts the balance between tissue repair and cellular clearance, resulting in pathological remodeling and persistent fibrogenesis. Early differentiation of BA from other neonatal cholestatic (NC) disorders remains clinically challenging; therefore, identifying dysregulated molecular pathways may aid in the discovery of reliable diagnostic biomarkers and therapeutic targets. **Methods:** Peripheral blood and extrahepatic biliary tissue samples from BA patients and healthy controls (HC) were analyzed using customized RT² Profiler PCR arrays targeting fibrosis and apoptosis related genes. Gene expression data underwent PCA, hierarchical clustering, and WGCNA to identify dysregulated molecular networks. Feature selection and biomarker prioritization were performed using multi-model machine learning with cross-validation. Candidate genes were validated by qPCR and IHC in an independent cohort comprising HC, NC, and BA patients. Functional enrichment and molecular interaction analyses were conducted using IPA, while correlation and ROC analyses were performed to evaluate clinical and diagnostic utility. **Results:** Publicly available BA datasets (GSE122340 and GSE46960) revealed significant enrichment of apoptosis- and fibrosis-related pathways in BA. Gene expression profiling identified a molecular signature comprising GREM1, SNAI1, IL-10, FASLG, TNF-α, and COL1A1 with strong discriminatory power between BA and controls. IPA demonstrated co-activation of the TGF-β/SMAD2/3 pathway. GREM1 and SNAI1 were significantly upregulated in BA compared with NC and HC ($p < 0.001$) and showed strong positive correlation with serum γ-GT levels ($r = 0.73$, $p < 0.001$). IHC confirmed distinct differential expression patterns with high diagnostic utility. ROC analysis demonstrated excellent performance, with SNAI1 showing an AUC of 0.818 and the combined TNF-α + SNAI1 panel achieving superior diagnostic accuracy (AUC = 0.975, sensitivity = 95.1%, specificity = 91.4%). **Conclusion:** This study establishes an apoptosis–fibrosis molecular framework underlying

progressive biliary injury in BA. GREM1, SNAI1, and TNF-α emerged as key regulatory hubs associated with fibrogenesis and hepatic injury. The combined TNF-α + SNAI1 panel demonstrated excellent diagnostic performance, highlighting its potential as a minimally invasive biomarker signature for differentiating BA from other neonatal cholestatic disorders. Targeting SNAI1-mediated signaling may further represent a promising therapeutic strategy to limit hepatic stellate cell activation and fibrotic remodeling in BA.

1018 | MRP9 MAINTAINS CHOLANGIOCYTE INTEGRITY THROUGH REGULATION OF PORPHYRIN HOMEOSTASIS AND MITOCHONDRIAL FUNCTION

Tanja Linnerz[1] Bryan Donnelly[1] Ramesh Kudira[1] Michelle Damen[1] Akanksha Sharma[1] Annika Yang Vom Hofe[1] Hannah Nartker[1] Isabella Herider[1] Manavi Singh[1] Maria Fields (n.e Moreno-Fernandez)[1] Alexander Miethke[1] Chunyue Yin[1], [1]Cincinnati Children's Hospital Medical Center

Background: Cholangiopathies are chronic progressive disorders that target cholangiocytes and can cause significant morbidity and mortality due to a lack of effective therapies. We previously identified biallelic frameshift variants in *ABCC12*, encoding the multidrug resistance-associated protein MRP9, in a patient with cholangiopathic cholestasis. Studies in human liver tissue and zebrafish and mouse models demonstrated that MRP9 is expressed in cholangiocytes and that its loss increases susceptibility to bile acid-induced cholangiocyte death. We further observed mitochondrial localization of MRP9 and found that MRP9 deficiency causes mitochondrial injury and ectopic accumulation of the heme intermediate protoporphyrin IX (PPIX) in cholangiocytes. This study tested the hypothesis that MRP9 regulates porphyrin homeostasis to maintain mitochondrial function and cholangiocyte integrity. **Methods:** H69 human cholangiocyte cell line homozygous for the index patient *ABCC12* variant and *abcc12-/-* zebrafish were used as *in vitro* and *in vivo* models. Chemical and genetic approaches were employed to reduce porphyrin biosynthesis or enhance mitochondrial biogenesis and quality, and their effects on cholangiocyte survival were evaluated. Untargeted metabolomic profiling was performed on wild-type and *ABCC12-/-* H69 cells. Pharmacologic inhibitors were used to define the cell death mechanism responsible for cholangiocyte injury. **Results:** Inhibition of porphyrin biosynthesis with succinylacetone, an ALAD inhibitor, significantly reduced aminolevulinic acid-induced cell death in *ABCC12-/-* H69 cells. *In vivo*, hemin treatment rescued cholangiocyte loss in *abcc12-/-* zebrafish. Genetic suppression of the porphyrin transporter ABCG2 reduced PPIX accumulation and attenuated cholangiocyte death in *abcc12-/-* zebrafish. To determine whether mitochondrial dysfunction contributes to cholangiocyte injury, we generated transgenic zebrafish overexpressing human PGC1α, a master regulator of mitochondrial biogenesis, specifically in cholangiocytes. PGC1α overexpression reduced cholangiocyte loss in *abcc12* mutants. Untargeted metabolomics revealed tricarboxylic acid cycle dysfunction and a metabolic shift toward glycolysis in *ABCC12-/-* H69 cells. Finally, ferrostatin-1 treatment of H69 cells indicated that ferroptosis is a major driver of cholangiocyte death caused by MRP9 deficiency. **Conclusion:** These novel findings identify MRP9 as a critical regulator of porphyrin homeostasis in cholangiocytes and demonstrate that MRP9 loss leads to PPIX accumulation, mitochondrial dysfunction, and ferroptotic cell death of cholangiocytes. Importantly, targeting porphyrin metabolism or enhancing mitochondrial function mitigated cholangiocyte loss, highlighting potential therapeutic strategies for MRP9-associated cholangiopathies.

1019 | HEPATOBILIARY OUTCOMES IN ADULTS WITH CYSTIC FIBROSIS: A PROPENSITY-MATCHED TRINETX ANALYSIS

Hazem Abosheaishaa[1] Camelia Ciobanu[1] Marina Takawy[2] Ghada Mohamed[3] Ahmed Salem[4] Mohammed Youssef[5] Nermin Elhossiny[6] Madhavi Reddy[1], [1]The Brooklyn Hospital, [2]Rochester Regional Health Unity Hospital, [3]Lahey Hospital and Medical Center, [4]Maimonides Medical Center, [5]Hunt Regional Medical Center, [6]St. Marry General Hospital

Background: Cystic fibrosis (CF) is increasingly recognized as a multisystem disease with significant hepatobiliary manifestations in adults. However, large-scale real-world data evaluating the risk of advanced liver-related outcomes in adults with CF remain limited. Therefore, this study aimed to evaluate the risk of primary biliary cirrhosis (PBC), portal hypertension, liver transplantation, and mortality among adults with CF compared with matched non-CF controls. **Methods:** We performed a retrospective cohort study using the TriNetX US Collaborative Network including adults aged $\geq$18 years from January 2015 onward. Patients with CF were identified using ICD-10 code E84 and compared with adults without CF. Propensity score matching (1:1) was performed for age, sex, race, viral hepatitis, primary sclerosing cholangitis, alcohol dependence, and nonalcoholic steatohepatitis. Outcomes included PBC, portal hypertension, liver transplantation, and all-cause mortality. Risk ratios (RR) and hazard ratios (HR) with 95% confidence intervals (CI) were calculated. **Results:** After propensity score matching, 29,786 patients were included in each cohort. Adults with CF had significantly higher risks of hepatobiliary complications compared with matched controls. The risk of PBC was markedly increased in the CF cohort (0.5% vs 0.1%; RR 8.24, 95% CI 5.06–13.44; HR 8.45, 95% CI 5.18–13.78; $p < 0.001$). Portal hypertension was also more common among patients with CF (1.7% vs 0.3%; RR 5.45, 95% CI 4.36–6.80; $p < 0.001$). Additionally, liver transplantation occurred more frequently in the CF cohort (0.8% vs 0.1%; RR 11.50, 95% CI 7.36–17.96; $p < 0.001$). Mortality risk was significantly higher in adults with CF compared with controls (12.7% vs 3.5%; RR 3.64, 95% CI 3.41–3.90; HR 3.75, 95% CI 3.50–4.02; $p < 0.001$). **Conclusion:** Adults with cystic fibrosis are at substantially increased risk of advanced hepatobiliary disease, liver transplantation, and mortality compared with matched non-CF controls. These findings highlight the importance of longitudinal hepatology surveillance and early multidisciplinary management in the growing adult CF population.

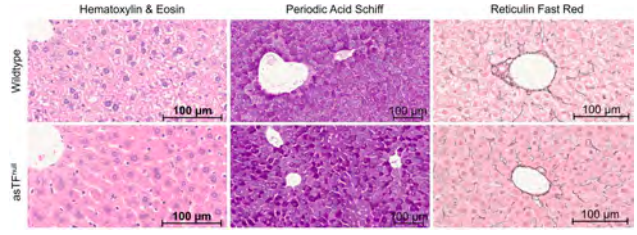
1020 | ALTERNATIVELY SPLICED TISSUE FACTOR IS INTEGRAL TO NORMAL HEPATIC FUNCTION: LESSONS FROM THE ASTF^{NULL} MOUSE.



Clayton Lewis[1] Hailey Doerflein[2] Sabahat Ahsan[2], [1]University of Cincinnati College of Medicine, [2]University of Cincinnati IM Gastro Hep

Background: The tissue factor gene encodes two proteins with different biological functions. Full-length tissue factor is membrane-bound and serves as a scaffold for the activation of the extrinsic pathway of coagulation. In contrast, the alternatively spliced isoform (asTF) is a soluble protein that is dispensable for normal coagulation – instead it serves as a potentiator of integrin activity. Previously, we reported histological findings demonstrating that in normal human liver asTF expression is zonally and spatially regulated – asTF is expressed by zone 3 hepatocytes and held in exocysts polarized toward their biliary canaliculi. In specimens from patients with varying degrees of MASH-related fibrosis, we found asTF levels rise with worsening disease and begins to be expressed by all hepatocytes, not just zone 3. To set the foundation for understanding the role asTF may play in disease progression, we sought to determine the native biologic function of asTF in the liver. **Methods:** Utilizing CRISPR/Cas9, we generated a novel mouse lacking intron 4 in the tissue factor gene, which precludes alternative mRNA splicing and production of asTF. Mice homozygous for this deletion – termed asTF^{null} – were characterized via clotting assays and histological assessment of the liver in comparison to heterozygous and wildtype litter mate controls. These three genotypes were subjected to dietary challenge using diet high in fat, fructose, and cholesterol for 24 weeks and compared to kcal matched chow diet controls. **Results:** Immunohistochemical evaluation of wildtype mice revealed asTF expression is confined to pericentral hepatocytes adjacent to canalicular membranes, as observed in humans. No difference was found in clotting times between adult asTF^{null} mice and littermate controls in a tail clipping assay. Histochemical analysis of asTF^{null} livers revealed a distinct pathological phenotype characterized by i) enhanced sinusoidal dilation, ii) hypergranular hepatocytes, iii) altered glycogen storage pattern, and iv) active zone 1 regeneration. Immunohistochemical analysis of male and female adult mice revealed 50% more cholangiocytes in asTF^{null} mice

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

than their littermates. In dietary challenge studies, we found male asTF^{null} mice gained weight more rapidly than littermate controls. asTF^{null} mice had a significantly higher liver weight to body weight ratio and developed more severe liver pathologies than littermate controls including cholangiocarcinoma. **Conclusion:** Here we demonstrate asTF serves an integral function in normal liver biology. When compared to wildtype controls, asTF^{null} mice have distinct pathologic features, supporting the ongoing hypothesis that asTF supports biliary canaliculi architecture by facilitating integrin binding.

1021 | ORAL CANNABIDIOL ATTENUATES EXPERIMENTAL CHOLANGIOPATHY BY MODULATING INTESTINAL ENDOCANNABINOID SYSTEM AND BARRIER-DEFENSE SIGNALING

Lixian Chen[1] Chunbao Sun[1] Panpan Huang[1] Guihua Pan[1] Xing Gao[1] Rahul Pushparaj[1] Lihua Zhang[1] Wenke Feng[1], [1]Tulane University

Background: Primary sclerosing cholangitis (PSC) is a progressive cholangiopathy with no approved drug therapy to halt progression. Gut barrier dysfunction and gut-derived inflammation are increasingly implicated in PSC pathogenesis. The endocannabinoid system (ECS) regulates intestinal barrier integrity, mucosal inflammation, and hepatic injury, but whether ECS-targeted modulation attenuates cholangiopathic injury remains unclear. Cannabidiol (CBD), a non-intoxicating cannabinoid, modulates ECS tone and intestinal homeostasis. We hypothesized that oral CBD protects against PSC-relevant cholangiopathy through a gut-engaged mechanism via intestinal ECS/barrier-defense restoration. **Methods:** Ten-week-old male C57BL/6 mice were fed a 0.1% 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC) diet for 4 weeks to induce cholangiopathic liver injury. CBD was administered at 2 mg/kg/day by oral gavage in sesame oil beginning on the first day of DDC feeding. A separate DDC-fed cohort was also treated with intraperitoneal CBD at 2 mg/kg/day. Serum liver injury and cholestasis markers, including AST, ALT, ALP, and total bilirubin, were measured. Liver ductular reaction, hepatic inflammation, apoptosis, and fibrosis were assessed by CK19, CD68, TUNEL, and Sirius Red staining, respectively. Hepatic and ileal CB1/CB2 expression and intestinal barrier-defense markers, including Claudin-1, IgA, and Reg3γ, were evaluated by molecular and histologic approaches. Bacterial translocation to the liver was assessed by 16S rRNA gene qPCR in liver tissue and portal vein blood. **Results:** Oral CBD significantly attenuated DDC-induced elevations in serum liver injury and cholestasis markers and reduced ductular reaction, hepatic macrophage accumulation, apoptosis and fibrosis. Compared with oral CBD, intraperitoneal CBD showed only limited effect, with reducing ALT but not broadly improving AST, ALP, or total bilirubin. DDC feeding decreased CB1 and CB2 expression in both liver and ileum. Oral CBD did not restore hepatic CB1/CB2 expression but partially restored ileal CB1/CB2 expression, supporting selective intestinal ECS modulation. DDC-induced cholangiopathy was also associated with impaired intestinal barrier-defense signatures, including reduced ileal Claudin-1 and IgA staining and decreased Reg3γ expression. Oral CBD improved intestinal barrier-associated responses. Oral CBD also reduced bacterial translocation, as indicated by decreased 16S rRNA gene levels in liver tissue and portal vein blood. **Conclusion:** Oral CBD attenuates DDC-induced cholangiopathic injury and associates with selective restoration of ileal but not hepatic CB1/CB2 expression. Together with improved intestinal barrier-defense markers, these findings support a gut-engaged mechanism of CBD action and nominate intestinal ECS-associated barrier-defense signaling as a potential therapeutic axis for PSC-relevant cholangiopathy.

1022 | THE MDR2-/- MICE MODEL FEATURES OF PRIMARY SCLEROSING CHOLANGITIS IN THE LIVER AND INTRAHEPATIC BILE DUCTS, BUT NOT IN THE EXTRAHEPATIC BILE DUCTS

Takuki Sakaguchi[1] Ashley Calder[2] John Tobias[3] Nataliya Razumilava[1], [1]University of Michigan, [2]University of Michigan Medical Center, [3]University of Pennsylvania

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

Background: Primary sclerosing cholangitis (PSC) targeting epithelial cells of the biliary tree is characterized by inflammation with biliary hyperproliferation, fibrosis and cholestasis. PSC affecting the large intra- and extra- hepatic bile ducts (IHBDs and EHBDs) carries a high risk of developing cirrhosis and biliary tract cancer. Treatment options for patients with large duct PSC are limited by a poor understanding of PSC pathophysiology and limited pre-clinical models. Mice deficient in Mdr2(Abcb4) lack phosphatidylcholine in bile and are widely used to model PSC with liver and intrahepatic bile duct inflammation and fibrosis. Whether Mdr2-/- mouse model recapitulates PSC in the perihilar and extrahepatic biliary tree, the important targets of PSC in humans, is currently unknown. Aim: to investigate the utility of Mdr2-/- mice as a model of large duct PSC in the extrahepatic bile duct. **Methods:** Mdr2-/- mice were maintained on a C57BL/6 background. Liver and EHBD tissues were isolated and examined with immunohistochemistry, morphometrics and transcriptomics as bulk RNA-seq and gene ontology analyses. Mouse serum was tested for liver function tests. **Results:** As anticipated, Mdr2-/- mice showed liver fibrosis at 3 months of age as assessed by Sirius red histologic examination and had increased Col1a1 expression as compared to wild-type (WT) livers. Mdr2-/- mice had increased expression of cholangiocyte marker genes Krt19 and Krt7 within the liver suggestive of cholangiocyte expansion and ductular reaction. However, the EHBD of Mdr2-/- mice showed no overt histologic changes by H&E and had decreased KI67+ (proliferation marker) expression as compared with WT mice. There were limited transcriptional changes in the EHBD of Mdr2-/- mice with less than 100 differentially expressed genes with + >0.5 Log2FC and no changes in genes encoding collagens or cholangiocyte markers Krt7 or Krt19 as compared with WT EHBDs. **Conclusion:** The Mdr2-/- mouse model of inflammatory fibrotic cholangiopathy models PSC features in the liver and intrahepatic bile ducts with limited to no phenotype in EHBDs, which are often affected in PSC. This highlights the model limitations and difference in intra- and extra- hepatic bile duct pathology with a remaining need for models recapitulating features of PSC in large EHBDs.

1023 | ACTIVATION OF CANNABINOID RECEPTOR 2 REGULATES MACROPHAGE CYTOKINE SECRETION TO IMPROVE CHOLESTATIC LIVER FIBROSIS

Suxian Zhao[1], [1]Hebei Medical University Third Hospital

Background: Cirrhosis is the progression of various chronic liver diseases to a pathological stage characterized by diffuse fibrosis of the liver, pseudo follicular formation, and proliferation of intra- and extrahepatic blood vessels. Cirrhosis of the liver has a variety of causes, of which cholestasis is an important one. Herein, we explored the therapeutic potential of targeting the cannabinoid-2 receptor (CB2-R) utilizing a commonly used mouse model of liver fibrosis, induced by bile duct ligation (BDL). **Methods:** Liver perforated paraffin tissues were collected from 50 patients with primary biliary cholangitis hospitalized in the Department of Traditional and Western Medical Hepatology of the Hebei Medical University Third Hospital from 2021 to 2024, and the patients were classified into early and late stages based on histological diagnostic criteria, and immunohistochemical staining for CD68 and CD163 was performed on the patients with early and late stages, respectively. 12-16 week-old C57BL/6J male mice were used and BDL was performed as described earlier. Following surgery, the animals were randomly assigned to one of six groups: Sham, Sham (AM-1241-treated), Sham (vehicle-treated), BDL, BDL(AM-1241-treated), and BDL, (vehicle-treated). The protein levels of YAP, TAZ, CTGF, α-SMA, ARG1、INOS、CD11b、F4/80 and TGF-βwere detected by Western blotting, while the mRNA levels of IL-6、IL-10、TNF-α、TGF-β、INOS、ARG1、MCP1、MIP1α、MIP2、CD68、CD163、CB2 and α-SMA were examined by real-time polymerase chain reaction (RT-PCR). **Results:** In advanced PBC patients, the expression of CD68 and CD163 is significantly higher compared to that in early-stage patients. The CB2-R agonist AM1241 is capable of modulating macrophage phenotypes, significantly reducing the expression of pro-inflammatory cytokines in the liver and alleviating the inflammatory response in the liver. Furthermore, AM1241 notably decreases the protein expression levels of YAP, TAZ, CTGF, and α-SMA. Histologically, AM1241 restricts the extension of fibroplasia and breaks the course of bridging fibrosis. **Conclusion:** Our results suggest that macrophages play a role in the development and progression of cholestatic liver disease. Additionally, CB2 receptor

agonists significantly alleviate the inflammatory response to cholestatic liver fibrosis and ameliorate hepatic fibrosis through the YAP/TAZ signaling pathway.

1024 | LOW PHOSPHOLIPID-ASSOCIATED CHOLELITHIASIS (LPAC) SYNDROME: A FOUR-GENERATION FAMILIAL CLUSTER ASSOCIATED WITH CIRRHOSIS AND HEPATOCELLULAR CARCINOMA

Gerond Lake-Bakaar[1], [1]St. Anthony Hospital, Lakewood, CO, USA

Background: Low Phospholipid-Associated Cholelithiasis (LPAC) is a rare genetic form of cholelithiasis linked to pathogenic variants in **ABCB4** (MDR3), resulting in reduced biliary phosphatidylcholine, cholesterol supersaturation, and bile-mediated hepatocellular injury. We report a multigenerational family in which LPAC phenotype co-segregates with advanced liver disease, including cirrhosis and hepatocellular carcinoma (HCC). **Methods:** The proband is a 47-year-old man with a first attack of pancreatitis at age 19, followed by a second episode later that year. At that time, gallstones were detected in the absence of cholecystitis. He subsequently underwent cholecystectomy. However, despite the cholecystectomy, he went on to develop recurrent intra- and extrahepatic bile duct stones and multiple episodes of cholangitis, managed with repeated ERCPs. Most recently, in April 2026, he underwent another ERCP for cholangitis, with extraction of stones and biliary sludge. The early onset of symptomatic cholelithiasis, post-cholecystectomy recurrence, and a striking family history prompted evaluation for LPAC. Pedigree analysis, spanning four generations and including 13 relatives, was conducted. The patient was initiated on ursodeoxycholic acid (UDCA). **Results:** Pedigree review identified 10 first-degree relatives with available clinical data: five developed cirrhosis, and three of these progressed to HCC, two requiring orthotopic liver transplantation. Multiple relatives underwent cholecystectomy at young ages or had documented gallstone disease. No cases of cholangiocarcinoma were identified in this family. The clinical pattern—early symptomatic gallstones, recurrent biliary lithiasis after cholecystectomy, and clustering of advanced hepatobiliary disease—supports an inherited ABCB4-related disorder with a high penetrance for progressive liver injury in affected members. **Conclusion:** LPAC should be suspected in patients with gallstone disease presenting at a young age (< 40 years), with recurrent biliary lithiasis after cholecystectomy. Familial ABCB4/MDR3 deficiency may predispose to chronic hepatocellular injury, cirrhosis, and HCC. Early recognition, targeted genetic testing, cascade family screening, genetic counseling, and consideration of medical management with UDCA may reduce progression to advanced liver disease and inform surveillance strategies for at-risk relatives.

1025 | REAL-WORLD TREATMENT RESPONSE AND HISTOLOGICAL CHARACTERISTICS OF PRIMARY BILIARY CHOLANGITIS IN A LARGE CHINESE COHORT

Zuxiong Huang[1] Qiaorong Gan[1] Qiuxiang Lin[1] Zhechang Chen[2] Aifang Lin[2] Xuwei Wu[2], [1]Mengchao Hepatobiliary Hospital of Fujian medical university, [2]Menchao Hepatobiliary hospital of Fujian medical University

Background: Primary biliary cholangitis (PBC) is a chronic autoimmune cholestatic liver disease that may progress to cirrhosis and liver failure. Ursodeoxycholic acid (UDCA) is the standard first-line therapy; however, a substantial proportion of patients exhibit inadequate biochemical response. Real-world data integrating demographics, histology, and treatment response in non-Western PBC populations remain limited. **Methods:** We conducted a retrospective cohort study of patients diagnosed with PBC at Mengchao Hepatobiliary Hospital of Fujian Medical University in China from January 2017 to March 2026. Demographic characteristics, liver biopsy findings, and treatment data were collected. Histological inflammation and fibrosis stages were evaluated in patients undergoing liver biopsy. Biochemical response was assessed after ≥ 12 months of UDCA monotherapy or UDCA plus fenofibrate using standard criteria. **Results:** A total of 1,974 patients with PBC were included, with a female predominance (71%). Most patients were middle-aged, with the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

highest proportion between 51–60 years; patients aged ≤30 or >70 years accounted for smaller proportions. Liver biopsy were performed on 317 patients, revealing heterogeneous disease stages. Most patients diagnosed at a non-cirrhotic stage, while 10.74%(33/317) patients had established cirrhosis.Among 1,646 patients with follow-up data, 1,623 received UDCA therapy. The biochemical response rate to UDCA monotherapy was 62.3% (1,011/1,623). A total of 612 patients showed inadequate response to UDCA; among them, 125 received add-on fenofibrate therapy, with a response rate of 28.7% (36/125). Inadequate responders were more frequently observed among patients with advanced histological stages and cirrhosis. **Conclusion:** In this large real-world Chinese PBC cohort, patients were predominantly middle-aged women but demonstrated substantial heterogeneity in histological stage at diagnosis. More than one-third of patients had an inadequate biochemical response to UDCA, and response to add-on fenofibrate therapy remained limited. These findings highlight persistent unmet therapeutic needs in PBC, particularly among patients with advanced fibrosis, and support the need for more effective second-line treatment strategies.

1026 | ◆ SE-1 ANTIBODY-CONJUGATED MSC EXOSOMES ENHANCE LSEC-TARGETED DELIVERY FOR LIVER FIBROSIS THERAPY

Hyung Tark Lee[1] Seul Ki Han[2] Moon Young Kim[2], [1]Department of Internal Medicine, Yonsei University Wonju, [2]Department of Internal Medicine, Yonsei University Wonju College of Medicine, Korea

Background: Liver sinusoidal endothelial cell dysfunction is a critical event in liver fibrogenesis. Loss of LSEC fenestration and subsequent capillarization impair hepatic microcirculation, facilitate hepatic stellate cell activation, and accelerate extracellular matrix deposition. We reported that MSC-derived exosomes have shown anti-inflammatory, anti-fibrotic, and regenerative potential. We aimed to develop an LSEC-targeted MSC exosome platform by combining PEGylation for prolonged circulation with SE-1 antibody conjugation for active sinusoidal endothelial targeting. **Methods:** Human MSC-derived exosomes were isolated using tangential flow filtration. Exosomes were surface-modified with polyethylene glycol and subsequently conjugated with anti-SE-1 antibodies. Particle size distribution and stability were assessed by nanoparticle tracking analysis, and cellular toxicity was evaluated using a CCK-8 assay. Targeting specificity was examined in vitro using primary LSECs. In vivo biodistribution and liver accumulation were analyzed after systemic administration in mice to compare SE-1 antibody-conjugated exosomes with unmodified control exosomes. **Results:** Engineered SE-1 antibody-conjugated exosomes demonstrated a stable and uniform particle profile after surface modification. PEGylation improved physicochemical stability without inducing significant cytotoxicity. Compared with unmodified exosomes, SE-1 antibody-conjugated exosomes showed significantly greater binding affinity to primary LSECs in vitro, supporting cell-specific targeting through SE-1 recognition. After intravenous administration, engineered exosomes showed improved systemic persistence and enhanced hepatic accumulation compared with native exosomes. These findings suggest that PEGylation and SE-1 antibody conjugation can cooperatively improve circulation stability and active delivery to the hepatic sinusoidal endothelium. **Conclusion:** SE-1 antibody-conjugated MSC exosomes achieved enhanced LSEC-specific binding and hepatic accumulation, addressing major delivery limitations of native exosomes. This engineered exosome platform represents a promising strategy for precision delivery of regenerative and anti-fibrotic signals and may provide a foundation for future LSEC-targeted therapy in liver fibrosis.

1027 | ◆ APOLIPOPROTEIN J RESTRAINS LIVER REGENERATION BY DESTABILIZING CDK1 THROUGH A TRIM28-LINKED SUMO-UBIQUITIN AXIS

Zhaohong Mo[1] Kai Ke[1] Shanyu Zhao[1] Guandou Yuan[1] Songqing He[1] Shuangdi Duan[1], [1]The First Affiliated Hospital of Guangxi Medical University

Background: Liver regeneration requires precise cell-cycle re-entry and progression, with tightly controlled protein homeostasis (proteostasis) as an essential prerequisite. However, the chaperone network, a central arm of the proteostasis machinery, remains poorly defined during liver regeneration. Apolipoprotein J (ApoJ/clusterin) is a stress-responsive molecular chaperone implicated in several liver disorders, but its role in regenerative growth is unknown. Here we sought to define the function and mechanism of ApoJ during liver regeneration and to

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

assess whether this pathway is therapeutically tractable. **Methods:** We performed integrative transcriptomic screening, single-cell analyses, and in vivo validation to identify regeneration-associated chaperone after 70% partial hepatectomy. Hepatocyte-specific ApoJ knockout mice, AAV-mediated ApoJ overexpression, 70% partial hepatectomy, and CCl4-induced liver injury models were used to evaluate the functional role of ApoJ in liver regeneration. Mechanistic studies were conducted to examine the interaction among ApoJ, CDK1, and TRIM28, as well as the effects of ApoJ on CDK1 SUMOylation, ubiquitination, proteasomal degradation, and G2/M cell-cycle progression. Based on these findings, a CDK1-derived competitive peptide was designed to disrupt the ApoJ-CDK1 interaction and tested in hepatectomized mice. **Results:** ApoJ was identified as a hepatocyte-enriched chaperone induced during liver regeneration after 70% partial hepatectomy, and its induction was driven, at least in part, by the stress-responsive transcription factor Sp3. Hepatocyte-specific deletion of ApoJ accelerated regenerative proliferation, whereas AAV-mediated ApoJ overexpression impaired liver regeneration after partial hepatectomy and CCl4-induced injury. Mechanistically, ApoJ bound the C-lobe of CDK1, disrupted the TRIM28-CDK1 interaction, reduced protective SUMOylation of CDK1, and promoted ubiquitin-dependent proteasomal degradation, resulting in decreased CDK1 abundance and delayed G2/M progression. The CDK1-derived competitive peptide disrupted the ApoJ-CDK1 interaction, preserved CDK1 protein abundance, and enhanced liver regeneration in hepatectomized mice. **Conclusion:** ApoJ acts as a stress-induced brake on liver regeneration by destabilizing CDK1 through a TRIM28-linked SUMO-ubiquitin proteostatic pathway. Targeting the ApoJ-CDK1 interaction may therefore represent a potential strategy to improve delayed or insufficient hepatic regeneration.

1028 | ◆ UNDERSTANDING LIVER COMMUNICATION: MOLECULAR CROSSTALK BETWEEN HEPATOCYTES AND NONPARENCHYMAL CELLS IN A HEPACTOCYTE-SPECIFIC *FUT8* DELETED MODEL

Andrew Bauer[1] Hongyan Liang[1] Mengjun Wang[1] Shaaron Ochoa-Rios[2] Anand Mehta[1], [1]Medical University of South Carolina, [2]Moffitt Cancer Center

Background: Over the last decade, MASLD prevalence has climbed to an estimated 30% of the global population, with industrialized countries often being affected disproportionately. Likewise, HCC has become much more widespread, causing approximately 800,000 deaths a year. We have previously shown changes in N-linked glycosylation in both MASLD and HCC in tissue and on individual cells. Of the changes, core fucosylation, a post-translational modification also found on the cancer biomarker AFP-L3, is one of the most common alterations associated with both MASLD progression and HCC. Little is known about the role of hepatic core fucosylation, and thus, this was tested through a hepatocyte-specific deletion of the only involved gene, fucosyltransferase 8 (*FUT8).* **Methods:** Female FUT8 flox/flox ($FUT8^{f/f}$) mice were bred with male mice positive for Albumin Cre in the liver, generating mice that had a hepatocyte-specific *FUT8* deletion. For data analysis, both $FUT8^{f/f}$ and $FUT8^{-/-}$ mice were sacrificed using standard procedures, perfusing their livers before isolating either primary hepatocytes or nonparenchymal cells. Each isolated cell type was then individually spotted on amine-reactive slides and MALDI-MSI was used to obtain the m/z values and the intensity level of expressed lipids and N-linked glycans. **Results:** Initial results indicate that deletion of *FUT8* in primary hepatocytes significantly decreases surface level lipids and N-linked glycans, excluding a small subgroup in the N-linked glycans and lipids. For the N-linked glycans, two nonfucosylated glycans are elevated in the $FUT8^{f/f}$ hepatocytes. Similarly, a subgroup of twenty-seven lipids consisting of ten PEs, six PSs, six SMs, three Hex2Cers, and two PCs had higher expression in the $FUT8^{f/f}$ hepatocytes. In nonparenchymal cells, almost all observed N-linked glycans and lipids found in stellate cells isolated from hepatocyte-specific $FUT8^{f/f}$

deleted livers showing an increase in expression. In endothelial cells, N-linked glycans showed a slight decrease in expression while lipid signals were split into two groups of higher and lower presence. Of note is the significant increase in four core fucosylated N-linked glycans in stellate cells that share the same basal structure with differences only existing in small post-translation modifications. **Conclusion:** Based on the results, core fucosylation may be a necessary component in expression of specific lipid structures along with impacting N-linked glycosylation. Furthermore, the increase of N-linked glycans in FUT8$^{f/f}$ associated stellate cells, including ones of high fucosylation and similar structure, suggests that the nonparenchymal cells are attempting to compensate for the decreased levels in hepatocytes. It is also likely that the specific glycans in the stellate cells represent a specialized stress signal to communicate the issues that are occurring within the liver both to other local cells and the rest of the body.

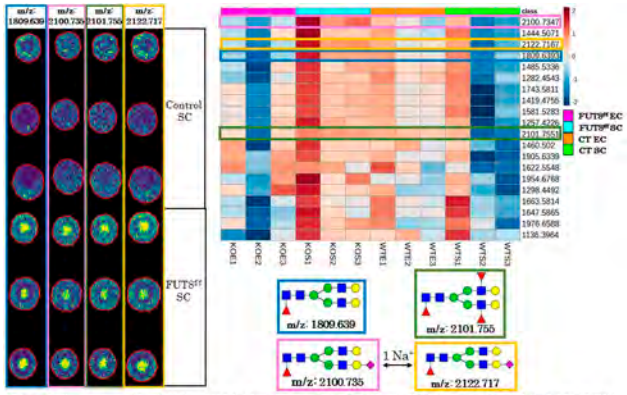

Figure 1. The top twenty N-linked glycans of the four nonparenchymal cell types (FUT8$^{f/f}$-associated endothelial cells, FUT8$^{f/f}$-associated stellate cells, control endothelial cells, and control stellate cells) and their intensity in a heatmap along with Bruker SCiLS images showing the intensity of m/z 1809.639, 2100.735, 2101.755, and 2122.717 in each stellate cell type. Each highlighted m/z corresponds in color to a proposed structure. Multiple of these structures share the same basal structure with minor post-translation modification or ionic changes, suggesting a coordinated response by the cell type to communicate with surrounding cells and potentially compensate for deficiencies. Heatmap is transformed by Log10 and auto scaled.

1030 | SINGLE-CELL PROFILING OF CHOLESTATIC LIVER INJURY REVEALS AN NLRP3+ INFLAMMASOME-ASSOCIATED NEUTROPHIL SUBPOPULATION DRIVING RECIPROCAL BILIARY CROSSTALK

Sofia Jerez[1] Papawee Sutthirat[1] Zhang Zhensheng[2] Abid Anwar[2] Alexander Wixom[2] Vijay Shah[1] Robert Huebert[1] Moira Hilscher[2] Nidhi Jalan-Sakrikar[1], [1]Mayo Clinic Rochester, [2]Mayo Clinic

Background: Primary sclerosing cholangitis (PSC) is a cholestatic liver disease in which cholangiocytes acquire a pro-inflammatory phenotype recruiting immune cells, including neutrophils, to periportal bile ducts. Although neutrophils are enriched within this biliary immune niche, their transcriptional diversity and contribution to cholangiocyte–immune crosstalk during PSC progression remain poorly defined. **Methods:** Fixed single-cell RNA sequencing (FLEX) was performed on liver tissue, intrahepatic leukocytes, and bone marrow cells from wild-type (Chow-fed), and two murine models of PSC, DDC-fed (2 or 10 days) and Mdr2-/-mice. Bioinformatic analyses included clustering, differential gene-expression, pseudotime trajectory, and pathway-enrichment. Cell populations were annotated using canonical marker genes, followed by neutrophil-focused sub-clustering. Ligand–receptor interaction was analyzed using CellChat between cholangiocytes and different neutrophil subsets. **Results:** Neutrophil sub-clustering identified seven transcriptionally distinct subsets: myeloid progenitor, proliferative (Mki67+), reactive oxygen species-associated (Cybb+), matrix-remodeling (Mmp8+), interferon-responsive (Ifit3+), chemotactic/inflammatory (Retnlg+), and inflammasome-associated (Nlrp3+). Pseudotime trajectory analysis revealed a maturation continuum, with progenitor/proliferative in early states to chemotactic/inflammatory and inflammasome-associated as terminally differentiated. Nlrp3+ was the predominant intrahepatic subset in injury models, exhibiting the strongest NETosis-associated program and high immunoregulatory signatures, suggesting a disease-associated inflammatory neutrophil state. Ligand–receptor analysis shows enhanced bidirectional communication during disease. Cholangiocytes signaled to disease-associated neutrophil subsets through adhesion, chemokine, and immune-recruitment pathways (Spp1–Cd44, Jam1–Itgal/Itgb2, App–Sorl1, C3–Itgam/Itgb2, and Fn1–Cd44). Mature neutrophil subsets signaled back to cholangiocytes through Sema4a/Sema4d–Plxnb1/Plxnb2, Tgm2–Adgrg1, Osm–Osmr/Il6st, and Tgfb1-associated receptor complexes. Network-level analysis identified the Nlrp3+ subset cholangiocytes axis as a major hub, suggesting that this reciprocal signaling may amplify the biliary immune niche during cholestatic liver injury. **Conclusion:** Single-cell profiling identifies Inflammasome-associated neutrophils as a dominant disease-associated neutrophil subset in cholestatic liver injury. Bidirectional cholangiocyte–neutrophil signaling suggests that injured cholangiocytes and mature neutrophil subsets reciprocally reinforce the biliary immune niche, potentially promoting inflammation and fibrosis. Targeting pathogenic neutrophil states or specific crosstalk axes may represent a novel therapeutic strategy for PSC.

1031 | FORMATION OF FIBROSIS RESOLUTION MACROPHAGES IS INDUCED BY OXYSTEROLS VIA ACTIVATION OF THE INTEGRIN–FOCAL ADHESION KINASE PATHWAY

Ayobami Dare[1] Kyle Yuquimpo[1] Isabel Aranzazu Pulido Ruiz[2] Sheetal Rooge[1] Madhulika Sharma[1] Ann Wozniak[1] Irina Tikhanovich[1] Steven Weinman[1], [1]University of Kansas Medical Center, [2]The University of Kansas Medical Center

Background: Resolution of liver fibrosis following cessation of chronic injury requires active extracellular matrix (ECM) remodeling mediated in part by fibrolytic macrophages (Mφ). Previously published scRNAseq analysis in a mouse model of alcohol-associated liver disease identified a population of fibrolytic Mφ, enriched for matrix metalloproteinases (MMPs). These represent a subpopulation of monocyte-derived Kupffer cells. Studies have shown that the Notch, BMP, and LXR signaling pathways are critical for Kupffer cells formation. We have previously shown that oxysterols play an important role in the acquisition of the fibrosis resolution phenotype, however, the signaling mechanisms responsible for fibrolytic Mφ development are not understood. This study aimed to determine the signaling pathways responsible for the transformation of monocyte-derived cells into fibrolytic Mφ. **Methods:** Bone marrow-derived macrophages (BMDMs) were incubated with 25-hydroxycholesterol (25-HC) in vitro. MMP12 and MMP13 were measured by RT-qPCR. Inhibition studies were performed with Notch/LXR inhibitors, myeloid-specific $RBPJ^{-/-}$ cells, and integrin/focal adhesion kinase (FAK) inhibitors. These pathways were further evaluated using LXR agonists, and immobilized DLL4 and fibronectin. Ingenuity Pathway Analysis (IPA) was performed on transcriptional datasets from 25-HC-treated Mφs. FAK phosphorylation was determined by western blot, and collagen degradation activity was measured by DQ collagen assay. **Results:** 25-HC induced a fibrolytic phenotype in BMDM characterized by increased MMP12 and MMP13 expression and enhanced collagen degradation activity. The effect of 25-HC was partially inhibited by LXR antagonists and Notch inhibition, suggesting that both LXR and Notch activation were important. However, agonist treatment to selectively activate LXR or Notch had no effect, suggesting that these were necessary but not sufficient. IPA analysis showed that 25-HC robustly activated the FAK pathway and 25-HC caused FAK phosphorylation in vitro, suggesting Integrin-FAK as a possible mediator of 25-HC effects. FAK inhibitor completely blocked both basal and 25-HC-stimulated MMP12 expression and collagenase activity. scRNAseq data showed that fibrolytic KCs selectively express Itga5 and also express Itgb1, the components of integrin α5β1 (fibronectin receptor). A peptide integrin α5β1 inhibitor reduced MMP expression, while direct exposure of BMDM to a fibronectin matrix caused an increase in mRNA expression of MMP12 and MMP13. **Conclusion:** These findings reveal a previously unrecognized role for integrin–FAK signaling in regulating oxysterol-induced macrophage-mediated ECM degradation. Although oxysterols are LXR agonists, LXR activation only modulates this integrin-FAK effect and is not sufficient, by itself, to induce the fibrolytic phenotype.

1032 | INVESTIGATING HEPATOCYTE PLOIDY IN MURINE AND HUMAN LIVER

Dale Brokaw[1] Sydney Shaffer[1], [1]The University of Pennsylvania

Background: Hepatocytes are unique variably in genome copy number per cell, or ploidy, ranging from two genome copies per cell to as many as 16 copies per cell divided between one or two nuclei. The function of polyploid hepatocytes in the liver remains unknown. Diploid hepatocytes have been observed be more proliferative and more resistant to acetaminophen injury relative to polyploid hepatocytes; polyploid hepatocytes are more robust to loss of function mutations but are associated with higher levels of oxidative damage and Metabolic Associated Fatty Liver Disease (MAFLD). Difficulty capturing polyploid cell states has limited the investigation of polyploidy in the liver. Here, we use spatial transcriptomics to describe the gene expression and localization of polyploid hepatocytes in

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

the mouse and human liver. **Methods:** Mouse data: A custom 215-gene seqFISH panel was applied to wildtype, low-ploidy (E2F7-/- E2F8-/-), and aging C57BL/6J mice (3, 10, and 20 months). Data was generated on the Spatial Genomics GenePS platform and processed in Scanpy (Python). Human data: Liver biopsies from seven patients (ages 26–64) were profiled using the 10x Genomics Xenium 5K panel across tumor, adjacent, and distant regions, then processed in Scanpy. PloidyXPress: Nuclear ploidy was inferred from nuclear area and intron counts in mice, and nuclear area alone in humans, classifying nuclei as 2n, 4n, or 8n+. Binuclear cells were identified by nearest-neighbor pairing, and paired nuclei expression profiles were summed. **Results:** Expression: Total transcripts per cell scaled with cell area and sublinearly with genome copy number, limiting the dosage response of individual genes. Multiple metabolic (Mlxipl, Angptl4, Gckr, Usp40) and cell-cycle related genes (Ccnl2, Zbtb16, Rfx7) showed ploidy-dependent expression independent of zonation. These dosage responses were conserved across aging. Localization: Using cholangiocytes and the pericentral Glul+ hepatocytes to define bile ducts and central veins, we found that genome copy number increased from periportal (zone 1) to pericentral (zone 3) regions in mouse liver. This gradient was driven largely by enrichment of hyperpolyploid 8N+ hepatocytes, persisted with aging, and colocalized with cycling hepatocytes. Translation: Human Xenium liver data revealed conserved ploidy-dependent expression of several genes, including Mlxipl and Zbtb16. However, unlike mouse liver, human samples did not display a clear periportal-to-pericentral ploidy gradient. **Conclusion:** This study provides a spatial characterization of gene expression changes in polyploid hepatocytes. We identify conserved dosage regulation of ploidy-associated genes across mouse and human liver. In mice, but not humans, hepatocyte ploidy forms a stable periportal-to-pericentral gradient, suggesting species-specific mechanisms of polyploidization.

1033 | TRANSCRIPTIONAL PROFILING OF THE MATERNAL LIVER ACROSS THE REPRODUCTIVE CYCLE REVEALS COORDINATED PROGRAMS OF GESTATIONAL GROWTH AND POSTPARTUM INVOLUTION

Anisha Jain[1] Satdarshan (Paul) Monga[1] Jia-Jun Liu[1] Silvia Hu[1], [1]University of Pittsburgh

Background: Pregnancy requires substantial hepatic adaptation to meet fetal metabolic demands, including organ growth during gestation and postpartum regression. Lactation sustains continued hepatic adaptation, while weaning triggers acute regression toward the prepartum state. The molecular programs coordinating these transitions and the mechanisms by which the liver restores homeostasis postpartum remain poorly defined. We aimed to characterize the temporal dynamics and molecular architecture of hepatic adaptation across the full reproductive cycle in mice. **Methods:** Liver RNA was collected from age-matched nulliparous (NP) controls and mice at gestational days 6, 12, 14, 16, and 18, and postpartum days 1, 10, 20, 22, 25, 27, and 31 (n = 3 per timepoint). Weaning occurred at day 21; day 22 was the first post-weaning timepoint. Bulk RNA-seq was performed and unsupervised hierarchical clustering identified co-expressed gene modules across the reproductive timeline. Gene Ontology Molecular Function (GO-MF) enrichment was performed per cluster, and targeted analysis of key gene families was conducted within involution-associated clusters. **Results:** Clustering identified five transcriptionally distinct modules with temporally coordinated expression. Early gestation featured upregulation of ATP hydrolysis, GTPase binding, ubiquitin ligase binding, and protein-folding chaperone activity. Peak gestation was associated with extracellular matrix structural constituents, glycosaminoglycan binding, lipid transporter activity, and growth factor binding, consistent with active scaffold remodeling to accommodate hepatic expansion. Post-weaning involution was characterized by ribosomal constituent activity, RNA polymerase II transcription factor binding, and immunoglobulin binding. Concurrently, post-weaning involution engaged proteostatic clearance machinery, including proteasomal shuttle proteins (Rad23b) and selective autophagy receptors (Calcoco1), showing progressive induction through PP27–PP31 and indicating parallel engagement of proteasomal and autophagic degradation. Global gene expression returned to NP baseline by postpartum day 31, confirming a complete and reversible transcriptional cycle. **Conclusion:** The maternal liver executes a coordinated, reversible transcriptional program across reproduction, comprising ECM-driven gestational expansion followed by post-weaning involution marked by proliferative shutdown and engagement of proteostatic degradation machinery. This temporal architecture is previously undescribed and establishes a framework for hepatic plasticity that may illuminate mechanisms disrupted in pregnancy-associated liver disease.

1034 | TARGETING TEAD1 ALTERNATIVE SPLICING IN HEPATIC MYOFIBROBLASTS SUPPRESSES CHOLESTATIC FIBROSIS AND BILIARY REACTIVITY

Roi Isaac[1] Jinyue Wang[1] Jerrold Olefsky[1] John Youhanna[1] Theresa Rohm[1] Ludovic Vallier[2] Carla Frau[2] Tatiana Kisseleva[1], [1]University of California, San Diego, [2]Berlin Institute of Health Center for Regenerative Therapies, BIH@Charite, Berlin, Germany

Background: Primary sclerosing cholangitis (PSC) is a cholestatic liver disease characterized by biliary inflammation and periductal fibrosis, for which effective treatments are lacking. Portal fibroblasts (PFs) and hepatic stellate cells (HSCs) are key fibrogenic myofibroblasts. We showed that active TEAD1 (TEAD1$^{\Delta Ex5}$), generated by hnRNPU-mediated skipping of exon 5, drives HSC activation. Here, we tested whether targeting this TEAD1 alternative splicing axis with a splicing-modulating antisense oligonucleotide (TEAD1-Ex5-ASO) deactivates both PFs and HSCs, thereby alleviating cholestatic injury and paracrine biliary and inflammatory pathology. **Methods:** Human PSC liver RNA-seq was analyzed for TEAD target expression. Primary human and mouse PFs and LX-2 HSCs were transfected with TEAD1-Ex5-ASO, and bulk RNA-seq was performed on treated LX-2 cells. *In vivo* ASO efficacy was assessed in sorted GFP+ myofibroblasts from ColGFP/Mdr2KO mice. Male Mdr2KO mice received weekly intraperitoneal injections of TEAD1-Ex5-ASO (10 mg/kg) or control ASO for 4 weeks (ages 6–10 weeks). Paracrine effects of HSC-conditioned media (CM) were evaluated on H69 cholangiocytes, human intrahepatic cholangiocyte organoids (ICOs), and macrophages. **Results:** The TEAD1 target gene, CYR61, was elevated in PSC liver and correlated with fibrosis stage, supporting the relevance of TEAD1/YAP in disease. TEAD1-Ex5-ASO reduced levels of the active TEAD1$^{\Delta Ex5}$ isoform and suppressed pro-fibrotic and inflammatory targets CTGF, ACTA2, and IL6 in PFs and HSCs. RNA-seq further revealed broad suppression of the TEAD1/YAP transcriptional program, TGFβ-induced genes, and ECM organization pathways, as well as a defined secretome including PDGFB, CCN2, FGF1, and MMP7. Isoform-specific suppression was confirmed in sorted ColGFP/Mdr2KO myofibroblasts, accompanied by downregulation of *Col1a1*/*Msln* and upregulation of *Bambi*. ASO-treated Mdr2KO mice exhibited 30-50% reductions in ALT/AST and marked attenuation of periductal and periportal fibrosis, as assessed by hydroxyproline and Sirius red staining. Although cholangiocytes express >90% TEAD1$^{\Delta Ex5}$, the ASO failed to reduce the active isoform. However, HSC-CM deactivated H69 cholangiocytes by attenuating TGFβ signaling, reducing PAI1, FN1, and IL6. HSC-CM also suppressed expansion and increased apoptotic markers in ICOs, and attenuated pro-inflammatory macrophage gene expression, downregulating *Nos2* and *Il6*. **Conclusion:** Targeting the hnRNPU-TEAD1 splicing axis deactivates both PFs and HSCs, markedly reducing cholestatic injury and periductal fibrosis through direct myofibroblast deactivation and paracrine suppression of biliary reactivity and inflammation.

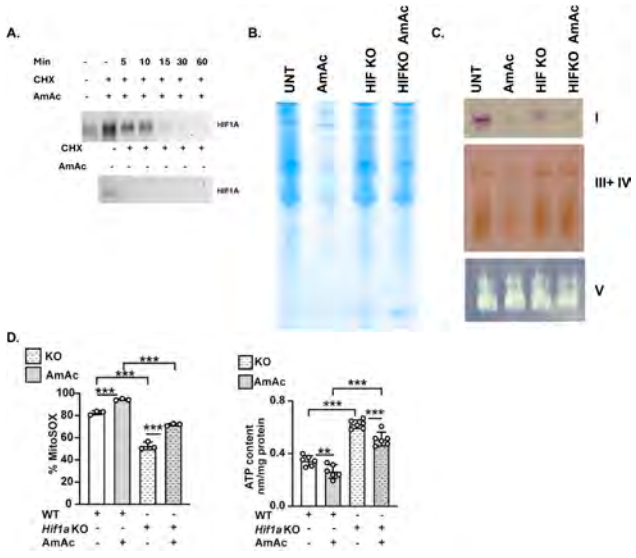
1035 | HYPERAMMONEMIA STABILIZES MUSCLE HYPOXIA INDUCIBLE FACTOR (HIF)-1A BY DECREASED HYDROXYLATION AND INCREASED ACETYLATION



Nicole Welch[1] Pugazhendhi Kannan[1] Seshu Pothabathula[1] Saurabh Mishra[1] Annette Bellar[1] Vandana Agrawal[1] Jasmin Cunningham[1] Srinivasan Dasarathy[1], [1]Cleveland Clinic

Background: HASR causes sarcopenia in cirrhosis and stabilizes skeletal muscle HIF1a, but the post-translational mechanisms of HIF1a stabilization are unknown. Since normoxic HIF1a turnover requires hydroxylation, Von Hippel-Lindau protein (pVHL) recognition, and proteasomal degradation, we tested whether hyperammonemia stabilizes HIF1a by decreasing hydroxylation and degradation while increasing acetylation. **Methods:** C2C12 myotubes, hiPSC-derived myotubes were untreated/treated with 10mM ammonium acetate (AmAc) and skeletal muscle from mice with/without muscle specific HIF1a deletion (KO) were implanted with osmotic pumps containing either vehicle (phosphate buffered saline) or 2.5 mmol/kg/d AmAc infused over 28 days, and human skeletal muscle biopsies from the vastus lateralis of subjects with cirrhosis were studied. HIF1a protein, mRNA and target genes, nuclear/cytoplasmic localization, hydroxylated(OH-)HIF1a, pVHL, p300, GCN5, and Ac-HIF1a were quantified by immunoblotting(IB). In vivo imaging luciferase assay, immunoprecipitation of HIF1a/IB for acetyl-lysine, and MG132 protease inhibitor and

cycloheximide chase (CXH) were used to determine HIF1a stability. Dimethyl alpha keto glutarate (dmaKG) rescue was studied. Protein synthesis and senescence signaling and mitochondrial supercomplex assembly/in-gel activity quantified in HASR with HIF KO. **Results:** AmAc increased HIF1a protein in C2C12 myotubes, hiPSC-derived myotubes, mouse muscle, and human muscle without increasing HIF1a mRNA. HIF1a accumulated in nuclear and cytoplasmic fractions and increased HIF-dependent transcriptional activity. AmAc prolonged HIF1a stability by CHX(**1A**). Although AmAc decreased aKG, dm-aKG did not reverse HIF1a stabilization in myotubes, and EGLN/PHD expression was not increased. AmAc decreased OH-HIF1a while total HIF1a increased, and pVHL-dependent studies in RCC VHL-/- and transfected RCC expressing pVHL-plasmid showed stabilization of HIF1a with AmAc was equivalent in control/AmAc treatment and restored with pVHL exogenous expression. In parallel, in myotubes, AmAc increased p300, GCN5, and acetyl-HIF1a, and HIF1a immunoprecipitation followed by acetyl-lysine immunoblotting confirmed increased HIF1a acetylation. HIF1a KO reversed AmAc-mediated suppression of p-P70S6K and p-eIF2a signaling, partially restored mitochondrial in-gel activity(**1B**), supercomplex assembly(**1C**), reactive oxygen species, ATP(**1D**) and reduced post-mitotic senescence signaling, including p21 and p-p53 (not shown). **Conclusion:** Hyperammonemia stabilizes HIF1a through decreased hydroxylation, impaired pVHL-dependent degradation, and increased p300/GCN5-associated acetylation. HIF1a mediates impaired protein synthesis, mitochondrial dysfunction, and post-mitotic senescence during HASR identifying acetylation-dependent HIF1a stabilization as a mechanism of sarcopenia in cirrhosis.

1036 | OXIDIZED LOW-DENSITY LIPOPROTEIN (OXLDL)-DEPENDENT CD36 SIGNALING DECREASES LYMPHATIC ENDOTHELIAL PERMEABILITY IN CHRONIC LIVER DISEASE

Destiny DeNicola[1] Abbigayl Burtis[1] Nathaly Limon de la Rosa[1] Matthew Burchill[2], [1]University of Colorado Anschutz Medical Campus, [2]University of Colorado - Anschutz

Background: Lymphatic drainage is critical for maintaining liver homeostasis, and impaired lymphatic function contributes to progression of chronic liver disease. Previous studies demonstrated that oxidized low-density lipoprotein (oxLDL) drives lymphatic dysfunction through increased VE-cadherin (V-Cad) expression in liver lymphatic endothelial cells (LECs), while restoration of lymphatic drainage improves liver injury in mouse models of metabolic dysfunction-associated steatohepatitis. However, the signaling mechanisms by which oxLDL regulates V-Cad and lymphatic permeability remain unknown. Here, we sought to define the signaling pathways mediating oxLDL-induced lymphatic dysfunction. **Methods:** Primary human LECs or vascular endothelial cells (VECs) were treated with oxLDL, LDL, or HDL in the presence or absence of blocking antibodies targeting CD36, LDLR, and LOX-1 or specific inhibitors of AKT and SRC signaling. V-Cad expression, oxLDL uptake, and downstream signaling were assessed by western blot, immunofluorescence, and flow cytometry. Proteins that interact with V-Cad in LECs were identified by immunoprecipitation and mass spectrometry. In vivo confirmations of in vitro findings were performed using oxLDL injection, lymphatic drainage assays, and lymphatic-specific CD36 knockout mice. **Results:** Primary human LECs increased surface V-Cad in response to oxLDL through CD36-dependent signaling, while LOX-1 and LDLR were dispensable. Inhibition of oxLDL interactions with CD36 did not prevent oxLDL uptake in LECs, indicating that ligand internalization alone is insufficient to drive junctional remodeling. Treatment with LDL or HDL did not alter V-Cad levels, demonstrating ligand specificity. This response was specific to LECs, as oxLDL treatment did not increase V-Cad expression in VECs. Further, we found that both AKT and SRC are phosphorylated in a CD36 dependent manner in LECs following oxLDL treatment and inhibition of AKT, but not SRC, partially attenuated

V-Cad accumulation. Additionally, co-immunoprecipitation results showed that oxLDL treatment reduced V-Cad association with p47 and VCP, consistent with altered AKT-dependent cadherin trafficking. Finally, in vivo studies confirmed that CD36 is required on LECs for oxLDL-induced V-Cad increase and lymphatic drainage dysfunction. **Conclusion:** These studies conclude that the interaction between oxLDL and CD36 alters lymphatic permeability *in vitro* and *in vivo* through promoting the retention of V-Cad on the surface of LECs and identifies AKT signaling as the primary driver of this response downstream of CD36. These findings provide mechanistic insight into lymphatic dysfunction in chronic liver disease and identify potential therapeutic targets for restoring lymphatic function in MASH and related inflammatory liver diseases.

1037 | *ALCOHOL-ASSOCIATED LIVER DISEASE DRIVES DUCTULAR REACTION IN HUMAN PRECISION CUT LIVER SLICES.*

Sehrish Naz[1] Susmita Bhattarai[2] Shanshan Su[2] Hua Xu[2] Sofia Izunza Barba[2] Denisse Rubio Cruz[2] Imad Nasser[3] Z. Gordon Jiang[3] Gyongyi Szabo[3], [1]Beth Israel Deaconess Medical Centre, Harvard medical school, [2]BIDMC, Harvard medical school, [3]Beth Israel Deaconess Medical Center

Background: Precision cut liver slice (PCLS) is a human tissue derived 3D culture that captures the native architecture of the donor liver. We have recently established an extended PCLS culture model, thus enabling the study of tissue remodeling during extended human PCLS culture. In this study, we compared differential tissue remodeling in PCLS derived from explant livers of alcohol-associated liver diseases (ALD) and control livers, which potentially recapitulates human pathologies of alcohol-associated hepatitis (AH). **Methods:** We procured liver tissue from explants of patients enrolled in the End-Stage Liver Disease Registry. ALD patients included those with alcohol-associated cirrhosis (AC) and AH, while control tissues were obtained from patients with metastatic cancer or polycystic liver diseases. PCLS preparation, culture and quality assessment was performed using an optimized protocol as previously published. We evaluated tissue remodeling using histology and gene expression analyses. **Results:** PCLS from explant liver can be cultured for up to 14 days as visualized by whole mount imaging of tissue with simultaneous staining of live and dead cells by different probes. In PCLS with normal liver microarchitecture, progressive fibrosis occurred spontaneously with increasing number of cells expressing alpha smooth muscle actin (ASMA) driven by stellate cell activation. By day 7, there was evidence of hepatocellular regeneration characterized by clusters of cells with homogenous morphology and lacking basement membrane, which was universally seen surrounding native hepatocytes. These findings supporting hepatocellular regeneration were not seen in PCLS derived from ALD patients. In contrast, ALD-derived PCLS exhibited progressive expansion of CK19+ cells representing cholangiocytes(Fig.1). These ductular reactions were most prominent around the periphery of hepatic lobule and circumference of the PCLS where oxygen availability was highest. A significant subset of CK19+ cells also expressed EPCAM and SOX9, markers of hepatic progenitor cells and Ki67, markers of active proliferation. **Conclusion:** During extended culture, PCLS remodels itself in response to the stress of a new *in vitro* environment. Our observation suggests that this intrinsic capability is shaped by the donor liver state, and to a significant extent, reflects the biology or pathology of the donor liver. PCLS with normal liver microarchitecture exhibits hepatocyte regeneration, restoring the tissue through proliferation. In ALD, the diseased microenvironment triggers a robust hepatocyte-to-biliary transition in PCLS, replacing the normal regenerative route, a finding that may recapitulate the pathophysiology of AH. PCLS preserves complex cell-to-cell interactions in the liver tissue *in vitro* and enables studies of cellular plasticity, ductular reaction, and fibrogenesis.

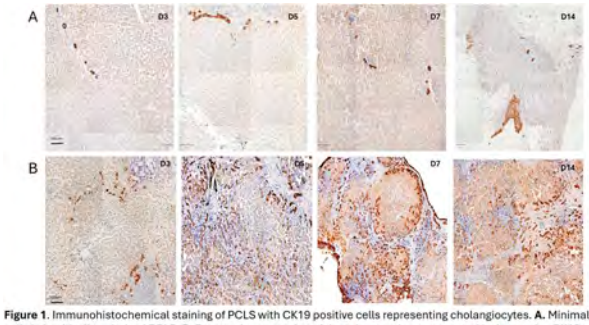

Figure 1. Immunohistochemical staining of PCLS with CK19 positive cells representing cholangiocytes. **A.** Minimal CK19+ cells in healthy liver derived PCLS. **B.** Progressive expansion of ductular reaction represented by increasing CK19+ cells in ALD-derived PCLS.

1038 | MYELOID FOCAL ADHESION KINASE PROMOTES MACROPHAGE ACCUMULATION BUT IS DISPENSABLE FOR TUMOR PROGRESSION IN HEPATOCELLULAR CARCINOMA

Eugene Ham[1] Claudia Rose Keating[1] Kyle Boedeker[1] Ruisong Ye[1] Xianzhong Ding[1] Jonathan Rennhack[1] Wei Qiu[2], [1]Loyola University Chicago, [2]Loyola University Health System

Background: Hepatocellular carcinoma (HCC) develops within an immunologically complex tumor microenvironment heavily shaped by infiltrating myeloid cells. Despite immune-based regimens like atezolizumab plus bevacizumab, durable responses remain uncommon, motivating efforts to identify signaling programs that sustain pro-tumor myeloid states. Focal adhesion kinase (FAK, encoded by *PTK2*) integrates adhesion, growth factor, proliferative, and inflammatory signaling, but the contribution of FAK in myeloid cells to HCC has not been tested. **Methods:** In this study, human HCC transcriptomic datasets were analyzed to characterize *PTK2* expression and associated transcriptional changes in myeloid cells. Single-cell analyses were performed using the PRHCCdb and NCI-CLARITY datasets. To test the functional role of FAK in myeloid cells, we generated myeloid-specific FAK knockout (LysMCre; $FAK^{f/f}$) mice and evaluated baseline conditions and after induction of MET/ß-catenin-driven HCC via hydrodynamic tail vein injection. **Results:** Analysis of the PRHCCdb single-cell database showed that *PTK2* expression was enriched in myeloid populations. Higher *PTK2* expression in myeloid-rich TCGA-LIHC tumors was associated with a significantly worse overall survival. Further analysis of the NCI-CLARITY single-cell dataset localized the strongest FAK-associated transcriptional programs to a monocyte-derived macrophage state marked by *VCAN* and *COLEC12*. This population demonstrated an enriched transcriptional signature for hypoxia-associated, inflammatory, and angiogenic programs. Deletion of myeloid-specific FAK in mice did not alter baseline liver morphology, liver-to-body weight ratio, or proliferation. When challenged with the MET/ß-catenin-driven HCC model, myeloid-specific FAK deletion did not significantly affect survival, gross tumor burden, or tumor proliferation. However, tumors from the LysMCre;$FAK^{f/f}$ mice showed significantly reduced $F4/80^{+}$ macrophage accumulation compared with $FAK^{f/f}$ controls. **Conclusion:** These findings identify a *PTK2*-associated transcriptional program within specific myeloid populations in human HCC and suggest that myeloid-specific FAK supports macrophage accumulation but is dispensable for tumor progression in this oncogene-driven HCC model.

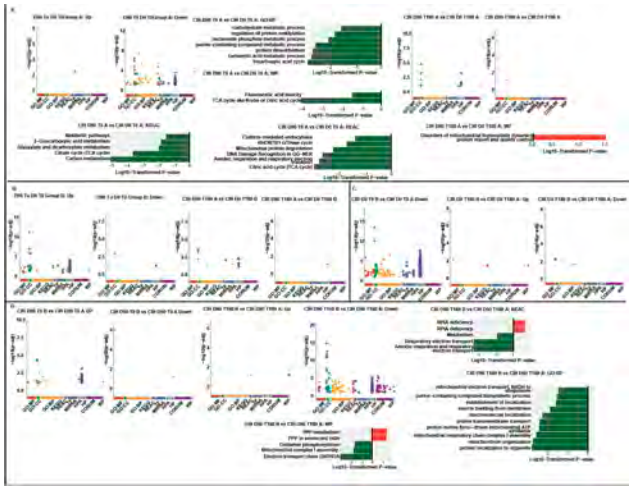
1039 | SKELETAL MUSCLE REMODELING FOLLOWING LEUCINE-ENRICHED ESSENTIAL AMINO ACID SUPPLEMENTATION



Annette Bellar[1] Nicole Welch[1] Ryan Musich[1] Pugazhendhi Kannan[1] Saurabh Mishra[1] John Kirwan[2] Marielle Engelen[3] Nicolass Deutz[4] Srinivasan Dasarathy[1], [1]Cleveland Clinic, [2]Pennington Biomedical Research Center, [3]Texas A&M University, [4]Texas A & M University

Background Sarcopenia and impaired skeletal muscle metabolism are common complications of cirrhosis and contribute to reduced functional status and poor clinical outcomes. The molecular responses to long-term leucine-enriched amino acid supplementation in cirrhosis are not known. **Methods:** Patients with compensated cirrhosis were prospectively randomized to receive either a leucine-enriched essential amino acid (LEAA; n = 11, age 53 $\pm$ 11 range 33-66, 100% alcohol related liver disease) or an isonitrogenous balanced amino acid (BAA; n = 11 age 57 $\pm$ 11 range 46-71, 54% alcohol related liver disease, 37% Hep-C, 9% MASH) supplement twice daily for 90 days (NCT03208868). Body composition and vastus lateralis muscle biopsies were obtained at baseline and end of study. Plasma and muscle tissue untargeted proteomics and metabolomics, and targeted amino acid profile analyses were performed baseline and Day 90 **Results:** Patients on LEAA had greater increases in plasma leucine, isoleucine, and valine compared with subjects receiving BAA with both acute and long term supplementation (all $p < 0.05$). Longitudinal skeletal muscle proteomic

analyses demonstrated distinct remodeling patterns between groups (**Fig.1A-D**). Within-group analyses identified differential protein expression following 90 days of supplementation in both groups. Integrated pathway enrichment analyses further demonstrated significant coordinated alterations in mitochondrial and oxidative metabolic pathways following leucine-enriched supplementation ($p < 0.05$; **Fig. 1A-D**). In the LEAA group, enriched pathways included tricarboxylic acid cycle metabolism, carbon metabolism, aerobic respiration, respiratory electron transport, oxidative phosphorylation, mitochondrial ATP synthesis, and mitochondrial organization. BAA subjects showed weaker and less coordinated pathway enrichment patterns (**Fig.1B,C**). Comparative analyses between groups identified significant divergence in pathways related to mitochondrial organization, respiratory chain assembly, proton motive force-driven ATP synthesis, and electron transport chain activity following intervention ($p < 0.05$; **Fig.1D**). Our multiomics analyses in serial and longitudinal muscle biopsies in compensated cirrhosis identify a distinct pattern of metabolic remodeling of skeletal muscle mitochondria following LEAA vs BAA. **Conclusion:** Our data provide a unique skeletal muscle metabolic signature of mitochondrial oxidative responses with LEAA acutely which persisted over 90 days of use, supporting a long-term supplementation program to restore muscle responses in cirrhosis.

1040 | UNBIASED IN VIVO CRISPRI SCREENING IDENTIFIES ACMSD AS A CANDIDATE MODULATOR OF HEPATIC NAD⁺ FOR LIVER REGENERATION

Salah Adlat[1] Lance Cai[2] Dingzi Yin[2] Markus Lee[2] David Frederick[3] Joseph Baur[3] Kirk Wangensteen[2], [1]Mayo Clinic, Rochester, [2]Mayo Clinic, [3]University of Pennsylvania

Background: Liver regeneration after acute injury or major resection lacks approved pharmacologic therapies that directly enhance hepatocyte repair. NAD^+ supports mitochondrial respiration, redox balance, and cell-cycle entry, but mechanisms controlling hepatic NAD^+ availability during regeneration remain incompletely defined. ACMSD is a liver-enriched kynurenine-pathway enzyme that diverts tryptophan-derived intermediates away from quinolinate, the obligate precursor for *de novo* NAD^+ synthesis. We hypothesized that ACMSD limits regenerative NAD^+ availability and represents a candidate metabolic target to support liver repopulation. **Methods:** To identify regulators of NAD^+ turnover during hepatocyte repopulation, *in vivo* CRISPRi screens were performed using a CRISPRi gRNA library targeting 143 NAD^+-pathway genes with 715 gRNAs and 100 non-targeting controls. Screens were conducted in *Fah*$^{-/-}$; *dCas9*$^+$ and *Nampt*$^{-/-}$;*Fah*$^{-/-}$;*dCas9*$^+$ mice, the latter modeling regeneration under impaired NAD^+ production. Transposon plasmids encoding *Fah* and the gRNA library were delivered to hepatocytes by hydrodynamic tail vein injection, followed by NTBC withdrawal to induce clonal expansion. gRNA enrichment was quantified by high-throughput sequencing and MAGeCK. ACMSD knockdown was further evaluated using CRISPRi in a cell line. For human validation, de-identified precision-cut liver slices (PCLS) were treated with TES-1025, a selective ACMSD inhibitor, and assessed by H&E, LDH release, and LC-MS/MS quantification of NAD^+-related metabolites normalized to protein. **Results:** The CRISPRi platform was highly reproducible, with strong concordance between replicate gRNA readouts in both models ($R^2 > 0.987$). ACMSD emerged among the top positively selected candidates in both the NAD-wildtype and the NAD-deficient screening background, with multiple independent sgRNAs enriched during repopulation, suggesting that ACMSD suppression may confer a selective advantage under regenerative and low-NAD^+ stress. Acmsd knockdown was confirmed by RT-qPCR, with ~70% reduction in expression ($p < 0.01$). In human PCLS,

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

targeting ACMSD with TES-1025 preserved tissue architecture by H&E and did not show evidence of toxicity by LDH measurement. Targeted LC-MS showed variable changes in NAD^+-related metabolites, with trends toward higher levels of several pathway metabolites that require validation in additional donor tissues. **Conclusion:** *In vivo* CRISPRi screening identified hepatic ACMSD as a candidate regulator of NAD^+-linked hepatocyte repopulation. Initial human PCLS studies support the feasibility of testing TES-1025 in intact liver tissue, while its metabolic effects remain preliminary. Expanded donor cohorts, ^{13}C-flux tracing, and PHx studies are ongoing to define ACMSD's role in hepatic NAD^+ metabolism and regeneration.

1041 | HYPERAMMONEMIC STRESS TRIGGERS A CONTEXT SPECIFIC MALADAPTIVE PARTIAL STRESS RESPONSE IN SKELETAL MUSCLE

Pugazhendhi Kannan[1] Nicole Welch[1] Saurabh Mishra[1] Annette Bellar[1] Jasmin Cunningham,[1] Seshu Vardhan Pothabathula,[1] Shashi Shekhar Singh[2] Vandana Agrawal[1] Maria Hatzoglou[2] Srinivasan Dasarathy[1],
[1]Cleveland Clinic, [2]Case Western Reserve University

Background: Hyperammonemia is a major metabolic complication of liver disease that induces a cytotoxic hyperammonemic stress response (HAS) in skeletal muscle and contributes to muscle wasting. Cellular adaptation to stress is regulated through the integrated stress response (ISR), mediated by the GCN2/PERK/PKR/HRI kinases, and the unfolded protein response (UPR) consisting of the IRE1α, PERK, and ATF6 arms. However, whether HAS globally activates these pathways or selectively regulates specific ISR and UPR signaling arms remains unclear. We investigated if hyperammonemia activates the GCN2 arm of the ISR together with the IRE1α arm of the UPR independent of PERK and ATF6, resulting in a context specific maladaptive partial stress response during HAS. **Methods:** Studies were performed in differentiated C2C12 myotubes and skeletal muscle tissues from hyperammonemic mice. Hyperammonemic stress response (HASR) was induced using 10 mM ammonium acetate in myotubes and continuous ammonium acetate infusion (2.5 $mmol \cdot kg^{-1} \cdot day^{-1}$ for 28 days) or saline in mice. Activation of integrated ISR kinases, including GCN2 and PERK, together with canonical UPR branches involving IRE1α-XBP1s, PERK, and ATF6 signaling, was evaluated by immunoblotting across multiple experimental models. To distinguish selective hyperammonemic stress signaling from canonical ER stress, PERK mobility shift were performed to assess PERK phosphorylation and activation status during HASR. **Results:** Hyperammonemic stress activated the GCN2 arm of the ISR and selectively activated IRE1α branch of the unfolded protein response UPR in both C2C12 myotubes and skeletal muscle tissues from hyperammonemic mice. Hyperammonemia significantly increased pGCN2 ($p < 0.01$), peIF2α ($p < 0.05$), and pIRE1α expression ($p < 0.05$), accompanied by enhanced XBP1 splicing, demonstrating activation of IRE1α endonuclease signaling during HASR. In contrast, other ISR kinases, including PERK, remained unchanged during hyperammonemic stress, as confirmed by immunoblotting and PERK mobility shift. Similarly, the canonical UPR branches mediated by PERK and ATF6 were not activated under HAS **(Fig.1)** . Collectively, these findings demonstrate that hyperammonemia induces a context-specific maladaptive partial stress response characterized by activation of the GCN2 and selective activation IRE1α-XBP1s axis pathways independent of canonical PERK and ATF6 mediated ER stress signaling. **Conclusion:** These findings demonstrated that hyperammonemic stress activated the GCN2 arm of the ISR and the IRE1α-XBP1 arm of the UPR without activation of PERK or ATF6 signaling. Unlike canonical ER stress, hyperammonemia induced a context specific maladaptive partial stress response, identifying selective GCN2 and IRE1α/XBP1s as a key mechanism underlying hyperammonemia associated skeletal muscle stress pathology.

1042 | GCN5/KAT2A DEPENDENT ACETYLATION OF PGC1A CAUSE STRUCTURAL AND FUNCTIONAL DEFECTS DURING HYPERAMMONEMIA

Saurabh Mishra[1] Seshu Vardhan Pothabathula[1] Pugazhendhi Kannan[1] Vandana Agrawal[1] Jasmin Cunningham[1] Annette Bellar[1] Dhanachandra Singh Khuraijam[1] Nicole Welch[1] Srinivasan Dasarathy[1], [1]Cleveland Clinic

Background: PGC-1α is a master transcriptional coactivator that orchestrates mitochondrial biogenesis and cellular energy homeostasis. Under hyperammonemic stress, GCN5-mediated acetylation of PGC-1α attenuates its transcriptional activity, promotes nuclear export, and contributes to mitochondrial dysfunction. The present study aimed to characterize the structural basis of the GCN5–PGC-1α interaction and evaluate the therapeutic potential of competitive inhibitory peptides targeting this axis. **Methods:** Three dimensional structures of GCN5/KAT2A (Q9JHD2) and PGC-1α (O70343) were retrieved from the AlphaFold database. Protein–protein docking was performed using HDOCK2.4 to evaluate binding affinity and conformational stability, followed by cluster RMSD analysis. Structural refinement and interaction profiling were conducted using GROMACS (GROMOS96 43a1 force field) and ChimeraX, respectively. Degron motifs were identified using DEGRON OPEDIA. Based on the predicted interaction interface, three cell penetrating peptides were rationally designed: a scrambled peptide (RPADSGDRETFAGGGGGRQIKWFQNRRMKW), a cyclic peptide (LPLPFLASPALGGGGGRQIKWFQNRRMKW), and a linear peptide (CGKIRPDTRCGGGGGRQIKWFQNRRMKW). Peptides were synthesized commercially, and cellular uptake of the FITC-conjugated linear peptide was validated by fluorescence microscopy. **Results:** Docking analysis demonstrated a highly favorable interaction between GCN5 and PGC-1α, with a minimum binding energy of −82 kcal/mol. Critical interaction residues, including Ser738–Lys253 and Asn408–Lys412, were identified as key contributors to complex stabilization and acetylation-associated conformational regulation. A. Fluorescence imaging confirmed efficient intracellular penetration of the designed peptides within 30 minutes of treatment. Among the tested constructs, the linear peptide exhibited superior efficacy in disrupting the GCN5–PGC-1α interaction, as determined by pulldown and immunoblot analyses. Hyperammonemic stress significantly suppressed the expression of downstream mitochondrial regulatory proteins, including NRF1, NRF2, TFAM, and OXPHOS complexes. Notably, inhibition of the GCN5:PGC-1α interaction restored the expression of these mitochondrial targets, indicating functional recovery of mitochondrial oxidative pathways. **Conclusion:** Collectively, these findings establish the GCN5–PGC-1α interaction as a structurally stable and functionally critical regulatory mechanism during hyperammonemia. Competitive inhibition of this interaction, particularly using rationally designed linear peptides, represents a promising therapeutic strategy for restoring mitochondrial bioenergetics and oxidative metabolism under hyperammonemic conditions.

HCC, clinical efficacy is limited by low response rates and frequent acquired resistance. MerTK macrophage is subpopulation of tumor-associated macrophages (TAMs) frequently restrict $CD8^+$ T cell infiltration and establish a "cold tumor" phenotype. Mediators and mechanism underlying its polarization remain elusive. **Methods:** PROS1 and MerTK expression profiles were analyzed using GEO and single-cell RNA-sequencing datasets, and differentially expressed genes in MerTK-high macrophages were identified. Expression of PROS1 and MerTK was further confirmed using clinical samples. Crosstalk between cells was evaluated by co-culture systems. Western Blot and qRT-PCR were used for protein and mRNA measurement. Tumor-suppressive efficacy were analyzed through cell counting kit-8 (CCK-8), and orthotopic HCC mouse models, respectively. **Results:** MerTK-high macrophages exhibited 151 differentially expressed genes enriched in immune regulation and proliferation pathways. Single-cell sequencing and IHC revealed that PROS1 was predominantly expressed in tumor cells and expression level of PROS1 was positively correlated with MerTK macrophages infiltration in human HCC. Knockdown or neutralizing PROS1 in vivo significantly impaired MerTK macrophage and TAM formation, tumor growth but increased CD8+T cell infiltration and immune therapy efficacy. In addition, we found that PROS1 served as MerTK ligand which was essential for maintaining tumor promoting phenotype in macrophage. **Conclusion:** PROS1-MerTK axis drives TAM polarization, contributing to immunosuppressive tumor microenvironment. Therapeutic targeting PROS1-MerTK axis might potentiate novel options against human HCC.

1044 | CELL DIFFERENTIATION INCREASES HEPATOCELLULAR SENSITIVITY TO ENDOPLASMIC RETICULUM STRESS

Zewei Zhang[1] Theo Velarde[1] Thomas Rutkowski[1], [1]University of Iowa Carver College of Medicine

Background: Hepatocellular identity is established through the differentiation from stem cells through definitive endoderm toward hepatic lineage. This liver identity is disrupted by unfolded protein response (UPR) when misfolded proteins are accumulated in the endoplasmic reticulum, also known as endoplasmic reticulum stress. Both hepatic identity disruption and endoplasmic reticulum stress are implicated in liver injury and disease. We have previously reported that loss of hepatic identity protects liver cells from endoplasmic reticulum stress. However, it remains unclear how differentiation states affect hepatocellular responses to endoplasmic reticulum stress. **Methods:** Human induced pluripotent stem cells (iPSCs) were differentiated into endoderm cells or iPSC-derived hepatocytes (iHeps) through a stepwise treatment of small-molecule cocktails. Cells at individual differentiation states were challenged with endoplasmic reticulum stress inducers, tunicamycin or thapsigargin. Cells were then assessed for endoplasmic reticulum stress readouts, including UPR gene expression and cell death. **Results:** In response to tunicamycin or thapsigargin, iPSCs, endoderm cells, and iHeps showed mild, moderate, and strong increases in UPR target gene expression, respectively. The greatest increase occurred during the differentiation from iPSCs to endoderm. Also, upon exposure to tunicamycin or thapsigargin, iPSCs exhibited minimal cell death, while endoderm cells underwent greater loss of viability. At the molecular level, compared with iPSCs, endoderm cells demonstrated higher expression of IRE1α protein and more active splicing of XBP1 mRNA. **Conclusion:** These findings suggest that differentiation along the hepatic lineage enhances cellular sensitivity to endoplasmic reticulum stress, providing insights into how impaired cell identity and stress response contribute together to liver injury and disease.

1045 | MITOCHONDRIAL PEROXISOMAL CROSSTALK AS A MECHANISTIC DRIVER IN FONTAN-ASSOCIATED LIVER DISEASE

Moumita Chakraborty[1] Zulfeqhar Syed[2] Valentina Baena Echeverri[2] Rownock Afruza[1] Nivedha Vaidy[1] Mary Winnicki[1] Anjali Rai[1] Theo Heller[1], [1]NIH/NIDDK, [2]NIH/NHLBI

Background: Fontan-Associated liver disease (FALD) is an inevitable consequence of the Fontan circulation and a major cause of progressive liver failure in young congenital heart disease survivors. Chronic elevation of central venous pressure and reduced cardiac output impose sustained hepatic congestion and hypoxia, leading to fibrosis, cirrhosis, and hepatocellular carcinoma often in the absence of reliable biochemical predictors. The cellular mechanisms initiating this progression remain undefined. Because oxygen tension governs zonated hepatic metabolism, we hypothesized that coordinated mitochondrial peroxisomal dysfunction represents a central, yet unexplored, driver of FALD pathogenesis.

Aim: To test that congestion driven hypoxia induces coupled mitochondrial injury and peroxisomal depletion, establishing an organelle failure axis that amplifies oxidative stress and fibrogenesis in FALD. **Methods:** We conducted high-resolution transmission electron microscopy of liver tissues from FALD patients (n = 5) and controls (n = 14) to systematically characterize mitochondrial morphology, cristae architecture, organelle clustering, peroxisome abundance, and extracellular matrix deposition. **Results:** FALD hepatocytes demonstrated coordinated and progressive organelle remodeling. Compared to controls, FALD samples exhibited marked collagen deposition within the space of Disse, pronounced mitochondrial clustering, solitary grossly swollen mitochondria with lucent matrix and disrupted cristae, megamitochondria formation, and significant mitochondrial ($p = 0.022$) and peroxisomal depletion ($p = 0.003$). Moreover, a significance increase of mitochondrial area ($p = 0.006$) was found in FALD samples as compared to controls. These findings reveal a synchronized breakdown of mitochondrial peroxisomal integrity consistent with impaired metabolic flux and redox disequilibrium, supporting a mechanistic model of hypoxia driven organelle failure preceding advanced fibrosis. **Conclusion:** This study reframes FALD as an active hepatocellular organelle failure model rather than passive congestion model, establishing mitochondrial-peroxisomal crosstalk as a novel and actionable mechanistic axis. By defining early ultrastructural biomarkers of organelle failure, this work lays the foundation for mechanistically targeted interventions that could transform risk stratification and therapeutic development for FALD an urgent need in congenital heart disease patients.

1046 | GPC3 CAR ARMORED WITH DOMINANT NEGATIVE APOPTOSIS MEDIATING SURFACE ANTIGEN FAS/ TGF-BETA RECEPTOR II AND PROLIFERATION ELEMENT IL-7R DEMONSTRATE ENHANCED EFFICACY IN HEPATOCELLULAR CARCINOMA

Yuling Zhang[1] Ji Liu[1] Qi Cao[1] Haihua Gu[1] Shaun Cordoba[1], [1]JW Therapeutics R&D (Shanghai)

Background: Glypican-3 (GPC3) is a glycosylphosphatidylinositol-anchored protein overexpressed in hepatocellular carcinoma (HCC) but absent in normal adult liver, making it an attractive immunotherapy target. However, clinical GPC3 CAR-T therapies have shown limited durability due to the immunosuppressive tumor microenvironment (TME), which induces apoptosis and limits T cell persistence. We developed a fully human GPC3 CAR-T ("GPC3 turbo") armored with dominant-negative FAS (dnFAS), dominant-negative TGF-β receptor II (dnTGFβRII), and IL-7 receptor (IL-7R) to counteract FASL/TGF-β–mediated suppression and enhance persistence. **Methods:** Primary $CD4^+$ and $CD8^+$ T cells were lentivirally transduced to generate CAR-T cells. Cytotoxicity was assessed using xCELLigence RTCA in co-culture with HepG2 cells. Proliferation was measured by cell counting. Armor function was evaluated under soluble FASL and/or TGF-β1 conditions. In vivo efficacy was tested in an NCG xenograft HCC model. Tumor growth and CAR-T persistence were assessed by tumor volume and flow cytometry. **Results:** GPC3 turbo CAR-T cells showed enhanced cytotoxicity and proliferation versus non-armored CAR-T under FASL and TGF-β1 exposure. dnFAS and dnTGFβRII reduced apoptosis and TME-mediated suppression, while IL-7R improved survival under cytokine deprivation. In vivo, GPC3 turbo demonstrated superior tumor clearance and increased persistence. **Conclusion:** Armoring GPC3 CAR-T cells with dnFAS, dnTGFβRII, and IL-7R enhances resistance to TME suppression, reduces apoptosis, and improves persistence. GPC3 turbo shows improved antitumor activity and supports further clinical development for advanced $GPC3^+$ HCC.

1047 | DISTINCT TRANSCRIPTOMIC AND LIPIDOMIC PATTERNS IN HUMAN INDUCED PLURIPOTENT STEM CELLS (IPSCS) FROM MASH/CIRRHOSIS AND NORMAL PATIENTS

Moloud Aflaki Sooreshjani[1] Xiaoying Liu[1] Ryan Shaw[1] Nate Schmidt[2] Noah Greenberg[1] Ekta Minocha[2] John G Purdy[2] Jason A Wertheim[2] Richard Green[1], [1]Northwestern University Feinberg School of Medicine, [2]University of Arizona

Background: MASLD is the leading cause of abnormal liver function tests in the United States and a major driver of cirrhosis, liver failure, and hepatocellular carcinoma. Genetic factors contribute

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

substantially to disease susceptibility, with heritability estimates ranging from 25–50%. Although only 20% of patients with fatty liver develop MASH, robust molecular and lipid biomarkers to identify patients at risk of MASH and disease progression to cirrhosis are lacking. We used human iPSCs as a platform for modeling disease mechanisms and to test whether iPSCs can be used to identify gene expression and lipidomic signatures differences between patients who develop MASH/Cirrhosis (MASH/CIR) and healthy controls (CON). iPSC-based models have applications for precision medicine and tailoring patients directed therapies. **Methods:** iPSCs reprogrammed from PBMCs isolated from patients with MASLD/Cirrhosis listed for liver transplantation were compared to normal healthy controls. iPSCs were treated with either fatty acid free bovine serum albumin (BSA) vehicle or 125 μM oleic acid/25 μM palmitic acid (OA/PA) for 48 hours. Cells were harvested and analyzed for gene expression using RNA-Seq or RT-PCR and for lipid analysis using liquid chromatography–tandem mass spectrometry. Gene set enrichment analysis (GSEA) with Hallmark gene sets was used with RNA-seq and comparison between groups used T-tests with the Benjamin–Hochberg procedure to control for the false discovery rate. **Results:** Human iPSC pluripotency was verified and similar in both groups. After OA/PA treatment in MASH/CIR group, GSEA revealed significant upregulation of pathways for unfolded protein response, oxidative phosphorylation, TNFα signaling via NF-κB and mTOR signaling ($p < 0.05$). In contrast, OA/PA treatment in CON iPSCs did not increase any inflammatory or UPR pathways. Lipidomic analysis demonstrated that BSA-treated MASH/CIR iPSCs had ~ 50% higher total triglyceride (TG) content compared to BSA-treated CON iPSCs ($p < 0.003$). Treatment with OA/PA induced a 3–4-fold increase in iPSC TG content in both groups, with no statistically significant differences between groups. In response to OA/PA treatment, 62 TGs were increased with 53 being increased in both groups and 9 unique to the CON group (TG: 66:8, 64:5, 62:4, 68:8, 66:7, 64:10, 66:6, 58:2, 68:9). **Conclusion:** These data indicate that iPSCs can serve as a model to distinguish transcriptomic and lipidomic signatures that differ between MASH/CIR and healthy patients. This may have important applications to determine the pathogenesis of MASH progression and for the development of biomarkers.

1048 | THE SAMM50 REGULATES MITOCHONDRIAL REDOX HOMEOSTASIS AND FERROPTOSIS DURING MASLD PROGRESSION

Shu-Chi Wang[1] Chi-Sheng Chen[1] Chia-Yang Li[1] Hui-Kuan Lin[2] Mohammed Eslam[3], [1]Kaohsiung Medical University., [2]Duke University, [3]The University of Sydney

Background: Mitochondrial dysfunction is a central feature of metabolic dysfunction–associated steatotic liver disease (MASLD). Sorting and Assembly Machinery Component 50 (SAMM50), a critical outer membrane protein, maintains mitochondrial architecture, yet its role in regulating metabolic stress-induced cell death remains poorly understood. This study investigates the SAMM50-GPX4 axis as a key determinant of ferroptosis sensitivity and disease severity in MASLD. **Methods:** We employed a long-term Western diet and sugar-drinking (WDSD) murine model to induce progressive MASLD. Hepatic transcriptomics and pathway analyses were used to identify core regulatory nodes. Functional assays in SAMM50-knockdown hepatocytes evaluated mitochondrial dynamics, ATP production, and ROS generation. The therapeutic potential of targeting this axis was assessed using the ferroptosis inhibitor UAMC-3203. Clinical relevance was validated by analyzing SAMM50 expression in human datasets across the spectrum of NAS scores and fibrosis stages. **Results:** In the progressive MASLD model induced by WDSD, classic steatosis and fibrosis were accompanied by a significant loss of mitochondrial SAMM50 inside the hepatocytes of liver tissues. Whole liver transcriptomic analysis indicated reduced oxidative phosphorylation, disrupted mitochondrial homeostasis, and enrichment of ferroptosis-related pathways. Mechanistically, SAMM50 deficiency enhances hepatocyte sensitivity to ferroptosis via decreased GPX4, upregulation of Transferrin Receptor (TFRC) and ferritin, and promoting lipid peroxidation. This sensitivity is further exacerbated by iron overload but pharmacologically mitigated by UAMC-3203. *In vivo* treatment with the ferroptosis inhibitor UAMC-3203 robustly alleviated hepatic steatosis and fibrotic progression, while concurrently blunting the aberrant activation of the cGAS-STING axis and its downstream inflammatory mediators, p-IRF3 and p-NF-κB. Multiple-database analysis shows that diminished SAMM50 expression strongly correlates with advancing fibrosis and elevated NAFLD Activity Scores (NAS) in patients. **Conclusion:** Our findings identify the SAMM50-GPX4 axis as a pivotal regulator of mitochondrial redox homeostasis. The metabolism-driven suppression of this axis reveals a latent vulnerability to ferroptosis, driving the transition from simple steatosis to advanced fibrosis. Targeting the SAMM50-GPX4 axis or inhibiting the downstream ferroptotic response offers a promising translational strategy for MASLD treatment.

1049 | MALADAPTIVE IRE1α-XBP1S AXIS DISRUPTS MITOCHONDRIAL DYNAMICS DURING HYPERAMMONEMIC STRESS IN SKELETAL MUSCLE

Pugazhendhi Kannan[1] Nicole Welch[1] Annette Bellar[1] Saurabh Mishra[1] Shashi Singh[2] Jasmin Cunningham[1] Seshu Vardhan Pothabathula[1] Vandana Agrawal[1] Maria Hatzoglou[2] Srinivasan Dasarathy[1], [1]Cleveland Clinic, [2]Case Western Reserve University

Background: Hyperammonemia resulting from impaired ammonia metabolism in cirrhosis induces a cytotoxic hyperammonemic stress response (HASR) in skeletal muscle that contributes to sarcopenia through disrupted mitochondrial homeostasis. Mitochondrial dysfunction during HASR is characterized by impaired oxidative phosphorylation, altered mitochondrial dynamics, excessive mitochondrial fission, defective fusion, and accumulation of dysfunctional mitochondria. Since hyperammonemic stress selectively activates inositol-requiring enzyme-1 alpha (IRE1α), a conserved arm of the unfolded protein response (UPR), we investigated if the activation of the IRE1α-XBP1s signaling axis mediates mitochondrial fission–fusion imbalance and mitochondrial oxidative dysfunction during HASR-induced skeletal muscle sarcopenia. **Methods:** Studies were performed in differentiated C2C12 myotubes and in male and female C57BL6 mice with/without muscle-specific deletion (msd) of XBP1. HASR was induced using 10 mM ammonium acetate (AmAc) in myotubes and continuous AmAc infusion (2.5 mmol·kg^{-1}·day^{-1} for 28 days) or saline in mice. Integrated multiomics analyses, including RNA seq, and proteomics were performed in myotubes and skeletal muscle tissue to define the role of IRE1α-XBP1 signaling in mitochondrial remodeling during HASR. Mitochondrial oxidative function, mitochondrial dynamics, and signaling proteins regulating mitochondrial fission and fusion were quantified by immunoblotting and mitochondrial respiration using high resolution respirometry by substrate uncoupler inhibitor titration protocols. Mito and ER dynamics were evaluated by live cell fluorescence imaging using MitoTracker and ER Tracker to assess mitochondrial morphology, ER remodeling, and mito-ER interactions during HAS. **Results:** Hyperammonemic stress disrupted mitochondrial dynamics in skeletal muscle by increasing mitochondrial fission, as evidenced by elevated p-DRP1^{Ser616} ($p < 0.05$), DRP1, FIS1 ($p < 0.01$), and MFF expression, while suppressing mitochondrial fusion p-DRP1^{Ser637}, MFN1, MFN2, and OPA1 markers ($p < 0.05$), resulting in pathological mitochondrial fragmentation. Based on multiomics (Fig. 1) and experimental validation, deletion of XBP1 reversed these maladaptive alterations by attenuating mitochondrial dysfunction restoring dynamics (fission/fusion) and biogenesis, thereby preserving mitochondrial integrity and mitochondrial homeostasis during HAS. **Conclusion:** Hyperammonemic stress activates the IRE1α-XBP1s signaling axis to drive maladaptive mitochondrial dynamics (fision/fusion) and biogenesis in skeletal muscle. Deletion of XBP1 restored mitochondrial integrity and preserved mitochondrial homeostasis during HASR, identifying the IRE1α-XBP1s pathway as a central regulator of mitochondrial dynamics and a potential therapeutic target for hyperammonemia induced skeletal muscle sarcopenia.

1050 | ALYREF DRIVES HEPATOCELLULAR CARCINOMA PROGRESSION VIA LIQUID–LIQUID PHASE SEPARATION–MEDIATED ENHANCEMENT OF MRNA NUCLEAR EXPORT

Chun-Ming Wong[1] Xiaodan Zhang[1] Qidong Li[1] Carmen Wong[1] Irene Oi-Lin Ng[1], [1]The University of Hong Kong

Background: Efficient mRNA transport from the nucleus to the cytoplasm is essential for protein synthesis and cellular function. While transcriptional regulation has been extensively studied in hepatocellular carcinoma (HCC), the role of mRNA nuclear export in HCC progression remains largely unexplored. The transcription–export (TREX) complex is a conserved nuclear assembly that couples mRNA processing to export through the nuclear pore complex (NPC), with ALYREF serving as a critical RNA export adaptor that directly binds mRNAs. **Methods:** RNA sequencing (RNA-Seq) was employed to profile the expression of TREX complex components in primary HCC and matched non-tumorous liver tissues. Additionally, RNA-Seq was used to separately analyze nuclear and cytoplasmic mRNA pools to assess the impact of ALYREF on mRNA nuclear export. ALYREF knockdown HCC cell lines were generated using shRNA. Data-independent acquisition (DIA) proteomic analysis was performed to evaluate downstream protein changes. Immunofluorescence staining, in vitro phase separation assays, and fluorescence recovery after photobleaching (FRAP) assays were conducted to characterize ALYREF-mediated liquid–liquid phase separation (LLPS) and condensate formation. Nude mice subcutaneous orthotopic xenograft models were used to study tumor formation in vivo. GalNAc-conjugated siRNA (GalNAc-siRNA) targeting ALYREF was administered to evaluate therapeutic potential in mouse models. **Results:** Multiple TREX complex components, including ALYREF, were significantly upregulated in human HCC tissues and correlated with poor patient prognosis. ALYREF contains an intrinsically disordered region (IDR) that mediates LLPS to form nuclear condensates, facilitating nuclear export of cell cycle–related mRNAs. This mechanism promotes proliferation and migration of HCC cells. ALYREF knockdown markedly suppressed tumor cell growth in vitro and in vivo, effects rescued by wild-type but not IDR-mutant ALYREF. Targeted delivery of GalNAc-siRNA against ALYREF significantly inhibited HCC tumor growth in mice. **Conclusion:** Our findings establish ALYREF as a key LLPS-dependent RNA export adaptor that drives oncogenic gene expression programs in hepatocellular carcinoma. ALYREF represents a promising therapeutic target for intervention in HCC progression.

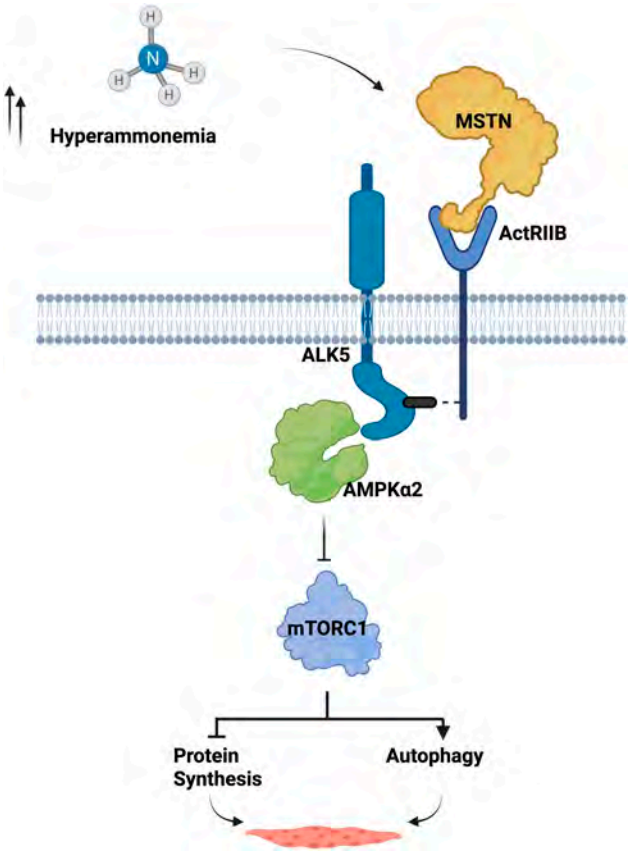
1051 | TARGETING ALK5 ATTENUATES HYPERAMMONEMIA INDUCED AMPK ACTIVATION AND DOWNSTREAM METABOLIC DYSFUNCTION



Saurabh Mishra[1] Muaz Alsabbagh Alchirazi Alchirazi[1] Annette Bellar[1] Seshu Vardhan Pothabathula[1] Pugazhendhi Kannan[1] Mohan Maradumane[1] Dhanachandra Khuraijam[1] Yuxin Wang[1] Nicole Welch[1] Srinivasan Dasarathy[1], [1]Cleveland Clinic

Background: We have previously reported that TGF-β superfamily member myostatin to cause sarcopenia during hyperammonemic stress response (HASR), a multicomponent response to perturbed ammonia metabolism, in cirrhosis. HASR also induces phosphorylation and activation of AMP-activated protein kinase (AMPK), with dysregulated protein homeostasis and sarcopenia. Canonical, myostatin signaling occurs via TGF-β receptor type I kinases ALK4/5-dependent activation of the transcription factor SMAD2/3 to cause muscle loss. Here we identified that AMPK to be an ALK5 target during HASR. **Methods:** Differentiated murine C2C12 myotubes with shRNA-mediated knockdown (KD) of canonical AMPK kinases (CaMKIIβ, TAK1, LKB1), and ALK4, ALK5, and both ALK4/5 were treated with 10 mM ammonium acetate (AmAc) for 24 h to induce HASR. Phosphorylated AMPKThr172 and canonical target ACCSer79 were quantified by immunoblotting. Functional rescue studies were performed by overexpressing ALK4, wild-type ALK5 (WT-ALK5), constitutively active ALK5 (ALK5-TD), and kinase-dead ALK5 (ALK5-KR) in myotubes with ALK4 or ALK5 KD. In vitro kinase assays using purified ALK4, ALK5, and active/inactive AMPK proteins. Myotubes were treated with ALK4 inhibitor SB-431542 and selective ALK5 inhibitor SB-525334 to determine non-canonical activation of AMPK during HASR. Mice with HASR induced by infusion of 2.5mmo.kg-1.-d for 28 days

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

were treated with vehicle or ALK5 inhibitor for 14 days. **Results:** In vitro kinase assays demonstrated that both ALK4 and ALK5 phosphorylated AMPK, and this phosphorylation was inhibited by ALK4/5 inhibitors. In cellular experiments during HASR, KD of only ALK5 or double KD of ALK4/5 but not ALK4 alone or other canonical AMPK kinases CaMKIIβ, TAK1, LKB1, reversed AMPK phosphorylation/activation. Overexpression of wild type, full length ALK5 but not ALK4 restored HASR-induced AMPK phosphorylation/activation in KD myotubes. Expression of AMPK^{Thr172Ala} mutant in AMPK knockout C2C12 myotubes reversed ACC^{Ser79} phosphorylation, showing canonical AMPK^{Thr172} phosphorylation during HASR. Pharmacological inhibition of ALK5, but not ALK4, significantly inhibited phosphorylation of both AMPK and ACC. Muscle mass was restored with ALK5 inhibitor in mice with HASR. **Conclusion:** ALK5 is the principal kinase mediating HASR-dependent AMPK activation in skeletal muscle. Pharmacological inhibition of ALK5 attenuates downstream AMPK and ACC signaling, providing the rationale to target ALK5 to treat sarcopenia in cirrhosis.

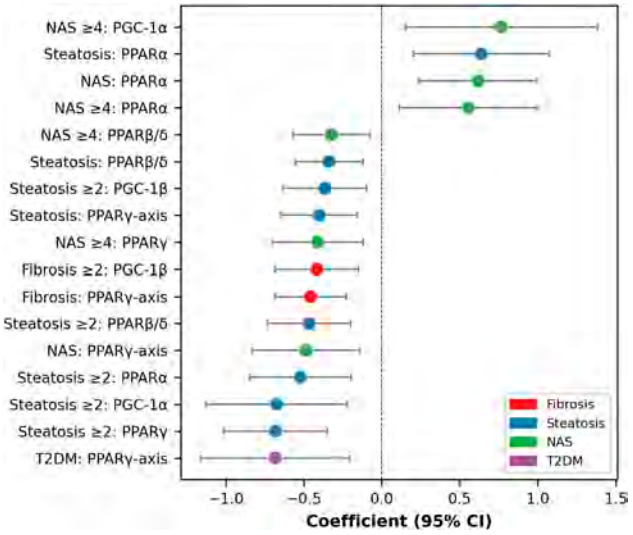
1052 | COORDINATED METHYLATION ACROSS PPAR ISOFORMS IN PLASMA CELL-FREE DNA REFLECTS PATHWAY-WIDE EPIGENETIC DYSREGULATION IN MASLD AND SUPPORTS A PAN-PPAR THERAPEUTIC RATIONALE



Manal Abdelmalek[1] Soheil Damangir[2] Guillaume Wettstein[3] Amin Naghdloo[2] Chong Lu[2] Leila Bazargan[2] Hamed Amini[2] Anna Mae Diehl[4], [1]Mayo Clinic Rochester, [2]Hepta Bio, Inc., [3]Inventiva, [4]Duke University

Background: PPARα, PPARβ/δ, PPARγ, and the PPARγ coactivators PGC-1α and PGC-1β jointly govern hepatic lipid metabolism, inflammation, and fibrogenesis. Pan-PPAR therapeutic strategies engage all three isoforms on the premise that their complementary activities address distinct aspects of MASLD pathophysiology. While methylation changes occur at many genes in MASLD, whether the PPAR family stands apart as a coordinated pathway, beyond what would be expected from genome-wide variation, has not been established. Prior methylation studies have used small targeted panels at single isoforms without comparison to the broader genome. We used whole-methylome plasma cfDNA to test whether the PPAR family, as a group, shows MASLD-associated methylation changes beyond what is seen across other genes in the genome. **Methods:** 278 plasma samples (59 controls; 219 biopsy-confirmed MASLD, F0–F4) from the Duke Biobank underwent whole-methylome cfDNA sequencing. For PPARα, PPARβ/δ, PPARγ, and the PPARγ coactivators PGC-1α and PGC-1β, co-methylated blocks in promoter, CpG island, and gene body regions were tested against fibrosis, steatosis, NAS (ordinal logistic; age, sex, T2DM-adjusted) and T2DM status (binary logistic; age, sex-adjusted), at pathway-group and individual-gene levels. The same pipeline was applied to other gene groups across the protein-coding genome; permutation testing evaluated whether PPAR's MASLD association exceeded this genome-wide reference. p-value < 0.05 was reported. When appropriate p-values were corrected for multiple hypothesis testing using Benjamini Hochberg. **Results:** Promoter regions of PPARγ was hypermethylated. All five PPAR family genes showed coordinated gene body hypomethylation in moderate-to-severe steatosis (OR 0.51–0.69). The PPARγ-axis was associated with

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

fibrosis (p = 0.0008; via PGC-1β), steatosis (p = 0.011), NAS (p = 0.027), and T2DM (p = 0.046); PPARα with steatosis and NAS (both p = 0.012); PPARβ/δ with steatosis (p = 0.011). Effect directions at PPAR gene body loci were concordant across outcome pairs (steatosis vs NAS 100%, steatosis vs fibrosis 83%, fibrosis vs NAS 83%). PPAR family genes were more consistently associated with MASLD severity across all four outcomes than 99.9% of other gene groups in the protein-coding genome (permutation p < 0.001). **Conclusion:** Plasma cfDNA reveals coordinated gene body methylation change across the PPAR family in MASLD, with overlapping but distinct isoform contributions (PGC-1β to fibrosis, PPARα to disease activity, pan-PPAR involvement in steatosis) mirroring their complementary biological roles. This pathway-wide epigenetic signature supports the biological rationale for engaging multiple PPAR isoforms rather than targeting a single isoform. Detectability in cfDNA further suggests potential utility as a non-invasive readout of pan-PPAR pathway engagement and treatment response, to be explored in on-treatment cohorts.

1053 | COMPREHENSIVE MAPPING OF BILE ACID METABOLISM, TRANSPORT, AND SIGNALLING GENES IN THE MOUSE WHOLE BRAIN: A SINGLE-CELL ATLAS BRIDGING THE LIVER-BRAIN AXIS

Emmanuel Dixon[1], [1]Medical University of Vienna

Background: Emerging evidence identifies BAs as signalling molecules that cross the blood-brain barrier and modulate neurological function via receptors, including the FXR and TGR5, contributing to the growing recognition of the liver-brain axis. Disruptions in BA signalling have been implicated in several neurological and psychiatric disorders, including Alzheimer's disease, Parkinson's disease, depression, and metabolic-associated cognitive impairment. However, our understanding of how BA metabolism and signalling machinery are distributed across the mammalian brain remains remarkably limited. Most studies have focused on targeted regions like hypothalamus or hippocampus, and a systematic, cell-type-resolved map of BA-related gene expression across the entire brain has never been generated, representing a critical gap between hepatology and neuroscience. **Methods:** We leveraged the Allen Brain Cell Atlas Mouse Whole Brain 10Xv3 single-cell RNA sequencing dataset comprising 2,341,350 cells across 26 anatomically defined brain regions, processed using Seurat v5 with BPCells on-disk matrix storage. Following quality control, normalisation, dimensionality reduction, and Louvain clustering (103 clusters), we systematically mapped expression of genes spanning BA synthesis, transport, nuclear and membrane receptors across all annotated neuronal subtypes and glial populations. **Results:** Our findings reveal striking regional and cellular heterogeneity in the expression of BA-related genes. Notably, key nuclear receptor such as *Nr1h2* (LXRβ) was ubiquitously expressed across virtually all brain regions, while *Nr1h4* (FXR) was enriched in specific GABAergic and glutamatergic subtypes. *Gpbar1* (TGR5) showed selective enrichment in cerebellar regions, midbrain, and hypothalamus. These patterns suggest that discrete neuronal circuits may be particularly sensitive to circulating or locally produced BAs. *Fgf15, Fgfr4,* and *Klb,* showed widespread neuronal expression, with the highest enrichment in the hypothalamus, thalamus, and hippocampus, consistent with a neuroendocrine signalling role. The observation of region-specific enrichment of *Cyp7b1, Cyp27a1,* and transporters *Slc10a2, Abcb11* further supports the possibility of localized BA production and transport within the CNS. Transport genes, including *Slc51a/b* (OSTα/β), were detected in glial populations. **Conclusion:** This preliminary analysis presents the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

first comprehensive single-cell atlas of BA-related gene expression across the mouse brain, establishing a molecular foundation for the liver-brain axis. On-going analysis is underway to integrate MERFISH spatial transcriptomics, which will enable 3D anatomical mapping and identification of BA-sensing neuronal circuits.

1054 | MZB1 LOSS DISRUPTS EARLY TRANSCRIPTIONAL REPROGRAMMING OF METABOLIC, PROLIFERATIVE, AND STRESS-RESPONSE GENE NETWORKS DURING LIVER REGENERATION

Jiang Li[1] Noriko Kitano[1] Lorien Walker[1] Sudrishti Chaudhary[1] Jia-Jun Liu[1] Silvia Liu[1] Juliane Beier[1] Oliver Eickelberg[1] Marta Bueno[1] Gavin Arteel[1], [1]University of Pittsburgh

Background: We previously reported that MZB1 expression is elevated in human fibrotic liver disease and that MZB1 knockout (KO) mice develop more severe CCl4-induced liver injury and fail to regenerate normally following 70% partial hepatectomy (PHx), with hepatocytes blocked at the G0-G1 transition at 24 hours. Those findings established MZB1 as a regulator of hepatocyte proliferation, but the upstream mechanism remains unknown. The early post-PHx period represents a critical priming phase during which transcriptional programs governing metabolic adaptation and growth factor signaling are established prior to cell cycle entry. The present study examined 6-hour transcriptional events following PHx to determine how MZB1 loss disrupts this program. **Methods:** Wild type and MZB1 KO mice underwent 70% PHx, with liver tissues harvested at 6 and 24 hours. RNA sequencing (RNAseq) was performed on both time-points and analyzed by Ingenuity Pathway Analysis (IPA), Gene Ontology and KEGG pathway enrichment, and STRING/Cytoscape protein network analysis. **Results:** At 6 hours post-PHx, MZB1 KO livers showed 2,000 differentially expressed genes (DEGs) relative to WT controls (872 uniquely dysregulated in KO, 1,128 shared), with 1,015 DEGs persisting at 24 hours. Both whole-body and inducible conditional KO models showed concordant results, supporting a cell-autonomous transcriptional phenotype rather than a developmental compensation effect. IPA identified dysregulation of pathways governing connective tissue cell proliferation and tumor cell growth, with transcriptional regulators STAT1, STAT6, MEK3, and TP73 among the most significantly altered. GO and KEGG enrichment analyses identified impairment of steroid and lipid metabolic processes, xenobiotic and retinol metabolism, bile secretion, and steroid hormone biosynthesis. STRING and Cytoscape network analyses confirmed disruption of protein interaction hubs central to regenerative signaling, including HGF/c-Met, STAT3, and mTOR pathway components. In WT mice, 6-hour PHx samples showed expected enrichment in metabolic pathways, TNF and MAPK signaling, insulin resistance pathways, and stress-response processes, demonstrating that WT livers mount the expected early transcriptional response, which is substantially attenuated in KO animals. **Conclusion:** The early transcriptional disruption observed here precedes the G0-G1 cell cycle block reported previously and clarifies the mechanism by which MZB1 supports hepatocyte proliferation. The exacerbated injury phenotype in KO mice reflects a proliferative rather than antifibrotic role for MZB1 in the liver, contrasting with its profibrotic function in lung and skin. These data strengthen the rationale for targeting MZB1 as a strategy to improve liver regeneration in clinical settings.

1055 | TERRESTRIAL–COSMIC COMPARISON: LIVER COMPENSATORY MECHANISMS IN HUMAN DISEASE AND SPACEFLIGHT-EXPOSED MICE

Mary Winnicki[1] Nivedha Vaidy[1] Rownock Afruza[1] Moumita Chakraborty[1] Anjali Rai[1] Theo Heller[1], [1]National Institutes of Health

Background: Mitochondrial stress is a central and reproducible biological response to spaceflight. Because mitochondrial dysfunction is implicated in hepatic injury and liver disease progression, spaceflight-exposed liver may provide a useful model for studying mitochondrial-associated mechanisms of hepatic vulnerability. Prior studies have shown that spaceflight-exposed mouse liver develops disease-like metabolic remodeling. However, whether these changes involve broader conserved stress-response programs shared with liver disease is not well defined. By comparing mouse spaceflight-exposed liver with human liver disease datasets, this project seeks to identify conserved pathways that may represent mitochondrial-associated mechanisms of hepatic dysfunction. **Methods:** Mouse liver transcriptomic datasets were acquired from the NASA Open Science

Data Repository (OSDR). Compared cohorts included basal controls, ground controls, spaceflight mice sacrificed onboard the International Space Station (ISS), and live animal return (LAR) mice that returned to Earth before tissue collection. Raw count data were analyzed for differential expression, and resulting gene-level statistics were used for gene set enrichment analysis to identify pathways altered by spaceflight exposure. Network-based integration of enriched pathways, leading-edge genes, and WGCNA-derived co-expression modules was then used to define coordinated stress-response signatures. Mouse-derived pathway and module signatures were mapped to human orthologs and compared with human liver disease datasets to identify conserved stress-response programs shared between liver disease and spaceflight-exposed liver. Exploratory feature-prioritization analyses were used to assess whether conserved signatures distinguished spaceflight-exposed liver from controls and aligned with human disease patterns. **Results:** Spaceflight-exposed liver showed recurrent enrichment of mitochondrial, metabolic, immune, and cytoskeletal stress-response programs across mouse datasets. The relative contribution of these programs varied by strain, flight duration, and dissection location, but conserved stress signatures were still observed across spaceflight models. Notably, immune-associated pathways appeared to be partially decoupled from metabolic and cytoskeletal features, suggesting distinct adaptive stress-response axes during spaceflight exposure. **Conclusion:** Spaceflight-exposed liver demonstrates conserved stress-response signatures despite model-specific variation in mitochondrial, metabolic, immune, and cytoskeletal remodeling. These findings support its use as both a comparative model for liver disease vulnerability and a unique system for identifying spaceflight-associated mechanisms of hepatic stress remodeling.

1056 | *METABOLIC REMODELING INDUCED BY GERANYLGERANYL COMPOUNDS IN HEPATOCELLULAR CARCINOMA CELLS*

Ignasi Bofill verdaguer[1] Damelia Echevarria[2] Carmen Garcia-Ruiz[2] Jose Carlos Fernandez-Checa[2], [1]Institute of Biomedical Research of University of Sao Paulo, [2]Spanish National Research Council

Background: Geranylgeraniol (GGOH) is a diterpene obtained from dietary sources and also synthesized endogenously from geranylgeranyl diphosphate (GGPP), a key end-product of the mevalonate (MVA) pathway. GGOHcan either be oxidized into bioactive metabolites such as geranylgeranoic acid (GGA), or phosphorylated back into GGPP. Beyond this metabolic role, GGOH has been reported to downregulate the MVA pathway and to exert pleiotropic biological effects, including anticancer activity. Given these dual roles, identifying non-metabolizable analogues that retain its regulatory and anticancer properties could provide new tools to modulate the MVA pathway without being rapidly metabolized. **Methods:** To address this, we investigated the metabolic and functional effects of GGOH and teprenone (geranylgeranylacetone), a synthetic diterpene analogue, in human hepatocellular carcinoma HepG2 cells. We performed in vitro radiolabeling experiments to assess GGOH metabolism, its incorporation into cellular components, and the impact of teprenone on these processes. Lipid extraction and lipidomics analyses were conducted to evaluate changes in lipid composition and acetate incorporation into lipid species. Additionally, transcriptional profiling was used to examine the regulation of genes involved in mitochondrial function and key metabolic pathways, including lipid and carbohydrate metabolism. **Results:** Radiolabeling experiments revealed that teprenone interferes with GGOH metabolism, reducing its incorporation into cellular proteins and enhancing its cytotoxic effects. Teprenone alone, and more prominently in combination with GGOH, disrupted the MVA pathway. Both diterpenes altered cellular lipid composition and reduced acetate incorporation into lipids, with the strongest effects observed under co-treatment conditions. At the mechanistic level, both compounds induced an anti-Warburg effect, shifting cellular metabolism away from glycolysis and toward mitochondrial respiration. This was accompanied by broad transcriptional changes affecting genes involved in mitochondrial function, lipid and carbohydrate metabolism. **Conclusion:** Together, these findings establish GGOH as both an endogenous lipid precursor and a regulator of cellular bioenergetics, with significant effects on lipid metabolism and mitochondrial function. Teprenone emerges as a non-metabolizable analogue that preserves many of GGOH's biological activities, including MVA pathway modulation and anticancer effects, while avoiding its metabolic conversion. These results highlight the potential of both GGOH and teprenone as valuable tools for studying metabolic regulation and as promising candidates for therapeutic strategies targeting cancer and metabolic diseases.

1057 | AN ENDOGENOUS RETROVIRUS-DERIVED GENE MAINTAINS THE EPITHELIAL STATE OF HUMAN HEPATOCYTES

Yuki Nakaya[1] Kazuhisa Murai[2] Daichi Onomura[1] Tomoko Yamagata[1] Masao Honda[3] Kazumoto Murata[1], [1]Jichi Medical University, [2]Kanazawa University Graduate School of Medical Sciences, [3]Kanazawa University Graduate School of Medical Science

Background: Endogenous retroviruses (ERVs) are remnants of ancestral retroviral infections in the germline and are increasingly recognized to play physiological roles in humans. Recent studies have suggested that a human ERV-derived transcript (HERV-X) is preferentially expressed in normal liver tissues, although its precise function remains unclear. Here, we characterized its molecular functions and detailed expression profile in hepatocytes. **Methods:** The protein encoded by the HERV-X transcript was characterized. Loss- and gain-of-function studies assessing gene expression, cell growth, and migration were performed in HepG2 cells. HERV-X transcription levels in primary human hepatocytes (PHHs), hepatocellular carcinoma (HCC) cell lines, and paired non-cancerous and cancerous liver tissues from identical patients (n = 20) were analyzed by HERV-X-specific RT-qPCR. **Results:** Although the HERV-X transcript contained three open reading frames (ORFs), only ORF1, derived from the envelope region, efficiently produced a detectable protein localized predominantly in the nucleoli of HCC cells. ORF1 exhibited RNA nuclear export activity, likely mediated by its nuclear export signal and nuclear localization signal, similar to HERV-K Rec. Depletion of ORF1 in HepG2 cells (HepG2ΔORF1) induced epithelial–mesenchymal transition (EMT)-related genes, including β-catenin, TGF-β2, and SNAI2, resulting in E-/N-cadherin switching and enhanced cellular growth and migration. Transient re-expression of ORF1 in HepG2ΔORF1 cells partially reversed the E-/N-cadherin switch. ORF1 transcription levels were significantly higher in non-cancerous liver tissues than in cancerous tissues, consistent with the findings in PHHs and HCC cell lines. Moreover, ORF1 expression was associated with the EMT status of HCC cells. **Conclusion:** HERV-X ORF1 is required for maintaining the epithelial state of human hepatocytes and may contribute to the suppression of tumorigenesis. Our findings provide new insights into the physiological functions of ERVs in previously underexplored biological contexts.

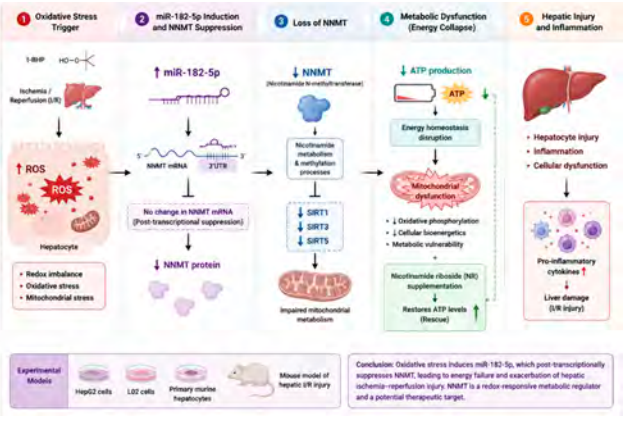
1058 | OXIDATIVE STRESS SUPPRESSES NNMT VIA MIR-182-5P TO IMPAIR HEPATOCELLULAR ENERGY HOMEOSTASIS: IMPLICATIONS FOR ISCHEMIA–REPERFUSION INJURY



Yun Gyeong Kim[1] Haneul Kim[1] Eun Jin Shin[1] Kyu Min Kim[1], [1]Department of Biomedical Science, Chosun University, Gwangju, Korea

Background: Oxidative stress is a major driver of hepatic ischemia–reperfusion (I/R) injury, yet how redox imbalance is mechanistically coupled to hepatocellular metabolic dysfunction remains poorly defined. Nicotinamide N-methyltransferase (NNMT) consumes nicotinamide via methyl-group transfer and influences NAD^+ availability and cellular energy homeostasis. We investigated how oxidative stress regulates NNMT expression in hepatocytes and whether NNMT modulates energy metabolism under oxidative stress. **Methods:** Oxidative stress was induced with tert-butyl hydroperoxide (t-BHP) in HepG2 cells, L02 cells, and primary murine hepatocytes. NNMT was assessed at the mRNA and protein levels, with antioxidant treatment and protein degradation assays used to define the mode of regulation. Candidate microRNAs were identified by screening,

and miR-182-5p was evaluated using luciferase reporter assays and mimic/inhibitor experiments. Functional effects were examined by measuring ROS generation, cytotoxicity, and intracellular ATP, including after nicotinamide riboside supplementation and NNMT overexpression. NNMT expression was also assessed in a murine hepatic I/R injury model. **Results:** t-BHP markedly reduced NNMT protein expression across all hepatocyte models, whereas antioxidant treatment restored NNMT expression, indicating redox-dependent regulation. NNMT downregulation occurred without changes in mRNA levels or protein degradation, implicating post-transcriptional control. miR-182-5p was significantly upregulated by oxidative stress; luciferase reporter assays confirmed direct binding to the 3′-untranslated region of NNMT, and mimic and inhibitor experiments demonstrated reciprocal regulation of NNMT expression. NNMT modulation did not significantly alter ROS generation or cytotoxicity; however, NNMT inhibition aggravated ATP depletion under oxidative stress, whereas nicotinamide riboside supplementation restored intracellular ATP levels. NNMT overexpression increased expression of the NAD^+-dependent regulators SIRT1, SIRT3, and SIRT5, linking NNMT to NAD^+-dependent metabolic signaling. Consistently, hepatic NNMT expression was significantly decreased in the murine hepatic I/R injury model. **Conclusion:** NNMT is a redox-responsive metabolic regulator that is post-transcriptionally suppressed by miR-182-5p during oxidative stress. By supporting NAD^+-linked energy metabolism and sirtuin expression, NNMT contributes to hepatocellular energy homeostasis and may represent a potential therapeutic target for hepatic I/R injury.

1059 | AGING DISRUPTS HEPATOCYTE ZONATION HOMEOSTASIS IN MICE AND HUMANS

Saloni Sinha[1] Tuo Zhang[1] Jason Sethiadi[1] Robert Schwartz[1], [1]Weill Cornell Medicine

Background: Aging-induced changes in the liver increase the risk of chronic liver disease, yet underlying mechanisms remain poorly defined. Hepatocyte zonation, the spatial segregation of metabolic functions across periportal (zone 1), intermediate (zone 2), and pericentral (zone 3) regions is essential to liver function. We investigated how aging alters liver architecture, intercellular communication, and hepatocyte zonation in mice and humans. **Methods:** Livers from young (2-mo) and aged (>24-mo) C57BL/6J mice were analyzed by histology and single-nucleus RNA sequencing (snRNA-seq). Differentially expressed genes (DEGs) were identified by pseudobulk analysis; intercellular signaling was inferred with CellChat; transcription factor (TF) activity was profiled by SCENIC. Zonation was assessed by immunostaining for ASS1 (zone 1), CYP2E1 (zones 2/3), and GS (zone 3). For translational validation, biopsies from healthy young (≤25YO) and aged (>60YO) human donors without obesity, liver disease, or abnormal liver enzymes underwent parallel analyses. **Results:** Aged mouse livers showed no fibrosis but marked hepatocyte enlargement, lipofuscin accumulation, and immune infiltration. snRNA-seq of 41,568 nuclei resolved 21 clusters across hepatocytes, HSCs, LSECs, KPCs, BECs, and fibroblasts, with altered cell-type proportions and zone-specific changes (663 DEGs in zone 1; 267 in zone 2; 231 in zone 3). CellChat revealed a ~4-fold increase in intercellular interactions (410 vs. 110), enriched in VEGFA–VEGFR2, IGF1–IGF1R, FGF1–FGFR, and F2–Pard3 signaling. Immunostaining confirmed expansion of ASS1+, CYP2E1+, and GS+ zones with discontinuous marker expression around veins. Strikingly, aged livers harbored "bi-zonal" hepatocytes co-expressing ASS1 and GS near central veins. SCENIC identified downregulation of key zonation TFs (Ctnnb1, Foxo1, Tcf7l2, Cebpb, Clock), with compensatory Rspo3/Wnt2 upregulation from HSCs and LSECs. IL-6 and TNF-α were elevated. Aged human livers recapitulated these findings: enlarged hepatocytes, expanded ASS1+/CYP2E1+/GS+ zones, and bi-zonal hepatocytes without fibrosis. **Conclusion:** Aging disrupts hepatic zonation homeostasis via widespread transcriptional remodeling, altered Wnt/Rspo3 signaling, and emergence of bi-zonal hepatocytes are hallmarks

1060 | CELL-FREE DNA PROFILING IDENTIFIES DISTINCT MOLECULAR SUBTYPES OF HEPATOCELLULAR CARCINOMA

Paola Cruz Rivera[1] Gopanandan Parthasarathy[2] Renumathy Dhanasekaran[1], [1]Stanford Healthcare, [2]Stanford University

Background: The molecular relationship between hepatocellular carcinoma (HCC) and cholangiocarcinoma (CCA) remains poorly characterized in liquid biopsy. We applied unsupervised clustering to cfDNA profiles to define HCC molecular subtypes and determine whether HCC and CCA occupy distinct or shared molecular space. **Methods:** HCC (n = 59; median age: 69 years, 7% male; etiology: alcohol-associated liver disease 30%, MASLD 28%, HCV 24%, HBV 24%) and CCA (n = 63; median age: 66 years; 52% female) cases seen at Stanford Hospital Center were analyzed using the Guardant360 panel. A binary somatic gene mutation matrix was constructed from non-CHIP alterations. Principal component analysis (PCA) followed by k-means clustering was performed on HCC samples alone (using genes present in $\geq$5% of HCC samples) and on combined HCC+CCA samples (using tumor-type discriminating genes). Optimal cluster number was selected by silhouette analysis. Gene enrichment was assessed by Fisher's exact test with Benjamini-Hochberg correction. **Results:** HCC harbored significantly more somatic alterations than CCA (median 17 vs 4 per sample; $p < 0.0001$). HCC molecular subtypes: Silhouette analysis identified four HCC subtypes ($k = 4$). Cluster 1 (16% of cohort) was defined by near-universal CTNNB1 mutation (93% vs 14% in other clusters; $p < 0.0001$), with co-enrichment of ARID1A (64% vs 15%; adj $p = 0.002$) and NOTCH1 (36% vs 8%; adj $p = 0.03$), higher median tumor fraction (20% vs 10%), and a median age of 73 years representing a Wnt/CTNNB1-activated, epigenetically disrupted subtype. Cluster 2 (80% of cohort) was enriched for TERT promoter mutations (39%), representing canonical TERT-driven HCC. Clusters 3 ($n = 2$) and 4 ($n = 2$) were small subgroups with distinct co-alteration patterns: TP53/POLE with highest tumor fraction (30%), and TERT/PDGFRA with the highest median AFP (64 ng/mL), respectively. Overall survival did not differ significantly between clusters (median 11.9–16.7 months; all pairwise comparisons $p > 0.4$). HCC and CCA showed markedly different genomic profiles: TERT (47% vs 1%; $p < 0.0001$) and CTNNB1 (28% vs 1%; $p < 0.0001$) were virtually exclusive to HCC, while PIK3CA (6% vs 19%; $p = 0.025$), PTEN (0% vs 11%; $p = 0.002$), and RET (0% vs 9%; $p = 0.005$) were CCA-enriched. Unsupervised clustering of 153 combined samples identified two molecular groups ($k = 2$; $\chi^2 = 26.19$; $p = 3.1\times10^{-7}$). Cluster 1 ($n = 27$, 96% HCC) was defined by TERT and CTNNB1 alterations, an HCC-specific molecular signature. Cluster 2 ($n = 126$) was molecularly ambiguous: TP53-driven HCC co-clustered with CCA, sharing oncogenic space despite distinct histologies. **Conclusion:** ctDNA profiling reveals a biologically and clinically relevant convergence between a subset of HCC and CCA. These findings open new avenues for subtype-informed therapeutic strategies. This advances the case for cfDNA-based molecular profiling as a clinically meaningful tool in the management of liver cancers.

1061 | ◆ LIVER-DIRECTED PRIME EDITING CORRECTS *ATP7B* P. H1069Q AND RESTORES COPPER HANDLING IN WILSON DISEASE MODELS

David Waterman[1] Tiernan O'Malley[1] Michelle O'Connor[1] Andrew Taylor[1] Alan Wilhelm[1] XiChun Zhang[1] Shivangi Modi[1] Celia Chang[1] Weiyi Li[1] Caroline Focht[1] Tyler Harvey[1] Luis Santos[1] Rowshon Alam[1] Jacob Stewart-Ornstein[1] Seth Alexander[1] Jon Winnay[1] Andrea De Erkenez[1] Jon Levy[1] Andrew Anzalone[1] Vivian Choi[1], [1]Prime Medicine

Background: Wilson disease (WD) is caused by *ATP7B* loss-of-function mutations that disrupt copper homeostasis and cause toxic copper accumulation in the liver and other organs. Current therapies are lifelong, burdensome, and do not correct the underlying genetic defects. Prime Editing enables precise correction of pathogenic *ATP7B* mutations to wild-type sequence without requiring DNA double-strand breaks or installing bystander edits. PM577a is a liver-directed lipid nanoparticle-formulated Prime Editor (PE) designed to precisely correct *ATP7B* p.H1069Q. We describe studies evaluating PM577a-mediated *ATP7B* p.H1069Q mutation correction and copper homeostasis across multiple humanized WD mouse models. We are also advancing a second PE that corrects *ATP7B* p.R778L. These two mutations account for >40% of WD alleles in the US, EU, and East Asia and Pacific regions. **Methods:** PM577a activity was evaluated in hepatocyte models containing *ATP7B* p.H1069Q and in humanized *ATP7B* p.H1069Q mice, including adult homozygous mutant mice with advanced liver disease. Pharmacodynamic endpoints included hepatic *ATP7B* precise editing, corrected *ATP7B* transcript, ATP7B protein expression, and hepatic copper content. Copper handling was assessed using ^{64}Cu challenge followed by positron emission tomography (PET) imaging. Additional studies evaluated Prime Editing in *ATP7B*$^{H1069Q/R778L}$ compound heterozygous mice, durability in non-human primates using an *ATP7B* surrogate PE, and unintended editing in human hepatocytes and patient-derived cells. **Results:** PM577a achieved efficient *ATP7B* p.H1069Q mutation correction in hepatocyte models and dose-dependent precise editing in humanized *ATP7B* p.H1069Q mice. Precise editing leads to *ATP7B* transcript correction, restoration of wild type ATP7B protein expression, and reduced hepatic copper. At sub-saturating doses, PM577a restored copper homeostasis as determined by ^{64}Cu PET imaging and reduced hepatic copper accumulation. Editing and copper-lowering activity were also observed in *ATP7B*$^{H1069Q/R778L}$ compound heterozygous mice. Durability was supported in non-human primates, with hepatic editing maintained >1.5 years after infusion of an *ATP7B* surrogate PE. No detectable off-target edits were observed in human hepatocytes or WD patient-derived cells. Learnings from PM577a were applied to rapidly develop a second PE using the same liver LNP platform to correct a second pathogenic mutation, R778L, achieving >90% hepatocytes gene correction *in vivo.* **Conclusion:** PM577a precisely corrects the *ATP7B* p.H1069Q mutation and restores copper homeostasis across multiple WD models. Preclinical ^{64}Cu PET data support restoration of copper handling and provide a translational pharmacodynamic approach for clinical evaluation. PRIME-0211, an observational study in Wilson disease patients, has been initiated to identify individuals who could be eligible for PM577a clinical evaluation.

1062 | ◆ DIAGNOSTIC PERFORMANCE OF A PLASMA CFDNA METHYLATION PANEL TARGETING GNB4 AND RIPLET FOR LIVER CANCER DETECTION

Lianglu Zhang[1] Dihan Zhou[1] Lanlan Dong[1] Jun Zhou[1] Hong Guo[1], [1]Wuhan Ammunition Life-Tech Co., Ltd.

Background: Primary liver cancer is a leading cause of cancer-related death worldwide, with poor prognosis mainly due to late diagnosis. Circulating cell-free DNA (cfDNA) methylation-based liquid biopsy is a promising non-invasive method for early liver cancer detection, overcoming limitations of invasive biopsy and suboptimal performance of conventional biomarkers such as alpha-fetoprotein (AFP). We developed a dual-gene cfDNA methylation assay targeting GNB4 and Riplet and evaluated its diagnostic performance for liver cancer. **Methods:** A total of 1182 plasma samples were prospectively collected from three hospitals, including 430 liver cancer

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

patients and 752 controls. Cases covered all TNM stages (I–IV) and main pathological subtypes: hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma (ICC), and combined hepatocellular-cholangiocarcinoma (cHCC-CCA). Controls included benign liver diseases and non-hepatic malignancies. Methylation levels of GNB4 and Riplet were quantified by methylation-specific PCR (MSP). Diagnostic accuracy was assessed against the clinical reference standard. **Results:** The dual-gene assay achieved an overall sensitivity of 92.3% (95% confidence interval [CI]: 89.3%–94.6%) for liver cancer. Sensitivities for HCC, ICC, and cHCC-CCA were 91.9% (95% CI: 87.4%–94.9%), 93.3% (95% CI: 85.4%–97.2%), and 90.0% (95% CI: 66.9%–98.2%), respectively. Stage-specific sensitivities for TNM stages I–IV were 84.4% (95% CI: 76.5%–90.1%), 93.6% (95% CI: 86.8%–97.2%), 98.1% (95% CI: 92.8%–99.7%), and 100.0% (95% CI: 91.6%–100.0%). Overall specificity in controls was 93.4% (95% CI: 91.3%–95.0%), with 97.6% (95% CI: 95.7%–98.7%) in benign liver diseases and 85.3% (95% CI: 80.2%–89.2%) in non-hepatic malignancies. **Conclusion:** Plasma cfDNA methylation analysis of GNB4 and Riplet shows high sensitivity and specificity for liver cancer. It effectively detects early-stage (TNM I) cancers and maintains high specificity in benign liver diseases. This accurate, convenient, non-invasive test holds great potential for auxiliary diagnosis of liver cancer and screening of high-risk populations.

1063 | ◆ HSD17B13 LOSS-OF-FUNCTION ATTENUATES THE BENEFIT OF MEDICATIONS FOR ALCOHOL USE DISORDER (MAUD) ON LIVER OUTCOMES: A PHARMACOGENOMIC TARGET TRIAL EMULATION IN 63,951 HEAVY DRINKERS FROM ALL OF US COHORT

Hyunseok Kim[1] Derin Celtik[1] Walid Ayoub[1] Alexander Kuo[2] Paul Martin[2] Aarshi Vipani[2] Yun Wang[2] Stephen Pandol[2] Debiao Li[2] Yee Hui Yeo[2] Suthat Liangpunsakul[3] David Cohen[2] Shelly Lu[2] JuDong Yang[2], [1]Cedars-Sinai Medical Center, [2]Cedars Sinai Medical Center, [3]Indiana University Medical Center

Background: Recent observational studies suggest naltrexone reduces hepatic complications in alcohol-associated cirrhosis, while comparative effectiveness data for acamprosate and baclofen remain mixed. Whether benefits of medications for alcohol use disorder (MAUD) extend to prevention populations before cirrhosis develops, and whether they are modified by established liver-disease variants, is unknown. **Methods:** We conducted a prespecified target trial emulation among 63,951 heavy drinkers (AUDIT-C ≥ 4 [women] or ≥ 5 [men], or ICD-coded alcohol use disorder [AUD]) from the All of US data with whole-genome sequencing (1.0% baseline cirrhosis; AMR, EUR, and AFR ancestries; median follow-up 4.9 years [exposed] and 3.6 years [unexposed]). MAUD exposure required ≥ 3 prescriptions per ingredient. The composite outcome included hepatic decompensation, hepatocellular carcinoma, liver transplant, and liver-related death. Confounding by indication was addressed using ancestry-stratified gradient-boosted propensity scores, weight truncation, and empirical-overlap trimming in the AMR stratum. Cox proportional hazards models tested a prespecified PNPLA3 rs738409 × MAUD and an exploratory HSD17B13 rs72613567 × MAUD interactions. **Results:** Across 1,209 composite events, naltrexone ($n = 968$) was the only protective agent (HR 0.41, 95% CI 0.28-0.62, $p < 0.0001$), with the greatest benefit in years 1-3 (HR 0.31, 95% CI 0.15-0.65) and effects sustained through 5 years. Acamprosate ($n = 164$) showed no significant benefit. Baclofen ($n = 1,252$) demonstrated early harm attributed to channeling (HR 3.29 at 0-1 year) followed by a late liver benefit (HR 0.51 at 5+ years, $p = 0.007$); however, only 59% had AUD diagnostic codes despite all meeting heavy-drinking criteria, limiting causal interpretation. Naltrexone's protective effect persisted when analyses were restricted to participants without baseline liver disease (HR 0.38; peak 1-3 year HR 0.15), extending prior findings to a pre-cirrhotic prevention population. The prespecified PNPLA3 × MAUD interaction was null (HR 1.04, 95% CI 0.39-2.82, $p = 0.94$). By contrast, HSD17B13 loss-of-function (LOF) carriage attenuated MAUD benefit (interaction HR 3.99, 95% CI 1.53-10.44, $p < 0.01$), an effect that was strongest in years 0-3, and remained significant across sensitivity analyses. **Conclusion:** We report the first pharmacogenomic interaction between MAUD and an established liver-disease locus: HSD17B13 LOF attenuates MAUD benefit through a plausible ceiling-effect mechanism, while PNPLA3 had no effect. Naltrexone was associated with early and sustained reductions in liver-related outcomes, with effects persisting in pre-cirrhotic populations. These hypothesis-generating findings warrant external validation and may inform precision-medicine strategies for ALD prevention and progression.

1065 | CLONAL HEMATOPOIESIS IS ENRICHED IN LIVER CANCERS AND ASSOCIATED WITH GREATER SOMATIC TUMOR COMPLEXITY

Gopanandan Parthasarathy[1] Paola Cruz Rivera[2] Renumathy Dhanasekaran[1], [1]Stanford University, [2]Stanford Healthcare

Background: Clonal hematopoiesis of indeterminate potential (CHIP) are somatically mutated, clonally expanded hematopoietic stem cells, associated with chronic liver disease and could modulate the hepatic tumor microenvironment. Ultra-sensitive cell-free DNA platforms enable CH mutation detection in nontumor cells from peripheral blood across a wide variant allele frequency (VAF) range, though the biologically relevant threshold remains undefined. We examined CH prevalence and clinical associations in a contemprorary cohort of primary liver cancer patients. **Methods:** Plasma cfDNA from patients with liver cancers (n = 122) HCC (n = 59; median age 69 y, 71% male; alcohol-associated liver disease 30%, MASLD 28%, HCV 24%, HBV 24%; 74% with cirrhosis) and cholangiocarcinoma (CCA; n = 63; median age 66 y; 52% female) profiled at our center using the Guardant360 panel were analyzed. CH variants were identified across 39 genes and reported at two thresholds: VAF $\geq$2% (CHIP, standard threshold) and VAF $\geq$0.5% (CH, exploratory analysis). CH prevalence was compared between tumor types by Fisher's exact test; continuous outcomes by Mann-Whitney U test; gene associations by Fisher's exact test with Benjamini-Hochberg correction. Overall survival (OS) was compared between CH+ and CH– HCC patients. **Results:** At VAF $\geq$2% threshold, CHIP was prevalent in 12% of HCC and 10% of CCA (P = 0.77). At VAF $\geq$0.5%, CH mutations were detected in 51% of HCC (30/59) and 16% of CCA (10/63; $P < .01$, despite similar age (69 vs 66 y; P = .18). DNMT3A was the predominant CH mutation, enriched in HCC versus CCA (36% vs 11%; adj $P < 0.05$), with PPM1D trending higher in HCC (8% vs 2%). HCC patients with CH mutations were significantly older than those without (median 71 vs 65 years; $P < 0.05$), consistent with age-driven somatic mutagenesis. Despite higher CH mutational burden, OS did not differ significantly between CH+ and CH– HCC patients (median 14.0 vs 13.4 months; $P = 0.39$). Among HCC, CH+ patients had greater somatic mutational burden than CH– samples (median 22 vs 10 alterations; P < .001), suggesting co-occurrence of hematopoietic and tumor genomic instability. In CCA, somatic BAP1 mutations were enriched in CH+ patients (30% [3/10] vs 6% [3/53]; P < .05), identifying a subgroup with convergent disruption of DNA damage response pathways across hematopoietic and epithelial compartments. **Conclusion:** CH mutations are common in HCC and CCA, driven by DNMT3A and PPM1D variants, associated with greater somatic tumor complexity, but without impact on OS in this cohort. A cfDNA-appropriate VAF threshold for CH mutation detection in peripheral blood remains undefined but CH mutations are 3-fold more common in HCC compared to CCA. These findings support a model of parallel genomic disruption across hematopoietic and tumor compartments in HCC and CCA. The high prevalence of CH detection by cfDNA has important implications for liquid biopsy interpretation in primary liver cancers.

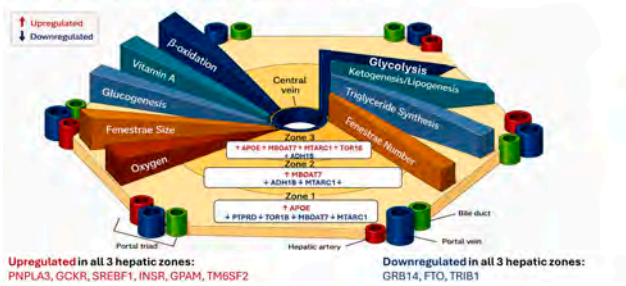
1066 | SINGLE-NUCLEUS RNA SEQUENCING OF FFPE HUMAN LIVER TISSUE IDENTIFIES ZONE-SPECIFIC EXPRESSION PATTERNS OF MASLD-ASSOCIATED GENES

Lishi Yin[1] Yanhua Chen[1] Ye Chen[1] Antonino Oliveri[1] Prabhu Ponnandy[1] Elizabeth Speliotes[2], [1]University of Michigan - Ann Arbor, [2]University of Michigan Medical Center



Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is a leading cause of chronic liver disease worldwide. Our previous genome-wide association studies (GWAS) identified 17 MASLD loci; however, the hepatic zones in which these genes act are unclear. Recent advances in single-nucleus RNA sequencing (snRNA-seq) now enable transcriptomic profiling of archived formalin-fixed paraffin-embedded (FFPE) liver tissue. **Methods:** We carried out single cell and spatial transcriptomic analyses on 16 FFPE samples spanning the MASLD spectrum from the Michigan Genomics Initiative. Quality control, normalization, integration, clustering, cell marker identification (using FindAllMarkers) was done using Seurat v5. We identified periportal (zone 1), interzonal (zone 2), and pericentral (zone 3) hepatocytes using published markers and subcluster analysis. We performed differential expression analysis using Model-based Analysis of Single-cell Transcriptomics (MAST) to evaluate expression patterns of genes previously implicated by MASLD GWAS. Significance was determined after Bonferroni correction for 18,129 genes expressed (P adjusted < 0.05). **Results:** Our FFPE snRNA-seq dataset identified expected hepatic cell populations and hepatocyte zonation patterns across MASLD stages. Fifteen among the 17 MASLD-associated loci demonstrated significant differential expression in hepatocyte populations, with distinct zone-specific transcriptional signatures. PNPLA3, GCKR, GPAM, INSR, SREBF1, and TM6SF2 were broadly upregulated, whereas FTO, GRB14, and TRIB1 were consistently downregulated across hepatocyte zones. Other genes, including ADH1B, APOE, MBOAT7, MTARC1, and TOR1B, exhibited heterogeneous zonal expression patterns. PTPRD is only down regulated in zone 1 hepatocytes. ADH1B was downregulated in zone 3 and zone 2 hepatocytes only; APOE was upregulated in zone1 and zone3 hepatocytes; MBOAT7 was upregulated in zone 2 and zone 3 hepatocytes but downregulated in zone 1 hepatocytes. MTARC1 was upregulated in zone 3 hepatocyte and downregulated in zone 2 and zone 1 hepatocytes; TOR1B was upregulated in zone 3 hepatocytes and downregulated in zone 1 hepatocytes. **Conclusion:** We established a human liver FFPE snRNA-seq cohort spanning MASLD stages and mapped the cell-type and zone-specific expression patterns of MASLD GWAS genes. Our findings suggest spatially distinct roles for GWAS identified MASLD genes. Our future work will integrate a spatial transcriptomics cohort to interpret the local biology of these genes.

Table 1. Average log2 fold change of GWAS identified MASLD genes

Gene	Periportal hepatocyte (Zone 1)	interzonal hepatocyte (Zone 2)	pericentral hepatocyte (Zone 3)
PNPLA3	1.06 (P = 5.7e-188)	1.25 (P = 4.2e-120)	1.07 (P = 2.5e-44)
GCKR	0.54 (P = 9.4e-193)	0.71 (P = 4.8e-84)	0.18 (P = 8.1e-48)
SREBF1	1.06 (P = 1.3e-127)	1.16 (P = 2.8e-68)	1.03 (P = 4.9e-66)
INSR	0.59 (P = 1.8e-66)	0.41 (P = 1.3e-31)	0.27 (P = 3.4e-40)
GPAM	0.54 (P = 5.3e-61)	0.56 (P = 6.3e-29)	0.48 (P = 2.1e-24)
TM6SF2	0.77 (P = 1.7e-55)	0.93 (P = 1.4e-24)	0.41 (P = 6.7e-21)
GRB14	-0.57 (P = 1.1e-106)	-0.39 (P = 3.5e-28)	-0.35 (P = 8.2e-10)
FTO	-0.22 (P = 1.8e-22)	-0.28 (P = 5.1e-06)	-0.20 (P = 7.7e-03)
TRIB1	-0.48 (P = 1.4e-96)	-0.14 (P = 2.2e-23)	-0.25 (P = 3.1e-60)
MTARC1	-0.68 (P = 7.4e-117)	-0.40 (P = 2.5e-32)	0.25 (P = 8.6e-39)
ADH1B	NS	-0.13 (P = 8.8e-41)	-0.10 (P = 1.0e-54)
MBOAT7	-0.16 (P = 6.5e-25)	0.48 (P = 2.3e-12)	0.65 (P = 2.6e-13)
APOE	0.51 (P = 3.5e-252)	NS	0.12 (P = 1.3e-237)
TOR1B	-0.33 (P = 1.6e-16)	NS	0.23 (P = 2.1e-08)
PTPRD	-0.48 (P = 1.7e-09)	NS	NS

Values represent average log2 fold change from differential expression analysis.
P values shown in parentheses are Bonferroni-corrected adjusted P values.
"NS" indicates not statistically significant after Bonferroni correction.

1067 | BLOOD DNA METHYLATION SIGNATURES PREDICT INCIDENT ALL-CAUSE LIVER CIRRHOSIS IN THE MILLION VETERAN PROGRAM

Josephine Johnson[1] David Kaplan[1] Philip Tsao[2] Timothy Morgan[3] Julie Lynch[4] Kyong-Mi Chang[5] Marijana Vujkovic[5], [1]Corporal Michael J. Crescenz VA Medical Center;University of Pennsylvania, [2]VA Palo Alto Healthcare System; Stanford University School of Medicine, [3]VA Long Beach Healthcare System, [4]VA Informatics and Computing Infrastructure;University of Utah School of Medicine, [5]Corporal Michael J. Crescenz VA Medical Center;Perelman School of Medicine

Background: Liver cirrhosis is a major complication of chronic liver disease predominantly caused by alcohol use, viral hepatitis, and metabolic dysfunction-associated steatotic liver disease (MASLD), often manifesting silently over decades. Current biomarkers for early

detection are limited, making it difficult to identify individuals at risk before irreversible liver damage occurs. Because DNA methylation reflects both genetic susceptibility and environmental exposures, it may serve as a minimally invasive, blood-based marker of early disease risk and progression. **Methods:** We conducted an epigenome-wide association study (EWAS) in European ancestry participants from the Million Veteran Program, analyzing 768,569 CpG sites among 45,460 individuals on the Illumina EPIC array. Cases were individuals who developed cirrhosis at least two years after enrollment and blood draw (177 cases; 26,689 population controls), analyzed via logistic regression with genomic inflation correction using BACON. **Results:** We identified 46 CpG sites significantly associated with incident cirrhosis risk after adjustment for demographic factors, technical covariates, and clinical risk factors including alcohol use disorder, viral hepatitis, MASLD, HIV, smoking, and medication history. Signals were predominantly hypomethylated, consistent with global epigenetic dysregulation in chronic liver disease. Notably, 41 of the 46 incident CpG sites were also associated with Horvath epigenetic age acceleration, suggesting faster biological aging in at-risk individuals prior to disease onset.To characterize the cellular and genetic architecture of the cirrhosis signals, we performed cell-type interaction analyses using cellDMC and cis-mQTL analyses. CD8 T-cells were the primary immune cell type driving incident CpG associations, contributing to eight CpGs signals, with a smaller contribution from eosinophils at two CpG sites. Cis-mQTL analysis identified 285 independent genetic variants regulating cirrhosis-associated CpG sites (FDR < 5%). Gene-environment interaction analyses between top cis-mQTL variants and major etiologies revealed that viral hepatitis and HIV amplified genetic effects on methylation at nominal significance ($P < 0.05$). Cross-compartment validation in an independent liver tissue dataset supported *HIVEP3* promoter methylation as a marker of disease progression. **Conclusion:** These findings demonstrate that blood DNA methylation signatures can identify individuals at increased cirrhosis risk and capture immune-mediated, aging-related, and exposure-specific pathways, highlighting the potential of methylation-based biomarkers for early risk stratification.

1068 | METHYLOME-WIDE ANALYSIS OF ALCOHOL ASSOCIATED CIRRHOSIS RISK IN MILLION VETERANS PROJECT

Marco Abreu[1] Callie Zaborenko[1] Josephine Johnson[2] Marijana Vujkovic[2] Kyong-Mi Chang[2] Timothy Morgan[3] Tae-Hwi Schwantes-An[1], [1]Indiana University School of Medicine, [2]University of Pennsylvania, [3]VA Long Beach Healthcare System

Background: Alcohol-associated liver cirrhosis (ALC) is a major contributor to liver-related mortality and transplant worldwide. Although genome-wide association studies have identified risk loci, including *PNPLA3*, *TM6SF2*, and *HSD17B13*, these only explain a modest proportion of heritability. Chronic alcohol exposure also induces widespread DNA methylation changes through oxidative stress, inflammation, and disrupted one-carbon metabolism, suggesting epigenetic mechanisms may contribute to ALC susceptibility. Using an methylation cohort from the Million Veteran Program, we conducted an epigenome-wide association study (EWAS) of ALC. **Methods:** Cases were participants with at least one ICD-9/10 diagnosis code for alcohol-associated liver cirrhosis. Controls had ICD-9/10 diagnoses related to heavy alcohol use but no history of MASLD or alcohol-associated liver disease. Genome-wide methylation across >751,000 CpG sites was assessed using the EPIC v1 array. Linear regression models were fitted using *limma* in R to evaluate methylation differences at each CpG site while adjusting for age, sex, 5 technical PCs, 5 genomic PCs, sample storage duration, estimated cell-type proportions, and scanner batch effects. **Results:** The discovery cohort included 550 cases and 3,173 controls clustering with EUR reference samples; the replication cohort included 215 cases and 1,867 controls from AFR samples. We identified 32 differentially methylated regions (DMRs; ≥5 CpGs) associated with ALC at genome-wide significance (adjusted $p < 5x10^{-08}$) in the

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

EUR cohort. Of these, 20 DMRs replicated in AFR cohort (adjusted $p < 0.05$). Replicated DMRs mapped to genes involved in interferon/antiviral response, innate immune and cytokine signaling, and inflammatory remodeling. **Conclusion:** In the largest EWAS of alcohol-associated cirrhosis to date, we identified 20 replicated DMRs implicating coordinated immune and inflammatory epigenetic dysregulation in ALC susceptibility among heavy drinkers. Enrichment for interferon-responsive and innate immune pathways suggests that chronic immune activation may be a central feature of ALC biology beyond known genetic risk loci. Because of the cross-sectional nature of the study, we cannot determine whether these methylation changes precede disease development or arise because of cirrhosis. Further longitudinal and functional studies are needed to clarify the directionality and biological significance of these epigenetic alterations.

1069 | UNDERSTANDING HEPATOBLASTOMA HETEROGENEITY AND TUMOR MICROENVIRONMENT FOR PRECISION MEDICINE: FOCUS ON HIGH-RISK HEPATOBLASTOMA-ASSOCIATED NEUROENDOCRINE TUMOR CELLS

Elise Lelou[1] Abhishek Murti[1] Saphia Nguyen[1] Matthew Choi[1] Cindy Ament[1] Nikita Sajai[1] Phoebe Miller[1] Soo-Jin Cho[1] E. Alejandro Sweet-Cordero[1] Amar Nijagal[1] Bruce Wang[1], [1]University of California, San Francisco, United States of America

Background: Hepatoblastoma (HB) is the most common primary pediatric liver cancer. Among childhood tumors, it has one of the highest mortality rates, with 20% of cases resulting in death or liver transplantation. We previously used single-cell RNA sequencing (scRNA-seq) to identify 5 tumor cell types shared across patients. We now expand this analysis, using scRNA-seq, single-nuclei RNA sequencing (snRNA-seq), and spatial transcriptomics to further characterize tumor cells and their microenvironments. **Methods:** scRNA-seq was performed using microwell capture on 12 freshly dissociated tumors, and snRNA-seq was performed using droplet capture on 18 banked frozen tumors. Data was analyzed using Scanpy. Tissue microarrays of FFPE-Hepatoblastoma from 17 patients were prepared for Xenium spatial transcriptomics using a custom liver 480-gene panel based on our scRNA-seq dataset and analyzed with Scanpy and Squidpy. **Results:** We confirmed the reproducibility of tumor cell populations across techniques using matched sc/snRNA-seq patient samples. Our expanded sc/snRNA-seq datasets validated the previously identified 5 tumor cell populations, and identified 4 new populations (Hepatoblast-III, Wnt-I, Wnt-II, and Neuroendocrine-II (*CHGB*+)). Surprisingly, neuroendocrine tumor cell types, rarely reported in the literature for HB, were identified in 4 of 21 patients, with Neuroendocrine-I (*CHGA*+, *CHGB*+) being specific to the high-risk HB patient 8. Spatial transcriptomics revealed that distinct tumor cell types occupied discrete spatial regions within the tumor. Furthermore, using neighborhood analysis, we found that each tumor cell type had a distinct microenvironment. Neuroendocrine-I and II tumor cells form tumor nests. While Neuroendocrine-I nests have no other cell types enriched within and are enriched with fibroblasts at their interface, Neuroendocrine-II nests contain Wnt-I/II tumor cells and fibroblasts inside, and have cholangiocytes (BEC) at their interface. Using cell-cell interaction analysis, we found that Neuroendocrine-I, which may be associated with high-risk, exhibited somatostatin autocrine signaling and *SLIT*--mediated fibroblast crosstalk. **Conclusion:** We established a molecular and spatial single-cell-resolution atlas of HB. We identified clinically relevant shared tumor cell types with distinct microenvironments, including 2 neuroendocrine tumor cell types. These results could improve risk stratification and identify tumor cell type-specific microenvironmental interactions representing therapeutic target candidates, like the high-risk HB-associated Neuroendocrine-I somatostatin signaling pathway. This can be tested using patient-derived organoids from freshly resected tumors that maintain patient features and that we developed in our lab.

1070 | GENOMIC PROFILES AS DETERMINANTS OF THERAPEUTIC EFFICACY IN HEPATOCELLULAR CARCINOMA: TOWARDS PRECISION MEDICINE

Pil Soo Sung[1], [1]Seoul St Mary's Hospital

Background: As therapeutic options for hepatocellular carcinoma (HCC) expand, optimizing treatment selection based on individualized genomic profiles remains a clinical challenge. We hypothesized that patient-specific mutational landscapes and associated biological characteristics significantly influence treatment efficacy and tumor burden. **Methods:** We analyzed 42 patients treated for HCC between January 2025 and February 2026 who had available tumor biopsy samples. Targeted Next-Generation Sequencing (NGS) was performed to identify genomic alterations. These profiles were correlated with etiology, pathological features (CK19, GPC3, PD-L1 CPS), initial tumor markers, and therapeutic responses across systemic and localized modalities. PD-L1 expression was specifically analyzed using a threshold of CPS $\geq$ 10. Genomic instability was assessed using the HRD sum score. **Results:** In the overall cohort (N = 42), the most frequent genomic alterations were mutations in TP53 (45.2%), TERT promoter (45.2%), and CTNNB1 (23.8%). In HBV-related HCC, the top alterations were TP53 (42.9%), TERT promoter (33.3%), and RIT1 (23.8%) whereas in MASLD-related HCC was TERT promoter (69.2%), CTNNB1 (46.2%), and TP53 (38.5%). Regarding tumor burden, baseline markers were notably high in cases with FGF-family amplifications (Median AFP 4,601) or AXIN1 mutations (Median AFP 2,324), whereas CTNNB1 mutations were associated with a significantly lower baseline tumor burden (Median AFP 40.8). TP53 mutations and FGF-family amplifications were strongly associated with PD-L1 expression (CPS > = 10: 52.6% and 75.0%, respectively) and GPC3 positivity (78.9% and 75.0%, respectively). AXIN1 mutations and RIT1 amplifications were consistently associated with refractory disease, with AXIN1 mutants and RIT1 amplification showing rapid progression and AFP/PIVKA-II surge under ICI (AFP +2,658.6, +1,939.6 ng/mL respectively). ARID1A mutants exhibited response dissociation, showing better extrahepatic control under ICI despite intrahepatic progression. CTNNB1 mutants showed poor response to ICI (PD-Ref 25.0%) but showed stable response under Lenvatinib (100% SD, Mean Delta AFP +0.27). ARID1A alterations are favorable for ICI, while CTNNB1 is best managed with Lenvatinib or HAIC. Conversely, TP53 and AXIN1 mutations had high resistance to ICI but remain sensitive to HAIC, with significant marker reduction (TP53: Mean AFP -2,912.1 ng/mL). **Conclusion:** Genomic profiling via targeted NGS provides critical insights into HCC tumor burden and treatment-specific outcomes. The dominance of CTNNB1 in NBNC HCC, its association with lower tumor burden, and the clinical stability of Lenvatinib and HAIC highlight the importance of genotype-directed strategies. Integration of mutational data into clinical decision-making enables optimized, personalized treatment in HCC.

1071 | COMPUTATIONAL PATHOLOGY OUTPERFORMS CLINICAL AND MOLECULAR PROGNOSTIC MARKERS AND REVEALS TARGETABLE MORPHOLOGIC PHENOTYPES IN HEPATOCELLULAR CARCINOMA

Tyler Yasaka[1] Shaila Afrin[2] Junyan Tao[1] Po-Yuan Chen[1] Chang Kyung Kim[1] Anisha Jain[1] Laura Molina[3] Rebekah Dadey[1] Riyue Bao[1] Satdarshan (Paul) Monga[3] Yu-Chiao Chiu[1], [1]University of Pittsburgh School of Medicine, [2]University of Pittsburgh School of Medicine, [3]University of Pittsburgh

Background: Hepatocellular carcinoma (HCC) is a leading cause of cancer-related mortality, and outcomes remain poor despite well-characterized transcriptomic subtypes that have not translated into routine clinical care. By utilizing routine hematoxylin and eosin (H&E) staining, computational pathology may bridge this gap by extracting molecular-grade biological and prognostic information from morphologic features, enabling scalable precision medicine for HCC. **Methods:** We developed a computational

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

pathology framework (Tissue Encoded Subtype Elucidation and Risk Assessment or TESERA) that generates morphology-based embeddings from routine H&E whole-slide images. Embeddings from The Cancer Genome Atlas Liver Hepatocellular Carcinoma (TCGA-LIHC; $n = 336$) cohort were analyzed by unsupervised clustering, with subtype-defining biology characterized via pathway and mutational enrichment analyses; a candidate target was tested by pharmacologic inhibition in a corresponding murine model. For patient-level prognostication, a Cox model trained on histologic embeddings was benchmarked head-to-head against clinical variables, bulk transcriptomic principal components, and published HCC prognostic signatures, then evaluated in an independent in-house cohort ($n = 48$). **Results:** Unsupervised clustering of histologic embeddings using TESERA yielded two transcriptionally coherent subtypes—TES1 and TES2—that recovered the metabolism-versus-proliferation axis of HCC biology directly from morphology and stratified overall survival (OS; $p < 0.0001$). TES1 (favorable) was enriched for fatty acid β-oxidation, PPARα target genes, and *CTNNB1* mutations; TES2 (poor prognosis) was enriched for proliferative programs and *TP53* mutations. In a murine model recapitulating TES1 transcriptional features, pharmacologic PPARα inhibition—nominated by subtype-enriched fatty acid β-oxidation—significantly reduced tumor burden ($p < 0.05$), validating a morphology-derived therapeutic vulnerability in vivo. In head-to-head benchmarking, the supervised risk model outperformed all comparators (C-index 0.731; 1-, 3-, 5-year AUCs 0.82, 0.80, 0.79), remained independently prognostic after multivariable adjustment (HR 2.97, 95% CI 1.62–5.40, $p < 0.001$), and stratified OS in external validation (C-index 0.655; AUCs 0.80, 0.79, 0.70). **Conclusion:** By recovering metabolism- and proliferation-based HCC subtypes from routine H&E alone, TESERA shows that morphology encodes clinically actionable molecular biology. It outperformed established clinical and transcriptomic prognostic benchmarks, generalized to an external cohort, and identified a therapeutic vulnerability validated in vivo. Released as a publicly accessible pipeline, TESERA offers a scalable foundation for HCC precision medicine and demonstrates that routine histology can deliver molecular-grade insights.

1072 | GENETIC DETERMINANTS OF THE CHOLESTATIC BIOCHEMICAL PHENOTYPE IN MASLD: INSIGHTS FROM THE SPANISH HEPAMET REGISTRY

Antonio Gil-Gómez[1] Rocio Aller[2] Douglas Maya-Miles[1] Juan Pericàs[3] David Marti-Aguado[4] Águeda González-Rodríguez[5] Jose Luis Calleja[6] Jesus Rivera-Esteban[7] Judith Gomez-Camarero[8] Manuel Romero-Gómez[9] Javier Ampuero Herrojo[10], [1]Departamento de Fisiología, Facultad de Biología, Universidad de Sevilla, [2]Centro de Investigación de Endocrinología y Nutrición, Hospital Clínico Universitario de Valladolid, [3]Liver Unit, Vall d'Hebron University Hospital Campus, Vall d'Hebron Institut de Recerca, Universitat, [4]Clinic University Hospital, INCLIVA Health Research Institute, Valencia, Spain., [5]Instituto de Investigaciones Biomédicas Sols-Morreale (IIBM), CSIC-UAM, Madrid 28029, Spain., [6]Digestive Department, Hospital Universitario Puerta de Hierro, Madrid, Spain., [7]Gastroenterology and Hepatology, Puerta de Hierro University Hospital of Majadahonda, Spain, [8]Digestive Department, Hospital Universitario de Burgos, Burgos, Spain., [9]Virgen del Rocio University Hospital, [10]Digestive Department, Hospital Universitario Virgen del Rocío, Sevilla, Spain

Background: Recent studies have highlighted not only the existence but also the clinical relevance of a cholestatic biochemical pattern in patients with MASLD. This phenotype has been associated with differences in liver histology and prognosis, independently of other disease-related features. Considering the role of genetic burden in the development and progression of MASLD, this study aimed to assess the impact of genetic background on MASLD phenotypes defined by the biochemical pattern of liver injury. **Methods:** A total of 879 patients from different centers included in the Spanish HEPAMET Registry with a diagnosis of MASLD were included. Patients were classified according to the SAF score into steatosis or steatohepatitis, and according to fibrosis stage. In addition, patients were categorized based on the presence of a cholestatic biochemical pattern, defined by the formula: (ALT/ALT ULN)/(ALP/ALP ULN) < 2. Patients were genotyped for 60 genetic

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

variants previously associated with MASLD or theoretically involved in pathways related to hepatocellular or cholestatic liver injury. **Results:** Overall, 56% of patients (490/879) showed a cholestatic biochemical pattern. In multivariate analysis adjusted for demographic, clinical and biochemical variables, four genetic variants were independently associated with the cholestatic phenotype, located within or near genes including *PTPRD* [OR 0.10 (0.06-0.18); p = 0.001], *ABCA1* [1.65 (1.07-2.53); p = 0.022], *ASGR1* [1.63 (1.03-2.06); p = 0.039] and *NR1H4* [0.75 (0.53-0.99); p = 0.048]. Moreover, the impact of genetic background differed according to the biochemical phenotype. Among patients with a cholestatic pattern, five SNPs were independently associated with advanced fibrosis. In contrast, among patients with a non-cholestatic phenotype, six different SNPs were associated with advanced fibrosis (Table 1). **Conclusion:** MASLD patients with a cholestatic biochemical pattern display a distinct clinical and genetic profile. Beyond differences in age, sex, metabolic features and liver enzymes, specific genetic variants were independently associated with the cholestatic phenotype, suggesting a potential genetic contribution to this form of disease presentation. Besides, the different SNPs associated with advanced fibrosis across cholestatic and non-cholestatic phenotypes suggest partially divergent genetic determinants of disease progression. These findings reinforce the heterogeneity of MASLD and highlight the potential value of integrating biochemical phenotyping and genetic profiling for refined patient stratification.

1074 | IDENTIFICATION OF TISSUE-OF-ORIGIN RESOLVED BIOMARKER CANDIDATES FOR STEATOSIS, STEATOHEPATITIS, AND FIBROSIS USING AN INTEGRATIVE MULTI-OMICS APPROACH

Yash Bhagat[1], [1]David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Background: With advancements in medications targeting reversal of liver steatosis and fibrosis, the lack of an accurate and economical non-invasive diagnostic test to identify patients with these conditions remains the biggest hurdle in preventing progression to cirrhosis. While FIB-4, liver elastography, and magnetic resonance imaging aid in diagnosis of liver disease, they suffer from a low specificity. Fortunately, advancements in omics have allowed multiplexed screening of serum biomarkers. **Methods:** As such, our study utilizes shotgun proteomics and RNA-sequencing (RNA-seq) in tissues that contribute to steatosis, steatohepatitis and fibrosis, including the liver and adipose, to nominate disease-specific tissue-resolved biomarkers for future diagnostic modelling. **Results:** We first performed ultracentrifugation on cultured monolayers of hepatocellular carcinoma cells (HepG2), primary human preadipocytes (PAd), and in vitro differentiated adipocytes (Ad) individually to obtain their secreted exosomes. Shotgun mass spectrometry on the exosome isolates identified 1,438, 389, and 349 secreted proteins from HepG2, PAd, and Ad, respectively. The 2,176 proteins were enriched in cellular compartment gene ontology annotations of secretory vesicle (p = 2.86x10-95), thus validating their secretion by the tissues of interest. Next, we leveraged cohorts with histologically graded liver biopsies for steatosis, lobular inflammation, hepatocellular ballooning, and fibrosis to define steatosis, steatohepatitis and fibrosis. We first used bulk subcutaneous adipose tissue (SAT) and liver RNA-seq data (nLiver = 267, nAdipose = 217) from the KOBS cohort to find that the transcripts of 890 exosome hepatokines and 28 exosome adipokines significantly correlate with steatosis, steatohepatitis or fibrosis (adjusted p < 0.01). Then, we performed Wilcoxon testing on counts derived from single nucleus RNA-seq data in independent replication cohorts with SAT (KOBS) and liver biopsies (Kim et al., Journal of Hepatology, 2024) (nLiver = 17, nAdipose = 59) and liver histology graded phenotypes to find cell-type-specific correlations for the disease states. Our analysis identified 122, 199, and 135 proteins as potential biomarkers, originating from HepG2, Ad, or Pad, the transcripts of which associated with steatosis, steatohepatitis and fibrosis in a cell-type-specific manner (adjusted p < 0.01). **Conclusion:** Altogether, we combined histologically determined liver phenotypes in cohorts with adipose and liver RNA-seq

data and mass spectrometry-based secreted exosome proteins, which nominated tissue-of-origin resolved biomarkers for our machine learning models targeted to design a non-invasive diagnostic model for steatosis, steatohepatitis and fibrosis.

1075 | ETIOLOGY-SPECIFIC TRANSCRIPTIONAL AND EPIGENETIC PROGRAMS IN HBV-, HCV-, AND NON-VIRAL HEPATOCELLULAR CARCINOMA REVEALED BY ANCESTRY-ADJUSTED MULTI-OMIC PROFILING

Amerti Guta[1] Aditya Bhagwate[1] Daniel O'Brien[2] Lewis Roberts[1] Jean-Pierre Kocher[1], [1]Mayo Clinic, [2]Ambry Genetics

Background: Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death worldwide, yet responses to immune checkpoint inhibitor therapy remain variable and poorly predicted across principal etiologic subtypes: hepatitis B virus (HBV), hepatitis C virus (HCV), and non-viral disease. Each etiology drives hepatocarcinogenesis through distinct biological mechanisms, but the extent to which these differences produce unique transcriptional and epigenetic tumor landscapes, independent of ancestry-related confounding, has not been systematically characterized. **Methods:** We analyzed 325 HCC tumors from the TCGA-LIHC cohort (113 HBV, 48 HCV, 164 non-viral) classified by viral status using Exogene viral read detection. Differential expression analysis was performed using edgeR on TCGA RNA-seq data. Tumor versus normal comparisons were conducted by integrating TCGA tumor RNA-seq data processed through the MAPRSeq pipeline with GTEx normal liver samples. Batch effects were corrected using ComBat. Ancestry-associated genes were excluded to reduce population stratification confounding. Pathway enrichment analysis was performed using ShinyGO and DNA methylation data from TCGA were integrated to assess epigenetic regulation of etiology-specific gene sets. **Results:** The three groups differed significantly in age (HBV mean 53.9 years versus HCV 62.1 years versus non-viral 63.0 years; $p < 0.001$), sex (HBV 78.8% male; $p < 0.001$), racial composition (HBV 92.9% Asian versus HCV and non-viral predominantly White; $p < 0.001$), histologic grade, and fibrosis burden. HBV-associated HCC showed 39 consensus upregulated genes enriched for cell cycle processes (BIRC5, CDC20, TERT, E2F1, MYBL2, UBE2C) and 27 consensus downregulated genes reflecting loss of hepatic detoxification (ADH4, CYP2A6, SULT1B1). HCV-associated HCC showed a dominant immune signature with 81 consensus upregulated genes enriched for interferon-stimulated genes and immunoglobulin loci reflecting intratumoral immune infiltration, and 16 consensus downregulated genes with no pathway enrichment. Non-viral HCC yielded only 2 consensus upregulated genes including CYP17A1, suggesting altered steroidogenic metabolism. A shared pan-tumoral program of cell cycle activation and hepatic metabolic suppression was identified across all subtypes relative to normal liver(fig1&2). DNA methylation analysis revealed group-level epigenetic differences consistent with etiology-specific transcriptional regulation. **Conclusion:** HBV, HCV, and non-viral HCC harbor molecularly distinct transcriptional and epigenetic landscapes. The predominance of immune and interferon signaling in HCV-HCC, cell cycle dysregulation in HBV-HCC, and CYP17A1-associated steroidogenic pathway dysregulation in non-viral HCC define etiology-specific molecular features with implications for biomarker development and therapeutic stratification

1076 | THE IFNL4-PRODUCING GENOTYPE IS ASSOCIATED WITH AN INCREASED RISK OF CIRRHOSIS AND LIVER CANCER IN PATIENTS WITH CHRONIC HEPATITIS C

Alexis Moore[1] Bennett Waxse[2] Keisuke Fukutomi[3] Joshua Denny[2] Barbara Rehermann[4], [1]NIDDK, National Institutes of Health, [2]NHGRI, National Institutes of Health, DHHS, [3]National Institutes of Health, [4]NIH/NIDDK

Background: The interferon lambda 4 protein (IFNL4) is produced by the ancestral rs368234815-ΔG allele. Conversely, the rs368234815-TT/TT genotype causes a frameshift mutation that abrogates IFNL4 production. The rs368234815-TT/TT genotype is only found in humans and was positively selected for after the out-of-Africa migration. As a result, around 70% of people with African ancestry have the IFNL4-producing genotype, compared to around 10-20% of people with Asian ancestry. Paradoxically, the IFNL4-producing genotype impairs spontaneous clearance of hepatitis C virus but

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

has been associated with reduced liver inflammation in those with chronic hepatitis C. **Methods:** We utilized the *All of Us* Research Program to investigate in a large cohort the effect of *IFNL4* genotype on the long-term outcome of chronic liver disease. We identified 17,543 subjects with ICD codes for chronic liver disease (encompassing viral, metabolic, alcohol-associated, autoimmune, and cholestatic etiologies) and 4,189 subjects with ICD codes for chronic hepatitis C. A control cohort consisted of 163,066 subjects without chronic liver disease ICD codes. For all cohorts, time-to-event analyses were performed over a follow-up period exceeding 25 years using a Cox proportional hazards model with liver cirrhosis and liver cancer as separate outcomes. Results were adjusted for age, sex, and inferred genetic ancestry based on principal component analysis. **Results:** In the chronic liver disease cohort, subjects who produce IFNL4 had a 13% higher hazard of liver cirrhosis (HR 1.13, 95% CI 1.01-1.26, $p = 0.033$) and a 64% higher hazard of liver cancer (HR 1.64, 95% CI 1.24-2.17, $p < 0.001$) compared to subjects who do not produce IFNL4. Similar associations were observed in the chronic hepatitis C cohort (cirrhosis: HR 1.20 95% CI 1.003-1.44, $p = 0.046$; liver cancer: HR 1.71, 95% CI 1.18-2.49, $p = 0.005$), but not in the control cohort (cirrhosis: HR 0.97, 95% CI 0.82-1.14, $p = 0.705$; liver cancer: HR 1.34, 95% CI 0.88-2.03, $p = 0.174$). Other chronic liver diseases, including MASLD, MASH, and hepatitis B, showed directionally consistent, but non-significant, hazard ratios when looking at the outcome of liver cancer. This may suggest a broader effect of the IFNL4 genotype on liver cancer risk. **Conclusion:** The IFNL4-producing genotype is associated with a higher risk of liver cirrhosis and liver cancer in patients with chronic hepatitis C, despite previous literature reporting reduced liver inflammation.

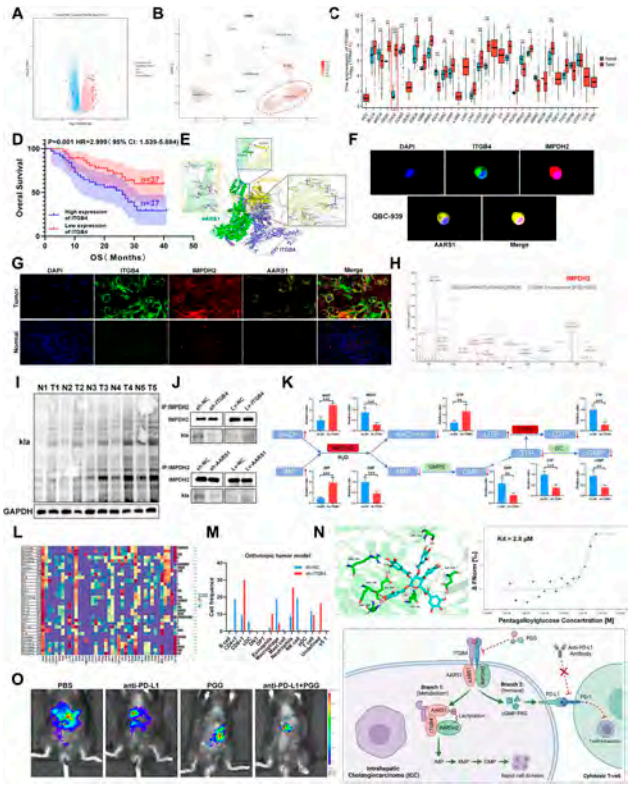
1077 | ITGB4 PROMOTES INTRAHEPATIC CHOLANGIOCARCINOMA PROGRESSION BY REGULATING PURINE METABOLISM AND IMMUNE EVASION VIA MEDIATING LACTYLATION MODIFICATION OF IMPDH2.ITGB4通过介导IMPDH2的乳酸化修饰,调节嘌呤代谢和免疫逃避,促进肝内胆管癌的进展



Taiyang Chen[1] HaiBo Yu[1], [1]People's Hospital of Zhengzhou University

Background: Intrahepatic cholangiocarcinoma (ICC) ranks as the second most prevalent primary liver cancer with steadily rising incidence. Characterized by insidious early symptoms and the absence of specific diagnostic biomarkers, approximately 60%–70% of patients are diagnosed at advanced stages unresectable for radical surgery. Conventional radiotherapy and chemotherapy yield limited therapeutic efficacy. Although immunotherapy has achieved preliminary breakthroughs, low overall response rates and elusive drug resistance mechanisms render ICC a clinically intractable malignancy. Elucidating the unique molecular regulatory mechanisms and immune microenvironment of ICC, is critical to breaking therapeutic barriers and improving patient prognosis.肝内胆管癌(ICC)是第二大流行的原发性肝癌,发病率稳步上升. 其特点是早期症状隐匿,缺乏特异性的诊断性生物标志物,大约60% - 70%的患者被诊断为晚期,无法进行根治性手术. 传统的放化疗治疗效果有限. 尽管免疫治疗已经取得了初步突破,但低总体反应率和难以捉摸的耐药机制使ICC成为临床难治性恶性肿瘤. 阐明ICC独特的分子调控机制和免疫微环境,对打破治疗障碍、改善患者预后至关重要. **Methods:** ICC clinical samples were applied for candidate biomarker screening using single-cell and high-throughput sequencing. Clinical specimens, cell lines and mouse xenograft models were utilized for functional validation combined with clinical prognostic analysis. Transcriptomics, co-IP, mass spectrometry, targeted and untargeted metabolomics were adopted to explore molecular interaction and metabolic pathways. Lactylation modification mechanism was verified via mass spectrometry, molecular docking and site-directed mutagenesis. Immune microenvironment alterations were evaluated by mass cytometry. ITGB4 targeted small molecule inhibitor PGG was identified by virtual screening and MST, and its synergistic anti-tumor efficacy with anti-PD-L1 antibody was validated in preclinical models.ICC临床样本应用单细胞和高通量测序进行候选生物标志物筛选. 利用临床标本、细胞系和小鼠异种移植模型进行功能验证并结合临床预后分析. 采用转录组学、协同ip、质谱、靶向和非靶向代谢组学来探索分子相互作用和代谢途径. 通过质谱分析、分子对接和定点诱变验证了乳酸化修饰机理. 免疫微环境改变用细胞计数法测定. 通过虚拟筛选和MST鉴定ITGB4靶向小分子抑制剂PGG,并通过临床前模型验证其与抗pd - l1抗体的协同抗肿瘤效果. **Results:** ITGB4 is specifically upregulated in ICC and serves as an adverse prognostic indicator. Rather than activating classic signaling pathways, ITGB4 acts as a scaffold protein to recruit AARS1 and bind IMPDH2, inducing K205 lactylation of IMPDH2. This modification triggers purine metabolic reprogramming and activates the cGMP-PKG-PD-L1 axis, ultimately resulting in $CD8^+$ T cell exhaustion and tumor immune evasion. PGG specifically targets ITGB4, and combination treatment with anti-PD-L1 antibody presents potent

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

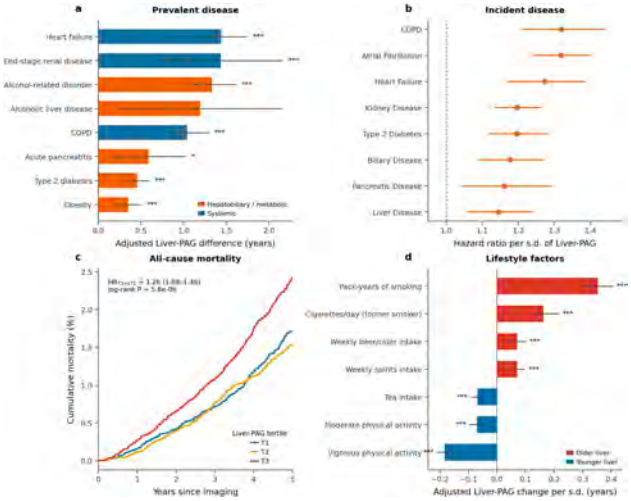
1078 | MRI DERIVED LIVER AGE GAP IS ASSOCIATED WITH PREVALENT OR INCIDENT LIVER DISEASE, MORTALITY, AND LIFESTYLE IN 67,130 UK BIOBANK PARTICIPANTS



Yufeng Wang[1] Zengtian Deng[1] Lixia Wang[1] Abdelrahman Attia[1] Minsun Kwak[2] Saeid Rezaee-Zavareh[3] Stephen Pandol[1] Yibin Xie[1] Hyunseok Kim[1] Debiao Li[1] Ju Dong Yang[4], [1]Cedars Sinai Medical Center, [2]Seoul National University Hospital, [3]Middle East Liver Diseases (MELD) Center, [4]Cedars-Sinai Medical Center

Background: Chronological age incompletely reflects liver health. We developed a deep-learning liver MRI age clock and evaluated whether the resulting liver-predicted age gap, Liver-PAG, captures accelerated liver aging associated with prevalent/incident liver disease, all-cause mortality, and modifiable lifestyle factors. **Methods:** Four-channel abdominal Dixon MRI from 67,130 UK Biobank participants underwent automated liver segmentation. A MedNeXt model was trained to predict chronological age in a strictly healthy reference subset. Liver-PAG was defined as bias-corrected predicted liver age minus chronological age, with positive values indicating an older-appearing liver. Cross-sectional associations with prevalent disease were assessed using covariate-adjusted linear models. Prospective associations with incident disease and all-cause mortality over 5 years were evaluated using Cox models among participants free of the corresponding outcome at baseline, adjusted for age, sex, BMI, smoking, and alcohol use. A Healthy Lifestyle Score, or HLS, was derived by summarizing 108 lifestyle variables across five domains: diet, physical activity, sleep, alcohol use, and smoking. Associations of Liver-PAG with HLS and individual lifestyle factors were tested in adjusted models. **Results:** The model predicted chronological age accurately (mean absolute error 2.75 years; $R^2 = 0.776$). Higher Liver-PAG was observed in alcohol-related disorders (+1.33 years; FDR < 0.001), alcohol-associated liver disease (+1.19 years), type 2 diabetes (+0.46 years; FDR < 0.001), heart failure (+1.44 years), and COPD (+1.04 years) (Panel A). Each SD increase in Liver-PAG was associated with a higher risk of incident liver disease (HR 1.14, 95% CI 1.06–1.24), biliary disease (HR 1.18, 1.09–1.27), type 2 diabetes (HR 1.20, 1.12–1.28), and all-cause mortality (HR 1.15, 1.08–1.22) (Panel B). Compared with the lowest Liver-PAG tertile, the highest tertile was associated with higher 5-year all-cause mortality risk (HR 1.26, 1.08–1.46; log-rank P < 0.001) (Panel C). Higher HLS was associated with lower Liver-PAG (−0.14 years per one-point increase in HLS). Among individual lifestyle factors, greater smoking burden was associated with older-appearing liver age (+0.35 years per SD of pack-years), whereas

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

vigorous physical activity was associated with younger-appearing liver age (−0.18 years per SD) (Panel D). **Conclusion:** A deep-learning derived liver age clock quantifies an organ-specific imaging biomarker of accelerated liver aging. Liver-PAG is associated with prevalent hepatic and systemic disease, incident hepatobiliary and cardiometabolic outcomes, all-cause mortality, and modifiable lifestyle exposures. These findings support Liver-PAG as a scalable, non-invasive imaging biomarker for liver and systemic health risk stratification.

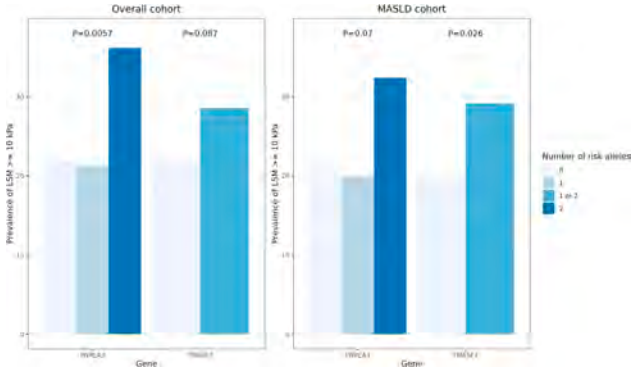
1079 | PNPLA3 GENOTYPE IS ASSOCIATED WITH INCREASED PROGRESSION TO CIRRHOSIS INDEPENDENT OF LIVER STIFFNESS MEASUREMENT BY VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY IN STEATOTIC LIVER DISEASE



Kira Zhao[1] Vincent Chen[1], [1]University of Michigan

Background: *PNPLA3*-rs738409 and *TM6SF2*-rs58542926 genotypes are associated with increased risk of cirrhosis/fibrosis and major adverse liver outcomes (MALO) in steatotic liver disease (SLD). Genetics provides prognostic information beyond FIB4 and histologic fibrosis stage for MALO risk. However, whether genetics improves upon vibration-controlled transient elastography (VCTE) for development of advanced liver disease is not known. **Methods:** This was a single-center study of patients with SLD at Michigan Medicine who underwent VCTE and genotyping. The primary predictors were *PNPLA3*-rs738409 and *TM6SF2*-rs58542926 genotype. The primary outcomes were new diagnosis of cirrhosis, and MALO defined as hepatic decompensation, hepatocellular carcinoma, or liver-related death. Associations were modeled as Cox proportional hazards models with effects shown as hazard ratios (HR). Models were unadjusted or adjusted for age, sex, body mass index, diabetes status, and principal components 1-5 to account for genetic ancestry. **Results:** The cohort included 875 patients, of whom 753 had MASLD and 122 had ALD. The median age was 57 years; 49% were female and 84% were white. Median follow-up was 47 months (IQR 16-77 months). The mean body mass index was 31.5 kg/m^2 and 47%, 75%, and 72% had type 2 diabetes, dyslipidemia, and hypertension, respectively. Median liver stiffness measurement (LSM) was 6.1 kPa, with 201 (23%) having LSM >= 10 kPa and 93 (11%) having LSM >= 15 kPa. The *PNPLA3*-rs738409-G allele was associated with a higher proportion of LSM >= 10 kPa (36% vs. 22% for GG vs. CC alleles, p = 0.0057); this remained significant in multivariable models. *TM6SF2*-rs58542926-T carriage had a borderline significant association with LSM >= 10 kPa (29% vs. 22% for CC vs. CT/TT alleles, p = 0.087). After exclusion of patients with alcohol-associated liver disease (ALD), the association between *PNPLA3* genotype and LSM >= 10 kPa lost significance (p = 0.07) while that between *TM6SF2* genotype and LSM >= 10 kPa became significant (29% vs. 20% for CC vs. CT/TT alleles, p = 0.026). *PNPLA3*-rs738409-GG was associated with greater incidence of cirrhosis diagnosis (HR 2.04 [95% CI 1.18-3.51] vs. CC genotype, p = 0.010); this association remained significant in a multivariable model. After additional adjustment for baseline LSM, the association was attenuated but remained significant (HR 1.78 [95% CI 1.01-3.15], p = 0.048). *PNPLA3* genotype was not associated with incident cirrhosis in patients with baseline LSM < 10 kPa or after excluding ALD patients. *TM6SF2* genotype was not associated with incident cirrhosis. Neither *PNPLA3* nor *TM6SF2* genotype was associated with MALO. **Conclusion:** In patients with SLD, *PNPLA3* genotype associated with higher baseline LSM by VCTE, and increased risk of progression to cirrhosis independent of baseline LSM.

1080 | DIVERGENT EFFECTS ON HISPANIC (AMERINDIAN) ANCESTRY ON DISEASE SUSCEPTIBILITY AND HISTOLOGIC SEVERITY IN MASLD

Tae-Hwi Schwantes-An[1] Jie Yao[2] Callie Zaborenko[1] Jingyi Tan[2] Marco Abreu[1] Kent Taylor[2] Matthew Budoff[2] Xiuqing Guo[2] Samer Gawrieh[1] Aaron Hakim[3] Jerome Rotter[2] Naga Chalasani[4] Brent Neuschwander-Tetri[5], [1]Indiana University School of Medicine, [2]Lundquist Institute, [3]Beth Israel Deaconess Medical Center, [4]Indiana University Medical Center, [5]Saint Louis University

Background: Hispanic individuals exhibit a higher prevalence of metabolic dysfunction–associated steatotic liver disease (MASLD), a phenomenon largely attributed to genetic factors such as *PNPLA3* variants. However, whether Hispanic (Amerindian [AMR]) ancestry influences disease risk and histologic severity or phenotype is not fully understood. We interrogated AMR ancestry– MASLD prevalence and severity associations across population-based and biopsy-confirmed cohorts. **Methods:** We analyzed the association between genetically inferred proportion of AMR ancestry and MASLD phenotypes in two complementary datasets: (1) the Multi-Ethnic Study of Atherosclerosis (MESA), a population-based cohort, and (2) the NASH CRN, liver biopsy-confirmed cohort of MASLD patients. Multivariable logistic regression models adjusting for age, sex, body mass index, and diabetes were used to assess associations between AMR ancestry (continuous proportion) and MASLD presence (MESA) or histologic features (NASH CRN), including steatosis, lobular inflammation, ballooning, NAS ≥ 4, and advanced fibrosis. Mediation by *PNPLA3* genotype was evaluated. **Results:** In MESA, AMR ancestry was strongly associated with MASLD (OR 7.33 [5.15–10.4] in all participants; OR 4.47 [2.45–8.13] and within Hispanic individuals (both $P < 0.001$). Adjustment for *PNPLA3 G-allele* attenuated the ancestry effect by >50% (OR falls from 4.47 to 2.17 for AMR ancestry), indicating partial mediation via *PNPLA3* .In contrast, in the NASH CRN cohort, increasing AMR ancestry was associated with **lower odds of steatosis** in the entire cohort (OR 0.5 [0.3–0.8], $P = 0.003$) and within Hispanic individuals (OR 0.3 [0.1–0.9], $P = 0.04$), but **higher odds of lobular inflammation** in the entire cohort (OR 1.8 [1.1–2.8], $P = 0.01$) and within Hispanic individuals (OR 3.1 [1.0–9.1], $P = 0.04$). No significant associations were observed for advanced fibrosis, NAS ≥ 4, ballooning, or portal inflammation. **Conclusion:** These findings suggest a **cohort-dependent divergence** in ancestry–MASLD associations. While AMR ancestry confers increased susceptibility to MASLD at the population level, with significant contribution from *PNPLA3* variation, a biopsy-based cohort reveals a different phenotype characterized by lower steatosis but higher inflammation.

Table 1: Relationship with AMR Ancestry and the risk for MASLD susceptibility and histological severity

		All ancestry groups		Self-reported Hispanic group	
Study	Phenotypes	OR (95% C.I.)	Pvalue	OR (95% C.I.)	Pvalue
MESA	MASLD	7.33 (5.15-10.4)	<0.001	4.47 (2.45-8.13)	<0.001
NASH CRN	Advanced Fibrosis within MASLD	0.6 (0.3-1.0)	0.06	1.2 (0.5-2.8)	0.68
NASH CRN	NAS ≥ 4 within MASLD	1.0 (0.6-1.6)	0.97	1.1 (0.4-3.4)	0.88
NASH CRN	Steatosis within MASLD	0.5 (0.3-0.8)	2.67E-03	0.3 (0.1-0.9)	0.04
NASH CRN	Lobular Inflammation within MASLD	1.8 (1.1-2.8)	0.01	3.1 (1.0-9.1)	0.04
NASH CRN	Portal Inflammation within MASLD	0.8 (0.4-1.4)	0.39	2.7 (0.5-13.3)	0.23
NASH CRN	Ballooning within MASLD	1.3 (0.8-2.1)	0.32	2.1 (0.7-6.5)	0.2

1081 | CLINICAL CHARACTERISTICS AND REAL-WORLD OUTCOMES OF ENZYME REPLACEMENT THERAPY IN PATIENTS FROM THE US WITH LYSOSOMAL ACID LIPASE DEFICIENCY: DATA FROM THE INTERNATIONAL LAL-D REGISTRY

Thomas Kerr[1] Lorenzo D'Antiga[2] Daniel Staub[3] Sophie Kitchen[3] Florian Abel[3] William Balistreri[4], [1]UT Southwestern, [2]University of Milano–Bicocca, [3]Alexion, AstraZeneca Rare Disease, [4]Cincinnati Children's Hospital Medical Center

Background: Lysosomal acid lipase deficiency (LAL-D) is a rare, progressive autosomal recessive lysosomal storage disease, leading to progressive liver disease and atherogenic dyslipidemia. Enzyme replacement therapy (ERT) with sebelipase alfa is available since 2015, but US-specific real-world data are limited. We aimed to characterize the disease burden, diagnostic delay, and outcomes of US patients with LAL-D enrolled in the International LAL-D Registry. **Methods:** We conducted a retrospective analysis of data from US patients who were not included in a clinical trial with sebelipase alfa enrolled in the International LAL-D Registry (NCT01633489) as of March 2, 2026. Descriptive analyses assessed demographics, diagnostic delay, longitudinal liver and lipid parameters and liver histology. **Results:** Of 64 US registry patients, 38 met the inclusion criteria. Median age at diagnosis and first reported symptom was 13.38 years and 7.5 years, respectively (n = 34), the median time from symptom onset to diagnostic testing was 4.27 years (n = 27). Hepatomegaly and splenomegaly raised the suspicion of LAL-D in 13/38 and 7/38 patients, respectively.20 patients had baseline liver biopsy results; mixed macro- and microvesicular steatosis and microvesicular steatosis only were most frequent (7/20, 35% and 6/20, 30%, respectively). Fibrosis stage was reported for 7/20 patients, with 43% showing stage ≥ 3 fibrosis, including cirrhosis (1/7).Overall, 36/38 (94.7%) participants received sebelipase alfa.Among treated patients with paired alanine aminotransferases (ALT) data (n = 24), mean ALT decreased from 2.90×ULN at baseline to 1.21×ULN at last follow-up, with normalization increasing from 4.2% to 54.2% and ALT ≥ 3×ULN decreasing from 37.5% to 4.2%. AST showed similar improvement. All patients with paired biopsies (4/4) had decreased fibrosis stage, and among those with paired abdominal imaging (n = 12), 7/12 (58.3%) had hepatomegaly at baseline that resolved by last follow-up.Dyslipidemia was frequent, with elevated LDL in 34.2% (12/38), and elevated triglycerides in 31.6% (12/38) of patients. In patients not receiving lipid-modifying therapy (N = 10), dyslipidemia was more pronounced, with 90% exhibiting elevated LDL-C (> 130 mg/dL), including 60% with levels > 160 mg/dL; mean LDL-C was 187.7 mg/dL and mean HDL-C was 34.0 mg/dL. Mean LDL-C decreased from 187.7 mg/dL to 140.2 mg/dL, mean HDL-C increased from 34.0 mg/dL at baseline to 48.1 mg/dL at last follow-up. **Conclusion:** US patients with LAL-D commonly present with liver involvement and dyslipidemia and experience a clinically meaningful diagnostic delay. Sebelipase alfa ERT is associated with sustained improvements in liver and lipid parameters.

1082 | GENETIC SUSCEPTIBILITY TO HEPATITIS C–ASSOCIATED HEPATOCELLULAR CARCINOMA ACROSS DIVERSE ANCESTRIES: A GWAS FROM THE MILLION VETERAN PROGRAM

Theodore Feldman[1] Lauren Carter[2] Kaelyn Nannini[2] Chunlei Zhang[3] Karlynn Dulberger[2] Meghana Yellanki[2] David Kaplan[4] Gyorgy Baffy[2] Timothy Morgan[5] Daniel Dochtermann[6] Saiju Pyarajan[6] Mary Brophy[3] Nathanael Fillmore[3] Nhan Do[2], [1]VA Boston Healthcare System; Harvard Medical School, [2]VA Boston Healthcare System, [3]VA Boston Healthcare System; Boston University School of Medicine, [4]University of Pennsylvania, [5]VA Long Beach Healthcare System, [6]Center for Data and Computational Sciences (C-DACS), VA Boston Healthcare System

Background: Host genetic factors contributing to progression from chronic hepatitis C virus (HCV) infection to hepatocellular carcinoma (HCC) remain

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

incompletely understood. We performed a multi-ancestry genome-wide association study (GWAS) to identify susceptibility loci associated with HCV-related HCC (HCV-HCC) within the Million Veterans Program (MVP). **Methods:** We analyzed 2,628 HCV-HCC, 11,761 HCV-only, and 2,091 HCC-only participants from the MVP. GWAS analyses were performed using Scalable and Accurate Implementation of GEneralized mixed model (SAIGE) with adjustment for age, sex and genetic ancestry. Analyses included Cosmopolitan and ancestry-stratified Harmonized Ancestry and Race/Ethnicity (HARE) cohorts including African American (AFR), European (EUR), and Hispanic (HIS) groups. Fine mapping, credible set construction, pathway enrichment, overrepresentation analyses, and linkage disequilibrium (LD)-based trait clustering were subsequently performed. **Results:** The strongest associations localized to immune-related loci within the major histocompatibility complex (MHC) region. Variants in HLA-DQB1/DQB2 differentiated HCV-HCC from both HCV-only and HCC-only cohorts at genome-wide significance. In the Cosmopolitan cohort, rs3519547 (HLA-DQB1) differentiated HCV-HCC from all controls (P = 3.08×10^-19, OR 0.67 [0.62–0.73]). Variants in interferon signaling genes, including IFNL4/IFNL3P1, were also significantly associated with HCV-HCC. rs1418044546 demonstrated genome-wide significance in the comparison of HCV-HCC versus all controls (P = 1.34×10^-9, OR 1.22 [1.14–1.30]). Additional significant associations involved CD81-AS1, MTCO3P1, DMD, SAMD5, PTPRD, KLHL8, and TERT. Previously reported MASLD-associated variant rs3747207 in PNPLA3 differentiated HCV-HCC from HCC-only cohorts in both Cosmopolitan and EUR analyses. Fine mapping resolved several loci into small or single-variant credible sets with high posterior inclusion probabilities, supporting potential causal signals. Pathway analyses demonstrated modest enrichment of interferon signaling, IL2-STAT5 signaling, p53-related pathways, and metabolic pathways, although none reached predefined significance thresholds. Trait clustering identified overlapping viral, inflammatory, and metabolic phenotypes. **Conclusion:** HCV-related hepatocarcinogenesis demonstrates a complex multi-ancestry genetic architecture enriched for immune-regulatory, interferon-signaling, and metabolic susceptibility loci. These findings support interactions between antiviral immunity and metabolic-inflammatory pathways in HCV-HCC progression and identify candidate loci for future mechanistic and translational investigation.

1083 | *PNPLA3 I148M* RNA EDITING OUTPERFORMS *PNPLA3* SILENCING IN IMPROVING HEPATOCYTE LIPID METABOLISM *IN VITRO* AND *EX VIVO*

Ginnie Yang[1] Yuan Yin[1] Chikdu Shivalila[1] Genliang Lu[1] Stearne Briem[1] Michael Byrne[1] Alyse Faraone[1] Naoki Iwamoto[1] Tomomi Kawamoto[1] Richard Looby[1] Frank Favaloro[1] Stephany Standley[1] Suma Veeramachineni[1] Hailin Yang[1] Hui Yu[1] Pachamuthu Kandasamy[1] Chandra Vargeese[1] Erik Ingelsson[1], [1]Wave Life Sciences

Background: *PNPLA3 I148M* is both a gain- and loss-of-function variant that disrupts hepatic lipid homeostasis and retinol metabolism and is associated with substantially increased risk of liver-related deaths, including from MASH. We developed RNA editing oligonucleotides, or AIMers, to edit the base sequence of *PNPLA3 I148M* transcripts to restore functional protein. Emerging evidence shows that PNPLA3 plays an important role in hepatic lipid metabolism. For the treatment of *PNPLA3 I148M* liver disease, an RNA editing approach that restores PNPLA3 enzymatic function may be preferable to silencing *PNPLA3,* which causes a loss of function. **Methods:** We synthesized GalNAc-conjugated AIMers to edit the I148M variant in hepatocytes and compared their impact to silencing PNPLA3 by GalNAc-siRNA. GalNAc-AIMer editing efficiency was quantified by Sanger sequencing in human homozygous *PNPLA3 I148M* primary hepatocytes. The impact of editing or silencing on intracellular lipid droplet density was evaluated using the human homozygous I148M hepatocytes in a HEPATOPAC system and in long-term primary human hepatocyte monolayer cultures. Using an *ex vivo* human *PNPLA3 I148M* model, we compared the impact of PNPLA3

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

AIMers to PNPLA3 siRNA on lipid metabolism, fibrosis, mitochondrial function, and inflammation. Lipid metabolic pathway flux was also compared between M/M, I/M, and I/I human hepatocytes. Mice were also dosed subcutaneously with GalNAc-AIMers, and tissue concentrations of PNPLA3 AIMers in liver were quantified by ELISA after one week. **Results:** The most effective AIMers directed potent (EC_{50} 12 nM) and efficient (~70%) editing of *PNPLA3* transcripts. In the HEPATOPAC system, PNPLA3 GalNAc-AIMers significantly decreased lipid droplet density compared to mock treatment ($p < 0.0001$), whereas PNPLA3 GalNAc-siRNA did not have a significant effect. In long-term cultures of human primary hepatocytes, ~50% PNPLA3 RNA editing corresponded with a substantial lowering of lipid droplet density. The impact of PNPLA3 AIMer on lipid metabolism, inflammation, and fibrosis pathways will be presented. In mice expressing only wild-type mouse *Pnpla3*, GalNAc-AIMers dosed subcutaneously reached up to ~1,000 µg/g in liver. **Conclusion:** These data demonstrate that AIMers supporting *PNPLA3 I148M* editing restore functional PNPLA3 protein, decrease fat content in hepatocytes, and outperform *PNPLA3* silencing in lowering lipid density. PNPLA3 GalNAc-AIMers dosed in mice reached concentrations expected to yield substantial RNA editing based on in vitro experiments in hepatocytes. Overall, these data support continued advancement of AIMers for the treatment of *PNPLA3 I148M* liver disease, and we expect to file a CTA to advance this program in 2026.

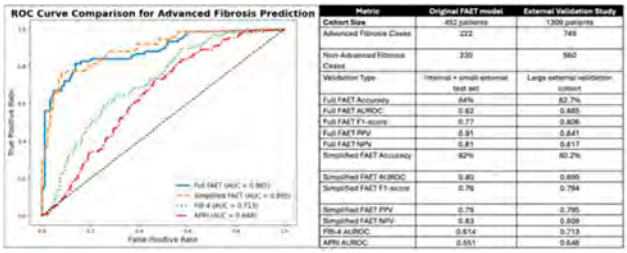
1084 | EXTERNAL VALIDATION OF THE SIMPLE MACHINE LEARNING MODEL (FAET SCORE) FOR PREDICTION OF ADVANCED FIBROSIS IN A LARGE BIOPSY-PROVEN MASLD PATIENT COHORT



Ashok Kumar Choudhury Radhika Sharma[1] Shobha Sharma[2] Archana Rastogi[1] Sandip Kumar[1] Tapan Gandhi[2] Manoj Kumar[1] Shiv Kumar Sarin[1] Bishnupriya Sahoo[3], , [1]Institute of Liver and Biliary Sciences, [2]Indian Institute of Technology Delhi, [3]SGT University, Faculty of Medicine

Background: MASLD with fibrosis associated with disease progression, liver related events and mortality. Commonly used non-invasive FIB-4 and APRI limited by accuracy and our previous study showed a simple Fibrosis Assessment using Extra Trees (FAET) score has a better accuracy for prediction of advanced fibrosis non-invasively from simple parameters using AI. We performed external validation of both the FAET model and the simplified score in a large biopsy-proven MASLD cohort. **Methods:** This retrospective medical records of biopsy proven 1309 MASLD patients were analyzed. Patients were classified into non-advanced fibrosis (F0-F2, NAF) and advanced fibrosis (F3-F4, AF) groups. External validation of the original 13-feature FAET model and the simplified 5-feature FAET simple model was performed for prediction of advanced fibrosis. A comparative ROC analysis with FIB-4, APRI and LSM from VCTE was performed. Calibration analysis, SHAP explainability analysis, decision curve analysis, and repeated stratified cross-validation were used to evaluate model reliability and clinical applicability. **Results:** A total of 1309 biopsy-proven MASLD patients [F0-325, F1-117, F2-118, F3-118 and F4-631 patients] with analysis cohort as AF-749 (57.2%) and NAF-560 (42.8%). Patients with advanced fibrosis were older and had significantly lower hemoglobin and platelet counts, along with higher AST, ALP, GGT, and bilirubin levels. The externally validated full 13-feature FAET model showed strong predictive performance with an AUROC of 0.885, accuracy of 82.7%, F1-score of 0.806, sensitivity of 77.3%, specificity of 87.4%, PPV of 84.1%, and NPV of 81.7%. The simplified 5-feature FAET model, which included age, presence of diabetes mellitus, platelet count, AST, and total cholesterol demonstrated a discrimination with AUROC of 0.895, accuracy of 80.2%, and F1-score of 0.784. The simplified FAET models performed better than conventional fibrosis scores i.e. FIB-4 (AUROC 0.713) and APRI (AUROC 0.648). Calibration analysis demonstrated good agreement between predicted and observed probabilities, while decision curve analysis showed favorable clinical utility across clinically relevant threshold probabilities. Cross-validation further confirmed stable and reproducible model performance. **Conclusion:** External validation demonstrated excellent performance of the FAET framework consisting simple parameters (age, DM, platelet count, AST, and total cholesterol) hold valid and accurate. Simple and routinely available clinical and biochemical parameters in this FAET model with excellent discriminatory ability may be better tool for screening high-risk MASLD patients over and above the existing

1085 | ENDOTHELIAL IDENTITY COLLAPSE AND RNA STRUCTURAL REPROGRAMMING IN HEPATOCELLULAR CARCINOMA: A TCGA-LIHC TRANSCRIPTOMIC AND RNAFOLD-BASED DISCOVERY OF DRUGGABLE RNA TARGETS

Yana Joshi[1] Ayanjeet Chowdhury[2] Sharvari Kulkarni[2],
[1]Henry M. Jackson High School, [2]BDG Life Sciences

Background: Hepatocellular carcinoma (HCC) is the most common primary liver malignancy and remains a major cause of cancer-related mortality worldwide. Although transcriptomic profiling has identified widespread gene dysregulation in HCC, expression changes alone do not fully explain post-transcriptional mechanisms that contribute to tumor progression. This study integrated transcriptomic analysis with RNA secondary structure prediction to identify endothelial-associated, structurally distinctive RNA targets in HCC. **Methods:** Publicly available RNA-sequencing data and clinical annotations from the TCGA Liver Hepatocellular Carcinoma (TCGA-LIHC) cohort were obtained through UCSC Xena. Primary Tumor samples (n = 371) were compared with Solid Tissue Normal samples (n = 50). Differential expression analysis was performed in R using the limma empirical Bayes framework with Benjamini-Hochberg false discovery rate correction. Genes with false discovery rate < 0.05 and absolute log2 fold change ≥ 1 were considered significant. Candidate genes were prioritized based on statistical significance and endothelial relevance. The 3′ untranslated region sequences of the top five targets were retrieved using Ensembl BioMart and analyzed with ViennaRNA RNAfold to evaluate minimum free energy and ensemble diversity. **Results:** A total of 3,690 genes were significantly dysregulated in HCC. Endothelial-associated genes CLEC4M, CLEC4G, STAB2, and BMPER were strongly downregulated, with log2 fold changes of -8.38, -8.17, -7.18, and -5.79, respectively, consistent with loss of normal sinusoidal endothelial identity. GABRD was markedly upregulated (log2 fold change +4.33). RNA secondary structure analysis showed substantial heterogeneity across candidate 3′-UTRs. BMPER demonstrated the most extreme structural profile, with minimum free energy of -1255.1 kcal/mol and ensemble diversity of 923.19, suggesting a highly stable yet structurally plastic regulatory region. STAB2 and CLEC4M also displayed pronounced structural complexity, whereas GABRD exhibited the lowest conformational diversity. **Conclusion:** HCC is characterized not only by extensive transcriptomic dysregulation but also by marked RNA structural remodeling in selected vascular- and microenvironment-associated transcripts. These findings identify BMPER, STAB2, CLEC4M, CLEC4G, and GABRD as candidate RNA-based biomarkers and potential druggable RNA targets in HCC, supporting future structural validation and RNA-directed therapeutic investigation.

1086 | SPATIAL TRANSCRIPTOMICS REVEALS SEX-SPECIFIC MOLECULAR ZONATION SIGNATURES IN F2 MASLD FIBROTIC LIVERS

Mohamed Abdelnabi[1] Aydin Herik[1] Wagdi Almishri[2] Konstantin Koro[1] Erika Prando-Munhoz[1] Mark Swain[1] Henry Nguyen[3], [1]University of Calgary, [2]Cumming School of Medicine | University of Calgary, [3]University of Calgary Cumming School of Medicine

Background: Metabolic dysfunction–associated steatotic liver disease (MASLD) is a growing global health issue, affecting approximately 30% of adults worldwide and projected to impact one in three Canadians within five years. The disease includes a spectrum of liver pathology including steatosis, inflammation, fibrosis, and tumor development, with fibrosis being the main determinant of progression and adverse outcomes. MASLD pathogenesis is complex and multifactorial, with limited therapies, highlighting the need to better understand its mechanisms. Sexual dimorphism contributes to MASLD pathogenesis and fibrosis progression but is often overlooked in clinical and translational studies. Using the Calgary Liver Unit biobank, we sought to investigate sex-specific signatures in MASLD patients with F2-stage fibrosis, a transition stage linked to higher progression risk. **Methods:** We profiled >18,000 protein-coding genes using the GeoMx Digital Spatial Profiler on FFPE liver biopsies from 14 MASLD patients all with F2 liver fibrosis (7 males, 7 females). Inclusion criteria included histological confirmation based on the NAFLD Activity Score (NAS) assessed on FFPE liver biopsy specimens and independently reviewed by a pathologist, patient age between 46 and 70 years, and absence of other chronic liver diseases (e.g., viral hepatitis, autoimmune hepatitis, or inherited/metabolic liver disorders). Exclusion criteria included alcohol misuse, insulin therapy, use of oral hypoglycemic agents, and weight-loss medications (including GLP-1 receptor agonists). Two patients (one male and one female) were excluded due to inadequate biopsy quality, resulting in a final cohort of 14 patients. Regions of interest were selected and annotated as Portal and Non-Portal. Data were analyzed in R (v4.4.2), including quality control, normalization, batch correction, differential expression, enrichment, and clinical association analysis. **Results:** We identified significant sex-associated transcriptomic differences in MASLD across both non-zonal and zone-specific analysis. Global or non-zonal signatures (174 genes, FDR <0.05) were enriched for pathways related to antigen processing and presentation, mineral absorption, and fatty acid metabolism. Sex-specific zonal signatures in portal zones included neutrophil degranulation, phagocytic activity, and cytoskeletal remodeling (54 genes, FDR < 0.05), while in Non-Portal zones they comprised cholesterol metabolism, oxidative phosphorylation, and glycolysis (468 genes, FDR < 0.05). Notably, the global sex signature correlated positively with peripheral lymphocytes, and neutrophils in women, but negatively in men. **Conclusion:** Our findings suggest sexual dimorphism at both global and zonation-specific levels in MASLD liver biopsies, potentially influencing disease progression differently in men and women.

1087 | A MISSENSE VARIANT IN *DNAJC22* REDUCES HEPATOCYTE LIPID ACCUMULATION AND PROTECTS AGAINST STEATOTIC LIVER DISEASE

Aaron Hakim[1] James Park[2] Brian Hobbs[3] Niek Verweij[3] Michael Cho[2] Naga Chalasani[4] Tae-Hwi Schwantes-An[5] Jerome Rotter[6] John Doench[7] Rajat Gupta[2], [1]Beth Israel Deaconess Medical Center, [2]Brigham and Women's Hospital, [3]Regeneron Genetics Center, [4]Indiana University Medical Center, [5]Indiana University School of Medicine, [6]The Lundquist Institute for Biomedical Innovation at Harbor-UCLA Medical Center, [7]Broad Institute

Background: The accumulation of lipid droplets within hepatocytes plays a causal role in the pathogenesis of steatotic liver disease. We previously identified that CRISPR Cas9-mediated knockout of *DNAJC22* reduced lipid droplet accumulation in hepatocytes. Additionally, a rare (allele frequency ~1%) missense variant in *DNAJC22* (rs146774114, p.A163T) protected against chronic liver disease in UK Biobank, FinnGen, and Million Veteran Program. It remains unknown whether the p.A163T variant reduces lipid droplet accumulation in hepatocytes. Here, we used pooled cytosine base editing to compare the effect of the p.A163T variant in *DNAJC22* versus complete knockout of *DNAJC22* on hepatic lipid

accumulation. We also explored whether *DNAJC22* p.A163T protected against chronic liver disease in the Indiana University (IU) Biobank and the Geisinger Health System (GHS) MyCode cohort. **Methods:** We optimized a base editing protocol to introduce the *DNAJC22* p.A163T mutation into HuH7 cells using mRNA nucleofection of the cytosine base editor BE4max. The pool of mutant and wildtype cells was incubated with oleic acid to stimulate lipid droplet accumulation; lipid droplets were stained with BODIPY$^{493/503}$, and cells were sorted into five equal bins using FACS based on degree of lipid droplet accumulation. Next-generation sequencing was used to determine the fraction of variant-edited cells relative to wildtype in each bin. We performed similar experiments to introduce a premature stop codon (p.Q164X) or synonymous control mutation (p.L172L) in *DNAJC22*. In the IU and GHS biobanks, we evaluated the association of *DNAJC22* p.A163T with chronic liver disease by ICD-10 codes using Firth penalized logistic regression. **Results:** We achieved a >25% editing rate of the p.A163T variant with a low rate of off-target mutations. There was a dose-dependent enrichment of p.A163T-edited cells in bins with successively lower lipid droplet accumulation (log_2fold change -0.55, p = 1.2x10^{-09}). The premature stop codon in *DNAJC22* had a larger impact on reducing lipid droplet accumulation compared to the p.A163T missense variant (log_2fold change -1.29, p = 2.57x10^{-10}). The synonymous control mutation did not impact lipid droplet accumulation (log_2fold change = -0.05, p = 0.165). *DNAJC22* p.A163T reduced risk of chronic liver disease in IU Biobank (OR = 0.57, p = 2.3x10^{-02} , n = 1,033 cases, n = 3,239 controls) and in the GHS cohort (OR = 0.89, p = 5.1x10^{-03}, n = 22,185 cases, n = 103,006 controls). **Conclusion:** Complete loss-of-function of *DNAJC22* had a larger cellular phenotypic effect on lipid droplet accumulation than the p.A163T variant. This suggests that p.A163T is a partial loss-of-function mutation. Given that the *DNAJC22* p.A163T variant is associated with reduced liver disease risk across multiple human genetic biobanks, complete therapeutic silencing of *DNAJC22* may have even stronger protective effects.

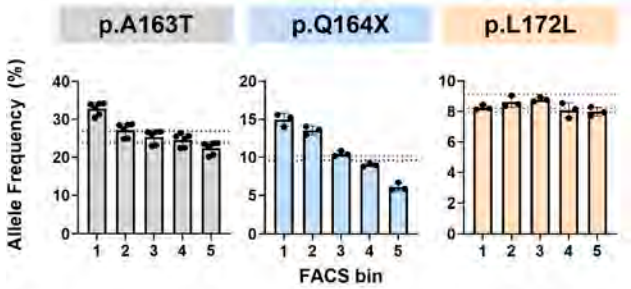

Figure 1: Frequency of base-edited variant in *DNAJC22* relative to wild type. Bin 1 reflects the lowest and Bin 5 reflects the highest lipid droplet accumulation. Dotted lines reflect the frequency of the variant in the unsorted population per replicate

1088 | SERUM DITHIOTHREITOL-OXIDIZING CAPACITY (DOC) AS A PAN-ETIOLOGY BIOMARKER FOR CHRONIC LIVER DISEASE, INDEPENDENT OF ALT LEVELS

Zhenhua Zhang[1] Zhenhua Zhang[1] Chunhui Tao[1] Pengyue Zhang[1] Zhengqi Gao[1] Lumin Yang[2] Jinsong Zhang[2], [1]Department of Infectious Diseases, the Second Affiliated Hospital of Anhui Medical University, [2]Anhui Agricultural University

Background: Dithiothreitol-oxidizing capacity (DOC) as a novel serum biomarker developed by our group has already shown excellent monitoring capability across all stages of chronic hepatitis B. This study aimed to systematically evaluate the monitoring performance and clinical applicability of DOC in chronic liver disease (CLD) patients with different etiologies. **Methods:** Serum DOC was measured in healthy controls and patients with autoimmune liver disease (AILD), chronic hepatitis C (CHC), alcohol-associated liver disease (ALD), and metabolic dysfunction–associated steatotic liver disease (MASLD). Diagnostic performance, ability to identify disease progression risk and clinical utility of DOC were assessed using receiver operating characteristics (ROC) curve, sensitivity at 95% specificity, stratified and correlation analyses, etc. **Results:** DOC showed robust monitoring performance across the four CLD cohorts and retained effective in CLD patients with normal alanine aminotransferase (ALT), with area under the ROC curve of 0.991 (AILD), 0.958 (CHC), 0.920 (ALD), and 0.837 (MASLD), and sensitivities at 95% specificity of 93.44%, 83.61%, 78.31%, and 60.68%, respectively. DOC levels increased from non-cirrhosis to cirrhosis and were significantly correlated with aspartate aminotransferase-to-platelet ratio index (APRI) (r = 0.47, P < 0.0001) and fibrosis-4 index (FIB-4) (r = 0.48, P < 0.0001). Furthermore, DOC demonstrated superior rule-in and rule-out performance (positive likelihood ratios, LR+ ≥ 15.51; negative likelihood

ratios, LR− ≤ 0.33), greater net clinical benefit, and improved identification of disease progression risk. Combined use of DOC and ALT enhanced clinical monitoring and facilitated identification more severe disease stages. **Conclusion:** DOC demonstrated strong monitoring performance and clinical applicability across diverse CLD etiologies, particularly in CLD patients with normal ALT levels, supporting its role as a complementary biomarker for CLD screening, monitoring and risk assessment.

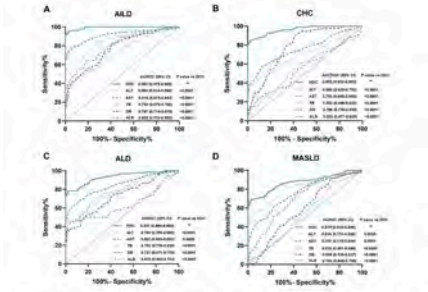

Figure 1. ROC analyses of the AILD (A), CHC (B), ALD (C) and MASLD (D) patients respectively.

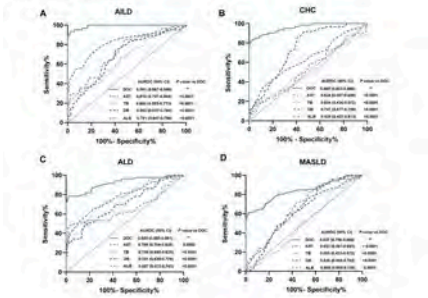

Figure 2. ROC analyses of the AILD (A), CHC (B), ALD (C), and MASLD (D) patients with normal ALT levels.

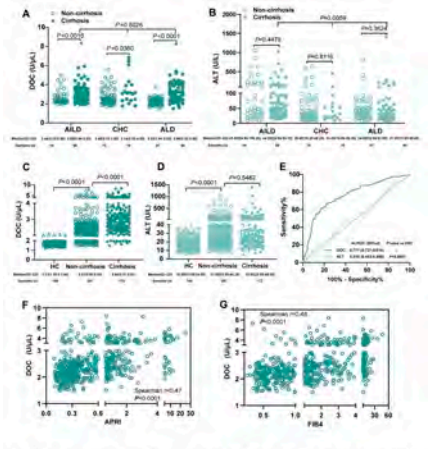

Figure 3. Correlation and stratified analysis of DOC with CLD severity. (A-B) Comparison of DOC (A) and ALT (B) levels between non-cirrhosis and cirrhosis in AILD, CHC, and ALD patients. (C-D) Comparison of DOC (C) and ALT (D) levels between HC, non-cirrhosis and cirrhosis in all CLD patients. (E) ROC analyses of DOC and ALT in non-cirrhosis and cirrhosis patients. (F-G) Spearman correlation analysis between DOC and APRI (F) or FIB-4 (G) in CLD patients.

1089 | ALLAGILE SYNDROME-RELATED VARIANTS ASSOCIATED WITH ADULT CHOLESTATIC PHENOTYPES IN THE SETTING OF INTRAHEPATIC CHOLESTASIS OF PREGNANCY (ICP) OR DRUG INDUCED LIVER INJURY (DILI). A CASE SERIES.

Fabian Rodas[1] Sarvanand Patel[2] Carmen Landaverde[3] Prasun Jalal[4] Youseph Karouni[4], [1]University of Texas San Antonio/The Texas Liver Institute, [2]The Texas Liver Institute, [3]University of Texas San Antonio/The Texas Liver Instutute, [4]Baylor College of Medicine

Background: Intrahepatic cholestasis of pregnancy (ICP) was first described in 1999 in patients heterozygous for MDR3 deficiency.(1). Since then, growing evidence shows that individuals with certain cholestatic monogenic variants are potentially linked to chronic liver disease (CLD). (2). The rapidly evolving filed of precision medicine now allow us to understand the human protein funtionality and expand our ability to recognize the disease spectrum in adults. Emergent data reveals that nearly 30% CLD remains unknow, and up to 28% of these cases may be explained to newly discovered cholestatic variants. (3-4). Within this context, we investigated the contributions of variants in genes associated with AGLS, such as JAG1 and NOTCH2, using next-generation sequencing combined with deep clinical phenotyping to better characterized adults with ICP-like phenotypes. **Methods:** Case series of 5 adult female patients from 3 tertiary hepatology centers (UTHSCSA, Texas Liver Institute Austin, Baylor St Luke's Houston). Patients were retrospectively reviewed through institutional electronic medical records (EPIC) from 4/2023 to 5/2026. Inclusion criteria included positive genetic testing for ALGS variants using next-generation sequencing panels. Data collected included GGT, alkaline phosphatase, total bilirubin, serum bile acids, platelet count, liver stiffness measurement, liver histology, MRCP, pruritus (WI-NRS), and comprehensive cholestasis genetic panel during pregnancy or postpartum and during DILI and recovery phase. **Results:** Five females with median age of 35 years (range 31-43), heterozygous JAG1 (n = 2) or NOTCH (n = 3) variants. Three patients presented with ICP-Like phenotype; two of whom subsequently developed postpartum cholestasis/AMA (-) PBC overlap. Two patients presented with drug induced liver injury (DILI) phenotype or

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

inflammatory cholangiopathy. The most marked pregnancy-related cholestasis occurred in one NOTCH2 case with serum bile acid peaks of 262 and 442 µmol/L, falling postpartum to 14 and 6 µmol/L. In contrast, both JAG1 cases showed high-GGT cholangiopathy (565 and 1407 U/L), inflammatory bile-duct pathology, and stage 2 fibrosis. Additionally, two patients (2-3) were characterized as ICP but developed cholestasis 3 months postpartum. Available MRCPs were negative in all four evaluated patients. One patient received IBAT therapy for 4 months; WI-NRS improved from 8/10 to 6/10, serum bile acids remained 25 µmol/L, and diarrhea required dose interruption and reduction. **Conclusion:** Heterozygous JAG1 and NOTCH2 variants may predispose adults patients without classic syndromic features of ALGS to pregnancy-triggered cholestasis and postpartum inflammatory cholangiopathy or DILI- phenotypes. Further segregation studies, RNA/functional assays, and systematic extrahepatic ALGS with deep clinical phenotyping are needed.

1090 | MONOALLELIC PKHD1 VARIANTS MAY NOT BE PHENOTYPICALLY SILENT: A COMPARATIVE CASE SERIES OF MONOALLELIC AND BIALLELIC VARIANTS

Anish Saikumar[1] Abdullah Zafar[1] Hussein Harb[1] Sarvanand Patel[2] Eugenia Tsai[2] Lisa Pedicone[2] Jan Petrasek[2] Carmen Landaverde[2] Eric Lawitz[2] Fred Poordad[2] Fabian Rodas[2], [1]University of the Incarnate Word, [2]Texas Liver Institute

Background: PKHD1 mutations are implicated in hepatorenal ciliopathies, though genotypic-phenotypic variability remains incompletely understood. While biallelic mutations are classically associated with congenital hepatic fibrosis (CHF) and Caroli syndrome, emerging data suggest select monoallelic variants may contribute to hepatic phenotypes. We present a case series of biallelic and monoallelic PKHD1 variants with heterogeneous hepatic manifestations. **Methods:** Clinical, radiographic, histopathologic, and genetic data were retrospectively reviewed for patients with monoallelic and biallelic PKHD1 variants presenting with hepatic manifestations. **Results:** This series includes six patients (P1-P6): three siblings (P1-3) with biallelic PKHD1 mutations and three unrelated patients (P4-6) with monoallelic variants. The siblings were offspring of a consanguineous union. P1 (26M) developed biopsy-confirmed CHF complicated by portal hypertension (pHTN), recurrent variceal bleeding (VB), and intrahepatic biliary ductal dilatation. P2 (25M) developed CHF with pHTN and recurrent VB without significant biliary involvement. P3 (19F) developed CHF in infancy with subsequent Caroli syndrome. Genetic testing demonstrated homozygous PKHD1 mutations, including c.8518C > T (p.Arg2840Cys) in P1/P2. P4 (40F) was born with congenital biliary atresia and polysplenia with Kasai portoenterostomy performed at birth. She later developed chronic cholangitis, pHTN, multifocal biliary strictures, and hepatic adenoma; testing identified a heterozygous c.5273C > T (p.Ala1758Val) variant. P5 (28M) presented with non-cirrhotic pHTN and mild pericellular fibrosis with a heterozygous c.217C > T (p.Arg73Trp) variant. P6 (59M) with HIV and cryptogenic cirrhosis demonstrated elevated portal pressures without HIV-associated cholangiopathy; testing identified heterozygous c.11260G > A (p.Val3754Met) variant. **Conclusion:** PKHD1 mutations provide a broad spectrum of phenotypic expression. Biallelic mutations do portend clinically relevant disease; however this series highlights that genotype and inheritance pattern does not fully predict disease expression. Among the sibling cohort, one patient developed Caroli syndrome while another demonstrated minimal biliary involvement despite similar genetic findings. Most monoallelic variants manifested predominantly with pHTN rather than overt biliary disease, though one patient demonstrated significant cholangiopathic features, suggesting possible phenotypic overlap between PKHD1-associated disease and congenital biliary disorders. These findings support that select heterozygous PKHD1 variants may contribute to hepatic fibrocystic phenotypes or susceptibility to portal hypertensive disease.

1091 | CLINICAL UTILITY OF GENETIC EVALUATION IN ADULTS WITH UNEXPLAINED CHOLESTASIS: A MULTICENTER STUDY

Anne Mentzinger[1] Cecelia Tamburro[1] Bonnie Chen[1] Gledys Martinez[2] Daniel Dykas[1] Allen Bale[1] Marina Silveira[1] David Assis[1] Cynthia Levy[2] Silvia Vilarinho[1], [1]Yale School of Medicine, [2]University of Miami

Background: Chronic liver disease affects over 1 billion people worldwide, yet many patients remain undiagnosed. Advances in next-generation sequencing technologies have significantly improved our understanding of the genetic underpinnings of liver disease. Although these disorders have traditionally been recognized in childhood, emerging evidence suggests that these disorders can present as adult-onset idiopathic liver disease. Prior studies from our group and others have demonstrated that whole-exome sequencing (WES) can establish a molecular diagnosis in approximately 25% of patients with otherwise unexplained liver disease, with cholestasis representing a particularly high-yield phenotype category. We sought to determine the diagnostic yield of genetic evaluation in adults with unexplained cholestatic liver disease and to characterize the clinical phenotypes associated with genetic diagnoses made in adulthood. **Methods:** Whole-exome sequencing and respective analysis were performed in 33 adults with unexplained cholestasis recruited from two academic centers following an unrevealing comprehensive diagnostic workup. **Results:** In the 33-patient cohort, 70% were female, 89% were white, and 55% were Hispanic, with a mean age of 42 years. A definitive or presumed genetic diagnosis was identified in 11 patients, indicating a diagnostic yield of 33%. Variants in *ABCB4* were the most frequently identified, accounting for 9 out of 11 diagnoses. The remaining diagnoses included variants in *ABCB11* and *JAG1*. Diagnostic yield was not associated with sex or family history of liver disease. However, younger age at presentation (<40 years-old) was significantly associated with a genetic diagnosis (OR = 13.35 and $p = 0.0089$). Importantly, positive antinuclear antibody (ANA) status did not decrease the likelihood of attaining a genetic diagnosis. **Conclusion:** Our findings support and validate the clinical utility of genetic testing in adults with idiopathic cholestatic liver disease, with a diagnostic yield above 30%. Younger age (<40 years-old) at presentation was significantly associated with an increased likelihood of identifying a monogenic disorder. Importantly, an isolated positive ANA titer should not preclude genetic testing. A genetic diagnosis uncovers the underlying molecular pathogenesis and provides a roadmap for improved management, prognosis and appropriate family counseling.

1092 | THE IFNL4 GENE POLYMORPHISM IS ASSOCIATED WITH A TRANSCRIPTOMIC SIGNATURE OF INCREASED INTERFERON RESPONSE, LIPID METABOLISM, AND FIBROGENESIS IN THE LIVER

Keisuke Fukutomi[1] Alexis Moore[1] Sabitree Shahi[1] Vicky Chen[2] Marc Ghany[3] Barbara Rehermann[1], [1]Immunology Section, Liver Diseases Branch, NIDDK, National Institutes of Health, [2]Integrated Data Sciences Section, Research Technologies Branch, NIAID, National Institutes of Health, [3]Clinical Hepatology Research Section, Liver Diseases Branch, NIDDK, National Institutes of Health

Background: Interferon lambda 4 (IFNL4) is produced by the ancestral rs368234815-ΔG allele. An additional rs117648444-A/G SNP results in a P70S mutation that attenuates the function of IFNL4, and the rs368234815-TT allele leads to a frameshift that abrogates IFNL4 production. While the IFNL4-producing genotype has been associated with reduced liver inflammation in chronic hepatitis C virus (HCV) infection, it is unknown how IFNL4 affects individual cell populations in the liver and whether these effects persist after treatment-induced HCV clearance. **Methods:** To investigate the effects of *IFNL4* in the liver following HCV clearance, we performed single-cell RNA-seq on liver biopsies from 20 subjects (15 male, 5 female) who cleared HCV five years prior to this study in response to direct-acting antivirals. **Results:** All 20 subjects had minimal liver inflammation (median HAI score 3; 0-18 scale) and fibrosis (median Ishak fibrosis score 0.5; 0-6 scale), normal ALT levels, and undetectable HCV RNA. Fifteen produced IFNL4, of whom two produced a functionally weak IFNL4 due to the P70S mutation. The remaining five subjects did not produce IFNL4.Single-cell RNA-seq identified comparable proportions of immune cell subsets, liver sinusoidal endothelial cells (LSECs), stellate cells, and hepatocytes across all subjects, irrespective of *IFNL4* polymorphism. ISG expression was observed in all cell types. It was strongest in subjects who produced IFNL4 (rs368234815-ΔG/ΔG or -ΔG/TT), moderate in those with the P70S mutation (rs117648444-A/G), and weakest in those without IFNL4 (rs368234815-TT/TT). Of note, ISG expression was significantly higher in males than in females with the IFNL4-producing genotype (without P70S mutation).In hepatocytes, Hallmark gene enrichment analysis revealed an enrichment of the fatty acid degradation pathway and depletion of the steroid biosynthesis pathway in those who produced IFNL4, compared to those who did not, suggesting a beneficial metabolic effect.In LSECs, capillarization-related genes (basement membrane and extracellular matrix-related) transcripts were upregulated, and *KLF2* gene transcripts were downregulated in those who produced IFNL4, suggesting a pro-fibrotic character of LSECs. **Conclusion:** After HCV clearance, the IFNL4-producing genotype is associated with persistent intrahepatic ISG activation across cell types, lipid metabolic reprogramming in hepatocytes, and pro-fibrotic transcriptomic alterations in LSECs.

1093 | A COHORT STUDY OF *ABCB4*-RELATED LIVER DISEASE IN ADULT PATIENTS

Sateesh Maddirevula[1] Abdullah AlFhaid[1] Waleed Al Hamoudi[1] Bandar Aljudaibi[1] Mohammad Shagrani[1] Dieter Broering[1] Saleh Alqahtani[1] Saad Alghamdi[1], [1]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia

Background: Progressive familial intrahepatic cholestasis (PFIC) has historically been recognized as a pediatric disorder causing early-onset cholestatic liver disease. However, with the increasing incorporation of genetic testing into the evaluation of patients with unexplained cholestasis and cryptogenic cirrhosis, pathogenic variants in cholestasis-related genes are increasingly being identified in adolescents and adults. *ABCB4*-related liver disease demonstrates a heterogeneous clinical phenotype and may progress to advanced liver disease, portal hypertension, and hepatocellular

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

carcinoma (HCC). In this study, we describe the genotype-phenotype characteristics and clinical outcomes of a cohort of adult patients with *ABCB4*-related liver disease. **Methods:** We retrospectively collected clinical, biochemical, and genetic data of adult patients ($n = 20$) with molecularly confirmed *ABCB4*-related liver disease from electronic medical records at our center. **Results:** Twenty adult patients with genetically confirmed *ABCB4*-related liver disease were included, of whom 55% were female. All the patients are homozygous for 8 unique variants in *ABCB4*. The mean age at presentation was 22.4 ± 8.5 years, while the mean age at diagnosis was 25.1 ± 8.9 years. A family history of PFIC was identified in 50% of patients. Vast Majority of patients (90%) had evidence of cirrhosis at presentation. Portal hypertension-related complications were common, including varices in 57.9% and ascites in 40.0% of patients. Hepatocellular carcinoma developed in 15.0% of the cohort, and 50.0% required liver transplantation during follow-up.Biochemically, patients demonstrated a predominantly cholestatic liver profile with elevated gamma-glutamyl transferase (mean 256.8 U/L) and bile acid levels (mean 141 µmol/L). Median bilirubin was 49 µmol/L, while median ALT and AST were 70 U/L and 83 U/L, respectively. Autoimmune serologies were infrequently positive. Several patients had been previously misdiagnosed with autoimmune hepatitis (15.8%) or Wilson disease (5.9%). **Conclusion:** Adult *ABCB4*-related liver disease is associated with substantial morbidity, including early-onset cirrhosis, portal hypertension, hepatocellular carcinoma, and frequent need for liver transplantation. The disease may mimic other chronic liver disorders, resulting in delayed or inaccurate diagnosis. Increased awareness and broader utilization of genetic testing may facilitate earlier diagnosis and improve management of affected patients.

Clinical characteristics of adult *ABCB4*-related liver disease

Variable	n (%)
Female	11 (55.0%)
Male	9 (45.0%)

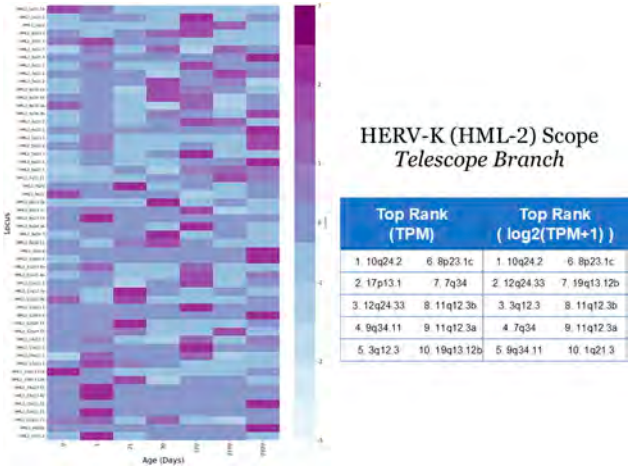
1094 | REFERENCE LANDSCAPE OF HERV-K (HML-2) IN PEDIATRIC NORMAL LIVER



Silvia Carrau[1] Manali Singha[2] Amanda Macke[2] Gary Schweickart[1] KJ Schmidt[1] Eleni Kyriakou[3] Xinlei Li[1] Benjamin Kelly[4] David Brigstock[1] Sara Rasmussen[1], [1]AWRI, Nationwide Children's Hospital, [2]AWRI, Nationwide Children's Hospital, [3]University of Athens, [4]AWRI Nationwide Children's Hospital

Background: Human endogenous retrovirus K (HERV-K, HML-2) expression has been implicated in normal physiology and multiple malignancies. However, baseline HERV-K expression in the pediatric population remains poorly characterized. The limited availability of pediatric normal liver specimens represents a major challenge for studies investigating transposable element expression in hepatoblastoma and other pediatric liver diseases. In addition, repetitive genomic architecture complicates accurate assignment of HERV-derived transcripts using conventional RNA sequencing approaches. To address this gap, we performed locus-specific HERV-K (HML-2) profiling in a rare cohort of pediatric normal liver samples using a curated Telescope-based RNA sequencing analysis pipeline. **Methods:** RNA sequencing data from seven pediatric normal liver samples (from 0 to 8.1 years-old, 25.15 ± 41.62 days, mean ± SD; source Autopsy samples from the Pediatric Division of the Cooperative Human Tissue Network, pCHTN) were analyzed using a locus-specific transposable element pipeline incorporating quality control, trimming, alignment to the hg38 reference genome, and HERV-K (HML-2) assignment using Telescope. Expression profiles were generated at the individual genomic locus level. Heatmap visualization and expression ranking analyses were used to identify recurrently expressed HERV-K loci across samples. Transcript abundance was evaluated using transcripts per million (TPM) and complementary expression ranking metrics. **Results:** Locus-specific analysis identified detectable HERV-K(HML-2) expression across all pediatric normal liver samples. Multiple loci demonstrated recurrent expression patterns across samples, with loci at 10q24.2, 17p13.1, 12q24.33, 3q12.3, and 9q34.11 consistently ranking among the most abundant HERV-K(HML-2) elements. Heatmap visualization demonstrated reproducible expression profiles with inter-sample variability typical of biologic tissue heterogeneity. These findings establish the first reference landscape of HERV-K expression in pediatric normal

liver tissue and demonstrate the feasibility of applying Telescope-based transposable element analysis to rare pediatric biospecimens. **Conclusion:** This study provides the first locus-specific characterization of HERV-K(HML-2) expression in pediatric normal liver tissue using Telescope-based RNA sequencing analysis. Pediatric normal liver specimens are exceptionally difficult to obtain, and the absence of appropriate pediatric reference controls has limited interpretation of HERV expression studies in pediatric liver tumors. These data establish an important reference resource for future investigations of HERV-K(HML-2) dysregulation in hepatoblastoma and other pediatric liver diseases.

1095 | DEVELOPMENT AND VALIDATION OF A SENSITIVE HBV GENOTYPING ASSAY IN DNA-SUPPRESSED PATIENTS

Kirsteen Maclean[1] Sanne van Gils[1] Joel Meybloom[1], [1]Cerba Research

Background: HBV genotyping is a key parameter in clinical trials, enabling patient stratification and interpretation of genotype-related differences in antiviral response. Today, HBV genotyping conventionally requires detectable plasma HBV DNA. However, for trial participants receiving nucleos(t)ide analogue (NUC) therapy, HBV DNA is often undetectable. Because HBV RNA persists in a subset of these individuals, it provides an alternative target for genotyping. We aimed to validate a novel sequencing assay utilizing both HBV RNA and DNA, alongside a serological backup for non-amplified samples. **Methods:** Reverse transcription followed by nested PCR amplified a fragment spanning the S-gene and RT-domain. Libraries were then sequenced using Illumina short-read technology, with genotypes assigned phylogenetically. When no PCR product is generated, we used the IMMUNIS HBV Genotype EIA kit, which detects genotype-specific PreS2 epitopes (genotypes A–D). **Results:** The sequencing assay achieved sensitivities of 79 copies/mL (HBV RNA) and 6 copies/mL (HBV DNA) and successfully genotyped a 15-sample panel (genotypes A–G). The IMMUNIS assay confirmed the sensitivity indicated by the manufacturer (3 IU/mL) and accurately identified genotypes A–D; however, as expected, genotypes E and G were classified as D, and F remained unclassified. **Conclusion:** This combined sequencing and serological approach provides a highly sensitive workflow for HBV genotyping in NUC–suppressed populations, supporting accurate genotype assignment in clinical trials.

1096 | PHENOTYPIC DELINEATION OF *TULP3*-RELATED HEPATORENOCARDIAC CILIOPATHY

Sateesh Maddirevula[1] Abdullah AlFhaid[1] Hadeel Almanea[1] Mohammad Shagrani[1] Saleh Alqahtani[2] Saad Alghamdi[3], [1]KFSHRC, [2]King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia, [3]King Faisal Specialist Hospital and Research Center

Background: *TULP3,* a ciliary trafficking gene, has been established with progressive degenerative liver fibrosis, fibrocystic kidney disease, and hypertrophic cardiomyopathy, and knockdown models also recapitulated hepatorenocardiac degenerative fibrosis. To this day, 21 patients are reported in the literature with the spectrum of phenotype with variable age onset. **Methods:** *Describtive study of 2 families with several family members affected of this extremely rare disease.* **Results:** We describe four patients from two unrelated families. Family 1 harbored a novel loss of function variant (c.1292dup:p.(Leu432SerfsTer3)) with three affected siblings, and family 2 harbored a biallelic founder variant (c.492+1G > A:p.?) with variable disease onset. We described the spectrum of phenotype by including the available literature to understand the natural history of the disease. Hepatic involvement (cholestasis or jaundice and elevated liver function

tests) is highly common; 100% of the patient cohort (n = 25) presented with some form of liver disease. Elevated liver enzymes were the most prevalent specific phenotype at 85%, followed closely by portal hypertension/varices and cirrhosis/bridging fibrosis at 80% each, whereas kidney disease (65%), liver transplantation (20%), and cardiac involvement (15%) were less frequently observed. **Conclusion:** Our study adds more patients with novel and founder variants. Clinical manifestations mimic different types of ciliopathies; molecular testing is highly recommended to diagnose *TULP3* related hepatorenocardiac ciliopathy. **Disclosures:** Sateesh Maddirevula:Nothing to Disclose, Abdullah AlFhaid:Nothing to Disclose, Hadeel Almanea:Nothing to Disclose, MOHAMMAD SHAGRANI:Nothing to Disclose, Saleh Alqahtani:Nothing to Disclose, Saad Alghamdi:Nothing to Disclose.

1097 | ◆ A PSEUDOMONAS-DERIVED METABOLITE; PYOCYANIN LINKS ALCOHOL-ASSOCIATED HEPATIC DYSBIOSIS TO PKC&ETA;-DRIVEN STEROID RESISTANCE IN SEVERE ALCOHOL RELATED HEPATITIS

Jaswinder Maras[1] Manisha Yadav[2] Sanju Rao[2] Gaurav Trapathi[2] Neha Sharma[2] Shimona Ahlawat[2] Kavita Yadav[2] Vipul Sharma[2] Yash Magar[2] Deepanshu Deepanshu[3] Jayesh Kumar Sevak[1] Vasundhra Bindal[2] Babu Mathew[2] Sushmita Pandey[2] Nupur Sharma[2] Anupama Kumari[2] Shvetank Sharma[1] Shiv Kumar Sarin[2], [1]Institute of Liver and Biliary Sciences, [2]ILBS, [3]national institute of immunology

Background: Severe alcohol-related hepatitis (SAH) is a life-threatening disease with ~60% of patients respond to corticosteroids, that too for a short-term. The molecular basis of steroid resistance in SAH remains unclear, particularly how microbial factors alter glucocorticoid signaling and drive steroid non-response. **Methods:** Liver multi-omics of 19 SAH patients (10 responders, 9 non-responders to corticosteroid), identified bacterial-peptides, metabolites, and host kinases linked to glucocorticoid non-response. Findings were validated using immunohistochemistry (n = 20) and RNA-seq (n = 32), followed by functional studies in PBMCs of SAH patients and experimental models of binge alcohol (NIAAA mice model) and 24 weeks chronic alcohol rat model. Pharmacological inhibition of candidate kinases was assessed for restoration of glucocorticoid sensitivity first in SAH PBMC followed by NIAAA mice model. **Results:** Liver metaproteomics showed 9,080 bacterial peptides from 257 species(FDR < 0.01). Non-responders showed distinct alpha/beta diversity ($p < 0.01$) with enrichment of pathogenic Staphylococcus aureus, and Pseudomonas aeruginosa (> 5FC, $p < 0.05$) linked to signal transduction and energy utilization. Liver phospho-proteomics showed 568proteins increased linked to TH17 signaling, CREB phosphorylation, JAK-STAT and glucocorticoid receptor inhibitors (> 2FC, $p < 0.05$), whereas steroid-response proteins HSP90 and DUSP3 were significantly reduced (> 2FC, $p < 0.05$). Non-responders showed increased PRKCH, PRKAA1, and MINK1 activity (> 2FC, $p < 0.05$), with enhanced phosphorylation of NR3C1 at ser201/203 leading to reduced NR3C1 also validated by IHC (> 2FC, $p < 0.05$). Integrated liver metaproteome, functional metabolome, and kinome showed positive associations of PRKCH (↑ in NR) with P. aeruginosa (↑ in NR) and pyocyanin levels (↑ in NR), and negatively with NR3C1 (↓ in NR, $r^2 > 0.7$, $p < 0.01$). Alcohol drive pyocyanin production by increasing liver pyocyanin-biosynthesis metabolites and enzymes (PHZm, PHZs, Shikimic acid > 2-fold, $p < 0.05$), significantly inducing ROS/PRKCH activation (> 3FC, $p < 0.01$) validated in Non-responders, NIAAA mice and 24 weeks alcohol Rat(FC > 2, $p < 0.05$). Pharmacological inhibition of PRKCH using staurosporine (validated using IHC) restored HSP90, DUSP3 (negative-regulator of PRKCH), and NR3C1 expression, boosting prednisolone sensitivity, and reducing inflammatory signaling (NFKB, MAPK signaling, $p < 0.05$) in SAH PBMC and NIAAA model respectively. **Conclusion:** Alcohol-induced hepatic enrichment of Pseudomonas aeruginosa and its metabolite pyocyanin activated PRKCH, impairing NR3C1 nuclear translocation and expression to drive steroid resistance. These findings identify the PRKCH–NR3C1 axis as a therapeutic target, with PRKCH inhibition representing a promising strategy to restore glucocorticoid responsiveness in SAH.

1098 | ◆ MICROBIOTA-DERIVED D-2-HYDROXYGLUTARATE DRIVES KUPFFER CELLS LOSS AND PRO-INFLAMMATORY MACROPHAGE REPLACEMENT IN CIRRHOSIS

Xixuan Wang[1] Jun Guo[2] Jing Fan[2] Ruiqi Li[2] Shuling Chen[2] Xiaoying Dong[2] Jiale Shen[2] Yuhang Weng[2] Hao Ren[2] Hongli Liu[2] Shangzhen Li[2] Dawei Yang[2] Dandan Yin[2] Caiyun Zhang[2] Wei Chen[2] Changhua Yi[2] Qingfang Xiong[2] Zihao Liang[2] Yongfeng Yang[2], [1]The Second Hospital of Nanjing, Medical School, Southeast Un, [2]The Second Hospital of Nanjing

Background: Gut-liver axis dysfunction drives cirrhosis progression, yet the specific microbial metabolites responsible remain poorly defined. We investigated the role of D-2-hydroxyglutarate (D-2-HG), a gut microbiota-derived metabolite, in hepatic immune microenvironment remodeling during cirrhosis. **Methods:** Fecal and serum D-2-HG were measured in a prospective cohort of healthy controls, compensated cirrhosis (CC), and decompensated cirrhosis (DC) patients (training cohort, n = 295; validation cohort, n = 96) with 24-month follow-up. Fecal microbiota transplantation (FMT) and CCl_4-induced cirrhosis mouse models were used to establish causality. D-2-HG-producing bacteria were identified through integrated metagenomic analysis and isotope tracing. KC-specific AAV8-Clec4f-Stat1 overexpression mice and myeloid-specific FTO knockout mice were generated to dissect mechanisms. Proteomics, ChIP-qPCR, and flow cytometry characterized downstream pathways. **Results:** Fecal and serum D-2-HG increased progressively from HC to CC to DC, predicting acute decompensation (AD), acute-on-chronic liver failure (ACLF), and mortality. Portal vein D-2-HG exceeded peripheral levels, indicating intestinal origin. *Fusobacterium nucleatum* was identified as the primary producer via its *serA* gene using glutamine. In cirrhotic mice, D-2-HG suppressed Kdm4b-mediated H3K9me3 demethylation at the *Stat1* promoter, simultaneously upregulating pro-apoptotic Bnip3l/Bcl2l11 and downregulating antimicrobial Gbp5/Ifit1, driving KC apoptosis and impaired bacterial clearance. At low concentrations, D-2-HG-derived α-ketoglutarate activated FTO-mediated m^6A demethylation of *RELA* mRNA, stabilizing NF-κB p65 and promoting monocyte-derived M1 macrophage recruitment. KC-specific Stat1 overexpression rescued bacterial clearance and attenuated ACLF. Rifaximin reduced *F. nucleatum*, D-2-HG levels, and partially restored hepatic immunity. **Conclusion:** Gut microbiota-derived D-2-HG, predominantly produced by F. nucleatum, drives KC depletion and pro-inflammatory macrophage replacement through Stat1-dependent dual mechanisms, representing a targetable metabolic axis in cirrhosis progression.

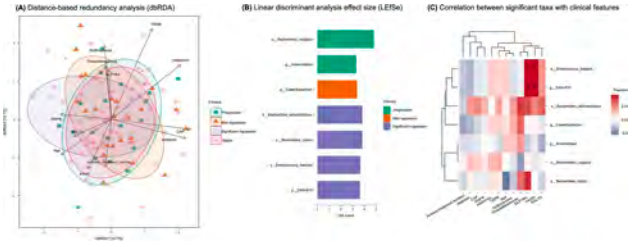
1099 | ◆ GUT MICROBIAL SIGNATURES: POTENTIAL BIOMARKERS LINKING ANTIDIABETIC TREATMENT TO FIBROSIS REGRESSION IN CHRONIC HEPATITIS B



Lu Li[1] Saisai Zhang[1] Wenyi Tan[1] Wenjie Li[1] Man-Fung Yuen[1] Lung-Yi Mak[1] Wai-Kay Seto[1], [1]The University of Hong Kong

Background: Despite the recognized role of the gut-liver axis in chronic hepatitis B (CHB), microbial signatures of fibrosis progression and regression remain poorly defined. We aimed to identify distinct gut microbial biomarkers associated with liver fibrosis in CHB patients with virological suppression under nucleos(t)ide analogue (NA) therapy. **Methods:** We enrolled CHB patients on NA therapy (HBV DNA < 10 U/mL ≥ 12 months) with baseline liver stiffness measurement (LSM) ≥ 7 kPa and follow-up LSM. Fibrosis progression was ≥ 30% LSM increase; regression stages: stable (-30% to +30%), mild (≥ 30% to < 50% decrease), and significant (≥ 50% decrease). Fecal full-length 16S rRNA sequencing (PacBio) was

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

performed. Distance-based redundancy analysis (dbRDA) (Bray-Curtis) first assessed the overall microbial differences across stages. Linear discriminant analysis effect size (LEfSe) was then conducted to identify differentially abundant taxa. Correlation analysis evaluated relationships between signature taxa and clinical factors. **Results:** A total of 125 patients (64% with type 2 diabetes [T2D], 62% with liver steatosis, 56.8% on antidiabetics) were included, of whom 70 had stable fibrosis, 19 had progression, 23 had mild regression, and 13 had significant regression. dbRDA revealed moderate separation of significant regression samples from stable and progression groups. Gut microbial β-diversity was significantly associated with T2D ($R2 = 0.39$, $P = 0.001$) and metformin use ($R2 = 0.32$, $P = 0.001$). Notably, use of antidiabetic agents including SGLT2i, DPP4i, and GLP-1RA was positively correlated with regression samples. LEfSe identified enrichment of Bacteroids vulgatus in the progression group, whereas Bacteroides cellulosilyticus, Bacteroides clarus, and Enterococcus faecalis were enriched in the significant regression group (LDA score > 3, $p < 0.05$). Bacteroides vulgatus was enriched in CHB patients using antidiabetic drugs in MaAsLin3 analysis (nominal $p < 0.01$), but this association did not remain significant after multiple-testing correction ($q = 0.96$). Furthermore, correlation analysis revealed Enterococcus faecalis was positively correlated with use of glucagon-like peptide-1 receptor agonist (GLP-1RA) ($r = 0.37$, $p < 0.001$) and insulin ($r = 0.37$, $p < 0.001$); Bacteroides cellulosilyticus was positively correlated with thiazolidinediones ($r = 0.31$, $p < 0.05$); Bacteroides clarus was positively correlated with GLP-1RA ($r = 0.33$, $p < 0.01$). **Conclusion:** This study reveals gut microbial signatures of fibrosis regression in CHB that are linked to antidiabetic drug use, suggesting antidiabetic-driven microbial benefits. These findings suggest that the gut microbiome may act as a mediator of antidiabetic effects and support microbiome-based biomarkers for CHB fibrosis. Supported by Shenzhen Natural Science Foundation Basic Research Fund-General Program (JCYJ20250604180826035).

1100 | ◆ NOVEL GUT MICROBIOME METAGENOMIC SIGNATURE OF STEATOTIC LIVER DISEASE AMONG PEOPLE WITH HIV

Federica Tavaglione[1] Mark Holton[1] Megan O'Hara[1] Wathnita Sarik[1] Alyssa Ing[1] Ricki Bettencourt[1] Laura Wilson[2] Kara Wegermann[3] Mark Sulkowski[4] Naga Chalasani[5] Rob Knight[1] Guillaume Urtecho[1] Rohit Loomba[1], [1]University of California, San Diego, [2]Johns Hopkins Bloomberg School of Public Health, [3]Duke University, [4]John Hopkins University, [5]Indiana University School of Medicine

Background: Steatotic liver disease (SLD) has emerged as the leading cause of chronic liver disease among people with HIV (PWH). Advanced fibrosis (AF) is the strongest predictor of liver-related morbidity and mortality in individuals with SLD, including PWH, making its identification essential to detect those at highest risk of disease progression. Growing evidence supports gut microbiome profiling as a non-invasive biomarker of SLD severity and progression, but data in PWH with SLD remain limited and may differ from those observed in individuals without HIV. We aimed to identify a gut microbiome metagenomic signature associated with AF in SLD among PWH from the multicenter HIV NASH CRN study. **Methods:** This

cross-sectional study included 90 prospectively enrolled adult PWH from eight U.S. centers, on stable antiretroviral therapy (ART), with suppressed HIV RNA and without viral hepatitis co-infection, who underwent vibration-controlled transient elastography. Participants were categorized into three groups: SLD–AF (n = 12; CAP ≥ 263 dB/m and LSM ≥ 10 kPa), SLD–No AF (n = 43; CAP ≥ 263 dB/m and LSM < 10 kPa), and control (n = 35; CAP < 263 dB/m and LSM < 8 kPa). Gut microbiome composition was characterized using shotgun metagenomic sequencing of stool samples. An independent U.S. cohort of 86 individuals without HIV with biopsy-proven SLD served as a comparator. **Results:** The median (IQR) age and BMI of PWH were 55.5 (46.3–62.0) years and 29.7 (25.7–34.8) kg/m², respectively. Among PWH, DESeq2 differential abundance analysis identified microbial taxa within the Enterobacterales and Lachnospirales orders that were enriched with SLD and increasing fibrosis stage (**Fig.1A**). Both orders were also significantly associated with CAP as a measure of steatosis, while Lachnospirales were additionally associated with LSM as a measure of fibrosis. When comparing PWH with the non-HIV SLD cohort, taxa within Enterobacterales were associated with AF in both groups, whereas taxa within Lachnospirales were uniquely associated with AF in PWH (**Fig.1B**). Finally, in exploring associations between ART and the microbiome, bictegravir use was associated with a relative depletion of Lachnospirales and Enterobacterales (**Fig.1C**). **Conclusion:** This study identifies a novel gut microbiome metagenomic signature associated with AF in SLD among PWH. The observed association between bictegravir use and SLD-related favorable microbial taxa may reflect relationships between ART exposure, SLD severity, and gut microbiome composition.

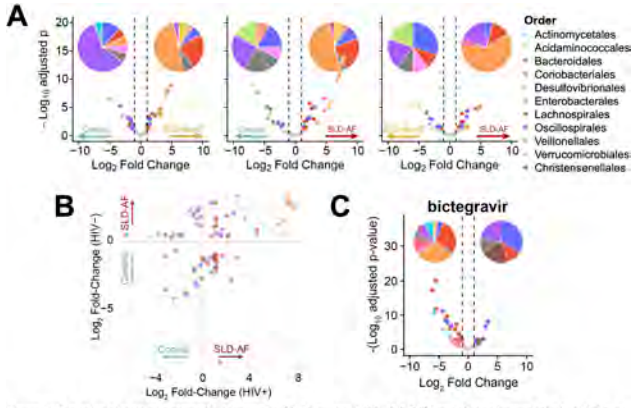

Figure 1: Gut microbiome metagenomic signature of SLD among PWH. (A) Differential enrichment of microbial taxa across the HIV NASH CRN cohort stratified by SLD presence and severity. Points represent individual taxa, with significantly altered taxa (FDR < 0.05) highlighted. **(B) Microbes associated with advanced fibrosis in the HIV NASH CRN cohort (HIV+) versus UCSD biopsy cohort (HIV-).** Scatterplot shows the $\log_2$(fold-change) in microbial abundance between participants with advanced fibrosis vs control group in the two cohorts. **(C) Differential microbial abundance associated with bictegravir use in the HIV NASH CRN cohort.** Volcano plots show DESeq2 differential abundance analyses comparing users versus non-users. AF, advanced fibrosis; SLD, steatotic liver disease.

1101 | A HUMAN MICROBIOTA-DERIVED *BACTEROIDES UNIFORMIS* STRAIN RESTORES THE GUT–LIVER AXIS AND AMELIORATES PORTAL HYPERTENSION IN CIRRHOSIS

Peishan Wu[1] Cheng-Yen Kao[2] Yu-Cheng Lin[3] Yun-Cheng Hsieh[4] Yi-Tsung Lin[5] Shih-Yun wu[6] Teh-Ia Huo[4] Ming-Chih Hou[1] Han-Chieh Lin[1] Kuei-Chuan Lee[7], [1]Taipei Veterans General Hospital, [2]Institute of Microbiology and Immunology, National Yang Ming Chiao Tung University, Taipei, Taiwan, [3]Department of Dentistry, National Yang Ming Chiao Tung University, Taipei, Taiwan, [4]Division of Gastroenterology and Hepatology, Department of Medicine, Taipei Veterans General Hospita, [5]Division of Infectious Diseases, Department of Medicine, Taipei Veterans General Hospital, Taipei, T, [6]Department of Stomatology, Taipei Veterans General Hospital, Taipei, Taiwan, [7]Division of Gastroenterology and Hepatology, Department of Medicine, Taipei Veterans General Hospit

Background: The gut–liver axis plays a central role in the pathogenesis and progression of cirrhosis. Experimental studies have shown that rodent-derived fecal microbiota transplantation (FMT) ameliorates portal hypertension, but the effects of human-derived FMT (hFMT) in cirrhotic models remain unexplored. This study aimed to evaluate the effects of hFMT on the gut–liver axis in experimental cirrhosis and to identify specific microbial taxa and microbiota-derived metabolites associated with therapeutic benefit. **Methods:** Cirrhosis was induced in Sprague–Dawley rats by bile duct ligation (BDL) or intraperitoneal injection of thioacetamide (TAA, 200 mg/kg twice weekly) for 16 weeks. BDL rats received daily oral gavage of autologous or human FMT for 2 weeks, beginning 2 weeks after surgery; TAA rats received FMT twice weekly during the final 8 weeks of TAA administration. Candidate bacterial strains identified following hFMT were isolated from fecal samples of healthy human donors and administered to both cirrhotic models. Intestinal inflammation, barrier function, endotoxemia, portal pressure, and gut microbiota composition were assessed. Short-chain fatty acid (SCFA) profiles were analyzed *in vitro* and *in vivo*. Human microbiota data were analyzed for translational validation. **Results:** hFMT attenuated intestinal inflammation and restored barrier integrity predominantly in the proximal small intestine of both cirrhotic models, accompanied by reduced endotoxemia and pro-inflammatory cytokine expression. *Bacteroides uniformis* was consistently enriched following hFMT in both TAA and BDL models. Administration of *B. uniformis* CC-143, a strain isolated from human donors, improved proximal intestinal inflammation, tight junction expression, hepatic macrophage infiltration, collagen deposition, and portal pressure. *In vitro* analysis demonstrated that *B. uniformis* CC-143 produced both straight-chain (acetate and propionate) and branched-chain SCFAs (iso-butyric acid and 3-methylbutyric acid). *In vivo*, circulating branched-chain SCFAs were preferentially increased following *B. uniformis* treatment in the BDL model. In the human cohort, *B. uniformis* abundance was significantly higher in healthy adults than in patients with cirrhosis and its abundance was further decreased in patients with more severe portal hypertension. **Conclusion:** hFMT improves gut barrier dysfunction in experimental cirrhosis and identifies *B. uniformis* as a potential mediator of portal hypertension improvement. Through modulation of proximal intestinal inflammation, barrier integrity, and microbiota-derived metabolites, *B. uniformis* may represent a promising candidate for targeted microbiota-based therapy in cirrhosis.

1102 | PPARALPHA AGONISM MAY IMPROVE BOTH HEPATIC AND INTESTINAL INFLAMMATION IN PSC-IBD

Mahesh Krishna[1] Yanhong Deng[1] Badr Al Bawardy[1] Marina Silveira[1] James Boyer[1] Clara Abraham[1] David Assis[1], [1]Yale University

Background: Primary sclerosing cholangitis (PSC) is a cholestatic liver disease with no cure and 60-80% concurrence with inflammatory bowel disease (IBD). Compared to PSC or IBD alone, PSC-IBD has distinct

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

liver and intestinal characteristics, so it is important to understand the impact of new candidate therapies on the whole gut-liver axis.Peroxisome proliferator-activated receptors (PPAR) agonists are an emerging drug class under active investigation in PSC. We aimed to characterize the impact of PPAR agonists on hepatic and intestinal disease in PSC-IBD. **Methods:** We performed a single-center retrospective cohort study of adult PSC-IBD patients who initiated fenofibrate (a PPARalpha agonist) for PSC as part of real-world care between 2013-2024 with available colonoscopy data pre- and post-fenofibrate. Patients on fenofibrate for < 6 months or with colectomy/liver transplant between endoscopies were excluded.The *primary outcome* for intestinal disease activity was a composite binary outcome of post-index endoscopic disease improvement. This was defined as improvement in disease-specific endoscopic scores (Mayo for ulcerative colitis [UC] and Simple Endoscopic Score for Crohn's disease [CD]) or stable and inactive disease. If there was no disease-specific score, response was adjudicated by 2 gastroenterologists where feasible.The *primary outcome* for PSC activity was > 30% improvement in alkaline phosphatase (ALP) at 6 months.Data was analyzed in R and paired t-test was utilized for analysis. **Results:** Of 22 patients, 15 had UC while 7 had CD. The mean disease duration of IBD at time of fenofibrate was 16 years. 32% of patients were treated with a biologic at time of fenofibrate and 27% had prior exposure to > 1 biologic.The mean disease duration of PSC at time of fenofibrate was 9.75 years; 82% of patients were diagnosed with large-duct PSC.The mean Mayo Endoscopic Score for UC patients (n = 14) mildly improved (0.93 to 0.71, p = 0.49), while the mean Mayo Clinical Score for UC patients (n = 12) significantly improved (1.71 to 0.83, p = 0.027) following fenofibrate treatment. Overall, 73% of all IBD patients (n = 22) met the primary IBD outcome.Mean ALP improved from 429 to 265 U/L (p < 0.001) and 81% of patients met the primary PSC outcome. Total bilirubin (1.30 to 1.05, p = 0.12) and Gamma-Glutamyl Transferase (207 to 159, p = 0.09) showed a trend favoring improvement.Importantly, 81% of patients had a concurrent result for both IBD and PSC primary outcomes. **Conclusion:** Fenofibrate is associated with both intestinal and hepatic clinical improvement, suggesting PPARalpha agonism may benefit each site of disease in PSC-IBD. Prospective, randomized-controlled trials on fenofibrate in PSC, and further research on the impact of PPARalpha agonism on IBD activity and the gut-liver axis in PSC-IBD, are warranted.

1103 | *VEILLONELLA DISPAR* TRIGGERS SHARED IMMUNOPATHOGENESIS BETWEEN PRIMARY BILIARY CHOLANGITIS AND SJ&OUML;GREN'S SYNDROME

JinShui Pan[1] Weiwei Zeng[1], [1]the First Affiliated Hospital of Fujian Medical University

Background: The prevalence of primary biliary cholangitis (PBC) and Sjögren's syndrome (SS) shows a marked sex disparity, and the two diseases frequently co-occur, being regarded as manifestations of the same pathological process affecting different target organs (bile ducts and exocrine glands). *Veillonella* are enriched in the gut and oral cavity of patients with PBC and SS. The aim of this study is to elucidate the shared immunopathogenesis by which *Veillonella dispar* drives PBC and SS through testosterone modulation. **Methods:** A male castration model and a *Veillonella dispar* oral gavage model were established. After 12 weeks of treatment in the castration group and the group receiving *Veillonella dispar* gavage combined with intraperitoneal injection of a peptide (The PDC-E2 peptide), serum biochemical parameters, as well as pathological changes in the liver, submandibular glands, and testes, were observed. Changes in salivary flow rate were measured, and the proportions of B lymphocytes in the submandibular gland lymph nodes and liver were detected by immunofluorescence and flow cytometry. **Results:** The castration model exhibited phenotypes such as liver and submandibular gland inflammation, as well as reduced saliva flow rate (Fig 1). Mice treated with 12 weeks of *Veillonella dispar* gavage combined with intraperitoneal injection of the peptide exhibited elevated serum ALP, decreased testosterone levels, elevated serum B-cell activating factor (BAFF) levels, B-cell infiltration in the submandibular glands and pericholangial spaces of the liver, an increased proportion of B lymphocytes in submandibular lymph nodes and the liver, and reduced salivary flow rates, compared to the group receiving PBS gavage combined with intraperitoneal injection of the peptide (Fig 2). Supplementation with testosterone or anti-BAFF treatment alleviated the PBC and SS-like manifestations induced by *Veillonella dispar* (Fig 3). **Conclusion:** *Veillonella dispar* reduces testosterone levels via the gut-testis axis and promotes elevated BAFF levels. This leads to B-cell infiltration in the liver and submandibular glands. This study sheds light on the underlying mechanisms behind the high prevalence of primary biliary cholangitis and Sjögren's syndrome in women. It highlights the significant role of *Veillonella dispar* in both disorders and emphasises its potential as a novel therapeutic target.

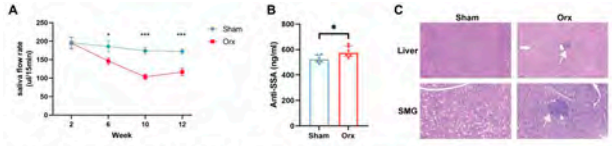

Fig 1. The castration model exhibited inflammation in the liver and submandibular gland.

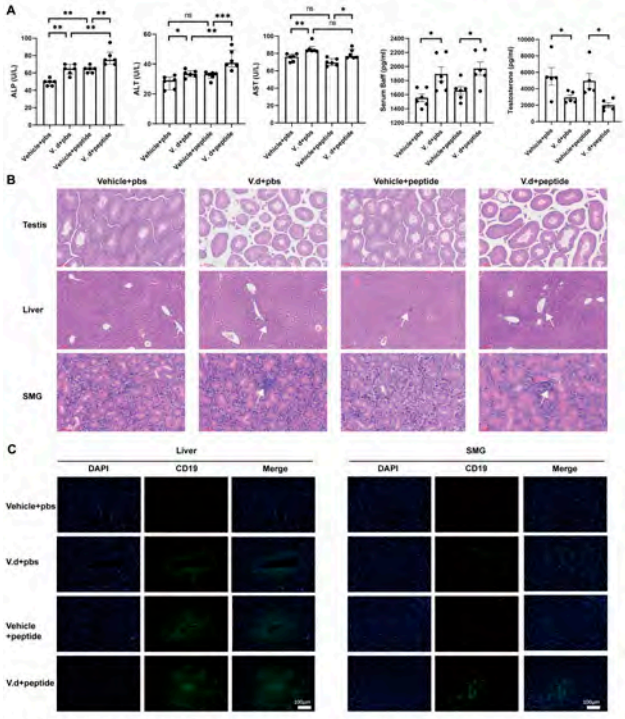

Fig 2. Mice treated with Veillonella dispar gavage combined with intraperitoneal injection of the peptide exhibited symptoms of cholangitis and Sjogren's syndrome. 1104 | AGE-RELATED LEAKY GUT IS MEDIATED BY AGE-DEPENDENT DECREASE OF SMP30-E-CADHERIN PATHWAY

Woo Jun Kim[1] Jae-Hyuk Yim[1] Jin-Kyu Park[1],
[1]Kyungpook National University

Background: Aging is a potential contributor to increased gut permeability. SMP30 (senescence marker protein 30) is a key molecule whose expression downregulates with age. Therefore, we investigated the role of intestinal SMP30 using aged and SMP30 knockout (KO) mouse models. Meanwhile, nanoplastics (NPs) are ubiquitous pollutants that can affect both humans and the environment. Considering the exposure route of NPs, increased gut permeability during aging may aggravate the accumulation of NPs. Overall, we aimed to investigate the role of SMP30 in regulating gut permeability, focusing on the age- and SMP30-dependent distribution of NPs. **Methods:** Aged and SMP30 KO mice were used to investigate the role of intestinal SMP30 and were orally administered fluorescently labeled polystyrene nanoplastics (PS-NPs) five times a week for three weeks. Additionally, an alcohol-induced intestinal permeability mouse model was established using a Lieber-deCarli diet to disrupt barrier function. Histopathological analysis, immunofluorescence, immunohistochemistry, serum biochemistry, ELISA, qPCR, and Western blot were performed to analyze phenotypes and underlying pathogenesis. Transcriptome analysis was performed in alcohol-induced permeability mouse models. To elucidate the underlying mechanisms, SMP30 knockdown was induced in the human colon carcinoma cell line Caco-2 under ethanol treatment. **Results:** In the older age group, more NPs were observed in the liver, spleen, and brain. Serum iFABP (intestinal permeability marker) level was dramatically increased in the older age group. Likewise, the SMP30 KO EtOH (KE) group exhibited more severe vacuolization in the intestinal villi and increased iFABP level compared with the WT EtOH (WE) group. The KE group showed increased NP accumulation in the lamina propria of villi as well as other parenchymal organs. Interestingly, the NP accumulation was significantly higher in SMP30 KO mice than in WT mice regardless of alcohol administration. In transcriptome analysis, actin filament organization or actin binding pathways were significantly downregulated in KE group compared to WE group. Also, the KE group showed decreased F-actin expression in the intestinal villi. Additionally, junctional proteins, such as occludin, claudin-1, and E-cadherin, were evaluated and only E-cadherin protein level was significantly decreased in KE group. SMP30 knockdown (KD) in Caco-2 induced E-cadherin downregulation at the mRNA and protein levels. Moreover, E-cadherin redistribution was promoted by SMP30 KD. **Conclusion:** This study demonstrates that SMP30 deficiency aggravates intestinal permeability via SMP30-Actin-E-cadherin pathway. We elucidate the novel function of SMP30 in intestinal epithelium, emphasizing E-cadherin mediated gut permeability in aged and SMP30 KO mouse models. Given that reduced SMP30 expression during aging, it may represent a promising therapeutic target for regulating gut permeability.

1105 | DREAM PREVENTS INTESTINAL FAILURE-ASSOCIATED LIVER DISEASE BY RESTORING GUT-LIVER BILE ACID SIGNALING IN SHORT BOWEL SYNDROME

Takahiro Ohkura[1] Shun Onishi[2] Chandrashekhara Manithody[2] Miguel Guzman[2] Sherri Besmer[2] Shin Miyata[2] Matthew McHale[2] Chelsea Hutchinson[2] Ajay Jain[2], [1]Saint Louis University / Pediatrics, [2]Saint Louis University

Background: Intestinal failure-associated liver disease (IFALD) is a major complication of short bowel syndrome (SBS), driven by disrupted enteral nutrition, barrier failure, inflammation, and altered bile acid signaling. Our patented DREAM (Distal Recirculation of Enteral contents Augmented Mechanically) system restores sustained enteral nutrient exposure after bowel resection. We tested whether DREAM prevents SBS-associated cholestatic liver injury and preserves gut-liver bile acid signaling. **Methods:** Twenty neonatal pigs were randomized to enteral nutrition control, SBS after 75% small-bowel resection, or DREAM. Serum bilirubin, GGT, bile acids, lipids, inflammatory cytokines, and portal LPS were measured. Liver injury was assessed by histology, cholestasis score, CK7, CD3, and CYP7A1 immunostaining. Hepatic and intestinal bile acid regulatory pathways were evaluated by qPCR and RNA-seq with KEGG and GO enrichment. **Results:** SBS produced severe cholestatic liver injury, while DREAM markedly protected against IFALD. Compared with SBS, DREAM lowered serum bilirubin, 0.11 vs 5.14 mg/dL, $p = 0.0008$; GGT, 23.2 vs 114.6 IU/L, $p < 0.0001$; and bile acids, 9.7 vs 39 µmol/L, $p = 0.0026$, with lipid profiles comparable to enteral controls. DREAM also reduced systemic and portal inflammatory drivers of liver injury, including IFN-γ, $p = 0.0296$; IL-1β, $p = 0.0349$; IL-6, $p = 0.0189$; TNF-α, $p = 0.0166$; and portal LPS, $p = 0.0130$, versus SBS. Histologically, SBS increased hepatic cholestasis score, CK7-positive ductular reaction, CD3-positive T-cell infiltration, and hepatocyte CYP7A1 expression; DREAM prevented these changes and preserved hepatic architecture. Hepatic bile acid signaling was restored with DREAM with preserved FGFR4 expression, BSEP induction was normalized, and CYP7A1 mRNA was reduced compared with SBS, $p = 0.0034$, consistent with restored suppression of bile acid synthesis. Intestinal FXR and TGR5 signaling were reactivated, supporting enterohepatic feedback. Hepatic RNA-seq further showed that DREAM reduced inflammatory mediators, TNF, ICAM1, and CCL2; restored peroxisomal and antioxidant genes, ACOX1, CAT, and SCP2; and improved lipid and redox pathways disrupted by SBS. **Conclusion:** DREAM prevents SBS-associated IFALD by reducing cholestasis, bile acid accumulation, hepatic inflammation, and CYP7A1-driven bile acid synthetic stress while restoring enterohepatic FXR-FGFR4/BSEP signaling. These findings position DREAM as a liver-protective strategy for intestinal failure and a translational platform for studying gut-liver mechanisms of IFALD.

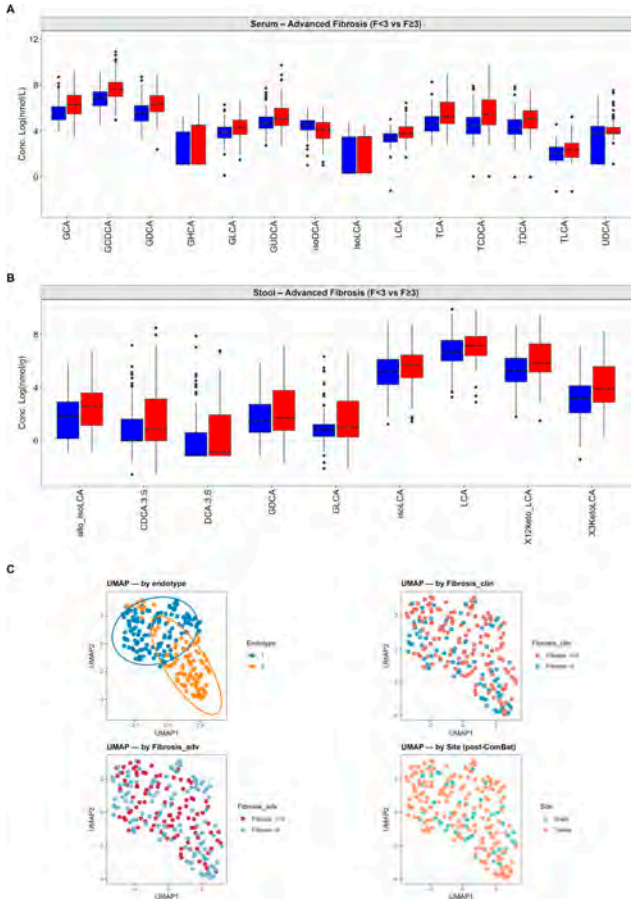
1106 | BILE ACID SIGNATURES OF FIBROSIS SEVERITY AND RELATED MICROBIOME SUBPOPULATIONS IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE MASLD



Isabel Veloso Alves Pereira[1] Yusuf Yilmaz[2] Claudia Oliveira[3] Fatih Eren[4] Jose Tadeu Stefano[5] Sebastião Mauro Duarte[5] jason Kang[6] Faridoddin Mirshahi[7] Huiping Zhou[7] Phillip Hylemon[7] Ekaterina Smirnova[7] Arun Sanyal[7], [1]Universidade de São Paulo, [2]Marmara Universitesi Tip Fakultesi, [3]University of Sao Paulo School of Medicine, [4]Marmara University School of Medicine, [5]Faculdade de Medicina da Universidade de São Paulo, [6]Stravitz-Sanyal Institute for Liver Disease and Metabolic Health, [7]Virginia Commonwealth University

Background: Several circulating bile acids are increased with increasing fibrosis in a single-center US cohort with MASH (Smirnova et al. 2022). It was not known if these findings were generalizable and if there were microbial subpopulations associated with distinct bile acid profiles. **Aims:** (1) To define and validate circulating bile acid signatures associated with increasing fibrosis stage. (2) To define microbial endotypes associated with distinct circulating bile acid profiles. **Methods:** A cross-sectional study in 2 cohorts with histologically confirmed MASLD from South America (Brazil, $n = 68$) and Eurasia (Turkey, $n = 170$) was performed ($\geq$ F3 $n = 107$). Bile acids from serum and fecal samples were measured using liquid chromatography-mass spectrometry (LC-MS) .16S rRNA sequencing was performed for microbiome analysis. Unsupervised multi-omics factor analysis (MOFA2) was used to identify endotypes in a joint microbiome-bile acids analysis. Microbiota–fibrosis associations were modeled with MaAsLin3, adjusting for site, age, sex, and BMI. **Results:** Total and glycine conjugated serum bile acids (GCDCA and GDCA) increased with increasing fibrosis stage. Of note, glycine-conjugated

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

hyocholic and ursodeoxycholic acid also increased concordantly with GDCA. Fecal bile acid profiles were not significantly different across fibrosis stages. Consistent with the literature *Ruminococcus callidus* was associated with advanced fibrosis (FDR = 0.045). Two endotypes (n = 123/91) were linked to microbiome-circulating bile acid profiles. Endotype 1 (dysfunctional) had more males (60 vs. 44%, p = 0.03) and higher ALT (median 63 vs. 48 U/L, p = 0.02). Endotype 1 was depleted of BSH-encoding *Parabacteroides* and butyrate-producing commensals (*R. bromii*, *F. prausnitzii*), consistent with the accumulation of primary bile acids (CA, UDCA, CDCA) and keto intermediaries (7-ketoDCA, 7-ketoLCA) indicating incomplete 7α-dehydroxylation. In contrast, Endotype 2 (functional) was associated with greater circulating secondary bile acids, including DCA and lithocholic acid and their derivatives. **Conclusion: Conclusion:s:** Circulating glycine-conjugated bile acids increase with fibrosis severity across ethnicities, confirming prior US findings. Integrated multi-omics analysis identified two bile acid–associated gut–liver axis endotypes, independent of fibrosis stage and predominantly driven by bile acid variation, with limited discriminative performance for fibrosis severity.

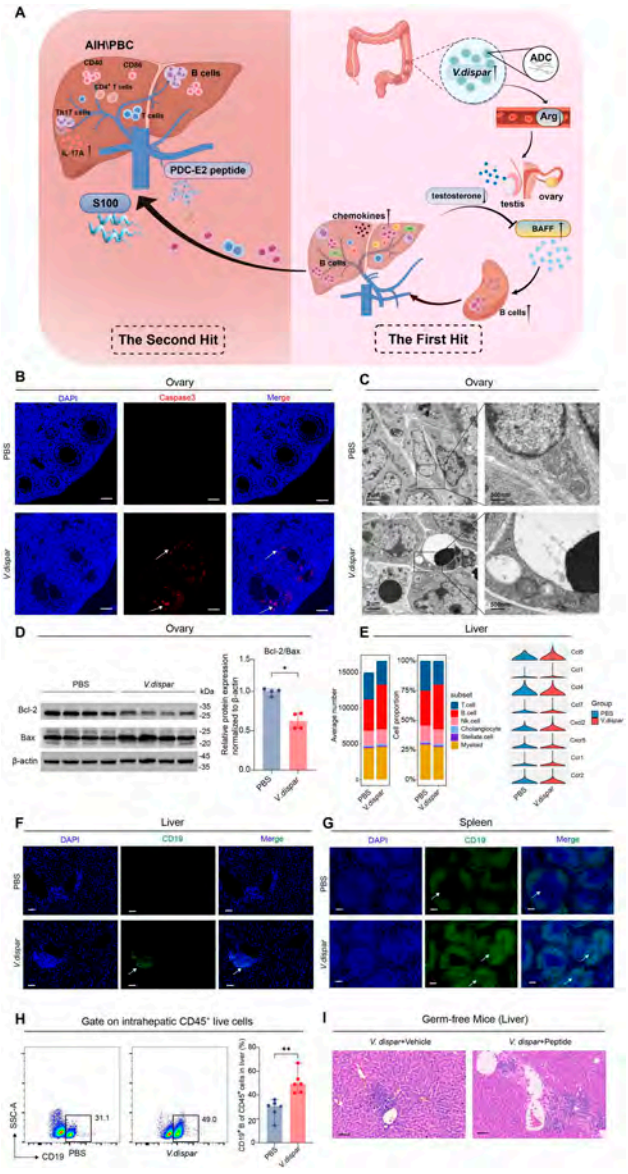
1107 | *VEILLONELLA DISPAR* TRIGGERS "DUAL-HITS" IN THE PATHOGENESIS OF AUTOIMMUNE HEPATITIS AND PRIMARY BILIARY CHOLANGITIS VIA TESTOSTERONE DEPLETION-BAFF-B CELL AXIS AND TH17 CELL ACTIVATION



JinShui Pan[1] YaLing Liu[1], [1]the First Affiliated Hospital of Fujian Medical University

Background: Autoimmune hepatitis (AIH) and primary biliary cholangitis (PBC) frequently present as overlap syndromes, characterized by shared sexual dimorphism and elevated intestinal *Veillonella dispar* (*V. dispar*) abundance, yet exhibiting distinct hallmark pathological manifestations. This study aimed to elucidate the shared pathogenesis, phenotypic differentiation mechanisms and sex-specific predisposition of AIH and PBC induced by *V. dispar*. **Methods:** Clean-grade and germ-free (GF) mice were employed to establish AIH and PBC models. Model induction involved oral gavage of *V. dispar* and intraperitoneal injection of either liver-specific antigen S100 (for AIH) or a pyruvate dehydrogenase complex E2 subunit (PDC-E2) mimetic peptide (for PBC). Single-cell RNA sequencing, metabolomics, transmission electron microscopy, western blotting, and flow cytometry were utilized to elucidate the underlying mechanisms. **Results:** *V. dispar* successfully induced autoimmune liver disease-like features in mice, characterized by significant intrahepatic B cell infiltration. Mechanistically, *V. dispar* caused systemic arginine reduction, leading to intrinsic apoptosis of gonadal stromal cells and a subsequent reduction in testosterone. This decreased testosterone weakened its inhibitory effect on B cell activating factor (BAFF) secretion, thereby amplifying B cell-mediated immune responses. Furthermore, in the presence of S100 or PDC-E2 mimetic peptide, *V. dispar* also facilitated Th17 cell activation, which guided the phenotypic differentiation into AIH or PBC, respectively. **Conclusion:** *V. dispar* induces reduced testosterone levels and upregulation of BAFF, leading to intrahepatic B cell expansion, which serves as the common pathogenic basis for AIH and PBC. The presence of S100 and PDC-E2 subsequently drives further maturation of these expanded B cells and promotes Th17 cell activation, thereby

1108 | DONOR METHYLATOR ENGRAFTMENT AND BACTERIAL SAM-CYCLE AXIS EXCLUSIVELY TRACKS MICROBIOME ENGAGED IN FMT MEDIATED RECOVERY IN ALCOHOL-ASSOCIATED LIVER DISEASE MODEL

Shvetank Sharma[1] Kavita Yadav[1] Rosmy Babu[1] Neha Sharma[1] Nishu Choudhary[1] Chhagan Bihari[1] Jaswinder Maras[1] Shiv Kumar Sarin[1], [1]Institute of Liver and Biliary Sciences

Background: Alcohol-associated liver disease (ALD) carries 5-year mortality exceeding 50%, and fecal microbiota transplantation (FMT) shows survival benefit in severe alcoholic hepatitis (SAH), yet its molecular basis is poorly defined. Most studies infer function from microbial abundance shifts rather than active microbial activity. We sought to characterize how the gut bacterial community functionally alters during recovery from ALD, comparing passive abstinence with standard FMT. **Methods:** ALD was induced in C57BL/6N mice (n = 6 per group) using Lieber–DeCarli ethanol + thioacetamide (150 mg/kg, twice weekly) over 12 weeks. Cecal sampling was performed at Wk4/8/12, after 2-week abstinence (Abst), and after 2-week FMT (oral gavage of healthy-donor fecal slurry on the abstinence baseline). Native-DNA Oxford Nanopore long-read sequencing called 5mC/6mA/4mC simultaneously from the same reads. Per-position methylation calls were aggregated to gene, KEGG pathway, and species level . Untargeted LC-MS/MS metabolomics, liver biochemistry and histology were integrated by Spearman correlation with Benjamini-Hochberg FDR. **Results:** The reversal in fibrosis and AST levels achieved by FMT was greater than passive abstinence (fibrosis 19.3 ± 1.1% vs. 14.0 ± 1.1%, $p = 0.0022$; AST 66.4 ± 13.5 vs 91.3 ± 16.4 U/L, $p = 0.041$). The methylating sub-community was significantly group-structured (PERMANOVA $F = 5.54$, $p = 0.002$ FMT vs Abst). Donor Dam (GATC) and Dcm (CCTGG) motif fingerprints transferred intact to FMT recipients (Jaccard = 1.00) but were absent in Abstinence, indicating donor-engrafted rather than expanded resident methylator activity. Pathway-level analysis identified FMT-elevated methylation of cysteine/methionine metabolism (ko00270, the SAM cycle host) and purine metabolism (ko00230) in both promoter and gene-body regions (**Figure**). Bacterial SAM-cycle backbone enzymes (MetK, AhcY, MetH) showed methylation positively correlated with stool 5′-deoxyadenosine ($q < 0.05$) and adenosine ($q < 0.10$) across endpoint samples. Species-level analysis identified *Enterobacter hormaechei* methylation as fibrosis-protective ($\rho = -0.75$, $q = 0.01$) and *Limosilactobacillus reuteri* methylation as disease-tracking (fibrosis $\rho = +0.71$, $q = 0.02$). *Phocaeicola massiliensis* MetK methylation arose exclusively in FMT recipients, a clean signature of donor engraftment. **Conclusion:** Native-DNA long-read methylation profiling identifies a structured gut bacterial methylator sub-community that tracks ALD recovery distinctly from abundance alone. Donor methylator engraftment and a methionine-salvage/SAM-cycle axis is distinct from abstinence recovery, and serves as a functional readout of post-FMT community activity and efficacy.

1109 | ORAL CANNABIDIOL AMELIORATED ALCOHOL-ASSOCIATED LIVER INJURY THROUGH INTESTINAL EPITHELIAL CELL AHR ACTIVATION-MEDIATED GUT-LIVER AXIS

Panpan Huang[1] Md Manirujjaman[2] Wenke Feng[1], [1]Tulane University, [2]LSU

Background: Alcohol-associated liver disease (ALD) is a major cause of liver-related morbidity and mortality, and effective therapies remain limited. Disruption of the gut–liver axis, characterized by intestinal barrier dysfunction and bacterial translocation, is central to ALD progression. Cannabidiol (CBD), a non-psychoactive compound from *Cannabis sativa*, has anti-inflammatory and antioxidant properties; however, the effects of oral CBD and its underlying mechanisms in ALD remain unclear. **Methods:** The effects of oral CBD in experimental ALD were evaluated in NIAAA chronic-plus-binge ALD mouse model. Mice were fed alcohol-containing Lieber DeCarli liquid diet for 10 days and one binge alcohol was gavaged to mice 9 hours before tissue harvesting. CBD was orally gavaged to mice at a dose of 2 mg/kg every other day. Liver injury, inflammation, bacterial translocation, and intestinal barrier integrity were assessed by biochemical assays, tissue histology, immunostaining, and hepatic 16S rRNA analysis. The role of aryl hydrocarbon receptor (AhR) was examined using pharmacological inhibitor (CH223191) and in intestinal epithelial cell-specific AhR knockout ($Ahr^{\Delta IEC}$) mice. *In vitro* studies were conducted in intestinal epithelial Caco-2 cells. **Results:** Oral CBD administration significantly reduced serum levels of ALT and AST and attenuated hepatic inflammation. Alcohol feeding increased circulating LPS levels, and hepatic bacterial 16S rRNA and *E. coli* accumulation, which were attenuated by oral CBD administration, indicating a reduction in alcohol-associated bacterial translocation. In the intestine, CBD improved epithelial integrity by restoring crypt architecture, reducing oxidative stress, preserving tight junction organization, enhancing goblet cells numbers and increasing IgA expression. Importantly, these protective effects of oral CBD were abolished by CH223191, an AhR inhibitor, and in $Ahr^{\Delta IEC}$ mice, suggesting a critical role of epithelial AhR activation. Fecal 16S rRNA analysis showed a reshaped gut microbiota homeostasis, such as an enrichment of *Akkermansia muciniphila*, a mucin-degradation commensal bacterium which plays a regulatory role in barrier integrity. In Caco-2 cells, CBD prevented acetaldehyde-induced epithelial cell barrier dysfunction measured by transepithelial electric resistance (TEER) assay, which was inhibited by CH22319. **Conclusion:** In conclusion, these findings demonstrate that the therapeutic effects of oral CBD are mediated by intestinal AhR, which regulates the gut-liver axis to preserve gut barrier integrity, attenuate bacterial translocation to the liver, and ultimately protect against alcohol-induced liver injury.

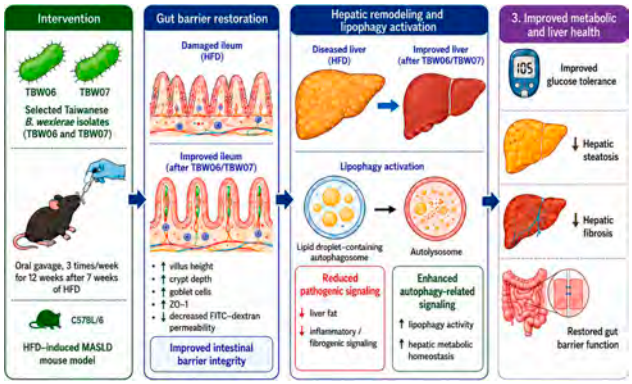
1110 | *BLAUTIA WEXLERAE* AMELIORATE EXPERIMENTAL MASLD THROUGH GUT-LIVER AXIS RESTORATION AND HEPATIC AUTOPHAGY ACTIVATION



Yu-Cheng Lin[1] Chun-Liang Chen[1] Yun-Er Li[1] Hsueh-Fang Lin[1] Yen-Hsuan Ni[2], [1]Taipei Veterans General Hospital, [2]National Taiwan University Hospital

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) is closely linked to gut microbial dysbiosis, yet species-level microbial candidates with therapeutic relevance remain insufficiently defined. In our previous full-length 16S rRNA sequencing analysis of children with obesity, *Blautia wexlerae* was depleted in those with MASLD compared with age-, sex-, and BMI-matched non-MASLD controls, suggesting a potential protective role. We therefore investigated whether selected Taiwanese *B. wexlerae* isolates could ameliorate MASLD and explored the underlying gut-liver axis mechanisms. **Methods:** Seven *B. wexlerae* isolates obtained from healthy Taiwanese individuals were cultured anaerobically. Cell-free culture supernatants were first screened in oleic acid-treated HepG2 cells using Oil Red O staining. Based on anti-steatotic activity, two

Taiwanese *B. wexlerae* isolates, designated TBW06 and TBW07, were selected for in vivo validation. Male C57BL/6JNarl mice were fed either chow diet or high-fat diet (HFD). After 7 weeks of HFD feeding, mice received oral gavage with TBW06, TBW07, or vehicle three times weekly for 12 weeks. Glucose metabolism, serum biochemistry, hepatic steatosis and fibrosis, hepatic metabolic and autophagy-related signaling, intestinal barrier integrity, and cecal bile acid composition were assessed. **Results:** Supernatants from the two selected Taiwanese *B. wexlerae* isolates reduced lipid droplet accumulation in oleic acid-treated HepG2 cells. In HFD-induced MASLD mice, treatment with these isolates improved glucose tolerance and reduced visceral adiposity. Histological analysis showed that HFD markedly increased hepatic steatosis and fibrosis, with lipid droplet area and collagen proportionate area reaching 42.9% and 10.2%, respectively. TBW06 reduced these values to 18.2% and 4.9%, while TBW07 reduced them to 14.1% and 4.2%. Mechanistically, treatment with the selected isolates suppressed hepatic CD36, p62, p-mTOR, and p-AKT expression, while enhancing LC3-II/I, BECN1, SIRT1, p-AMPK, and p-ULK1, consistent with reduced fatty acid uptake and activation of autophagy-related pathways. These isolates also restored ileal ZO-1 expression, reduced FITC-dextran permeability, and improved villus length, crypt depth, and goblet cell numbers. Cecal bile acid profiling suggested compositional modulation after treatment, although changes did not reach statistical significance. **Conclusion:** Selected Taiwanese *B. wexlerae* isolates ameliorated experimental MASLD by reducing hepatic steatosis and fibrosis, improving glucose metabolism, restoring intestinal barrier integrity, and enhancing hepatic autophagy-related signaling. These findings provide experimental evidence supporting *B. wexlerae*-based strategies as potential microbiota-directed therapeutics targeting the gut-liver axis in MASLD.

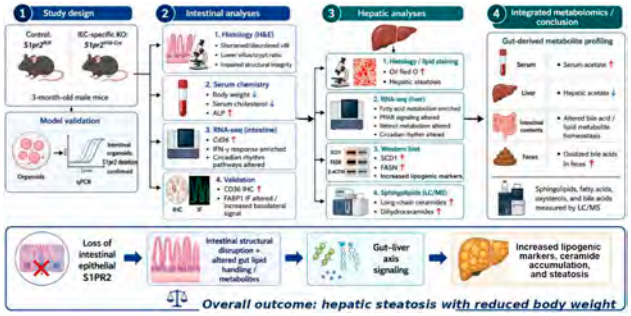
★ 1111 | INTESTINAL EPITHELIAL S1PR2 REGULATES GUT–LIVER LIPID HOMEOSTASIS AND HEPATIC STEATOSIS



Chen Chen[1] Lianyong Su[1] Meiyi Song[1] Grayson Way[1] Wu Nan[1] Derrick Zhao[1] Yunling Tai[1] Hongkun Lu[2] Hui Li[1] Sareh Bayatpour[1] Xuan Wang[1] Emily Gurley[1] Phillip Hylemon[1] Arun Sanyal[1] Huiping Zhou[1], [1]Virginia Commonwealth University, [2]Virginia Commonwealth Univerisity

Background: S1PR2 is a GPCR involved in bile acid signaling and lipid metabolism. Although hepatic S1PR2 contributes to metabolic regulation, the role of intestinal epithelial S1PR2 in gut–liver crosstalk remains unclear. After observing hepatic lipid accumulation in mice with intestinal epithelial S1pr2 deletion, we examined changes linking intestinal S1PR2 loss to steatotic injury. **Methods:** Male 12-week-old S1pr2fl/fl and intestinal epithelial S1pr2 knockout mice (S1pr2Villi-Cre) were used. S1pr2 deletion was verified in intestinal epithelial organoids. Intestine and liver RNAseq were performed. Targeted LC-MS/MS quantified sphingolipids, fatty acids, and bile acids in liver, serum, intestinal contents, and feces. Phenotypes were assessed by histology, serum biochemistry, western blotting, IHC, and IF. **Results:** S1pr2Villi-Cre mice had reduced epithelial S1pr2 expression and lower body weight than age-matched S1pr2fl/fl mice, with no change in liver/body weight ratio. Intestinal histology showed inflammatory cell accumulation, shortened/disorganized villi, mucosal thinning, and reduced villus/crypt ratio, supporting disrupted mucosal architecture and possible barrier dysfunction. Serum cholesterol decreased, whereas hepatic Oil Red O staining showed increased lipid accumulation. Liver RNAseq showed enrichment of fatty acid metabolism, PPAR signaling, retinol metabolism, and circadian rhythm pathways; SCD1 and FASN proteins increased, consistent with a hepatic lipogenic program. Intestinal RNAseq showed altered circadian genes and immune/inflammatory programs, including IFNγ response, with increased Cd36 expression. CD36 IHC and FABP1 IF supported altered intestinal lipid transporter expression/localization. Metabolomics showed increased circulating but decreased hepatic acetate, increased hepatic ceramide/dihydroceramide pools, and altered oxysterol and bile acid profiles, including elevated fecal oxidized bile acids. These data associate intestinal epithelial S1PR2 deficiency with mucosal injury, altered transporter/metabolite profiles, and hepatic steatosis despite reduced body weight. **Conclusion:** Intestinal epithelial S1PR2 loss is associated with disrupted intestinal architecture, altered gut–liver lipid/metabolite signaling, and hepatic lipid buildup.

1112 | ORAL MICROBIOME AND PERIODONTAL DISEASE DISTINGUISH PATIENTS WITH CIRRHOSIS WITH AND WITHOUT HEPATOCELLULAR CARCINOMA

Ângelo Zambam de Mattos[1] Giovana Dumoncel[1] Gabriel Stefani Leão[1] Cristiane Azevedo Alves[1] Luiza Cerutti[2] Raíssa Nunes dos Santos[1] Richard Salvato[1] Rafaela Ramalho Guerra[1] Maximiliano Schunke Gomes[2] Adriana Seixas[1], [1]Federal University of Health Sciences of Porto Alegre, [2]Pontifical Catholic University of Rio Grande do Sul

Background: Hepatocellular carcinoma (HCC) is the third most common cause of cancer-related deaths worldwide. Identifying factors associated with HCC might allow for the development of biomarkers capable of improving surveillance and early detection of this tumor. This study aims at comparing oral and gut microbiome of patients with cirrhosis with and without HCC. **Methods:** This cross-sectional study included individuals with cirrhosis and untreated HCC and a control-group of patients with cirrhosis without HCC, matched by age, etiology of cirrhosis and Child-Pugh classification. Saliva was collected by oral rinsing of sterile saline solution, and feces were collected by rectal swab. All patients underwent oral and dental examination. Saliva and stool samples underwent 16S rRNA gene sequencing (V3–V4 region), and microbial diversity and differential abundance were analyzed using standardized bioinformatic and statistical pipelines with false discovery rate (FDR) control. **Results:** Forty-two patients with cirrhosis were included in the study, 21 with HCC and 21 controls. Demographic and clinical parameters were comparable between groups, except for a non-significant trend towards a higher proportion of men in the HCC-group (52.4% vs 23.8%, $p = 0.112$). Among patients in the HCC-group, 52.4% had tumors within Milan criteria, and the median diameter of the largest tumor was 4.1cm (interquartile range – 2.2-6.8). Patients with HCC exhibited significantly reduced salivary alpha diversity, including lower observed richness ($p = 0.007$) and reduced Simpson-based evenness indices ($p = 0.012$), along with distinct beta diversity clustering compared with controls (Bray-Curtis – $R^2 = 0.034$, $p = 0.009$; Jaccard – $R^2 = 0.026$, $p = 0.002$). Differential abundance analyses consistently identified oral-associated genera contributing to this separation, particularly a significant depletion of Prevotella spp ($Log2FC = -3.33$, FDR < 10%). In parallel to oral dysbiosis, periodontal disease was also associated with HCC (probing depth – $p = 0.005$; attachment loss – $p = 0.049$). In contrast, fecal microbiome showed no significant differences in alpha or beta diversity and lacked a robust differential abundance signature between groups (Figure 1). **Conclusion:** HCC was associated with measurable alterations in the salivary microbiome, but not in fecal microbial diversity or structure within a clinically matched population of individuals with cirrhosis. Moreover, the differential profile of periodontal disease may reflect an inflammatory environment associated with oral dysbiosis. These findings support the oral microbiome as a potential component of host–microbiome interactions in hepatocarcinogenesis and warrant validation in longitudinal, multicenter studies integrating comprehensive oral health parameters and functional microbial analyses.

1113 | RIFAXIMIN REDUCES LIVER FIBROSIS AND EARLY HEPATOCARCINOGENESIS IN EXPERIMENTAL MASH BY MODULATING THE GUT–LIVER AXIS AND ANGIOGENIC SIGNALING

Kosuke Kaji[1] Norihisa Nishimura[1] Shinya Sato[1] Masafumi Oyama[1] Tatsuya Nakatani[1] Tadashi Namisaki[2] Hitoshi Yoshiji[1], [1]Department of Gastroenterology, Nara Medical University, [2]Nara medical university

Background: The gut–liver axis is critically involved in the progression of metabolic dysfunction–associated steatohepatitis (MASH). Translocation of gut-derived lipopolysaccharide (LPS) activates hepatic inflammation and fibrogenesis through toll-like receptor 4 (TLR4) signaling and contributes to angiogenesis during hepatocarcinogenesis. Rifaximin, a non-systemic antibiotic that acts within the intestine, has been reported to improve intestinal barrier function and decrease endotoxin exposure. The present study examined whether rifaximin could suppress liver fibrosis and early hepatocarcinogenic changes in MASH, focusing on the LPS–epiregulin–IL-8–mediated angiogenic pathway. **Methods:** Male Fischer 344 rats were fed a choline-deficient, L-amino acid-defined high-fat diet (CDAHFD) for 12 weeks to induce MASH. Animals received rifaximin (30 mg/kg/day) or vehicle orally during the feeding period. Liver pathology including fibrosis and preneoplastic alterations was evaluated histologically and biochemically. Portal LPS concentrations, Kupffer cell activation, and hepatic LPS/TLR4 signaling were assessed. Angiogenesis-related factors such as epiregulin, IL-8, CD34-positive microvessels, and proangiogenic gene expression were analyzed. Intestinal barrier integrity was examined through histological evaluation, tight junction protein expression, intestinal LPS levels, and FITC-dextran permeability assays. **Results:** Rifaximin treatment markedly reduced hepatic inflammation and fibrosis in CDAHFD-fed rats, as evidenced by decreased hydroxyproline levels and downregulation of profibrogenic genes. The number of glutathione S-transferase placental form (GST-P)-positive preneoplastic lesions was significantly lower, along with suppression of proliferation-associated genes. Rifaximin also decreased portal endotoxin levels and inhibited Kupffer cell activation, accompanied by reduced expression of Lbp, Cd14, Tlr4, and inflammatory cytokines. Importantly, hepatic expression of epiregulin and IL-8 was significantly diminished, which was associated with reduced CD34-positive neovascularization and downregulation of angiogenesis-related genes. These changes coincided with improved intestinal barrier function, characterized by restoration of villus morphology, increased tight junction protein expression, and reduced intestinal permeability. **Conclusion:** Rifaximin alleviates liver fibrosis and early hepatocarcinogenesis in experimental MASH by strengthening intestinal barrier integrity, reducing gut-derived endotoxin exposure, and inhibiting LPS–TLR4–epiregulin–IL-8–dependent angiogenic signaling. These findings suggest that modulation of the gut–liver axis with rifaximin may represent a potential chemopreventive strategy for MASH-related liver cancer.

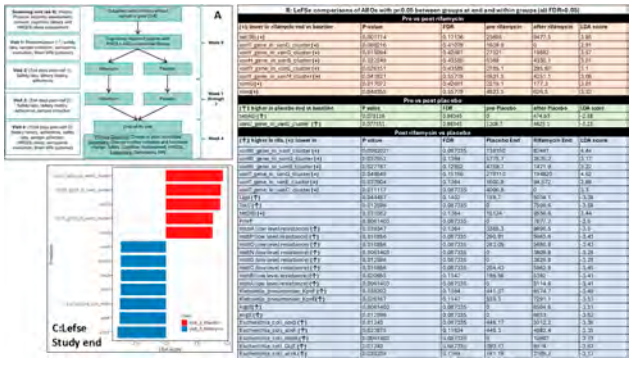
1114 | RIFAMYCIN THERAPY DOES NOT SIGNIFICANTLY CHANGE GUT MICROBIAL ANTIBIOTIC RESISTANCE GENE EXPRESSION IN CIRRHOSIS: RESULTS FROM A DOUBLE-BLIND, PLACEBO-CONTROLLED, RANDOMIZED CLINICAL TRIAL



Jasmohan Bajaj[1] Masoumeh Sikaroodi[2] Haley Obolewicz[3] Mary Leslie Gallagher[4] Travis Mousel[3] Puneet Puri[1] Brian Davis[5] Patrick Gillevet[2], [1]Virginia Commonwealth University, [2]George Mason University, [3]Richmond VAMC, [4]McGuire Veterans Affairs Medical Center, [5]Central Virginia VA Health Care System

Background: Antibiotic resistance is a growing issue in cirrhosis. Of late the non-absorbable antibiotic rifaximin has been implicated with emergence of gut microbial antibiotic resistance genes (ARGs), especially with vancomycin resistance, but with unclear clinical implications. The impact of *rifamycin*, a related rifampin antibiotic approved for traveler's diarrhea, on ARGs development in cirrhosis is unclear. **Methods:** The RIVET randomized controlled trial was conducted in compensated outpatients with cirrhosis and minimal HE. Patients were randomized 1:1 into placebo or rifamycin 600mg BID for 30 days in a double-blind manner (Fig A). Stool was collected at baseline and

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

drug-end. We performed metagenomics and ARGs and antibiotic resistance ontology (ARO) analysis using the CARD database. ARO abundances were compared between & within groups using LeFSe and using false discovery rates (FDR). **Results:** **Patient characteristics** : 30 patients (15 per group) with MHE without prior overt HE were included. Both groups had similar ages (67 vs 65 yrs mean), 93% men each, & MELDNa (8 vs 9 median). All patients completed the trial, which showed safety, improvement in sarcopenia in rifamycin group, but no change in cognition between groups. MELD score, complications of cirrhosis remained stable between/within groups. There were no infections noted during the follow-up. **AROs changes** pre/post and within groups showed no change that was FDR < 0.05 between or within groups (Fig B). Exploratory analyses were then performed with significant p-value changes. Pre vs post rifamycin : Multiple glycopeptide resistance operon components, including vanB-, vanC-, vanG-, vanL-, and vanM-associated genes, decreased following rifamycin compared to baseline and end-of-study. Remaining ARO changes were lowered tetracycline and nitroimidazole resistance.Pre vs post placebo : Increase in van-U (vancomycin resistance) & tetracycline were seen after placebo (Fig B).Rifamycin-end vs placebo-end : There was a lower vancomycin resistance post-rifamycin vs placebo while the increase in the Enterobacteriaceae were low-level chromosomal changes but high-level transmissible plasmid-driven resistance (Fig B /C). **Conclusion:** A prospective clinical trial of rifamycin versus placebo showed no major infections or safety risk. We found no significant changes in ARO gene expression between or within groups using strict FDR. Exploratory analyses showed a consistent reduction of enterococcal populations harboring van-associated resistance determinants compared to baseline values and at study end versus placebo. Increase in ARO genes post-rifamycin vs placebo were focused on inherent expression of chromosomal low-risk changes adapting to antibiotic exposure rather than high-risk transmissible resistance mechanisms. These findings suggest that rifamycin did not promote expansion of ARO and especially vancomycin-resistance pathways in cirrhosis.

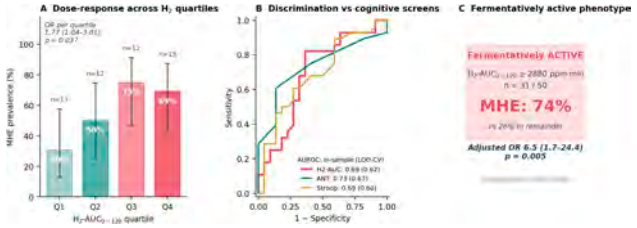
1115 | CUMULATIVE BREATH HYDROGEN REFLECTS A COLONIC FERMENTATION PHENOTYPE ASSOCIATED WITH MINIMAL HEPATIC ENCEPHALOPATHY IN MASLD PREDOMINANT CIRRHOSIS



Akash Roy[1] Shummy Das[1] Uday Chand Ghoshal[1] Mahesh Goenka[1], [1]Apollo Multispeciality Hospitals

Background: Hepatic encephalopathy is driven by gut microbial metabolism, yet the lactulose hydrogen breath test is interpreted only categorically in cirrhosis, discarding the quantitative information it generates. We hypothesised that cumulative breath hydrogen quantifies a colonic fermentation phenotype that tracks minimal hepatic encephalopathy (MHE) on an axis independent of liver-disease severity **Methods:** Prospective single-centre cross-sectional study of 50 adults with cirrhosis without overt HE. PHES (reference standard for MHE), Animal Naming Test (ANT) and EncephalApp Stroop were performed. Cumulative breath hydrogen (H2-AUC0–120; ppm·min) was computed from a standardised 10-g lactulose breath test. OCTT was defined by the classical double-peak rule: time to the second (colonic) H2 peak $\geq$ 20 ppm above baseline. Associations used Mann–Whitney U and Fisher tests; Firth-penalised logistic regression adjusted for MELD-Na. Discrimination was reported as in-sample and leave-one-out cross-validated (LOO-CV) AUROC. **Results:** MHE was present in 28/50 (56%); MASLD accounted for 76% of the cohort. H2-AUC showed a graded relationship with MHE with prevalence rising monotonically across quartiles (30%, 50%, 75%,69%; trend p = 0.024), adjusted OR per quartile 1.77 (95% CI 1.04–3.01, p = 0.037). At the Youden-optimal threshold of $\geq$ 2880 ppm·min, the fermentatively active phenotype (n = 31) had 74% MHE versus 26% in the quiescent phenotype; MELD-Na-adjusted OR 6.5 (1.7–24.4), p = 0.005. As a non-cognitive biomarker, H2-AUC discriminated MHE comparably to validated cognitive screens (in-sample / LOO-CV AUROC: H2-AUC 0.69/0.62; ANT 0.73/0.67; Stroop 0.69/0.60). The association was strongest in the MASLD subgroup (H2-AUC 5415 vs 1935 ppm·min in MHE vs no-MHE, p = 0.031). H2-AUC did not

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

co-relate with MELD-Na ($\rho = 0.01$), albumin, bilirubin, INR and BMI (all $|\rho| < 0.16$), indicating that fermentative burden indexes a risk axis independent to liver-disease severity. Findings persisted after adjustment for concurrent lactulose and rifaximin use (medication term non-significant, $p = 0.27$). **Conclusion:** In contemporary MASLD predominant cirrhosis, cumulative breath hydrogen reflects a graded colonic fermentation phenotype that identifies MHE independently of liver-disease severity and matches validated cognitive screens despite being a non-cognitive, gut-derived signal. Reframing the lactulose breath test as a quantitative microbiome metabolite assay offers a point-of-care window onto the gut–brain axis, and a potentially modifiable target for microbiome-directed therapy.

1116 | LIGILACTOBACILLUS SALIVARIUS–DERIVED INDOLE-3-LACTIC ACID ENHANCES NK CELL FUNCTION VIA MAPK SIGNALING TO SUPPRESS HEPATOCELLULAR CARCINOMA PROGRESSION

Zhewen Zhou[1] Xuefeng Huang[2] Yipeng Wang[2] Xiu Sun[3] Minghui Li[2] Ronghai Huang[2] Pu Liang[2] Xi Wang[2] Huichun Xing[2], [1]Beijing Ditan Hospital, Capital Medical University, [2]Beijing Ditan Hospital, [3]Shanxi Bethune Hospital

Background: Gut microbiota, particularly lactobacilli, produce tryptophan-derived metabolites with immunomodulatory potential. However, the metabolites involved in hepatocellular carcinoma (HCC) surveillance and the immune mechanisms remain largely undefined. We investigated the antitumor efficacy of *Ligilactobacillus salivarius* (*L. salivarius*) and its metabolite indole-3-lactic acid (ILA) in HCC and examined how ILA regulates NK cell-mediated immunity. **Methods:** Fecal samples from cirrhosis and HCC patients and paired HCC tumor/nontumor tissues were analyzed for microbiota changes. *L. salivarius* and ILA were evaluated in murine HCC models. Bulk RNA sequencing, assay for transposase-accessible chromatin using sequencing, and single-cell RNA sequencing were used to define ILA-mediated mechanisms in NK cells. In patients with HCC, cytotoxicity of peripheral blood NK cells was correlated with plasma tryptophan metabolites. ILA was evaluated in NSIG mice bearing HepG2 tumors receiving adoptive NK92MI-cell transfer. **Results:** Fecal *Ligilactobacillus*/*Lactobacillus* and tissue *Lactobacillales* were reduced in HCC. *L. salivarius* restored gut microbiota and reduced tumor burden, with increased intratumoral NK-cell infiltration and function. ILA was identified as an effector metabolite that reduced tumor burden, increased intratumoral NK-cell infiltration, and enhanced NK-cell cytotoxicity in vivo and in vitro. Multiomics showed that ILA remodeled NK-cell chromatin, upregulated MAP3K8, and activated MAPK signaling. Clinically, plasma ILA correlated with NK-cell cytotoxicity in HCC, and ILA pretreatment improved adoptively transferred NK92MI-cell efficacy in NSIG mice. **Conclusion:** *L. salivarius* and ILA attenuate HCC progression by enhancing NK-cell infiltration, promoting chromatin remodeling, and activating MAPK signaling, thereby strengthening NK cell-mediated antitumor immunity. Therefore, microbiota-derived ILA may represent a candidate for HCC immunotherapy.

Environmental Health, [4]Sri Aurobindo Institute of Medical Sciences, [5]Shalby Institute of Gastroenterology

Background: The gut–liver axis, representing the bidirectional communication between the gut microbiome and the liver, has emerged as a key modulator in liver-related disorders. Dysregulation of the gut microbiome has been implicated in several liver pathologies. However, our understanding of specific microbial enterotypes underlying the intricate gut-liver axis in these disorders and their correlations with hepatic injury markers remains largely limited. Therefore, this study aimed to characterize and compare gut microbiota composition in individuals with a decompensated alcoholic liver disease (DALD), alcohol use disorder (AUD), metabolic dysfunction associated steatotic liver disease (MAFLD), and healthy controls, and to identify disease-specific microbial patterns. **Methods:** It's a cross-sectional study enrolling 92 male participants and carried out high-throughput full-length 16S rRNA gene sequencing in their stool samples to compare gut microbiome profiles among patients with DALD, AUD, and MAFLD versus age- and demography-matched healthy controls. Alpha diversity, assessed using the Shannon and Chao1 indices, while Beta diversity analysis using principal coordinate analysis (PCoA) and PERMANOVA **Results:** This study reveals patients with alcohol-related liver diseases present depleted microbial diversity and reduced abundance of Faecalibacterium prausnitzii, Bifidobacterium adolescentis, Ligilactobacillus ruminis, and Prevotella copri, while harbouring a higher population of translocation-prone taxa, including Enterococcus, Veillonella, and Rothia spp. In contrast Phocaeicola. Bifidobacterium, Streptococcus, and Escherichia were reduced in MAFLD patients as compared with controls, while butyrate-producing taxa linked to metabolic disruption were retained. Analysis of shared and unique amplicon sequence variants (ASVs) identified 220 ASVs (1.9%) common to all groups, with group-specific ASVs numbering 3058 (26.4%) in controls, 2178 (18.8%) in AUD, 1779 (15.4%) in DALD, and 2608 (22.5%) in MAFLD. Overall, L. ruminis, B. massiliensis, A. rectalis, and B. adolescentis emerged as recurrent taxa positively associated with favorable liver function and metabolic health, while V. atypica, Enterococcus spp., and Escherichia spp. were consistently observed with the markers of hepatic dysfunction, particularly in alcohol-associated liver disease. **Conclusion:** 1.These findings reveal unique gut microbiome arrays underlying distinct liver disease subtypes, highlighting potential implications of these dysbiotic signatures in the pathophysiology of hepatic inflammation and metabolic regulation.2. Alcohol consumption is associated with distinct gut microbial signatures, with DALD exhibiting the most pronounced differences3.The enrichment of translocation-prone and opportunistic genera, coupled with depletion of beneficial commensals, is linked to advanced liver pathology.

Pittsburgh School of Medicine, [7]Johns Hopkins University, [8]University of Mississippi Medical Center, [9]Georgetown University, [10]University of Miami Miller School of Medicine, [11]SUNY Downstate Health Sciences University, [12]Emory University School of Medicine, [13]University of North Carolina at Chapel Hill, [14]Johns Hopkins Bloomberg School of Public Health, [15]Cook County Health

Background: Liver disease is a leading cause of non-AIDS mortality in people with HIV (PWH). PWH experience a high burden of hepatic fibrosis, and increasing evidence implicates the gut-liver axis as a contributor. Alterations in the gut microbiome, including changes in within-sample (alpha) and between-group (beta) diversity and depletion of short-chain fatty acid (SCFA)-producing taxa, have been linked to fibrosis in populations without HIV, but remain understudied in PWH. **Methods:** We conducted a cross-sectional analysis of PWH without moderate to heavy alcohol use, recent antibiotic use, or viral hepatitis within the MACS/WIHS Combined Cohort Study (MWCCS). Data included and stool-derived 16S rRNA sequencing and vibration-controlled transient elastography (VCTE) performed within 6 months of each other. Microbial diversity was evaluated using alpha (Shannon index) and beta (Bray-Curtis dissimilarity) diversity metrics with PERMANOVA to quantify variation in composition. Analyses were adjusted for age, sex, BMI, race, ethnicity, CD4 count, HIV-1 RNA, ART use and alcohol use. Differential abundance analysis (DAA) (ANCOM-BC2) was used to identify taxa enriched or depleted in those with prevalent F2 or greater fibrosis (VCTE liver stiffness 7.1 kPa) compared to those without fibrosis. **Results:** Among 293 participants, 69% were female, 54% were Black, 74% had HIV-1 RNA < 20 copies/mL, and 22% had fibrosis. In adjusted analyses (Figure 1), alpha diversity did not differ by fibrosis status. However, beta diversity analyses demonstrated a difference in overall microbial community composition between groups ($p = 0.03$, $R^2 = 0.01$). Unadjusted DAA identified multiple taxa associated with fibrosis, including depletion of members of the *Lachno* **Conclusion:** Among PWH, hepatic fibrosis is associated with alterations in gut microbial composition, characterized in part by depletion of SCFA-producing *Lachnospiraceae* taxa, which parallels microbial patterns in people without HIV. However, fibrosis in PWH was also characterized by distinct microbial signatures including an enrichment in *Salmonella*, thereby supporting a role for the gut-liver axis in HIV-specific hepatic fibrosis. Future studies are needed to identify likely causal relationships and evaluate microbiome-targeted interventions.

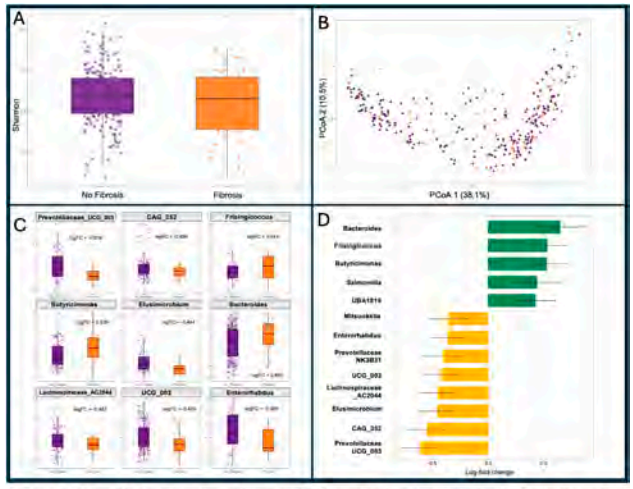

Figure 1: Microbial community analyses and differential abundance testing in PWH with and without hepatic fibrosis. Panel A: Covariate-adjusted alpha diversity (Shannon index) between PWH with and without fibrosis showed no significant differences between groups. **Panel B:** Covariate-adjusted beta diversity differed between groups based on Bray–Curtis dissimilarity (PERMANOVA p=0.01, R^2=0.01). **Panel C:** Differential abundance analysis of taxa associated with fibrosis. Boxplots depict the 9 taxa with the greatest differences in abundance between groups (fibrosis in orange, no fibrosis in purple). Log fold change (logFC) reflects the magnitude and direction of differences in taxon abundance between fibrosis and non-fibrosis groups. **Panel D:** Log-fold plot depicts the top microbial taxa enriched (green) or depleted (yellow) in PWH with hepatic fibrosis.

Radiology and Imaging Sciences, [5]National Cancer Institute, Bethesda

Background: Portal blood serves as the primary interface of the gut-liver axis, delivering microbial cells, nucleic acids, metabolites, and immune mediators directly from the intestine to the liver. Despite its critical position, the portal blood microbiome remains largely unexplored. Hepatitis C virus (HCV) infection provides an ideal model to study host-microbe dynamics, as antiviral therapy eliminates viral replication while liver injury and fibrosis persist. **Methods:** Cell-free DNA and RNA were extracted from portal plasma of patients with active HCV infection (HCVi, n = 29) and after sustained virologic response (SVR, n = 23). Non-human reads were mapped to the NCBI microbial database to characterize bacteria, fungi, viruses, and archaea. Microbial diversity was assessed using Shannon and Bray-Curtis indices. Cross-kingdom networks were identified via SparCC analysis, while multi-omics integration linked microbial taxa with circulating metabolites and host portal cell-free RNAs. **Results:** Portal microbiomes were dominated by bacteria, followed by fungi, viruses, and archaea. In cirrhotic patients, fungal abundance increased post-SVR while bacterial abundance and fungal diversity declined, with significant compositional shifts (Bray-Curtis, $p = 0.008$). Cross-kingdom analysis revealed that bacteria-fungi interactions accounted for over 80% of microbial correlations, with a fungal hub-driven competitive subnetwork emerging post-SVR in cirrhotics. Specific fungal taxa, including *Malassezia japonica* and *Aspergillus puulaauensis*, were associated with bile acids, lipids, and gamma-glutamyl peptides during advanced fibrosis. Host cfRNA pathways reflected translation and cellular stress during active HCV infection, shifting toward immune remodeling post-SVR. A selective enrichment of mitochondrial protein import and translation pathways (TOMM/TIMM complexes and mitochondrial ribosomal genes) in non-cirrhotics post-SVR only, reflecting preserved bioenergetic capacity after viral clearance. **Conclusion:** Portal microbiome restructuring persists after viral clearance in cirrhotic patients, with sustained dysbiosis and incomplete ecological recovery. Multi-omics integration of the portal blood reveals ongoing metabolic and transcriptional reprogramming driven by host-microbe interactions, highlighting fungi and bile acid signaling as potential therapeutic targets in HCV-associated cirrhosis.

1120 | RATIONAL FMT DONOR SELECTION FOR HEPATIC ENCEPHALOPATHY TRIALS USING LACTULOSE FERMENTATION CAPACITY

Soumok Sadhu[1] Katherine Barry[1] Ram Dahal[1] Michael Sadowsky[1] Levi Teigen[1] Jasmohan Bajaj[2], [1]University of Minnesota, [2]Virginia Commonwealth University

Background: Hepatic encephalopathy (HE), a major complication of advanced liver disease, remains a substantial clinical challenge. Current standard therapies, lactulose and rifaximin, target the gut microbiome with prebiotic and antibiotic effects, respectively. In a recent phase 2 randomized trial (THEMATIC), FMT reduced HE over placebo. However, some participants still suffered HE recurrence, highlighting the need for improved donor selection and dosing strategies before larger clinical trials are undertaken. Because the therapeutic effect of lactulose depends on microbial fermentation, we hypothesize that patients with advanced liver disease typically have reduced lactulose fermentation capacity. We further hypothesize that this defect can be restored through engraftment of healthy donor microbiota with high fermentation capacity. **Methods:** We developed an anaerobic mini-bioreactor platform to screen microbiota of FMT donors in our GMP program for lactulose consumption, pH lowering, and SCFA production. Microbiota were purified from stool using a rapid syringe-based method and cultured anaerobically with or without lactulose (~200 µg/mL) at standardized cell counts (~5×10^9 cells/mL) for up to two hours. **Results:** We tested fecal microbiota of 14 healthy individuals (Age 33.6 ± 9.4 years, 8 males, 6 females). We found considerable variability in lactulose utilization and acid production over 2 hours (ANOVA, ~10–90%, $p < 0.0001$), with parallel variability in acidification ($p < 0.0001$) and SCFA production ($p = 0.05$) (Figure 1). Lactulose consumption correlated with acid production (Spearman $r = 0.64$, $p = 0.014$) and SCFA production, establishing $\Delta[H^+]$ as a simple functional biomarker for donor selection. Of note, we could not identify any simple demographic factor predictive of lactulose fermentation capacity. We applied this metric to the 2 donors used in the THEMATIC trial where the recipients of stool from donor#1 showed no HE recurrence, while from

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

donor#2 had a 13% recurrence (Figure 1). The lactulose metabolizing capacity was significantly higher in donor#1 vs #2 (82.70% vs 24.63%, p = 0.011). **Conclusion:** Optimal donor-recipient matching is critical to enhance the success of HE-focused FMT. Measurement of lactulose consumption and acid production capacity of fecal microbiota provides a rational method for selection of FMT donors for prevention of HE.

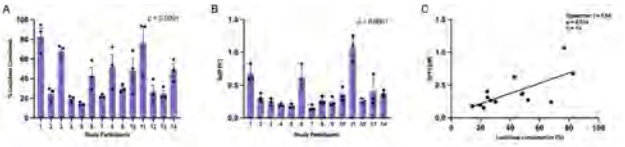

Figure 1. Donor's microbiota differ widely in their ability to ferment lactulose and acidify their environment. **(A)** Lactulose consumption by purified donor microbiota in the anaerobic mini-bioreactor assay varied significantly across donors ($p < 0.0001$). **(B)** Acid production from lactulose fermentation, measured as the change in hydrogen ion concentration ($\Delta[H^+]$), followed the same pattern ($p < 0.0001$), pointing to real differences in how strongly each donor's community acidifies its surroundings. **(C)** Lactulose consumption tracked with acid production (Spearman $r = 0.64$, $p = 0.014$, $n = 14$). Donors that fermented more lactulose also dropped pH further. Values are mean ± SEM of biological triplicates. Healthy donors are not metabolically interchangeable, and a functional readout of this kind may be more useful than composition alone for selecting FMT donors in hepatic encephalopathy.

1121 | PREVALENCE AND CLINICAL CORRELATES OF SMALL INTESTINAL BACTERIAL AND FUNGAL OVERGROWTH IN DECOMPENSATED CIRRHOSIS AND ACUTE-ON-CHRONIC LIVER FAILURE: A SNAPSHOT FROM NORTH INDIA

Rahul Rahul[1] Sumit Rungta[2], [1]King George Medical University, Lucknow, U.P. India, [2]KGMU

Background: Small intestinal bacterial overgrowth (SIBO) is a recognized feature of gut–liver axis disruption in cirrhosis, yet small intestinal fungal overgrowth (SIFO) is poorly characterized and culture-based Indian data are virtually absent. In this context, the study was aimed to estimate the prevalence of SIBO and SIFO in decompensated chronic liver disease (DCLD) and acute-on-chronic liver failure (ACLF) and examine their association with disease severity and complications. **Methods:** A single centre, hospital-based, analytical cross-sectional study enrolled 130 adults (116 DCLD; 14 ACLF, APASL criteria) who underwent endoscopy-guided duodenal aspiration using a sheathed microbiota sampler with quantitative bacterial and fungal culture. SIBO and SIFO were defined at $\geq 10^3$ CFU/mL; fungi were speciated by VITEK 2 and MALDI-TOF. A pre-specified, directed acyclic graph–guided multivariable analysis with E-value and alcohol-stratified sensitivity analyses was reported per STROBE guidelines. **Results:** Either of the overgrowths occurred in 38.5%: isolated SIBO 30.0%, combined SIBO–SIFO 6.9%, isolated SIFO 1.5%. SIBO prevalence was 36.9% (95% CI 29.1–45.5) and SIFO 8.5% (4.8–14.5). Isolates were 95.9% Gram-negative, with *Pseudomonas* spp. and *E. coli* co-dominant (each 32.7%); all fungi were *Candida* (*C. albicans* 72.7%, *C. tropicalis* 27.3%). Both states rose monotonically across Child–Pugh class and MELD-Na; combined overgrowth occurred only in Child–Pugh C. SIBO and SIFO co-occurred far above chance (OR 7.74; 95% CI 1.83–32.83; p = 0.002), asymmetrically, suggesting bacterial overgrowth precedes fungal proliferation. On adjusted analysis, age (aOR 1.05/year) and MELD-Na (aOR 1.06/unit) independently predicted SIBO, while MELD-Na (aOR 1.13/unit) and SIBO co-positivity (aOR 7.11) predicted SIFO (AU-ROC 0.86). SIFO was strongly linked to spontaneous bacterial peritonitis and prior rifaximin use. No SIFO or combined overgrowth occurred in ACLF despite greater severity. **Conclusion:** In advanced liver disease, small intestinal overgrowth, including an under-recognized fungal component, is common and is associated closely with hepatic severity. SIFO marks an advanced, SIBO-linked dysbiotic phenotype confined to the most decompensated patients.

1122 | BASELINE ORAL MICROBIOME COMPOSITION AND VITAMIN K BIOSYNTHESIS CAPACITY DISTINGUISH PATIENTS WITH LIVER STIFFNESS PROGRESSION IN A DIVERSE URBAN MASLD POPULATION

Adeeba Tak[1] Yulu He[1] Maryfe Coronel Novoa[1] Mark Miller[1] Victor Llanes[1] Asher Leviton[1] Jeremiah Faith[1] Frances Lee[1] Ryan Walker[1] Dania Valvi[1] Scott Friedman[1] Meena Bansal[2] Xiaotao Zhang[1], [1]Icahn School of Medicine at Mount Sinai, [2]Icahn School of Medicine at Mount Sinai (ISMMS)

Background: Fibrosis stage is the strongest predictor of outcomes in MASLD, yet progression is

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

heterogeneous and difficult to predict noninvasively. The oral microbiome, linked to metabolic disease and systemic inflammation, may provide a novel risk-stratification biomarker. We assessed whether baseline oral microbiome profiles distinguish MASLD patients with subsequent VCTE-defined liver stiffness progression from those without progression in a diverse urban cohort. **Methods:** Forty-three adults with MASLD from DAMILE prospective cohort underwent baseline oral metagenomic sequencing with taxonomic and pathway profiling. Liver stiffness (LSM) was measured by VCTE at baseline and follow-up; progression was defined as a $\geq$30% liver stiffness increases between scans separated by at least 6 months. Twenty passed longitudinal eligibility. Five progressed and 15 did not (median follow-up 1.4 years). Baseline community structure was tested by PERMANOVA (Aitchison distance), adjusted for age, sex, BMI, and ethnicity. Differential pathway abundance was tested using models adjusted for age, sex, BMI, diabetes, GLP-1 RA use, resmetirom use, ethnicity, baseline LSM, and follow-up duration. Three pre-specified pathway sets and a post-hoc composite of 13 menaquinol biosynthesis pathways were each tested under this adjustment. Given a small subset, all analyses are exploratory and hypothesis-generating. **Results:** Among 20 patients with oral microbiome data, median age was 59 years; 60% were female, 35% Hispanic, and 50% had diabetes. Progressors had higher baseline BMI than non-progressors (34.4 vs. 29.2 kg/m², $p = 0.033$) and more frequent baseline use of GLP-1 RA (60% vs. 27%) and resmetirom (20% vs. 7%). Groups were otherwise similar by age, sex, ethnicity, diabetes status, and baseline liver stiffness. Oral microbiome beta diversity, assessed by Aitchison distance, differed significantly by progression status ($p = 0.012$). In adjusted analyses, a composite of 13 menaquinol biosynthesis pathways was significantly lower among progressors ($\beta = -5.75$, $p = 0.023$) (**Figure 1).** The other pre-specified pathways showed no meaningful difference between groups: sugar metabolism was slightly higher in progressors but not significantly so, and LPS biosynthesis was unchanged. This suggests that the reduced vitamin K2 capacity is a targeted finding rather than a sign of a broadly altered oral microbiome. **Conclusion:** In this exploratory analysis, baseline oral microbiome profiles differed between MASLD patients with and without subsequent liver stiffness progression. Reduced predicted vitamin K/menaquinol biosynthesis capacity was associated with progression, suggesting a potential oral microbial-functional signal. Larger studies are needed to validate these findings and evaluate whether oral microbiome profiling can improve noninvasive risk stratification for fibrosis progression in MASLD.

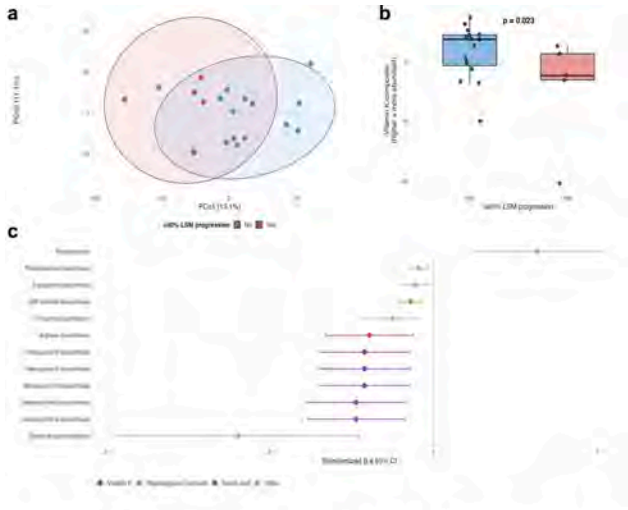

Figure 1. Baseline oral microbiome composition and vitamin K biosynthesis capacity distinguish MASLD patients with liver stiffness progression. DAMILE prospective cohort, longitudinal subset (N=20; 5 progressors, 15 non-progressors); progression defined as ≥30% LSM increase on paired VCTE ≥6 months apart. **(a)** Aitchison-distance PCoA of baseline oral microbiome by progression status with 95% confidence ellipses; PERMANOVA adjusted for age, sex, BMI, and ethnicity, p=0.012. **(b)** PC1 of a 13-pathway menaquinol (vitamin K) biosynthesis composite, significantly lower in progressors under full clinical adjustment (β=−5.75, p=0.023). **(c)** Standardized β (±95% CI) for the top 12 progression-associated pathways, by functional category. Analyses are exploratory and hypothesis-generating.

1123 | TRANSCRIPTIONAL UPREGULATION OF MICROBIAL MUCIN GLYCAN DEGRADATION IN THE GUT MICROBIOME OF NON-CIRRHOTIC PORTAL HYPERTENSION

Wesam Aleyadeh[1] Jenna Oringher[2] Meital Gewirtz[3] Yue Zhang[4] Neelam Redekar[5] James Haddad[6] Rownock Afruza[7] Moumita Chakraborty[7] Julian Hercun[8] Maria Mironova[9] Justin Lack[4] David Kleiner[10] Michail Lionakis[11] Christopher Koh[7] Theo Heller[12], [1]National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, [2]University of Pittsburgh & Carnegie Mellon University, [3]Northwestern University Feinberg School of Medicine, [4]NIH, [5]NIAID/NIH, [6]University of Wisconsin, [7]NIDDK, NIH, [8]Centre hospitalier de l'Universite de Montreal, [9]UCSD, [10]National Cancer Institute, Bethesda, [11]NIAID, NIH, [12]NIH/NIDDK

Background: Non-cirrhotic portal hypertension (NCPH) produces portal hypertension without the synthetic dysfunction of cirrhosis, offering a model to study portal hypertensive pathobiology without that confounder. Gut dysbiosis is well described in cirrhosis, but the NCPH microbiome remains poorly characterized. **Methods:** Cross-sectional analysis of 26 NCPH patients and 32 healthy controls (HC). DNA and RNA were extracted from stool and shotgun sequenced. Functional profiles were assigned to MetaCyc pathways (HUMAnN3). Metatranscriptomic differential expression was tested with a general linear model adjusted for paired metagenomic abundance, age, BMI, and sex. Community-level pathways differentially expressed in NCPH ($q < 0.1$, Benjamini-Hochberg) were stratified to the species level. **Results:** 111 community-level pathways were differentially expressed, all upregulated in NCPH. Two core mucin O-glycan degradation pathways were among the most strongly enriched: the superpathway of N-acetylglucosamine, N-acetylmannosamine, and N-acetylneuraminate degradation (GLCMANNANAUT-PWY; log2FC 3.34, $q = 0.006$) and the superpathway of N-acetylneuraminate (sialic acid) degradation (P441-PWY; log2FC 2.40, $q = 0.040$). These pathways catabolize the structural and terminal sugars of intestinal mucin. Of 65 differentially expressed species-level pathways, mucin glycan degradation was attributed to *Roseburia inulinivorans* (log2FC 1.30, $q = 0.084$), a host-glycan-foraging member of the Lachnospiraceae. Recognized mucolytic taxa, including *Ruminococcus gnavus* and *R. torques*, were among species associated with NCPH. **Conclusion:** The NCPH gut metatranscriptome shows coordinated upregulation of mucin glycan degradation, indicating increased microbial foraging on the colonic mucus barrier. Because mucus thinning promotes epithelial contact and translocation of microbial products through the portal circulation, this functional shift is a plausible, cirrhosis-independent contributor to portal hypertensive disease. Findings are limited by sample size and cross-sectional design and warrant validation with direct assessment of mucus integrity and gut barrier function.

1124 | AKKERMANSIA MUCINIPHILA ATTENUATES TUMORIGENESIS IN A MOUSE MODEL OF METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE-ASSOCIATED HEPATOCELLULAR CARCINOMA

Hsin Jou Lee[1] Ting Ting Chang[1], [1]National Yang Ming Chiao Tung University

Background: Metabolic dysfunction-associated steatotic liver disease-associated hepatocellular carcinoma (MASLD-associated HCC) is a common cause of liver disease, with a complex pathology including chronic inflammation, oxidative stress, and gut microbiota dysbiosis. *Akkermansia Muciniphila*, a human intestinal symbiont, has been found to protect the liver by reducing fatty liver and inflammation. The aim of the study was to investigate the beneficial effect and mechanism of heat-inactivated *Akkermansia Muciniphila* on MASLD-associated HCC. **Methods:** To generate a mouse model of MASLD-associated HCC, eighteen-day-old male C57BL/6J mice were administrated diethylnitrosamine via intraperitoneal injection and fed a high-fat diet for 24 weeks. The heat-inactivated *Akkermansia Muciniphila* was administered orally for 4 weeks. Serum fasting glucose, lipid profile, and liver function were followed. Tumor nodules in liver tissues were calculated. Meanwhile, hepatic protein expressions were analyzed using Western blotting. **Results:** The administration of heat-inactivated *Akkermansia Muciniphila* decreased serum triglyceride, total

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

cholesterol, alanine transaminase, and aspartate aminotransferase levels in MASLD-associated HCC mice. In parallel, the average hepatic tumor number and liver-to-body weight ratio in MASLD-associated HCC mice were reduced by the treatment of heat-inactivated *Akkermansia Muciniphila*. Moreover, the heat-inactivated *Akkermansia Muciniphila*-treated group showed downregulated proliferative, angiogenic, and inflammatory protein expressions as well as upregulated cell apoptotic protein expressions in the liver tissues of MASLD-associated HCC mice. **Conclusion:** Our current observations suggested that heat-inactivated *Akkermansia Muciniphila* might inhibit tumorigenesis through modulating the proliferative, angiogenic, inflammatory, and cell apoptotic signaling pathways in MASLD-associated HCC. Further experiments are warranted to elucidate the underlying mechanisms and evaluate the clinical potential of these findings.

1125 | A CASE OF FECAL MICROBIOTA TRANSPLANTATION FOR RECURRENT HEPATIC ENCEPHALOPATHY

JIayin Wang[1] Chao Yang[1] Yanchao Fu[1] Huiling Xiang[1], [1]Central Hospital, Tianjin University Tianjin Institute of Hepatobiliary Disease

Background: Hepatic encephalopathy (HE) is a common complication of liver cirrhosis. Standard regimens including lactulose, rifaximin and L-ornithine-L-aspartate are routinely applied, but some patients still experience recurrent episodes, which may lead to irreversible brain injury. Fecal Microbiota Transplantation (FMT) can reconstruct intestinal microecology and provides a novel therapeutic strategy for refractory hepatic encephalopathy. **Methods:** A 59-year-old male had a 6-year history of liver cirrhosis, with comorbidities of upper gastrointestinal bleeding, hypertension, post-splenectomy status, and hypothyroidism after iodine-131 therapy for hyperthyroidism. Over the past year, the patient has repeatedly experienced confusion of consciousness, tremors in the hands, and a decline in calculation ability. Despite conventional treatments such as liver protection and lowering blood ammonia, the effects have been unsatisfactory. Cranial MRI excluded cerebrovascular accidents and intracranial space-occupying lesions. The admission blood ammonia level was 89 μmol/L, and the patient was diagnosed with overt type C hepatic encephalopathy (West-Haven grade 2). Gut microbiota analysis revealed severe dysbiosis: *Veillonella* accounted for 58.95% of the intestinal flora, the B/E ratio was only 0.0164(the normal value was greater than 1.), and microbial diversity was markedly reduced, consistent with grade III intestinal dysbiosis. FMT was recommended. Pretreatment with lactulose and rifaximin was given for 5 days to reduce the abundance of *Veillonella*. Oral FMT capsules were administered (each capsule contained 0.211 g bacterial powder, equivalent to 0.2918×10^{14} CFU). Two days after the initial dose of 6 capsules once daily, the patient developed high fever, general myalgia and upper limb rash, accompanied by significantly elevated inflammatory markers. The presentation was considered a transient Herxheimer reaction related to FMT, which resolved after symptomatic management. A total of 45 capsules were subsequently completed via a dose-escalation regimen with good tolerance. **Results:** The patient was followed up for 11 months after FMT. No recurrence of hepatic encephalopathy symptoms was observed. Repeat examination showed significant recovery of intestinal microbiota diversity, a marked reduction in *Veillonella* abundance, and obvious improvements in the proportion of Lachnospiraceae, B/E ratio and short-chain fatty acid synthesis function. Intestinal mucosal barrier injury was alleviated. No adverse events such as infection, liver failure, liver transplantation or death occurred. **Conclusion:** For patients with recurrent hepatic encephalopathy refractory to conventional treatment, oral capsule-based FMT can effectively correct intestinal dysbiosis and prevent disease recurrence with satisfactory safety, demonstrating high clinical application value.

Table 1 Comparison of data before and after FMT

Index	Before FMT	1 month after FMT	6 months after FMT
Detection date	2025/06/20	2025/09/18	2026/03/12
Intestinal health total score	32	58	57
Microecology health index	42	56	60
Flora balance	Grade III dysbiosis	Grade II dysbiosis	Grade II dysbiosis
Core microbes	Severe deficiency	Low abundance	Low abundance
Beneficial bacteria	Low abundance	Normal	Normal
Diversity index	4.6493	6.4921	7.8137
Intestinal mucosal barrier	Moderate injury	Mild injury	Mild injury
Veillonella (%)	58.95	20.68	6.99
Lachnospiraceae (%)	0.87	5.59	6.67
B/E ratio(Normal value > 1)	0.0164	0.8556	2.6720
Short-chain fatty acid synthesis capacity			
Formic acid(Normal value > 60)	20	71	65
Acetic acid(Normal value > 60)	6	37	22
Propionic acid(Normal value > 60)	98	79	58
Butyric acid (Normal value > 60)	20	66	74

1126 | PROTON PUMP INHIBITORS AND ADVERSE OUTCOMES IN CIRRHOSIS: A LARGE PROPENSITY-MATCHED U.S. COHORT STUDY

Bolaji Ayinde[1] Bright Nwatamole[2] Abidemi Akinrinmade[3] Ihunanya Kanu[4] Kia Saeian[5], [1]Northeast Georgia Medical Center, [2]Zucker School of Medicine at Hofstra, [3]SUNY Upstate University, [4]Baptist Memorial Hospital- Golden Triangle, [5]Medical college of Wiscosin

Background: Proton pump inhibitors (PPIs) are common in patients with cirrhosis, and studies show inappropriate use in 47–60% of cases, frequently without guideline-concordant indications. Acid suppression can promote small intestinal bacterial overgrowth, and bacteria translocation through changes in the gut microbiome and inhibition of neutrophil oxidative burst may increase the risk for spontaneous bacterial peritonitis (SBP) or other infectious complications. Although PPI exposure has been associated with adverse outcomes in cirrhosis due to ascites, that association remains controversial secondary to a concern about confounding by indication. We investigated the association of PPI exposure with risks of SBP, hepatic encephalopathy, kidney injury, sepsis and mortality in a large real-world cohort. **Methods:** We performed a retrospective cohort study leveraging the US Collaborative Network in TriNetX over 114 million records, between January 1, 2019 and March 29, 2026. Adults with cirrhosis and ascites were identified and stratified by PPI use. Propensity score matching on demographics, malnutrition, and hepatic function panel variables yielded 51,334 patients per cohort. Outcomes were assessed over 5 years post-index. **Results:** PPI use was associated with increased risks of SBP (HR 1.95, 95% CI 1.81–2.11), hepatic encephalopathy (HR 1.95, 95% CI 1.86–2.04), acute kidney injury (HR 1.93, 95% CI 1.86–2.01), sepsis (HR 2.26, 95% CI 2.15–2.37) and all-cause mortality (HR 1.56, 95% CI 1.53–1.59). Kaplan–Meier analyses revealed significantly diminished event-free survival among PPI users (log-rank $p < 0.001$). **Conclusion:** In this large propensity-matched cohort, PPI exposure was associated with significantly increased risks of infectious complications, organ failure, and death in patients with cirrhosis and ascites. However, the retrospective design and reliance on administrative data preclude causal inference; residual confounding by disease severity, PPI indication, dose, and duration cannot be excluded despite matching. These findings support more judicious, guideline-based PPI prescribing in this population and warrant prospective validation.

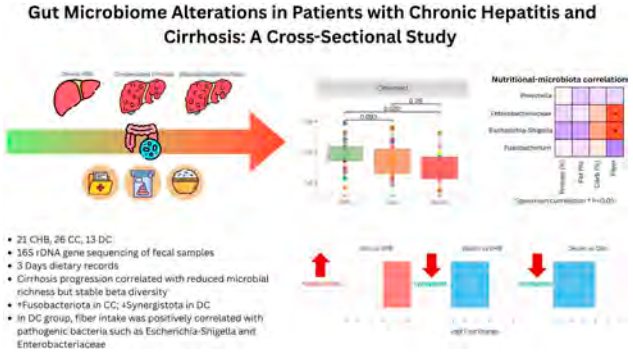
1127 | GUT MICROBIOME ALTERATIONS IN PATIENTS WITH CHRONIC HEPATITIS AND CIRRHOSIS: A CROSS-SECTIONAL STUDY



Poonyisa Tangsermvong[1] Pongphob Intaraprasong[1] Tanawat Jongraksak[1] Nantaporn Srivanitchapoom[1] Sarita Ratana-Amornpin[1] Sawannee Sutheeworapong[2] Pinidphon Prombutara[3] Abhasnee Sobhonslidsuk[1], [1]Ramathibodi Hospital, [2]King Mongkut's University of Technology Thonburi, [3]Mod Gut Co., Ltd.

Background: Gut dysbiosis in decompensated cirrhosis contributes to liver-related complications, and its pattern is influenced by ethnicity, dietary intake, and environment. Most current data are derived from Western populations who consume high-fat diets. This study characterizes the gut microbiota of Thai patients with chronic hepatitis B (CHB), compensated cirrhosis (CC), and decompensated cirrhosis (DC) in a population where rice is the primary dietary staple, and also explores the association between microbiota patterns and important factors. **Methods:** 60 participants (21 with chronic hepatitis B, 26 with compensated cirrhosis, and 13 with decompensated cirrhosis) were enrolled. Clinical and nutritional data (3-day dietary records) were collected alongside fecal samples. Gut microbiota was characterized via 16S rRNA gene sequencing on the Illumina MiSeq platform. Bioinformatic analysis was performed to assess microbial composition, alpha and beta diversity, and differential abundance. Spearman's rank correlation was used to evaluate relationships between microbial taxa and clinical/nutritional parameters. **Results:** Microbial richness (Observed index) significantly decreased as disease severity progressed from CHB to DC ($p = 0.022$), although beta diversity remained consistent across groups. At the phylum level, Fusobacteriota was more abundant in the CC

Symbols: ♦, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

group, while Synergistota showed a significant reduction in the DC groups (q = 0.002). At the genus level, a distinct finding was that *Faecalibacterium* abundance remained stable across stages, in contrast to the findings from Western studies. This stability may result from high intake of resistant starch type 3 present in rice and low consumption of animal fat. Additionally, fiber intake in the CC group (average 11.1 g/day) showed a strong positive correlation with beneficial *Prevotella* (r = 0.43, p < 0.05). Conversely, in the DC group (average 9.9 g/day), there was an increase in pathogenic bacteria, including *Escherichia-Shigella* (r = 0.67, p < 0.01) and *Enterobacteriaceae* (r = 0.65, p < 0.05). **Conclusion:** Alpha diversity decreased in patients with decompensated cirrhosis. Beneficial bacteria decreased, while pathogenic bacteria increased as the severity of liver cirrhosis worsened. However, in Thai patients with decompensated cirrhosis, the number of Synergistota decreased, but that of *Faecalibacterium* did not change. Differences in dietary patterns and environment may explain the findings. Further study may be warranted.

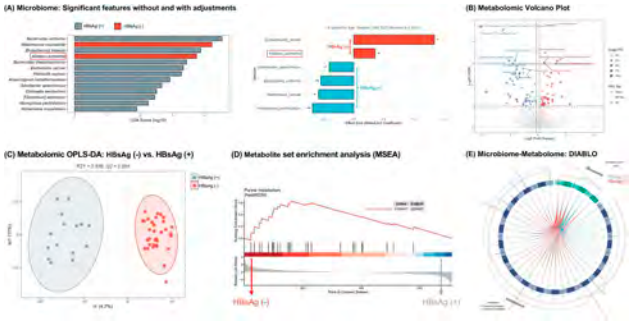
★ 1128 | GUT MUTI-OMICS PROFILES ASSOCIATED WITH SPONTANEOUS HBSAG SEROCLEARANCE IN CHRONIC HEPATITIS B



Saisai Zhang[1] Zhe Zhang[2] Lu Li[2] Ning Ma[2] Wenyi Tan[2] Lung-Yi Mak[2] Man-Fung Yuen[2] Wai-Kay Seto[2], [1] 1 The University of Hong Kong; 2 The University of Hong Kong-Shenzhen Hospital, [2] 1 The University of Hong Kong

Background: Seroclearance of hepatitis B surface antigen (HBsAg) is a prerequisite for functional cure in chronic hepatitis B (CHB), yet its underlying mechanisms remain poorly understood. We aimed to characterize gut microbiome and metabolomic signatures associated with spontaneous HBsAg seroclearance using a multi-omics approach. **Methods:** We enrolled 48 treatment-naïve CHB patients with prior documented HBsAg-positivity ≥ 6 months. Of these, 33 individuals achieved sustained HBsAg seroclearance (HBsAg-negative for ≥ 6 months with undetectable HBV DNA < 10 IU/mL), and 15 remained HBsAg positive serving as controls. Fecal samples were subjected to full-length 16S rRNA sequencing (PacBio) and widely targeted metabolomics. Multi-omics integration was performed using Data Integration Analysis for Biomarker discovery using Latent cOmponents (DIABLO). **Results:** Among the participants (38% male, median age 66 years), patients with spontaneous HBsAg seroclearance had a median seroclearance duration of 7.2 years. No significant differences in α-diversity were observed between groups; however, β-diversity analysis demonstrated distinct microbial community structures (PERMANOVA, p = 0.001). Linear Discriminant Analysis Effect Size (LEfSe) identified enrichment of *Alistipes putredinis* in the HBsAg-negative group, whereas *Bacteroides uniformis*, *Bacteroides caccae*, and *Monoglobus pectinilyticus* were enriched in the control group (LDA score > 2, p < 0.05), which remained significant after multivariable adjustment using MaAsLin3 for age, sex, liver stiffness, and T2DM. Metabolomic profiling identified 311 differential metabolites between groups, with 134 metabolites significantly enriched in the HBsAg-negative group. Orthogonal partial least squares discriminant analysis (OPLS-DA) demonstrated a clear separation of metabolomic profiles between the two groups (R^2Y = 0.946, Q^2 = 0.564, p < 0.005). Metabolite set enrichment analysis (MSEA) revealed the significant enrichment of purine metabolism in the HBsAg-negative group (p = 0.005), which has previously been reported associated with immune reprogramming. Integrative analysis using DIABLO and correlation analysis consistently identified 3,4-dimethylbenzoic acid as a key metabolite enriched in the HBsAg-negative group, which was positively correlated with *Alistipes putredinis* and inversely associated with *Bacteroides uniformis* and *Monoglobus pectinilyticus* (|rho| > 0.3, p < 0.05). **Conclusion:** Spontaneous HBsAg seroclearance is associated with distinct gut microbial and metabolomic profiles. The enrichment of *Alistipes putredinis* and its associated metabolite 3,4-dimethylbenzoic acid highlights a potential microbiota-metabolite axis involved in functional cure of CHB. *Supported by Shenzhen Natural Science Foundation Basic Research Fund-*

★ 1129 | INTESTINAL PATHOBIONT AGGRAVATES LIVER INJURY IN WESTERN DIET INDUCED MASLD

Einav Hubel Manor[1] Mohamed Abdelnabi[1] Henry Nguyen[2], [1]University of Calgary, [2]University of Calgary Cumming School of Medicine

Background: The gut–liver axis integrates dietary, microbial, and immune cues that influence hepatic homeostasis and disease progression. A Western diet rich in fat and sugar (HFHS) promotes metabolic stress, lipid accumulation, and chronic inflammation. These features characterize metabolic-associated steatotic liver disease (MASLD), a growing global health burden linked to obesity and insulin resistance. Progression to steatohepatitis and fibrosis is driven by both metabolic and immune dysregulation. *Helicobacter hepaticus* (Hh) is an intestinal pathobiont capable of aggravating liver steatosis. However, the long-term effects of Hh in shaping immune responses along the gut–liver axis under Western-diet-induced metabolic stress remain poorly defined. We aimed to determine how Hh drives immune activation and fibrogenesis in the liver and colon **Methods:** Male C57BL/6 mice were maintained on an HFHS diet for 40 weeks with or without Hh infection (n = 5 per group). Flow cytometry (FACS) profiled hepatic and colonic leukocytes for $CD45^+$ subsets, including macrophages, T cells ($CD4^+$, $CD8^+$), Th1, Th17, $Foxp3^+$ Tregs, $ROR\gamma t^+$ induced Tregs, dendritic cells (DCs), and neutrophils. Hepatic mRNA expression of inflammatory (*Tnf, Ccl2*) and fibrogenic (*Col1a1, Acta2*) genes were quantified by qPCR. Liver fibrosis was evaluated by Masson's Trichrome staining and scored blinded by a pathologist. **Results:** In the liver, FACS analysis showed that HFHS + Hh mice had elevated $CD45^+$ cell infiltration, T cells, and Th17 populations ($p < 0.01$), along with increased $Foxp3^+$ and $ROR\gamma t^+$ Tregs ($p < 0.05$–0.001) and macrophages. qPCR revealed higher *Tnf*, *Ccl2*, *Col1a1*, and *Acta2* expression, correlating with fibrogenic activation. Histological analysis confirmed greater collagen deposition in HFHS + Hh livers than HFHS alone. In the colon, FACS revealed a parallel trend with increased $CD45^+$ cells, Tc cells, immature thymocytes, DC subsets (moDCs, MoDr DCs), and neutrophils ($p < 0.05$), indicating coordinated immune activation along the gut–liver axis **Conclusion:** Chronic Hh colonization under Western-style dietary stress amplifies immune activation and fibrogenic remodeling within the liver and extends inflammation in the colon. Our parallel observation in the colon supports the idea of coordinated immune signaling along the gut–liver axis in MASLD, though it remains to be determined whether hepatic T cells are locally expanded or recruited from the intestinal compartment.

1130 | EFFECTS OF *ILEIBACTERIUM VALENS* SUPERNATANT IN METABOLIC DYSFUNCTION-ASSOCIATED STEATOTIC LIVER DISEASE IN MICE

Titilayo Olotu[1] Julie Centofanti[1] Shifat-E Ferdous[1] Matthew Dilts[1] Shannon Boehme[1] Jessica Ferrell[1], [1]Northeast Ohio Medical University

Background: Metabolic dysfunction-associated steatotic liver disease (MASLD) has a current prevalence of more than 30% among American adults, and its global prevalence is projected to be 55% by 2040, making this condition a global public health issue. The involvement of glucose, lipid, and inflammatory pathways in MASLD suggests that exploring a range of interventions is necessary. Takeda G protein-coupled receptor 5 (TGR5) is a bile acid receptor that regulates glucose homeostasis, inflammation, and energy expenditure. Previously, our lab discovered that $Tgr5^{-/-}$ mice fed a high-fat, high-fructose diet had increased steatosis but were protected from hepatic inflammation and fibrosis, and simultaneously had significantly increased relative abundance of *Ileibacterium valens* (*I. valens*) in the gut. *I. valens* is a newly identified species of the family Erysipelotrichaceae; prior research regarding the function of *I. valens* with respect to lipid metabolism is limited and controversial. We previously determined that administration of *I. valens* may induce hepatic reverse cholesterol transport in mice. Because evidence suggests that omitting bacteria and administering post-biotics in the form of supernatant may be safer than live probiotics, we next investigated the effects of *I. valens* supernatant in mice. **Methods:** To determine the physiological function of *I. valens* supernatant, we gavaged *I. valens* supernatant (SN) or sterile OTEB (vehicle) twice weekly to male C57BL/6J mice and simultaneously fed a high-fat, high-fructose diet (40% kcal fat, 20% kcal fructose, and 2% cholesterol) for 8 weeks. Lipid metabolism and glucose metabolism were assessed, and histology was performed to determine how *I. valens* supernatant may modulate lipid metabolism *in vivo*. **Results:** *I. valens* supernatant induces a decrease in hepatic free fatty acid (FFA) and a reduced trend in serum triglyceride & FFA. An increase in hepatic glucose uptake (*Glut2, Pygl, Pgcla*, *Cpt2*), and a decrease in steatosis via reduced macrovascular fat droplet counts and sizes. It inhibits hepatic inflammation (*Tnfa, Tnfr1b, NFkb*) & fibrosis (*Col1a2*) signaling. *I. valens* supernatant also induces ileal and colon lipid transporters (*Ldlr, Lxr, Abcg1*). Therefore, *I. valens* supernatant may affect lipid metabolism to alleviate MASLD. **Conclusion:** Our results indicate that *I. valens* supernatant may exert protective effects against diet-induced obesity and MASLD by increasing hepatic glucose uptake to enhance lipid metabolism and inhibiting hepatic inflammatory gene expression.

1131 | CORRELATION-BASED MOLECULAR NETWORKS REVEAL FUNCTIONAL METABOLITE RELATIONSHIPS IN MASLD AND HCC

Huang Lin[1] Lijun Zhang[2] Ali Lotfi[3] Alan Jarmusch[4] Iris Lee[5] Adam Kim[6] James Morton[7] Alexander Aksenov[3], [1]University of Maryland, [2]Tiposi, [3]University of Connecticut, [4]NIH, [5]Washington University in St. Louis, [6]UConn Health, [7]Gutz Analytics L.L.C.

Background: Molecular networking (MN) has transformed mass spectrometry (MS)-based metabolomics. MN organizes complex datasets into graphs that connect structurally related molecules using MS/MS spectral similarity. While powerful for identifying analogs and propagating annotations within spectral families, spectral similarity captures only one axis of molecular relatedness. Metabolites can be functionally related through shared sources, biosynthetic origins, or coordinated regulation despite limited structural similarity. Such relationships may be reflected in correlations across samples. **Methods:** Here we present MetVAE, a variational autoencoder-based framework for constructing correlation based molecular networks from large-scale metabolomics data. MetVAE addresses key statistical challenges of MS metabolomics data, including compositionality, missingness, confounding effects, and high dimensionality. For this study, we apply MetVAE to analyze metabolomics data from the high-fat diet-fed *MUP-uPA* mouse model of MASLD (Metabolic Dysfunction-Associated Steatotic Liver Disease) driven HCC (hepatocellular carcinoma). Then untargeted fecal metabolomics was performed. **Results:** MetVAE links monoacylglycerols, free fatty acids, bile acids, and fatty acid ethyl esters (FAEEs) in animals fed a high-fat diet. These associations raise the possibility of an endogenous "auto-brewery" route in which microbially produced ethanol esterifies with fatty acids to generate FAEEs, lipotoxic metabolites implicated in alcohol-associated liver disease, without alcohol consumption. These results may help contextualize the long-noted overlap between MASLD and alcohol-associated liver disease. Additionally, alcohol is a known carcinogen, so it may contribute to HCC progression in this model.

Conclusion: Across more than 20,000 samples, MetVAE scales to repository-sized datasets and reduces technical variation while preserving biological signal. Beyond biological discovery, correlation networks enable data-structure diagnostics, including detection of split chromatographic features, tracing metabolites to shared sources, and revealing coordinated metabolic regulation.

1132 | BIOFILMS ON LONG-TERM ASCITIC DRAINS: EARLY INSIGHTS INTO DEVICE-ASSOCIATED INFECTION A CASE SERIES

Melissa Zhao[1] Sandra Wilks[2] Ian Reddin[2] Mark Wright[1], [1]University Hospital Southampton NHS Foundation Trust, [2]University of Southampton

Background: Biofilm formation on indwelling medical devices is recognised as a key driver of chronic infection, antimicrobial tolerance, and device dysfunction. As long-term ascitic drains (LTADs) are increasingly used for refractory ascites and palliative symptom control, device-associated infection remains poorly understood. There is currently no literature specifically examining biofilm formation on LTADs or related microbial and genomic factors. This novel case series investigates biofilms on explanted LTADs using fluorescence microscopy and metagenomic sequencing. **Methods:** LTADs (Rocket® IPC™) from three patients with refractory ascites were collected. Biofilm architecture was assessed using EDIC microscopy and fluorescence imaging, including SYTO9/PI and DAPI/ConA staining. Drain-associated biofilm material and paired ascitic fluid underwent DNA extraction and shotgun metagenomic sequencing (Illumina NovaSeq X Plus, paired-end 150bp). Host depletion and taxonomic classification were perfomed using standard bioinformatics pipelines. Virulence factors (VFs) and antimicrobial resistance (AMR) determinants profiling used VFDB and CARD/RGI databases. **Results:** Median LTAD duration was 12 months (range 5–18). Two patients had persistent drain-associated infections despite multiple antibiotic courses, requiring drain removal. Conventional cultures identified *Staphylococcus epidermidis* and *Pseudomonas aeruginosa*. Underlying aetiologies were MASLD cirrhosis, cystic fibrosis-related liver disease, and hepatic amyloidosis. Median white cell count was 8 $\times 10^9$/L and median CRP 60 mg/L. EDIC and fluorescence microscopy demonstrated structured biofilm formation on all explanted drains, with dense extracellular matrix and bacterial aggregates. Metagenomic sequencing identified polymicrobial communities including *S. epidermidis*, *P. aeruginosa*, *Enterococcus faecalis*, and *Escherichia coli*. VFs associated with adhesion, biofilm maturation, and immune evasion were identified, including MSCRAMM adhesins, autolysins, proteases, lipases, nucleases, and beta-haemolysin. AMR determinants conferring resistance to multiple antibiotic classes were also detected, notably mecA confirming methicillin-resistant S. epidermidis (MRSE), alongside fluoroquinolone, β-lactam and macrolide resistance. **Conclusion:** This case series provides novel evidence of structured biofilm formation on LTADs. Combined microscopy and metagenomic analysis identified polymicrobial communities containing biofilm-associated VFs and AMR determinants. These findings suggest biofilm formation may contribute to persistent colonisation, antimicrobial tolerance, and LTAD-associated infection. Larger studies are needed to determine whether specific microbial or virulence signatures are associated with adverse clinical outcomes and could inform future infection prevention strategies.

Although microbial and metabolite alterations are recognized in alcohol-related cirrhosis (ALC), integrated analyses of intestinal microecology together with plasma and fecal metabolomes remain limited. **Methods:** This case-control study compared ALC patients and healthy controls (HC). Fecal microbiota was profiled by 16S rRNA sequencing. Untargeted LC-MS metabolomics was applied to plasma and feces. Group differences and clinical correlations were evaluated. **Results:** 1.Based on the analysis of fecal 16S rDNA amplicon sequencing, the gut microbiota of patients with alcoholic cirrhosis at the genus level exhibits a notable increase in the relative abundances of *Veillonella*, *Lactobacillus*, *Streptococcus*, *Klebsiella*, and *Escherichia*, along with a significant decrease in the relative abundances of *Ruminococcus*, *Bacteroides*, *Alistipes*, *Prevotella*, and other genera.2.The pathway enrichment analysis indicated that bile acid and amino acid metabolism were highly active in plasma. Using VIP values and fold change (FC) screening, we identified significant differences in bile acid- and amino acid-related metabolites. Plasma levels of cholic acid (CA) and deoxycholic acid (DCA) were significantly elevated in patients with alcoholic cirrhosis compared to healthy controls. Additionally, phenylalanine, tyrosine, methionine, indole, phenyllactic acid, phenylacetic acid, inosine, and urobilinogen were increasedns with *Streptococcus*, *Lactobacillus*, and *Veillonella*, while taurine exhibited a negative correlation with these genera.3.The plasma levels of deoxycholic acid (DCA), lithocholic acid (LCA), chenodeoxycholic acid (CDCA), and ursodeoxycholic acid (UDCA) were significantly lower in patients with alcoholic cirrhosis compared to healthy controls, whereas the concentrations of phenylalanine, tyrosine, methionine, threonine, tryptophan, and glycine were elevated. The levels of indole and betaine were relatively reduced. Furthermore, correlation analysis between gut microbiota and fecal differential metabolites revealed that glycoursodeoxycholic acid (GCA), CDCA, and bilirubin exhibited a positive correlation with genera such as *Streptococcus*, *Lactobacillus*, and *Veillonella*. LCA showed a negative correlation with these same genera. Additionally, indole demonstrated a positive correlation with *Streptococcus,* and methionine was positively correlated with *Veillonella*. **Conclusion:** Proliferating opportunistic pathogens (*Streptococcus, Lactobacillus*, *Veillonella*) are positively associated with harmful metabolites (bile acids, aromatic amino acids, indole derivatives) and negatively correlated with beneficial commensals like *Prevotella*. This suggests that specific gut bacteria may drive alcoholic cirrhosis progression via bile acid and amino acid metabolism dysregulation.

A. Alterations in the relative abundance in Phylum level of gut microbiota in patients with alcoholic liver cirrhosis

B. Alterations in the relative abundance in Genus level of gut microbiota in patients with alcoholic liver cirrhosis

C. Heatmap of differential bile acids and amino acid-related metabolites in plasma from patients with alcoholic liver cirrhosis. "Class" indicates the study group: yellow represents the alcoholic liver cirrhosis (ALC) group, and green represents the healthy control (HC) group. Metabolite levels are presented as relative abundances, with red indicating higher levels and blue indicating lower levels.

D. Correlation analysis between differential plasma metabolites and gut microbiota.

E. Heatmap of differential bile acids and amino acid-related metabolites in fecal samples from patients with alcoholic liver cirrhosis. "Class" indicates the study group: yellow represents the alcoholic liver cirrhosis (ALC) group, and green represents the healthy control (HC) group. Metabolite abundance is depicted as relative levels, with red indicating higher abundance and blue indicating lower abundance.

F. Correlation analysis between differential plasma metabolites and gut microbiota. The horizontal axis represents bacterial genera, and the vertical axis represents metabolites. Red denotes positive correlations, blue denotes negative correlations, with color intensity reflecting the strength of the association. * $P < 0.05$, ** $P < 0.01$. ALC: Alcoholic liver cirrhosis group; HC: Healthy control group.

Table1.Alterations in bile acid profiles in plasma and feces among patients with alcoholic liver cirrhosis

			Plasma (ALC/HC)	Feces (ALC/HC)
Unconjugated bile acid	Primary bile acid	cholic acid（CA）	↑	NA
		chenodeoxycholic acid（CDCA）	Undetected	↓
		deoxycholic acid（DCA）	↑	↓
	Secondary bile acid	lithocholic acid（LCA）		↓
		Isolithocholic acid（IsoLCA）	Undetected	NA
		ursodeoxycholic acid（UDCA）		↓
Conjugated bile acid	Primary bile acid	glycocholic acid（GCA）	↑	NA
		taurocholic acid（TCA）	↑	NA
	Secondary bile acid	Tauroursodeoxycholic acid（TCDCA）	↑	Undected
		tauroursodeoxycholic acid（TUDCA）	↑	NA
		taurodeoxycholic acid（TDCA）	↑	Undected

Table2. Alterations in Plasma and Fecal Amino Acid Profiles in Patients with Alcoholic Liver Cirrhosis

Metabolite	Metabolic pathways	Plasma (ALC/HC)	Feces (ALC/HC)
Glycine	Alanine metabolism	NA	↑
	Arginine and proline metabolism		
	Glutathione metabolism		
	Bile acid synthesis		
Taurine	Taurine metabolism	↑	NA
	Bile acid synthesis		
Betaine	Glycine and serine metabolism	↓	↓
	Methionine metabolism		
Methionine	Glycine and serine metabolism	↑	NA
	Methionine metabolism		
Threonine	Glycine and serine metabolism	NA	↑
Choline	Methionine metabolism	↑	↑
Sarcosine	Methionine metabolism	↓	NA
Phenylalanine	Phenylalanine and tyrosine metabolism	↑	↑
Tyrosine	Phenylalanine and tyrosine metabolism	↑	↑
Tryptophan	Tryptophan metabolism	NA	↑
Indole	Tryptophan metabolism	↑	↓
Formylanthranilic acid	Tryptophan metabolism	↑	NA
Leucine	Valine, leucine and isoleucine degradation	↓	↑

NA indicates no statistically significant difference. The red arrow denotes an increase in the alcoholic liver cirrhosis group, while the blue arrow denotes a decrease in the alcoholic liver cirrhosis group.

1134 | THE INTRAHEPTIC MICROBIOME OF CIRRHOTIC PATIENTS

Vijay Pandyarajan[1] Georgios Voidonikolas[1] Ekihiro Seki[2], [1]Cedars Sinai Medical Center, [2]Cedars-Sinai Medical Center

Background: The microbiome has been implicated in numerous pathological processes, including the progression and exacerbation of chronic liver diseases. Significant gut microbial dysbiosis has been demonstrated across multiple etiologies of liver disease and significant associations have been found between microbial species and their contribution to inflammation, fibrosis and disease progression. While internal organs have traditionally been considered sterile, emerging evidence suggests that microbial DNA may be detectable within solid organs, including the liver. The composition and potential relevance of these intrahepatic microbial signatures remain poorly understood. We therefore sought to characterize microbial signatures within human cirrhotic liver tissue in a pilot study. **Methods:** Explanted liver tissue was obtained from patients undergoing orthotopic liver transplantation at our institution or from patients undergoing hepatectomy. DNA was then extracted from tissue and submitted for 16S rRNA gene next-generation sequencing to assess microbial composition and relative abundance within liver tissue. **Results:** Alcohol-associated liver disease (ALD) accounted for 46% of cases, while the remaining patients underwent transplantation for a range of etiologies including primary biliary cholangitis (PBC), acute hepatitis B, biliary atresia, veno-occlusive disease (VOD) and metabolic dysfunction-associated alcohol-related liver disease (Met-ALD). Microbial DNA was detected in liver tissue samples across the cohort. Comparison of patients with alcohol-associated cirrhosis to those with other liver disease etiologies revealed notable differences in microbial composition. The genus *Sphingomonas* accounted for approximately 25% of the relative bacterial abundance in patients with ALD but was virtually absent in patients with non-alcohol related liver diseases. Similarly *Mesorhizobium, Centipeda, Caulobacter and Anaerococcus* were found in ALD patients and not identified in samples from other etiologies. These findings suggest the presence of etiology-specific intrahepatic microbial signatures. **Conclusion:** Our findings provide preliminary evidence supporting the presence of microbial DNA within human cirrhotic liver tissue and suggest that microbial composition may vary according to the underlying etiology of liver disease. Although limited by sample size these observations raise the possibility that distinct intrahepatic microbial communities may contribute to disease-specific pathophysiology. Larger, adequately powered studies are needed to validate these findings and to determine their biological and clinical significance.

Rotterdam, [22]University of Texas Southwestern Medical Center

Background: The effect of HMG-CoA reductase inhibitors (statins) are underutilized for patients with primary biliary cholangitis (PBC), perhaps due to concerns about liver safety. The effect of statins on liver outcomes in patients with primary biliary cholangitis is not well established. Aim: To investigate the association between statin-use and liver events in patients with PBC. **Methods:** A retrospective chart review at 13 sites across North America, South America, and Europe in the Global PBC Study Group. Decompensation was defined as variceal bleed, ascites, or encephalopathy. A major liver event (MLE) was defined as a decompensation, hepatocellular carcinoma (HCC), liver transplant, or death (any cause). Labs and variables were collected at one year after starting ursodeoxycholic acid (UDCA), which was defined as the T_{12M}. Cox multivariable regression was used to analyze predictors of decompensation and MLE, with statins analyzed as a time-variable covariant. **Results:** 1467 patients with PBC were followed over a mean of 9.7 years. Patients who decompensated were older (56.1 vs. 52.1 years $p < 0.001$), more likely to be cirrhotic at T_{12M} (31.3% vs. 5.7% $p < 0.001$), with a higher alkaline phosphatase (ALP) (225.1 vs 175.4 [CL1] [MP2] IU/L, $p < 0.001$), bilirubin (1.87 vs 0.69 mg/dL, $p < 0.001$) and lower platelets (191 vs. 225 $x10^9$ $p < 0.001$[HL3] [MP4]). There were 234 (16.0%) decompensations, 44 (3.0%) diagnoses of hepatocellular carcinoma, 46 (3.1%) liver transplant, and 162 (17.5%) deaths [CL5] [MP6] (124 [8.5%] liver-related deaths). 224 (17.3%) patients received a statin with a mean statin-use duration of 6.7 years after initiation of UDCA. Statins [CL7] [MP8] was associated with a lower risk of decompensation (aHR 0.22, 0.05-0.93, $p = 0.04$) when controlling for age (aHR 1.07, 1.04-1.09, $p < 0.001$), ALP > 1.67 x upper-limit-of-normal (ULN) (aHR 2.69, 1.65-4.39, <0.001), and bilirubin > ULN (aHR 6.99, 4.25-11.48, $p < 0.001$). Statins was also associated with a lower risk of MLE (aHR 0.49, 0.27-0.88, 0.016), when controlling for age (aHR 1.07, 1.06-1.09, $p < 0.001$), ALP > 1.67x ULN (aHR 1.87, 1.23-2.85, 0.003), and bilirubin > ULN (aHR 6.48, 4.15-10.13, $p < 0.001$[CL9] [CL10] [MP11]). Propensity matched (for bilirubin, ALP, cirrhosis, and age) survival analysis showed improvement in decompensation-free survival and MLE-free survival (both $p = 0.017$ and < 0.001, respectively) [Figure 1]. Only 5 (of 536) patients prescribed a statin stopped treatment due to liver-related issues (elevated liver chemistries). **Conclusion:** In this international cohort, use of statins during the course of PBC-related liver disease was associated with substantially lower risk of cirrhosis-related clinical events.

1136 | ◆ INVESTIGATION OF THE ETIOPATHOGENESIS OF BILIARY ATRESIA USING NEXT-GENERATION SEQUENCING

Tarun Sharma[1] Yashwant Kumar[2] Shailesh Solanki[3] Ravi Kanojia[4] Sadhna Lal[5] Suvradeep Mitra[4] Anit Kaur[4] Alka Bhatia[6], [1]Post Graduate Institute of Medical Education and Research, [2]Post Graduate Institute of Medical Education & Research (PGIMER), Chandigarh, [3]Post Graduate Institute for Medical Education and Research PGIMER, [4]Post Graduate Institute of Medical Education and Research PGIMER Chandigarh, [5]Postgraduate Institute of Medical Education and Research, [6]Postgraduate Institute of Medical Education and Research (PGIMER) Chandigarh

Background: Biliary atresia is a disease characterised by partial or complete obstruction of the bile duct in newborns. The result is cholestasis and cirrohsis. It may be fatal. The only management method is a Kasai Portro-enterostomy, which helps the patient survive while waiting for a liver transplant. The exact pathogenesis of BA is partially investigated. Previous studies suggest that the pathogenesis of the disease has a genetic component and may be poly-factorial. In this study, the coding portion (exome) of the patients compared to a healthy exome has been investigated. Variants will be identified and validated through genomic analysis. The impact of the variant on normal physiology and role in biliary atresia will be explored. **Methods:** Peripheral blood was obtained from 5 patients aged 6-8 weeks with confirmed biliary atresia. Whole DNA from peripheral blood was extracted and sequenced with 80-100X coverage on the Illumina platform. The raw data was processed beginning with a quality check, followed by preparation and variant calling compared to control exome. Patient wise pathogenicity and impact scores (such as CADD, PHRED, VEP) were derived. The discovered variants were assigned importance as per their potential impact in the patient and analysed step by step across an inclusive and detailed criteria. To derive a more comprehensive analysis, machine learning and deep learning analysis was also conducted. Publically available data sets were used to obtain expression data for search and validation of findings. **Results:** Detailed analysis from a discovery cohort of 5 patients yielded 29,756 mean variants per patient. The number of missense variants was the largest at 12,474. The variant VCF files were manually filtered for quality and variants potentially playing a role in BA pathology were filtered out for further analysis. From the results, a three-hit explanation of pathogenesis was hypothesized. It was observed that the patient may be experiencing a highly reduced immune tolerance, owing to a variation observed in NOTCH2 (multiple variations in a single patient) and GPC1 (possible frameshift). IL32 was found highly upregulated. It was also observed that loss in the integrity of the epithelial barrier, perhaps because of maternal response to PAMPS, would aggravate Immune response and cause inflammation. Variants in KIF7, TMEM67, CC2D2A, suggest specific failure in duct formation at the embryonic stage. **Conclusion:** The findings provide a potential new understanding of the pathogenesis of biliary atresia. As suggested by previous studies, the disease would begin at birth, from the developmental genetic variants. This may in turn lead to a complex auto-immune response, because of abnormal escalated immune cell activity present in the newborn. The organ specific response, which may be beginning at the closing of the ductus venosus, may be localised in the ciliary epithelium. This creates a progression causing rapid symptoms.

1137 | ◆ SELADELPAR IS ASSOCIATED WITH STABLE RENAL FUNCTION OVER 5 YEARS OF TREATMENT: INTERIM RESULTS FROM THE ASSURE STUDY

Kris Kowdley[1] Eric Lawitz[2] Sarah Proehl[3] Daria Crittenden[4] Xiangyu Liu[4] Robert Kustra[4] Kyung min Kwon[4] K. Gautham Reddy[5], [1]Liver Institute Northwest, Seattle, WA, USA, [2]Text Liver Institute, University of Texas Health San Antonio, San Antonio, TX, USA, [3]Gilead Sciences, Inc. Foster City, CA, USA, [4]Gilead Sciences, Inc., Foster City, CA, USA, [5]University of Chicago Hospitals, Chicago, IL, USA

Background: Seladelpar is a first-in-class delpar (selective PPAR-delta agonist) indicated for the treatment of primary biliary cholangitis in combination with ursodeoxycholic acid (UDCA) in patients (pts) with an inadequate response to UDCA or as monotherapy in pts unable to tolerate UDCA. In the Phase 3, placebo-controlled RESPONSE trial (NCT04620733), mean serum creatinine values were similar overall in the seladelpar and placebo groups, and there were no renal adverse events (AEs). Here, we present an analysis of long-term changes in creatinine, estimated glomerular filtration rate (eGFR), and other assessments of renal safety in pts treated with seladelpar for up to 54 months (M) in the ongoing open-label Phase 3 ASSURE study (NCT03301506). **Methods:** Pts from RESPONSE and legacy seladelpar studies enrolled in ASSURE and received open-label seladelpar 10 mg once daily. Pts were pooled at initiation of seladelpar in either RESPONSE or ASSURE. Mean values and percent change from baseline of creatinine and eGFR were examined up to M54, as were shifts in values from normal to abnormal. Renal-related AEs were assessed using a predefined search strategy. The data cutoff for this interim analysis was Jan 31, 2026. **Results:** This analysis included 337 pts. At seladelpar initiation, mean creatinine and eGFR values were normal (0.68 mg/dL and 97.8 mL/min/1.73 m2) and remained normal through M54 (0.67 mg/dL and 95.6 mL/min/1.73 m2; Figure). Mean (SE) percent changes from baseline at M54 for creatinine and eGFR were 0.1% (2.71) and −1.9% (2.09). Cumulatively through M54, 17 pts (5%) experienced a shift in creatinine from normal to elevated, of which 65% (11/17) resolved while on continued seladelpar treatment (6/17 were either unresolved or unknown as of the data cutoff). Renal-related AEs were infrequent and occurred in 2 pts (0.6%) cumulatively through M54. One pt experienced an event of acute kidney injury secondary to a urinary tract infection and sepsis, and the other pt experienced creatinine increase and proteinuria; both episodes resolved and were assessed by the investigator as not related to seladelpar. **Conclusion:** Renal function remained stable with seladelpar exposure up to M54 in the ASSURE study. Renal-related AEs were infrequent, and there were no events attributed to seladelpar. These data suggest treatment with seladelpar 10 mg has a favorable renal safety profile.

1138 | ◆ ALTERED BRAIN REGIONAL FUNCTIONAL NEURAL CONNECTIVITY ASSOCIATES WITH OBJECTIVE MEASURES OF COGNITIVE DYSFUNCTION IN PRIMARY BILIARY CHOLANGITIS

Bradley Goodyear[1] Meredith Borman[1] Laura Stinton[1] Kelly Burak[1] Stephen Congly[1] Mark Swain[2], [1]University of Calgary, [2]University of Calgary Liver Unit

Background: Cognitive impairment is a highly prevalent symptom in primary biliary cholangitis (PBC), involving impairments in memory, attention, and executive function. It occurs in up to 50% of PBC patients and is closely associated with fatigue, however, its neural basis and relationship to clinical features remain unclear. Therefore, we used resting-state functional MRI (fMRI) to investigate associations between clinical variables, changes in inter-brain regional neural functional connectivity (FC), and cognitive performance in PBC. **Methods:** 29 female PBC patients (age 54 ± 10 (SD) years) underwent resting-state fMRI and cognitive testing, including the Trail Making Test (TMT), Digit Span test (DST), and Corsi Block Tapping Task (CBTT). Impairment was defined as ≥ 1 SD below age-matched female controls (n = 12). Nine of the 29 PBC patients had TMT deficits (31%), 15 DST deficits (52%), and 9 CBTT (31%) deficits. Among PBC patients, clinical variables included ALP, ALT, liver stiffness (FibroScan®), symptoms (yes/no; yes for sicca n = 14/29, fatigue n = 16/29, and pruritus n = 10/29), and ursodeoxycholic acid (URSO) status (treatment naïve n = 12/29). FC was computed between predefined brain regions of interest using fMRI. General linear models assessed associations between clinical variables, FC, and cognitive performance controlling for age. **Results:** TMT impairment was directly associated with sicca ($p < 0.001$) and inversely associated with fatigue ($p = 0.023$). DST and CBTT deficits were not directly associated with any clinical variables. TMT impairment was also associated with decreased FC between anterior and posterior cingulate cortices ($p = 0.001$), and between the anterior cingulate and medial visual network ($p = 0.002$), while fatigue was associated with increased FC of these brain region neural connections. Reduced FC between the posterior cingulate and dorsal attention network ($p = 0.002$), and between the right insula and posterior cingulate ($p = 0.004$), were associated with both TMT impairment and sicca. ALT was negatively associated with multiple corticostriatal functional connections involving the basal ganglia (caudate, putamen, pallidum) and insula. **Conclusion:** Cognitive dysfunction in PBC is connected to significant alterations in cingulate-centered and corticostriatal brain networks known to critically regulate cognition, motor control, and memory, and are linked to specific clinical features, particularly sicca and fatigue. Opposing neural connectivity patterns associated with fatigue and TMT impairment suggest compensatory neural network engagement in fatigued individuals, in contrast to reduced neural network integration underlying objective measures of cognitive dysfunction. These findings support neural network-level brain alterations in regulating objective cognitive changes in PBC and highlight their association with fatigue and sicca.

1139 | ◆ REGN22044: A FULLY HUMAN IL-12P35 ANTIBODY POTENTLY AND SPECIFICALLY INHIBITS IL-12

Arielle Glatman Zaretsky[1] Kaitlyn Gayvert[1] Rachna Shah[1] Elsa Au-Yeung[1] Amanda Dorvilliers[1] Brian Hobbs[1] Katherine Siminovitch[1] Erica Ullman[1] Stephen DiMartino[1] Veronica Mas Casullo[1] Wei Keat Lim[1] Andre Limnander[1] Jennifer Maloney[1] Jamie Orengo[1], [1]Regeneron

Background: Primary Biliary Cholangitis (PBC) and Autoimmune Hepatitis (AIH) are rare autoimmune liver diseases with disparate manifestations of pathology. However, PBC and AIH have shared genetic associations, high co-prevalence and are associated with type 1 inflammation. IL-12, composed of IL-12p35 and IL-12p40, drives type 1 immune responses. IL-12 signals through a receptor formed by IL-12RB1 and IL-12RB2. IL-23 shares the IL-12p40 subunit and IL-12RB2 receptor component with IL-12. A monoclonal IL-12p35-specific antibody, REGN22044, has been developed that binds to IL-12p35 and potently and specifically inhibits IL-12 signaling. **Methods:** An IL-12 gene signature was established using RNASeq analysis to identify differentially expressed genes (DEGs) in response to IL-12 signaling. This IL-12 signature was evaluated in liver or PBMC gene expression datasets from patients with PBC or AIH to assess IL-12 signaling compared with healthy controls. Surface plasmon resonance, luciferase reporter and primary cell assays were used to quantify binding affinity, specificity, and functional activity of REGN22044. A xenotransplant mouse model was used to evaluate REGN22044 in vivo and a surrogate mouse IL-12p35 antibody was used to evaluate the relevance of IL-12 signaling in mouse models. **Results:** The IL-12 gene signature included upregulation of known Th1 inflammation genes *IFNG* and *TBX21* in all four immune cell populations evaluated and was upregulated in patients with PBC (*IFNG:* logFC = 6.2, q = 0.0001; *TBX21:* logFC = 3.3, $q = 6.8x10^{-6}$) and AIH (*IFNG:* logFC = 3.8, q = 0.007; TBX21: logFC = 1.7, q = 0.004) compared to controls. Genetics, transcriptomics and disease biology support the relevance of IL-12 signaling in PBC and AIH, motivating development of an IL-12p35 specific antibody. REGN22044 bound human IL-12 with picomolar affinity (KD ≤ 1.3E-11). Complete inhibition of IL-12 signaling by REGN22044 was observed in both luciferase reporter assays and primary human cell based assays, with no impact on IL-23 signaling, unlike an IL-12p40 antibody, which inhibited both IL-12 and IL-23 signaling. In vivo, REGN22044 completely inhibited production of human IFNg, weight loss, and mortality in response to human IL-12 treatment compared to control or anti-IL-12p40 treated animals. Blockade of IL-12 signaling using a mouse surrogate IL-12p35 antibody inhibited a mouse model of autoimmune liver disease. **Conclusion:** These data highlight specific suppression of the IL-12 pathway as a compelling therapeutic target in AIH and PBC. REGN22044 binds to IL-12p35 with high affinity and potently and specifically inhibits IL-12 signaling in vitro and in vivo, supporting its potential as a novel approach to the treatment of PBC and AIH.

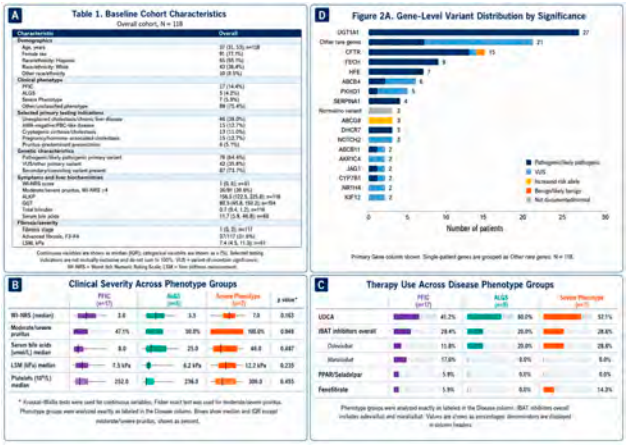
1140 | ◆ THE EMERGING ROLE OF GENETIC TESTING AND THE UNDERSTANDING OF THE DISEASE SPECTRUM IN ADULT MONOGENIC CHOLESTATIC DISEASE THE CLINICIAN ENHANCER



Fabian Rodas[1] Hussein Harb[2] Carmen Landaverde[3], [1]University of Texas San Antonio - The Texas Liver Institute, [2]University Health San Antonio, TIGMER, [3]University Hospital San Antonio / The Texas Liver Institute

Background: Adult cholestatic liver disease presents with a wide variety of clinical manifestations ranging from asymptomatic liver disease to severe cholestatic syndrome. Up to 30 % of chronic liver disease remains unknown. Genetic testing combined with deep clinical phenotyping may clarify undercharacterized cholestasis, define disease spectrum, and guide therapy. **Methods:** We performed a retrospective study of adults undergoing clinical genetic testing for suspected genetic cholestasis from 2/27/2025 to 5/20/2026 across University of Texas San Antonio/ Texas Liver Institute sites in San Antonio and Austin. Among a total of 118 patients, 46 underwent Prevention Genetics testing and 72 underwent Invitae panel testing. Our objective was to identify PFIC, ALGS variants, and a severe phenotype subgroup, (SPS) characterized by ALP ≥ 2x ULN, fibrosis stage ≥ F2, moderate/severe pruritus). **Results:** Among the

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

118 adults undergoing genetic testing for unexplained cholestasis, the most common indications were unexplained cholestasis, PBC/AMA-related cholestasis, ICP, and cryptogenic cirrhosis/cholestasis (Table 1). Clinician-assigned phenotype groups included PFIC- associated variants (n = 17, ALGS-associated variants (n = 5), and a SPS (n = 7). Pathogenic/likely pathogenic primary variants were present in 76 patients, and secondary/coexisting variants were common. UGT1A1 variants were most common followed by CFTR and then FECH (Figure 2A). The overall genetic positivity rate was 74.6% using stricter definition excluding low-penetrance and increased risk alleles. Compared with PFIC and ALGS groups, the SPS had greater clinical burden, with higher median WI-NRS (7.0 vs 3.0 and 3.5), serum bile acids (46.0 vs 8.0 and 25.0 umol), and LSM (12.2 vs 7.5 and 6.2 kPa. IBAT inhibitors were used in 29.4% of PFIC, 20 % of ALGS, and 28.6% of SPS patients. Secondary CFTR variants appear clinically enriched for higher WI-NRS, serum bile acids and fibrosis stage and lower platelet counts, likely reflecting co-occurrence with other variants or phenotypes. **Conclusion:** Genetic testing in adults with cholestatic and unexplained adult chronic liver disease identified high proportion of cholestatic variants. Deep clinical phenotyping refined high disease-burden severe phenotype subgroup characterized by severe pruritus, elevated serum bile acids, increased liver stiffness. PFIC-, ALGS-, and SPS-associated variants represented 24.6% of the cohort. However, disease penetrance was heterogenous partcularly among PFIC-associated monogenic variants emphasizing that treatment should be determined by cliniical phenotype rather than genotype. Secondary CFTR variants may act as disease modifiers in selected patients. These findings support integrating genetic testing with structured phenotyping to advance precision hepatology in adult cholestasis.

1141 | ◆ INFLAMMATORY BOWEL DISEASE IS ASSOCIATED WITH INCREASED HEPATOBILIARY AND PORTAL HYPERTENSIVE COMPLICATIONS IN HOSPITALIZED PATIENTS WITH COMMON VARIABLE IMMUNODEFICIENCY: A NATIONWIDE ANALYSIS

Ahmed Elmoursi[1] Ahmed Belasy[2] Abdelrahman Yousef[3] Ahmed Abomhya[4] Muhammad Adnan Haider[5] Samuel Sule-Saa[6], [1]Department of Medicine, Mayo Clinic, Phoenix, AZ., [2]Mayo Clinic, Phoenix, AZ., [3]University of New Mexico Health Sciences Center, [4]University of Kentucky Medical Centel, [5]HCA, Mission Hospital, Asheville, NC, [6]Interfaith Medical Center, NY, USA

Background: Common variable immunodeficiency (CVID) is associated with significant immune dysregulation and a broad spectrum of hepatobiliary manifestations, including autoimmune liver disease, portal hypertension, and cholestatic disorders. Inflammatory bowel disease (IBD) has independently been linked to immune-mediated hepatobiliary complications, particularly primary sclerosing cholangitis (PSC). However, the impact of concomitant IBD on hepatobiliary outcomes among hospitalized CVID patients remains poorly characterized. **Methods:** We performed a retrospective cohort study using the Nationwide Readmissions Database (NRD). Adult hospitalizations with CVID were identified using ICD-10-CM codes and stratified by the presence or absence of IBD. Hepatobiliary and pancreatic complications were compared using multivariable logistic regression models adjusted for demographics, payer status, income quartile, hospital characteristics, and urban/rural status. **Results:** Among 181,288 hospitalized CVID patients, 4,383 (2.4%) had concomitant IBD. Patients with concomitant IBD were younger and more commonly represented individuals aged 18–39 years (25.1% vs 13.9%, $p < 0.001$), with higher rates of private insurance coverage (41.7% vs 29.6%, $p < 0.001$). Compared with CVID patients without IBD, the CVID-IBD cohort demonstrated significantly higher

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

rates of portal hypertension (2.28% vs 1.59%, p < 0.001), variceal bleeding (1.00% vs 0.69%, p = 0.015), acute pancreatitis (1.48% vs 1.00%, p = 0.002), and chronic pancreatitis (2.14% vs 1.52%, p = 0.001). Age-stratified analyses demonstrated persistently increased PSC rates across all age groups, including patients aged < 40 years (2.69% vs 1.12%, p < 0.001), 40–64 years (1.93% vs 1.07%, p = 0.001), and ≥ 65 years (1.62% vs 0.86%, p = 0.004). On multivariable analysis, IBD remained independently associated with autoimmune hepatitis (aOR 2.06, 95%CI 1.47–2.89), Metabolic dysfunction-associated steatotic liver disease (MASLD) (aOR 1.45, 95%CI 1.21–1.74), acute pancreatitis (aOR 1.41, 95%CI 1.09–1.81), and chronic pancreatitis (aOR 1.40, 95%CI 1.13–1.72). **Conclusion:** Concurrent IBD in hospitalized CVID patients is associated with increased hepatobiliary and portal hypertensive disease burden, including autoimmune liver disease and pancreatic complications. These findings highlight the complex overlap between intestinal immune dysregulation and hepatobiliary disease in CVID, suggest a distinct hepatobiliary disease profile among patients with concomitant IBD, and support closer multidisciplinary hepatology surveillance in this high-risk population.

Disclosures: Ahmed Elmoursi:Nothing to Disclose, Ahmed Belasy:Nothing to Disclose, Abdelrahman Yousef:Nothing to Disclose, Ahmed Abomhya:Nothing to Disclose, Muhammad Adnan Haider:Nothing to Disclose, Samuel Sule-Saa:Nothing to Disclose.

1142 | ◆ IMPACT OF FATIGUE ON QUALITY OF LIFE IN PATIENTS WITH PRIMARY BILIARY CHOLANGITIS (PBC)

Magnus Doverskog[1] Robert Mitchell-Thain[2] Mo Christie[2] Nekshan Dalal[3] William Lobb[3] Rishi Choudhury[3] David Jones[4], [1]Umecrine Cognition AB, [2]PBC Foundation, [3]Indegene, [4]Newcastle University

Background: Fatigue is a common and debilitating symptom of primary biliary cholangitis (PBC) that markedly reduces health-related quality of life (HRQoL), yet it is often overlooked in routine care. Central fatigue, which manifests as cognitive issues such as what patients routinely characterize as "brain fog," and memory and concentration problems, is a burdensome symptom in PBC. This global study examined the prevalence of central fatigue in patients with PBC and analysed the impact of severity on HRQoL, daily functioning, and employment. **Methods:** An international cohort of 250 patients with PBC completed an online survey through the PBC Foundation app over 3 months. Participants reported PBC symptom burden, completed the EQ-5D-5L and PBC-40 questionnaires, and provided qualitative feedback on their disease experience and treatment expectations.Participants reporting central fatigue were classified as having mild (< 29), moderate (29–39), or severe (≥ 40) fatigue based on PBC-40 fatigue domain scores. Outcomes were compared across the three groups. **Results:** Majority of PBC patients reported central fatigue (92%), followed by bone or joint pain (75%), dry eyes or mouth (69%), peripheral fatigue (68%), and itching/pruritus (49%). Among the 92% who reported central fatigue, 14% (n = 34) were categorized as mild, 42% (n = 106) moderate, and 44% (n = 110) severe.Overall, in the 250 surveyed patients, mean EQ-5D score was 0.697, and mean EQ-VAS score was 65.3, in line with other reports on PBC. However, PBC patients with severe central fatigue reported significantly worse outcomes (p < 0.05) than those with moderate or mild central fatigue; EQ-5D scores (0.549 vs. 0.797 vs. 0.863) and EQ-VAS scores (51 vs. 66 vs. 79).Across EQ-5D dimensions, a substantially higher proportion of PBC patients with severe central fatigue reported limitations in usual activities (79% vs 23% vs 12%) than those with moderate or mild central fatigue.On the PBC-40, patients with severe central fatigue had significantly higher (p < 0.05) mean cognitive and emotional scores than those with moderate or mild central fatigue, indicating worse quality of life (cognitive: 21 vs 16 vs 13; emotional: 12 vs. 9 vs. 7).The impact on employment was staggering with 44% of patients with severe central fatigue stating that they were either unable to work, working part time or retired from work due to illness; rates were significantly lower in patients with moderate (16%) and mild central fatigue (6%).Sixty percent of patients prioritized central fatigue as the one PBC symptom most in need of a treatment. **Conclusion:** Central fatigue is highly prevalent in PBC and is linked to substantial declines in HRQoL, daily functioning, and ability to work, especially among patients with severe symptoms. These findings highlight fatigue as a major unmet need in PBC and underscore the urgent need for treatments that address it.

1143 | ◆ LOCATION AND ACTIVITY OF INFLAMMATORY BOWEL DISEASE ARE ASSOCIATED WITH COLECTOMY, BUT NOT WITH LIVER TRANSPLANT-FREE SURVIVAL IN PATIENTS WITH PRIMARY SCLEROSING CHOLANGITIS

Dennis Sneek[1] Bregje Mol[2] Marin de Jong[1] Adriaan Van der Meer[1] Pedro Miranda-Afonso[1] Akin Inderson[3] Rinse Weersma[4] Cyriel Ponsioen[2] Bettina Hansen[1] Annemarie de Vries[1], [1]Erasmus University Medical Center, [2]Amsterdam University Medical Center, [3]Leiden University Medical Center, [4]University Medical Center Groningen

Background: Primary sclerosing cholangitis (PSC) is a rare cholestatic liver disease characterized by chronic inflammation of the biliary tree. Up to 80% of patients with PSC are diagnosed with concomitant inflammatory bowel disease (IBD). PSC-associated IBD has been reported to present predominantly in the proximal colon and to follow a mild yet persistent course. We investigated whether IBD type, location, and activity in patients with PSC are associated with colectomy and liver transplant (LT)-free survival. **Methods:** Patients diagnosed with PSC and IBD who had at least one recorded colonoscopy were selected from the EpiPSC2 cohort, a dynamic population-based PSC registry in the Netherlands. Cox regression models were used to study the association of IBD type at diagnosis and time-varying IBD activity and location with colectomy and the composite of LT or PSC-related death. IBD activity was defined as the cumulative inflammatory burden (CIB) over follow-up, using the Mayo endoscopic subscore from 0 (none) to 3 (severe). IBD location was classified as right-sided colitis, left-sided colitis, or pancolitis. The index date was set to the second diagnosis, and the first colonoscopy was treated as the entry time to account for left truncation. **Results:** The analyses included 580 patients who had 3394 colonoscopies (median 5, interquartile range [IQR] 2–9). During follow-up, 221 patients had right-sided colitis at any time, 226 had left-sided colitis, and 277 had pancolitis. Among colonoscopies with active inflammation, the median severity of colitis was mild (Mayo 1, IQR 1–2). In 5509 patient-years of follow-up, 81 colectomies and 125 LTs were performed; 44 patients died of PSC-related causes.Left-sided colitis and pancolitis were associated with a 4-fold higher hazard of colectomy (hazard ratio [HR] 4.1, 95% confidence interval [CI] 2.3–7.5, p < 0.001; and HR 4.4, 95% CI 2.6–7.6, p < 0.001, respectively) than no inflammation, whereas right-sided colitis was not significantly associated (HR 0.7, 95% CI 0.3–2.1, p = 0.54). No differences were observed for the liver-related outcome (Figure 1). The CIB was associated with a 4.4-fold higher hazard of colectomy (95% CI 3.1–6.1, p < 0.001) and showed the strongest association in the left-sided colon (HR 4.3, 95% CI 2.9–6.3, p < 0.001). The CIB was not associated with the LT-free survival (HR 1.1, 95% CI 0.8–1.4, p = 0.68). The IBD type at diagnosis was not associated with either outcome. **Conclusion:** In this study, right-sided colitis, left-sided colitis, and pancolitis occurred with similar frequency in patients with PSC-IBD. Left-sided colitis and pancolitis were associated with a 4-fold higher hazard of colectomy, with a higher risk as the CIB increased. Right-sided colitis was not associated with a higher risk of colectomy as compared to no inflammation, suggesting this may be considered a separate IBD type. In our cohort, location and severity of IBD were not associated with LT-free survival.

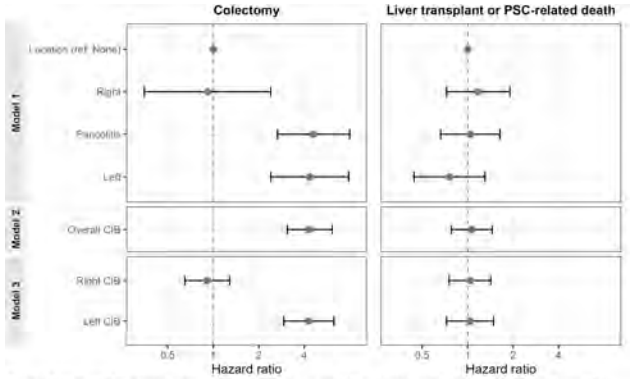

Figure 1 Multivariable Cox regression results. Adjusted hazard ratios and 95% confidence intervals for inflammatory bowel disease (IBD) location and severity. For the colectomy outcome we corrected for sex, age, IBD type, and years with IBD before primary sclerosing cholangitis (PSC) diagnosis. For liver transplant or PSC-related death we corrected for sex, age, IBD type, PSC subtype, colectomy, and years with PSC before IBD diagnosis. CI, confidence interval; CIB, cumulative inflammatory burden; PSC, primary sclerosing cholangitis; Ref, reference category.

1144 | ◆ CHARACTERIZING AUTOIMMUNE HEPATITIS (AIH) USING COMPLEMENTARY SINGLE-NUCLEI AND SPATIAL TRANSCRIPTOMICS TECHNIQUES

Nikita Sajai[1] Bruce Wang[1] Abhishek Murti[1] Cindy Ament[1] Michele Tana[2], [1]University of California San Francisco, [2]UCSF/ZSFG

Background: Autoimmune hepatitis (AIH) is a chronic liver disease characterized by immune cells attacking hepatocytes, leading to chronic inflammation, cirrhosis, and death if untreated. AIH incidence appears to be on the rise, disproportionately affecting women and people of color. Diagnosis often requires an invasive liver

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

biopsy, as serum biomarkers, including autoantibodies, lack sufficient sensitivity and specificity. Treatment can require lifelong immunosuppression with corticosteroids, and up to 25% of patients do not respond to treatment. Much remains unknown about the biological basis of AIH, including the autoantigen that leads to hepatocyte damage, the immune cell profile, and which molecular signaling pathways are active in the disease. **Methods:** Here, we use the Prospective Observational Study to Understand Liver Disease (POSULD), a well-characterized, diverse patient cohort with integrated clinical and molecular data to investigate disease mechanisms in AIH using a combination of single-nuclei RNA sequencing and spatial transcriptomics. To define the cellular and molecular mechanisms driving AIH, we performed single-nuclei RNA sequencing on liver tissues from 7 patients with AIH. We also included publicly available snRNA-seq data from 3 healthy controls. Next, we applied high-resolution spatial transcriptomics using the 10x Xenium platform to characterize disease-related changes in situ. To do so, we created a custom 480-gene human liver panel informed by our single-cell and bulk sequencing data for AIH. We then generated liver tissue microarrays using liver biopsy samples from 54 patients with AIH, control patients with metabolic-associated steatotic liver disease (MASLD), and healthy human controls. This approach enabled high-resolution in situ mapping of liver cell types and spatially informed identification of lobular regions (periportal, pericentral, and portal) using connectivity-based analysis. **Results:** Single-nuclei analysis revealed a massive increase in T lymphocytes in AIH and upregulation of the potential autoantigen AFF3 in periportal hepatocytes, implicating the periportal region in disease pathogenesis. We validated these findings in the spatial transcriptomics data. Unsupervised clustering based on spatial cell-type composition and regional gene expression profiles identified a subset of AIH patients characterized by shrunken periportal regions and expanded portal regions enriched for myeloid and lymphocyte populations. This subgroup also demonstrated elevated AIH panel scores, increased TGF-β signaling, and reduced STAT5B and heme biosynthesis pathway activity, highlighting spatially organized immune-hepatocyte interactions associated with severe disease. The spatial analysis showed that T cell expansion in AIH is localized to the portal region, where they form clusters with B cells. Cell-to-cell signaling analysis of our single-nuclei dataset identified CD40-CD40LG signaling between B and T cells as specifically upregulated in AIH livers, which we validated in the spatial transcriptomics data. **Conclusion:** These findings provide insight into the spatially organized immune-hepatocyte interactions that characterize AIH and highlight candidate pathways for targeted therapeutic intervention, advancing efforts toward precision medicine in this disproportionately affected population. It also demonstrates how a complementary approach combining single-cell and spatial transcriptomics can reveal novel molecular and cellular insights into liver disease pathophysiology.

1145 | ◆ SERUM IGFBP7 IS A PROGNOSTIC BIOMARKER FOR LIVER-RELATED EVENTS IN PRIMARY BILIARY CHOLANGITIS

Yoshiaki Kobayashi[1] Takanobu Iwadare[1] Takefumi Kimura[1], [1]Shinshu University School of Medicine

Background: Insulin-like growth factor binding protein 7 (IGFBP7) has been implicated in liver fibrosis, cellular senescence, and tissue remodeling in chronic liver diseases. However, its clinical significance and cellular origin in primary biliary cholangitis (PBC) remain unclear. We investigated whether serum IGFBP7 predicts liver-related events (LREs) and reflects histological disease severity in patients with PBC. **Methods:** This multicenter retrospective study included a biopsy-proven discovery cohort of 204 patients with PBC, excluding prior LREs or follow-up <3 months. Serum IGFBP7 levels were measured using stored baseline samples. LREs were defined as newly developed hepatocellular carcinoma, grade $\geq$II hepatic encephalopathy, refractory ascites requiring hospitalization, or gastroesophageal varices requiring intervention. A validation cohort included 70 patients with serologically diagnosed PBC without liver biopsy. Associations of IGFBP7 with LREs, histological severity, liver stiffness, and established fibrosis-related markers were evaluated. Multivariable Cox regression analysis was adjusted for age, sex, and Nakanuma classification. Single-cell RNA-sequencing data and RNA in-situ hybridization were analyzed to assess hepatic cellular expression of IGFBP7. **Results:** Patients who developed LREs had significantly higher baseline serum IGFBP7 levels than those without LREs. In the discovery cohort, IGFBP7 showed the highest AUROC for LRE development among evaluated markers: IGFBP7, 0.826; ALP, 0.602; FIB-4, 0.681; ALBI, 0.594; hyaluronic acid, 0.613; type IV collagen 7S, 0.657; Mac-2 binding protein glycosylation isomer, 0.649; and autotaxin, 0.768. The optimal IGFBP7 cutoff was 616.5 ng/mL, with 90.0%

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

sensitivity and 75.3% specificity. Kaplan–Meier analysis demonstrated a significantly higher cumulative incidence of LREs in patients with high IGFBP7 levels ($\geq$ 616.5 ng/mL; $p < 0.001$). Serum IGFBP7 levels were significantly associated with fibrosis stage, bile duct loss, Nakanuma classification, and Scheuer classification. In the validation cohort, IGFBP7 levels positively correlated with liver stiffness ($r = 0.477$, $p < 0.001$) and were higher in patients with LREs. In multivariable Cox regression analysis, high IGFBP7 levels remained independently associated with LRE development (HR 12.19; $p = 0.021$). Single-cell RNA-sequencing analysis showed increased IGFBP7 expression in fibroblasts, hepatic stellate cells, and sinusoidal endothelial cells in PBC. RNA in-situ hybridization demonstrated enhanced IGFBP7 expression in advanced fibrosis, particularly in portal areas with higher Nakanuma stages. **Conclusion:** Serum IGFBP7 was independently associated with LRE development in PBC and outperformed established fibrosis-related markers. These analyses suggest IGFBP7 reflects portal fibrotic remodeling and may serve as a noninvasive prognostic biomarker in PBC.

1146 | ◆ FACTORS INFLUENCING SECOND-LINE TREATMENT PRESCRIPTION IN PBC: A WORLDWIDE SURVEY AMONG PRACTITIONERS

Tiki D Blom[1] Alessandra Bonfichi[2] Merle Vos[1] Maria Papp[3] Jef Verbeek[4] Maria Londoño[5] Andreas Kremer[6] Christoph Schramm[7] Cynthia Levy[8] David Jones[9] Christophe Corpechot[10] Palak Trivedi[11] Emma Culver[12] Ana Lleo[13] João Madaleno[14] Michael Trauner[15] Henning Grønbæk[16] Annika Bergquist[17] George Dalekos[18] Aleksejs Derovs[19] Atsushi Tanaka[20] Gideon Hirschfield[21] Martin Weltman[22] Anna Mrzljak[23] Sona Frankova[24] Tamara Milovanovic[25] Piotr Milkiewicz[26] Ulrich Beuers[27] Marco Carbone[28] Bettina Hansen[1] Alessio Gerussi[29] Adriaan Van der Meer[1], [1]Erasmus University Medical Center, [2]University of Milano-Bicocca, IRCCS San Gerardo dei Tintori, [3]Division of Gastroenterology, Faculty of Medicine, University of Debrecen, [4]Department of Gastroenterology & Hepatology, University Hospitals Leuven, [5]Hospital Clinic Barcelona, [6]Department of Gastroenterology and Hepatology, University Hospital Zürich, University of Zürich, [7]University Medical Centre Hamburg-Eppendorf, [8]University of Miami, [9]Newcastle University, [10]Saint-Antoine Hospital, [11]University of Birmingham, [12]John Radcliffe Hospital and Nuffield Department of Medicine, University of Oxford, [13]Department of Biomedical Sciences, Humanitas University, Pieve Emanuele, [14]Liver Disease Unit - Department of Internal Medicine; Unidade Local de Saúde de Coimbra - Hospitais, [15]Medical University of Vienna, [16]Department of Hepatology & Gastroenterology, Aarhus University Hospital, [17]Karolinska Institutet, [18]University of Thessaly, [19]Riga East university hospital, [20]Teikyo University School of Medicine, [21]The Autoimmune and Rare Liver Disease Programme, Toronto General Hospital, [22]Nepean Hospital, [23]University Hospital Center Zagreb, [24]Department of Hepatogastroenterology, Institute for Clinical and Experimental Medicine, [25]University Clinical Center of Sebia, [26]Liver and Internal Medicine Unit Medical University of Warsaw, [27]Amsterdam University Medical Center, [28]ASST Grande Ospedale Metropolitano Niguarda; University of Milano-Bicocca, [29]University of Milano-Bicocca

Background: The second-line therapy (SLT) landscape for Primary Biliary Cholangitis (PBC) is evolving with the emergence of PPAR agonists and the regional withdrawal of obeticholic acid. This survey aimed to identify dominant factors influencing physicians' choice of bile acid-directed SLT in PBC. **Methods:** This cross-sectional survey among practitioners with experience in PBC was disseminated through international PBC networks via an open-access link. The 37-item survey comprised three sections: participant experience in PBC, ranking of the top 5 factors influencing SLT choice (weighted 5 to 1 points) and preferred SLT option across hypothetical clinical cases. Although participants were aware of regional availability, they were asked to assume all drugs were available for survey responses. **Results:** In total, 250 respondents from 45 countries were included. Of these, 56 (22.4%) were from Italy and 22 (8.8%) from the Netherlands; 204 (81.6%) worked in tertiary centers, and 172 (68.8%) had over 10 years of experience with PBC. When choosing between PPAR and FXR agonism, the three influencing factors with the highest cumulative points were patient symptoms (pruritus, fatigue; 659 pts), biochemical response data (590 pts), and safety profile (507 pts). Biochemical response data most often received the highest weight, 5 points, (45, 18%), followed by long-term outcome data (38, 15.2%) and patient symptoms (37, 14.8%). When selecting among PPAR agonists specifically, safety profile (555 pts), biochemical response data (522 pts), and patient symptoms (513 pts) received the most points, while costs (42, 16.8%), personal experience (41, 16.4%), and in-label versus off-label use (40, 16%) most frequently scored 5 points. In the base case of a 55-year-old patient with ALP 2.2xULN after 1 year of UDCA and F1 fibrosis without additional symptoms or co-morbidities, bezafibrate was most often selected as SLT (29.3%), followed by any in-label PPAR agonist (16.7%) and any PPAR agonist (13.5%). The top three preferred SLT options varied depending on

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

additional clinical features: refractory pruritus (Seladelpar [39.5%], Bezafibrate [31.2%], Elafibranor [9.8%]); incapacitating fatigue (Elafibranor [31.2%], Seladelpar [16.3%], Bezafibrate [16.3%]); eGFR 28 mL/min (Seladelpar [29.3%], any in-label PPAR [20.5%], no SLT [15.3%]); and concomitant statin therapy (Seladelpar [28.8%], any in-label PPAR [19.5%], Bezafibrate [15.3%]). **Conclusion:** This international survey shows that patient symptoms, biochemical response data and safety profile were dominant influencing factors when deciding between an FXR agonist and a PPAR agonist or on a specific PPAR agonist as SLT in patients with PBC. Treatment costs was the most frequently selected top ranked factor for selecting the type of PPAR agonist.

1147 | ◆ REAL-WORLD BIOCHEMICAL RESPONSE TO PPAR AGONISTS IN PRIMARY BILIARY CHOLANGITIS: A SINGLE-CENTER COHORT STUDY REPLICATING THE RESPONSE AND ELATIVE TRIAL ENDPOINTS

Sebastian Niezen[1] Victoria Abadi-Ron[1] Natalia Rojas-Amaris[1] Fernando Munguia[1] Ana Marenco-Flores[1] Behnam Saberi[1] Vilas Patwardhan[1] Alan Bonder[1],
[1]Beth Israel Deaconess Medical Center

Background: The PPAR agonists elafibranor and seladelpar achieved POISE composite biochemical response in 51% (ELATIVE) and 62% (RESPONSE) of patients with primary biliary cholangitis (PBC) in their respective pivotal trials. Real-world effectiveness in broader clinical populations is unknown. We applied the same endpoints used by the registrational trials to a consecutive real-world cohort to assess generalizability. **Methods:** Single-center retrospective cohort of 78 PBC patients initiated on a PPAR agonist (elafibranor n = 46, seladelpar n = 32) between June 2024 and April 2026. The primary endpoint was the POISE composite biochemical response at 6 months (ALP < 1.67× ULN AND ≥ 15% reduction AND total bilirubin ≤ ULN), tested against an assumed 20% placebo benchmark. Secondary endpoints included POISE response at 12 months, ALP normalization, percent change in ALP, pruritus improvement, treatment persistence, and adverse events. Pre-specified subgroup analyses examined response by agent, cirrhosis status, UDCA intolerance versus inadequate response, age, and baseline ALP tertile. **Results:** The cohort was 96% female with median age 64 years and median baseline ALP 215 U/L; 20% had baseline cirrhosis and 85% met criteria for UDCA inadequate response. At 6 months, POISE composite response was achieved in 31/58 evaluable patients (53%, 95% CI 40–66; p < 0.001 vs 20% placebo benchmark), closely paralleling the 51–62% rates reported in ELATIVE and RESPONSE. At 12 months, response was 11/31 (35%, 95% CI 21–53). Median ALP fell 38% from baseline at 6 months; ALP normalization occurred in 19%. Pruritus improved in 32/39 patients with baseline symptoms (82%, 95% CI 67–91). Treatment persistence was 92% (6 of 78 discontinued); adverse events occurred in 17%. Response rates were consistent across cirrhosis status, UDCA intolerance versus inadequate response, age, and agent. **Conclusion:** In a real-world PBC cohort treated with PPAR agonists, biochemical response rates and tolerability closely paralleled the ELATIVE and RESPONSE registrational trials, supporting generalizability of trial efficacy data to routine clinical practice. These findings reinforce PPAR agonists as effective second-line therapy across diverse PBC subgroups including patients with cirrhosis and UDCA intolerance.

1148 | ◆ DIAGNOSTIC PERFORMANCE OF ELASTOGRAPHY-BASED IMAGING MODALITIES FOR FIBROSIS ASSESSMENT IN PRIMARY SCLEROSING CHOLANGITIS: A SYSTEMATIC REVIEW AND META-ANALYSIS

Era Gupta[1] Omar Oudit[2] Aryan Gupta[3] Abdullah Sultany[4] Rewanth Katamreddy[4] Gautam Maddineni[5] Dushyant Singh Dahiya[6] Aakash Desai[7], [1]Guthrie/Robert Packer Hospital, PA, USA, [2]Brook Dale University Hospital Medical Centre, NY, USA, [3]Bangalore Medical College And Research Institute, India, [4]Guthrie/Robert Packer Hospital, PA, USA, [5]Creighton University, NE, USA, [6]The university of Kansas School Of Medicine, KS, USA, [7]Allegheny Health Network, PA, USA

Background: Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease associated with progressive biliary fibrosis and cirrhosis. Accurate fibrosis assessment is critical for prognostication and disease monitoring; however, liver biopsy is invasive and limited by sampling variability. Elastography-based modalities have emerged as promising noninvasive alternatives, though their diagnostic performance in PSC remains incompletely defined. We performed a systematic review and meta-analysis evaluating their diagnostic accuracy in PSC. **Methods:** This review followed PRISMA guidelines. PubMed, Google Scholar, and ScienceDirect were searched using a comprehensive strategy. Studies reporting AUC and/or technical failure rates for elastography modalities in PSC were included. Modalities assessed included point shear wave elastography (p-SWE), two-dimensional shear wave elastography (2D-SWE), vibration-controlled transient elastography (VCTE), and magnetic resonance elastography (MRE), including 2D gradient-recalled echo (2D-GRE-MRE) and 3D magnetic resonance elastography (3D-MRE). Data were analyzed using Meta, Metadata, and Metafor packages in R Studio. **Results:** Eight studies comprising 612 patients were included. The pooled AUC for fibrosis was 0.9873 (95% CI 0.97–1.00) , indicating excellent diagnostic performance with low heterogeneity. Among individual modalities, 2D-GRE-MRE demonstrated the highest diagnostic accuracy (AUC 0.9800, 95% CI 0.9400–1.0200), followed by p-SWE (AUC 0.9735, 95% CI 0.8614–1.0856) and VCTE (AUC 0.9500, 95% CI 0.8545–1.0455). 2D-SWE showed moderate performance (AUC 0.8500, 95% CI 0.5790–1.1210), while 3D-MRE/Tomoelastography demonstrated the lowest accuracy (AUC 0.6500, 95% CI 0.0969–1.2031).Technical failure rates were 0% for p-SWE, 6.1% for 2D-SWE, 9.6% for VCTE, and 1–8.4% across 2D-GRE-MRE studies; failure rate data being the highest for VCTE (9.6%). **Conclusion:** Elastography modalities demonstrate excellent diagnostic performance for fibrosis assessment in PSC, with high accuracy across ultrasound- and MRI-based techniques and low between-study heterogeneity. p-SWE and 2D-GRE-MRE showed the highest AUCs while VCTE had the highest failure rate. Stage-specific accuracy and standardized thresholds require further validation in prospective studies with histologic correlation.

1149 | ◆ SAFETY AND EFFICACY OF ADVANCED IBD THERAPIES AFTER LIVER TRANSPLANTATION FOR PRIMARY SCLEROSING CHOLANGITIS: A MULTICENTER EXPERIENCE

Hala Nabulsi[1] Fernando Gil-Lopez[1] Jana Hashash[1] Andrew Keaveny[1] Kymberly Watt[2] Darrell Pardi[2] Elizabeth Carey[3] Denise Harnois[1] Omar Mousa[1], [1]Mayo Clinic Florida, [2]Mayo Clinic Rochester, [3]Mayo Clinic Arizona

Background: Management of inflammatory bowel disease (IBD) following liver transplantation (LT) for primary sclerosing cholangitis (PSC) is challenging, and data on advanced therapy in this population remains limited. We aimed to investigate the safety and efficacy of advanced therapy for IBD following LT for PSC. **Methods:** We retrospectively reviewed adult patients who underwent LT for PSC between 1985 and 2022 and received advanced therapy for IBD post-LT at three large transplant centers. Patients with cholangiocarcinoma at LT were excluded. Clinical activity was categorized as no, partial, or complete remission based on IBD symptoms. Endoscopic activity was defined by mucosal healing (disappearance of ulcerations in Crohn's disease and Mayo endoscopic subscore ≤ 1 in Ulcerative Colitis). Post-LT infection rates and malignancy were captured from initiation of advanced therapy to the last follow-up. **Results:** Sixty-eight patients with PSC-IBD were included (44 ulcerative colitis, 23 Crohn's disease, 1 indeterminate colitis); 66.1% male, 91.2% Caucasian, mean recipient age 39.5 $\pm$12.8 years, mean MELD at LT 20.9, 25% living-donor recipients. Median follow-up from advanced therapy initiation was 5.26 years (range 0.12–24.9). The most frequently used agents were vedolizumab (n = 57), infliximab (n = 31), adalimumab (n = 24), ustekinumab (n = 22), risankizumab (n = 12), and upadacitinib (n = 10); 35.3% of patients received $\geq$ 3 sequential advanced agents post-LT. Complete clinical remission was achieved in 44.1% (30/68) and partial clinical remission in 38.2% (26/68); complete endoscopic remission was achieved in 30.9% (21/68) and partial endoscopic improvement in 51.4% (35/68). During cumulative follow-up after advanced therapy initiation, viral infections occurred in 82.3%, bacterial infections in 75.0%, and fungal/parasitic infections in 17.6% of patients; some of these events occurred during periods when advanced therapy was held or discontinued, with patients maintained on standard immunosuppression. The most frequent infections were Clostridioides difficile (39.7%), CMV (38.2%), SARS-CoV-2 (33.8%), Influenza (22%), and bacteremia (22%). Malignancy occurred in 30.8% of patients, most commonly non-melanoma skin cancer (14.7%). There were no reported deaths related to advanced therapy. **Conclusion:** In the largest multicenter PSC-IBD cohort post-LT, use of advanced therapy was associated with clinical and endoscopic improvement in 82.3% of patients. However, cumulative infections and malignancies were common over long-term follow-up. These findings support advanced therapy as a viable option for IBD after LT for PSC while underscoring the need for vigilant infection surveillance and skin-cancer screening in this immunosuppressed population.

Background: The UK-PBC risk score is used to assess the risk of developing end-stage liver disease (ESLD) in people with primary biliary cholangitis (PBC). The risk score has been validated in a tertiary cohort only. The aim of this study was to externally validate the UK-PBC risk score in a representative, national population of individuals with PBC. **Methods:** The retrospective Dutch PBC Cohort Study includes every identifiable patient with PBC from 1990 up to last data collection (2019-2023) from all 71 hospitals in the Netherlands. Where feasible, laboratory values were imputed using joint model multiple imputation. Patients with auto immune hepatitis, additional therapy (second-line/immunosuppressants) within the 1st year, or with <1 year of follow-up were excluded. The UK-PBC risk score uses baseline albumin and platelet levels, along with total bilirubin, alanine aminotransferase (ALT)/aspartate aminotransferase (AST), and alkaline phosphatase at 1 year. The score was calculated with the corresponding formula at 5, 10 and 15 years. In line with the derivation study, ALT was used by default and otherwise AST. ESLD was defined as liver-related death, liver transplant (LT), or - for people who were still alive and had never undergone LT - serum bilirubin ≥100 µmol/L for the first time. Calibration plots were constructed with the observed and predicted 5-, 10- and 15-year probabilities. Discrimination was assessed using the area under the receiver operating characteristic curve (AUC) at 5, 10, and 15 years. The Integrate Brier Score (IBS) summarized prediction error over time. **Results:** In total, 2770 individuals were included. At diagnosis, median age was 57.7 years (IQR 49.6-67.0), 2422 (87.4%) were female and 185 (6.7%) had cirrhosis. During a median follow-up of 8.3 years (IQR 4.0-13.7), 232 patients experienced the outcome of ESLD: 130 (56.0%) liver-related death, 63 (27.2%) LT and 39 (16.8%) bilirubin ≥100 µmol/L. The 10 year cumulative incidence of liver failure was 5.6% (95%CI 4.5-6.7). Overall, the c-statistic was 0.84 (95%CI 0.85-0.90) with an IBS of 0.02 over 10 years follow-up. In the 25% highest risk patients (UK-PBC score >6.5%), cumulative incidence at 10 years was 17.6% (95%CI 14.1-21.0) vs a predicted of 17.6%; in the 25% lowest risk patients (UK-PBC score <2.0%) the observed 10 year cumulative incidence was 0.5% (95%CI 0.0-1.3) vs predicted of 1.3% (p<.001). The AUC of the UK-PBC risk score was 0.85 (95% CI 0.81-0.90) at 5 years, 0.86 (95% CI 0.82-0.90) at 10 years and 0.82 (95% CI 0.77-0.86) at 15 years. In a subgroup of patients without cirrhosis, the AUC was ≥ 0.77 at 5, 10 and 15 years. **Conclusion:** In this nationwide unbiased cohort of people with PBC, the UK-PBC risk score was validated with high discrimination and accurate calibration for the assessment of liver-related prognosis. Especially in the high risk group, for whom risk prediction is most urgent, the UK-PBC risk score showed excellent prognostic performance.

1151 | ◆ OBETICHOLIC ACID ADJUNCT TO URSODEOXYCHOLIC ACID VS. UDCA MONOTHERAPY IN PRIMARY BILIARY CHOLANGITIS: A PROPENSITY SCORE–MATCHED COHORT ANALYSIS

Mahmoud Al-Bataineh[1] Jashanveer Johal[1] Archana Salek[1] Bianca Patel[1] Brandon Cunha[1] Abdallah Hussein[1] Jason Hyman[2] Yecheskel Schneider[1], [1]Virtua Health, [2]Einstein Medical Center, Philadelphia

Background: Ursodeoxycholic acid (UDCA) is the first-line treatment for primary biliary cholangitis (PBC), but up to 40% of patients have an inadequate biochemical response. Obeticholic acid (OCA), an FXR agonist, is approved as adjunctive therapy in UDCA-inadequate responders, yet real-world comparative data on hard clinical outcomes including mortality remain limited. **Methods:** We conducted a propensity score–matched retrospective cohort study using the TriNetX Global Collaborative Network (191.9 million patients). Cohort 1 comprised patients with PBC (ICD-10 K74.3) receiving both UDCA and OCA. Cohort 2 comprised PBC patients on UDCA monotherapy without OCA. Both cohorts excluded prior cirrhosis (K74.60), liver transplant status, and concurrent autoimmune hepatitis. Cohorts were balanced via 1:1 PSM yielding 655 patients per arm over a 6–120 month follow-up window. Pre-specified outcomes included liver transplantation, ALP normalization as a biochemical response surrogate, need for pruritus adjunctive therapy as a proxy for OCA-related adverse effect, inpatient encounters, and all-cause mortality. **Results:** Post-PSM cohorts were well-balanced across matched covariates. ALP normalization was significantly more frequent in the OCA adjunct arm (22.9% vs. 40.2%; RR 0.57; HR 0.44, 95% CI 0.36–0.54; log-rank $p < 0.001$), with median time to normalization of 3,149 days vs. 1,772 days in the UDCA-only arm. Need for pruritus adjunctive therapy was significantly higher in the OCA arm (11.9% vs. 6.0%; RR 2.0, OR 2.14; HR 1.89, 95% CI 1.29–2.78; log-rank $p = 0.001$), consistent with OCA's known on-target adverse effect profile. Inpatient encounter rates did not differ significantly between arms (17.7% vs. 24.1%; mean 6.2 vs. 6.6 encounters; $p = 0.75$). All-cause mortality was markedly lower in the OCA adjunct arm (5.2% vs. 11.0%; RR 0.47; HR 0.48, 95% CI 0.31–0.72; log-rank $p = 0.0003$). **Conclusion:** In this propensity-matched real-world cohort, OCA adjunct to UDCA was associated with significantly lower rates of ALP normalization failure, a 53% lower hazard of all-cause mortality, and a predictable increase in pruritus management requirements compared to UDCA monotherapy. These findings support the real-world effectiveness of OCA combination therapy in PBC while reinforcing the need for proactive pruritus monitoring and management. Liver transplant-free survival data should be incorporated in future analyses.

1152 | ◆ FEWER THAN ONE IN FOUR PBC PATIENTS WITH INADEQUATE UDCA RESPONSE RECEIVE SECOND-LINE THERAPY: A DECADE-LONG NATIONWIDE ANALYSIS OF 3,799 PATIENT

Jarell Jie-Rae Tan[1] Aldo Montano-Loza[2] Yu Jun Wong[3], [1]Department of Gastroenterology & Hepatology, Changi General Hospital, [2]Liver Unit, Division of Gastroenterology, University of Alberta, Edmonton, Alberta, Canada, [3]Department of Gastroenterology & Hepatology, Changi General Hospital Singapore

Background: Multiple second-line agents are now approved for primary biliary cholangitis (PBC) patients who fail ursodeoxycholic acid (UDCA), yet the real-world utilization of second-line (2L) treatment remains unknown. We examined real-world prescribing patterns, temporal trends, and clinical determinants of

Symbols: ◆, Poster of Distinction; ★, Foundation Award Recipient

© 2026 American Association for the Study of Liver Diseases. Published by Wolters Kluwer Health, LLC. Unauthorized reproduction of this article prohibited.

second-line therapy initiation across a large US-based cohort spanning the complete regulatory history of 2L PBC therapies. **Methods:** We performed a retrospective cohort study using the TriNetX global research network with deidentified electronic health records from 170 predominantly US healthcare organizations, 2015–2025. Eligible patients were adults with PBC and persistent alkaline phosphatase elevation after ≥12 months of UDCA, without concomitant chronic liver disease, decompensated cirrhosis, previous liver transplantation, malignancy, end stage kidney disease or dementia. Predictors of second-line initiation were identified by multivariable logistic regression. Prescribing trends were analyzed across sequential regulatory periods. **Results:** Of 3,799 patients with documented incomplete biochemical response to UDCA (defined as ALP>3x ULN), only 847 (22.3%) received any second-line therapy, which translates to close to 3,000 eligible patients being untreated over a decade. The cohort was 85.8% female, with a mean age of 66 years; 31% already had cirrhosis. Obeticholic acid was most commonly prescribed (10.9%), followed by fibrates (9.5%), seladelpar (4.4%), and elafibranor (3.2%). Younger age, female sex, and care at academic centers independently predicted 2L treatment uptake. Notably, 2L initiation rates were lower amongst higher risk group including male patients (vs female), and those under 35 years of age (vs >= 35 years) (both $p < 0.01$). Following regulatory approvals in 2025, 2L initiation rates increased modestly (23.1% vs. 19.3%; $p < 0.001$), accompanied by a marked shift from obeticholic acid toward PPAR agonists, though overall utilization remained far below what guideline-eligible disease burden would demand. **Conclusion:** Across 102 US healthcare systems over ten years, close to 3,000 PBC patients with documented UDCA failures, including those with established cirrhosis, never received a second-line agent. Temporal trends reflect increased awareness with new drug approvals, but only marginally increase the treatment coverage. Further work is needed to address this gap for UDCA-refractory PBC patients.

Disclosures: Jarell Jie-Rae Tan:Nothing to Disclose, Aldo Montano-Loza:Nothing to Disclose, YU JUN WONG:Nothing to Disclose.

1153 | ◆ SGLT2 INHIBITORS AND LONG-TERM OUTCOMES IN UDCA-TREATED PRIMARY BILIARY CHOLANGITIS WITH TYPE 2 DIABETES: A PROPENSITY-MATCHED ANALYSIS

Mohammad Alabbas[1] Akram Alnounou[2] Ahmad Alhusen[3] Omar Sims[1] Dian Chiang[4], [1]Cleveland Clinic Foundation, [2]Western Michigan University Homer Stryker M.D. School of Medicine, Kalamazoo, MI, USA, [3]Advocate Illinois Masonic Medical Center, Chicago, IL, USA, [4]Cleveland Clinic

Background: Primary biliary cholangitis (PBC) is frequently accompanied by type 2 diabetes mellitus (DM2), but long-term hepatic and cardiovascular outcomes associated with sodium-glucose cotransporter-2 inhibitor (SGLT2i) use in ursodeoxycholic acid (UDCA)-treated PBC remain uncertain. We evaluated outcomes associated with SGLT2i exposure versus no SGLT2i exposure in UDCA-treated PBC without prior hepatic decompensation. **Methods:** Using the TriNetX Research Network of 111 healthcare organizations, we identified adults with PBC receiving UDCA. SGLT2i users, representing a DM2-enriched subgroup, were compared with UDCA-treated nonusers after 1:1 propensity-score matching on demographics, comorbidities, medications, and laboratory values. Patients with major competing liver diseases or prior hepatic decompensation were excluded. Outcomes were assessed from day 1 after index through 3 and 5 years. The primary outcome was major adverse liver outcomes (MALO), a composite of liver-related events and death. Secondary outcomes included hospitalization, MACE, mortality, pruritus, fatigue, albumin ≤3.5 g/dL, ALP, and incident hepatic decompensation. **Results:** In the 3-year matched cohort, 362 SGLT2i users were compared with 362 nonusers. SGLT2i use was associated with lower hospitalization (23.5% vs 31.8%; RR 0.74, 95% CI 0.58–0.94) and incident hepatic decompensation (4.1% vs 9.4%; RR 0.44, 95% CI 0.25–0.80). MALO was numerically lower by risk analysis (29.3% vs 35.9%; RR 0.82, 95% CI 0.66–1.01) and lower by survival analysis (HR 0.77, 95% CI 0.59–0.99). Mortality was numerically lower but borderline, while MACE, pruritus, fatigue, albumin ≤3.5 g/dL, and ALP did not differ. In the 5-year matched cohort, 433 SGLT2i users were compared with 433 nonusers. SGLT2i use was associated with lower mortality (7.9% vs 14.1%; RR 0.56, 95% CI 0.37–0.83) and incident hepatic decompensation (5.3% vs 11.8%; RR 0.45, 95% CI 0.28–0.72). MALO, hospitalization, and albumin ≤3.5 g/dL were lower by survival analysis, whereas MACE, pruritus, fatigue, and ALP did not differ by risk analysis. **Conclusion:** In this propensity-matched cohort of UDCA-treated PBC enriched for DM2 and without prior hepatic decompensation, SGLT2i exposure was associated with lower incident hepatic decompensation at 3 and 5 years and lower mortality at 5 years, without excess MACE or worsening ALP. Prospective studies are warranted to define the role of SGLT2i in DM2-enriched patients with PBC.

Fatigue	7.6%	8.6%	0.88 (0.52–1.50)	0.644	0.80 (0.46–1.39)	0.425
Incident hepatic decompensation	5.3%	11.8%	0.45 (0.28–0.72)	0.001	0.42 (0.25–0.68)	<0.001

Abbreviations: PBC, primary biliary cholangitis; UDCA, ursodeoxycholic acid; T2DM, type 2 diabetes mellitus; MALO, major adverse liver outcomes; MACE, major adverse cardiovascular events; ALP, alkaline phosphatase.
RR values are from risk analysis; HR values are from time-to-event survival analysis.
P (RR/t) values are from risk analysis, except ALP where they are from t testing;
P (HR) values are from log-rank testing.
For pruritus, albumin ≤3.5 g/dL, and fatigue, analyses excluded patients with the outcome prior to the time window, so row-specific at-risk denominators differed from the matched cohort size.

1154 | ◆ EARLY DIAGNOSIS AND FAVORABLE RISK PROFILES IN SWISS PATIENTS WITH PRIMARY BILIARY CHOLANGITIS: A COMPARATIVE ANALYSIS USING THE GLOBE AND UK-PBC SCORES

Beatrice Barda[1] Claudai Di Bartolomeo[1] Rossella Forlenza[2] Andrea Cerny[1] Giulia Magini[3] Guido Stirniman[4] David Semela[5] Christine Bernsmeier[6] Andreas E Kremer[7] Christinet Montserrat Fraga,[8] Andrea De Gottardi[9] Magdalena Filipowicz Sinnreich[6] Benedetta Terziroli Piccoli[10] Antonio Galante[11],
[1]Epatocentro Ticino, [2]Fondazione Epatocentro Ticino, [3]HUG, [4]Inserlspital Bern, [5]Hoch, [6]Unibas, [7]USZ, [8]CHUV, [9]Luks, [10]EOC, [11]Epatocentro

Background: Primary Biliary Cholangitis (PBC) is a chronic cholestatic liver disease with a highly variable natural history. Prognostic tools like the GLOBE and UK-PBC scores have been validated internationally to predict liver-related outcomes. However, regional differences in screening and diagnostic practices may influence the clinical stage at presentation.The aim of our study is to compare the clinical characteristics and predicted outcomes of Swiss PBC patients with the original international GLOBE and UK-PBC derivation cohorts, testing the hypothesis that Swiss patients present at an earlier, less severe disease stage. **Methods:** We performed a retrospective analysis of 159 Swiss PBC patients treated with UDCA. Baseline demographics and biochemical markers (ALP, bilirubin, albumin, platelets) were analyzed. The GLOBE and UK-PBC risk scores were calculated after 12 months of UDCA therapy. Results were compared against published data from the original UK-PBC (n = 1,916) and GLOBE (n = 2,488) study groups. **Results:** In our Swiss cohort, we calculated both the GLOBE and UK-PBC score. In the Globe score cohort, we included 159 patients, the median age at diagnosis was 55.2 (47-64) years, and 135 (85%) were female. Compared to the original international cohorts, Swiss patients exhibited significantly lower baseline ALP levels 1.3 (0.74-2.75) VS 1.9 (1.2-3.5) x ULN and higher platelet ratio 1.65 vs 1. After 12 months of UDCA, ALP levels 1.2 (0.71-1.90) vs 1.34 (0.93-2.26) x ULN and higher platelet counts. In the UK score cohort, we included 115 patients, the median age at diagnosis was 50.3 (43-59) years, and 108 (94%) were female.The median GLOBE score of our cohort was 0.44, which was significantly lower than the derivation mean (0.78-0.86) ($p < 0.05$). Similarly, the UK-PBC 10-year risk of end-stage liver disease was 4.8% compared to 9-15% in the original cohorts. **Conclusion:** Swiss PBC patients appear to present at an earlier disease stage with more favorable prognostic markers than the original UK and Global cohorts. These findings suggest that robust diagnostic pathways in Switzerland may lead to earlier intervention, potentially correlating with improved long-term transplant-free survival.
